#### I. INTRODUCTION

The presence of smoke, dust, aerosol and exotic gases on the battlefield may impair the effectiveness of battlefield radar in such an environment. The object of the work described in this report was to review the unclassified and classified literature on the absorption and scattering processes undergone by 100  $\mu$ m to 1 cm wavelength radiation as it propagates through the atmosphere. The literature reviewed includes those papers that describe calculations and measurements of 100  $\mu$ m to 1 cm wavelength radiation and absorption by normal atmospheric gases and by water vapor, rain, ozone, atmospheric aerosols, clouds, fogs, battlefield dust and smoke and the exotic gases produced by motorized equipment and weapons during battle.

The government report literature surveyed during this study is listed in Appendix A of this report. An NTIS literature survey was obtained for use in this study. The NTIS survey was entitled "Submillimeter Wavelength Radiation Absorption and Scattering by Atmospheric Gases, Water Vapor, Ozone, Aerosols, Clouds, Fog, Battlefield Dust and Smoke." A total of 51 reports listed in the NTIS survey was ordered for use in this study. A number of the reports listed in the NTIS survey were already available in the RRA document files. A total of 190 unclassified, 34 limited, and 14 classified government sponsored research. reports were reviewed for this study. In addition, a number of books were reviewed and articles on millimeter radiation interactions in the atmosphere from the following journals were reviewed:

> IEEE Transactions on Microwave Theory and Techniques, 1970-1977 IEEE Transactions on Antenna and Propagation, 1970-1977 Journal of the Optical Society of America. 1970-1977 Applied Optics Infrared Physics, 1963-1977 Journal of Geophysical Research, 1963-1977

Journal of the Atmospheric Sciences, 1974-1976 Optics and Spectroscopy, (Russian Translation) 1970-1977 Radio Physics and Electronics (Russian Translation), 1969-1977 Nature and Nature/Physical Sciences, 1970-1977 Journal of the Faraday Society, 1970-1977 (and selected 1960's) Optical Engineering, 1973-1978 Physical Review (selected articles), 1965-1975 Review of Modern Physics (selected articles), 1973-1978 Journal of Molecular Spectroscopy, 1967-1977

Section II gives a summary of the unclassified documents in the open literature on: 1) attenuation by atmospheric water vapor and oxygen, 2) atmospheric index of refraction, 3) attenuation and scattering by fog, rain and clouds, 4) attenuation and scattering by snow, 5) attenuation by Ozone, 6) attenuation and scattering by aerosols and dust and 7) attenuation and scattering by battlefield generated dusts and smokes. Section III gives a summary of the limited distribution, unclassified literature on attenuation and scattering by rain and hail, attenuation by water vapor and the refractive indices for sea spray. Section IV discusses the results of the review of the classified literature.

A bibliography of the unclassified literature is given in Appendix A. Section V describes the methods used to index the contents of the articles reviewed. Recommendations for further work that is needed to further the understanding of the interaction processes undergone by mm and sub mm radiation as it propagates in the atmosphere are given in Section VI.

#### II. SUMMARY OF LITERATURE SURVEYED

The following sections present data taken from the reviewed literature which describe the current state of knowledge on the interaction cross sections for millimeter and submillimeter radiation when it is propagated through the atmosphere.

### 2.1 Attenuation by Water Vapor and Oxygen

Corcoran<sup>1</sup> has presented a table (shown here as Table I) of the atmosphere "Windows" and bounding absorption peaks, from 3.2 cm to 156  $\mu$ m for absorption due to water vapor and oxygen for a zenith path through a cloudless Maritime Polar atmosphere. The absorption is given for water vapor, oxygen, and combined gaseous attenuation for these chief atmospheric constituants.

Traub and Stier<sup>2</sup> has presented an atmospheric calculation for mid and far IR at 4 observing altitudes, 4.2 km (Mauna Kea), 14 km (aircraft), 28 km (balloon), and 41 km (balloon). Molecular abundances, effective pressures and temperatures used in the Curtis-Godson approximation as shown here in Table II (from Traub and Steier, Ref. 2). They used the AFCRL atmospheric absorption line parameter tape<sup>3</sup> to obtain the wavenumber, line strength, pressure broadening coefficient, and energy level of the lower state for over 109,000 known transitions of  $H_2^0$ ,  $O_3^0$ ,  $0_2$ ,  $C0_2$ , C0,  $N_20$ , and  $CH_4$  between .76  $\mu$ m and 3.26 mm. Figure 1 presents the results of their calculations of atmospheric transmission from 100  $\mu m$ to 1000  $\mu\text{m}$  using the initial conditions shown in Table II. The "4 km" labeled curve is really for the 4.2 km altitude of Mauna Kea. The vertical ordinate, the transmission, unreadable in the curves of Fig. 1 is linear from 0 to 1. A Lorentz line profile was used for simplicity, though a Van Vleck-Weiskopf line profile would have been more accurate in the wings of each line.

Table I. Candidate "Windows" in the Submillimeter and Microwave Bands, Arising from Absorption Spectra of Water Vapor and Oxygen, with Attenuation in Decibels Calculated for a Zenith Path through a Cloudless Maritime Polar Atmosphere (from Ref. 1)

$T(O_3)$	219.0 K	221.0	233.0	260.0

<sup>a</sup> The H<sub>2</sub>O abundances in the last three columns correspond to 2.25, 0.26, and 0.040 precipitable  $\mu$ m, respectively; the H<sub>2</sub>O at 4.2 km is assumed to have a scale height of 1.85 km. The abundances listed are for unit air mass; an additional factor of 2 is included in the actual calculations corresponding to a zenith angle of 60°. The base pressure at each altitude is given by *p*, and the effective pressure for collisional line broadening is indicated by p(eff),  $p(H_2O)$ , and  $p(O_3)$  for the first five species, H<sub>2</sub>O, and O<sub>3</sub>, respectively; the temperatures at the corresponding pressure levels are also listed.

t

<sup>b</sup>Data from Ref. 2.

Archie Straiton<sup>4</sup>, in a tutorial article, presents the results of a calculation of the attenuation in the 10-400 GHz wave bands (3.33 cm - .75 mm) due to oxygen and water vapor in a vertical path from sea level for a standard atmosphere. His results are shown in Fig. 2. We see graphically the major absorption lines and windows of the microwave-mm wave region; below 100 GHz, the absorption spectrum is dominated by the "22" GHz water vapor line, and the "60" GHz molecular oxygen line. Attention has been placed on communication systems operating in the 35 GHZ and 93 GHz regions of transmission maximum for long range requirements, and in the 60 GHz region, for short range, secure communications. Some authors have utilized the water vapor lines (in emission) at 22 GHz and 183 GHz to measure the atmospheric water vapor content. In his calculation, Straiton used the Gross<sup>5</sup>/ Zhevakin-Naumov<sup>6</sup> attenuations  $\Gamma(v)$  at a frequency v for a single line with center frequency  $v_{ii}$ 

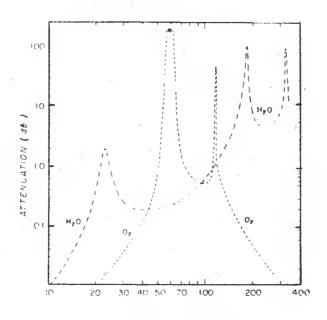

$$\Gamma(v) = \frac{S}{\pi} \frac{4\pi v^2 \alpha}{(v^2_{ij} - v^2)^2 + 4v^2 \alpha^2}$$

S = a measure of the strength of a line

 $\alpha$  = approximately the change in frequency from  $v_{ij}$  at which the attenuation has dropped to 1/2 (line breadth parameter =  $\simeq \Delta v$ )

Values of  $v_{i}$ , S, and  $\alpha$ , which are given by Burch<sup>7</sup> for water vapor from 0.5 to 36 cm<sup>-1</sup> are presented here as Table III. The water vapor line breadth parameter is given by (after Straiton, Ref. 4)

$$\Delta v = 2.62 (1 + 0.01 \frac{\rho T}{p}) \frac{(P/760)}{(T/3.18)^{0.625}},$$

where  $\rho$  = water vapor density in gm/cm<sup>3</sup>

T = absolute temperature, °K

P = pressure in mm mercury.

For water vapor, in the Gross equation for the attenuation, the strength function S is

$$S \sim \rho T^{-5/2} \exp(-a/T)$$
,

where a varies from line to line.

The line breadth depends on the collisions of the polar molecules with like molecules and other molecules in the atmosphere. For oxygen, Meeks and Lilley<sup>8</sup> give the line breadth  $\Delta\nu(P_1^T)$  by the equation

$$\Delta v(P_1T) = A P \left[ 0.21 + 0.78B \right] \begin{bmatrix} T \\ 0 \\ T \end{bmatrix}^{0.85}$$

where A specifies the line broadening at unit pressure (=  $1.95MHZ(mmHg\Gamma)$ ) and B specifies the relative effectiveness of the N<sub>2</sub> - O<sub>2</sub> collisions as compared to the O<sub>2</sub> - O<sub>2</sub> collisions (= .25 for pressures less than 267mmHg).

In a report by Richard Longbothum<sup>9</sup>, the water vapor resonant scattering cross sections  $\sigma$  (for high altitudes, 30 -80 km) at 22 GHz (22.235 GHz, or 1.35 cm) and at 183 GHz (183.31 GHz or 1.64mm) are given by

$$\sigma(v,T,N,v_o) = \frac{K_a(v,T,N,v_o)}{N(h)} ,$$

where

N(h) = number of water vapor molecules/cm<sup>3</sup> for a path length h.

At 22.235 GHz, the absorption coefficient  $K_a$ , for a pressure broadened line<sup>10</sup>, is given by

$$K_{a} = 1.05 \times 10^{-28} \frac{Nv^{2}}{T^{5/2}} \exp(-644/T) \qquad \frac{\Delta v}{(v - v_{0})^{2} + \Delta v^{2}} + \frac{\Delta v}{(v + v_{0})^{2} + \Delta v^{2}} + 1.52 \times 10^{-52} \frac{Nv^{2} \Delta v}{T^{3/2}} \text{ cm}^{-1}$$

where

N = Number density of water vapor molecules in a  $cm^3$ 

v =frequency in Hertz

T - Kinetic temperature in °K.

At 183.31 GHz, the absorption coefficient for a pressure broadened line is (after Croom, Ref. 11)

$$K_{a} = 6.46 \times 10^{-29} \frac{Nv^{2}}{T^{5/2}} \exp(-200/T) \qquad \left[ \frac{\Delta v}{(v - v_{0})^{2} + \Delta v^{2}} + \frac{\Delta v}{(v + v_{0})^{2} + \Delta v^{2}} \right] + 1.8 \times 10^{-52} \frac{Nv^{2} \Delta v}{T^{3/2}} \text{ cm}^{-1}.$$

When both doppler and pressure broadening are applicable (altitude above 70 km) the 1/2 width  $\Delta v$  is given by

$$\Delta v \simeq (\Delta v_{\rm p}^2 + \Delta v_{\rm D}^2)^{-1/2}.$$

The pressure broadening  $\Delta v_p$  is given by (Croom, Ref. 11) as

$$\Delta v_{\rm p} = 2.62 \times 10^9 \frac{\left(\frac{\rm P}{1013.25}\right)}{\left(T/318\right)^{0.625}} \cdot (1 + 0.0046\rho) \text{ Hz},$$

where

P = total atmospheric pressure in mb  $\rho$  = density of water vapor in gm m<sup>-3</sup> T = kinetic temperature in °K.

The doppler broadening  $\Delta v_{\rm p}$  is given by (Croom, Ref. 11) as

$$\Delta v_{\rm D} = 8.45 \times 10^{-7} v_{\rm Q} \sqrt{T} \, {\rm Hz}.$$

A plot of the absorption cross sections for the two main lines, at 22 and 183 GHz, is shown in Fig. 3. Data for this plot is tabulated in Table IV. These data were abstracted from Longbothum, Ref. 9. Persual of this table (which includes line widths) shows the broadening of line widths of the absorption cross sections as the altitude decreases from 120 km to 30 km.

One variable that is often elusive in a set of atmospheric transmission measurements is that of the water vapor pressure and atmospheric water content. These two parameters are presented next as Fig. 4, atmospheric water vapor content and Fig. 5, water vapor pressure as a function of temperature and relative humidity. Both of these curves are from A. R. Downs<sup>12</sup>.

Before leaving the discussion of basic atmospheric attenuation of mm and sub mm wavelengths, mention should be made of two papers on the physical properties of the oxygen molecule. Welch and Mizushima<sup>13</sup> have given a table of observed and calculated frequencies of the  $O_2$  molecule, from 53.066 GHz to 3865.81 GHz (given here as Table V). A result of a nonlinear least squares fit to 25 microwave and 3 sub mm and IR wavelengths is a set of molecular parameters for  $O_2$ , given here as Table VI.

Mar S.

Ott and Thomson<sup>14</sup> discussed the index of refraction of air (oxygen) in the 55-65 GHz region in their article "Characteristics of a Radio Link in the 55-65 GHz range." They give the path averaged refractive index n(v) as a sum of frequency dependent and independent parts,

$$n(v) = 1 + \frac{77.63}{T} \left(P + \frac{4810e}{T}\right) \cdot 10^{-6} + \frac{(S/\gamma) \cdot 10^{-4}}{(-i + Z)} \cdot \left(\frac{300}{T}\right)^2 \left(\frac{P}{1013.25}\right)$$

with 
$$Z = (v_0 - v)/\gamma$$
  
T = absolute temperature °K  
P and e are in millibars (1 mb = 0.75006376 Torr).

ο <sup>Ψ</sup>	-0.2525917		-0.2525865 (10)
<sup>µ</sup> 1	$-2.455 \times 10^{-7}$		$-0.2464$ (20) x $10^{-7}$
	¢.		

(Data from Ref. 13)

Note: The statistical uncertainties quoted are approximately two standard deviation limits and do not include explicitly experimental uncertainties of the frequencies measurements. The standard deviations were estimated from the last iteration of the nonlinear fitting procedure based upon Taylorseries expansion about the estimated values.

'n

These authors choose to use a "Lorentzian" line shape:

S = 5220 Hz  $\gamma$  = 3.92 GHz = line width  $\nu_0$  = center frequency in GHz

Different authors seemed to have "favorite" collision broadened reasonant line width functions (equivalent reasonant cross sections); from data by Burch (7), the experimental values favor (for v< 15.5 cm<sup>-1</sup>,  $\lambda$ >.645 mm) the Van Vleck-Weiskopf function. Above that frequency ( $\lambda$ <.645mm) Burch feels that the Gross/Zhevakin-Naumov form fits the data on water vapor best.

The general data coverage on atmospheric transmission is heavier on the microwave - mm wave end than it is on the 100  $\mu$ m end. A rough estimate is that there are 3 - 5 times the experimental and theoretical article coverage at the 30-300 GHz end (1 cm - 1 mm) than there is from 1 mm to 100  $\mu$ m.

As a final note on general atmosphere transmission, we would like to mention the following five papers which have attenuation calculations and measurements, line width functions, etc:

a) "Atmospheric Absorption of Radio Waves Between 150 and 350 GHz" by F. T. Ulaby and Archie Straiton  $^{16}$ 

b) "Calculations of Antenna Temperature, Horizontal Path Attenuation and Zenith Attenuation due to Water Vapor in the Frequency Band 150 - 700 GHz" by R. W. McMillan, J. J. Gallagher, and A. M. Cook<sup>17</sup>

c) "Water Vapor Absorption Spectra of the Upper Atmosphere" (45-185 cm), by G. C. Auguson, A. J. Mord et al.<sup>18</sup>

d) "Method of Calculating the Atmospheric Water Vapor Absorption of MM and Sub MM Waves" by A. Yu. Zrazkevskiy $^{19}$ 

e) "Temperature Dependence of the Absorption of Radio Waves by Atmospheric Water Vapor at the 10 cm - 0.27 mm Wavelengths," by K. A. Aganbekyan, A. Yu. Zrazkevskiy and V. G. Malinkin.<sup>20</sup>

Two curves from McMillan et al<sup>17</sup> serve to summarize much of the atmospheric attenuation data in the mm - sub mm range. Fig. 6 presents horizontal-path attenuation vs. frequency at sea level, and Fig. 7 presents the total zenith attenuation from sea level.

#### 2.2 Atmospheric Index of Refraction

The atmospheric index of refraction is an important parameter which has received much less attention in the literature than atmospheric propagation. An illustration of the problem is from Davis and Cogdell<sup>15</sup> who measured the "differential refractive index" with their 16 foot antenna on Mt. Locke. This is a measure of the difference in pointing direction between optical and radio frequency waves and for some high resolution antennae, this difference (antenna point angle error) can be on the order of the beam width of the antennae. Davis and Cogdell's analysis of their data suggests that the refractive index is fairly well known up to 100 GHz and is given by

N = (77.6P/T) [1 + (4810/T) (e/p)].

where

T = temperature K

P = pressure in mbar

e = water vapor partial pressure in mbar.

Above 100 GHz and below the 140 GHz atmospheric window there is a downward break in the index of refraction as a function of frequency.

In retrospect, one would expect a set of "sag effects" in the antenna pointing error each time the frequency crosses a main atmosphere resonance line. The main absorption lines, below 200 GHz, are at 22 and 183 GHz (water vapor) and at 60 and 118 GHz  $(0_2)$ . Davis and Cogdell saw their "sag effect" in the antenna point angle error on either side (97 and 140 GHz) of the 118 GHz  $0_2$  resonance line. It is suspected that

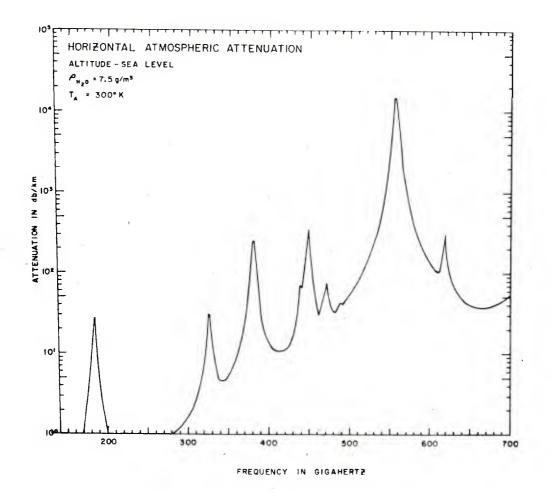

Fig. 6. Horizontal-path Attenuation Versus Frequency at Sea Level (Data from Ref. 17)

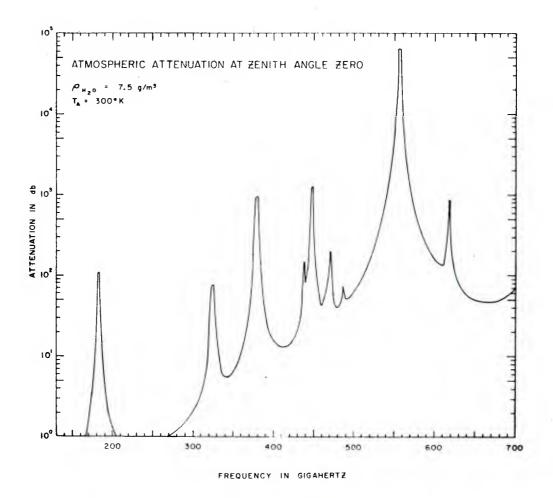

Fig. 7. Total Zenith Attenuation from Sea Level (Data from Ref. 17)

this sort of thing will happen on each side of major atmospheric reasonances, at the frequencies noted just previously, and at higher frequencies, as per the tables of resonances by Corcoran (Table 1) and by Burch (Table III). Also, as the atmospheric attenuation is a function of the relative humidity, so is the index of refraction; one might question if the "sag effect" is more pronounced about either side of the water vapor resonance/absorption lines than about the 60 and 110 GHz oxygen line.

## 2.3 Attenuation and Scattering by Fog, Rain and Clouds

If one knew the size distribution of the water droplets contained in fog, rain or clouds and the complex index of refraction for water as a function of wavelength and temperature, then it is possible to determine the scattering, absorption and extinction cross sections and the phase function with the application of Mie theory. The data available on the complex index of refraction is not very complete and there is not very good agreement in the various published values as a function of wavelength and temperature. For 20°C water, Deirmendjian<sup>21,22</sup> has compiled a set of measured data from 12  $\mu$ m to 1000  $\mu$ m. For wavelengths between 2 mm and 33 mm Deirmendjian used the Debye equation to compute the complex index of refraction for water.

Table VII presents Deirmendjian's collection of complex index of refraction data for water. Dorothy Stewart  $2^{3}$  has tabulated a set of indexes of refraction at 4 wavelengths, .55  $\mu$ m, 10.6  $\mu$ m, 870  $\mu$ m, and 1250 µm. Table VIII lists the data she used in her very comprehensive article on infrared and submillimeter extinction by fog. She mentions in her article about recent sources of complex index of refraction data on water. Table IX, from the 1971 Chemical Rubber Company Handbook of Chemistry and Physics,<sup>24</sup> is a listing of data from two different groups on how the static dielectric constant of water varies with temperature. The static dielectric constant is not a constant, as usually assumed, but varies with temperature. Hale and Querry 25 did a very extensive survey of the optical constants of water with 59 reference listings; they computed the real part of the index of refraction doing a Cauchy principle value integration of smooth curve fits of all available data on the imaginary parts of the index of refraction,  $k(\lambda)$ , of water, from 200 nm to 1 meter wavelength. They produced a table for the complex index of refraction of water from 20 nm to 200  $\mu m$  (just the 100  $\mu m$  - 200  $\mu m$  section is reproduced here as Table X.) R. K. Crane<sup>26</sup> in his article "Microwave Scattering Parameters for New England Rain" presented two sets of calculations of the microwave index of refraction: one set was based on Debye's formula of the index of refraction of water using Kerr coefficients and the other set is attributed by Crane to Grant et al. The results of these calculations

λ	Index of Refraction	λ	Index of Refraction
12.µm	1.111 - 0.199i	500.µm	2.22 - 0.740i

190	-0.501	2.119	
200	-0.504	2.130	

for frequencies between 8 and 70 Ghz are presented here as Table XI. The disagreements between the two sets of refractive indices are more pronounced in the complex part, n", than in the real part, n'. Crane took the Debye index of refraction to be defined by

$$n(\lambda) = \sqrt{\frac{88 - 5.5}{1 + \frac{i \cdot \Delta \lambda(T)}{\lambda}} - 5.5} = n' + i \cdot n''$$

where  $\Delta\lambda(T)$  = temperature-dependent 1/2 width. "88" is actually a temperature-dependent static dielectric constant at 0 frequency. Wilcox and Grazino<sup>27</sup> developed a compilation of the index of refraction of water vs temperature for  $\lambda$  = 1, 3, and 10 mm radiation, shown here as Table XII.

There seems to be a great amount of faith put on the use of the Debye formula for calculating the complex index of refraction of water in the microwave and millimeter wavelength range. It would be interesting to see some <u>measured</u> data in the 1250  $\mu$ m - 1 cm wavelength region, as there was in the 12  $\mu$ m - 100  $\mu$ m region for Deirmendjian's report.

To help visualize better some of the previously-described tabulated measured data on the complex index of refraction for water at wavelengths between 10 and 1000  $\mu$ m, several curves from Deirmendjian<sup>22</sup> are reproduced here as Fig. 8. Also, in Fig. 9. we present the extinction coefficient of water as given by Hale and Querry<sup>25</sup> (imaginary part of complex index of refraction) as a function of wavelength for wavelengths between 10<sup>-6</sup> m and 1 meter. Fig. 10 shows a set of plots from Hale and Querry<sup>25</sup> giving the real part of the index of refraction of water for the spectral region 0.2 - 200  $\mu$ m. The individual data points on each set of curves refer to individual authors data that Deirmendjian and Hale and Querry, respectively, used. For further details about these points, please consult Refs. 21, 22, and 25.

Table XII. Indices of Refraction for Water vs Wavelength (from data in Ref. 27)

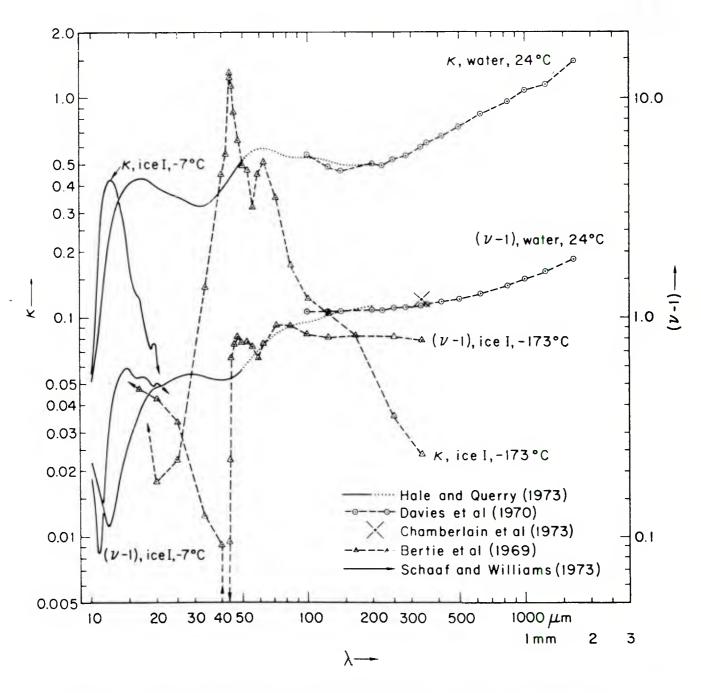

Fig. 8. Optical Constants of Water According to Recent Measurements (Data from Ref. 22)

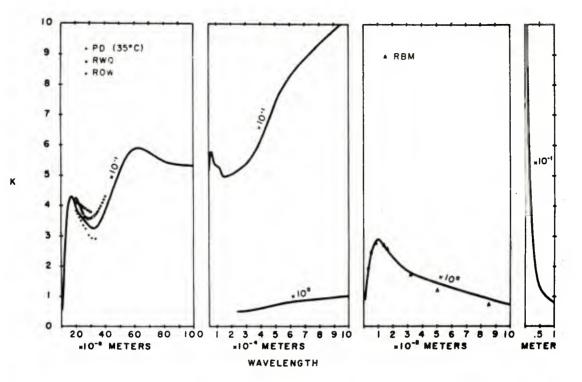

Fig. 9. Imaginary Part of the Index of Refraction of Water vs. Wavelength (from Ref. 25)

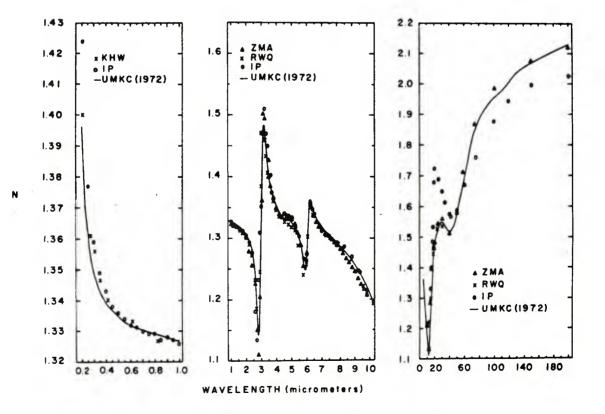

Fig. 10. Real Part of the Index of Refraction of Water vs. Wavelength (from Ref. 25)

Chamberlain, Zafer and Hasted<sup>28</sup> have measured the index of refraction of water between .1 mm and 0.5 mm using a Michelson interferometer. Results of their measurements, and some others they quote are shown in Fig. 11.

One needs to have indices of refraction (or the dielectric "constant", equivalently) available as a function of temperature when computing scattering, absorption and extinction cross sections with the use of Mie or Rayleigh theory.

The need for further work on the complex index of refraction for water is obvious; first in priority with respect to water is the need for experimental data on the complex index of refraction as a function of temperature over the entire wavelength range of interest. Most severe is the requirement in the 1 cm - 1 mm region where everyone seems to rely on the Debye equation with no references to actual dielectric/ refractive index measurements in that spectral region.

A. Stogryn<sup>29</sup> has developed a modification of the Debye equation for the complex dielectric "constant" of saline water. He has given parameters in the equation as functions of water temperature and salinity. The dielectric constant is defined by

$$K = \varepsilon_{\infty} + \frac{\varepsilon_{o} - \varepsilon_{\infty}}{1 - i \cdot 2\tau \pi f} + \frac{i\sigma}{2\pi \varepsilon_{o}^{*} f}$$

with

ε = temperature- and salt-control-dependent static dielectric constant

 $\tau$  = time constant as a function of temperature and normality of the salt solution =  $\tau(T, N)$ 

- f = frequency in Hertz
- ε<sub>∞</sub> = 5.5
- $\sigma$  = ionic conductivity of the dissolved salt in mho/meter  $\varepsilon_{0}^{*}$  = permittivity of free space = 8.854X10<sup>-12</sup> Farad/meter.

He gave  $\varepsilon_0$ ,  $\tau$ , and  $\sigma$  as a function of the normality of the salt solution.

A relationship of this sort should be valuable in the calculation of scattering by slightly salty fogs (sea spray), or fogs that have become

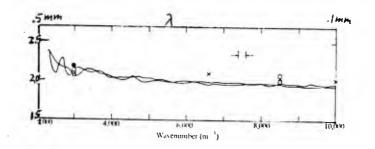

Fig. 11. Measured Values of the Real Component of the Refractive Index for Water (the full lines are from two independent measurements by the authors of Ref. 28. The points are measurements by other authors and by the authors of Ref. 28).

. . .

contaminated with ZnCl dust from smoke screens or from burning phosphorous, which forms  $P_2O_5$ , which becomes dilute phosphoric acid when the  $P_2O_5$  contacts a fog droplet.

There are several basic texts that are of value for information on dielectrics; these are: <u>Dielectrics and Waves</u>, by A. R. Von Hippel,<sup>30</sup> <u>Dielectric Materials and Applications</u>,<sup>31</sup> by A. R. Von Hippel, and <u>The</u> <u>Theory of Electric and Magnetic Susceptibilities</u><sup>32</sup>. Von Hippel's books have been the compendium of information on dielectric phenomena for 20 years. Van Vleck's treatise,<sup>32</sup> now 44 years old, still is one of the best introductions to dielectric and magnetic phenomena extant. Van Vleck recently<sup>33</sup> has written a revised version of his classic papers on line breadths and should be consulted for details as to validity of the formula presented here or by other authors regarding this area.

The principal difference between fog, rain and clouds when determining their scattering, absorption and extinction cross sections is in the range of drop diameters for each. The ranges of drop diameters for haze, fog, clouds, and rain, as given by G. D. Luhers,<sup>34</sup> are given in Table XIII. Note that although there is quite an overlap in drop diameters for fogs, clouds and rain, there is a tendency to larger drop diameters as the atmospheric conditions change from clouds to fog to rain.

The calculation of the absorption, scattering and extinction in a medium such as fog, clouds and rain is based on the knowledge of the absorption, scattering and extinction cross sections for individual particles. The theory for calculating these cross sections for individual spherical particles was developed by Mie.<sup>35</sup> Mie's work was extended by Stratton<sup>36</sup> and, as outlined in Kerr,<sup>37</sup> by Goldstein. A Comprehensive study of the theory of electromagnetic scattering from small particles is also given by Van De Hulst.<sup>38</sup>

A single dielectric sphere in the path of a plane wave will scatter and absorb some of the incident energy. These effects are characterized by several quantities called cross sections and have the dimensions

## Table XIII. Drop Diameters for Various Atmospheric Conditions (from Ref. 34)

ATMOSPHERIC CONDITION	DROP SIZE RANGE Micrometers
Haze	0.01 - 3
Fog	0.01 - 100
Clouds	1 - 50
Drizzle (0.25 mm/hr)	3 - 800
Moderate Rain (4.0 mm/hr)	3 - 1500
Heavy Rain (16.0 mm/hr)	3 - 3000

د،

of area. The Gunn and East<sup>39</sup> definitions of the scattering, absorption, extinction, and backscatter cross-sections are:

Scattering Cross Section = 
$$\frac{\text{Total Power Scattered (over 4\pi steradians)}}{\text{Incident Power Density}}$$
  
Absorption Cross Section =  $\frac{\text{Total Power Absorbed (as heat)}}{\text{Incident Power Density}}$   
Extinction Cross Section =  $\frac{\text{Total Power Lost (to the incident wave)}}{\text{Incident Power Density}}$ 

The term extinction is used to describe the energy lost by the incident wave to a single particle; attenuation is the energy lost to a continuous volume of particles.

It should be noted that the conservation of energy requires that

$$Q_e = Q_a + Q_s$$

and

 $\begin{array}{r} \mbox{Backscatter Cross Section} = \frac{\mbox{Total Power Scattered Backward (along the direction of incidence)}}{\mbox{Incident Power Density}} \end{array}$ 

The scattering and absorption properties of single particles are we complex functions of the size, shape, and index of refraction of the particles as well as the wavelength of the incident energy. The scattering, absorption, extinction and backscattering cross sections for 4.3 mm wavelength radiation interaction with spherical water spheres at 18°C (from Ref. 40), are presented in Fig. 12 as a function of the particle radius. It is seen that the cross sections increase with radius for radii between 0 and 6 mm.

For mm wavelength radar our interest lies in the backscatter and attenuation cross sections associated with a continuous distribution of particle sizes within a given volume. Particle size distributions for rain, fog and clouds are given by Deirmendjian<sup>22</sup> and Richard.<sup>40</sup> If the particle size distribution is known, the reflectivity and attenuation can be determined, using the appropriate scattering theory.

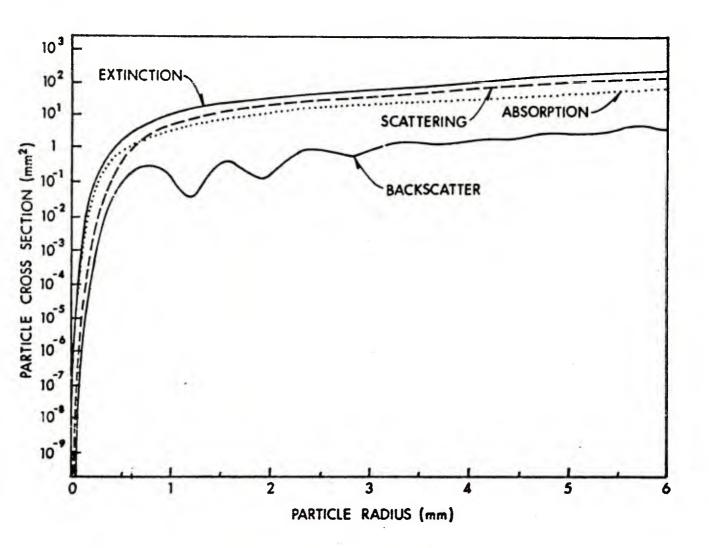

Fig. 12. Cross Sections of Water Spheres at 18°C for 4.3 mm Wavelength Energy (from Ref. 40)

The scattering theory to be used in the determination of the backscatter and attenuation of rain and fog depends on the size of the drops in the medium and the wavelength of the radiation. Mie scattering theory must be used for drops larger than 0.06 wavelength in diameter. For drops smaller than 0.06 wavelength the Rayleigh theory approximations are applicable.

Since rain is comprised of drops 258 micrometers (0.258 mm) and larger, Mie scattering theory must be used for millimeter wavelength radiation. The smaller drops in haze, fog and clouds allow the use of the Rayleigh approximation.

Fog results from the condensation of atmospheric water vapor into water droplets that remain suspended in the air. When the resulting cloud or water droplets or ice crystals envelop an observer and restrict his horizontal visibility to one kilometer or less, the international definition of fog has been satisfied. Evaporation and cooling are the principal physical processes which contribute to the formation of fog. Of the various fog classifications used by meteorologists, the two basic types of interest in radar applications are advection fog and radiation fog.

Advection is the horizontal movement of an air mass that causes changes in temperature or other physical properties. An advection (or coastal) fog is one which forms over open water as a result of the advection of warm moist air over colder water.

Radiation (or inland) fog forms in air that has been over land during the daylight hours preceding the night of its formation. Fogs which form in low, marshy land and along rivers on calm, clear nights are also considered radiation fogs.

The characteristics of these two fogs are given in Table XIV.

Note that the advection fog has a higher liquid water content, but greater visibility than the radiation fog. The correlation of visibility in fog to liquid water content is shown in Fig. 13 (from

Table	XIV.	Fog	Characteristics
-------	------	-----	-----------------

(Data from Ref. 40)

ч	RADIATION (INLAND) FOG	ADVECTION (COASTAL) FOG
Average Drop Diameter	10 microns	20 microns
Typical Drop Size Range	5-35 microns	7-65 microns
Liquid Water Content	$0.11 \text{ g/m}^3$	$0.17 \text{ g/m}^3$
Droplet Concentration	$200 \text{ cm}^{-3}$	40 cm <sup>-3</sup>
Visibility	100 m	200 m

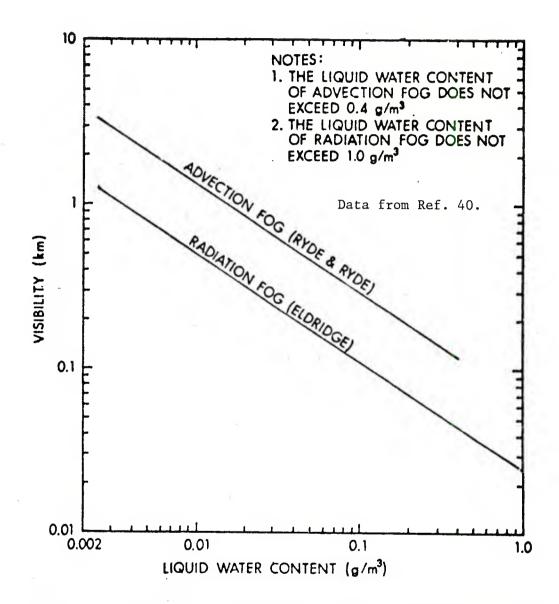

Fig. 13. Correlation of Visibility in Fog to Liquid Water Content

Ref. 40) for both advection and radiation fogs.

There is considerable variation in the water content of clouds and water fogs, but in general, stratus (or low) clouds and typical radiation or advection fogs have water contents on the order of  $0.25 \text{ g/m}^3$  or less. Mason<sup>41</sup> reports that the maximum liquid water content of an advection fog approaches  $0.4 \text{ g/m}^3$  when there is a strong temperature inversion. On rare occasions, the liquid water content can become as large as 0.5 to  $1.0 \text{ g/m}^3$  in very dense radiation fogs (with 20 to 30 meters visibility).<sup>42</sup>

The small size of water droplets comprising a fog allows the use of the Rayleigh approximations in the determination of the reflectivity and attenuation at 70 GHz. Atlas<sup>43</sup> shows that in the Rayleigh scattering region the one-way attenuation coefficient,  $\alpha$ , is given by

$$\alpha = \frac{81.86 \text{ M Im}(-K)}{\lambda \rho} \text{ dB/km},$$

where M =liquid water content per unit volume of fog in  $g/m^3$ , Im(-K) = absorption coefficient.

$$K = \frac{m^2 - 1}{m^2 + 2}$$

m = complex index of refraction,

 $\lambda$  = wavelength in mm,

 $\rho$  = density of water in g/cm<sup>3</sup>.

A density of 1 g/cm<sup>3</sup> for water is generally assumed for all temperatures, since the density varies no more than 0.78% over the 0°C to 40°C temperature range.

In the Rayleigh scattering region, attenuation is due mainly to absorption. To calculate the absorption coefficient for fog, the index of refraction for water must be determined for the frequencies of interest. The complex index of refraction, m, is given in terms of the complex dielectric constant,  $\varepsilon_{c}$ , by:

$$m^2 = \varepsilon_c = \varepsilon_1 - j\varepsilon_2,$$

where  $\epsilon$ , and  $\epsilon_2$  are the real and imaginary parts of the dielectric constant.

The dielectric constant may be evaluated by the Debye  $formula^{37}$ 

$$\varepsilon_{\rm c} = \frac{\varepsilon_{\rm o} - \varepsilon_{\rm o}}{1 + j \frac{\Delta \lambda}{\lambda}} + \varepsilon_{\rm o},$$

where  $\epsilon_{o}$  ,  $\epsilon_{\infty}$  and  $\Delta\lambda$  are empirically derived constants.

Let us now look at some of the data currently available on millimeter and submillimeter wavelength attenuation in fog, clouds, and rain. Victor W. Richard, in Ref. 40, has given a good description of rain, fog and cloud data, from which a lot of this section's information is derived. A summary of the data from Richard<sup>40</sup> is presented in Figs. 14 and 15. Fig. 14 shows the positions of the atmospheric "windows", and the "walls". The profitable areas for further work in the millimetersubmillimeter region apparently should center around wavelengths of 94 GHz, 140 GHz, 240 GHz, 360 GHz, 420 GHz, and 890 GHz. Past 240 GHz, long-range communications do not appear to be practical; however, short range uses as missile guidance radar and imaging, target designators, and others, should be feasible. Fig. 15 is a comparison of the one-way attenuation due to a fog of 100 m visibility having a density of 0.1  $gm/m^3$ with the one-way attenuation for 3 rain rates as a function of frequency. Fig. 16 (Ref. 40) shows in more detail the one-way attenuation of a fog as a function of frequency, temperature and liquid water content. A. R. Downs<sup>44</sup> has calculated haze and fog attenuation coefficients for visible and IR radiation, as well as for microwaves with frequencies between 9.375 to 240 GHz. These data are shown on Table XV. Downs' article references 27 different papers on atmospheric transmission on rain, fog and battlefield dust conditions.

Dorothy Stewart  $^{45}$  in her extensive literature search on fogs and their drop sizes, has computed the extinction of visible. IR, and

submillimeter energy by fogs. Results of her calculations are shown in Figs. 17, 18, and 19. Fig. 17 shows a comparison of the attenuation of 1250  $\mu$ m and 10.5  $\mu$ m radiation by fog droplets; Fig. 18 shows a comparison of the attenuation of 1250  $\mu$ m and 0.55  $\mu$ m radiation by fog droplets; and Fig. 19 shows a comparison of the attenuation of 1250  $\mu$ m and 870  $\mu$ m radiation by fog droplets. We see from Fig. 18 that the visibility at .55  $\mu$ m is not necessarily a good indicator of 1250  $\mu$ m attenuation, but that the correlation of 10.6 and 1250  $\mu$ m attenuation is pretty good. Also, the correlation of attenuations of 870  $\mu$ m and 1250  $\mu$ m radiation is good.

Downs<sup>44</sup> calculated the scattering coefficient for haze and fog at millimeter wavelengths and concluded that the scattering coefficient was between  $10^{-4}$  and  $10^{-5}$  (km<sup>-1</sup>) which is at least 6 orders of magnitude below that of the scattering coefficients for haze and fogs at wavelengths of .55  $\mu$ m - 10.6  $\mu$ m.

V. Corcoran<sup>46</sup> has calculated the fraction of the total attenuation along a zenith path through the atmosphere containing a 500-m thick stratocumulus cloud that results from the water droplets in the cloud and from the gaseous absorption along the total path. It is seen from Table XVI that the contribution to the attenuation by cloud droplets increases with an increase in the wavelength for wavelengths between 0.345 mm and 3 mm. Similarly the contribution to the attenuation by gaseous absorption increases with a decrease in wavelength. The attenuation resulting from gaseous absorption is seen in Table XVI to increase faster with decreasing wavelength than does the attenuation produced by the cloud droplets.

D. Deirmendjian<sup>22</sup> has calculated extinction coefficients according to 3 cloud models and 2 precipitation models; his results are shown in Fig. 20. His calculations were for wavelengths between 1.0  $\mu$ m to 100 mm. Tabulated values of this data are presented in Table XVII. Deirmendjian has also calculated a set of mass extinction coefficients for haze, clouds, and rain; this data are presented in Table XVIII for discrete wavelengths between 16  $\mu$ m to 2.0 mm.

Lo, Fannin and Straiton<sup>47</sup> have measured "the attenuation of 8.6 and 3.2 mm radio waves in clouds" by use of a millimeter wave radiometer. Results of their measurements are shown in Figs. 21, 22, and 23. Corrections were made to the measured data for the attenuation resulting from the atmosphere gaseous constituents to obtain estimates of the cloud attenuations. The correction for water vapor attenuation was based on ground-level water vapor density measurements. The sum was used as a source of millimeter wavelength radiation with the radiometer pointing at it through the clouds. Figure 21 presents 35 GHz (8.6 mm) attenuation vs 95 GHz (3.2 mm) attenuation for heavy pre-rain clouds. Figure 22 presents the total (zenith) attenuation due to cumulus clouds for 92

and 35 GHz radiation. Figure 23 shows the attenuation effects of an overcast sky versus air mass (secant of zenith angle) for 35 GHz and 92 GHz radiation.

As a function of cloud type,  $Lo^{47}$  <u>et al</u>. have summarized their measurements in two tables: the first, presented here as Table XIX gives the attenuation in db, for 35 and 95 GHz radiation, due to individual fair-weather cumulus clouds. In Table XX is a summary of zenith cloud attenuation for 35 and 95 GHz radiation by different cloud types.

Corcoran<sup>46</sup> has calculated data on the attenuation due to moderate rain of a 2-km depth (zenith path through a 500 m thick strato cumulus cloud). His data for attenuation of radiation with wavelengths in the atmosphere windows between 345  $\mu$ m to 3 mm are given in Table XXI.

There is a vast literature on the scattering and attenuation of millimeter and submillimeter radiation by rain. Before we get into the data and calcualtions that were found relevant, let us discuss some of the currently used size distributions for rain droplets. D. Deirmendjian<sup>22</sup> introduced a general raindrop sized distribution,

$$n(r) = ar^{\alpha} \exp(-br^{\gamma})$$

to model both clouds, hazes and raindrops. The parameters a,  $\alpha$ , b,  $\gamma$  are positive, real numbers that may be related to measurable parameters. For  $\gamma = 1$ ,

$$\int_{0}^{\infty} n(r)dr = N = \text{total number of particles per unit volume}$$

in the distribution. This gives

$$a = \frac{Nb^{\alpha+1}}{\Gamma(\alpha+1)}$$

Some other properties of Deirmendjian's distribution are that there is only one peak in the distribution, there is exponential decay in the number density in both increasing drop size and a cut-off on decreasing drop size.

<sup>a</sup>No allowance made at these wavelengths for possible reduction in attenuation due to moderate rain by the mechanism of forward scatter. <u>Note</u>: Values in parentheses are extrapolated.

Other prominently used drop-size distributions are those attributed to Laws and Parson<sup>49</sup>, Marshall and Palmer<sup>50</sup> and Best.<sup>51</sup> These distributions are illustrated by the following tables and graphs. Table XXII shows, for the Laws and Parson drop-size distribution, the percent of the total of water versus the particle size for 5 different rain rates. Similar data for the Marshall and Palmer distribution are shown in Table XXIII. The data in Tables XXII and XXIII were obtained from a paper by Wilcox and Graziano.<sup>52</sup> Figure 24 shows data based on the Best model that gives the drop radius concentration as a function of droplet radius for rainfall rates of 1, 4, 16, and 64 mm/hr. The Best model describes the fraction of the total liquid water contained in the water drops which have diameters less than x (mm) for a given rainfall rate R (mm/hr). The Best model is defined by:

where

 $F(x) = 1 - \exp[-(x/a)^{n}],$  $a = AxR^{p}.$ 

The total liquid water content expressed in  $mm^3/m^3$  is

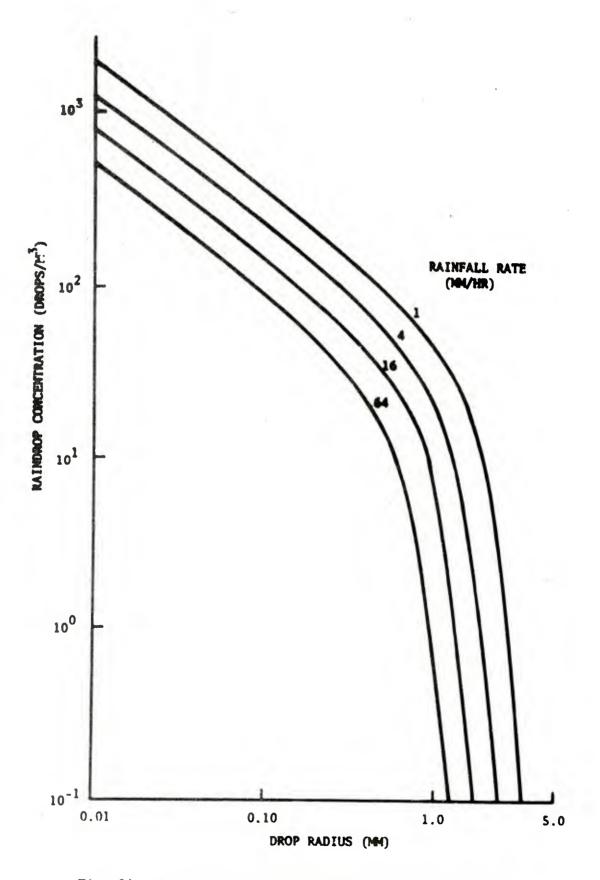

w =  $CxR^r$ A = 1.3, c = 60, p = 0.232, r = 0.846, and n = 2.25. Downs<sup>44</sup> felt that the Best distribution most accurately describes the 70 GHz scattering data for rain. He calculated a rain scattering coefficient as a function of rainfall rate (or visibility) for visible light, IR, microwaves and millimeter wave radiation. Downs used the Laws and Parson's drop radius distribution in calculating the microwave and millimeter wave rain scattering coefficients. Downs' results are depicted in Tables XXIV and XXV. Table XXIV gives the rain scattering coefficient in km<sup>-1</sup> vs visibility (or rainfall rate) for visible through 10.6  $\mu$ m radiation, and Table XXV gives the rain scattering coefficient per km vs rainfall rate for frequencies of 9.375 GHz through 240 GHz. Absorption coefficients in rain for 9.375 GHz to 240 GHz radiation were calculated by Setzer;<sup>53</sup> his results are shown here as Table XXXVI.

D. C. Hogg's<sup>54</sup> measured data on the one-way attenuation due to rain at 70 GHz and some theoretical data by Crane<sup>26</sup> and SRI<sup>40</sup> are presented in Fig. 25. Crane<sup>26</sup> calculated the one-way attenuation in rain vs rainfall rate and showed that the Laws and Parson's model fits Hogg's data best; Crane's data are for frequencies of 15.5, 35, 70, and 94 GHz. V. Richard<sup>40</sup> compiled this set of Crane's data, and his compilation is shown in Fig. 26.

D. Deirmendjian's<sup>22</sup> calculations of the extinction coefficient resulting from rainfall are given in Fig. 20, where the extinction coefficient  $\beta_{ext}$ , km<sup>-1</sup> vs wavelength is shown for 3 cloud models and 2 rainfall models. The wavelength coverage is from 1.0  $\mu$ m to 100 mm.

Downs<sup>44</sup> has combined the scattering and absorption tables for visible, IR, microwave and millimeter wave radiation, and his results, giving the rainfall attenuation coefficients vs rainfall rate, are presented in Table XXVII.

Wilcox and Graziano<sup>27</sup> calculated the combined atmospheric attenuation by water vapor ( $\alpha_w$  (vapor)), oxygen ( $\alpha_o$ ), and rain ( $\alpha_w$  (cond)). They plotted the total attenuation (db/km) vs rainfall rate for radiation of wavelength 3, 4, 8, and 10 mm, for rainfall rates of 0.1 mm/hr to 100 mm per hour. Their results are presented in Fig. 27.

Crane<sup>26</sup> has calculated the rain backscatter cross section per unit volume of rain at 0°C vs rainfall rate for 15.5, 35, 70, and 94 GHz, using the Mie scattering theory. His data are presented in Fig. 28. (Downs<sup>40</sup> collected Crane's curves and produced the composite curve presented here as Fig. 28.) Victor Richard and John Kammerer<sup>55</sup> of BRL have collected data from measurements and calculations of the radar backscatter cross section per unit volume for 9.375, 35, 70 and 95 GHz frequencies. These data are plotted as a function of rain rate, from 0.1 mm/hr to 100 mm/hr in Figs. 29, 30, 31, and 32. Figure 29 presents BRL's measured data of backscatter cross section vs rain rate for the 4 frequencies mentioned. Figure 30 presents BRL's 35 GHz backscatter cross section vs rain rate as well as a number of other calculations and measurements. Figure 31 presents BRL's 70 GHz data and a collection of other calculations and

measurements which were referred to in their article. Figure 32 presents BRL's 95 GHz data along with other calculations and measurements. The reader is referred to Ref. 55 for further details on these curves.

A. V. Sokolov<sup>56</sup> computed the attenuation in rain, in dB/km vs intensity of rainfall, 1-100 mm/hr, for visible, IR, and microwave frequencies, for .63  $\mu$ m - 8 mm, using Mie theory, where applicable, and Best's drop-size distribution. His results are shown in Table XXVIII.

Serge Godard<sup>57</sup> measured the reflectivity of rain drops as a function of drop radius for radiation of .86 cm, 3.21 cm, 5.5 cm, and 10 cm wavelength. His data on rain-drop reflections are shown here in Fig. 33. He also found that for 0.86 cm waves, the attenuation in rain is really independent of the drop-size distribution; even though the reflectivity is very much a function of drop diameter.

Malinkin, Sokolov, and Sukkonen measured the attenuation coefficient in dB/km for 8.6 mm radiation, and computed the attenuation for 1, 2, 4 and 8.6 mm radiation. The results of their calculations are shown in Fig. 34. Figure 35 shows more details of their measured and calculational data on the attenuation coefficient at  $\lambda$ =8.6 mm as a function of rainfall rate.

Sokolov and Sukkonen<sup>59</sup> computed the attenuation of radio-waves in the 0.1-2mm range using the drop-size distributions of both Best and Polyakova. For rain rate less than 10-12 mm/hr, using Mie theory, the computations were in agreement with experimental data at 0.96 mm. The results of their theoretical calculations are shown in Table XXIX.

Bakin. Zimin et al.<sup>60</sup> measured the attenuation in rain of radiowaves of 0.96 mm. The results of their measurements are shown in Fig. 36. They found that compared to radiation of 8.6 mm, the attenuation at 0.96 mm is larger roughly by a factor of 2.5 to 3.0. Table XXX tabulates their data (average values) with some of Medhurst<sup>61</sup> at 0.96, 4.3, 6.2, 8.6 and 9.6 mm for rainfall intensity of 5 and 12 mm/hr.

In 1970, V. I. Rozenberg<sup>62</sup> performed a critical review of radar characteristics of rain in the submillimeter range. He calculated the backscattering cross section and the attenuation coefficient for submillimeter radiation using the Marshall-Palmer and Best drop-size

6.2	3.0	6.5		
8.6	2.2	3.0		
9.6	1.2	2.0		

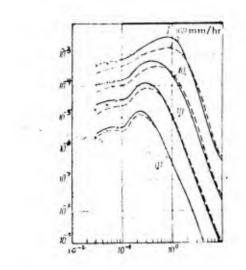

distributions. Results of his calculations for the backscattering cross section in units of  $(m^{-1})$  are shown in Fig. 37. His attenuation coefficient, in dB/km, is shown in Fig. 38. Both calculations were for radiation of wavelengths of 0.3 mm to 10 cm, and rainfall rates of 0.1, 1, 10, and 100 mm/hr. He presented a large bibliography on work performed prior to 1970, with 60 references.

Joerg Sander<sup>63</sup> measured the attenuation due to rain at 5.77, 3.3, and 2 mm. Simultaneously recorded were rainfall rate and a part of the drop-size spectrum. He calculated the total cross section of spherical water drops at a temperature of 10°C as a function of radius, from 0.3-3.5 mm, using Mie scattering theory. Sander's calculated cross section data are shown in Fig. 39. His measured attenuation data are presented in Figs. 40, 41, and 42 as scattergrams for 5.77, 3.3 and 2.0 mm wavelength radiation respectively. The measured data are compared in these figures with a calculation of the attenuation in dB/km vs rainfall rate for 5.77 mm, 3.3 mm and 2 mm radiation, respectively. Also plotted on these scattergrams were regression curves for rainfall rate with attenuation.  $\overline{R}_{A}|D$ , and attenuation with rainfall rate  $\overline{D}|R_{A}$ .

Robert Crane wrote a tutorial article on "Attenuation due to Rain, a Mini Review."<sup>64</sup> He reviewed progress on the development and verification of a theory of rain-caused attenuation, and considers the the statistical models required to predict attenuation, ca 1975. Wavelength coverage in his article appears to be from 15 cm to 0.8 cm.

R. R. Rogers<sup>65</sup> has reviewed "Statistical Rainstorms Models: Their Theoretical and Physical Foundations," in a long article, ca 1976. Most of the data discussed by Rogers is for propagation of 10-20 GHz radiation in rain, but some millimeter wavelength data is discussed. He has a number of suggestions for further research.

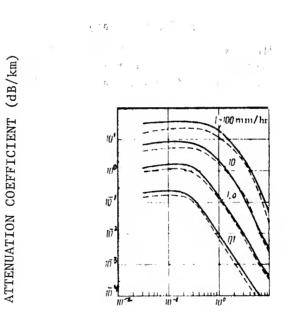

G. C. McCormick<sup>66</sup> wrote an article on theory of propagation in a precipitation medium, considering the polarization aspects of the rain. He concluded that the most advantageous polarizations for the measurements for (rain) medium characteristics are right-hand circular, left-hand circular, and  $\pm$  45° slant linear (with respect to the rainfall direction).

Radio waves of 16.5 - 30.9 GHz were considered in his calculations.

Julian Goldhirsh $^{67}$  computed some attenuation fade statistics for satellite to 2 ground stations separated by a distance d. He modeled the total (zenith path) attenuation by

$$A_{i} = \int_{0}^{li} k(l) dl \text{ (in } dB),$$

where

 $k(l) \simeq a[z(l)]^{b}$  in dB/km..

The values of a and b used by Goldhirsh are given in Table XXXI. He also computed the joint conditional probability that attenuation at two terminals separated by a distance d exceeds the abcissa at path elevation angle  $\theta = 45^{\circ}$  at 100 GHz. His joint probability calculations are presented here as Fig. 43. He has done similar calculations for frequencies of 13, 18, and 30 GHz. He used the radar reflectivity of rain at 2.8 GHz as part of his data base.

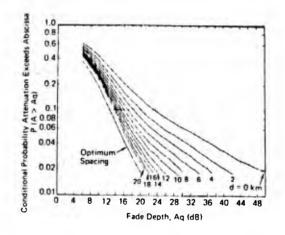

P. Wiley<sup>68</sup> in his PhD thesis, considered the non-sphericity of raindrops regarding scattering calculations, reviewing Oguchi's work of the 1960s. He then extensively reviewed the literature on cm and mm rainfall propagation experiments. He analyzed in detail some 19.3 GHz data for polarization effects. He compared his results for rainfall attenuation with that of Oguchi, for horizontal and vertical polarization for a 1.43 km path at 19.3 GHz. His data are shown here as Fig. 44. He calculated the cross polarization vs pathlength for a tilt angle of 60° and a frequency of 19.36 GHz. His results are shown in Fig. 45. He did similar calculations for a tilt angle of 75°; those results are shown in Fig. 46. Conclusions he reached regarding the influence of polarization on millimeter wave propagation through rain are the following:

 The best polarizations to use for a depolarization experiment are ± 45° from the vertical.
 Vertical and horizontal polarizations should not be used for a depolarization experiment.
 Vertical polarization suffers the least average attenuation during rainfall.
 Oguchi's attenuation and phase rotations for 19.36 GHz are correct.

percentage of oblate drops assumed in an analysis is critical to the predicted polarization level. 6) Polarization diversity is not feasible as a means of increasing resistance to rain-induced fading. 7) The use of polarization multiplexing utilizing orthagonal polarizations is limited to very short path lengths. 8) Use of a distribution of raindrop sizes is unnecessary to get good agreement between theory and experiment(!).

Louis Ippolito,<sup>69</sup> the NASA Goddard ATS-5 and 6 millimeter wave communications experiment manager, wrote his 1977 PhD thesis on "Scattering in Discrete Random Media with Implications to Propagation through Rain." Ippolito<sup>70</sup> investigated the multiple scattering effects on wave propagation through a volume of discrete scatterers. The mean field and intensity for a distribution of scatterers was developed using a discrete random media formulation, and second order series expansions for the mean field and total intensity derived for onedimensional and three-dimensional configurations. The volume distribution results were shown to proceed directly from the one-dimensional results. Ippolito's analyses demonstrated that either discrete or continuous techniques may be employed for the mean field and intensity expansions, as long as care is taken to insure non-overlapping scatterers in the formulation. The multiple scattering intensity expansion was compared to the classical "single scattering" intensity and the classical result was found to represent only the first three terms in the total intensity expansion. The Foldy approximation to the mean field was applied to develop the coherent intensity, and was found to exactly represent all coherent terms of the total intensity. An incoherent intensity term, secular in L, in path length, was found which was not accounted for in the Foldy approximation result or in the "single scattering" formulation. Ippolito's study demonstrated the feasibility of using discrete random media techniques for the determination of multiple scattering effects in propagation through a volume of discrete scatterers, and has provided some insight to the more general problem of multiple scattering in a rain volume.

L. Ippolito<sup>70</sup> chaired a meeting on the 20 and 30 GHz experiments with the ATS-6 satellite. A number of interesting papers on the attenuation and depolarization of 20 and 30 GHz radiation was presented at that meeting.

# 2.4 Scattering and Attenuation by Snow

The scattering of radiation by snow is different than the scattering by rain in that the dielectric constant of ice is much less than that of water, and that the ice particle making up snow is distinctly nonspherical.

M. D. Blue<sup>71</sup> of Georgia Tech measured the permittivity of water and ice at 97-103 GHz by a reflectivity measurement of water and ice relative to mercury. He found that the reflectivity of water was:

 $R = 0.392 \pm .014$  for 103.8 GHz radiation,

thus n - ik = 3.24 - 1.825i for the index of refraction for water and  $\varepsilon' - i\varepsilon'' = 7.16 - 11.825i$  for water's dielectric constant.

He also measured the reflectivity of water at temperatures from 32°C to 47°C at 103.8 GHz, though no sets of terms for Debye's equation were given, as a function of temperature. The index of refraction of ice at 99 GHz was found to be  $1.7 \pm .08$ , real, within experimental measuring ability.

The literature on scattering and attenuation by snow in the millimeter wave range is very sparse. Malinkin, Sokolov and Sukhonin<sup>58</sup> measured the attenuation due to snow at 8.6 mm wavelength. Their result, in dB/km vs snowfall rate in mm/hr is shown here as Fig. 47. They concluded that the attenuation in dry snow is 2.5-5 times smaller than the attenuation in rain of the same intensity. Reference 58 includes a reference list of 11 articles.

Yu. S. Babkin et al.<sup>72</sup>, measured the attenuation of radiation at a wavelength of 0.96 mm in snow, with a vertical polarization, and a 680 m path length. The following empirical relation was found to fit the mean attenuation in dB/km vs snowfall rate in mm/hr,

Measured Attenuation Coefficient at  $\lambda$ =8.6 mm vs Snowfall Rate (for a Snow Density of  $\rho \simeq 0.008 \text{ gm/cm}^3$ ). Dashed Curve Gives Averaged Experimental Data (from Ref. 58)

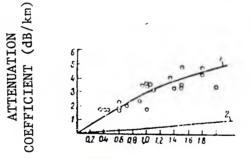

Fig. 48.

Comparison of Measured and Calculated Attenuation Coefficient in Snow vs Snowfall Rate for  $\lambda$ =0.96 mm (Curve 1 and Points are Experimental Data, Curve 2 is Based on Mie Computations) (Data from Ref. 72)

 $\gamma (dB/km) = 3.02 I.^{79}$ 

where I = snowfall rate per mm/hr.

When the authors of Ref. 72 tried to analyze the measured attenuation data with the use of Mie theory, they obtained results that disagreed with the measurements by a factor of about 3. They assumed that the ice index of refraction was 1.78-0.00024i, and estimated that a homogenous mixture of ice, water and air (making up snow) would have an index of refraction of

 $\text{m}_{_{\rm S}}$  = 1.052 - 0.00012i for  $\lambda$  = 0.96 mm.

They assumed that an equivalent volume of snow (melting ice) would have a density of 0.07 gm cm<sup>-3</sup>. They calculated an attenuation coefficient related to that of water of the same wavelength. Doing this, they found that attenuation in rainfalls is 30 - 40% <u>less</u> than in snow of the same equivalent water content. Babkin's data on snowfall attenuation in dB/km vs snowfall rate is shown in Fig. 48.

2.5 Attenuation by Ozone in the Atmosphere.

Ozone is an atmospheric constituent that manifests itself most at higher altitudes except during thunderstorms, lightning, etc., and in and around arcking electronic devices (brush type motors).

The most comprehensive article on the millimeter wave spectrum of ozone is by M. Lichtenstein, J. Gallagher, and S. A. Clough.<sup>73</sup> They used a Stark effect spectrometer and measured absorption lines for frequencies between 9.2 to 320 GHz. Results of their absorption measurements are given in Table XXXII. Note that the strongest lines (where the intensity is more than  $5\times10^{-4} \times 10^{-19}$  cm<sup>-1</sup>/molecule/cm<sup>2</sup>) occur at frequencies higher than 230 GHz.

A. Barbe, C. Secroun et al., more recently (1977) remeasured some of the absorption lines of ozone in the 15-80 GHz region; their

new results are presented here as Tables XXXIII and XXXIV. Table XXXIII is for rotational lines of  $0_3$  in the  $v_1$  (ground) state and Table XXXIV is for rotational lines of  $0_3$  in the  $v_3$  (ground) state.

A spacecraft instrument was developed for the measurement of the mm characteristics of ozone by personnel at the Ewin Knight Company.<sup>75</sup> They chose a line at 101.7 GHz for radiometrically measuring the emitted radiation of the air mass beneath the spacecraft. Reference 75 describes the design of the instrument from concept phase, laboratory phase, through a balloon-mounted instrument, and to a spacecraft flight instrument. Canton, Manneller et al.<sup>78</sup> define the ozone absorption coefficient as:

$$\alpha_{oz} = \frac{A_{1}e^{-A_{s}/T}}{T^{5/2}} NO_{3} \cdot v^{2} \left[ \frac{\Delta v}{(v-A_{3})^{2} + (\Delta v)^{2}} + \frac{\Delta v}{(v+A_{3})^{2} + (\Delta v)^{2}} \right]$$

where

$$\Delta v = \left[ \left[ A_4 P T^{-1/2} \right]^2 + \left[ A_5 T^{1/2} \right]^2 \right] \frac{1}{2}$$

For the 101.7 GHz transition,

$$A_1 = 1.2 \times 10^{-24} \text{km}^{-1}$$
;  $A_2 = 13.1^{\circ}\text{K}$ ;  $A_3 = 101.7368 \times 10^4 \text{Hz}$   
 $A_4 = 5.28 \times 10^7 \text{Hz} (^{\circ}\text{K}^{1/2}) \text{ mm}^{-1}$ ,  $A_5 = 7.31 \times 10^3 (^{\circ}\text{K})^{-1/2}$ 

These constants  $A_1$ ,  $A_2$ ,  $A_3$ ,  $A_4$  and  $A_5$  are from Gora,<sup>76</sup> and Townes and Schawlow.<sup>77</sup> A comparison of measured absorption profile data taken with use of the instrument described in Ref. 75 and calculated absorption profiles based on the above equation is shown in Fig. 49.

2.6 Attenuation and Scattering by Atmospheric Aerosols

First, let us consider just what constitutes an aerosol. Depending on where you are on the earth (or up in the stratosphere) an aerosol could mean various things.

Lendberg and Gillespie<sup>79</sup> at White Sands, New Mexico, collected dust samples and ran them through a fractionated dust stage to sort them out for sizes. They found that the particle composition varies as a function of their sieve pore size that allowed these dust particles to pass. The result is shown in Table XXXV. They measured the imaginary index of refraction of these dust sample stages from 0.3  $\mu$ m to 1.7  $\mu$ m and showed that there was a vast difference in this quantity with dust size.

The major reference on atmospheric dust and aerosols has to be the conference proceedings<sup>80</sup> "Atmospheric Aerosols; Their Optical Properties and Effects"; this conference was held at Williamburg, Virginia, December 13-15, 1976. K. Bullrich and G. Hänel<sup>80</sup> presented (Paper MH1) data on particle size distributions for different types of aerosols. Their distributions are shown in Fig. 50. They also showed that the humidity has a definite impact on the optical characteristics. The mass absorption coefficient  $k/\rho$  vs wavelength (1.0  $\mu$ m to 10.0  $\mu$ m) is given in Fig. 51 for 3 levels of humidity. One would expect that the humidity will also affect the absorption coefficient of aerosols at longer wavelengths.

H. E. Gerber et al. in paper TUA6<sup>80</sup>, presented a paper on "Laser Transmissions through a Concentrated Aerosol." They used a centrifuge-type device to concentrate aerosols to simulate a light path through the cell of up to 1 km. They measured data on the transmission as a function of time for a concentrated oil aerosol and for 0.63, 1.06, 3.8 and 10.6  $\mu$ m wavelength radiation. Their results are given in Fig. 52.

E. P. Shettle and F. E. Voltz,<sup>80</sup> in their paper MC14 "Optical Constants for a Meteoric Dust Aerosol Model" calculated the attenuation

Table XXXV.	Optically-Significant Components of Size Fractionated Dust Samples <sup>a</sup> (Data from Ref. 79)
	Stage number

			5	Stage 1	numb	er		
Component	7	6	5	4	3	2	1	0
Clay minerals <sup>b</sup>			X	X	X	X	x	x
Quartz			X	X	X	X	x	x
Calcite			_	X	X	X	X	$\hat{x}$
Gypsum			X	X	_			
Ammonium sulfate	X	X	—					
Carbon	X	X	_					

<sup>a</sup> The X indicates that the material was present; the symbol — indicates that the material was detectable but present in much lower concentration.

<sup>b</sup> Specifically montmorillonite, illite, and kaolin group clays.

<sup>c</sup> The presence of carbon was estimated by other means, as discussed in text.

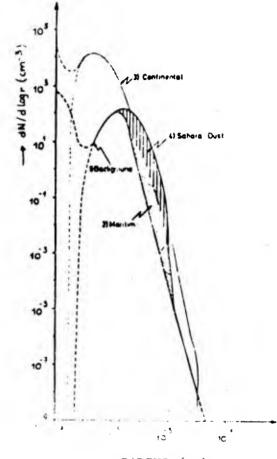

Fig. 50. Aerosol Particle Size Distributions as Measured by Bullrich and Hänel (Ref. 80) for Continental, Sahara Dust and Maritime Hazes

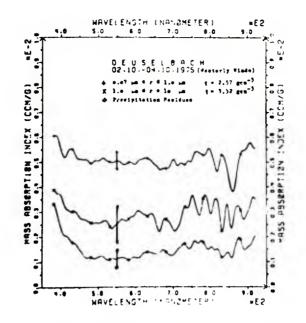

Fig. 51. Mass Absorption Cross Section,  $k/\rho$  , of Aerosols at Three Different Humidities (Data from Ref. 80)

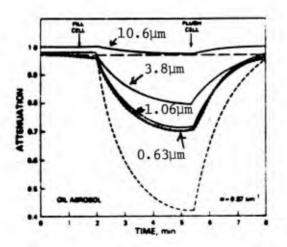

Fig. 52. Attenuation of Laser Radiation by Oil Aerosols as a Function of Time (Data from Ref. 80)

coefficient for a set of samples of meteoric dust whose reflectivity had been measured in the spectral region 2.5 to 40  $\mu$ m. A 9-oscillator model was fitted to these measurements using a nonlinear least squares optimization of his sets of equations, which were:

Ra = 
$$\frac{(n-1)^2 + k^2}{(n+1)^2 + k^2}$$
 = reflectivity

$$n^{2} - k^{2} = A_{o} + \sum_{j} \frac{2A_{j}(v_{j}^{2} - v^{2})}{(v_{j}^{2} - v^{2})^{2} + \gamma_{j}^{2}v^{2}}$$

nk = 
$$\sum_{j} \frac{A_{j} \gamma_{j} \nu}{(\nu_{j}^{2} - \nu^{2})^{2} + \gamma_{j}^{2} \nu^{2}}$$

 $v_j$  = frequency of jth oscillator  $A_j$  = oscillator strength  $\gamma_j$  = damping constant or band width

Results of their calculation of the aerosol attenuation coefficient are show in Fig 53.

James W. Fitzgerald at the Optical Submillimiter Atmospheric Propagation Conference<sup>81</sup> presented a paper on "Effect of Relative Humidity on Aerosol Size Distribution and Visibility-Modeling Studies." Fitzgerald derived a relationship between the relative humidity and the equilibrium size of an aerosol particle that had an insoluble core with a soluble covering in the form of a pure salt. The equilibrium saturation ratio, S, is described by

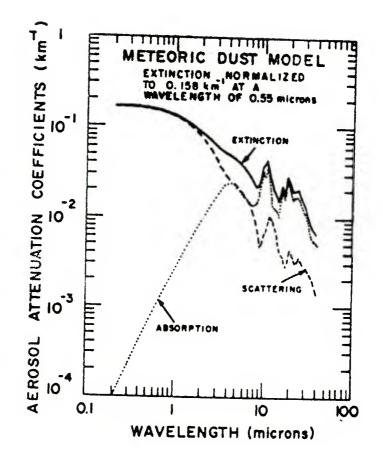

Fig. 53. Scattering, Absorption and Extinction Coefficients vs Wavelength for Meteoric Dust Model (Data from Ref. 80)

$$S = \exp\left[\frac{2\sigma'}{r\rho' R_v^T}\right] \left[1 + \frac{i \epsilon \rho_d M_w r_d^3}{M_s \{\rho' (r^3 - r_d^3 (1 - \epsilon)) - \epsilon \rho_d r_d^3\}}\right]^{-1}$$

where

- S = equilibrium saturation ratio (% relative humidity divided by 100),
- r = equilibrium radius of the particle (solution droplet)  $r_d$ ,  $\rho_d$  = radius and density of the dry particle,
  - M<sub>1</sub> = molecular weight of water,
  - $M_{S}$  = molecular weight of the soluble component,
    - i = Van't Hoff factor,
  - $R_{_{\rm TT}}$  = specific gas constant of water vapor,
    - $\epsilon$  = mass fraction of the soluble material on the dry particle
- $\sigma^{\,\prime}\,,~\rho^{\,\prime}$  = surface tension and density of the aqueous salt solution.

On a cruise off the coast of Nova Scotia, a sea-fog aerosol size distribution was measured, and compared with calculations obtained from the above model. Results of the calculations and measurements are shown in the next two figures. The first, Fig. 54, is for 10 km downwind of the formation edge of a fog, and the second, Fig. 55, is for 25 km downwind of the fog formation line. These are models that should prove useful for millimeter wave studies on sea-fog aerosols.

It is apparent that some calculations and measurements of radiation scattering by aerosol have been made for wavelengths up to 30  $\mu$ m in the IR region, but no measured data were found in the .1 mm to 1 cm region.

Information on the aerosol index of refraction needs to be generated and measurements made in the submillimeter region. Experimentally, the Fourier transform spectrometer could be used to determine the complex index of refraction of a number of different types of particles.

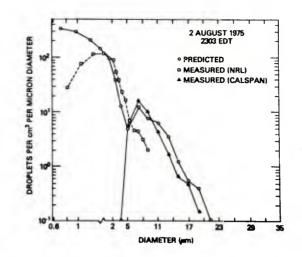

Fig. 54. Comparison of Observed and Predicted Droplet Size Distributions at a Point 10 km Downwind of the Forming Edge of the Fog on 2 August 1975 (Data from Ref. 81)

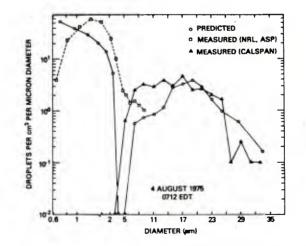

Fig. 55. Comparison of Observed and Predicted Droplet Size Distributions at a Point 25 km Downwind of the Forming Edge of the Fog of 4 August 1975 (Data from Ref. 81)

Some of the types of aerosol particles that need to be considered when making index of refraction measurements are:

and a

# 2.7 Attenuation and Scattering by Battlefield Dusts and Smokes

The literature relating to the attenuation and scattering properties of battlefield dust and smokes in the millimeter and submillimeter wave region in very sparse.

G. Tinsley and T. Cosden 82 measured the particle size distribution of some machine-gun smoke. The particle distributions shown in Fig. 56 are one-minute averages. The "1514" time is before the smoke reached the particle counter. At 1518, the smoke had largely passed. They calculated the extinction in this smoke for 3.9 µm radiation. E. W. Stuebing, F. O. Verderame et al., in paper 14 of the conference 81, presented a talk on the "Nature of Gun Smoke and Dust Observation." They developed the data listed in Table XXXVI which gives the products of nitro-cellulose combustion from a 30 mm Rarden cannon round. Stuebing et al. also modeled an obscuring smoke cloud which they assumed was due to a combination of gun smoke and the dust created from the ground by the muzzle blast of the cannon. They calculated the optical densities at 0.5, 1.06 and 10.6  $\mu m$  wavelengths that were provided by the smoke produced by the firing of a 30 mm Rarden cannon from measured transmission vs time measurements for those wavelengths. The optical density is defined by the equation  $T = 0.1^{D}$  where T is the measured transmission and D is the optical density. Figures 57 and 58 show the measured optical density vs time for the three wavelengths used in the measurements. Also shown in these figures are the optical densities obtained from model calculations. The transmission through the smoke has two minima: the first appears to result from the smoke produced by the products of nitrocellulose combustion (which was modeled as water) and the second results from the dust created from the ground. The comparison between the model results and the measured densities for  $\lambda$  = 0.53  $\mu m$  appears to be good. Although the data in Figs. 57 and 58 are for wavelengths in the visible and near infrared, the models giving the "smoke" particle size distribution vs time could be used with Mie theory to determine absorption, scattering and extinction coefficients for millimeter and submillimeter wavelength radiation.

Fig. 58. Measured and Calculated Optical Density due to Gun Smoke and Dust Model (from Ref. 81)

Alan Downs in Ref. 44 has reviewed the transmission of optical radiation through smoke and dust. The transmission through several smokes for visible and 10.6  $\mu$ m wavelength laser light as a function of the particle concentration is shown in Fig. 59. Further work of optical transmission in smokes is alluded to in Downs' report. Downs also reported data on transmission versus time for visible (.4 - .7 $\mu$ m), near IR (.7 - 1.1  $\mu$ m) and IR (3-5 $\mu$ m and 8-14 $\mu$ m) radiation through 105 mm HC round caused smoke cloud (presented here as Fig. 60), a 60 mm WP morter caused smoke cloud presented here as Fig. 61) and a fog oil smoke cloud (presented here as Fig. 62). The latter fog oil cloud was produced by 9-M-7 fog oil smoke pots. Downs reported that when 94 GHz and 140 GHz radar beams were transmitted through each of these clouds, the resulting signals showed no attenuation. Table XXXVII lists the time in minutes that each of the visible and IR systems could "see" the smoke phenomena that were described in the previous three figures.

Downs also presented data on transmissions through a dust cloud that were collected at Fort Sill during smoke tests. The transmission through the cloud is shown here in Fig. 63. The reduction in transmission during the 0 - 20 second time period is due to the smoke and the cause for the transmission loss in the 123 second - 200 second time period is due to dust.

Downs also reported on another dust cloud experiment. The results obtained from the experiment are shown in Fig. 64. Downs reported that there was no apparent attenuation of 94 GHz and 140 GHz radar by the dust.

## III. SUMMARY OF DOCUMENTS SURVEYED IN THE LIMITED DOCUMENT LITERATURE

Only documents that were felt worthy of mention, as containing information not found in the open literature will be discussed here. The technical areas will be along the same format as was in the unlimited version.

#### 3.1 Attenuation and Scattering by Rain and Hail

Vogel reports in Ref. 83 on Mie theory calculations for spheres of water (rain) and ice (hail) at frequencies of 30, 100, 150 and 300 GHz. The values he used for the index of refraction for water and for ice are given in Table XXXVIII. He points out that frozen rain (hail) scatters more radiation than does liquid rain for frequencies above 150 GHz. The Russians concur with this conclusion in their articles on attenuation by snow (see Ref. 72). Richard and Kammerer also points out that mm radiation scattering by ice will tend to be more peaked in the forward direction for frequencies above 100 GHz than that computed for water droplets. The single scattering of ice was found to be critically dependent on its conductivity. A number of different Mie theory calculations of the phase function for scattering are given in Ref. 55. Attenuations due to rainfall at 100 GHz based on the Mie theory calculations were compared with measurements taken by Setzer, Asari and Medhurst 61, and were found to be within the experimental error.

#### 3.2 Attenuation by Water Vapor

Gamble and Hodgens<sup>84</sup> reported on a literature survey for mm waves of wavelength 0.735 - 8.57 mm. They caution about dimer effects during heavy fog (relative humidity >95%) or rain (RH >80%). Dimer effects are  $(H_20) - (H_20)$  interactions that tend to broaden the water vapor absorption

Table	XXXVIII.	Index	of	Refrac	ction	of	Water	and	Ice	
		(Data	from	Ref.	84)					

Frequency		Index of
(GHz)	State	Refraction
30	Water 20°C	5.9 - 2.9j
	Ice	1.91 - 0.0021
100	Water 20°C	3.505-2.007j
	Ice	1.88 - 0.00076i
150	Water 20°C	3.039-1.575j
	Ice	1.88 - 0.00076i
300	Water 20°C	2.58 <b>7-</b> 0.937j
	Ice	1.88 - 0.00076i

.

85,86 lines. Dimer effects were also considered by Russian authors Gamble and Hodgens present data in Ref. 84 on the in band attenuation in dB/cm vs. visibility for a number of wavelengths between 320 mm to 8.57 mm and for atmospheric temperatures between 0° and 30°C in 5° C steps. A sample of their data is given here as Table XXXIX. Three figures of interest from Ref. 84 should be noted; data on the wavelength dependence of the refractive index of ice, presented here as Fig. 65; data giving the volume concentration of water droplets by size, presented here as Fig. 66, and the attenuation due to the liquid water content as a function of visibility for a number of wavelengths between 320  $\mu$ m and 8.57 mm and a temperature of 24° C, presented here as Fig. 67. Gamble and Hodgens conclude that at any particular wavelength chosen in the mm band, water vapor absorption will be the driving unknown parameter. and will be a strong function of temperature and humidity. He feels that high resolution measurements need to be made to back up the actual calculations to be certain of the absolute attenuation at a given frequency.

#### 3.3 Refractive Indices for Sea Spray

Eric Shettle<sup>87</sup> has reported on measurements of sea spray for wavelengths between 0.1  $\mu$ m and 40.0  $\mu$ m and a relative humidity of 80%. His data are presented here in Fig. 68. He also reported measured data on the refractive indices of water, sea spray aerosol and sea salt for wavelengths in the visible and infrared wavelength regions. There is a paucity of data on indices of refraction in the mm and sub mm wavelength ranges.

Total Attenuation (dB/km) For Water Vapor at  $20^{\circ}$  C (Data from Ref. 84) Table XXXIX.

### IV. SUMMARY OF DOCUMENTS SURVEYED IN THE CLASSIFIED LITERATURE

A review of the classified literature showed that all the physical properties of the atmosphere and other media, e.g., rain, aerosols, snow, and battlefield conditions, were treated in the unclassified section. The classified documents were effectively hardware related and no new physical properties of the atmosphere were discussed.

### V. RECOMMENDATIONS FOR FURTHER RESEARCH

Two of the most important attenuators of mm and sub mm radiation in the atmosphere are water vapor and oxygen. For the case of water vapor there are resonance frequency regions at approximately 1.3, 2.1, 3.2 and 8.6 mm where absorption is abnormally large. Much of the water vapor attenuation coefficient data currently available for the mm and sub mm wavelength range were measured or calculated over a decade ago. It appears that some new measurements would be useful for checking out the accuracy of band model calculations. The measurements need to consider the effects of temperature and pressure on the absorption cross section of water vapor. The Russians<sup>86,87</sup> have pointed out the importance of considering dimer effects, where attenuation is proportional to the square of the humidity, when calculating the absorption cross section for wavelengths in the 1.15 to 1.55 mm band. Most investigators have used a Lorentz line profile when calculating the contribution to the absorption cross section from the wings of each line. It appears that use of other line profiles, such as the Van Vleck-Weiskopf model, would probably produce more accurate water vapor absorption cross section data in the mm and sub mm wavelength range than that now available. The line broadening produced by  $(N_2 - H_20)$ ,  $(O_2 - H_20)$  and  $(H_20 - H_20)$  collisions needs further investigation.

The absorption by oxygen in the mm and sub mm wavelength is usually considered to be fairly well known. Even so, the experimental and theoretical data now being used is over a decade old and a comparison of transmission calculations based on that data with measurements would be useful.

The index of refraction of liquid water at 20°C is fairly well known, but at other temperatures it is not well known. Thus, the transmission of mm and sub mm radiation through clouds and fogs containing

water droplets may be considered to be well known at 20° C but only at that temperature. A measurement program is needed to determine the temperature dependent parameters needed in the Debye equation.

There are a fair number of measurements of the attenuation and scattering coefficients for rain at frequencies of 15, 20, 30, 35 and 70 GHz, much fewer at frequencies of 94, 140, 240 and 300 GHz and none at frequencies above 320 GHz. The need to consider the effects of non-sphericity of rain drops, as suggested by Oguiche and discussed by Wiley<sup>69</sup>, when computing scattering, absorption and extinction coefficients and phase function data with the use of Mie theory should be studied.

Propagation of mm and sub mm radiation through snow has not received much attention. At frequencies less than 50 GHz snow is not as important a scatterer as rain, but for frequencies greater than 150 GHz, and especially for wet snow, it will scatter more than rain. Calculations of the scattering and attenuation characteristics of snow with the use of Mie theory needs to consider the fact that snow flakes are not spheres. A measurement program is also needed to obtain more accurate values of the index of refraction for both ice and snow in the mm and sub mm wavelength range. Measurements of the index of refraction of ice and snow need to be made as a function of temperature and, for the case of snow, as a function of the "wetness" of the snow.

Aerosol effects have not been seriously considered for mm and sub mm wavelengths since for normal atmospheric aerosol size distributions the particle size is small enough for Rayleigh scattering theory to be applicable. Aerosol effects for battlefield type dust, which contains a significant fraction of large particles, needs further investigation. Studies need to be carried out on the scattering and absorption by large aerosol particles with a core of one material and an outside shell of another material. The index of refraction of aerosols for mm and sub mm

wavelengths needs to be measured so as to provide data to be used in Mie theory calculations.

There is no information available on the index of refraction for battlefield dusts, battlefield generated smokes and exotic gases and the aerosols produced by vehicle engines. Although some information on combustion products were found in the literature, there is a need for a study to define the specific combustion products emitted by the engines of battlefield vehicles and to determine which are important absorbers and scatterers of mm and sub mm wavelength radiation. Of great importance is the need for data on the size distributions of the particles contained in battlefield generated dusts and smoke.

Some data are available on the transmission of mm and sub mm radiation through battlefield generated dust and smoke (see Section 2.7). More effort needs to be expended to develop better models of the time and spatial dependent variation of battlefield smoke and dust particle size distribution. Since the particle sizes that are important in Mie theory calculations are those with diameters greater than 0.06 times the wavelength, the need to treat these large particles as nonspherical particles in Mie theory should be investigated.

The exotic gases produced under battlefield conditions should be identified and the absorption lines for these gases should be tabulated to determine which of the gases would be important absorbers for mm and sub mm wavelength radiation.

### APPENDIX A - BIBLIOGRAPHY

A bibliography of the unclassified unlimited and limited literature on the interaction phenomena occurring in the atmosphere for millemeter and submillemeter radiation is given in the Appendix.

To aid the user of this bibliography, a 7-digit identifier or index number, on the same theme as the Dewey Decimal classification or key-word description, is given to each bibliographical entry. This 7-digit index number has the following form:

The first digit of the identifier number, which is used to identify the materials discussed in the biographical entry. is assigned numbers as follows:

- 1) Water vapor
- 2) Rain and aqueous water
- 3) Snow
- 4) Clouds and Fog
- 5) Air
- 6) Oxygen, O<sub>2</sub>
- 7) Ozone
- 8) Nitrogen and its compounds (include Organic Compounds)

- . . . <sup>...</sup>

- 9) Exotic gases and Hydrocarbons
- A) Smoke and Aerosols
- B) Dust and Solid material
- C) Hardware Discussions
- D) Plasmas

The material identifiers listed above were selected to satisfy the terms of the work statement of the contract; additional identifiers are

provided because of titles specifically on these topics that had been reviewed and were considered useful peripheral information in mm wave technology. If an article discusses more than one material, and one of the materials discussed is one of those called out in the contract, then the article is listed under the material category called out in the contract. To identify the mm wave spectral region, the second digit of this 7 "digit" identifier is used in the following fashion:

- 1) 10-30 GHz (3.33 cm 1 cm)
- 2) 30-100 GHz (1 cm 3.33 mm)
- 3) 100-300 GHz (3.33 mm 1 mm)
- 4) 300-1000 GHz (1mm 333  $\mu$ m)
- 5) 1000 GHZ 3000 GHz (333 μm 100 μm)
- 6) Greater than 3000 GHz (wavelength less than 100  $\mu\text{m})$

For the third digit of the index number identifier, one of the following numbers for unclassified, unlimited distribution documents is used:

- 1) Experimental
- 2) Theory
- 3) Combination of Experimental and Theory

For limited distribution, unclassified documents, one of the following numbers for the third digit is used:

- 4) Experimental
- 5) Theory
- 6) Combination of Theory and Experimental

For confidential documents, the third digit was assigned as follows (to include the classification):

7) Experimental

8) Theory

9) Combination of Theory and Experimental

For secret classified documents, the third digit is assigned as follows:

- A) Experimental
- B) Theory
- C) Combination of Theory and Experiment

To identify the specific technical area described in the bibliographical entry, such as transmission, reflection, etc., the fourth "digit" is used in the following way:

- 1) Transmission
- 2) Reflection
- 3) Cross Section
- 4) Backscatter
- 5) Dielectric
  - 6) Index of Refraction
  - 7) Emission

The fifth digit of the identifier number, which describes the project area described in the bibliographical entry, is assigned as follows:

- 1) Radar
- 2) Astronomy
- 3) Radiometry
- 4) Fourier Transform Spectrometer
- 5) Spectrometer and Michelson Interferometer
- 6) Remote Sensing
- 7) Communications
- 8) General Use
- 9) Obscurant
- A) Laser and Maser
- B) Missile Seeker

1. 1 8 21 - 18

The sixth digit of the identifier number is used to indicate the number of articles in the bibliography on each title or technical area (1-9, A-Z). A computer code can be written to search on a file (tape or disc) where, with respect to an 80 column card, the first 7 columns would contain the 7 "digit" number. The last digit of the index number (the seventh) is used to designate the number of 80 column cards space in the file required to contain the subfile.

# A.1 Illustration of Indexing/Identifier Technique

Let us pick a number and see how it refers to the indexing system discussed above (Along with discussion on what is on a file):

C	2		2		7 8	8	Author's name*title of article*contract number or where published (if not a government document)* (ExampleApplied Optics, Vol. 10, No. 4, 738-748)
						and the second of the second	Date of Publication* and Government Publication Number such as AD-number*
						n valati da u u u u u u u u u u u u u u u u u u	Short Summary of article*(author's abstract used if it contains enough succinct information). The above information is packed to fit in as small a space as possible.
						-	=8 - 80 column card space used
					L.,	Eller Stranger	-7 th article of this type
		Ì			-	C. TRACK	Article is on Radar
					a ji akabut 🛁	يمو إسري معمر	Backscatter
Experimental Method, Unclassified						Experimental Method, Unclassified	
	<u> </u>				. 14 2 16 19 19 19 19	b/65 <b>4301</b> 8191111	-30 - 100 GHZ frequency range
				r" Angergan		and and the second	Hardware Discussion

To allow a computer to access the contents of the index card file on a disc or a tape, the information given after the 7 digit identifier must be spaced by a computer recognizable identifier, e.g., an asterisk. The end of the abstract will end uniformly by a double asterisk for an end of file identifier for each article file.
