10 **Human visual cortex is organized into dorsal, lateral, and ventral streams. A long-standing hypothesis**
11 **is that the functional organization into streams emerged to support distinct visual behaviors. Here,**
12 **we use a neural network-based computational model and a massive fMRI dataset to test how visual**
13 **streams emerge. We find that models trained for stream-specific visual behaviors poorly capture neural**
14 **responses and organization. Instead, a self-supervised Topographic Deep Artificial Neural Network, which**
15 **encourages nearby units to respond similarly, successfully predicts neural responses, spatial segregation,**
16 **and functional differentiation across streams. These findings challenge the prevailing view that streams**
17 **evolved to separately support different behaviors, and suggest instead that functional organization arises**
18 **from a single principle: balancing general representation learning with local spatial constraints.**

19 processing streams | topography | vision | neural network

20 Correspondence: dfinzi@stanford.edu

21 Confronted by the blooming, buzzing confusion of the world around us, we perform a diverse range of computations
22 on our visual inputs, including rapidly and accurately identifying objects in our surroundings, their locations, and
23 their actions. The human brain is accordingly thought to be divided into three processing streams, beginning in
24 early visual cortex and ascending through multiple areas to form different processing pathways: (1) a “what” Ventral
25 stream ascending from early visual cortex to the inferior aspects of occipital and temporal cortices [1, 2], (2) a
26 “where” or “visually-guided grasping” Dorsal stream extending superiorly along occipito-parietal cortex [1, 2], and (3)
27 a Lateral stream, extending through lateral occipitotemporal cortex to the superior temporal sulcus (STS), thought to
28 be involved in dynamic perception [3], particularly of actions [4], and social information [5, 6].

29 The prevailing hypothesis (*multiple behavioral demands hypothesis*) suggests that the organization into streams is
30 an outcome of evolutionary optimization for independent visual behaviors that can be done in parallel with dedicated
31 neural machinery, yielding a fast and efficient visual system [1, 7, 8, 9, 10, 11, 12]). An alternative hypothesis
32 suggests that a set of physical constraints, such as wiring length, could produce the functional organization of the
33 brain into streams (*spatial constraints hypothesis*). According to Nelson and Bower [13], “if the brain’s estimated 10^{11}
34 neurons were placed on the surface of a sphere and fully interconnected by individual axons 0.1 μm in radius, the
35 sphere would have to have a diameter of more than 20 km to accommodate the connections.” As a result of physical
36 constraints and a need for fast processing, there is a known bias in the brain toward short-range connections [14, 15].
37 One way to minimize wiring length locally is to encourage nearby neurons to respond similarly [16]. Indeed, locally
38 correlated responses are evident in the many cortical topographic maps, such as maps of the visual field [17, 18].
39 From an information theoretic standpoint, positioning neurons frequently involved in processing related information
40 close together also makes neural processing faster and more efficient [16, 19]. Thus, we ask: is the functional
41 organization of visual cortex into streams due to optimization for multiple distinct behaviors, or due to balancing
42 spatial and information constraints?

43 To test these hypotheses, we use a Deep Artificial Neural Network (DANN) approach. We instantiate the multiple
44 behavioral demands hypothesis by training three different models, each using a state-of-the-art DANN that is trained
45 using supervision on the stream-specific visual behavior: Dorsal: object detection [22], Lateral: action recognition
46 [23], Ventral: object categorization [24] (Fig. 1a). Each model is trained separately to encourage maximum
47 differentiation of the learned representations. We instantiate the spatial constraints hypothesis using a topographic
48 DANN (TDANN, [20, 25]), in which model units in each layer are assigned a position in a 2D simulated cortical sheet,
49 and during training a spatial constraint is balanced together with contrastive self-supervised learning (SimCLR [26],
50 Fig. 1b). The spatial constraint encourages nearby units to have more correlated responses than distant units, and
51 SimCLR encourages two snapshots of the same image (differing in incidental properties such as color or field of
52 view) to have similar representations that are distinct from others [26]. We choose SimCLR because it is one of
53 the best performing self-supervised approaches, and because it generates broadly useful representations that are
54 beneficial for a range of visual tasks [27].

55 To evaluate whether the multi-behavior models or the TDANNs better predict brain responses to visual stimuli, as
56 well as the cortical organization into different streams, we leverage the Natural Scenes Dataset (NSD) [28]. NSD is
57 a massive, high-resolution, fMRI dataset that measured responses to tens of thousands of natural images across
58 eight individuals. The same images are given as input to each of the candidate models. By comparing model and
59 brain responses on these images, we can test which model best predicts cortical responses and spatial segregation
60 into visual streams.

61 A major challenge in comparing computational models to the brain lies in establishing a mapping between model
62 representations and brain representations. We develop a new algorithm that estimates an optimal 1-to-1 mapping
63 between model units and voxels. The algorithm matches each model unit to a voxel by finding pairings that have the
64 highest response correlation using an iterative version of the Kuhn-Munkres algorithm [21] with an additional spatial
65 prior (Fig. 1c, Alg. 1) and has several appealing features. First, this 1-to-1 mapping allows us to evaluate topographic
66 organization, unlike typical approaches that either match a linear combination of model units to a brain voxel (linear
67 regression, [11, 29]) or examine the distributed representational similarity structure across units/voxels [30], thus
68 obscuring the topographic organization. Second, a unit in a neural network model abstracts neural computations;
69 as such, it may be a good model for the aggregated neural response of a voxel (i.e., in the Goldilocks zone of
70 computational abstraction [31]). Third, a 1-to-1 mapping provides a more stringent test of models [32, 33], allowing
71 a more rigorous evaluation of equivalences between DANNs and brains [34].

72 **The multi-behavior models fail to capture the functional organization of cortex into streams, while the TDANN** 73 **provides a much better match**

74 To evaluate whether models match the functional organization into streams, we quantify the spatial and functional
75 correspondence between candidate models and the NSD across subjects, hemispheres, and model seeds,

a) Multi-behavior models

b) Topographic Deep Artificial Neural Network (TDANN)

c) Linking models to brains

Measure brain & model responses to the same images

Find optimal 1-to-1 mapping that minimizes cost using iterative algorithm

Figure 1. To test competing theories, we use two candidate model classes: **(a) Multi-behavior models: object detection, action recognition, & object categorization.** Units are sampled from the final convolutional layer of the backbone architecture for all models and pooled to create candidate source units that are mapped to the brain. **(b) Topographic Deep Artificial Neural Networks (TDANNs)** developed in [20] contain units that are assigned positions on a simulated cortical sheet prior to training and are trained to minimize the sum of a functional loss and a spatial loss, controlled by a free parameter α . Units from the final convolutional layer are used as candidate source units for mapping to the brain. **(c) Overview of 1-to-1 mapping approach for linking model to brain.** 10,000s of images of natural scenes were presented to 8 individuals and candidate models. Responses are extracted from model units and brain voxels, and correlations between each unit-voxel pair computed. Correlations are transformed into an initial cost matrix ($1 - correlation$). Using the Kuhn-Munkres optimization algorithm [21] we determine an initial assignment such that each unit is assigned to a unique voxel and the average cost across all unit-voxel pairings is minimized (black: assignment). To promote general smoothness in the mapping, neighboring units' assigned voxels are used to calculate "spatially-valid zones", such that any voxels outside a unit's zone are set to have a prohibitive cost (indicated in white, see Alg. 1 for details). This updated cost matrix is used to redetermine assignments, repeated for 100 iterations.

76 evaluating 1216 model-to-brain mappings in total. Using the unique images seen by each participant, we first find
 77 the model-to-brain mapping between units in the model's convolutional end-layer and voxels in anatomical regions
 78 of interest (ROIs) corresponding to the ends of each stream. We assess spatial correspondence qualitatively on
 79 the cortical sheet (Fig. 2a) and quantitatively by computing how many units are mapped into the corresponding
 80 stream (e.g. object categorization and Ventral, see [Methods: Evaluating spatial correspondence](#) for details; Fig.
 81 2b). We assess functional correspondence by evaluating the average correlation between unit responses and
 82 voxel responses on an independent set of 515 left-out images seen by all subjects (Fig. 2c). We hypothesize
 83 that the best model for the human brain is another human brain. That is, the between-subject spatial and functional
 84 correspondence can serve as a benchmark to evaluate shared organizational principles [35]. Thus, to estimate a
 85 noise ceiling reference point, we use the same 1-to-1 mapping algorithm to map from one subject's brain to another
 86 subject's brain (brain-to-brain noise ceiling; gray bars).

87 Our analyses reveal that the multi-behavior model does not explain the organization of cortex into streams. We find

a) Model to brain topography

b) Model to brain spatial correspondence

c) Model to brain functional correspondence

Figure 2. The TDANN better matches spatial and functional organization of human visual system into streams (a) Unit-to-voxel mapping on an example subject flattened cortical surface. Left: multi-behavior models, each voxel is colored based on the training task for its assigned unit. Right: TDANN models, voxels are colored by location on the simulated cortical sheet of the last convolutional layer; polar angle (red \rightarrow green \rightarrow blue) and eccentricity (opacity, which decreases away from center). (b) Quantification of spatial correspondence. For multi-behavior models, we show the percentage of voxels for each stream that are assigned to units from the model trained on their hypothesized task. For TDANNs, we show the percentage of voxels for each stream are assigned to the corresponding third of the simulated cortical sheet (max correspondence, up to rotation and reflection). Each symbol represents a model-to-subject mapping. (c) Quantification of functional correspondence. Unit-to-voxel correlations on the test set (left-out 515 images). For (b) and (c) error bars: mean across subjects and hemispheres \pm SE. Self-supervised and supervised TDANNs shown for an optimal weighting of the spatial loss ($\alpha = 0.25$ for self-supervised, $\alpha = 2.5$ for supervised).

88 that neither highly performant models based on ResNet-50 [24, 23, 22], nor models based on ResNet-18 matching
 89 the TDANN architecture [36, 20, 25], recapitulate stream organization (Fig. 2). While we expected that a higher
 90 proportion of units from a model implementing the visual behavior associated with a stream would be assigned to
 91 the corresponding stream than other streams (e.g., units trained on object categorization would be primarily assigned
 92 to the Ventral stream), we instead find that unit-to-voxel assignments for the ResNet-50 models are noisy (Fig. 2a)
 93 with spatial correspondence not different from chance across all three streams ($ps > .2$), except Lateral which is
 94 significantly lower than chance ($t(7) = -4.9, p = 0.002$; Fig. 2b). Functionally, unit-voxel correspondences (Fig. 2c)
 95 are also poor: below $r = 0.13$ for all streams and tasks. Surprisingly, there is no dissociation of stream by visual
 96 behavior, with units trained on object categorization yielding the highest correlations to brain responses across all
 97 three streams. While a multi-behavior model based on a shallower ResNet-18 architecture provides significantly
 98 better spatial correspondence across all three streams and significantly better functional correspondence in Dorsal
 99 and Lateral than the ResNet-50 model (all $ps \leq .018$, Supplemental Tables 1 and 2), its correspondence remains
 100 lacking. Spatially, only about 50% of the units are assigned to their correct stream. And functionally, correspondence

101 remains low (at or below $r = 0.15$ for all streams and tasks), with again no dissociation of stream by visual behavior,
102 as units trained on object categorization best match brain responses across all three streams.

103 In contrast to the multi-behavior models, the self-supervised TDANN captures both stream function and topography.
104 Three distinct clusters of TDANN units map to the three different streams, qualitatively more smoothly on the cortical
105 sheet than multi-behavior models (Fig. 2a). Quantitatively, the self-supervised TDANN achieves significantly higher
106 spatial correspondence than the multi-behavior models across all three streams (all $ps \leq .012$, Supplemental Table
107 1, Fig. 2b). Additionally, functional correspondence of model units from the self-supervised TDANN to cortex
108 is significantly higher (Fig. 2c, Supplemental Table 2), almost doubling from the best multi-behavior ResNet-18
109 models across streams (improvement, Dorsal: mean 91% increase, Lateral: 65%, Ventral: 133%). Notably, the
110 functional correspondence approaches the brain-to-brain noise ceiling (Fig. 2c-gray bars) in both the Dorsal and
111 Ventral streams, as does the spatial correspondence in the Ventral stream (Fig. 2b-gray bars).

112 As the categorization task yields the best spatial and functional match among multi-behavior models, we
113 also implement a TDANN trained on object categorization. This TDANN achieves significantly better spatial
114 correspondence in the Dorsal and Ventral streams and better functional correspondence across all three streams
115 than the corresponding ResNet-18 trained on categorization (all $ps \leq .044$, Supplemental Tables 1 and 2). This
116 difference between the object categorization TDANN and the standard object categorization model is particularly
117 striking for the Ventral stream, suggesting that not only does the spatial constraint in the TDANN change the layout
118 of units, but it also changes their response properties to be more "brain-like". Nonetheless, across models tested,
119 the self-supervised TDANN provides the best functional and spatial match to the brain. The success of the TDANN
120 in matching both functional and spatial brain organization, above and beyond the multi-behavior models, suggests a
121 new explanation of why the brain is organized into visual processing streams.

122 **Both contrastive self-supervision and the spatial constraint during training are critical for functional** 123 **organization into streams**

124 We next ask what factors contribute to the emergence of streams in TDANNs. The TDANN has two key components
125 that may affect its performance: the training task and the relative strength of the spatial constraint. Thus, we test
126 TDANN models (5 seeds each), trained with either supervised categorization or self-supervised SimCLR, across a
127 range of spatial weightings (α) from $\alpha = 0$, where the model is essentially a standard ResNet-18 minimizing only
128 the task loss, to $\alpha = 25$, at which point the task is dwarfed by the spatial constraint. Models are evaluated on both
129 spatial (Fig. 3B-top panel) and functional (Fig. 3B-bottom panel) correspondence to the brain. As TDANNs contain
130 simulated cortical sheets, we evaluate the model-to-brain spatial correspondence using a distance similarity metric
131 that quantifies the similarity between the spatial topography of the model and that of the brain.

132 Across all three streams, self-supervised TDANNs with a spatial weight $0.25 \leq \alpha \leq 0.5$ provide the best spatial
133 and functional match to the brain. The clearest stream structure is evident for a self-supervised TDANN with
134 $\alpha = 0.25$, with each stream largely mapping to a distinct contiguous third of the simulated cortical sheet (Fig. 3a); this
135 structure is also visible using a continuous spatial gradient without pre-assigning voxels into streams (Supplemental
136 Fig. S4). Notably, there are significant and large gaps between self-supervised (purple) and supervised (gold)
137 TDANNs in their spatial and functional correspondence to the brain. Additionally, correspondence significantly
138 varies with the level of the spatial constraint and there is a significant interaction between the spatial constraint
139 and training task (Supplemental Tables 3 to 8). Self-supervised TDANNs achieve peak functional and spatial
140 correspondence at $0.25 \leq \alpha \leq 0.5$ (Fig. 3b). While a commonly-used, less strict mapping of model-units-to-brain
141 functional correspondence using linear regression estimates a higher functional correspondence, it critically masks
142 the effects of training task and spatial constraint (Fig. 3d). In fact, the improved functional correspondence to the
143 brain between TDANNs trained with biologically-plausible self-supervised training and models trained on supervised
144 object categorization nearly vanishes when models are evaluated using linear regression.

145 Another characteristic of visual cortex as a computational system is that the dimensionality of its representational
146 space, that is, the Effective Dimensionality (ED) of encoded information, is relatively low [37, 38, 39]. This
147 characteristic is thought to allow the brain to be robust to noise and well-generalize to new input distributions. We
148 postulate that if the TDANN is a good model of the brain, it should also exhibit this property. Thus, we hypothesize
149 that TDANNs that are more functionally similar to the brain may also be more similar to the brain in ED. Fig. 3c-gray
150 bars shows the functional similarity (horizontal bar) vs. the ED (vertical bar) of each stream. Comparing TDANNs to
151 this brain data reveals that self-supervised TDANNs (Fig. 3c-purple) have lower ED than supervised categorization
152 TDANNs (Fig. 3c-yellow), and increasing the spatial weighting in self-supervised TDANNs further decreases the ED.
153 Strikingly, in all streams, TDANNs that produce the most brain-like functional correspondence also have the most
154 brain-like ED.

Figure 3. Both self-supervised training and a mid-weight spatial constraint are key to predicting spatial and functional organization into streams. (a) Mapping between TDANN and the brain for an example flattened right hemisphere. Voxels are colored by location on the simulated cortical sheet (see inset). Left: TDANNs trained with no spatial weighting ($\alpha = 0$); Middle: TDANNs trained with $\alpha = 0.25$, best functional similarity for self-supervised TDANNs; Right: TDANNs trained with $\alpha = 2.5$, best functional similarity for TDANNs trained on categorization. (b) Across all three streams, the topographic and functional match to brain is best for self-supervised TDANNs trained with $0.25 \leq \alpha \leq 0.5$. Top row: Distance similarity between unit-voxel pairings per stream. Data averaged over unit-voxel pairing for lowest third of distances. Bottom row: average functional similarity (correlation) between unit-voxel pairings per stream. (c) TDANNs with most brain-like functional similarity also have most brain-like effective dimensionality (ED). Horizontal shaded gray bar: brain-to-brain functional similarity, averaged across subjects and hemispheres (\pm SE across target subjects). Vertical shaded gray bar: ED of brain responses by stream, averaged across subjects and hemispheres (\pm SE across subjects). Each dot: one model seed and subject combination, averaged across hemispheres. Opaque points: models with the highest correspondence (b) for each training task ($0.25 \leq \alpha \leq 0.5$: self-supervised; $\alpha = 2.5$: categorization). (d) Linear (ridge) regression mapping between model units and voxels for each stream. In (b) and (d): Values are averaged across model seeds and hemispheres, error bars: SE across subjects.

155 Functional segregation emerges from the TDANN model

156 Our findings suggest that visual processing streams can emerge in a network that learns via a single, self-supervised
 157 task, under a spatial constraint to minimize wiring. Nonetheless, empirical findings imply that there are functional
 158 differences across visual processing streams [1, 8, 5] such as differences in population receptive fields (pRFs [41,
 159 42]) and differences in task performance [1, 2]. Is the emergence of streams from a single training task at odds
 160 with functional differentiation across streams? To gain initial insights into this question, we test the extent to which
 161 TDANN model units assigned to different streams exhibit stream-relevant functional properties.

162 As pRFs in face-selective regions in the Ventral stream are more central than those of face-selective regions in the
 163 Lateral stream [41, 42], we evaluate the mean eccentricity of receptive fields (overlapping an $8^\circ \times 8^\circ$ stimulus) of
 164 TDANN face-selective units assigned to the Ventral and Lateral streams, respectively. Results show a qualitative
 165 model-to-brain correspondence: Ventral face-selective model units are significantly more foveal than Lateral ones
 166 (mean \pm SE: Ventral = 2.82 ± 0.01 ; Lateral = 2.94 ± 0.007 ; $t(15) = -8.2, p = 7.7 \times 10^{-5}$). Next, we test whether
 167 TDANN units assigned to the Dorsal and Ventral streams contribute to stream-specific hypothesized behaviors: (1)
 168 determining the object's position [40], associated with the Dorsal stream's role in determining where an object is, and
 169 (2) determining the object's category (a 1000-way Imagenet categorization task [43, 26]), associated with the Ventral
 170 stream role in determining what the object is. While position [40, 41] and category [44, 45] can be decoded from both
 171 Dorsal and Ventral streams, we hypothesize that units assigned to the Dorsal stream will outperform Ventral units for

Figure 4. Functional segregation, in alignment with known stream properties, emerges from the TDANN model. Data shown is for self-supervised TDANNs trained with $0.25 \leq \alpha \leq 0.5$. (a) Average receptive field eccentricity for face-selective TDANN units is further from the center for those units assigned to the Lateral vs. the Ventral stream. (b) Task transfer performance for TDANN units assigned to either the Dorsal or Ventral stream. Left: R^2 on an object position prediction task [40] (location in pixels of the object's center). Right: 1000-way object categorization accuracy on the Imagenet validation set. Green: units mapped to Dorsal stream; Blue: units mapped to Lateral stream; Red: units mapped to Ventral stream. Each dot: a model seed, subject, and hemisphere combination. Triangles: left hemisphere; circles: right.

172 position prediction and units assigned to the Ventral stream [46, 45], will out-perform Dorsal stream units on object
 173 categorization. We find that this is indeed the case: Dorsal units achieve significantly higher performance than Ventral
 174 units on predicting object position (mean \pm SE: Ventral = $48 \pm 0.06\%$; Dorsal = $50\% \pm 0.10\%$; $t(7) = -16.4, p =$
 175 7.7×10^{-7}), whereas Ventral units achieve significantly higher accuracy than Dorsal units on object categorization
 176 (mean \pm SE: Ventral = $43.6\% \pm 0.04\%$; Dorsal = $43.0\% \pm 0.10\%$; $t(7) = 4.21, p = .004$; Supplemental Fig. S5,
 177 extended results including Lateral).

178 Discussion and conclusions

179 We find that a single, biologically plausible, computational principle - self-supervised learning of the statistics of
 180 visual inputs under a spatial constraint that encourages nearby units to have correlated responses - better explains
 181 the functional and spatial organization of the human visual system into processing streams than a system trained to
 182 perform different visual behaviors in parallel. These data necessitate a rethinking of an inherent idea in philosophy
 183 [47], psychology [48, 49], computational theory [50, 12, 51], and neuroscience [52], that different portions of our
 184 visual system have explicitly evolved to support a collection of distinct visual behaviors. Instead, our results suggest
 185 an intriguing new idea that evolution may lead to the emergence of a flexible visual system that can learn a
 186 task-general representation in a self-supervised manner, while being constrained by the physical size and layout
 187 of cortical tissue. In this conception, the visual system can learn from visual input alone without necessitating
 188 human-unique inputs such as language [53]. Moreover, it still develops distinct streams with functional properties
 189 suitable for different visual behaviors [1, 2, 3, 4, 5], and it is information efficient [16, 19, 38].

190 This understanding would not have been possible without conceptual, empirical, and methodological innovations,
 191 including a full end-to-end TDANN that is both trainable and simulates the topographic arrangement of units on
 192 the cortical sheet [20, 25], a massive fMRI dataset [28] that enables comparing DANNs to the human brain, and
 193 a 1-to-1 mapping algorithm between model units to brain voxels. Recent success of DANNs in explaining neural
 194 responses in the visual system [11, 30, 54, 29] has elicited excitement that this class of models has the potential
 195 to explain why the brain is organized the way it is [55, 52, 31, 51, 56, 57]. At the same time, there is considerable
 196 theoretical debate as how to evaluate if a model accurately explains the brain [35, 32, 31, 58] as commonly used
 197 metrics, such as linear regression between model units and brain responses, do not distinguish between models
 198 [29, 33]. Here we show that a more stringent criterion - a 1-to-1 mapping between model units and brain voxels -
 199 is able to distinguish between models of the brain, including providing evidence for a definitive advantage of a more
 200 biologically-plausible self-supervised training over the best-to-date supervised categorization training [27, 11, 30, 29]
 201 in explaining brain responses in visual cortex. These findings, together with computational-theoretical advancements
 202 in developing metrics to compare systems that preserve neural tuning [33, 32], not just representational space

203 [11, 12, 59, 29, 51, 60], underscore the necessity of using stricter metrics not only to adjudicate between putative
204 models of the brain, but also to glean new understanding of biological systems.

205 The success of the TDANN underscores the necessity of modeling not only brain functional responses, as is the
206 prevalent approach [11, 30, 27, 52, 31, 57, 56], but also brain topography. This follows insights from several recent
207 studies that have investigated the emergence of regional topographic maps in the ventral stream [61, 62, 25, 20]
208 suggesting that wiring [61], smoothness [62], and a balancing of spatial and functional constraints [20] can produce
209 topographic organization. The key insight from the present work is that a local spatial constraint that allows fast
210 processing [16] and may contribute to minimizing local wiring length [63, 15] can percolate up to create broad-scale
211 stream structure. As parallel processing streams exist in other species [64], cortical systems [65, 66, 67, 68], and
212 spatial scales [69, 70], future research can test if the same principles trained on other sensory and multimodal inputs
213 lead to the emergence of parallel processing streams across the brain. Overall, this study suggests a paradigm
214 shift: any end-to-end computational model of the brain that learns from the sensory input needs to include physical
215 constraints, and not just behavioral goals, in order to accurately predict brain function.

379 **Materials and methods**

380 **Code and data availability**

381 Original code for this study is available at <https://github.com/dawnfinzi/spacestream>. The neural
382 data analyzed in this study comes from the Natural Scenes Dataset (NSD) [1] available at [http://](http://naturalscenesdataset.org/)
383 naturalscenesdataset.org/.

384 **"Training phase": Neural network architectures and training**

385 **Multi-behavior models.** To test the *multiple behavioral demands hypothesis*, we used three models, each trained on a
386 different task: object categorization, action recognition, and object detection. We chose these tasks as these are the
387 computer vision equivalents of the proposed behaviors each stream is thought to support (Ventral: what is it, Lateral:
388 what is it doing, Dorsal: where is it).

389 We used two versions of multi-behavior models: one version with a ResNet-50 base architecture, for optimal task
390 performance, and one version with a ResNet-18 base architecture as a control to more closely match the TDANN
391 architecture, and the number of visual areas in primate cortex [2, 3]. For the object categorization model, we used the
392 base model (ResNet-50 or ResNet-18) [4] trained on object categorization on ILSVRC-2012 (ImageNet Large-Scale
393 Visual Recognition Challenge [5]). For the action recognition model, we used the SlowFast model architecture [6],
394 which is a dual-pathway network with a 3D ResNet backbone trained on the Kinetics-400 video dataset [7]. Finally,
395 for the ResNet-50 object detection model, we used a Faster R-CNN [8] trained on MS-COCO [9]. For the ResNet-18
396 object detection model, we used a single-stage object detection network, SSD [10], for greater correspondence with
397 the other multi-behavior models, and trained on Pascal VOC (2007 and 2012) [11], in order to avoid any confounds
398 with both training and testing on MS-COCO (as the NSD images are also from MS-COCO).

399 We randomly subsampled an equal number of units from layer 4.1 or its equivalent from each network (ignoring
400 any "visually non-responsive" units that did not respond to any of the images) so that the total number of units was
401 equal to the total number of voxels. In order to allow for the most direct comparison against TDANN models, the
402 units sampled from the task-trained models were assigned random positions on a two-dimensional simulated cortical
403 sheet. We then followed the same pre-optimization procedure as in [Initialization of model unit position: Stage 2](#) in
404 order to be able to fairly apply the same mapping algorithm.

405 **Topographic Deep Artificial Neural Network (TDANN).**

406 **Model architecture and training** The TDANN model class, which we used to evaluate the *spatial constraints*
407 *hypothesis*, is based on ResNet-18 architecture, with two key differences: (1) model units are assigned positions
408 on a 2D simulated cortical sheet and (2) the model is trained to jointly minimize a spatial and a task loss. All TDANN
409 models were built using the ResNet-18 [4] base architecture (from the *torchvision* implementation) and trained using
410 modifications to the VISSL framework [12]. ResNet-18 was chosen because it has been shown to achieve strong
411 task performance, accurately predict neuronal responses across the visual system [13], and has roughly comparable
412 number of layers to stages (areas) in the primate visual system [14, 3]. Models were trained for 200 epochs using the
413 ILSVRC-2012 [5] training set, with each model being trained from five different random initial seeds. We optimized
414 the network parameters using stochastic gradient descent with momentum (with γ set to 0.9), a batch size of 512,
415 and a learning rate initialized to 0.6, which then decayed according to a cosine learning schedule [15] Models were
416 trained using a self-supervised contrastive objective "SimCLR" [16] or a supervised 1000-way object categorization
417 task.

418 **Initialization of model unit position** Prior to training, model units in each layer were assigned fixed positions in a
419 two-dimensional simulated cortical sheet specific to that layer. The size of the cortical sheet in each layer, and the
420 size of the "cortical zone" used during training (computation of the spatial loss is restricted to units within the same
421 cortical zone), was determined by the presumed correspondence, based on previous work comparing convolutional
422 neural networks (CNNs) and the primate visual system [17, 18, 19], between model layers and human visual areas
423 (see [2] for further details). Positions were then assigned in a two-stage process.

424 **Stage 1: Retinotopic initialization** As each layer convolves over the outputs of the previous layer, the resulting
425 responses are structured into spatial grids. To maintain this inherent organization, we assigned each model unit to a
426 specific area of the simulated cortical sheet that aligns with its spatial receptive field.

427 **Stage 2: Pre-optimization of positions** In CNNs, filter weights are shared between units at different locations, which
428 means that local updates to one unit affect all units with the same filter weights. This global coordination constraint
429 makes it challenging to achieve local smoothness when the units are arbitrarily positioned. To address this, a
430 pre-optimization of unit positions was necessary to identify a set of positions that enables learning smooth cortical

431 maps. We spatially shuffled the units of a pre-trained CNN on the cortical sheet, so that nearby units had correlated
432 responses to a set of sine grating images. The use of sine gratings is based on studies that show that propagating
433 retinal waves drive development of the visual system in the womb in primates and other mammals [20, 21, 22, 23]

434 The spatial shuffling works as follows: 1) Randomly select a cortical zone. 2) Compute pairwise response
435 correlations for all units in the zone 3) Select a random pair of units, and swap their locations in the cortical sheet. 4)
436 If swapping positions decreases local correlations (measured as an increase in the Spatial Loss function described
437 below), undo the swap. 5) Repeat steps 3-4 500 times. 6) Repeat steps 1-5 10,000 times.

438 **Loss functions** We trained the TDANN models using a weighted sum of two types of loss functions: a task loss,
439 which served to encourage learning of visual representations and a spatial loss, which encourages local correlations
440 in responses to visual inputs. Optimization on the total loss function leads to both successful visual representation
441 learning and minimization of inter-layer wiring length [2].

442 *Spatial loss* The spatial loss function encourages nearby model units on the simulated cortical sheet to be
443 correlated in their responses to the training stimuli. Specifically, SL_l is the spatial correlation loss computed for
444 the l -th layer and SL_l is computed on a given batch by randomly sampling a local cortical zone and calculating for
445 pairs of units, (1) correlation (Pearson's r) between the response profiles, (\vec{R}) , and (2) the the stabilized reciprocal
446 Euclidean distances (\vec{D}) :

$$\vec{D} = \frac{1}{(1 + \vec{d})} \quad (\text{S1})$$

447 where \vec{d} is the vector of pairwise cortical distances. These two terms are then related as follows:

$$SL_l = 1 - \text{Corr}(\vec{R}, \vec{D}) \quad (\text{S2})$$

448 such that SL_l is minimized when nearby units have correlated responses to the training stimuli.

449 *Task loss* The task loss (TL) is computed from the output of the final model layer. We tested two candidate
450 TL s: supervised object categorization cross-entropy loss [24] and the self-supervised SimCLR objective [16]. The
451 SimCLR objective is a contrastive loss function which works by creating two "views", or augmentations, of each image
452 in a batch, using random cropping, horizontal flips, color distortion, and Gaussian blur. These views are passed to
453 the network and the final layer outputs are passed through a 2-layer multi-layer perceptron (MLP), producing a
454 low-dimensional representation of each view which serves as the input to the loss function. The SimCLR loss
455 function then attempts to maximize the similarity of representations for two views of the same source image, while
456 pushing that representation away from all other images in the batch.

457 **Overview of training** In sum, the TDANN is trained on Imagenet [5] to minimize this total loss, which is the sum of
458 the weighted spatial loss for each layer and the task loss as follows:

$$\text{Total Loss} = TL + \alpha \sum_{l \in \text{layers}} SL_l \quad (\text{S3})$$

459 where α is the weight of the spatial loss component (fixed across all layers), and SL_l is the spatial correlation loss
460 computed for the l -th layer.

461 The total model training process consists of 6 steps:

- 462 1. The ResNet-18 model is trained using the task loss only.
- 463 2. Positions are initialized to preserve coarse retinotopy in each layer (Stage 1).
- 464 3. Positions are pre-optimized in an iterative process that preserves retinotopy while bringing together units with
465 correlated responses to sine gratings (Stage 2).
- 466 4. After pre-optimization, positions are permanently frozen.
- 467 5. All network weights are randomly re-initialized.
- 468 6. The network is trained to minimize the total loss.

469 **"Mapping phase": Linking model to brain**

470 **Neural data.** As our neural comparison, we used the Natural Scenes Dataset (NSD) [1], a high-resolution fMRI dataset
471 that densely sampled responses to up to 10,000 natural images in each of eight individuals over the course of 32-40
472 scan sessions. Full details on data collection and processing can be found in Allen et al. [1]. Briefly, scanning

473 was conducted at 7T using gradient-echo EPI at 1.8-mm isotropic resolution with whole-brain coverage. Images
474 were taken from Microsoft's COCO image database [9], square cropped to 425 pixels x 425 pixels, and presented
475 at fixation at a size of 8.4° x 8.4° for 3 seconds with 1 second gaps in between images. Data were preprocessed
476 using one temporal resampling (to correct for slice timing differences) and one spatial resampling (to correct for head
477 motion, EPI distortions and gradient non-linearities), resulting in upsampled 1.0mm resolution (temporal resolution
478 1.0 s). Single-trial beta weights were estimated using a general linear model approach designed to optimize the
479 quality of single trial betas (GLMsingle [25]). The single-trial responses were then z-scored across images for each
480 voxel and session and then averaged across 3 trial repeats. We used cortex-based alignment to align all data to the
481 fsaverage surface. Throughout reporting of the results, we refer to the brain units of measurement as “voxels”, for
482 interpretability, though they are more technically “vertices” as we are using the fsaverage preparation.

483 **ROIs** We defined regions of interest (ROIs) for early, intermediate, and high-level visual cortex for each of the three
484 streams based on a combination of anatomical landmarks, noise ceiling estimates (Supplemental Fig. S1), and a
485 constraint to roughly match the number of voxels per stream. We focus only on the high-level visual ROIs for the
486 purposes of this paper and compare the end point of the models to the end points of the processing stream in each
487 brain. However, the full details for drawing all seven (one early, three intermediate and three higher-level) ROIs are
488 included here for completeness and because the high-level ROIs share boundaries with the intermediate ROIs. ROIs
489 were drawn on the fsaverage surface as follows:

490 Early visual cortex ROI: The early visual cortex ROI was drawn as the union of the V1v, V1d, V2v, V2d, V3v and V3d
491 ROIs from the Wang retinotopic atlas [26]. Additionally, V2v and V2d, as well as V3v and V3d, were connected such
492 that the part of the occipital pole typically containing foveal representations was included in the ROIs.

493 Intermediate ROIs: Three intermediate ROIs were drawn corresponding to each of the three streams: Ventral, Lateral
494 and Dorsal. All three ROIs border the early visual cortex ROI on the posterior side. The intermediate Ventral ROI
495 was drawn to reflect the inferior boundary of hV4 from the Wang atlas [26] and includes the inferior occipital gyrus
496 (IOG), with the anterior border of the ROI drawn based on the anterior edge of the inferior occipital sulcus (IOS). The
497 intermediate Lateral ROI was drawn directly superior to the intermediate ventral ROI, with the superior and anterior
498 borders determined as the LO1 and LO2 boundaries from the Wang atlas [26]. The intermediate Dorsal ROI was
499 drawn directly superior to that to include V3A and V3B from the Wang atlas.

500 Higher-level ROIs: Three higher-level ROIs were drawn for each of the Ventral, Lateral and Dorsal streams, bordering
501 their respective intermediate ROIs on their posterior edges. The ventral ROI was drawn to follow the anterior lingual
502 sulcus (ALS), including the anterior lingual gyrus (ALG) on its inferior border and to follow the inferior lip of the inferior
503 temporal sulcus (ITS) on its superior border. The anterior border was drawn based on the midpoint of the occipital
504 temporal sulcus (OTS). The lateral ROI was drawn such that the higher-level ventral ROI was its inferior border and
505 the superior lip of the superior temporal sulcus (STS) was used to mark the anterior/superior boundary. The rest of
506 the superior boundary traced the edge of angular gyrus, up to the tip of the posterior STS (pSTS). The dorsal ROI
507 was drawn to reflect the boundary of the lateral ROI on its inferior edge and to otherwise trace the borders of and
508 include the union of IPS0, IPS1, IPS2, IPS3, IPS4, IPS5 and SPL1 from the Wang retinotopic atlas.

509 The three higher-level ROI were then trimmed using the prepared noise ceiling maps for beta version b3 and the
510 fsaverage surface [1]. The noise ceiling estimates represent the amount of variance contributed by the signal
511 expressed as a percentage of the total amount of variance in the data, for the average of responses across three trial
512 presentations. An approximate cutoff of 10% was used to guide trimming of the higher-level ROIs, such that we were
513 left with reduced ROIs where all voxels had a noise ceiling $\geq 10\%$ theoretically predictable variance. These ROIs
514 were contiguous and roughly matched in size (number of voxels per ROI right hemisphere: Dorsal = 6688, Lateral =
515 6839, Ventral = 5638; left hemisphere: Dorsal = 6182, Lateral = 5849, Ventral = 6126).

516 **Model data.** For each of our neural network models, we extracted features in response to the same set of 73,000
517 total NSD images seen by participants in the scanner. Features were extracted from layer 4.1 in ResNet18 and
518 ResNet50 or equivalent. This layer was chosen as past work shows that it has the best functional correspondence
519 to higher-level visual areas, including on the NSD [3, 2, 27]. This results in a matrix of features of the form *number*
520 *of images* x *number of units*, where the number of units is $7 \times 7 \times 512 = 25,088$, i.e. the total number of units in
521 layer 4.1, for the TDANN models, and 19,164 total subsampled units for the multi-behavior models (6,388 units per
522 model), which matches the maximum number of voxels per hemisphere. Thus, for all models, the number of source
523 units was of the same order of magnitude as the number of target voxels [28, 29].

524 **1-to-1 mapping.** Development of the mapping algorithm was done using the case of the brain-to-brain mapping, with
525 the reasoning being that if we failed to recover an element of the functional organization in the model-to-brain case,
526 we would not be able to arbitrate between a failure in the model and a failure in the mapping, unless we had already

527 shown that such functional organization could be captured in the brain-to-brain case using an identical mapping.
528 We found that incorporation of the spatial prior (see below) into the mapping significantly improves accuracy in
529 assignment (Supplemental Fig. S2). Once satisfied with the mapping algorithm in the brain-to-brain case, we used
530 that algorithm with as few modifications as possible (neighborhood radius and stimuli used, detailed below) to map
531 model-to-brain.

532 For each pair of subjects (source subject mapped to target subject), we used the single-trial z-scored betas for
533 each source voxel and each target voxel in response to the 515 images shared across all subjects (80% used for
534 assignment, 20% used for evaluation) and computed the correlations between each pair of voxels. This correlation
535 matrix was then transformed into a cost matrix ($1 - \text{correlation}$) and assignment was first attempted purely on the
536 basis of this cost matrix ("functional only") using the Kuhn-Munkres algorithm [30], a combinatorial optimization
537 algorithm which solves the assignment problem in polynomial time. The "functional only" algorithm performed above
538 chance in assigning voxels to the correct streams but did not fully recover the spatial organization (Supplemental
539 Fig. S2). We thus added a minimal smoothness constraint to the optimization procedure; the smoothness constraint
540 encourages neighboring voxels in the target space to "pick" neighboring voxels in the source space (given a small
541 local radius of 5 mm; full algorithm provided below:1). As this recovered more of the known spatial organization
542 in the voxel-to-voxel case (Supplemental Fig. S2), this was the mapping algorithm we chose to then apply in the
543 unit-to-voxel case. To convert the radius of 5 mm used in the voxel-to-voxel case to the model space, we calculated
544 what percentage of the max voxel-to-voxel distance (237 mm) the brain radius cutoff was and then multiplied that
545 percentage by the max model distance (12.9). This yielded a model radius cutoff of approximately 0.27, resulting in
546 the following two radii used in the unit-to-voxel case, 5 mm for the brain distances and 0.27 for the model distances.
547 Additionally, in the unit-to-voxel case, we leveraged the full set of unique images (up to 9485 per individual) to link
548 models to individual brains. The 515 shared images were then reserved for evaluating theories ("Test phase").

Algorithm 1 1-to-1 mapping with spatial prior (Fig. 1c)

Require: Cost matrix C of dimension $N_s \times N_t$, where N_s is the number of source units and N_t is the number of target units, and each entry in C is $1 -$ the pairwise correlation of the response vectors. Source distance matrix, D_s , of dimension $N_s \times N_s$, with the pairwise distances between all units in the source space. Target distance matrix, D_t , of dimension $N_t \times N_t$, with the pairwise distances between all units in the target space. Radius r to use as neighborhood size.

procedure MAPPING ALGORITHM(C, D_s, D_t, r)

Assignments $A \leftarrow$ Kuhn-Munkres(C) ▷ Initialized based on "functional only" mapping

while Mean movement of assignments from iteration to iteration has not converged **do**

$C_{\text{temp}} \leftarrow C.$ copy()

for each target unit, v_t **do**

Find all neighboring target units, V_{tn} within distance r

Initialize candidate matrix, V_{sn}

for each unit in V_{tn} **do**

Find their assigned source unit, v_s , from A

$v_{sn} \leftarrow$ all units in source space within distance r from v_s

Append v_s and v_{sn} to V_{sn}

end for

Fit a 2D Gaussian, G , to point cloud, V_{sn} in source space

$M_{sn} \leftarrow$ mahalanobis(V_{sn}, G)

for each unit, u , in V_{sn} **do**

if $M_{sn}[u] > 2$ **then**

Remove u from V_{sn}

end if

end for

$C_{\text{temp}}[v_t, \neg V_{sn}] = 1000$

▷ all source units not in V_{sn} are set to have a prohibitive cost

end for

$A \leftarrow$ Kuhn-Munkres(C_{temp})

end while

return A

end procedure

549 **Total models tested.** We evaluated 5 instances initialized with different random seeds per each of the TDANNs across
550 2 training tasks (SimCLR and categorization) and 7 levels of spatial weightings (α), as well as 2 base architectures

551 (Resnet-18 and ResNet-50) for each of the 3 multi-behavior models (detection/action/categorization). Each model
552 was then mapped to the 2 hemispheres for each of the 8 participants, totaling 1216 model-to-brain mappings tested.

553 "Test phase": Evaluating theories

554 **Evaluating spatial correspondence.** We evaluated the spatial correspondence in two ways. First, to compare
555 multi-behavior models and TDANNs directly we calculated a percentage spatial correspondence metric. In the case
556 of multi-behavior models, this is calculated as the percentage of voxels for each stream that were assigned to the
557 multi-behavior model trained using that stream's corresponding task (i.e. Ventral and object categorization). In the
558 case of TDANNs, we divided the simulated cortical sheet into three sections (candidate stream partition scheme),
559 assuming a log-polar transform, and calculated the highest percentage of voxels that match the partition scheme
560 across candidate partitions (reflection and 5° rotations).

561 Second, when comparing across TDANNs that have simulated cortical sheets, we additionally calculated a distance
562 similarity metric. The distance similarity metric measures, for each unit-to-voxel pairing, the correlation between
563 the normalized distances on the model cortical sheet (from that unit to other units) and normalized distances on
564 the actual cortical surface (for the assigned voxel to the other units' assigned voxels), averaged across-unit-to-voxel
565 pairings. For each unit, this metric is calculated across only the closest 33% of units, to simulate stream boundaries,
566 which has the additional benefit of discounting high distances where there are few pairs. The same calculation
567 was performed in the brain-to-brain case to determine the actual cortical level of distance similarity. We report the
568 average distance similarity across unit-to-voxel pairings.

569 **Evaluating functional correspondence.** To evaluate functional correspondence between candidate models and the
570 brain, we report the 1-to-1 correlations calculated on the left-out set of 515 shared images, using the unit-to-voxel
571 assignments determined by the mapping procedure. Each unit-to-voxel correlation was normalized by the individual
572 voxel noise ceiling (r) of that assigned voxel (see [1] for information on the calculation of the intra-individual voxel
573 noise ceilings in NSD). 1-to-1 correlations were calculated on an individual subject and hemisphere basis for each
574 of the candidate models. The voxel-to-voxel assignments were used to calculate the overall inter-individual i.e.
575 brain-to-brain noise ceiling (correlations evaluated on test set of 20% of the shared images, averaged across 5 splits
576 for each source and target subject combination).

577 **Linear regression.** To compare the 1-to-1 mapping results to the commonly used mapping method of linear regression
578 between model units and the brain [18, 31, 13], we also calculated TDANN model to brain correspondence by
579 regressing model responses from the final convolution layer onto individual voxel responses using ridge regression.
580 As in [13], to decrease computational costs without sacrificing performance, we first projected unit activations into
581 a lower dimensional space using a subsample of the ImageNet validation images and retained the first 1000 PCs.
582 Performance was evaluated on a left-out test set (8/9 train, 1/9 test, shared images excluded, 10 splits) for each
583 subject separately. Test R^2 for each voxel is normalized by the individual voxel noise ceiling (R^2). To evaluate the
584 upper-bound model performance given the shared variance across subjects, we again calculated a brain-to-brain
585 noise ceiling for each stream by repeating the same ridge regression procedure as for model-to-brain but instead
586 using all other subjects' responses to predict the left-out subject (80/20 train-test split using the set of 515 shared
587 images, 10 splits).

588 Effective dimensionality

589 To calculate effective dimensionality, i.e. the dimensionality of the space of how information is represented by a
590 system (also referred to as the latent dimensionality), we considered the responses of the subset of units assigned
591 to each stream by subject. Using the unit activations (in the case of the models) or z-scored betas (in the case of
592 the human subjects), we computed the eigenspectrum of these responses to the MSCOCO images used in NSD.
593 Following [32] and [33], we computed effective dimensionality from the eigenvalues (λ) as:

$$ED = \frac{\left(\sum_{i=1}^N \lambda_i\right)^2}{\sum_{i=1}^N \lambda_i^2} \quad (\text{S4})$$

594 where N is the number of eigenvectors. Intuitively, if the eigenspectrum decays slowly, that means there are many
595 informative dimensions, and the ED, which in words is simply the squared sum of the eigenvalues over the sum
596 of squares of the eigenvalues, will be high. On the other hand, if the eigenspectrum decays rapidly, meaning that
597 information is largely encoded in only a few dimensions, then the ED will be low.

598 **Model unit selectivity and receptive field properties**

599 Previous studies reported that voxels in face-selective regions in the Lateral stream are more peripheral than those in
600 face-selective regions of the Ventral stream [34]. To test if this functional feature was also present in the TDANN, we
601 identified face-selective units in each stream and then estimated the eccentricity of their receptive fields. To identify
602 face-selective units in the TDANN, we used the functional localizer (fLoc) stimulus set [35]. fLoc contains stimuli from
603 five categories, each with two subcategories consisting of 144 images each. The categories are faces (adult and
604 child faces), bodies (headless bodies and limbs), written characters (pseudowords and numbers), places (houses
605 and corridors), and objects (string instruments and cars). These stimuli have been previously used to localize and
606 describe category-selective responses in human higher visual cortex in fMRI studies [35, 34, 36]. Selectivity was
607 assessed by computing the t -statistic over the set of functional localizer stimuli and defining a threshold above which
608 units were considered selective.

$$t = \frac{\mu_{\text{on}} - \mu_{\text{off}}}{\sqrt{\frac{\sigma_{\text{on}}^2}{N_{\text{on}}} + \frac{\sigma_{\text{off}}^2}{N_{\text{off}}}}}, \quad (\text{S5})$$

609 where μ_{on} and μ_{off} are the mean responses to the "on" categories (adult and child faces) and "off" categories (all
610 non-face categories), respectively, σ^2 are the associated variances of responses to exemplars from those categories,
611 and N is the number of exemplars being averaged over. As in fMRI experiments, units with $t > 3$ were classified
612 as face-selective. For each unit, eccentricity was then calculated based on the unit's (x,y) position from the center
613 of the 7×7 filter, converted to degrees of visual angle (by multiplying by 8° input stimulus / 7 grid size). From there,
614 we divided these units based on which stream they were assigned to and report the mean eccentricity across
615 face-selective units for each model seed x subject x hemisphere combination.

616 **Task transfer**

617 We tested performance of self-supervised TDANNs units mapped to the Dorsal and Ventral stream, on new tasks,
618 position prediction and object categorization, respectively, associated with each stream (results for the Lateral stream
619 and additional tasks in Supplementary Fig. S5). We refer to this as task transfer performance as the TDANN model
620 was not trained on any of these tasks and model weights were frozen. Performance on the transfer task was tested
621 for the self-supervised TDANNs which best match the brain ($0.25 \leq \alpha \leq 0.5$ in Fig. 4, full results across spatial
622 weightings in Supplementary Fig. S5) and each hemisphere of each subject.

623 **Position task.** We evaluated the performance of TDANN units assigned to each stream on predicting the vertical and
624 the horizontal locations in pixels of an object center in an image, using the stimulus set from Hong et al., which has
625 also been used in the evaluation of neural network models of the mouse [38] and primate [31, 39] visual systems.
626 This stimulus set consists of 5760 gray-scale images of 64 distinct objects chosen from one of eight categories
627 (animals, boats, cars, chairs, faces, fruits, planes, tables) placed on randomly chosen, realistic background scene
628 images. Object position, pose and size in this stimulus set varied at different levels from no variation, to medium
629 variation and high variation levels.

630 For each TDANN model and individual subject, smaller "stream models" were created for each of the three streams
631 by selecting the 5000 units assigned to that stream with the highest correlations. We extracted activations from these
632 units and reduced the dimensionality of the activations to 1000 dimensions using principal components analysis
633 (PCA). We used Ridge regression, with the regularization parameter, α , cross-validated from

$$\alpha \in [0.01, 0.1, 1, 10] \quad (\text{S6})$$

634 to predict the vertical and the horizontal locations in pixels of the object center in the image. We performed five-fold
635 cross-validation on the training split of the no- and medium-variation image subsets, consisting of 3200 images,
636 and computed performance on the test split of the high-variation set consisting of 1280 images. Ten different
637 category-balanced train-test splits were randomly selected. We report R^2 on the high-variation test set, averaged
638 across the 10 splits.

639 **Categorization task.** To evaluate the performance of TDANN units assigned to each stream on a downstream
640 categorization task, we used the 1000-way ImageNet object categorization task [5]. For each TDANN model and
641 individual subject, smaller "stream models" were created for each of the three streams as in the position prediction
642 task. A single linear layer was then trained directly from the outputs of those units. The linear layer was trained for 28
643 epochs of the ILSVRC-12 ImageNet training set (1,281,167 images) with a batch size of 1,024 and a learning rate
644 which was initialized to 0.04 and decreased by a factor of 10 every eight epochs. We report the top-1 performance
645 on the held-out validation set (50,000 images).

646 Supplementary tables

Table 1. Linear mixed-effects model to test effect of candidate model type on spatial correspondence for each of the three streams. To test if there were differences between candidate models on spatial correspondence with the brain, we used linear mixed-effects models, with fixed effects for candidate model type (intercept denotes multi-behavior candidate model with ResNet-18 base, i.e. MB ResNet-18) and a random intercept for each subject. Model specification was as follows: spatial correspondence \sim candidate model type + 1 | subject. A separate model was run for each of the three streams. Positive values indicate better spatial correspondence than the MB ResNet-18 (first row) and negative values indicate worse spatial correspondence. For example, the β coefficient of -15.87 for MB ResNet-50 in Dorsal indicates that there is an average decrease of 15.87% in spatial correspondence for the MB ResNet-50 model relative to the MB ResNet-18 model, while the β coefficient of 11.91 for the supervised TDANN indicates an average increase of 11.91%, again relative to the MB ResNet-18 value of 50.2%. Corrected p-values indicate p-values Bonferroni-corrected for multiple comparisons between candidate model types. Significant predictors ($p < .05$) are shown in bold. MB = multi-behavior. These statistics are related to Fig 2b.

		Coefficients \pm SE	z-value	p-value	corrected p-value
Dorsal	Intercept (MB ResNet-18)	50.20\pm1.54	32.61	2.6x10⁻²³³	
	MB ResNet-50	-15.87\pm2.12	-7.48	7.5x10⁻¹⁴	2.2x10⁻¹³
	Self-supervised TDANN	6.13\pm2.12	2.89	.004	.012
	Supervised TDANN	11.91\pm2.12	5.61	2.0x10⁻⁸	6.1x10⁻⁸
Lateral	Intercept (MB ResNet-18)	50.58\pm1.43	35.28	1.3x10⁻²⁷²	
	MB ResNet-50	-19.89\pm1.65	-12.06	1.8x10⁻³³	5.3x10⁻³³
	Self-supervised TDANN	7.71\pm1.65	4.67	3.0x10⁻⁶	8.9x10⁻⁶
	Supervised TDANN	-2.51 \pm 1.65	-1.52	0.13	0.38
Ventral	Intercept (MB ResNet-18)	48.35\pm1.34	36.14	5.9x10⁻²⁸⁶	
	MB ResNet-50	-13.99\pm1.89	-7.39	1.4x10⁻¹³	4.3x10⁻¹³
	Self-supervised TDANN	21.85\pm1.89	11.55	7.5x10⁻³¹	2.2x10⁻³⁰
	Supervised TDANN	18.22\pm1.89	9.63	6.1x10⁻²²	1.8x10⁻²¹

Table 2. Linear mixed-effects model to test effect of candidate model type on functional correspondence for each of the three streams. To test if there were differences between candidate models on functional correspondence with the brain, we used linear mixed-effects models, with fixed effects for candidate model type (intercept denotes multi-behavior candidate model with ResNet-18 base, i.e. MB ResNet-18) and a random intercept for each subject. Model specification was as follows: functional correspondence \sim candidate model type + 1 | subject. A separate model was run for each of the three streams. Positive values indicate better functional correspondence than the MB ResNet-18 (first row) and negative values indicate worse functional correspondence. For example, the β coefficient of -0.01 for MB ResNet-50 in Ventral indicates that there is an average decrease in the correlation with brain responses of 0.01 for the MB ResNet-50 model relative to the MB ResNet-18 model, while the β coefficient of 0.18 for the self-supervised TDANN indicates a massive average increase in correlation of 0.18 , again relative to the MB ResNet-18's value of 0.14 , meaning that the self-supervised TDANN had an average correlation across subjects of 0.32 to Ventral brain responses. Corrected p-values indicate p-values Bonferroni-corrected for multiple comparisons between candidate model types. Significant predictors ($p < .05$) are shown in bold. MB = multi-behavior. These statistics are related to Fig 2c.

Figure S1. Voxel-wise noise ceiling estimates and ROI boundaries. Noise ceiling estimates (% explainable variance) across all image repeats per subject and then averaged across subjects, visualized on the fsaverage surface. Values are thresholded at 10% explainable variance, the cutoff used to guide drawing of the higher-level ROI boundaries. Figure illustrates that, (1) by design, much of the reliable signal is included in the ROIs drawn, and (2) the noise ceiling is high (minimum 10% explainable variance and numerous voxels above 50% explainable variance) across Ventral, Lateral, and Dorsal. Dashed black line: region shown in main text figures.

Figure S2. Representations differ across streams in NSD. (a) Multidimensional scaling of representation structure. For each individual and ROI, we computed the similarity (Pearson's r) between distributed responses across the ROI to all pairs of shared images, resulting in a representational similarity matrix (RSM) from which we extract the flattened lower triangle as a representation vector. Representation vectors were correlated across all subject and ROI combinations (corrected by the trial-to-trial reliability) to generate a 2nd-order RSM, which characterizes the similarity of representations across subjects and ROIs. To visualize the structure, we computed a multidimensional scaling (MDS) of this matrix. We find a rough hierarchical progression from early visual cortex (EVC) ROIs in the top-right (gray), to mid-level ROIs (light colors, middle), to high-level ROIs in the lower-left. Additionally, there is a large-scale separation by stream for high-level ROIs, rather than subject or hemisphere, with lateral high-level ROIs (blue) separated and more superior from a tight ventral cluster (magenta), which is in turn, largely distinct from the dorsal ROIs (green, though these show greater between subject variability). (b) Comparison of ROIs as models of each other, using representational similarity analysis (RSA) and linear regression (Ridge regression). Pearson's r and R^2 values are normalized by the respective noise ceilings (NC). Each dot represents a subject. White: within-ROI (i.e. subject-to-subject noise ceiling); Gray and Black bars: ROI X's prediction of ROI Y's responses. (c) To further test whether each stream showed a distinct representational structure, we parcellated cortex into 1000 equally spaced ROIs and then calculated the correlation between each pair of parcels. Each comparison was grouped based on whether both parcels were located within the same stream (black) or whether they were located in two different streams (white), revealing significantly higher correlations within than across streams for this three-stream organization (main effect of within vs. across: $p=4.19 \times 10^{-7}$). The difference in parcel correlations within vs. across streams did not simply reflect anatomical proximity, as the neighboring lateral and dorsal streams showed the greatest differentiation.

Figure S3. Validating the 1-to-1 mapping algorithm by testing how well it maps one brain onto another brain. (a) Right hemisphere voxels in Target (Subj. 2) brain colored by their assignment to streams in Source (Subj. 1) right hemisphere voxels using the algorithm [30] that matches each unit to a voxel solely based on functional similarity. Essentially, all spatial information was removed and voxels in the Target brain were assigned to voxels from the Source brain purely on the basis of how correlated they were in their responses to the shared stimuli across subjects. We refer to this mapping as functional only. (b) Right hemisphere voxels in Target (Subj. 2) brain colored by their assignment to Source (Subj. 1) right hemisphere voxels using the full algorithm that additionally incorporates a gentle smoothness constraint, which encourages neighboring voxels in the target space to "pick" neighboring voxels in the source space (algorithm used in main text). (c) Spatial correspondence between brains using the functional only or full algorithm. Bars: Comparison of right hemisphere voxel-to-voxel correspondence. Data show substantially higher correspondences when using the full algorithm in both the right (Ventral: $t(7) = 41.3, p = 1.3 \times 10^{-9}$, Lateral: $t(7) = 15.6, p = 1.1 \times 10^{-6}$, Dorsal: $t(7) = 27.0, p = 2.5 \times 10^{-8}$) and left hemisphere (panel f; Ventral: $t(7) = 18.2, p = 3.7 \times 10^{-7}$, Lateral: $t(7) = 18.1, p = 4.0 \times 10^{-7}$, Dorsal: $t(7) = 21.8, p = 1.1 \times 10^{-7}$). Data plotted for high-level ROIs across three streams, averaged across source subjects for each target subject. Color represents stream (pink: Ventral, blue: Lateral, and green: Dorsal). Dotted line: chance level (33%). Error bar: 95% CI, each dot is a subject. Data show that the full algorithm achieves a better brain-to-brain mapping. (d), (e), and (f), same for left hemisphere.

Figure S4. Model-to-brain 1-to-1 mapping visualized on the simulated cortical sheet of the last convolutional layer of the TDANN model. TDANN model-to-brain mapping visualized on the simulated cortical sheet, for TDANNs trained using the self-supervised, SimCLR task (a) or the supervised, object categorization task (b). This visualization is the reverse of the visualization in Fig. 2a and Fig. 3a of the main text. Here, each square panel shows model units (each dot is a model unit) on the simulated cortical sheet. Units are colored based on the spatial location of their assigned voxel in an example target brain. Opacity of the units reflects the strength of the model-to-brain correlation between responses to NSD images and units are colored by stream (top) or superior-to-inferior spatial gradient (y-position in flat map, bottom). This second color scheme is "stream-agnostic" in that it does not presuppose the existence of three streams, yet stream clustering emerges at self-supervised $0.25 \leq \alpha \leq 0.5$. Each column displays the model-to-brain mapping for an example subject and model seed for a particular spatial weight.

Figure S5. Adding the spatial loss component to the TDANN during training can improve later transfer performance for some tasks. Transfer performance for units from the self-supervised TDANNs across a range of weightings (α) on the spatial loss function for four tasks: object categorization, object position estimation, object pose estimation (y-axis rotation), and object size estimation. For three of the four tasks: position, pose, and size estimation, the addition of a spatial loss term improves performance, with peak performance in the same range of weighting on the spatial loss term that leads to best correspondence with the brain ($0.25 \leq \alpha \leq 1.25$). Units were divided by their assigned stream and then assessed on transfer performance using supervised linear readouts. Results are averaged across model seeds (5), subjects (8) and hemispheres (2) totaling 80 models per point, with the exception of (a) where results represent only one model seed, due to compute constraints. Shaded error bar: \pm SE. Larger circles indicate model by stream combinations evaluated main text Figure 4.
