Cytoplasmic Microtubules in Strial Marginal Cells

Joseph Santos-Sacchi

120 Street and Broadway, New York, N.Y. 10027, USA

It has been known for some time that primary glutaraldehyde fixation and primary osmium fixation may offer different ultrastructural detail (Merck et al., 1974; Santos-Sacchi, 1977). Of significance is the almost selective ability of glutaraldehyde fixation to preserve labile cytoplasmic microtubules (CMT). In fact, Behnke and Forer (1967) reported that CMT of Crane-fly spermatids would not have been discovered if glutaraldehyde fixation were not employed. Apparently, CMT depolymerise during primary osmication.

The ubiquity of CMT within eukaryote cells is well acknowledged. They have been implicated in cytoskeletal support (Tilney, 1968), cellular morphologic maturation (Heywood et al., 1975), intracytoplasmic transport (La Vail and La Vail, 1974), secretion (Le Marchand et al., 1975), and organelle stratification (Neve et al., 1975).

Most research on the fine structure of the stria vascularis has employed primary osmium fixation (Smith, 1957; Hinojosa and Rodriguez-Echandia, 1966; Sugar et al., 1972). Generally, the cytoplasm of the marginal cells has been described as having a dense matrix. CMT have been reported rarely. However, recently Hilding and Ginsberg (1977) while studying melanogenesis in the stria reported the presence of cross-sectioned CMT within the marginal cell basal processes. Primary aldehyde fixation was employed. Their cross-sectioned CMT were identical to the 200 Å vesicles found within the marginal cell processes by Spondlin (1967).

The presumed secretory or absorptive function and the tenuous anatomy of the strial cells make them likely candidates for CMT inclusions. It is the purpose of this short communication to report upon the marginal cell microanatomy following glutaraldehyde fixation, with special reference to CMT.

Procedure

Cochleae of young adult albino mice were fixed by immersion either in 1% OsO₄ or 2% glutaraldehyde in 0.1 M cacodylate buffer at 4° C for 2 h. Post-osmication for 2 h followed glutaraldehyde fixation. The cochleae were dehydrated in graded series of acetone, the stria dissected free and embedded in

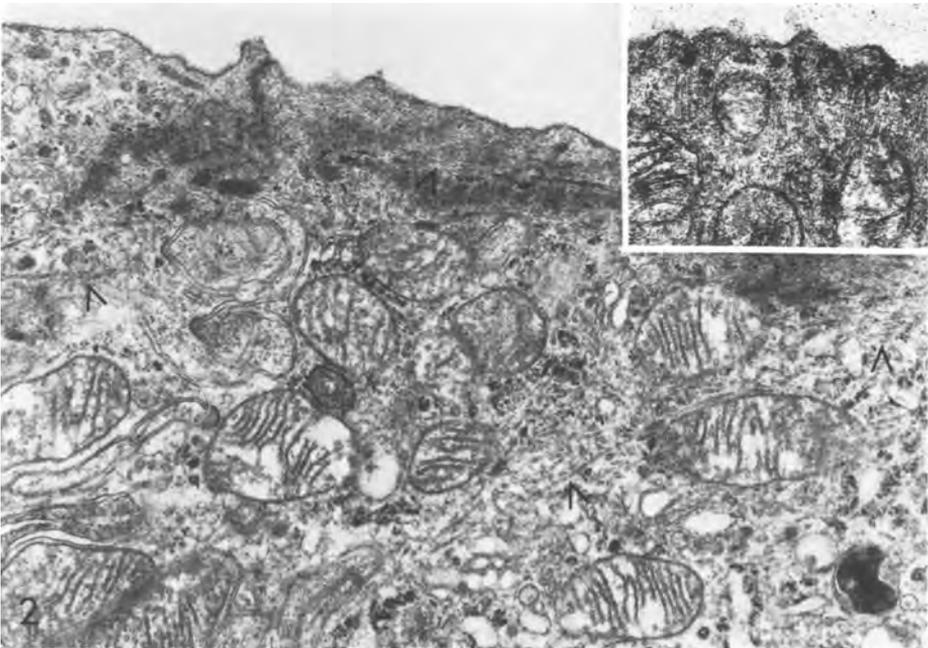

Fig. 2. Cytoplasmic microtubules in the apical cytoplasm of the stria vascularis ($\times 21,960$). Insert: Microtubules approaching apical membrane perpendicularly ($\times 29,822$)

Epon at 60° C. Ultrathin sections were stained with saturated uranyl acetate and lead citrate, and were examined with a Zeiss 9S-2 EM.

Results

In all animals, abundant numbers of CMT were present in the marginal cells only after primary fixation in glutaraldehyde. Only a dense cytoplasmic matrix was visible after primary osmication. Marginal cell CMT were seen both in cross and longitudinal section in the cell processes (Fig. 1). They extended parallel to each other for several microns and filled most of the cytoplasm not occupied by other organelles. CMT were also abundant in the apical cytoplasm (Fig. 2). They were observed coursing perpendicular, oblique, and parallel to the endolymphatic surface. CMT and apical membrane contacts were seen, as well as occasional associations with apical vesicles.

Discussion

CMT have not been reported within the marginal cells to the extent observed in this report. Apparently, the dense cytoplasmic matrix of the marginal cells reported in the past was due to the depolymerisation of CMT during primary osmication. The preservation of CMT by glutaraldehyde is thought to be due to the fixative's superior cross-linking of protein.

Speculative roles for marginal cell CMT are numerous. For example, they may play a role in the development of strial interdigitations, since during early development, marginal cells form a single layer of cuboidal epithelium which proceeds to send out basal processes (Kikuchi and Hilding, 1966). Indeed, the regression of adult strial tissue to early developmental forms as a result of various toxic materials may be due to CMT disruption. CMT inhibitors have been known to cause the retraction of cellular processes (Tilney, 1968). Also, the secretory or absorptive nature of the stria may be linked to CMT, since a correlation between secretion and microtubule numbers has been suggested (Sloper and Grainger, 1975). Marginal cell CMT-vesicle interactions may be important for apical vesicle transport.

Certainly, the vast number of CMT present in the marginal cells argues for roles similar to those observed in other cells, viz., cytoskeletal support and intracytoplasmic transport. The study of these structures in pathologic states may prove fruitful.

Abstract The development of motor protein activity in the lateral membrane of the mouse outer hair cell (OHC) from postnatal day 5 (P5) to P18 was investigated under whole-cell voltage clamp. Voltage-dependent, nonlinear capacitance (C_v), which represents the conformational fluctuations of the motor molecule, progressively increased during development. At P12, the onset of hearing in the mouse, C_v was about 70% of the mature level. C_v saturated at P18 when hearing shows full maturation. On the other hand, C_{lin} , which represents the membrane area of the OHC, showed a relatively small increase with development, reaching steady state at P10. This early maturation of linear capacitance is further supported by morphological estimates of surface area during development. These results, in light of recent prestin knockout experiments and our results with quantitative polymerase chain reaction, suggest that, rather than the incorporation of new motors into the lateral membrane after P10, molecular motors mature to augment nonlinear capacitance. Thus, current estimates of motor protein density based on charge movement may be exaggerated. A corresponding indicator of motor maturation, the motor's operating voltage mid-

point, V_{pkcm} , tended to shift to depolarized potentials during postnatal development, although it was unstable prior to P10. However, after P14, V_{pkcm} reached a steady-state level near -67 mV, suggesting that intrinsic membrane tension or intracellular chloride, each of which can modulate V_{pkcm} , may mature at P14. These developmental data significantly alter our understanding of the cellular mechanisms that control cochlear amplification and provide a foundation for future analysis of genetic modifications of mouse auditory development.

Introduction

The organ of Corti, the auditory sensory epithelium of the mammal, has two types of hair cells, the inner hair cell (IHC) and the outer hair cell (OHC). In mammals, the OHC can contract and elongate at acoustic frequencies upon electrical stimulation (Brownell et al. 1985; Ashmore 1987; Santos-Sacchi 1992; Dallos and Evans 1995; Frank, Hemmert and Gummer 1999). Such voltage-dependent length change is termed “electromotility” and is thought to provide a means for improving mammalian cochlear sensitivity and frequency selectivity (Dallos 1992). Recently, on the basis of subtractive cloning between motile OHCs and nonmotile IHCs, a cDNA clone that is specifically expressed in OHCs was isolated and termed “Prestin” (Zheng et al. 2000b). The expressed motor protein prestin, which resides exclusively in the lateral membrane (Belyantseva et al. 2000), is likely key to cochlear amplification (Zheng et al. 2000b; Liberman et al. 2002). It is common practice to evaluate OHC motor activity either by

measuring changes in OHC length or motor-derived nonlinear capacitance (C_v), both being inextricably related (Santos-Sacchi and Dilger 1988; Ashmore 1987, 1990; Santos-Sacchi 1990, 1991). GLUT5, another protein initially considered a motor candidate (Geleoc et al. 1999) that also resides within the lateral membrane, does not express nonlinear capacitance (Ludwig et al. 2001). In the OHC, then, membrane capacitance (C_m) is the sum of motor-derived capacitance and capacitance resulting from the intrinsic capacity of membrane, i.e., surface area (Santos-Sacchi and Navarrete 2002).

The onset of hearing in the mouse is approximately at postnatal day 12 (P12), and full maturation is at P18 (Ehret 1976; Steel and Bock 1980). While the mouse is currently an important model for studies on hearing and the genetics of hearing, there is no information on the development of OHC motor activity in this species. However, OHC motor development has been studied in two other species, the rat and gerbil (He, Evans and Dallos 1994; Oliver and Fakler 1999; Belyantseva et al. 2000). He et al. (1994) reported that postnatal OHCs of gerbils begin to acquire electromotile properties at P7 in the basal cochlear turn and at P8 in the apical turn, reaching adult characteristics at about P13–14. In rat OHCs, the density of motor protein matured near P11 (Oliver and Fakler 1999; Belyantseva et al. 2000); Oliver and Fakler (1999) further concluded that the increase in membrane capacitance after P11 was due to an increase in membrane area containing the same density of motor proteins. Here, we investigated the density of the motor protein in the lateral membrane of the mouse OHC during development and demonstrate that, whereas cell size of OHCs matures at P12, voltage-dependent capacitance increases continuously up to P18. We argue that this increase, in the face of fixed surface area, derives from maturation of motor activity and not from additional motor incorporation. These observations impact on basic mechanisms of motor development as well as interpretation of genetic manipulations of the motor protein prestin.

Materials and Methods

OHCs were obtained from acutely dissected organs of Corti from C57BL/6J mice. Though this strain exhibits age-related hearing loss, normal hearing persists to 2 months of age (Wu et al. 2004). Additionally, we limited our cell harvesting to low-frequency regions (middle to apical turn) that remain normal well beyond that time. The persistence of normal cochlear amplification into adulthood indicates that development occurs normally in this strain. We additionally used this strain in order to make direct comparisons with the prestin knockout results (Liberman et al. 2002). The mice were killed in accordance with the

Guidelines for Animal Experimentation, Hiroasaki University. Cochleae were dissected, and the organs of Corti were separated from the modiolus and stria vascularis. The organs were then digested with trypsin (1 mg/ml) in external solution for 10–12 min at room temperature and transferred into 35-mm plastic dishes (Falcon, Lincoln Park, NJ) with 2 ml external solution. OHCs were isolated by gentle trituration. The dish was mounted on an inverted microscope (IX71; Olympus, Tokyo, Japan).

The external solution contained (mM) 100 NaCl, 20 tetraethylammonium, 20 CsCl, 2 CoCl₂, 1.52 MgCl₂, 10 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES) and 5 dextrose (pH 7.2), 300 mosmol • liter⁻¹, in order to block ionic conductances. The patch pipette solution contained (mM) 140 CsCl, 2 MgCl₂, 10 ethyleneglycoltetraacetic acid (EGTA), 10 HEPES (pH 7.2), 300 mosmol • liter⁻¹ (adjusted with dextrose).

The cells were whole-cell voltage-clamped with an Axon (Burlingame, CA) 200B amplifier using patch pipettes having initial resistances of 3–5 MΩ. Series resistances, which ranged 5–20 MΩ, remained uncompensated for C_m measurements, though corrections for series resistance voltage errors were made offline. All data acquisition and analyses were performed with the Windows-based patch-clamp program jClamp (SciSoft, New Haven, Connecticut).

C_m functions were obtained 1 min after establishment of the whole-cell configuration, following sufficient time for wash-in of pipette solutions in these small cells. C_m was assessed using a continuous high-resolution (2.56 ms sampling) two-sine voltage stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz) superimposed onto a voltage ramp (200 ms duration) from -150 to +150 mV (Santos-Sacchi 2004; Santos-Sacchi, Kakehata and Takahashi 1998). Capacitance data were fit to the first derivative of a two-state Boltzmann function (Santos-Sacchi 1991).

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin}$$

$$b = \exp\left(\frac{-ze(V_m - V_{pkcm})}{kT}\right)$$

where Q_{\max} is the maximum nonlinear charge moved, V_{pkcm} is voltage at peak capacitance or half-maximum charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. Density was calculated as $d = (Q_{\max}/e)/(C_{lin}/0.008)$, i.e., based on a conversion of 0.008 pF/μm² (as measured directly, see Results). This conversion factor is within the range of factors commonly used (Solsona, Innocenti and Fernandez 1998). A further discussion of OHC linear capacitance can be found in Santos-Sacchi and Navarrete

(2002). For analyses, we quantified C_v , an estimate of voltage-dependent, nonlinear capacitance (NLC), as the absolute peak capacitance minus linear capacitance. In order to estimate surface area (A_{ohc}), we modeled the OHC as a cylinder composed of three pieces, the cuticular plate area (A_{cut}), the lateral membrane area (A_{lat}) and the basal area (A_{bas}). Cell width was determined at three equidistant positions along the cells' length.

$$A_{ohc} = A_{lat} + A_{cut} + A_{bas}$$

where

$$A_{lat} = 2\pi r(L - r)$$

$$A_{cut} = \pi r^2$$

$$A_{bas} = \frac{\pi(2r)^2}{2}$$

For P5–8 (see Fig. 1B), where the length and width were similar and the cell appeared more spherical, area was calculated as a sphere with an average diameter: (width + length)/2. Cell width for this age group was measured at the cell's midpoint. Dimensions were measured at 1 min following membrane patch rupture. On average, cell

lengths are compressed 5.99% after the whole-cell configuration. OHC images were captured by a digital charge-coupled device camera and recorded with AQUA-Lite (version 1.2; Hamamatsu, Shizuoka, Japan). All data are given as mean \pm standard error of the mean (SEM). Fits to the data were made with a sigmoidal logistic function (Sigma Plot 9.0; Systat, San Jose, California). All electrophysiological and morphometric measures were made on each cell for direct comparison.

To estimate the prestin mRNA level during development, a two-step reverse transcription (RT) and quantitative polymerase chain reaction (QPCR) was employed. Total RNA was extracted from the organ of Corti at P5, P8, P10 and P15, using TRI reagent and reverse-transcribed using random decamers according to the manufacturer's instructions (Invitrogen, Carlsbad, CA). QPCR was done using a 1:10 dilution of cDNA. QPCR was performed with a Brilliant SYBR Green qPCR kit and Stratagene MX3000 (both from Stratagene, La Jolla, CA). Each amplification was done in duplicate. Amplification conditions were 94°C for 30 s, 60°C for 30 s and 72°C for 1 min. Primer sequences were as follows: prestin, TGGGGTCAAAA-CAAAGCGG and GCAAACCAAAAACCATCAGGC (spanning intron between exons 8 and 9); glyceraldehyde-3-phosphate dehydrogenase (GAPDH), AGGTCCGGTGTGAACGGATTG and TGTAGACCATGTAGTTGAGGTCA. Amplification specificity was confirmed by melting curve analysis and agarose gel electrophoresis (Metaphor; ICN, Irvine, CA). Data were normalized to GAPDH expression.

Results

The signature electrical response of an adult OHC is a bell-shaped, voltage-dependent capacitance. In postnatal OHCs, C_m showed bell-shaped voltage dependence from P7; C_v was not detectable at either P5 or P6. Examples of the change of C_m functions with development are shown in Figure 1A. Examples of digitally captured phase-contrast images of developing OHCs are shown in Figure 1B. From such data we determined estimates of the cells' linear capacitance (a correlate of membrane surface area), which increased slightly from P5 to P9, thereafter remaining stable (Fig. 2A, colored symbols). In that same figure, surface area estimates (see Materials and Methods) correspond to measures of C_{lin} . Linear capacitance measures more accurately assess the surface area since these measures are not dependent on geometrical models. Although surface area remains fixed after P9, dimensions change, with cell width decreasing and cell length increasing. A plot of their correspondence (Fig. 2B) shows this inverse relationship and indicates that after OHCs attain about

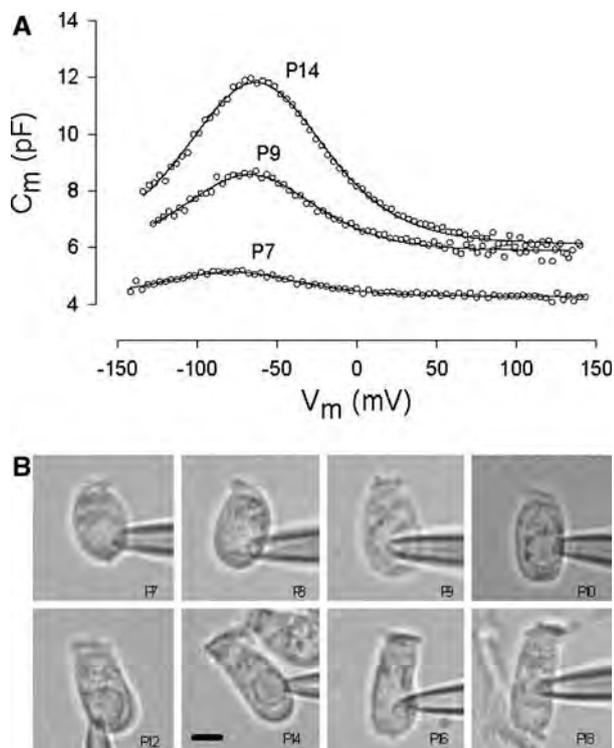

Fig. 1 (A) Examples of C_m functions from three postnatal days. In addition to an increase in peak capacitance, note the shift in V_{pkcm} to the right during maturation. Fitted parameters were $Q_{max} = 0.091$ pC, $z = 0.89$ at P7; $Q_{max} = 0.263$ pC, $z = 0.95$ at P9; $Q_{max} = 0.542$ pC, $z = 0.89$ at P14. (B) Images of patch-clamped OHCs from P7 to P18. Scale bar (7.5 μ m) in P14 figure applies to all images

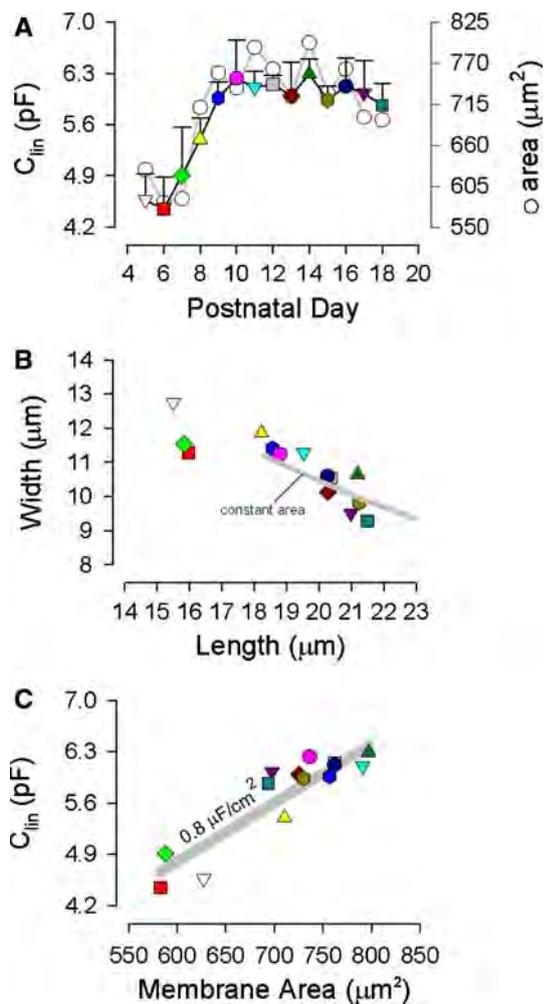

Fig. 2 Cell dimensions as a function of postnatal day. (A) Linear capacitance (with standard error bars) and surface area as a function of postnatal day. Note saturation of each measure at P10. (B) Inverse relationship between measured length and width of OHCs. *Solid gray line* denotes constant surface area constraint on width vs. length for the cylindrical model (see Materials and Methods). Surface area was constrained at 740 μm² (P10). (C) Relationship between linear capacitance and calculated surface area. *Solid gray line* denotes a specific membrane capacitance of 0.008 pF/μm²

18 μm in length, dimensional changes are constrained by constant surface area (solid gray line). That is, length and width of the cylindrical cell continue to change during development but do so while maintaining a fixed surface area. A specific membrane capacitance of 0.008 pF/μm² characterizes the plasma membrane of developing OHCs (Fig. 2C).

NLC, unlike linear capacitance, increases throughout the developmental time period studied. Figure 3A shows the sigmoidal rise of C_v (colored symbols), reaching a saturating level (7.66 pF) at P18. Correspondingly, the unitary charge density (open circles) increases to saturation (10,956 e⁻/μm²) but, being determined by the surface area (which remains fixed above P9), shows a relative boost,

over C_v , as maturation advances. The bimodal change in C_v vs. C_{lin} is highlighted in Figure 3B, where both C_v and C_{lin} increase linearly between P5 and P10 but, following that, only C_v increases. The changes in capacitance that occur early (P6–P10) are accompanied by a highly variable operating voltage range (V_{pkcm} , Fig. 4); however, when C_v is solely on the rise (>P10), V_{pkcm} shifts rightward to more stably occupy a voltage near -67 mV. The voltage sensitivity or valence, z , remained stable from P6 to P18 (0.875 ± 0.014).

Figure 5 shows the expression of prestin and GAPDH using a two-step RT-QPCR. Both the absolute and normalized levels of prestin RNA peaked near P10, consistent with our electrophysiological results. Absolute prestin RNA levels at P5, P8 and P15 were, respectively, 18%, 32% and 58% of that at P10. Similarly, prestin RNA levels at P5, P8 and P15, normalized to GAPDH RNA expression, were, respectively, 66%, 66% and 30% of that at P10. These quantitative data wholly support our electrophysiological conclusions that prestin expression matures at P10.

Discussion

Hearing in altricial mammals develops following birth. The mouse is first capable of detecting sounds as early as P12 (Ehret 1976; Steel and Bock 1980). However, this rudimentary ability does not benefit from the enhanced fine tuning and sensitivity afforded by cochlear amplification, the result of active, electromechanical feedback into the basilar membrane by mature OHCs. During the next several days, sensitivity and frequency tuning mature until at P18 the hearing organ is fully mature as measured by masked auditory brainstem response tuning curves (Song, McGee and Walsh 2006). Here, we provide the first detailed developmental study of mouse OHC motor protein expression in order to assess the OHCs' contribution toward the development of cochlear amplification (Zheng et al. 2000a; Liberman et al. 2002). Our data bear not only on this developing contribution toward mature audition but also on molecular mechanisms of motor maturation itself.

OHC Maturation

Certain characteristics of mouse OHC maturation correlate well with the development of hearing, though it should be kept in mind that the attainment of adult cochlear function undoubtedly profits from a concerted developmental contribution from a variety of cellular and acellular structures (Shnerson, Devigne and Pujol 1981; Shnerson and Pujol 1981; Souter and Forge 1998; Forge, Souter and Denman Johnson 1997; Souter, Nevill and Forge 1995). Nevertheless, considering the unusually important contribution of

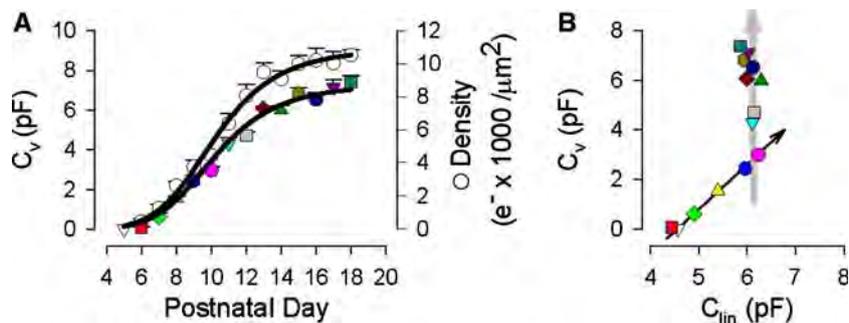

Fig. 3 (A) NLC (C_v , colored symbols) and unitary charge density (open circles) as a function of postnatal day. Each function saturates at P18. Charge density was computed using C_{lin} to calculate surface area with the specific membrane capacitance of $0.008 \text{ pF}/\mu\text{m}^2$. Logistic fits were made with C_v or density = $\max/[1+(\text{day}/\text{mid}) \times b]$.

Charge density fit (max, b, mid): 10,956, -5.65 , 10.22. C_v : 7.66, -5.33 , 10.66. The number of cells was (from P5 to P18) 2, 5, 5, 9, 5, 6, 10, 9, 5, 10, 6, 9, 5 and 5. Standard error is plotted. (B) Relationship between C_v and C_{lin} . Note the continued increase in C_v after C_{lin} (or surface area) saturates

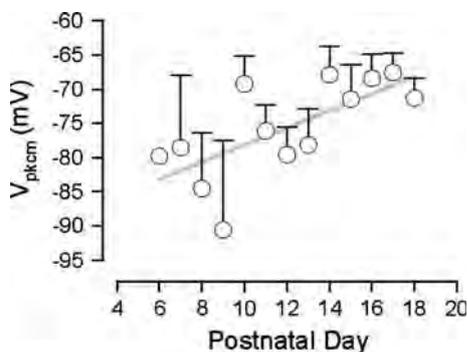

Fig. 4 Voltage at peak capacitance (V_{pkcm}) changes during development. Note variability during early stages and eventual shift toward depolarized voltages, stabilizing near -67 mV

OHCs to cochlear amplification, the development of OHC electromotility is considered one of the key features in this process. Our data show that motor activity (C_v or NLC) of the mouse OHC reaches adult levels at P18, having its onset at P7. Marcotti and Kros (1999) studied OHC motility and capacitance. However, they measured capacitance only at a fixed membrane voltage of -84 mV ; therefore, they could not detect linear and nonlinear capacitance. In addition, they did not study beyond P12. Similar results have been found in other altricial species, including the gerbil, guinea pig and rat (Pujol et al. 1991; He et al. 1994; Oliver and Fakler 1999; Belyantseva et al. 2000). In the rat, NLC matures at P17 (Belyantseva et al. 2000) and is detectable as early as P0 in apical turn OHCs (Oliver and Fakler 1999). Interestingly, for apical turn OHCs, Oliver and Fakler (1999) found a growth correspondence in linear capacitance and NLC for P10–14, which differs from our measures that show saturation of linear capacitance in the face of increasing NLC. Consequently, we find an increasing charge density out to adult performance times (P18, Fig. 3A), whereas they calculate a saturated charge density after P11. While species differences must be considered, methodological differences in measuring NLC may play a role. Our methodology provides unbiased estimates of C_m in the face of changing voltage-dependent impedance (Santos-Sacchi 2004); however, the stair-step protocol employed by Oliver and Fakler (1999) could have been influenced by the inability of the fixed (5 ms) voltage step protocol to adequately evaluate charge transfer across the range of OHC voltage-dependent time constants evoked by the wide-ranging voltage ramp. Their early developmental data for linear capacitance (P0–10) show a saturating increase from P0, which is stable from P4 to P11. Thus, we speculate that the abrupt increase in linear capacitance that they found after P11 obscures a continuing increase in charge density out to later days.

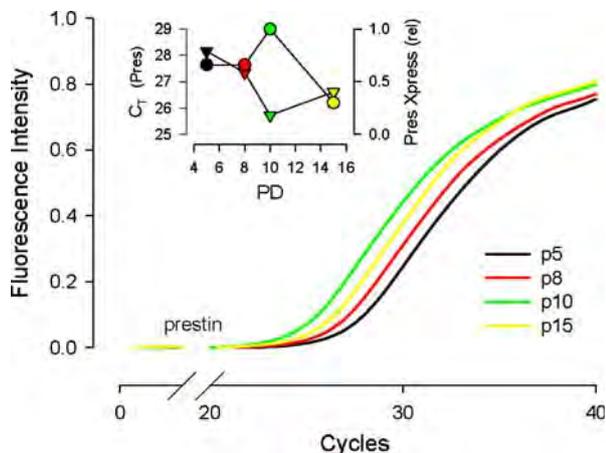

Fig. 5 Expression of prestin changes with development and peaks at P10. QPCR amplification of cDNA from cochlea RNA obtained on P5 (black), P8 (red), P10 (green) and P15 (yellow) are shown. Inset shows the C_t values of prestin and the relative amplification of prestin corrected for GAPDH expression at P5, P8, P10 and P15. The lower C_t value (triangles) at P10 confirms the highest expression at this time point. The relative expression (circles) of prestin is compared to expression at P10

Supporting this contention, Belyantseva et al. (2000) found nonlinear charge density to increase beyond P17 in the rat, and He et al. (1994) found an inverse relationship between length and width of developing gerbil OHCs, similar to what we found. We should also note that the developmental shift of V_{pkcm} that we observed, though similar in direction to that observed by Oliver and Fakler (1999), matured at a potential more negative than their value, i.e., near -67 mV, the resting potential found in adult guinea pig OHCs *in vivo* (Dallos, Santos-Sacchi and Flock 1982).

OHC Motor Maturation

Though we find that OHC motor activity saturates at P18, which is coincident with the attainment of mature hearing in the mouse, our data actually indicate that this saturation does not directly reflect the attainment of adult motor density in the lateral membrane. Instead, our data likely characterize the maturation of an already fixed pool of membrane motor proteins at P10 that we have measured with QPCR. Indeed, prestin expression in the rat has also been shown to plateau after P10 in the rat, confirming our results (Reisinger et al. 2005). These direct measures are additionally supported by the observation that motor protein membrane residence contributes to membrane surface area in the OHC. In fact, not only does prestin occupy space in the OHC membrane but the amount of surface area it occupies is voltage-dependent (Kalinec et al. 1992; Iwasa 1994; Santos-Sacchi 1993; Santos-Sacchi and Navarrete 2002). Thus, in prestin knockout mice, it was shown that the length of OHCs diminished relative to the length of normal OHCs in the control C57BL/6J mouse (Lieberman et al. 2002). From Lieberman et al.'s morphometric data on OHCs isolated from the apical region of the cochlea, the length reduction corresponds to about $134 \mu\text{m}^2$ surface area occupancy by prestin. Our data show that from P6 to P10 surface area increases by about $165 \mu\text{m}^2$, remaining fixed thereafter (Fig. 2A). This increase in surface area is coterminous with the increase in C_v that accompanies prestin expression; thus, we hypothesize that from P6 to P10 a full complement of motor proteins is expressed in mouse OHCs. Our hypothesis is strongly supported by our and others' (Reisinger et al. 2005) QPCR data, which show prestin expression to plateau at p10. Previous studies have concluded that the saturation of motor activity in the OHC represents the attainment of adult levels of motor protein density in the lateral membrane. For example, Belyantseva et al. (2000) found a correlated development of motor charge density and prestin antibody fluorescence in the lateral membrane. Souter et al. (1995) also found that the density of intramembranous particles (a presumed ultrastructural correlate of the motors) in the lateral membrane matures at P16 in the gerbil. How could the density of motors increase in the

lateral membrane given our observation that a fixed pool of motors resides within the OHC following P10? In tackling this question, it must be realized that all motor charge data arise from measures of the whole OHC membrane. Recently, it has been shown that during development of rat OHCs prestin is initially expressed throughout the basolateral membrane and subsequently redistributes only to the lateral membrane between days P7 and P12 (Weber et al. 2002). Thus, it is possible for the density of motors in the lateral membrane to increase over time by redistribution into the lateral membrane, where, in the adult, motor activity is restricted (Kalinec et al. 1992; Huang and Santos-Sacchi 1993a). However, it is not clear that a simple redistribution of motors within the membrane would have an effect on the magnitude of motor charge movement. So, in the face of a fixed pool of motors following P10, how might C_v increase? It is well established that prestin-derived NLC can be modulated by a variety of biophysical forces, perhaps these forces themselves being developmentally regulated.

Two of the most significant biophysical influences on the OHC motor are its sensitivity to membrane tension and chloride ions (Iwasa 1993; Gale and Ashmore 1994; Kakehata and Santos-Sacchi 1995; Oliver et al. 2001; Rybalchenko and Santos-Sacchi 2003; Song, Seeger and Santos-Sacchi 2005), each capable of shifting V_{pkcm} and modulating the magnitude of C_v . The simultaneous changes in V_{pkcm} and C_v that we find during maturation at P10–18 may thus result from developmental changes in membrane tension and/or intracellular chloride activity. It is well known that changes in intracellular chloride levels during development can alter the anion's equilibrium potential, bringing about significant changes in inhibitory neurotransmitter response characteristics (Rivera et al. 1999). In the OHC, development of the adult architecture of the lateral wall, including the cortical cytoskeleton and its interaction with the lateral membrane, could alter membrane tension. Additionally, the increasing density of motors could alter motor-motor interactions, leading to the maturation of motor-derived tension within the membrane. Such motor interactions have been modeled to account for prepulse effects on NLC V_{pkcm} within the OHC lateral membrane and prestin transfected cells (Santos-Sacchi et al. 1998, 2001). Finally, it may be that other factors can influence the maturation of motor activity, including second messenger/phosphorylation effects on the motor itself or on associated cytoskeletal elements (Huang and Santos-Sacchi 1993b; Frolenkov et al. 2000; Deak et al. 2005).

ABSTRACT

This composite article is intended to give the experts in the field of cochlear mechanics an opportunity to voice their personal opinion on the one mechanism they believe dominates cochlear amplification in mammals. A collection of these ideas are presented here for the auditory community and others interested in the cochlear amplifier. Each expert has given their own personal view on the topic and at the end of their commentary they have suggested several experiments that would be required for the decisive mechanism underlying the cochlear amplifier. These experiments are presently lacking but if successfully performed would have an enormous impact on our understanding of the cochlear amplifier.

Introduction

by Barbara Canlon

Mechano-electrical transduction in the mammalian cochlea occurs due to vibrations of the basilar membrane that cause the stereocilia of the outer hair cells to deflect resulting in the gating of mechanosensitive transducer channels. There is an active mechanical response that amplifies low-level and compresses high-level basilar membrane displacements. The amplification is frequency

dependent and results in high auditory sensitivity and an extended dynamic range.

The idea of an active process in the cochlea was first proposed by Gold, 1948, and has been the focus of intense research for more than many decades. In 1983 Hallowell Davis wrote, "We are in the midst of a major breakthrough in auditory physiology. Recent experiments force us, I believe, to accept a revolutionary new hypothesis concerning the action of the cochlea namely, that an active process increases the vibration of the basilar membrane (BM) by energy provided somehow in the organ of Corti". In his insightful paper he describes a cochlear model to include an active process and its underlying properties.

Numerous scientific reports have been aimed at characterizing the biophysical, biochemical and molecular properties of the active process. Two main mechanisms have been put forth to explain the mechanism underlying the cochlear amplifier. In brief, one is a voltage-dependent somatic motility resulting from the activity of the motor protein prestin in the lateral membrane of the outer hair cells. The other is dependent on hair-bundle motility driven by calcium currents. There is a continuum of articles being published

regarding the role of stereocilia versus somatic motility as the mechanism for the active process and these publications often spark up intense discussions among the auditory community.

There are two main mechanisms discussed in these commentaries (somatic and stereocilia based active processes) and several authors are suggesting that mechanical amplification is driven by both somatic and stereocilia contributions. However, all authors are in agreement that further experimentation is needed to be fully convinced of the mechanistic basis of outer hair cell motility. There are still many basic questions that remain to be answered before the basis of the cochlear amplifier or amplifiers is fully understood. As mentioned in the commentaries, some basic experiments that are needed include determining the characteristics of amplification along the basilar membrane (high versus low frequencies); dissecting the contribution of somatic motility from hair-bundle motility via genetic modifications and finally targeted biophysical experiments to alter ion channels and protein levels in hair cell membranes and in stereocilia. Hopefully the suggested experiments will soon be tested by inquisitive scientists to help generate a full characterization of the cochlear amplifier. There is most probably no definitive experiment but a combination of studies that will help solved the many years of debate and controversy around the cochlear amplifier.

Cochlear amplification – Somatic or stereociliar forces? A first-person response

by Jonathan Ashmore

It is always said that experimental artefacts are the most convincing of results. From the moment that Brownell and colleagues in Geneva reported that when an outer hair cell was depolarised it shortened (Brownell et al., 1985), there was always a nagging doubt that this was an epiphenomenon – a consequence of doing the experiments in a particular way. The Geneva finding used Ake Flock's earlier (re-)discovery at the Karolinska Institute of how to produce good-looking isolated OHCs. Ian Russell and I even took some home-built equipment to Stockholm in late 1982 to measure isolated cell resting potentials. We always found that the electrical V–I curves were difficult to record at hyperpolarised potentials. As a good electrophysiologist, straight from working in the retina, I did not think to look down the microscope while

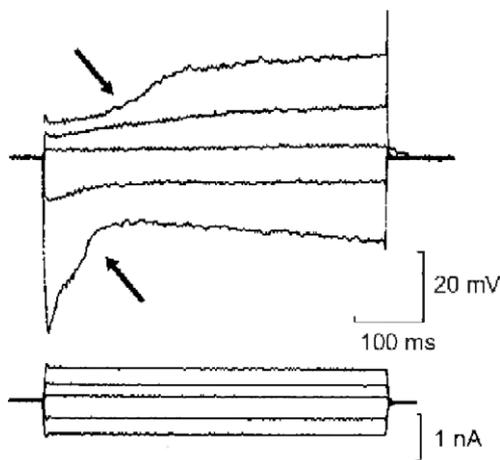

Fig. 1. Current-induced OHC movement. A microelectrode recording of potentials in an isolated guinea pig OHC during current injection, ca. 1983. Allowing for a low resting potential (ca. -30 mV), the voltage–current curves match data subsequently obtained by patch clamp recordings. The voltage distortions during current injection (arrowed) are almost certainly the result of the OHC changing length during the commands (Ashmore, unpublished).

recording data. Of course I know now, in retrospect, that the records were contaminated by the cell expanding off the microelectrode (Fig. 1). Reliable recordings of the cell biophysics required patch clamp techniques, but that came three years later. So why do I still think that OHC motility underlies the cochlear amplifier?

It is a robust mechanism: OHC motility has been recorded in so many laboratories with so many different techniques that it is hard to believe any more that it is an artefact. The cells produce forces and motility is a robust phenomenon. This seems to me to be a necessary condition for its involvement in amplifying sound in the cochlea, or more specifically for injecting power into basilar membrane mechanics. The cochlea itself needs to be built with components which withstand some, if not all, the vicissitudes of life. I also like the idea that the sensor and the effector should be distinct and separated components of the cell. I do not think such arguments are foolproof, but experiments which point to hair-bundle forces are technically difficult to carry out. Although not ruled out for this reason, bundle forces appear to be much less robust.

It is fast: We now know that OHC length changes can be driven experimentally at acoustic speeds to over 70 kHz, (Frank et al., 1999). Bill Brownell and I managed to convince ourselves that OHCs could be driven faster than 1 kHz one December day in 1985 by using a photosensor and a huge, hardwired signal averager called a Biomac (serial number 5, since you asked, and whose 60 discrete component circuit boards I came to know intimately). But to relate these results to *in vivo* cochleas, it is necessary to argue around the ‘RC-time constant problem’ where any potential changes are filtered out by the membrane at acoustic frequencies. The host of ingenious resolutions of this problem, (including bundle forces), all involve some sort of cochlear modelling. I think that some of the most physiologically convincing (and most intuitively accessible) models which resolve the problem invoke larger transducer currents in basal cochlear OHCs to offset the membrane filter. Recent work with Pavel Mistrik also leads me to think that current flow along the cochlea, through the gap junctions, enhances the extracellular potentials with the correct phase so that the potentials driving prestin are further increased at high frequencies. In brief, there are cochlear models which seem to work.

It can be knocked out: Sydney Brenner once declared that if you delete a gene and something happens you have a party; if you delete a gene and nothing happens, you still have a party as it means that your gene is so important there is compensation. With prestin knocked out, auditory thresholds rise (Liberman et al., 2002); so there is a phenotype and you can have a party. The data is compelling, although there is still room for doubt as prestin may have other regulatory roles in the cell, for example, by controlling cell pH and metabolism (Ikeda et al., 1992). Mutated or absent prestins could easily distort other, non-motor, aspects of OHC physiology. There may be an opportunity for bundle mechanisms to steal in here, but the window is a small one.

What experiments might change my mind?

No effect of ‘clean’ prestin motor alterations: I would like to see more experiments to decouple transduction from the action of the prestin motor. There are some of these experiments under way, for example in a knockin mouse where the prestin voltage dependence is altered by a minimal peptide mutation (Dallos et al., 2008). It would also be good to design ‘gain of function’ mutations in prestin making a situation where the motor forces are enhanced. But what I would like to see most would be acute, reversible, experiments where the basilar membrane mechanics is measured during instantaneous inhibition of prestin – a ‘caged salicylate’, suddenly released, might be an attractive way to do this. And then to be surprised when nothing happened.

Convincing hair-bundle movements in the kilohertz range: I would like to see bundle force measurements carried out on mammalian hair bundles at frequencies over 5 kHz. For technical reasons, many of the arguments advanced so far for stereocilia forces are extrapolations from the data. To be convinced I would like to see measurements of the magnitude and the phase of real bundle forces from real mammalian cells. Moreover these need to be made from cells taken from different cochlear positions, for models predict that bundle forces should depend upon cochlear position before they contribute to the cochlear amplifier.

Top connectors of the hair-bundle are required for waveform distortion and suppression masking but not cochlear amplification

by Paul Avan, Christine Petit*

Several major properties of sound perception rest upon the pre-processing of sound by the outer hair cells (OHC) in the mammalian inner ear, that is, one stage ahead of the mechano-electrical transduction eventually achieved by inner hair cells (IHC). Those OHCs are the key element of a feedback loop whereby sound stimuli are mechanically amplified in a widely popular view (Davis, 1983; Gold, 1948). It is the most common explanation brought forward for explaining why the auditory system of mammals is sensitive enough to detect sound power levels hardly an order of magnitude above the thermal noise. Moreover, the fine tonotopy observed in the cochlea and reflected in the remarkable ability to discriminate two sounds with slightly different pitches, is also attributed to the regenerative amplifier with feedback, working through OHCs and that operates in a frequency-selective manner.

Natural sounds pose an additional challenge: several frequency components are presented simultaneously instead of sequentially. Spectral complexity increases in the presence of competing sound sources or background acoustic noise. In such cases, if applied indiscriminately to all spectral lines, gain would be inadequate because, acting equally on signal and noise, it would leave the latter swamp neural messages. Because the gain produced by OHCs is accompanied by filtering, but also because the nonlinearities it entails generate suppressive masking interactions, acoustic messages can be cleaned up.

The place of cochlear nonlinearities in the analysis of frequency mixtures deserves to be specifically examined. The concept of non-linearity is very general, applying to any system whose response to two simultaneously presented signals is not the arithmetic sum of its responses to either signal when presented alone: instead, when mixed up, some components increase at the expense of others. Masking is a typically nonlinear psychophysical event defined by the fact that the loudness of one sound decreases or even vanishes when another sound interferes. Its cochlear correlate is suppressive masking whereby the mechanical or electrical response to a test tone decreases in the presence of a masking tone. This phenomenon, felt as a nuisance when it is the signal of interest that gets masked, globally turns as an advantage in that it allows the dominant frequency component at one place in the cochlea to become even more dominant by exerting a masking effect on competing, weaker signals. Therefore, suppressive masking can enhance contrasts.

There is now no doubt that cochlear mechanics is far from linear and it can express its nonlinearities in several ways. Besides suppressive masking, another example is that contrary to high-fidelity devices, OHC operation introduces conspicuous waveform distortions. These distortions are large enough to be heard although not being present in the initial sound stimulus (e.g., Tartini, 1754; Goldstein, 1967). In response to bitonal stimuli at frequencies f_1 and f_2 , distortion of their waveforms generates combination

tones at arithmetic combinations of f_1 and f_2 – hence the best known cubic difference tone at $2f_1 - f_2$, assuming $f_2 > f_1$. Not only does the cochlea produce audible sound distortion but it also re-emits them as one category of otoacoustic emissions, namely distortion-product otoacoustic emissions (DPOAE) (Kim et al., 1980). Otoacoustic emissions have become a prominent tool for achieving neonatal hearing screening: when by being absent they signal OHC dysfunction and, according to the most popular interpretation, failure of the cochlear amplifier, inner hair cells also happen to be impaired in many cases, owing to the structural and functional kinship of the two types of sensory cells. Sensorineural deafness is then a likely diagnosis.

In summary, the currently accepted picture is that gain and filtering are two closely associated properties ensured by OHCs and that their way of operating induces strong waveform distortions coming out as non-invasively detectable DPOAEs. Last, the very mechanism that leads to instantaneous distortion of sound waveforms is likely strong enough to contribute to suppressive masking. This holistic view placing OHCs and their nonlinear behavior at the heart of the concept of cochlear amplifier and of many perceptive phenomena does not allow for the fact that the nonlinearities produced by OHCs do not share the same meaning and may thus have different structural or functional origins – e.g., the mechanotransduction channel for some of them, other molecules or substructures in the stereocilia bundle or cell body for others. Some types of nonlinearities in current use in electroacoustic amplifiers do not produce instantaneous waveform distortion, as is the case for compressive devices in hearing aids. Conversely, other types of nonlinearities do not need gain to generate waveform clipping.

Until now holistic models posited that at the core of OHC ability to produce gain, and the combination of filtering, and waveform distortion, and masking that comes with gain, is a common source, i.e., the intrinsic properties of the mechanotransduction channels.

A common explanation might be inherent to the mandatory nonlinearity associated with the thermodynamics of the mechanotransduction channel. This channel exists in at least two states, open and closed. Its opening probability relates to stereocilia deflection according to Boltzmann's law accounting for the different energies associated with the opened and closed states. Boltzmann's law is a sigmoid instead of a straight line, thus when stereocilia bundles are deflected by the sinusoidal pressure wave of a pure tone coming from outside, the current through mechanotransduction channels, proportional to the opening probability, exhibits a distorted waveform. The resulting mechanical feedback exerted through bi-directional transduction thus injects distortion into the initially sinusoidal sound wave. It was thought that waveform distortion, Tartini tones and DPOAEs were produced in this manner by OHCs. Simple mathematics then shows that waveform distortion generates suppressive masking (Engebretson and Eldredge, 1968).

This view of mechanotransduction channel properties as a central player in all aspects of sound pre-processing by OHCs suggested that OHCs ensured, in a remarkably parsimonious manner, a whole set of functions sharing a common origin. As a counterpart, failure of this intrinsic property of channels should also result in hearing impairment in relation to loss of cochlear amplification, and in the concomitant loss of all other beneficial aspects of cochlear pre-processing of sound.

A recent study of a mutant strain of mice in which the gene coding for stereocilin is inactivated has shown that the aforementioned holistic view seems not valid (Verpy et al., 2008). When these mutant mice are young enough (around 14–15 postnatal days, P14–15), their cochlear sensitivity is normal, as illustrated by the fact that across the whole frequency spectrum auditory brainstem evoked (ABR) and compound action potential (CAP) thresholds do not statistically differ in mutant mice and wild-type

littermates. Cochlear filtering is also normal in mutant mice, as indicated by the normal Q10s of their CAP masking tuning curves. Mechano-electrical transduction currents derived from round-window measurements of cochlear microphonics are normal as well. These characteristics indicate the presence of a full supply of normally functioning mechanotransduction channels. Their thermodynamics thus obeys a normal Boltzmann law and the curve relating the transduction current to stereocilia deflection must be the same sigmoid as in normal ears. Yet in the absence of stereocilin, mice no longer distort waveforms, and for example their cochlear microphonics in response to loud tones remain sinusoidal up to 100 dB SPL. The electrical cochlear response to pure tones does not contain harmonics. Likewise, DPOAEs are totally absent. Furthermore, with even more significant perceptive consequences, when these mutant mice are exposed to a mixture of sounds, suppressive masking is absent or strongly diminished. The level of a masking tone must be about 20 dB louder than in a normal ear for the CAP response to a probe tone to decrease. CAP masking tuning curves can still be plotted; however, because the line-busy neural mechanism of masking, alone, persists: this is what allowed Q10s to be found similar in mutants and controls. Therefore, in the presence of a mixture of sounds, the mutant cochlea is no longer able to significantly act on the contrasts among components.

Stereocilin enters in the composition of hair-bundle fibrous links, the top connectors, bonding the apexes of stereocilia inside the bundle. In mutant mice, top connectors are absent and the tips of stereocilia in OHCs are more remote than in non-mutant mice.

So, suppressive masking and waveform distortion come with each other and can vanish even though OHC mechanotransduction channels provide normal amplification and filtering. This unusual experimental situation leads to conclude that the top connectors, and possibly the stereocilin-mediated contact of the stereocilia bundle to the tectorial membrane contribute to a major cause of distortion, larger than that in relation to the Boltzmann statistics of mechanotransduction channels. Stereocilin-dependent connectors could distort either as a result of an intrinsic property or indirectly by a constraint they might exert on the displacement of the stereocilia bundle or on the response to sound of some of its components.

We thus propose that in mutant mice as well as in normal ones, the operating curve of OHC mechanotransduction channels relating displacement to current exhibits a normal sigmoid shape because its becoming straighter would affect cochlear gain by negatively affecting channel sensitivity, which was not the case. Likely, this nonlinearity, on its own, is not large enough to generate measurable distortion. In normal mice, it is the presence of top connectors that enables waveform distortions, DPOAEs and suppressive masking to show up in standard measurements. In mutant mice, the same measurements detect none of these properties even though the cochlear amplifier works, thanks to a normally nonlinear mechanotransduction in OHCs.

Stereocilin mutants show that dissociation between normal auditory thresholds and missing DPOAEs is possible, if not commonplace. Previous work on acute cochlear ischemia has shown, conversely, that DPOAEs can persist and keep many of their normal properties although cochlear gain has vanished (Avan et al., 2003). Put together, these observations should warn clinicians against too systematic attempts at interpreting DPOAEs in terms of cochlear amplification and hearing sensitivity.

Membrane-based amplification in hearing

by William E. Brownell*

Acoustic vibrations enter and neuronal action potentials leave the inner ear. An interplay of mechanical and electrical energy re-

sults in hair-cell receptor potentials that ultimately trigger neurotransmitter release at the afferent synapse. The diffusion of neurotransmitter across the synaptic cleft depolarizes 8th nerve terminals and initiates action potentials that travel to the central nervous system. The action potentials encode information about the spectral and temporal content of environmental sounds. The ability to localize predator or prey is improved by analyzing sounds over a wide range of frequencies resulting in an evolutionary selection pressure for detecting ever higher frequencies. Nature has incorporated diverse strategies to overcome physical constraints for high-frequency hearing. The constraints include: (1) viscous damping by inner ear fluids; (2) electrical filtering by cell membranes; and (3) temporal limitations imposed by chemical cascades at the synapse. The mechanisms that overcome viscous damping have been called the “cochlear amplifier” in mammalian ears and an “active process” in vestibular and other hair cell systems. These must work in concert with mechanisms for increasing membrane bandwidth and assuring the temporal precision of afferent fiber action potentials if high-frequency hearing is to be achieved.

It is likely that the cochlear amplifier originated in the stereocilia bundle of early vertebrates. Several mechanisms for bundle motility have been proposed but it is the one responsible for fast voltage-dependent bundle movement or flicks (Cheung and Corey, 2006) that suggests an evolutionary origin for the voltage-dependent somatic motility of the outer hair cell. In order for high-frequency voltage-dependent electromechanical transduction to take place in either the bundle or the soma there must be a mechanism that increases the electrical bandwidth of the membrane. Membrane flexoelectricity and converse flexoelectricity are suited for high-frequency bundle and somatic motility as well as increasing membrane bandwidth. A flexoelectric based “synaptic amplifier” may also help to assure the temporal precision of afferent fiber action potentials.

When outer hair cell electromotility was first observed (Brownell et al., 1985) it was a strong candidate for the mammalian cochlear amplifier. The OHC is unique to the mammalian cochlea and is perhaps the most exotically specialized hair cell (see Fig. 2). Morphological and molecular features of its lateral wall endow it with the ability to generate mechanical force at high frequencies (Frank et al., 1999). The force generating mechanism is located in the lateral wall plasma membrane where the transmembrane electric field is converted directly into mechanical force. Biological membranes are soft, thin ensembles of lipids, proteins, and other molecules. The proportions of the components vary but lipids dominate reaching 10^2 lipid molecules for every protein in some membranes. Membrane constituents diffuse freely within the plane of the membrane unless they are anchored to the cytoskeleton. Membranes are very thin (typically ~ 5 nm) yet cover large surface areas ($>10^3 \mu\text{m}^2$ in the case of the plasma membrane). Living cells expend metabolic energy to sustain electrochemical gradients (~ 100 mV) across their membranes and the associated transmembrane electric field is large (>10 MV/m – compare to the ~ 3 MV/m fields associated with atmospheric lightning). Living cells also expend energy to maintain a characteristic asymmetry in the number of lipid associated fixed charges on the inner and outer surfaces of their membranes. Integral membrane proteins can contribute to the electrical charge difference at the two surfaces. The net charge asymmetry of the membrane gives rise to an intrinsic electrical polarization that sets the stage for a piezoelectric-like force generation (Brownell, 2006). The electrical field is converted directly into mechanical stress and charge displacement is converted into mechanical strain. Experimental evidence demonstrates that electromechanical coupling occurs naturally in lipid bilayers where it is called the flexoelectric effect (Petrov, 2006; Sachs et al., 2009). This phenomenon is an analogue of the electromechanical

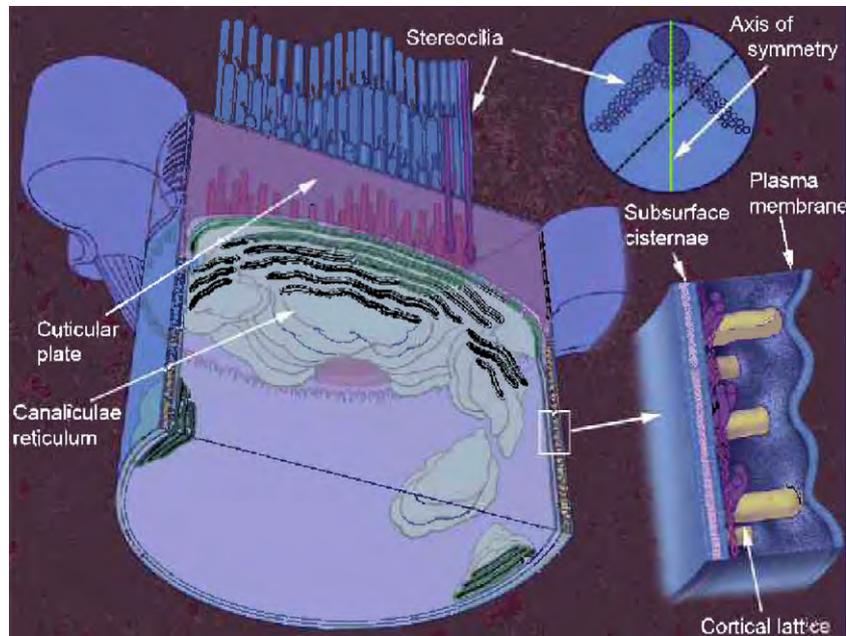

Fig. 2. Membrane organization of the outer hair cell stereocilia bundle and lateral wall. Both the apical pole and the lateral wall are composed of three layers. The plasma membrane is the outermost layer in both locations. The innermost layer is composed of a membrane bound organelle called the canalicular reticulum in the apex and the subsurface cisterna in the lateral wall. In between outer and inner membrane layers is a cytoskeletal structure called the cuticular plate at the apex and the cortical lattice in the lateral wall. Insert on the right portrays a high power rendering of the outer hair cell lateral wall. Insert at upper right is a view of the apical end showing the plane at which the outer hair cell has been opened. Adapted from Fig. 1 in Brownell, 2002.

behavior of piezoelectric crystals. Two kinds of flexoelectricity are typically discussed: (1) the direct flexoelectric effect describes changes in the electrical polarization of the membrane resulting from changes in curvature; and (2) the converse flexoelectric effect is the reciprocal phenomena in which the membrane curvature changes in response to applied electric fields. Both somatic (Raphael et al., 2000) and stereocilia bundle (Breneman et al., 2009) motility have been modeled to arise from converse flexoelectricity.

While membranes can produce high-frequency mechanical force (Anvari et al., 2007; Frank et al., 1999; Ludwig et al., 2001; Zhang et al., 2007) in response to experimentally applied electric fields the functional significance of this ability has been questioned because commonly studied cell membranes are considered to be low-pass electrical filters and therefore unable to sustain transmembrane receptor potentials at high frequencies. A solution for the low-pass constraint is provided by coupling electrical and mechanical energy. The ready conversion of one form of energy to the other endows the membrane with a biological piezoelectricity that pushes the cell membrane cutoff frequency to higher frequencies (Rabbitt et al., 2009; Spector et al., 2003; Weitzel et al., 2003).

Prestin is an integral membrane protein belonging to the Slc26A family of anion transporters that enhances the piezoelectric properties of transfected test cells (Ludwig et al., 2001; Zhang et al., 2007; Zheng et al., 2000). Prestin-associated charge movement is at least three orders of magnitude larger and qualitatively different than the nonlinear charge movement of untransfected cells (Farrell et al., 2006). Electromotile force production, in contrast, is increased by well under an order of magnitude (Anvari et al., 2007; Ludwig et al., 2001). The large prestin-associated non-ohmic, reactive displacement currents are thought to arise from the movement of cytoplasmic anions such as chloride and bicarbonate into and out the membrane. A model of the electrodiffusion of anions into a model protein is able to quantitatively reproduce several features of this charge movement (Sun et al., 2009). Prestin may help overcome the low-pass problem by facilitating a phaseshifted

charge movement that compensates for membrane capacitance in a manner similar to the negative-capacitance circuits found in voltage-clamp amplifier headstages.

Both outer hair cell electromotility and neurotransmission at the inner hair cell synapse are rapid, membrane-based, mechanical events that are controlled by the hair cell receptor potential. Since neurotransmitter release can be synchronized to high frequencies (approaching 10 kHz) in some species, broad-band electrical properties are also required to allow synaptic stimulation. The magnitude of inner hair cell receptor potentials varies with stimulus intensity yet the timing of neural discharge is intensity invariant for both clicks and best frequency tones (if neurotransmitter release were only a function of current it would occur at different times as the intensity changed). Temporal invariance in the presence of receptor potentials of increasing magnitude argues for a feedback mechanism resembling that of the cochlear amplifier on basilar-membrane vibrations. OHC mechanical feedback preserves the temporal fine structure of basilar-membrane vibrations throughout a wide range of intensities (Shera, 2001). Temporal shifts of basilar-membrane vibration zero-crossings and local peaks and troughs would occur in the absence of mechanical feedback and these shifts are not observed experimentally (Recio and Rhode, 2000). Membrane flexoelectric mechanisms could provide an electromechanical feedback to exocytosis at the afferent synapse and help to insure intensity independent temporal precision (Brownell et al., 2003). The cochlear amplifier, broad-band electrical properties and the synaptic amplifier could all benefit from membrane electromechanics.

There are several experiments whose results could validate or disprove the flexoelectric concepts presented in this section. High-frequency axial displacements of the stereocilia bundle similar to those observed in membrane tethers (Zhang et al., 2007) is required to determine if converse flexoelectricity is contributing to the bundle motor. Experimental confirmation of the inverse relation between the radius of curvature of the membrane and electromechanical force production by the membrane is also

required. Such an experiment would require ultramicroscopic measures of the curvature. High resolution structural information for prestin is required to unravel its precise role in the outer hair cell somatic motor. The existence of acoustically evoked, non-ohmic, displacement currents in cochlear fluids is predicted by the prestin-associated charge movement measured in isolated cells. Experimental confirmation of cochlear displacement currents could explain the discrepancy between maximal hair cell receptor currents in isolated hair cells and those predicted from earlier cochlear current density measures (Zidanic and Brownell, 1990).

Feedback in the cochlea

by Peter Dallos

Science thrives on controversy and scientists love a good clean fight. Students of how mammalian “cochlear amplification” comes about have been in the ring for more than 30 years; more than 60 if we consider Gold’s (1948) initial suggestions. The development of two schools of thought, championing outer hair cell (OHC) somatic motility and OHC ciliary motility as the means of amplification, is amply documented and need no review here (Dallos, 2008; Hudspeth, 2008). The common thread, that OHCs are the amplifier elements, arose early on the basis of experiments with chemical ablation of OHCs using ototoxic agents and the examination of resulting behavioral threshold shifts and alterations of neural tuning curves (Ryan and Dallos, 1975; Dallos and Harris, 1978; Liberman and Dodds, 1987). Inner hair cell (IHC) stereocilia have no firm contact with the tectorial membrane (Lim, 1980), consequently these cells are unlikely to participate in mechanical amplification.

Here I briefly list a few items that have been adduced as supportive or contrary to either amplifier schemes, which I consider to be less than deal breakers.

Probably the most often cited problem with somatic motility being the amplifier is its voltage dependence (Santos-Sacchi and Dilger, 1988). Inasmuch as the passive OHCs’ lateral membranes are electrical low-pass filters with low cutoff frequencies (<1 kHz; Housley and Ashmore, 1992; Preyer et al., 1996) the receptor potential, which presumably drives electromotility, is attenuated at high frequencies. This seemingly fatal problem for electromotility-based amplification has been attacked by a whole host of schemes. These are in four major categories. One approach is to see if gross cochlear potentials might be sufficient to provide the voltage gradients for OHCs at high frequencies (Dallos and Evans, 1995; Fridberger et al., 2004; Iwasa and Sul, 2008), or if the cochlear electroanatomy is sufficiently influential (Mistik et al., 2009). The second is based on the realization that the OHC is a reciprocal electromechanical system (Weiss, 1982). As a consequence, its effective time constant is not what is simply measured by electrical means in an isolated cell, but one modified by the reflection of the mechanical elements upon the electrical side of the network during contractile activity (Mountain and Hubbard, 1994; Spector et al., 2003; Ramamoorthy et al., 2007). The third possibility is that the collective action of a group of OHCs in a negative feedback circuit provides amplification at high frequencies even if individual OHCs are limited in their frequency response range (Lu et al., 2006 b). Finally, local activation of motor molecules by basolateral ionic current has been proposed as a means of avoiding the low-pass filter conundrum (Rybalchenko and Santos-Sacchi, 2003; Spector et al., 2005). While full experimental verification of any of these schemes is yet forthcoming, they, individually or collectively in some combinations, are sufficiently compelling as to render the principal objection to the somatic motility mechanism much less troublesome. The speed of stereociliary motility has been addressed as well. While the forward mechanotransducer channel activation is extremely fast (Corey

and Hudspeth, 1983), fast adaptation of the channel, which is associated with the fast feedback process, is slower (Ricci et al., 2005). The development of force associated with OHC transducer channel activity has been measured (Kennedy et al., 2005). Negative stiffness (departure from linear stiffness) develops over time, but, while not proven, it is possible that *in vivo* the time course is adequately fast.

The second widely cited objection to the dominant role of somatic motility is that this process itself is not tuned. The context of this issue is the often-stated question: what tells an OHC to provide amplification for a given stimulus? The usual formulation is to postulate a need for a second system of graded filters, different from the traveling wave, which would provide the input to appropriately located amplifying OHCs. Tectorial membrane resonance is one of the favored means of such filtering (Allen, 1980; Zwislocki and Kletschy, 1979; Gummer et al., 1996). Another possibility is to enlist the inherent band-pass nature of the ciliary amplifier as a pre-filter to somatic motility (Ricci, 2003; Hudspeth, 2008). Tuning of ciliary motile processes (Martin and Hudspeth, 1999) may be a significant advantage, by itself, to this means of amplification.

One question raised about ciliary amplification pertains to the adequacy of the force that this source can deliver into the cochlear mechanical load. It is now reasonably certain that the collective action of circumscribed groups of OHCs can produce enough force to displace the cochlear partition, including the basilar membrane (Hudspeth, 2008; Dierkes et al., 2008). While the force produced by somatic motility is significantly greater, this should not preclude ciliary motility as a mechanism for amplification.

Are there definitive experiments that rule out the contribution of either candidate mechanism in the mammal? The short answer is no. There *are* experiments that suggest some combined operation of the two systems (Kennedy et al., 2006). The work of Chan and Hudspeth, 2005 intimates that ciliary motility is sufficient to provide cycle-by-cycle amplification, with slow somatic motility serving as an adjustor of the former system’s operating point. A difficult problem in all experiments that attempt to parcel the process into its two possible components is eliminating one while sustaining the other. *In vitro*, the complete suppression of either process is difficult and may not have been achieved. *In vivo*, inasmuch as the cochlea operates as a feedback system any alteration of the feedback loop will affect the response of all components. Thus the difficulty of interpreting the results derived from mouse models in which the OHC motor molecule (prestin) was absent has been appreciated. In the absence of prestin from OHCs in the prestin knockout mouse, the cells become shorter and more compliant (Liberman et al., 2002; Cheatham et al., 2004; Dallos et al., 2008). Consequently, raised thresholds and lack of tuning in these mice could result from non-existing somatic motility, altered ciliary motility due to changed mechanical load, or a combination. While the model does not yield unequivocal results, the electrophysiological phenotype is essentially the same as one obtains in the absence of OHCs. In order to overcome incidental changes attendant to the lack of prestin, a mouse model was developed that incorporated the V499G/Y501H mutation in its prestin molecules (Dallos et al., 2008). OHCs in 499/501 mice have normal lengths and stiffnesses, but the prestin-produced somatic motility is more than 90% reduced. These animals have hearing loss and lack of tuning, not unlike the knockout mice. It was concluded that the presence of functional prestin is essential for the full expression of cochlear feedback. The result could be explained two ways. Somatic motility is the entire feedback amplifier and its elimination negates all gain. Alternatively, ciliary motility produces the feedback, but it is under tight control by somatic motility. At this time, further experimental refinement of the choice is lacking. The ubiquity of ciliary feedback-based amplification among vertebrates and indeed in some insects speaks for the primacy of this mechanism (Manley, 2001:

Hudspeth, 2008). Its suggested control by somatic motility in the mammal is more problematic. The commonly postulated low-frequency adjustment of the ciliary amplifier by somatic motility (e.g., Chan and Hudspeth, 2005) is not likely to occur due to the fact that, at low-levels, where amplification is most pronounced, the high-pass filter nature of mechanotransducer-channel fast-adaptation should virtually eliminate DC mechanical inputs to OHCs. Simply stated, the putative controlling DC signal in cochlear mechanics is significantly reduced. Of course, one should also ask what evolutionary pressure could have produced the voltage-activated prestin motor that has the demonstrated and unique capability of operating at ultrasonic frequencies (Frank et al., 1999), if its function would be effective only at DC?

Bottom lines: Prestin-based somatic motility and ciliary motility may both contribute to the total cochlear feedback. Examination of the cochlear output of genetically modified mice suggests that without functional prestin essentially all amplification is eliminated. The many suggested schemes to counteract OHC membrane filtering of receptor potentials suggest the possibility that the filter is not a necessary impediment to somatic motility providing the feedback at any frequency. It is unlikely that OHCs can provide DC control of a ciliary amplifier.

Coupled hair-bundles could endow the cochlear amplifier with sharp frequency tuning and nonlinear compression

by Kai Dierkes, Benjamin Lindner, Frank Jülicher*

The key signatures of the auditory amplifier are (i) a frequency tuned and sensitive response to weak stimuli, (ii) a compressive nonlinear response over a large amplitude range, and (iii) spontaneous otoacoustic emissions (Dallos, 1992; Hudspeth, 2008). These signatures are reflected in observed basilar-membrane vibrations (Robles and Ruggero, 2001) and can be understood as the consequence of the presence of nonlinear dynamic oscillators operating in a critical regime (Camalet et al., 2000; Eguiluz et al., 2000; Duke and Jülicher, 2003). This suggests that the working of the cochlear amplifier is based on nonlinear oscillators. It is commonly thought that that active amplification is mediated by mechano-sensory hair cells (Dallos, 1992; Hudspeth, 1997; Manley et al., 2001; Fettiplace and Hackney, 2006). Two important features of hair cells have been suggested to contribute: (i) outer hair cell electromotility can provide mechanical feedback to the basilar-membrane vibrations (Brownell et al., 1985; Santos-Sacchi, 2003; Ashmore, 2008; Dallos et al., 2008) and (ii) mechanosensitive hair-bundles have been shown to be active elements which can generate spontaneous movements and noisy oscillations (Crawford and Fettiplace, 1985; Martin and Hudspeth, 1999; Martin et al., 2001; Kennedy et al., 2005). Individual hair bundles can act as nonlinear oscillators capable to amplify stimuli (Martin and Hudspeth, 1999; Martin and Hudspeth, 2001) albeit with restricted performance which is limited by intrinsic noise at the cellular scale (Nadrowski et al., 2004). This limitation as well as the small forces associated with movements of individual hair-bundles have put doubts on the role of active hair-bundle motility for the cochlear amplifier.

In many vertebrate inner ear organs hair-bundles are linked to overlying elastic membrane structures, such as otolithic and tectorial membranes (see Fig. 3a) and (Freeman et al., 2003). This introduces the possibility that the cooperation of hair-bundles plays a role to enhance the properties of hair-bundle-mediated amplification (Manley and Köppl, 2008). Recently, we have shown that small groups of hair bundles which are coupled by elastic elements can respond much more sensitively to periodic stimuli than isolated hair-bundles. Furthermore, such groups of hair-bundles display spontaneous movements with sharply peaked power spectra and behave as sharply tuned amplifiers that exhibit compressive nonlinearities over a wide range of signal amplitudes (Dierkes et al., 2008).

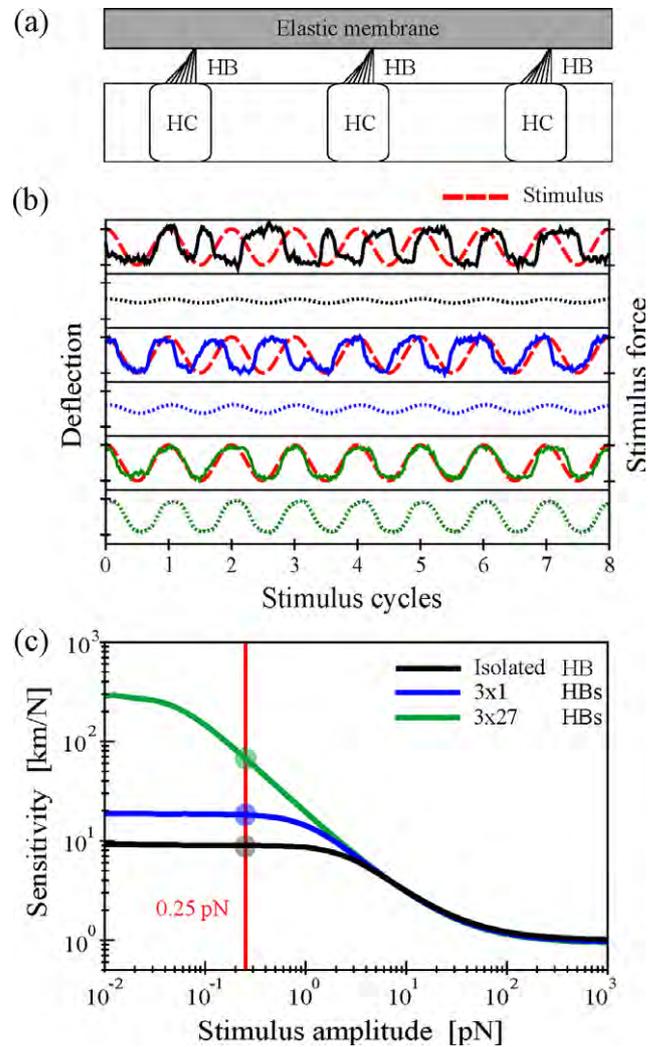

Fig. 3. (a) Schematic of three hair cells (HC) with their hair-bundles (HB) coupled elastically via an overlying membrane. (b) Illustration of phase-locking for an isolated hair-bundle (black) and the central hair-bundle of groups of coupled hair-bundles (3×1 HBs, blue; 3×27 HBs, green). Sample trajectories of simulation results (solid lines) are shown together with the periodic stimulus force $F(t) = A \cos(2\pi f_0 t)$ with $A = 0.25$ pN (broken red line) for coupling stiffness matched to stereociliar pivotal stiffness, $K = K_{sp} = 0.6$ pN/nm. Each system is driven at its characteristic frequency f_0 ($f_0 = 8.91$ Hz (1×1), 9.90 Hz (3×1), 10.54 Hz (3×27)). The respective time-dependent average responses over many repetitions of the stimulus are shown as dotted lines below. Distance between ticks is 40 nm for deflection and 0.5 pN for stimulus force. (c) Nonlinear response of coupled hair-bundles. For the three systems studied in (b) the sensitivity (average response amplitude divided by stimulus amplitude) is displayed as a function of stimulus amplitude. The red vertical line indicates the stimulus force used in (b). Note that the sensitivity to weak stimuli and the amplitude range of nonlinear compression increase with increasing system size.

sive nonlinearities over a wide range of signal amplitudes (Dierkes et al., 2008).

In our study we employed a model of the single hair-bundle that can account quantitatively for its active mechanical properties and the stochastic features of hair-bundle motility (Nadrowski et al., 2004; Tinevez et al., 2007). The model incorporates stereociliar pivotal stiffness, channel gating elasticity, the properties of adaptation motors, as well as calcium feedback on these motors. Fluctuations reflecting thermal interactions of the hair-bundle with the surrounding fluid, stochastic transitions of transducer channels and adaptation motors are also taken into account. Limitations of the single hair bundle's ability to respond faithfully to an external stimulus (see Fig. 3b, broken red lines) are consequences

of these fluctuations (see Fig. 3b, black solid line). Fluctuations thereby limit the detector's sensitivity to weak stimuli and also the sharpness of frequency tuning, as well as the amplitude range over which nonlinear amplification occurs.

Our results were obtained by considering groups of $N \times M$ hair-bundles that are arranged on a square lattice with their excitatory directions aligned along the same lattice axis. Coupling is described by linear springs of stiffness K that connect nearest neighbors including diagonal connections. Homogeneous systems of identical hair-bundles as well as heterogeneous systems of hair-bundles with varying characteristic frequency were considered. In the homogeneous case the quality of spontaneous oscillations exhibits a threshold-like dependence on coupling strength K . A sudden increase of quality occurs for $K \approx K_{SP}$, with K_{SP} denoting the stereociliar pivotal stiffness. When a group of hair-bundles is driven by a weak periodic stimulus at the characteristic frequency (see Fig. 3b, broken red lines), the system shows an enhanced phase-locking to the external signal (see Fig. 3b, cf. blue and green solid lines to black solid line). This higher degree of phase-locking leads to an increase of the time-dependent average of the response amplitude (see Fig. 3b, dotted lines). Thus coupling of hair-bundles increases the sensitivity (defined as the ratio of the mean response amplitude to the stimulus amplitude) in response to a weak stimulus (see Fig. 3c). For increasing stimulus amplitude, the sensitivity decreases, indicative of the compressive nonlinear response of the system. The range of stimulus amplitudes over which this nonlinear response is observed increases for increasing system size (see Fig. 3c). The response to strong stimuli is determined by the passive stiffness of the single hair-bundles and does not depend on system size. As a consequence the amplification gain, which is the ratio of sensitivities to weak and strong stimuli, increases almost linearly with system size. For a system of 81 hair bundles a gain of up to 400 is obtained for optimal coupling strength.

In the mammalian cochlea, nonlinear compression of the basilar-membrane vibration amplitude in response to stimuli at the local characteristic frequency have been reported, that range up to four orders of magnitude of sound pressure amplitude (Robles and Ruggero, 2001). The corresponding amplification gains are of the order of 1000 (Robles and Ruggero, 2001). These properties can be understood as resulting from the combination of a global excitation of the basilar membrane (the traveling wave) and the effects of nonlinear active elements which govern the basilar-membrane vibration in the vicinity of the characteristic place (Nobili and Mammano, 1996; Duke and Jülicher, 2003). While the properties of the active elements in the cochlea exceed by far the abilities of an isolated hair-bundle, our work suggests that groups of coupled hair-bundles can approach their performance.

In the mammalian cochlea the basilar membrane exhibits a graded profile of characteristic frequencies and the sensory hair cells display a morphological gradient (Dallos et al., 1996). This raises the question whether enhanced signal detection due to coupling can also work in heterogeneous systems. We thus performed simulations of systems of 3 times 27 hair-bundles (representing three rows of outer hair cells) with varying intrinsic frequencies, resulting from a gradient of pivotal stiffness. For intermediate coupling strength $K \approx \bar{K}_{SP}$, where \bar{K}_{SP} is the average pivotal stiffness of the hair-bundles, the amplification gain is still enhanced by coupling, while a frequency gradient is also maintained (Dierkes et al., 2008). This implies that in order to make use of mechanical coupling in the cochlea the elasticity of the overlying membrane has to be locally adjusted to the hair-bundle pivotal stiffness. It has been shown that hair-bundle stiffness as well as tectorial membrane stiffness vary gradually along the cochlea in such a way that coupling strength and the stereociliar stiffness could indeed be matched (Strelioff and Flock, 1984; Gueta et al., 2006; Richter et al., 2007).

What does the above imply about the cochlear amplifier? There is strong evidence that outer hair cell electromotility plays an important role in cochlear amplification (Dallos et al., 2008). Electromotility introduces an electromechanical feedback that couples hair-bundle movements back to basilar-membrane vibrations (Ashmore, 2008; Nowotny and Gummer, 2006). However, electromotility does not exhibit significant nonlinearities for physiological voltage variations and it does not show frequency tuning (Ashmore, 2008). In contrast, small groups of hair bundles do show all the necessary features: sharp frequency tuning, high sensitivity and compressive nonlinearity (Dierkes et al., 2008). However, there are two limitations. Firstly, the high amplification gain observed in the cochlea is not easily reached in our model if at the same time a frequency gradient is maintained. Secondly, hair-bundle movements may be inefficient to significantly drive basilar-membrane vibrations. These issues could be resolved by regarding the cochlear amplifier as a combination of outer hair cell electromotility and active motility of locally coupled hair-bundles. In this scenario, the frequency selectivity and the compressive nonlinear properties of the cochlear amplifier are provided by coupled hair-bundles. Outer hair cell electromotility is a largely linear element that may allow hair-bundle movements to efficiently drive basilar-membrane vibrations. By varying properties of the electromotile feedback the sensitivity and amplification gain of the amplifier could be adjusted. Careful regulation of nonlinear amplification is important to guarantee the stable operation of nonlinear oscillators in the inner ear (Camalet et al., 2000) and thereby to enhance the detection of complex sounds in varying environments. The electromotile feedback is well suited to mediate such a regulation. This may explain why outer hair cells receive signals from the brain via efferent fibers which could influence electromotility.

The origin of the cochlear amplifier

by Robert Fettiplace*, Carole M. Hackney

The mammalian cochlea is a unique cellular array the properties of which vary systematically along the organ. These range from the stiffness and size of gross features such as the basilar and tectorial membrane and the dimensions of the outer hair cells (OHCs) (Lim, 1986) to the amplitude of the mechanotransducer channels (Beurg et al., 2006). All features must ultimately conspire to establish the tonotopic map. Passive mechanical tuning is augmented by the cochlear amplifier which endows sharp frequency selectivity and accounts for the 20–60 dB of extra tip to the tuning curves measured for vibrations of the mammalian basilar membrane (Robles and Ruggero, 2001). The amplifier incorporates a compressive nonlinearity such that the gain and sharpness of tuning are diminished at higher sound levels. The underlying process is thought to involve electromechanical feedback by the OHCs probably through a filter whose frequency characteristics change along the tonotopic axis (Fig. 4). Work over the past 20 years has demonstrated voltage-dependent contractility of the OHCs underpinned by aggregation of the motile protein, prestin, in the lateral membrane (Zheng et al., 2000). However, somatic deformation of the OHC is only one step in a feedback pathway that also includes motion of the tectorial membrane and hair-bundles, mechano-electrical transduction and generation of a receptor potential to drive the prestin motor. It is assumed that OHC contractions supply force to boost the vibrations of the basilar membrane. A primary argument for the somatic motor is that molecular modifications or knock out of prestin largely abolish amplification (Lieberman et al., 2002; Dallos et al., 2008). A criticism of this approach is that interfering with prestin merely alters a feedback loop, any part of which could be the site of amplification. For example, knock out of the mechanotransducer channel protein (although not currently feasible) would presum-

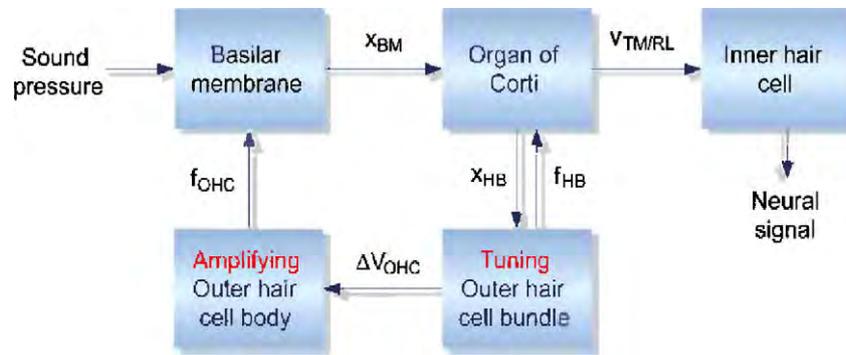

Fig. 4. Process involved in the cochlear amplifier. Sound causes displacements of the basilar membrane, x_{BM} , and organ of Corti leading to deflection of the OHC hair-bundle, x_{HB} . Activation and adaptation of the mechanotransducer channels generate a tuned transducer current culminating in a change in OHC membrane potential, ΔV_{OHC} , that drives the somatic motor. The force, f_{OHC} , produced by OHC electromotility augments basilar membrane motion and may also deform the organ of Corti (Mammano and Ashmore, 1993). Gating of the mechanotransducer channels may generate sufficient force, f_{HB} , to move the hair-bundles (the hair-bundle motor) and the organ of Corti. The inner hair cell bundles are stimulated by the relative velocity, $v_{TM/RL}$.

ably also eliminate amplification. An alternative view is that amplification is linked to active hair-bundle motion, powered by calcium influx promoting fast adaptation of the mechanotransducer channels (Ricci et al., 2000). To appreciate the contributions of the different processes, it is necessary to understand the micromechanics of the organ of Corti and how forces generated by the OHC somatic and hair bundle motors vibrate the basilar membrane and are transmitted to inner hair cells that also exhibit similar sharp tuning.

The prevailing view, that the somatic motor is at the heart of cochlear amplification, is strongly endorsed by recent work mutating prestin or proteins of the tectorial membrane (Dallos et al., 2008; Mellado Lagarde et al., 2008). However, there are several details not fully explained. How is the somatic motor controlled on a cycle-by-cycle basis at high frequencies where the periodic component of the receptor potential will be filtered by the OHC time constant? Several solutions have been proposed (summarized in Ashmore, 2008) but none has been fully confirmed experimentally. How does the somatic motor supply frequency selective feedback? In many attempts to simulate the sharp basilar membrane tuning, an additional filter or phase shift is introduced to match simulations with experimental results but somatic motility itself is not inherently frequency selective. The extra filter invoked in modeling is often assigned to a resonant tectorial membrane (Nobili and Mammano, 1996). Although the properties of the tectorial membrane, both stiffness and mass, change substantially along the cochlea (Richter et al., 2007), the evidence for membrane resonance is controversial. Finally, how do OHC properties change to generate the necessary forces at high frequencies to counter the increase in viscous load and basilar membrane stiffness? Again in simulations, the force achieved by OHC contraction is assumed to increase (sometimes >100-fold; Lu et al., 2006a) in progressing from the low- to high-frequency end of the cochlea. However, there is no evidence for such an increase in force generation (Iwasa and Adachi, 1997) and if the prestin concentration in the OHC lateral membrane shows little variation with cochlear location (Mahendrasingam et al., 2008), force production remains constant despite different cellular dimensions. Most of the direct evidence for performance of the somatic motor has accrued from measurements on isolated OHCs which invariably lack forward transduction. The operation of the motor may be clarified by studying OHC mechanics in an intact organ of Corti preparation.

The case for a role of the hair-bundle motor is based on its properties in non-mammals. In those animals it can amplify the extrinsically induced hair-bundle vibrations in a frequency-selective manner (Martin et al., 2000; Ricci et al., 2000). The frequency selec-

tivity stems at least partly from tonotopic variation in the fast adaptation time constant for mechanotransduction. Why should it be less important in mammals? Perhaps the bandwidth of the process is insufficient to cope with the extension of the frequency range in mammals. A similar problem exists with electrical tuning of the receptor potential based on gating of potassium channels which is the major source of auditory frequency selectivity in non-mammals (Fettiplace and Fuchs, 1999). Although there is no direct evidence, it seems likely that hair-bundle amplification is employed in the high-frequency region of the avian cochlea, up to 9 kHz in owls (Köppl and Yates, 1999), in which short hair cells (analogous to OHCs) lack prestin or somatic contractility (He et al., 2003). Because the hair-bundle motor is driven by gating of the mechanotransducer channels, it does not suffer the frequency dependent attenuation imposed by the membrane time constant. The mechanotransducer channels must open and close on a microsecond time scale to explain transduction in animals such as bats and cetaceans that hear up to 120 kHz. However, the hair-bundle motor is thought to be coupled to fast channel adaptation (Ricci et al., 2000) which may itself be frequency limited due to the kinetics of calcium binding and unbinding (Nam and Fettiplace, 2008). Speed restrictions to the process remain an open question because attempts to measure active hair-bundle motion in mammalian preparations are currently limited by the bandwidth of force delivery using flexible fiber stimulation (Beurg et al., 2008). Nevertheless, amplification mediated by calcium influx via mechanotransducer channels has been observed in an isolated mammalian cochlea (Chan and Hudspeth, 2005). To fully characterize the hair-bundle motor in OHCs, the speed of the measurement techniques must be improved to ascertain whether the primary mechanical event is a recoil (negative feedback; Ricci et al., 2000) or a release (positive feedback; Martin et al., 2003; Kennedy et al., 2005) synchronous with fast adaptation. A drawback of the hair-bundle motor is the small force it can generate, a few hundred pN at most, more than 10-fold less than the prestin motor. Nevertheless, the feedback can be frequency tuned unlike that for the somatic motor. Furthermore, the force developed will increase with location due to a decrease in height and increase in number of stereocilia per bundle (Lim, 1986). Such frequency selectivity may be enhanced by tight coupling of the hair-bundles to the tectorial membrane (Nam and Fettiplace, 2008).

The most reasonable conclusion is that both somatic and hair-bundle motors collaborate to produce cochlear amplification and that the hair bundle motor has not been discarded but rather supplemented in extending the frequency range. Mechano-electrical transduction in the hair-bundle may largely confer frequency

selectivity and the compressive nonlinearity, whereas the somatic motor may be the major force generator (Fig. 4). However, the relative importance of the two mechanisms may change between base and apex which differ in the shapes of their basilar membrane tuning curves and degree of low-level amplification and nonlinearity (Robles and Ruggero, 2001). To apportion the contributions of the two motors, the most promising experimental approach is to assay hair cell responses and cochlear mechanics in an *in vivo* preparation (Nuttall et al., 2009). However, these techniques may still have insufficient resolution to define the motion at specific points within the organ of Corti. In the long run, an understanding of the micromechanics will be needed to determine the efficacies of the two motors in vibrating the basilar membrane at both low- and high-frequency locations.

A critical need in hearing

by Pascal Martin*, A.J. Hudspeth

One may investigate the basis of the active process in either of two ways. Most studies have focused on the subcellular and molecular details of the candidate mechanisms, membrane-based electromotility and active hair-bundle motility. Despite the present uncertainties in the field, such detailed mechanistic investigations must ultimately reveal the origins of the four cardinal aspects of the active process: amplification, frequency tuning, compressive nonlinearity, and spontaneous otoacoustic emission (Manley, 2000).

A second approach is to inquire, not about mechanistic details, but instead about the principles underlying the active process. What feature of the active process accounts for the unusual phenomena associated with hearing? What is the connection between the four manifestations of the active process observed in amphibians, reptiles including birds, and mammals? We contend that the answers to these questions are the same: critical oscillation at a Hopf bifurcation.

A physical system displays a Hopf bifurcation when its behavior changes abruptly from quiescence to spontaneous oscillation as the value of a control parameter varies (Strogatz, 1997). If the control parameter is poised at or near the critical value at which spontaneous oscillation emerges, the system is termed a critical oscillator. Any critical oscillator is endowed with generic properties that do not depend on the specific mechanism that produces the oscillatory instability (Choe et al., 1998; Camalet et al., 2000; Eguiluz et al., 2000; Jülicher et al., 2001; Duke and Jülicher, 2008).

Precisely what phenomena can be explained by a critical oscillator?

- (i) A critical oscillator can mobilize internal resources of energy to compensate for frictional losses and provide power gain, the defining feature of the cochlear amplifier.
- (ii) The amplification of a critical oscillator is tuned to a narrow band of frequencies centered at the characteristic frequency of spontaneous oscillation. In addition, the bandwidth of this active resonance is inversely related to the intensity of the stimulus; weak stimuli are amplified with sharper frequency selectivity.
- (iii) As observed in basilar-membrane recordings (Ruggero et al., 1997), the response of a critical oscillator to sinusoidal stimuli near resonance displays a compressive nonlinearity such that the amplification preferentially boosts weak signals. In contrast, the response is linear for stimulus frequencies that differ significantly from the characteristic frequency of critical oscillation.
- (iv) As it traverses the Hopf bifurcation, a critical oscillator becomes unstable and enters into limit-cycle oscillation, a likely cause of spontaneous otoacoustic emission.

- (v) Like the human ear (Goldstein, 1967), a critical oscillator displays “essential” nonlinearity in the sense that distortion products persist even for weak acoustic stimuli, decreasing more-or-less linearly with the amplitude of stimulation until they reach the threshold of detectability.
- (vi) The responsiveness of a critical oscillator to a sinusoidal stimulus is diminished by the presence of a second stimulus at a nearby frequency, a phenomenon akin to psychoacoustical masking, or two-tone suppression, in the human ear.

A ubiquitous feature of vertebrate hair cells, active hair-bundle motility has been observed *in vitro* in the eel (Rüsch and Thurm, 1990), frog (Benser et al., 1996; Martin et al., 2003; Tinevez et al., 2007), turtle (Crawford and Fettiplace, 1985; Ricci et al., 2002), chicken (Hudspeth et al., 2000), and rat (Kennedy et al., 2005). In the frog’s sacculus, active hair-bundle motility exhibits each of the six characteristics listed above (Martin and Hudspeth, 2001; Martin et al., 2001; Barral and Martin, unpublished observations). If intrinsic hair-bundle fluctuations are taken into account, a simple critical-oscillator model quantitatively emulates the observed behaviors (Nadrowski et al., 2004). Although intrinsic noise seriously limits amplification at the single-cell level, most hair-bundles are mechanically coupled by overlying membranous structures. By effectively reducing noise, cooperation among a few tens of neighboring hair-bundles apparently allows active hair-bundle motility to achieve a dynamic range of responsiveness compatible with that of hearing (Dierkes et al., 2008). The functional unit of the active process may thus comprise a small cluster of coupled hair cells with similar characteristics, which together achieve critical oscillation at a particular frequency.

Precisely because critical oscillation is generic, any dynamical system operating near a Hopf bifurcation must display the same properties. The mammalian lineage, which diverged from those of the other amniotes some 320 million years ago, has had ample opportunity to find novel ways of achieving critical oscillation. The phenomenon of membrane-based somatic electromotility, which is unique to mammalian outer hair cells, has been implicated in the production of active basilar-membrane movements (Dallos et al., 2008; Mellado Lagarde et al., 2008). Electromotility cannot operate alone, however, for this process is nearly linear over a physiological range of membrane potentials and lacks frequency selectivity (Ashmore, 2008). The nonlinearity and frequency selectivity of the cochlear amplifier are usually thought to emerge from respectively the saturating nonlinearity of mechano-electrical transduction by the hair-bundle and passive mechanical resonance within the cochlear partition (Nobili and Mammano, 1996). Modeling studies suggest that electromotility can provide negative friction to turn each segment of the cochlear partition, described as a spring-mass system, into a highly tuned resonator (Nobili et al., 1998). If negative damping overcomes passive sources of friction, the system is expected to become unstable and oscillate spontaneously. We suspect that successful cochlear models have been adjusted to operate in a stable regime near an unrecognized Hopf bifurcation. If the simulated behaviors are generic, the success of a given model does not necessarily validate the underlying assumptions; this difficulty may explain why no particular model of cochlear amplification has yet been accepted as definitive.

Models that rely only on passive resonance to set the characteristic frequency of each segment of the cochlear partition confront an important problem. The measured range of stiffness along the cochlear partition does not suffice to account for the thousandfold frequency range of mammalian hearing (Naidu and Mountain, 1998). It is more likely that the frequency is set, at least in part, by the local active process (Duke and Jülicher, 2003). Active hair-bundle motility, which occurs in the mammalian cochlea (Chan and Hudspeth, 2005; Kennedy et al., 2005), may provide both the

necessary nonlinearity and the frequency selectivity of the active process.

The critical-oscillator hypothesis also bears on the propagation of signals within the cochlea. The cochlear partition may be viewed as a set of oscillator modules with characteristic frequencies tonotopically distributed along the longitudinal axis of the cochlea. Although the traveling wave that results from hydrodynamic coupling of these modules is doubtlessly important in distributing sound energy to appropriately tuned hair cells, critical oscillators can account for the sharp peaking of the wave at the characteristic place. When critical oscillation is invoked, relatively simple models of cochlear hydrodynamics suffice to capture the known qualitative features of the traveling wave (Duke and Jülicher, 2003; Kern and Stoop, 2003; Magnasco, 2003).

The actual behavior of the mammalian cochlea differs in four ways from the abstract representation of a single critical oscillator (Fig. 5). First, the presence of intrinsic noise limits the amplification of faint stimuli; the gain saturates at a constant value below some threshold level, whereas the gain of a critical oscillator formally diverges at resonance for vanishingly small stimuli. Next, the restricted dynamic range of some process, perhaps active hair-bundle motility, implies that amplification wanes at very high stimulus levels. Third, by curtailing responsiveness to stimuli above the characteristic frequency, the traveling-wave mechanism introduces a sharp asymmetry in real tuning curves. Finally, longitudinal shifts of the tuning curve at increasing stimulus levels, as well as nonlinear modifications of the pressure stimulus traveling from the cochlear base to the characteristic place, can distort the power-law behaviors that are typical of the compressive nonlinearity generated by a single critical oscillator. We expect generic behaviors to emerge most clearly by following the peak of basilar-membrane response and relating the magnitude of this response to the local pressure.

The wealth of experimental observations on mammalian hearing implies that few experimentally accessible tests of the critical-oscillation hypothesis remain to be performed. Put another way, the strength of the hypothesis lies less in its predictive ability than in its capacity to accommodate a broad range of existing observations in a unified model. There are nevertheless striking predictions from the hypothesis that could lead to its falsification. Because the various manifestations of the active process are posited to emerge together from critical oscillation, they should be coupled obligatorily. If a control parameter can be adjusted systematically, for example by pharmacological manipulations (Martin et al., 2003) or genetic engineering (Holt et al., 2002), the strengths of the several effects should rise or fall together. More-

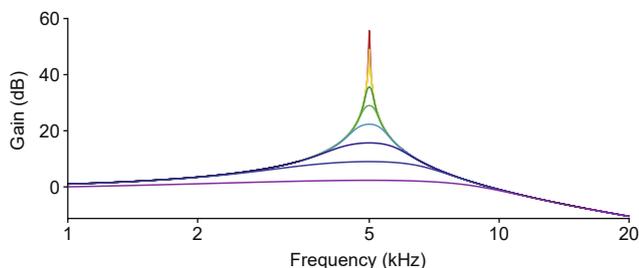

Fig. 5. The characteristic features of a critical oscillator emerge in a doubly logarithmic plot of the relation between stimulus frequency and gain for a series of sinusoidal stimuli. Gain is defined as the ratio of the oscillator's sensitivity to a given stimulus to that evoked by intense stimulation at the same frequency. A weak stimulus evokes a sharply tuned response with high gain. As the stimulus level rises in 10-dB increments, the gain at the characteristic frequency of 5 kHz declines as the two-thirds power of the stimulus amplitude and the bandwidth of amplification increases. Although the system displays compressive nonlinearity near resonance, its behavior remains linear for stimulus frequencies that differ significantly from the characteristic frequency of the critical oscillator.

over, if conditions can be found in which some features of the active process are definitely suppressed while others clearly persist, the critical-oscillator hypothesis must be modified or abandoned.

Predicting the role of OHC somatic motility and HB motility in cochlear amplification using a mathematical model

by Julien Meaud*, Karl Grosh

Introduction

Outer hair cells (OHC) have been shown experimentally to exhibit somatic electromotility at frequencies covering the entire mammalian frequency range (Frank et al., 1999). To predict the high sensitivity of the mammalian cochlea to low-level acoustic stimulus, previous mathematical models have included OHC somatic motility as in Mammano and Nobili, 1993 and Ramamoorthy et al., 2007. These models can predict the high gain as well as the sharp tuning of the frequency response of the basilar membrane (BM) to low-level acoustic input. When these models were developed there was no experimental evidence of active hair-bundle (HB) motion in the mammalian cochlea. However, activity (as evidenced by distortion products and spontaneous otoacoustic emissions) and amplification without any OHC somatic motility in the hearing organ of non-mammalian vertebrates have been demonstrated. Experimental and theoretical studies have shown that the non-mammalian HB can produce a force due to the action of a calcium dependent process. This active force production is linked to the fast adaptation of the transduction current (Ricci et al., 2000) and can amplify an external stimulus (Martin and Hudspeth, 1999). Moreover, recent experiments show that the mammalian HB also exhibits fast adaptation of the transduction current (Kennedy et al., 2003) and can produce a force in a submillisecond time scale (Kennedy et al., 2005). This new evidence provides an alternative to the prevailing theory that somatic motility is the basis of the cochlear amplifier. In our mathematical model, we selectively include OHC somatic motility, HB motility and a combination of both, with the goal of understanding the role of these two active sources in the mammalian cochlea.

Model

Our mathematical model is based on a box model of the guinea pig cochlea with a 3 D representation of the fluid, as described in Ramamoorthy et al., 2007. Viscous dissipation in the subreticular space is included. The BM interacts with the fluid via linearized Euler relation and with the organ of Corti which is coupled to the tectorial membrane (TM). Each cross-section of the TM is modeled as a rigid body with two degrees of freedom corresponding to the motions in a transverse and radial direction (see Fig. 3 in Ramamoorthy et al., 2007). Electrical conduction in the scalae of the cochlea is represented by longitudinal cables which allow current to pass down the length of the cochlea as well as into the transduction channels of the OHC (see Fig. 2 in Ramamoorthy et al., 2007). The system is linearized about the stationary point to predict the response of the system to low-level acoustic stimulation. We consider time harmonic vibrations ($e^{-i\omega t}$ time dependence). Somatic electromotility is modeled by linearized piezoelectric relations between the OHC deformation, $u_{\text{OHC}}^{\text{comp}}$, the fluctuating part of the transmembrane voltage, $\Delta\phi_{\text{OHC}}$, the OHC force (per unit length of the BM), F_{OHC} , and the current (per unit length of the BM), I_{OHC} , which

$$F_{\text{OHC}} = K_{\text{OHC}} u_{\text{OHC}}^{\text{comp}} + \epsilon_3 \Delta\phi_{\text{OHC}} \quad (1)$$

$$I_{\text{OHC}} = \frac{\Delta\phi_{\text{OHC}}}{Z_m} - i\omega\epsilon_3 u_{\text{OHC}}^{\text{comp}} \quad (2)$$

where K_{OHC} is the stiffness (per unit length of the BM) of the OHC, ϵ_3 is the electromechanical coupling coefficient of the OHC and Z_m is the impedance of the basolateral portion of the OHC.

In a nonlinear physiological model of HB transduction and motility, the dynamics of the HB are fairly complicated. In the linearization of such a model the properties are expected to be frequency dependent (as discussed in Ricci et al., 2000). Here, however, we use frequency independent properties and assume the transduction channel conductivity to be directly proportional to the stereocilia deflection, u_{HB} . Further the HB force is taken to be proportional to the HB deflection u_{HB} and velocity $-i\omega u_{\text{HB}}$. In this simple model, if the HB is to add energy to the system in a cycle-by-cycle manner, the real part of the HB impedance must be negative (i.e., some form of negative damping). Hence the HB force in the shear or radial direction is:

$$F_{\text{HB}} = k_{\text{HB}}u_{\text{HB}} - i\omega c_{\text{HB}}^{\text{act}}u_{\text{HB}} \quad (3)$$

where k_{HB} is the HB stiffness and $c_{\text{HB}}^{\text{act}}$ is the (negative) active damping coefficient. The constant is chosen to provide forces and energies that are in the physiologically relevant ranges, limited by experimental evidence given in Kennedy et al., 2005 and Choe et al., 1998, respectively. The energy is assumed to arise from a calcium binding event that is not included in other models (Mammano and Nobili, 1993; Ramamoorthy et al., 2007).

Results

The response of the BM to acoustic stimulation is plotted as a function of frequency in Fig. 6. The green dashed line represents the response of the BM in the passive system, i.e., neither somatic nor HB motility are included. It compares very well to the experimental measurements of de Boer and Nuttall, 2000 at 100 dB SPL (shown in blue dashed line).

When we add somatic motility to the model (thick blue dashed line), we see an increase in the gain and in the sharpness of the tuning and a shift of about half an octave in the peak frequency

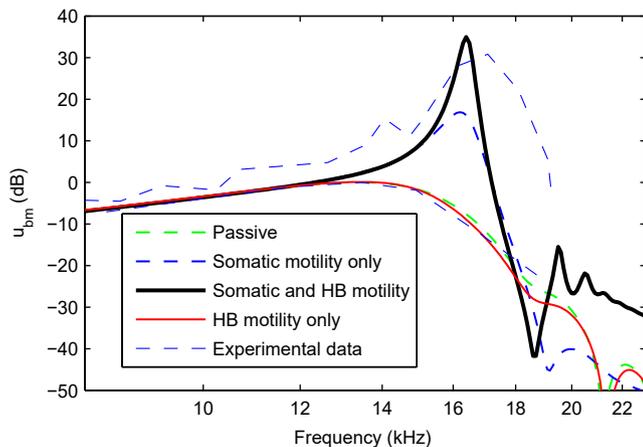

Fig. 6. Response of the BM to acoustic stimulation at the 17 kHz best place. The responses are normalized to the maximum passive BM response. The model predictions are compared to measurements from de Boer and Nuttall, 2000 at 20 and 100 dB SPL (thin blue dashed lines). The parameters used in the simulations are, for OHC somatic motility, $\epsilon_3 = -8.4 \times 10^6$ N/m/mv and for HB motility $c_{\text{act}}^{\text{HB}} = -3.15 \times 10^{-8}$ N/m/s. The passive model prediction (thick green dashed line) follows closely the measurements at 100 dB SPL. When somatic motility is included (thick blue dashed line), the peak gain is about 20 dB higher than in the passive case and the tuning of the response is sharper as in the experimental data at 20 dB SPL. When somatic motility and HB motility are included (thick solid black line), the gain is about 10 dB higher than in the previous case. For the case when only HB motility is included (red solid line), the response is almost the same as the passive model response.

as seen in the experimental data at 10 dB SPL. In the results presented here, the electromechanical coupling coefficient was chosen such that the model that includes both somatic and HB motility is stable. With this value of ϵ_3 , the predicted magnitude of the BM gain of the model only including somatic motility is lower than the experimental value. However, if we use a slightly higher value for ϵ_3 (about 16% higher), the prediction for the magnitude of the BM gain when only somatic motility is included can match the experimental value as shown in Ramamoorthy et al., 2007. Despite the basolateral RC filtering of the transmembrane voltage, somatic electromotility can amplify the BM motion thanks to an electromechanical resonance in the organ of Corti and the high sensitivity of the transduction channels.

If we add HB motility to somatic motility (thick black solid line), there is another 10 dB increase in the gain. For a 0.5 nm displacement (which corresponds approximately to a 20 dB acoustic input), the magnitude of the OHC somatic force is about 60 pN (on the order of magnitude predicted by Iwasa and Adachi, 1997) and the power added to the system by HB motility is about 60zJ, which is lower than the maximum value postulated by Choe et al. (about 2000zJ, Choe et al., 1998). For this case (somatic motility and HB motility) as well as the previous one (somatic motility only), the tuning of the response is not due to an intrinsic tuning of somatic or HB motility, but to an electromechanical resonance in the organ of Corti.

However, when only HB motility is included (red solid line) using the same active damping coefficient, $c_{\text{act}}^{\text{HB}}$, as in the previous calculations, the response is similar to the passive model response, with a low gain and broad tuning. When the active damping coefficient is increased, the model becomes unstable before the maximum gain of the BM reaches the experimental value for low-level sounds.

Conclusions

In these preliminary results with a simple HB model, OHC somatic motility is necessary for cochlear amplification whereas HB motility is not. This is consistent with measurements on prestin-knockin mice (Dallos et al., 2008) which also show that prestin-based somatic motility is necessary for normal cochlear function. With the parameters used here and the current experimental data, HB motility does not appear to be necessary to predict the BM gain to acoustic stimulus. However, as our results suggest, HB motility could still play a significant role and work in synergy with somatic motility to provide a higher BM gain and sharper tuning than with OHC motility alone. A more realistic HB model needs to be developed in order to make more conclusive remarks about the relative roles of OHC somatic and HB motility.

New experiments needed to change or elaborate our claims

- *In vitro* measurements of the mechanical response of mammalian HB to a stimulus more rapid than the time course of adaptation: The mechanical response of mammalian HB have only been measured with a stimulus having a time constant similar to or greater than the adaptation time constant. Measurements of HB with a faster time scale and/or with a small harmonic stimulation in the 5–20 kHz frequency range would help to find realistic parameters for a linearized HB model in the mammalian auditory frequency range, which are needed for a more precise prediction of the role of HB motility.
- *In vivo* measurements of the BM response to acoustic input in a cochlea perfused with salicylate: Current evidence that prestin somatic motility is necessary for normal cochlear function is based on prestin-knockin mice. The transduction channel of

these mutant mice appear to be normal. However the genetic mutation could affect other properties of the mouse cochlea during the development of the animal. Moreover data is only available for mice since genetic mutation have only performed on mice. Measurements of the BM response in a cochlea perfused with salicylate could be another way to block somatic motility while not affecting HB motility. It could potentially validate or invalidate the claim that prestin is necessary for cochlear amplification.

- Measurements of the BM frequency response to acoustic stimulation with endolymph with reduced calcium concentration: Using a perfusing scheme similar to Zheng et al., 2007, a controlled alteration of the endolymphatic calcium concentration can be reversibly applied. Reduction of the calcium concentration should slow down adaptation, increase the transduction current and reduce the magnitude of the active HB force. Because of the increase in the transduction current, it should also increase the magnitude of the OHC somatic force. Since OHC somatic motility is the main source of cochlear amplification according to our present model, we expect a net increase of the gain of the BM (provided the phase of the increased current is not deleteriously altered).
- *In vivo* measurements simultaneous measurements of the motion of the BM, the TM and the different structures of the organ of Corti in response to acoustic stimulation: Our mathematical model of the cochlea predicts the relative amplitude of the motion of the TM and the BM that are difficult to verify due to the lack of experimental data. In our results the gain of the BM and TM are similar. If HB motility had a greater effect than what we predict, we should expect the TM to have a much higher gain than the BM since the HBs are attached directly to the TM and can apply a force in the TM shear direction.

The mammalian cochlear amplifier done

by J. Santos-Sacchi

Introduction

I think we all agree that mammalian cochlear amplification must arise from the activity of OHCs, and that such activity must be physically coupled to the cochlear partition. The upshot of this is that (1) the evolution of OHCs to perform this special job arguably might have included a design to improve on extant mechanisms, namely, to recruit a new cellular component or modify an existing one, and (2) whether a somatic or stereociliar mechanism, it must link to the partition. Indeed, stereocilia embed in the tectorial membrane and the OHC soma join apically to the reticular lamina and basally to the basilar membrane via Deiters' cells. These required connections potentially allow OHC mechanical activity to provide a boost of stimulus to the inner hair cell stereocilia. Methods to uncouple these links or immobilize the underlying mechanics will tell which rules in the mammal.

Stereocilia drive the mammalian cochlear amplifier ... not

There are clear examples showing that prestin generated mechanical responses underlie mammalian amplification. Included are (1) our results (Santos-Sacchi et al., 2006) that BM sensitivity and tuning is modulated by anion control of prestin, and (2) definitive knockout results from the Dallos lab (Dallos et al., 2008). Another key observation is that when the coupling between stereocilia and the tectorial membrane is abolished, the BM behavior characteristic of normal amplification evoked by electrical stimulation is unaffected (Mellado Lagarde et al., 2008). Furthermore, it is not clear to me that evidence for bundle contributions (Chan and

Hudspeth, 2005; Kennedy et al., 2005; Kennedy et al., 2006) cannot be explained by underlying prestin-based mechanisms (Jia and He, 2005). I note that the use of salicylate as a tool to remove prestin effects is not absolute, as we have previously shown that residual mechanical responses remain in OHCs after such treatments (Kakehata and Santos-Sacchi, 1996). Given that the preponderance of evidence indicates that a prestin-based mechanism is responsible for mammalian amplification, we hope to put this issue to rest and focus on how this amazing protein prestin works at the cellular and molecular level.

Anions work as prestin's voltage sensor ... not

The initial suggestion that anions influence the electrical signature of prestin, nonlinear capacitance (NLC), because they subserve voltage sensation by a dysfunctional prestin transporter (Oliver et al., 2001) is not supported by many pieces of data. These include (1) conformational state of the motor is altered by anions at fixed voltage, (2) effects on the motor depend not simply on the presence of anions, but also on anion species and structure, (3) there is not the expected relationship between anion valence and motor unitary charge, (4) prestin is an anion transporter, (5) intrinsic amino acid residue charge contributes to voltage sensing, and (6) mutations of prestin can divorce NLC and anion transport capabilities (Bai et al., 2009; Rybalchenko and Santos-Sacchi, 2003; Rybalchenko and Santos-Sacchi, 2008; Song et al., 2005). We view the effects of anions working in an allosteric fashion, just as allosteric actions of voltage and Ca^{2+} ions control the behavior of the Ca-K channel, for example (Horrigan et al., 1999). For the OHC, this allosteric mechanism may rival the well known allosteric effects of Ca^{2+} on the stereociliar MET conductance (Fettiplace and Ricci, 2003).

How I envision the ear's works working

Enhanced tuning exists within cochleae that possess prestin-endowed OHCs; however, how such sharpening occurs requires more than amplification of a passive travelling wave. We suggested that interactions among coupled OHCs could provide such sharpening and give rise to nonlinearities characteristic of the amplifier (Zhao and Santos-Sacchi, 1999). Interestingly, a recent model of coupled hair-bundle activity suggests that improvements in tuning and amplification can result from interacting adjacent hair cell bundles (Dierkes et al., 2008). I think that just as the generic Hopf bifurcation model for bundle function can be usurped to understand the action of the electromotility nonlinearity, so too can this new coupling model. In fact, I think there are many analogies between proposed bundle mechanisms of amplification and prestin-driven amplification. Ironically, work on the bundle may help us understand how electromotility might work! One notable hypothesis that we suggested was the possible action of an ion underlying the mechanical event that drives amplification. Thus, in analogy with the process whereby Ca^{2+} influx through the molecularly-identified transduction channel conductance (G_{met}) drives bundle movements, we suggested that Cl^- could be fluxed via the molecularly-identified, mechanically-active lateral membrane conductance (G_{metL}) to effect prestin conformation change (Rybalchenko and Santos-Sacchi, 2003). We have shown that manipulation of Cl^- flux across the lateral membrane can reversibly alter cochlear amplification on the BM *in vivo* (Santos-Sacchi et al., 2006). Clearly, if such flux could be effected at acoustic rates, such a mechanism would bypass the membrane filter problem identified as a consequence of the voltage-dependence and nonlinear nature of electromotility (Santos-Sacchi, 1989). In this regard, we did show that G_{metL} is gated at acoustic rates (Rybalchenko and Santos-Sacchi, 2003), and it was shown that

deformations of the OHC soma occur during acoustic stimulation (Fridberger and De Monvel, 2003) – a possible stimulus for G_{metL} .

I am now captivated by a possibility that stereocilia and the prestin-based mechanism may team up to overcome the membrane time constant problem intrinsic to the conventional concept of prestin activation (Fig. 7). Interestingly, a correspondence between apical and lateral membrane activities has been observed *in vivo*, where bundle biasing and other manipulations appeared to affect OHC mechanical activity (Kirk, 2001; Kirk and Yates, 1998). Possible mechanisms included an alteration of intracellular chloride levels. Could the bundle influence cochlear amplification in a manner unrelated to active bundle mechanics and not due to the direct action of voltage on the motors? Could this involve chloride? I see two possibilities in this regard. One challenging dogma and another recently identified.

Here is the first scenario. Ion channels are characterized by their selectivity, their ability to pass particular ions over others based on size and/or charge. For all channels, the selectivity is not perfect, and ranges from extremely poor selectivity (e.g., (Oliver et al., 2001; Singh et al., 2007; Uhl et al., 1988)), to high selectivity (e.g., K channels).

Still, the most select ones can pass small amounts of ions that are generally considered impermeable (e.g., <1%). It is true that the bundle channel is nonselective for cations (Corey and Hudspeth, 1979; Crawford et al., 1991; Ohmori, 1985), but even though the replacement of chloride with sulfate has no apparent effects on cation currents (Valli et al., 1979), detailed anion selectivity has never been studied. It may sound like heresy today, but concessions that anion selectivity of the transduction channel require further investigation have been made (Hudspeth, 1983; Ohmori, 1985), and I am unaware of any further investigations on this topic since that time, especially in OHCs. Interestingly, one of the most

abundant proteins in stereocilia, CLIC5 (Gagnon et al., 2006), only nominally an intracellular chloride channel, has recently been shown to form channels in bilayers (Singh et al., 2007). Selectivity for charge is mildly cationic, with poor specificity, and measured multi-conductance levels of ~ 105 and ~ 17 pS. OHC MET channel conductance is about 110 pS (Geleoc et al., 1997). Imagine if CLIC5 were the MET channel! It is modulated by F-actin (Singh et al., 2007), making it potentially sensitive to Ca^{2+} and tension. It would be ironic should hair cells use only a few of an abundant supply of molecules – what redundancy for a critical mission! Let's check these ideas!

The second scenario involves an observation (Furness et al., 2008) made this past year showing that stereociliar rootlets insert into the junctional region of the apical lateral membrane. The potential for mechanical perturbation of the lateral membrane by the bundle therefore exists. Thus, bundle displacement, via the rootlets, is hypothesized to mechanically activate G_{metL} , promoting a flux of Cl^- at the apical region of the OHC. One further exciting prediction arises – a travelling wave of chloride flux along the apical to basal extent of the lateral membrane. This will occur because activation of G_{metL} causes a local flux of Cl^- which in turn causes the motor to change conformation, thereby mechanically triggering adjacent G_{metL} conductances to gate. A regenerative wave of activity should spread basally down the lateral membrane! An anion permeant MET channel could do the same. Let's measure it!

Finally, we should remember that efferent control of the cochlear amplification may also benefit from the modulation of chloride levels via GABA receptors at the cell's base (Maison et al., 2003; Plinkert et al., 1993). Here I can imagine a reverse travelling wave of contracture moving apically! Let's look for it!

Summary

Here, in this short space, I have revealed some of my inner most thoughts on mammalian cochlear amplification and associated problems. I have touched on why I think prestin rules, but offer up as consolation that the bundle may work with prestin. We need bold ideas like this and others (electro-osmosis, flexoelectricity) in our field to drive us to uncover the truth – to truly understand how hearing happens.

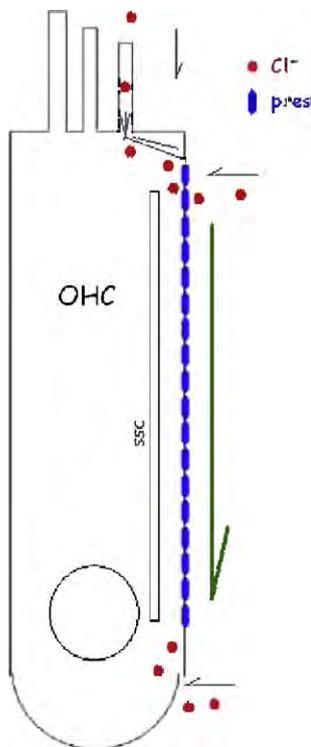

Fig. 7. The OHC is anion driven. The schematic illustrates the possible routes that chloride may take to alter prestin activity intracellularly. We have already shown that the expanse of the lateral membrane fluxes chloride via the mechanically active G_{metL} (Rybalchenko and Santos-Sacchi, 2003). Other proposed routes are through the stereociliary MET channel directly, or via rootlet perturbations of G_{metL} . Chloride may also flux during efferent activation of GABA receptors.

ABSTRACT The integral membrane protein prestin, a member of the SLC26 anion transporter family, is responsible for the voltage-driven electromotility of mammalian outer hair cells. It was argued that the evolution of prestin's motor function required a loss of the protein's transport capabilities. Instead, it was proposed that prestin manages only an abortive hemicycle that results in the trapped anion acting as a voltage sensor, to generate the motor's signature gating charge movement or nonlinear capacitance. We demonstrate, using classical radioactive anion (¹⁴C]formate and [¹⁴C]oxalate) uptake studies, that in contrast to previous observations, prestin is able to transport anions. The prestin-dependent uptake of both these anions was twofold that of cells transfected with vector alone, and comparable to SLC26a6, prestin's closest phylogenetic relative. Furthermore, we identify a potential chloride-binding site in which the mutations of two residues (P328A and L326A) preserve nonlinear capacitance, yet negate anion transport. Finally, we distinguish 12 charged residues out of 22, residing within prestin's transmembrane regions, that contribute to unitary charge movement, i.e., voltage sensing. These data redefine our mechanistic concept of prestin.

INTRODUCTION

It is now well established that prestin drives voltage-dependent electromotility in mammalian outer hair cells (1–4). Although its primary sequence places it in the SLC26 family of anion transporters, two early findings suggested that prestin (SLC26a5) was different from other members of this family. First, prestin uniquely imparts voltage-dependent mechanical activity and its corresponding electrical signature, gating charge movements, or nonlinear capacitance (NLC) (1,2). Second, unlike its nonmammalian orthologs and mammalian family members, prestin reportedly cannot transport anions (6,7). An attempt to discover how prestin senses voltage led to mutation analyses of 21 charged residues found in prestin that are not conserved in SLC26a6, its closest phylogenetic-related protein that lacks NLC (8). Such mutations failed to alter the Boltzmann parameter that corresponds to a voltage-evoked unitary gating charge (α or z). These observations led Oliver et al. (8) to invoke an incomplete transport cycle (with a hemimovement of anions within the intramembranous protein) as the mechanism by which prestin achieves its voltage sensitivity, thereby underlying the generation of NLC (8). This is generally known as the extrinsic voltage sensor or partial anion transporter hypothesis. Evidence was presented against this hypothesis, and in favor of the argument that anions work allosterically, by modifying the energy profile of the intramembranous motor protein, prestin (9–11).

Here we test key premises underlying the extrinsic voltage sensor hypothesis, i.e., that prestin is not an anion

transporter, and that prestin lacks an intrinsic voltage sensor. We show that: 1), prestin transports anions; 2), intrinsic charged residues contribute to voltage sensing; and 3), by mutation, these two functions of prestin can be divorced. These observations, in conjunction with others (9,10,12), cast doubt on a simple extrinsic voltage-sensing scheme.

METHODS

The assumption that mammalian prestin is unable to transport anions is based, in part, on a reported failure of anion transport in oocytes (7), involving data that we have replicated (J.-P. Bai and D. Navaratnam, unpublished observations). Therefore, we chose to use heterologous expression in Chinese hamster ovary (CHO) cells to evaluate prestin's ability to transport [¹⁴C]formate and [¹⁴C]oxalate. CHO cells were used extensively to characterize prestin's NLC.

We fused YFP (in eYFPN1, Clontech, Mountain View, CA) to the C-terminus of prestin (including all mutants), as previously described (13). This step allowed us to verify that transfection efficiency was comparable, and to identify cells transfected with prestin for electrophysiological recording. We expressed murine SLC26a6 (14) in pcDNA 3.1, which contains the identical cytomegalovirus promoter. We mutated individual residues using the Quikchange mutagenesis kit (Stratagene, La Jolla, CA). Mutagenesis was confirmed by sequencing the entire transcript.

Each transport experiment was performed using a 24-well plate (Costar/Corning, Lowell, MA). Cells were plated at a concentration of 200,000 cells per well, and transfected with lipofectamine 24 h after plating (as previously described) (13). Each experimental variable was evaluated in triplicate wells. Each experiment included three wells transfected with empty vector (negative control), and three wells transfected with prestin (positive control) to control for experimental variables (e.g., transfection/plating efficiency). We used 0.8 μ g of DNA and 1.6 μ L of lipofectamine per well. Formate or oxalate uptake was assayed 24 h after transfection. Cells were incubated with 120 mM NaCl, 20 mM HEPES, 5 mM KCl, 5 mM glucose, 2 mM CaCl₂, and 1 mM MgCl₂ (pH 7.4) for 30 min. After aspiration of the NaCl solution, cells were incubated in 130 mM K gluconate, 20 mM HEPES, and 5 mM glucose (pH 7.4), containing 20 μ M of [¹⁴C]formate

control (YFP vector only). The plot shows mean uptake per 200,000 cells contained in a well (of a 24-well plate) \pm SE. Data were normalized to vector-only controls ($n = 3$, in each case). Controls were assigned a value of 100. The uptake of [^{14}C]formate by prestin and Slc26a6 was 183 (± 0.7) and 171 (± 17.3), respectively, i.e., significantly different from controls ($p < 0.01$, one-way ANOVA). The uptake of [^{14}C]oxalate by prestin and Slc26a6 was 198 (± 13.5) and 187 (± 24.0), respectively, i.e., significantly different from vector-only controls ($p < 0.05$, one-way ANOVA). The absolute prestin-induced uptake of oxalate was 1.5-fold greater than formate uptake; this was obscured by normalization. Uptake is denoted in relative counts (see Methods).

(or [^{14}C]oxalate) for 8 min (in the standard assay, or at other time points indicated in timed experiments). Cells were washed three times with ice-cold 130 mM K gluconate, 20 mM HEPES, and 5 mM glucose. Cells were then lysed with 0.2 mL of 0.5 M NaOH, neutralized with 0.5 M HCl, and [^{14}C]formate (or [^{14}C]oxalate) uptake was determined by liquid scintillation counting. All data are reported as [^{14}C]formate (or [^{14}C]oxalate) uptake per 200,000 cells, and are mean values from 3–4 experiments (\pm SE) that were normalized to vector-only controls. Thus, uptake in the figures is denoted in relative counts. Each experiment, in turn, represents the mean of triplicate wells. The absolute mean uptake of [^{14}C]formate and [^{14}C]oxalate in a given control well across a number of experiments was ~ 20 pmol and 28 pmol per 200,000 cells, respectively. In independent experiments, we established by both protein and DNA assays that transfection with different plasmids did not affect the cell number within the first 24 h. Knowing the intracellular concentration of transported anions would be important in evaluating the actual fluxes that may occur in vivo. We are aware of no data concerning intracellular concentrations of oxalate or formate, or methods for their measurement. Fortunately, we are simply making a determination here that anion transport occurs, and this determination is independent of intracellular concentrations. Confocal microscopy was performed as previously described, using YFP fusions of each mutant (13).

Whole-cell patch clamp recordings were performed at room temperature, using an Axon 200B amplifier (Axon Instruments, Union City, CA), as described previously (13). Cells were recorded 48 h after transfection, to allow for stable measurements of nonlinear capacitance. Ionic blocking solutions were used to isolate capacitive currents. The bath solution contained (in mM): TEA 20, CsCl 20, CoCl₂ 2, MgCl₂ 1.47, HEPES 10, NaCl 99.2, and CaCl₂ \cdot 2H₂O 2, pH 7.2, and the pipette solution contained (in mM): CsCl 140, EGTA 10, MgCl₂ 2, and HEPES 10, pH 7.2. Osmolarity was adjusted to 300 ± 2 mOsm with dextrose. Command delivery and data collections were performed with a Windows-based whole-cell voltage-clamp program, jClamp (Sciosoft, New Haven, CT), using an NI PCI 6052E interface (National Instruments). We corrected for the effects of series resistance. Capacitance was evaluated with a continuous high-resolution, two-sine wave technique fully described elsewhere (15,16). Capacitance data were fitted to the first derivative of a two-state Boltzmann function, to extract Boltzmann parameters (17). A two-state Boltzmann model adequately describes prestin's charge movement (18,19)

FIGURE 1 Prestin-transfected CHO cells indicate anion transport. (A) CHO cells transfected with prestin show a time-dependent uptake of [^{14}C]formate that was greater than that of CHO cells transfected with empty vector alone (control). Uptake of [^{14}C]formate by prestin-transfected cells at 2, 4, and 8 min was 60 (± 8.2), 135 (± 10.4), and 160 (± 9.5), respectively. In contrast, the uptake of control cells at corresponding time points was 44 (± 8.2), 84 (± 2.2) and 100 ($n = 3$). Data were normalized to vector-only controls at 8 min, which was given a value of 100. (B) There is a dose-dependent increase in [^{14}C]formate uptake in cells transfected with increasing quantities of prestin-YFP plasmid. The mean uptake for cells transfected with 0.12 μg , 0.6 μg , and 1.2 μg of prestin plasmid DNA were 107 (± 4), 131 (± 8.5), and 166 (± 31), respectively. Control wells were transfected with 1.2 μg of YFP plasmid DNA ($n = 3$). (Inset) Linear relationship between transport induced by prestin (after subtracting background) and amount of DNA used in transfection. (C and D) CHO cells transfected with prestin and Slc26a6 show increased uptake of [^{14}C]formate (C) and [^{14}C]oxalate (D) compared with

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin}, \quad (1)$$

where

$$b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right).$$

Q_{\max} is the maximum nonlinear charge transfer, V_h is the voltage at peak capacitance or half-maximal nonlinear charge transfer, V_m is the membrane potential, C_{lin} is the linear capacitance, z is the unitary charge movement or valence (also a metric of voltage sensitivity), e is the electron charge, k is Boltzmann's constant, and T is the absolute temperature. Q_{\max} is reported as Q_{sp} , the specific charge density, i.e., the total charge moved, normalized to linear capacitance. Student's t -test and analyses of variance (ANOVAs) were used to evaluate the effects of mutations on different parameters of NLC and transport.

RESULTS

Prestin is an anion transporter

Although prestin-induced anion transport is not demonstrable in oocytes, it is possible that transport occurs in other systems. To test whether prestin transports anions in alternative expression systems, we transfected CHO cells with prestin (*Meriones unguiculatus*), and compared anion transport in these cells and in CHO cells transfected with empty vector. As shown in Fig. 1 A, CHO cells transfected with prestin showed a time-dependent increase in [^{14}C]formate uptake, compared with cells transfected with vector alone. The CHO cells possess an intrinsic anion-uptake mechanism that accounts for the levels of [^{14}C]formate uptake in cells transfected with empty vector alone. As expected, we also found that the accumulation of [^{14}C]formate was dose-dependent, i.e.,

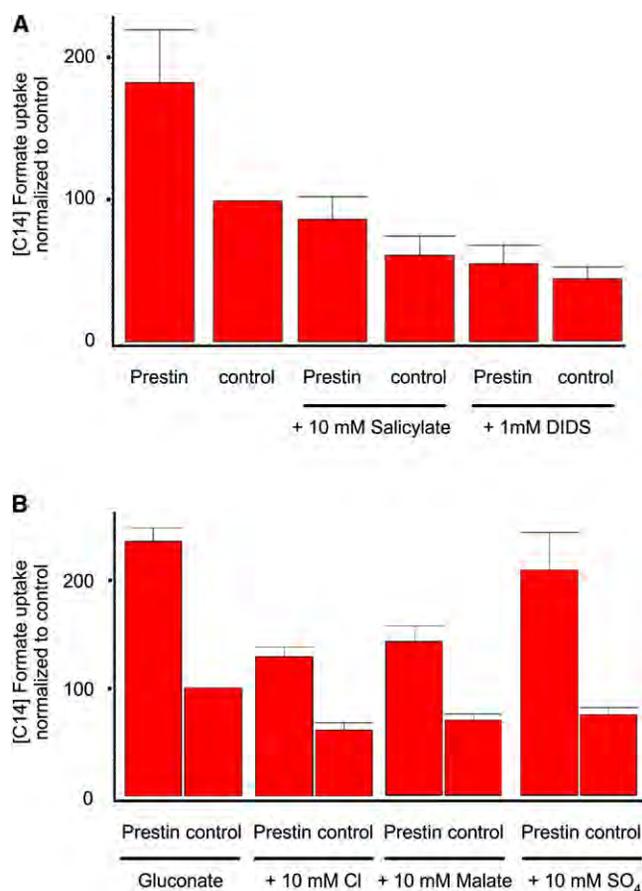

FIGURE 2 Prestin-induced uptake of [¹⁴C]formate can be blocked. (A) [¹⁴C]formate uptake in cells transfected with prestin and vector only, and similarly transfected cells treated with 10 mM salicylate and 1 mM DIDS in incubation/preincubation medium. Prestin-induced uptake of [¹⁴C]formate was reduced by both agents. Mean values for the six groups were: prestin, 183 (±37); control, 100, prestin with salicylate, 87 (±16); control with salicylate, 61 (±13.0); prestin with DIDS, 53.9 (± 13.0); and control with DIDS, 44 (±8.5) (*n* = 3). (B) Effects of various test anions on prestin-induced uptake of [¹⁴C]formate. Prestin-transfected cells were incubated with Na gluconate and Na gluconate to which various indicated test anions were then added. Both chloride and malate decreased prestin uptake, whereas SO₄²⁻ had minimal effects on prestin-induced [¹⁴C]formate uptake. Mean values for the eight groups were: prestin, 237 (±11.8); control, 100; prestin + chloride, 130 (±8.6); control + chloride, 61 (±6.7); prestin + malate, 142 (±15); control + malate, 70 (±5.7); prestin + SO₄²⁻, 209 (±35); and control + SO₄²⁻, 75 (±6.5). Uptake of [¹⁴C]formate by prestin was significantly reduced by chloride and malate (*p* < 0.05, one-way ANOVA), but not by SO₄²⁻ (*p* > 0.05) (*n* = 3). Data were normalized to vector-only controls. Uptake is denoted in relative counts (see Methods).

the amount of prestin plasmid used for transfection correlated with [¹⁴C]formate accumulation (Fig. 1 B). We then compared the uptake of prestin with SLC26a6, a member of the SLC26 anion transporter family that is most closely related to prestin. As indicated in Fig. 1 C, cells transfected with prestin showed a marked increase in [¹⁴C]formate uptake that was comparable to that of CHO cells similarly transfected with SLC26a6. The uptake induced by transfected transporters was significantly greater than that for cells transfected

with vector only (*p* < 0.01, ANOVA). Fig. 1 D summarizes similar positive transport studies with [¹⁴C]oxalate. SLC26a6 has a preferred affinity for the oxalate anion, and knockouts of SLC26a6 have defective epithelial Cl-oxalate exchange, leading to oxalate urinary calculi (14,20). The absolute prestin-induced uptake of oxalate was 1.5-fold greater than formate uptake, and is not reflected in the figures, which were normalized to our controls. As noted above, we reinvestigated anion transport in oocytes using [¹⁴C]formate and [¹⁴C]oxalate uptake, and in contrast to our data with CHO cells, we failed to demonstrate an uptake of these anions by prestin. At best, we found an inconsistent increase in uptake, even when we attempted to maximize translation by using unidirectionally capped cRNA at a concentration of 50 ng per oocyte. These results are consistent with other work in the field, and may result from an absence of an associated cofactor for prestin in oocytes, which is present in CHO cells. Because we lack a quantitative mechanism for determining the expression of prestin on the cell surface, we cannot ascertain if the absence of transport in oocytes results from inadequate surface expression.

Prestin's anion transport is similar to SLC26 family-member anion transporters

The uptake of [¹⁴C]formate induced by prestin in CHO cells was blocked by 1 mM 4,4'-diisothiocyanatostilbene-2,2'-disulfonic acid (DIDS), a well-characterized blocker of anion transport (Fig. 2 A) (14). Anion transport by other members of the SLC26 anion transporter family was shown to require up to 1 mM DIDS to completely block anion transport. Furthermore, anion transport was also blocked by 10 mM salicylate, which is known to block prestin's NLC (Fig. 2 A) (21,22).

After establishing that prestin mediates formate and oxalate transport, we tested the ability of other anions to compete for formate uptake. Anion transporters of the SLC26 family have a variable ability to transport different anions that is, in part, explained by their relative affinity for these anions (23,24). Fig. 2 B summarizes experiments where [¹⁴C]formate uptake by prestin-transfected CHO cells was measured in the presence of competing extracellular (10 mM) test anions. As is evident, both chloride and malate were able to inhibit the uptake of formate (*p* < 0.01, ANOVA), whereas the divalent anion sulfate had minimal effects on formate uptake (*p* > 0.05, ANOVA). The result with sulfate is interesting, because sulfate was originally thought not to support NLC (8), but was subsequently shown to support robust NLC and electromotility in outer hair cells (9–11,25,26).

Prestin's anion-transporter function can be separated from NLC: the role of a potential chloride-binding site

Chloride plays an important role in generating NLC, whether as its extrinsic voltage sensor or as an intracellular allosteric

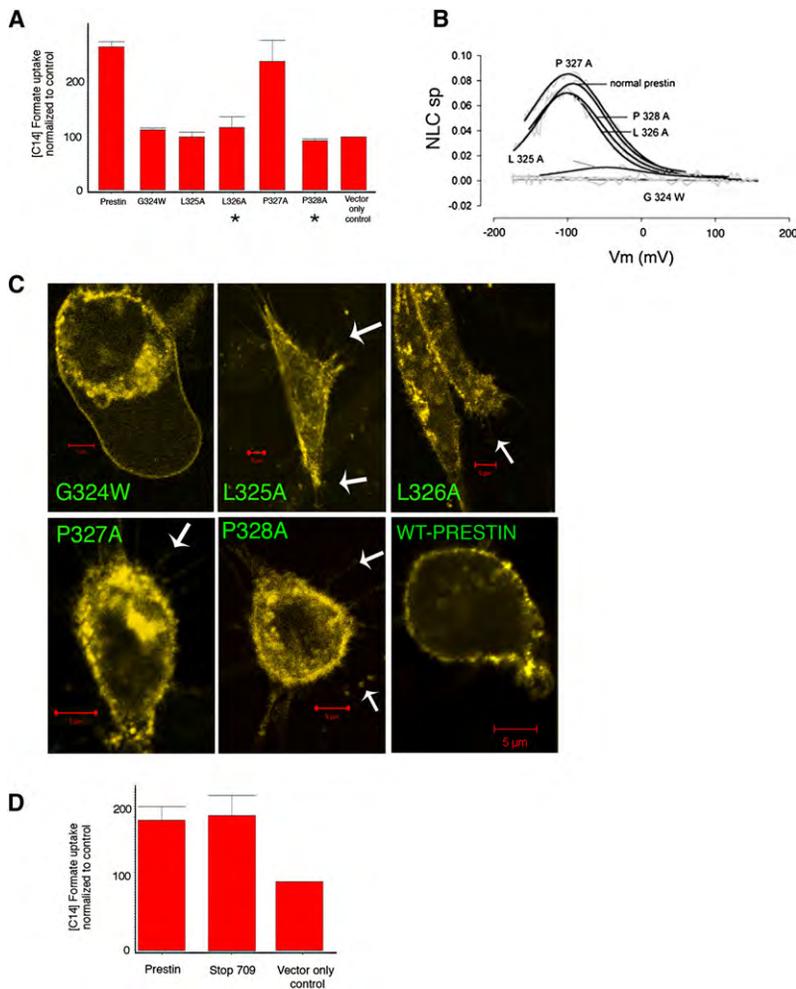

FIGURE 3 Effects of truncations and mutations in prestin on prestin-induced uptake of [^{14}C]formate. (A) Single mutations in potential chloride-binding motif decrease anion transport. All mutants except P327A show decreased anion transport. Mean uptake of [^{14}C]formate of prestin, G324W, L325A, L326A, P327A, P328A, and vector-only control cells were 269 (± 9), 113 (± 3), 100 (± 9), 117 (± 20), 241 (± 40), 93 (± 3.5), and 100, respectively. The uptake of [^{14}C]formate by prestin and P327A-transfected cells was significantly greater than in controls ($p < 0.05$, one-way ANOVA) ($n = 4$). (B) Effects of these mutations on NLC. Two mutants P328A and L326A show preserved NLC but decreased anion transport (indicated by asterisk in A). P327A has preserved NLC and anion transport, whereas remaining mutants eliminated (G324W) or significantly decreased (L325A) NLC, while also decreasing anion transport. (C) Confocal microscopy of YFP fusions of prestin and individual mutants (G324W, L325A, L326A, P327A, and P328A) shows membrane targeting. Arrows indicate filopodia containing prestin-YFP fluorescence. (D) Truncation of C-terminus at amino acid 709 (stop 709) that eliminates NLC shows preserved anion transport. Mean [^{14}C]formate uptake values for prestin, stop 709, and vector-only control were 188 (± 18), 197 (± 28), and 100, respectively. The [^{14}C]formate uptakes in prestin and stop 709-transfected cells were significantly greater than in controls ($p < 0.05$) ($n = 3$). Uptake is denoted in relative counts (see Methods).

modulator (8–10). In seeking to understand the action of intracellular chloride, we identified one potential chloride-binding motif in prestin, based on its homology with a proven chloride-binding site (GXXXP) in the bacterial CLC channel (27), where it is thought to bind chloride ions traversing the channel's pore. In prestin, this sequence, GLLPP (amino acids 324–328), lies on the predicted intracellular surface of the protein between transmembrane loops 6 and 7 of the 10-transmembrane model (13). We mutated individual amino acids in this motif, and determined their effects on NLC and anion transport. Four mutations (G324W, L325A, L326A, and P328A) abolished prestin-induced anion transport ($p < 0.01$, one-way ANOVA; Fig. 3 A). Correspondingly, one mutation (G324W) abolished NLC, and another (L325A) profoundly reduced NLC, whereas three mutations (L326A, P327A, and P328A) had normal NLC (Fig. 3 B). Consequently, two of our mutants (L326A and P328A) exerted differential effects on NLC and anion transport, each preserving the former and reducing the latter. As shown in Fig. 3 C, confocal imaging confirmed that all these mutants were targeted to the plasma membrane, even showing an unequivocal fluorescence of filopodia, processes that lack

confounding intramembranous organelles. Of course, plasmalemmal targeting was expected for mutations showing NLC, because NLC (or transport) was observed in these mutants, and such functional activity could only have occurred if the proteins were targeted to the membrane where they could sense voltage or mediate the cellular transport of anions.

Although these data clearly show a divorce between transport and NLC, we sought unequivocal corroboration. In previous studies, we and others showed that serial truncations of prestin's C-terminus reduce and then abolish NLC (13,28). Truncation of the C-terminus at amino acid 709 results in a loss of NLC. We tested anion transport (Fig. 3 D) in this mutant lacking NLC (stop 709), and found that it had preserved anion transport, equivalent to normal prestin and statistically greater than in cells transfected with control YFP vector alone ($p < 0.05$). We previously demonstrated via confocal microscopy and flow cytometry that this mutant was targeted to the plasma membrane. These transport data confirm the truncation's proper membrane targeting. Clearly, the demonstration of preserved anion transport with this NLC-incompetent mutant confirms that anion transport can be separated from NLC.

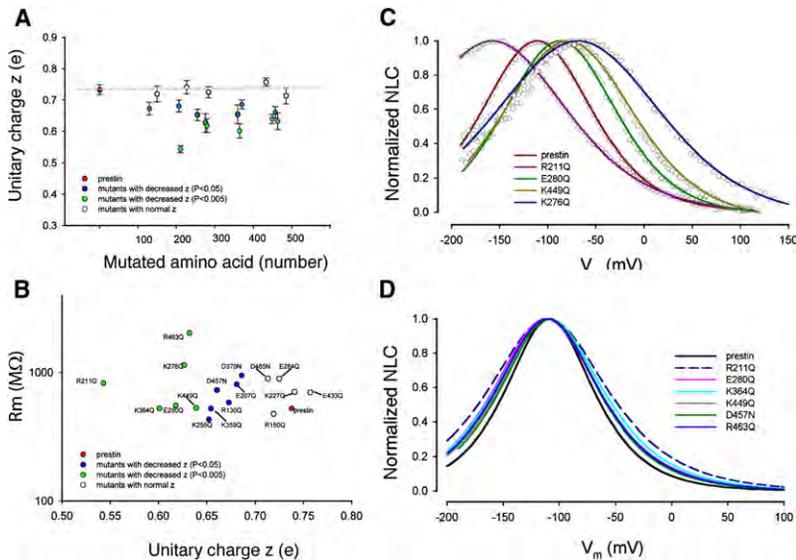

FIGURE 4 Effects of single amino-acid substitutions of charged residues that are within or in close proximity to predicted membrane-spanning regions. (A) Effects on unitary charge (z) are shown and plotted against amino-acid position. Data include only those mutants that showed nonlinear capacitance. Residues are grouped according to how significantly different their z values were, compared with wild-type prestin (*red*). Those residues are in blue where $p < 0.05$ (R130Q, R211Q, K255Q, K359Q, D269N, and D457N), and in green where $p < 0.005$ (E207Q, K276Q, E280Q, K364Q, K449Q, and R463Q). (B) Average membrane resistance of prestin and prestin mutants in A. These data confirm that changes in z were independent of membrane resistance. (C) Normalized examples of NLC of prestin and four mutants that showed a reduction in z . Data points are fitted with Eq. 1. (D) Normalized average fits of individual mutants are aligned to wild-type prestin's V_h , for a better demonstration of decrease in voltage sensitivity evidenced by a broadening of the functions.

Prestin has an intrinsic voltage sensor

Our results so far provide evidence that key components of the extrinsic voltage-sensor hypothesis (i.e., that transport is absent, along with the reasonable inference that NLC arises from the loss of a full transport cycle) are untenable. Although these results do not disprove the extrinsic-voltage hypothesis, they warrant a reexploration of the model. Moreover, these results beget the question: is there an alternative or additional mechanism whereby prestin senses voltage? We sought to determine if charged residues in prestin's transmembrane domains contribute to its gating charge movement. To do so, we neutralized 22 charged residues that were predicted to lie in its transmembrane regions by site-directed mutagenesis, and determined the effects on the unitary charge movement, z . In contrast to findings by Oliver et al. (8), all these residues were conserved between prestin and its closest relative, SLC26a6. We relied on measures of unitary charge derived from the traditional two-state Boltzmann function as a metric of charge movement within a single motor. It is our best (and only) estimate of charge movement within a single motor. Moreover, empirical data as they relate to prestin function (both charge and electromotility) fit exceedingly well with the two-state Boltzmann function (17–19). Of 22 mutated, charged residues, we found a subset of 12 that significantly reduced z (Fig. 4 A and Table 1). We were careful to exclude potential alterations in membrane resistance characteristics in our evaluations, because membrane resistance remained equivalent to controls (Fig. 4 B). The reduced z , evidence of altered voltage-sensing as reflected by reduced voltage sensitivity (i.e., broader NLC functions), is most readily seen in the normalized NLC traces in Fig. 4, C and D.

In Fig. S1 of the Supporting Material, we show representative C-V functions from all 12 mutants. These 12 residues that affected z are located across the entire span of the

transmembrane core of prestin (Fig. 5, A and B). Of the remaining 10 residues, mutations of five residues failed to affect z (R150, K227, E284, E433, and D485); mutations of four residues (D83, E293, E374, and E404) resulted in absent NLC; and the mutation of one residue (R399) resulted in a V_h shift to an extreme negative range, making the estimation of z impossible. The mutations of the four residues that showed absent NLC were likely attributable to poor membrane-targeting, as evidenced by confocal imaging (data not shown). Of the residues that affected z , four were negatively charged (E207, E280, D370, and D457), and eight residues were positively charged (R130, R211, K255, K276, K359, K364, K449, and R463). The effects on z of all these charged residues varied. These mutations also affected the operating voltage of the protein (V_h), although there was no relationship between z and V_h (Fig. 6). As expected, there was a correlation between z and the total

TABLE 1 Z values (\pm SE) of individual mutations, p values of a t -test compared with wild-type prestin, and number of cells recorded

Amino acid position	z		Number of cells recorded
	z	p	
Wild-type prestin	0.73 ± 0.02		19
R130Q	0.67 ± 0.02	<0.05	11
E207Q	0.68 ± 0.02	<0.05	10
R211Q	0.54 ± 0.01	<0.00000001	15

Also indicated are specific amino-acid numbers, which in turn are color-coded as in Fig. 4 A, to indicate residues and their effects on z .

charge movement in prestin and all of its point mutations that affected z (Fig. 7).

DISCUSSION

Here we unequivocally showed that prestin, in contrast to our previous understanding, is an anion transporter, much like its closest relative, SLC26a6. Moreover, our results are consistent with the concept of prestin's voltage sensitivity deriving at least in part (and perhaps even entirely) from intrinsic charged residues in the protein. Finally, we were able to separate these two functional characteristics of prestin by mutations to residues within a putative anion-binding site.

The widely accepted notion of an absence of intrinsic voltage-sensing in prestin followed experiments by Oliver et al. (8), who failed to find a change in unitary gating charge after mutating charged residues in prestin that were absent in SLC26a6 (the closest relative that does not exhibit gating charge movement). They reasoned that the gating charge in prestin was attributable to newly acquired charged residues in prestin. In reviewing their mutagenesis experiments, we noted that a significant number (10/21) of charged residues that were different between the two proteins lay outside its predicted transmembrane domain, and therefore could not have sensed transmembrane voltage. Indeed, we mutated charged residues in the intracellular C-terminus, and found that such mutations did not alter the unitary charge relative to controls (29). To test fully for intrinsic voltage-sensing, we mutated every charged residue in prestin that lies within or in very close proximity to the predicted transmembrane segments (of both the 10-transmembrane and 12-transmembrane models; Fig. 5, A and B), and determined the effect on unitary charge (z). We identified a large number of charged residues (12 out of 22)

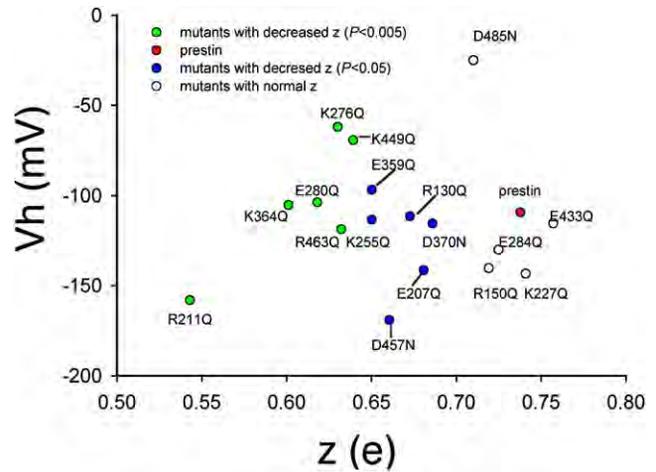

FIGURE 6 Relationship between voltage of peak capacitance (V_h) and unitary charge (z). There is no relationship between z values and V_h , although most of the mutants caused a negative shift in V_h .

within prestin's transmembrane domains that are also conserved in SLC26a6, and that contribute to the generation of NLC. These data require a fundamental rethinking of how prestin brings about electromotility.

Three features of the identified residues and their relationship to voltage sensitivity are noteworthy. First, prestin shows much less voltage sensitivity than conventional ion channels. Thus, the unitary charge per motor in prestin amounts to $\sim 0.74 e$, and contrasts with values of 13.6e for Shaker potassium channels, 10e for sodium channels, and 2.6e for large-conductance, calcium-activated potassium channels (30–33). Second, mutations that produced a reduction in z , although they were as low as 0.55, clustered around a mode of 0.65e, indicating that these residues contributed a similar amount of charge to the total gating-charge movement. Third, all of these residues are conserved between prestin and SLC26a6, which does not exhibit gating-charge movement (8) (J.-P. Bai and D. Navaratnam, unpublished observations).

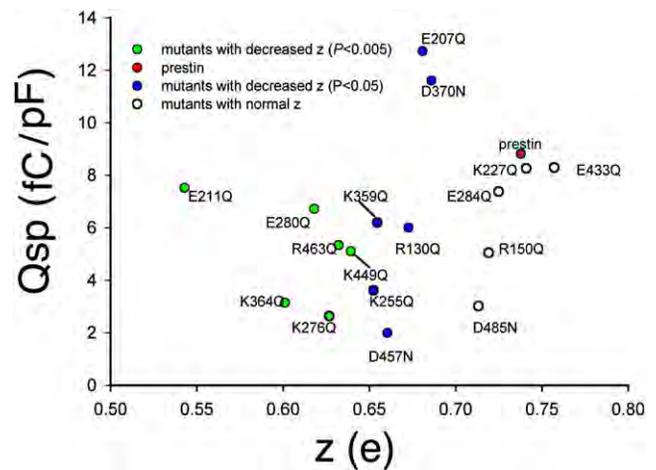

FIGURE 7 Relationship between unitary charge z and specific capacitance. There is a positive trend between z and Q_{sp} ($Q_{max}/\text{linear capacitance}$).

Why should conserved residues generate a charge movement in one family member but not the other? There are parallels in ion channels where residues that contribute to gating charge and voltage sensitivity in one protein are conserved in a related orthologous protein, yet do not contribute to gating charge or voltage sensitivity in the orthologous protein. For example, the Shab delayed rectifier potassium channel and its mammalian homolog Kv2.1 have the same number of charged residues in their voltage sensors, yet carry different gating charges (7.5e and 12.5e, respectively) (34). Similarly, the gating charge in mSlo channels (2.6e) is fivefold less than that in Shaker channels (13e), although mSlo contains three of the five residues most important for gating charges (33). According to a widely held consensus, these differences are likely attributable to a smaller movement of these residues in both mSlo and Shab (33–35). A similar mechanism could explain the apparent discrepancy between prestin's gating-charge movement and its absence in SLC26a6, which has the same residues implicated in prestin's charge movement. Alternatively, there may be a movement of charged residues of opposite polarity neutralizing their effects in SLC26a6. In any event, the movement of charge through the voltage field in prestin and the contribution from each of these residues to total charge movement are small, when compared with voltage-gated ion channels. In this respect, prestin differs from voltage-gated ion channels, where a few charged residues account for the majority of voltage sensitivity.

Perhaps more germane to the workings of prestin, a member of a transporter family, is the observation that in some transporters, when substrate is removed, presteady-state currents are revealed (36–38). Transient, presteady-state currents are equivalent to the gating-charge movements or NLC measured in prestin, and represent voltage-sensor activity. For example, in line with our determinations for prestin, the voltage-sensing mechanisms in the Na⁺-glucose transporter were shown to involve intrinsic charge movements of the protein, rather than only Na⁺ binding/unbinding to sites within the protein's membrane field (38,39). Interestingly, the charge valence *z* of 1e is close to that of prestin. Similarly, it is known that the GABA transporter's charge movement is derived from extrinsic (chloride) and intrinsic charge (36). Indeed, even the chloride dependence of gating in CLC channels is known to arise because of competition with a glutamate gate charge, rather than functioning as a mobile extrinsic voltage sensor (40). Thus, the use of intrinsic charged residues is clearly a general mechanism of voltage-sensing proteins, and prestin is no different (41).

Our data showing separated NLC and anion transport by mammalian prestin contain several implications. First, our data extend work showing that nonmammalian orthologs of prestin are able to transport anions in an electrogenic manner (6). In that study (6), electrophysiological methodology was used solely to assess electrogenic transport, and the authors reasoned that electrogenic transport in mam-

lian prestin does not occur. Interestingly, however, some electrophysiological characteristics of mammalian prestin were successfully modeled as a result of the exact type of electrogenic transport found in nonmammalian orthologs of prestin (25). Our data cannot resolve this controversy, because the classic transport techniques that we used, although thoroughly sufficient for the demonstration of anion transport, cannot assess electrogenicity. Second, our data suggest that the advent of NLC/electromotility occurs independent of anion transport, and is not coincident with its loss, as previously suggested. Indeed, an evolutionary analysis suggests that SLC26a6, which lacks the ability to generate NLC or electromotility, arose from SLC26a5 (Dr. Kirk Beisel, Creighton University, personal communication, 2008). Third, because each outer hair cell is estimated to contain up to 10 million prestin motors (42,43), our data imply the presence of a powerful homeostatic mechanism for controlling anion concentration in these cells. This is especially the case in light of ample data showing that prestin's operating voltage range is affected by intracellular anion concentration (10,12,44). Fourth, our data showing intrinsic voltage-sensor activity in prestin establish an alternative or additional molecular mechanism for voltage-sensing in the outer hair cell motor. The original extrinsic voltage-sensor or partial anion-transporter model of prestin voltage-sensing, where monovalent chloride anions serve as sources of voltage-sensor charge movement or NLC (8), has received serious challenges. For example, whereas sulfate anions were found to abolish NLC in prestin-transfected cells (8), several groups showed that sulfate supports NLC and electromotility in OHCs (10,11,25,26). Furthermore, anion-charge valence does not dictate gating-charge valence, as would be expected in the extrinsic voltage-sensor model (9). We suggested that anions serve as allosteric modulators, because the conformational state of prestin depends not only on the concentration of intracellular anions, but on their structure as well (9). In this regard, it is interesting that alkylsulfonic anions of differing hydrocarbon chain lengths variably shift prestin's operating voltage range, conceivably because of interactions with the different voltage-sensing residues that we identified here.

Finally, our data raise an important question. Because the advent of the outer hair cell motor is thought to be a recent evolutionary event, and because the residues in prestin responsible for sensing voltage are also present in SLC26a6, what additional features in prestin allow these charged residues to move in response to changes in transmembrane voltage?

OPEN

Prestin kinetics and corresponding frequency dependence augment during early development of the outer hair cell within the mouse organ of Corti

Jun-Ping Bai⁴, Dhasakumar Navaratnam^{1,3,4} & Joseph Santos-Sacchi^{1,2,3*}

Several studies have documented the early development of OHC electromechanical behavior. The mechanical response (electromotility, eM) and its electrical correlate (nonlinear capacitance, NLC), resulting from prestin's voltage-sensor charge movement, increase over the course of several postnatal days in altricial animals. They increase until about p18, near the time of peripheral auditory maturity. The correspondence of auditory capabilities and prestin function indicates that mature activity of prestin occurs at this time. One of the major requirements of eM is its responsiveness across auditory frequencies. Here we evaluate the frequency response of prestin charge movement in mice over the course of development up to 8 months. We find that in apical turn OHCs prestin's frequency response increases during postnatal development and stabilizes when mature hearing is established. The low frequency component of NLC, within *in situ* explants, agrees with previously reported results on isolated cells. If prestin activity is independent of cochlear place, as might be expected, then these observations suggest that prestin activity somehow influences cochlear amplification at high frequencies in spite of its low pass behavior.

The outer hair cell (OHC) enhances cochlear sensitivity up to 3 orders of magnitude, and the cellular basis of this feat resides within the OHCs that populate the organ of Corti. OHCs are electro-motile, responding to transmembrane current perturbations with changes in cell length, termed electromotility (eM)^{1,2}. Though the pertinent electromechanical characteristics (e.g., voltage-dependence, and magnitude) of OHC eM had been studied since the mid-80s^{3,4}, the identification of the membrane protein, SLC26a5 (prestIn), driving this response required over a decade⁵. Various candidates were considered along the way, similar to the quest for the stereociliar MET channel⁶.

Prestin drives OHC electromotility (eM), known to be responsible for cochlear amplification (CA) in mammals⁷. The electrical signature of eM is a bell-shaped nonlinear capacitance (NLC), the first derivative of prestin sensor charge vs. membrane voltage (dQ_p/dV_m), which peaks at a characteristic membrane voltage (V_h)^{8,9}. We have previously studied the development of NLC in OHCs of the mouse¹⁰. Those studies demonstrated that increases in prestin charge (Q_{max}) continued after stabilization of linear capacitance (at p10), which corresponds to total membrane surface area (sum of membrane and embedded prestin surface area). Thus, though the number of prestin molecules appeared to stabilize, additional changes in NLC characteristics ensued, indicating some sort of maturational events. Here we study, in developing OHCs, the maturation of prestin kinetics, which has recently been shown to possess low pass characteristics in adult guinea pig OHCs¹¹. We find that during development the frequency response of NLC increases, stabilizing near 6 kHz in adults at the apical turn of the cochlea at room temperature. We also find that linear capacitance decreases with aging, and is indicative of reduced prestin

insertion in the membrane. Nevertheless, specific motor charge density (a metric for prestin density within the membrane) remains fairly constant.

Methods

C57/B6 pups aged postnatal days 6–18, and months 2 and 8 were used. All experimental protocols were approved by the Yale Animal Care and Use Committee, and were in accordance with relevant guidelines and regulations. Apical turns of the organ of Corti were dissected out and recorded with ionic current blocking solutions, thereby removing interference on measures of membrane capacitance. The extracellular solution contained (in mM): 100 NaCl, 20 tetraethylammonium (TEA)-Cl, 20 CsCl, 2 CoCl₂, 1 MgCl₂, 1 CaCl₂, 10 HEPES, pH 7.2. The intracellular solution contained (in mM): 140 CsCl, 2 MgCl₂, 10 HEPES, and 10 EGTA, pH 7.2. Pipettes were coated with M-coat to reduce stray capacitance, and had resistances of 3–5 MΩ. Gigohm seals were made and stray capacitance was balanced out with amplifier circuitry prior to establishing whole-cell conditions. A Nikon Eclipse E600-FN microscope with 40× water immersion lens was used to observe cells during voltage clamp. Whole cell voltage clamp recordings were performed from all rows of outer hair cells (OHCs) of whole mount organ of Corti. We limited the recording area within 1/4 turn. OHCs were recorded at room temperature using jClamp software and an Axopatch 200B amplifier. Data were low pass filtered at 10 kHz and digitized at 100 kHz with a Digidata 1320 A.

Chirp voltage stimuli were delivered across frequency and analyzed within 300–7000 Hz, where stray capacitance was removed. The voltage chirps were generated in jClamp using the Matlab logarithmic “chirp” function (10 mV pk; pts = 4096; F0 = 24.4141 Hz; F1 = 50 kHz; t1 = 0.04095 s). Chirp responses were not averaged at each voltage step (−160 to +120 in 40 mV steps). Cell currents were either averaged for analysis (6–8 cells/group) for surface plot presentations or analyzed individually for statistical measures. Detailed analysis of C_m was performed in Matlab. Capacitance was measured using dual-sine analysis at harmonic frequencies (Santos-Sacchi *et al.*, 1998; Santos-Sacchi, 2004). Briefly, real and imaginary components of membrane current at harmonic frequencies were determined by FFT in jClamp, corrected for the roll-off of recording system admittance¹² and residual stray capacitance¹³. R_s , R_m and C_m were extracted using the dual-sine, 3-parameter solution of the standard patch clamp model^{14,15}, based on the original single sine solution¹⁶. In order to extract Boltzmann parameters, capacitance-voltage data were fit to the first derivative of a two-state Boltzmann function.

$$C_m = NLC + C_{sa} + C_{lin} = Q_{max} \frac{ze}{k_B T} \frac{b}{(1+b)^2} + C_{sa} + C_{lin} \quad (1)$$

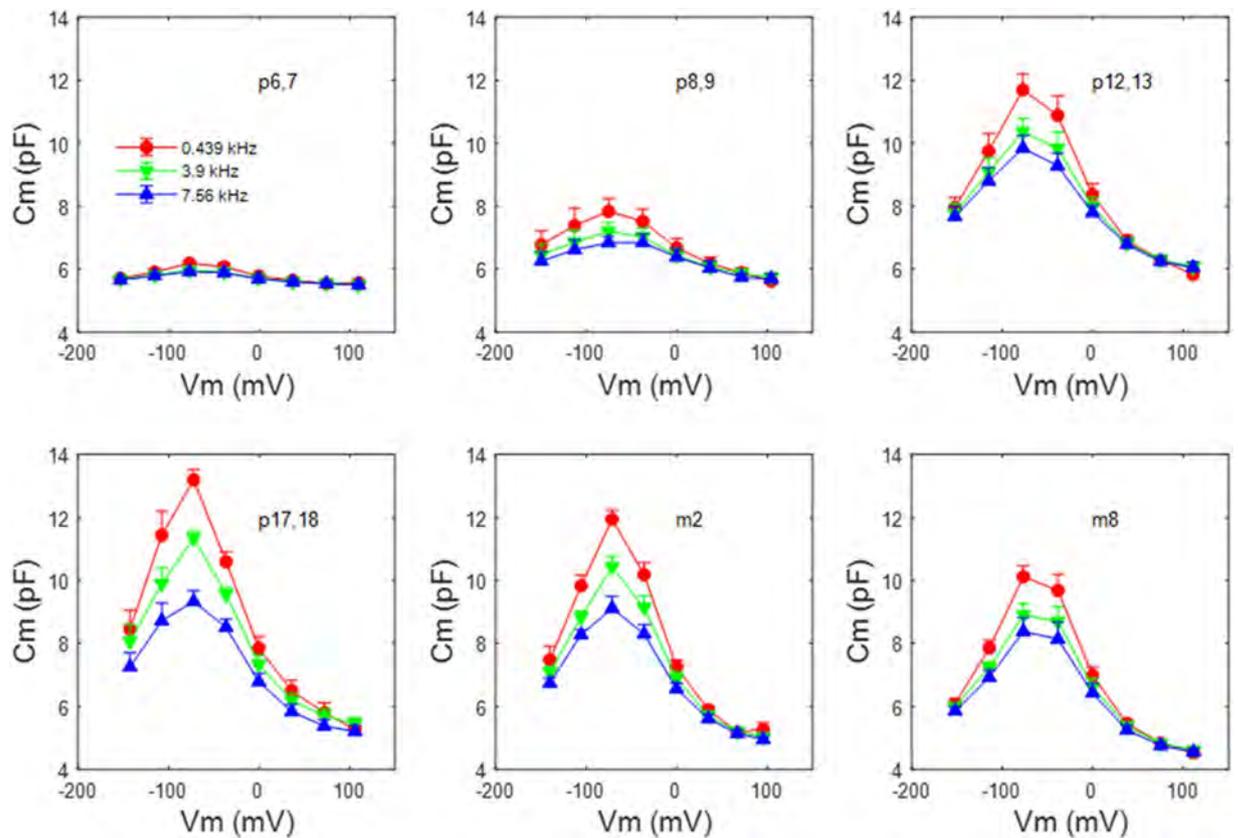

Figure 2. NLC (mean \pm se) as a function of postnatal age at select stimulating frequencies. Peak NLC reaches maximal values at p17/18 across frequency. C_{lin} increases until p12/13 as a result of surface area increase, but decreases thereafter. NLC also reduces following p17/18. By 8 months, C_{lin} has markedly decreased. P6,7 n = 7; p8,9 n = 7; p12,13 n = 6; p17,18 n = 8; 2 month n = 8; 8 month n = 9.

$$\text{where } b = \exp\left(-ze\frac{V_m - V_h}{k_B T}\right), C_{sa} = \frac{\Delta C_{sa}}{(1 + b^{-1})}$$

Q_{max} is the maximum nonlinear charge moved, V_h is voltage at peak capacitance or equivalently, at half-maximum charge transfer, V_m is R_s -corrected membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k_B is Boltzmann's constant, and T is absolute temperature. C_{sa} is a component of capacitance that characterizes sigmoidal changes in specific membrane capacitance¹⁷. ΔC_{sa} is the total sum of unitary changes per prestin motor protein. Q_{sp} denotes charge density, namely Q_{max}/C_{lin} .

A Lorentzian function (or the sum of two Lorentzians) (Gale and Ashmore, 1997; Santos-Sacchi and Tan, 2018) was used to fit NLC across frequency.

$$NLC(f) = NLC_0/[1 + (2\pi f\tau)^2]^{1/2} \quad (2)$$

where NLC_0 is the zero frequency component, and $\tau = 1/F_c$, the cut-off frequency. Additionally, a power fit of NLC across frequency was performed.

$$NLC(f) = NLC_0 + a * f^b \quad (3)$$

where NLC_0 is the zero frequency component, and a and b control the frequency response.

Results

Figure 1 illustrates our methodology to measure NLC across frequency. With our Boltzmann fit (Eq. 1) we obtain the usual Boltzmann parameters while extracting NLC, and additionally determine C_{sa} , a component of capacitance that we believe arises from changes in membrane surface area or membrane thickness as prestin alters its conformational state across voltage^{17–20}.

Figure 2 shows mean (\pm se) NLC at 3 selected frequencies within our measurement bandwidth, as a function of postnatal age. As determined previously, NLC reaches maximal values at p17/18 in rodents^{10,21}. Here we find the same pattern across frequencies. C_{lin} increases until p12/13 as a result of surface area increase as the cells mature, lengthen and express increasing amounts of prestin within the membrane. However, C_{lin} decreases

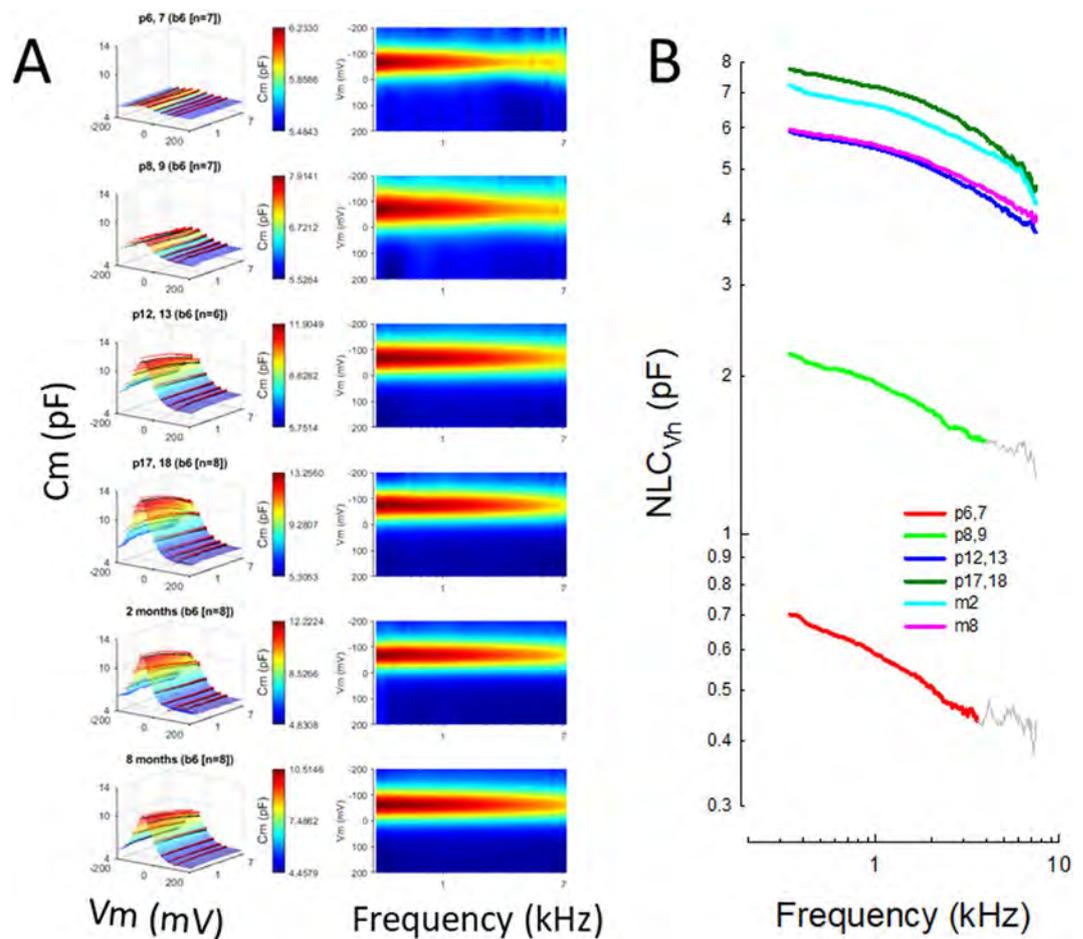

Figure 3. (A) Left panels show full NLC spectrum (0.39–7 kHz) surface plots as a function of postnatal age, illustrating the bell-shaped NLC and its roll-off with increasing frequency. Black dots indicate means and pink dots are \pm se, which sit atop the Boltzmann fits. The panels on the right show the same data top-down, and provide a clearer view of the frequency response changes during aging. (B) NLC_{V_h} for each age group is log-log plotted to more clearly show the low-pass behavior that changes during aging. The colored points were used for fitting in Fig. 5. For the 2 youngest groups grey lines show regions omitted from fits because of noise at high frequencies.

thereafter at all frequencies. By 8 months, C_{lin} has decreased by more than 25%. NLC also reduces following p17/18. The plots also highlight a substantial roll-off of peak NLC across frequency, which we investigate in more detail further below.

Because we limited our recordings to a quarter turn of the apical coil of the cochlea, we determined whether the variability in hair cell length within that region could impact our C_{lin} data. OHC lengths in different rows of the cochlear apex are indistinguishable²². In the mouse strain we used, they determined that OHC lengths from middle (17.3 μm) and apical (21.3 μm) turn regions differed by 4 μm . Assuming that this progression will translate into our quarter turn (as their plots suggest) we would maximally expect about a 1 μm length variability in our hair cell recordings. Given the cylindrical geometry of the OHC and its diameter in mice ($\sim 7 \mu\text{m}$), we calculate an expected maximal variability in linear capacitance (based on surface area arising from our measured membrane specific capacitance of 0.08 $\text{pF}/\mu\text{m}^2$ ²⁰ of 0.26 pF. This is well below our finding of -1.6 pF (25% reduction from p12/13) during aging. Utilizing a more stringent estimate of 0.05 $\text{pF}/\mu\text{m}^2$ for specific membrane capacitance²³, giving 0.165 pF variability, our results are even less likely to be influenced by sampling within the quarter turn. We conclude that the C_{lin} changes during aging are real.

In Fig. 3 we show the NLC recorded between 0.39 and 7 kHz at 24 Hz resolution. The data show that NLC is maximal at low frequencies and decreases at higher frequencies, depending on the age of the animal. In Fig. 3A, the 3D plots on the left highlight the voltage dependence of NLC (mean \pm se of the data overlies the smooth Boltzmann fits), whereas those 2D plots on the right highlight the frequency response of NLC. In Fig. 3B, we plot NLC at V_h , illustrating the changing frequency dependence as animals age. The low pass nature of NLC at all ages is apparent. A quantification of this roll-off is supplied below. Nonetheless, the representations in Fig. 3 provide a rich picture of the magnitude, voltage-dependence and frequency extent of NLC across age.

Boltzmann parameters (mean \pm se) for three disparate bandwidths are plotted in Fig. 4 as a function of age. A comparison to our previous isolated cell mouse data¹⁰ obtained at low frequency (dotted lines) is made.

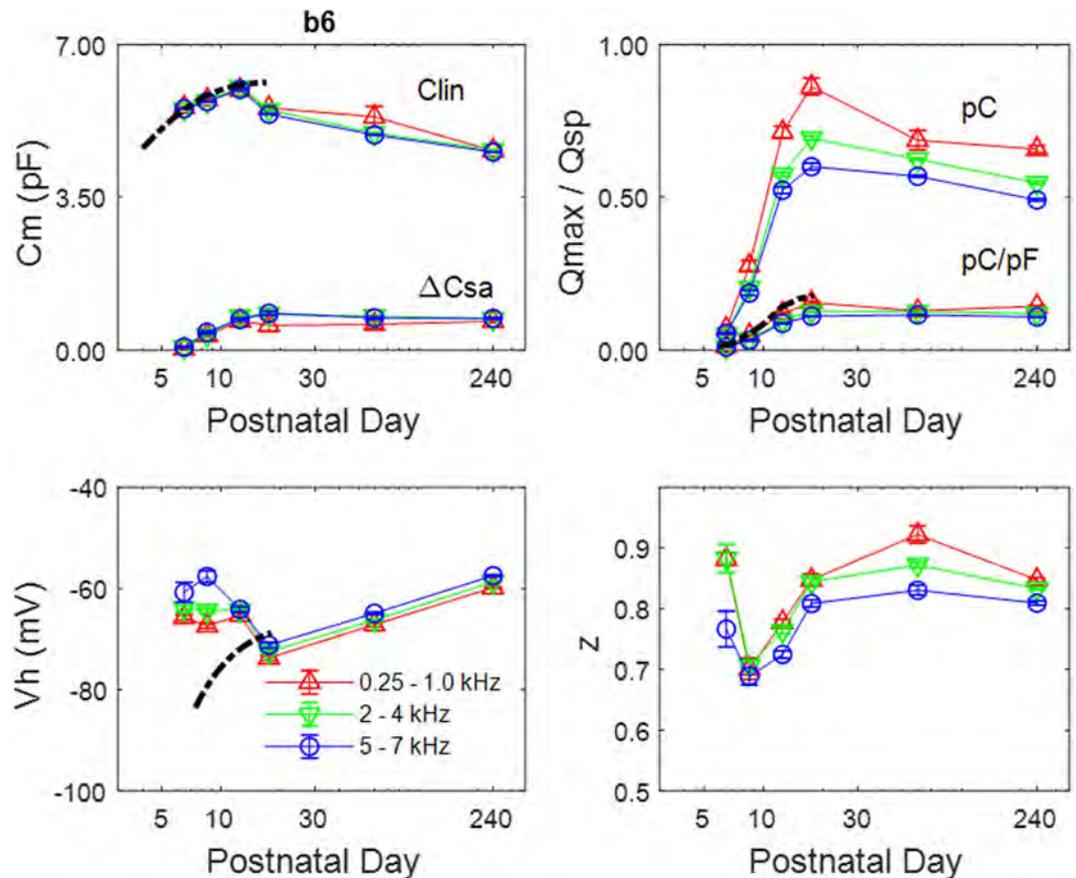

Figure 4. Boltzmann characteristics (mean \pm se) for selected bandwidths. The dashed line denotes NLC measured at low frequencies from isolated OHCs (Abe *et al.*, 2010). Note abrupt decline of C_{lin} , while C_{sa} remains steady. V_h is initially at a more positive potential than isolated cells. Q_{max} (pC) and Q_{sp} (pC/pF) increase rapidly during development. Q_{max} decreases after p17/18, with a clear difference between low and high frequencies, but Q_{sp} stabilizes because of the C_{lin} drop. Following some variability at p6/7, z increases with age, and also tends to be smaller at higher frequencies. P6/7 n = 7; p8,9 n = 7; p12,13 n = 6; p17,18 n = 8; 2 month n = 8; 8 month n = 9.

Quantification of Q_{max} and C_{lin} confirms their initial rise between p6/7 to p12/13 as the cells increase in surface area, and mirror measures made in isolated cells. The development of Q_{sp} in the low frequency region also corresponds to measures from isolated cells. After p17/18, Q_{max} decreases, while Q_{sp} appears to stabilize, due to simultaneous decrease in C_{lin} . The additional frequency information provided by chirp analysis shows that both Q_{max} and Q_{sp} following p17/18 depend on frequency, with higher frequencies showing reduced values. Interestingly, V_h within the explant differs from isolated cells during early development, and may result from forces that normally exist in the organ of Corti, e.g., membrane tension. It is well known that many factors can influence V_h , including membrane tension and intracellular Cl^- ,^{14,24–30}. The Boltzmann parameter z , which characterizes the voltage sensitivity of prestin or the distance sensor charge is moved within the membrane field, is variable in p6/7 animals, but clearly increases after this time period over age. Some frequency dependence of z in the adult is evident, and reduction in z at high frequencies in the adult guinea pig was originally noted by Gale and Ashmore³¹.

Finally, in Fig. 5 we explore the changes in frequency cut-off (F_c) of NLC at V_h . Since the reduction of NLC _{V_h} across frequency is clearly not a simple process, three methods of fitting were evaluated to estimate frequency roll-off (Fig. 5A). We provide fits to average data. Examples of the 3 fit types for p17/18 OHCs are shown, including single Lorentzian, dual Lorentzian (sum of 2 Lorentzians) and power fits. The blue line depicts the fit and red lines show 95% confidence predictions of the fits (fitting performed in Sigmaplot). The poorest fit is with a single Lorentzian, followed by dual Lorentzian and power fits. In regard to the power fit, we have previously found evidence of multi/stretched exponential behavior in NLC^{32,33}. The stretched exponential (known as the Kohlrausch-Williams-Watts [KWW] relaxation function), first devised by Kohlrausch (1854) to describe the behavior of capacitor discharge in a Leyden jar, is also applicable to the viscoelastic behavior of glasses³⁴, and other systems where time-dependent behavior results from overcoming a multitude of energy barriers. Interestingly, cytoskeletal dynamics is one such system³⁵. The KWW function has a related counterpart in the frequency domain³⁶, termed the Havriliak-Negami [HN] relaxation function. Fitting our data with that counterpart, we obtain similar quality fits to the power functions (for example, at p17,18 the fit R^2 is 0.9975 and 0.9974 for power and HN). Since the power function fit has fewer parameters (one less) than HN, we have chosen to

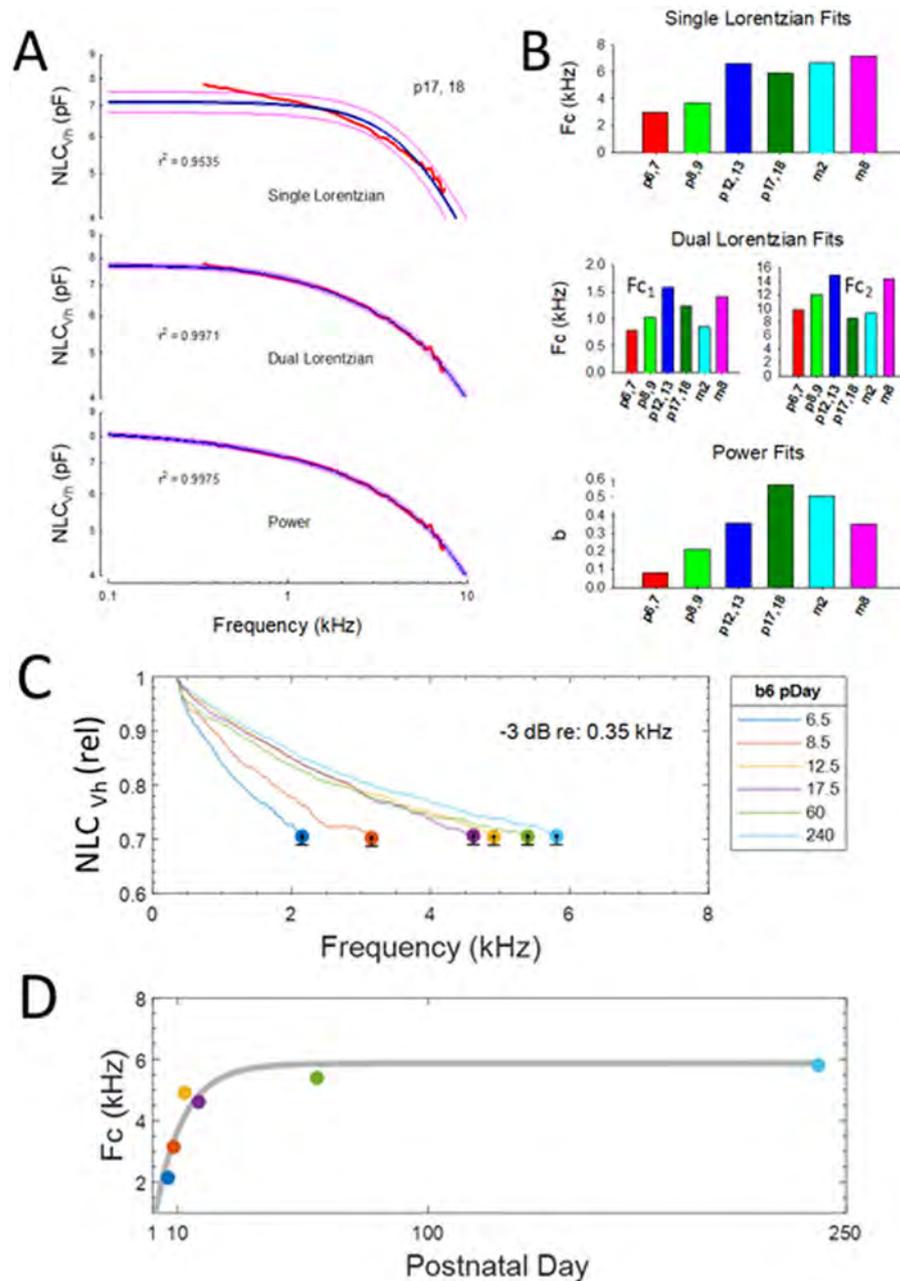

Figure 5. Changes in frequency response of NLC during aging. **(A)** Three types of fits to mean NLC_{vh} were performed to estimate frequency roll-off. Examples of the 3 fits for p17/18 OHCs are shown. Blue line is fit and red lines are 95% confidence predictions of the fits (done in Sigmaplot). The poorest fit is with a single Lorentzian, followed by dual Lorentzian and power fits (f in kHz). Nevertheless, each provides evidence for increases in frequency responsiveness during development. The $\langle a \rangle$ parameter, as all others, was not constrained, but was not age-dependent and similar for all fits [p6,7 - m8: $-1.4055, -1.3548, -1.5980, -1.1960, -1.1552, -1.5031$; mean \pm se $-1.369 (0.07)$]. The small se indicates little variability. **(B)** Bar plots of frequency cut-off parameters of the fits. **(C)** Another metric of frequency response roll-off was to determine the -3 dB magnitude of NLC_{vh} relative to 350 Hz values, denoted here with circles. It should be noted that the F_c 's simply reflect the relative roll-off during aging, and their absolute values will differ depending on the cut-off frequency. During the life span, F_c increases. The se indicates the variability at the cut-off frequencies. **(D)** The F_c data were fit to a power law function in Matlab (grey line; $F_c = a \cdot (1 - b \cdot \text{pDay})$, where $a = 5.867$ and $b = 0.9065$; $R^2 = 0.849$), and indicates a stabilization near 6 kHz. P6,7 n = 7; p8,9 n = 7; p12,13 n = 6; p17,18 n = 8; 2 month n = 8; 8 month n = 9.

illustrate power fits. The usage of the term *low-pass* for the power function should not be construed in a strict engineering sense, but here denotes domination of low pass components whose slope changes over maturation. Figure 5B shows that regardless of the utilized fitting function, each provides evidence for increases in frequency responsiveness during development, as indicated by the bar plots. The dual Lorentzian gives dubious F_{c2} cut-offs

since they are above the sampled frequency. In Fig. 5C, we provide another metric of frequency response roll-off by finding the -3dB magnitude of NLC_{V_h} relative to 350 Hz. During the life span, F_c increases and appears to stabilize near 6 kHz in our older animals. Interestingly, the cut-offs roughly correspond to those of the single Lorentzian fits. We are cognizant that these cut-off estimates cannot be considered true cut-off frequencies, but only indicate that the NLC response has lost much of its steady state magnitude even at low frequencies. That is, the F_c 's simply reflect the relative roll-off among aging groups, and their absolute values will differ depending on the reference frequency. Thus, all methods to quantify roll-off indicate that frequency responsiveness increases with age. Possible reasons for this are discussed below.

Discussion

Studying the development of OHC function can reveal important determinants of adult auditory function. A variety of OHC characteristics mature during the course of post-natal development in altricial animals, including stereociliar transduction and eM. By using such animals, these characteristics can be conveniently studied in isolated cells or explants following birth. The development of eM and its corresponding electrical correlate, nonlinear membrane capacitance (NLC), have been found to reach maturity near p18 in the rodent^{10,21,37}, close to the onset of hearing. These studies did not include an assessment of prestin frequency dependence during development, a likely important factor for OHC performance in the adult animal's acoustic environment. Here we evaluated the development of NLC frequency response in the *in situ* mouse cochlea, and find that its frequency cut-off (F_c) increases from p6 to p18, thereafter stabilizing out to 8 months at about 6 kHz at room temperature. Assuming that the frequency response is solely limited by the kinetics of prestin (however, see below) and given a Q_{10} of 2³⁸, the F_c would approach 15 kHz. The data indicate that the F_c is lower pass in nature than the full auditory capabilities of the mouse, since prestin's intrinsic kinetics is likely place independent. That is, prestin's molecular structure, molecular interactions, and especially molecular behavior have yet to show significant differences among OHCs from various turns of the cochlea^{39,40}.

Importantly, most developmental prestin characteristics measurable within the *in situ* organ of Corti correspond to those measures obtained in isolated cells^{10,21}, i.e., at low measurement frequencies. However, we find that V_h in young animals differs from isolated cell studies, and this may be due, for example, to changes in turgor pressure or membrane tension upon isolation. It is notable that for a simple two-state voltage-dependent protein, V_h is determined by the ratio of forward and backward transition rates of conformational change. Thus, V_h alterations may inform on changes in prestin kinetics. Considering the differences of V_h *in situ* vs. in isolated cells, it may be desirable to analyze the effects of prestin mutations, e.g. the "499" knock-in mutation⁷ in the explant, rather than isolated cells.

We find that C_{in} decreases following the attainment of mature NLC. The decrease corresponds to a decrease in Q_{max} , indicating that the absolute number of prestin motors in OHCs decreases with age. This result implies that the surface area of the cells decrease because prestin occupies less surface area, and this is expected since in the prestin KO OHC surface area/length is markedly reduced⁴¹. The reduction of surface area and prestin in OHCs may have influential effects on the mechanical properties of the cochlear partition. Indeed, in the prestin KO mouse, Mellado Lagarde *et al.* have found that frequency tuning of the partition changes⁴². Thus, we might expect altered hearing in the aging mouse based on the reduction of prestin content that we find.

Why does the frequency response of prestin change during aging? Several possibilities exist. Prestin function itself could change during maturation due to changes in 1) phosphorylation or glycosylation^{43,44}; 2) multimerization^{45–47}; or 3) molecular crowding within the lateral membrane. Extrinsic influences may also change; for example, during the development of the spaces of Nuel supporting cell rearrangements may occur, and less cell-cell contact could reduce interactive mechanical constraints. Certainly, such types of interactions can affect auditory performance⁴⁸. Finally, cytoskeletal influences on prestin^{49,50} may change during development. We recently, determined that MAP1S, a small microtubule binding protein interacts with both actin and prestin, and co-expression in heterologous cells promotes targeting and alteration in prestin characteristics⁵¹. Cytoskeletal forces acting on prestin may work to influence conformational switching by the well-known piezoelectric nature of the protein^{27,28,30}, which has been extensively modelled^{52–54}. Thus, there may well be mechanical filtering of prestin performance depending on whole-cell mechanics that simultaneously impacts the F_c of both NLC and eM, as the two are well coupled^{55,56}. In any case, whatever mechanisms that enhance prestin's frequency response during the developmental likely limits its frequency response in adults. Interestingly, quite low pass estimates ($F_c \sim 1.5\text{ kHz}$) of adult OHC eM frequency response have been found in the high frequency region of the living gerbil using optical coherence microscopy (OCT) vibrometry⁵⁷. Thus, at this point, the mechanism whereby OHC eM influences very high frequency hearing is under question.

Prestin is a member of the SLC26 family of anion transporters that is responsible for outer hair cell (OHC) electromotility. Measures of voltage-evoked charge density (Q_{sp}) of prestin indicated that the protein is highly expressed in OHCs, with single cells expressing up to 10 million molecules within the lateral membrane. In contrast, charge density measures in transfected cells indicated that they express, at best, only a fifth as many proteins on their surface. We sought to determine whether associations with other OHC-specific proteins could account for this difference. Using a yeast two-hybrid technique, we found microtubule-associated protein 1S (MAP1S) bound to prestin. The interaction was limited to the STAS domain of prestin and the region connecting the heavy and light chain of MAP1S. Using reciprocal immunoprecipitation and Forster resonance energy transfer, we confirmed these interactions. Furthermore, co-expression of prestin with MAP1S resulted in a 2.7-fold increase in Q_{sp} in single cells that was paralleled by a 2.8-fold increase in protein surface expression, indicating that the interactions are physiological. Quantitative PCR data showed gradients in the expression of prestin and MAP1S across the tonotopic axis that may partially contribute to a previously observed 6-fold increase in Q_{sp} in high frequency hair cells. These data highlight the importance of protein partner effects on prestin.

Prestin is a member of the SLC26 family of anion transporters that is responsible for outer hair cell (OHC)³ electromotility, the basis of mammalian cochlear amplification (1–4). Prestin is found in the lateral membrane of the OHC (5, 6) and has piezoelectric properties, deriving from reciprocal voltage and mechanical sensitivity (7–10). The voltage sensor of the protein, which is integral to electromotility, generates charge movement that can be detected as a nonlinear capacitance (NLC) (11, 12). NLC parallels electromotility and has been established as an excellent surrogate marker for electromotility (11). There are three commonly described attributes of NLC as

follows: V_h , the voltage of peak capacitance; z , an estimate of charge carried by a single motor; and Q_{sp} the charge moved across a unit of membrane. V_h reflects the steady state energy profile of the protein, and Q_{sp} provides an estimate of the density of the protein in the plasma membrane.

Prestin in OHCs exists in very high density. It is estimated that OHCs contain up to 10 million of these molecules in the lateral membrane of a given cell (13, 14). Measures of NLC in transfected cells, however, have not yielded this high density of prestin. Measures of Q_{sp} can reach 5 fC/pF in transiently transfected CHO cells (15) but contrasts with a Q_{sp} of 220 fC/pF in the mature OHC (16). Although differences in transcription could account for this change, we have been unable to induce OHC-like prestin expression levels in the membrane in transfected cells using the best available promoters, including cytomegalovirus and the tetracycline-inducible promoter. Moreover, mRNA expression in OHCs is not as robust as would be expected for a protein with such high levels of expression (17), indicating low turnover of prestin that is stable in the membrane. In contrast, exogenous expression of prestin using a cytomegalovirus promoter in chick hair cells results in NLC measures that were significantly increased compared with CHO cells.⁴ These data have led us to speculate on the existence of post-translational mechanisms or protein associations in hair cells that are absent in transfected cells. We have other reasons to hypothesize post-translational mechanisms or associations that modulate prestin activity. For instance, whereas prestin possesses many of the major features of the OHC motor, there were notable discrepancies in the behavior of the OHC motor and that of prestin in transfected cells. For example, the magnitude of the effects of prior (prepulse) voltage and membrane tension is somewhat less than found with the native OHC motor (18). These data prompted us to seek other additional mechanisms that would modify prestin activity.

It is evident over the last 15 years that many membrane proteins, including ion channels and receptors, interact with other proteins to form large complexes. The components of these complexes affect the delivery of these proteins to the surface as well as their function. For instance, there is substantial literature showing the effect of ancillary proteins on ion channels and receptors (19–21). In view of these findings, we sought to find proteins that interacted with prestin. We used the yeast two-hybrid technique to identify proteins that interacted with prestin. We used the intracellular C terminus of prestin in a Gal-4-

based yeast two-hybrid technique to probe a brain cDNA library. We identified several proteins that interacted with prestin. Here, we describe the interaction between one of these proteins, microtubule-associated protein 1-S (MAP1S), and prestin, and we explore its physiological consequences.

EXPERIMENTAL PROCEDURES

Yeast Two-hybrid Experiments—Yeast two-hybrid experiments were done as described previously (49). Briefly, the C terminus of prestin (amino acids 491–744) was subcloned into pGBKT7 and used as bait to interrogate a rat brain cDNA library in pGAD T7 (Clontech). AH109 cells were serially transfected with both constructs and plated on drop out medium lacking histidine, adenine, tryptophan, and leucine. Single colonies were isolated and serially re-plated in similar conditions on plates containing 5-bromo-4-chloro-3-indolyl- β -D-galactopyranoside (X-gal). Cultures from single isolated colonies were used for yeast mini preps. Plasmid was electroporated into DH101 *Escherichia coli*, grown in ampicillin and plasmid DNA isolated for sequencing.

DNA Constructs and Transfection—Gerbil prestin and MAP1S sequences used were as described previously (1, 38). For NLC recording, transient co-transfection of prestin (0.8 μ g per well of 24-well plate) and MAP1S-CFP (or CFP) (0.8 μ g per well of 24-well plate) into CHO cells was achieved with Lipofectamine (Invitrogen) in accordance with the manufacturer's recommendations. We identified MAP1S-CFP (or CFP)-transfected cells with CFP fluorescence for electrophysiological recording, and only cells that showed NLC were analyzed. We were thus able to determine with certainty that these cells contained both plasmids. For co-immunoprecipitation, FLAG-MAP1S-CFP was transfected into a prestin-Myc stable line in human embryonic kidney (HEK) cells established in our laboratory⁵ or HEK cells with Lipofectamine.

Prestin Surface Expression and Western Blots—Surface expression of prestin alone or with MAP1S was determined using a surface biotinylation assay (Thermo Scientific/Pierce, Rockford, IL). Transiently transfected CHO cells were washed with PBS and incubated in the presence of sulfo-NHS-biotin (sulfo-succinimidyl-2-(biotinamido) ethyl-1,3-dithiopropionate) for 30 min at 4 °C. Free sulfo-NHS-biotin was quenched by washing cells in 140 mM Tris-Cl, and the cells were lysed in lysis buffer containing the following (in mM): 20 Tris, pH 8.0, 137 NaCl, 5 NaEDTA, 5 NaEGTA, 10% glycerol, 0.5% Triton X-100, 0.2 phenylmethylsulfonyl fluoride, 50 NaF, 20 benzamide. The lysates were cleared by centrifugation, and its protein concentration was assayed (Bio-Rad) and equalized with sample buffer. Streptavidin-agarose was added, and the mixtures were incubated for 1 h at room temperature with constant agitation. After centrifugation at 1000 \times g, the beads were washed with washing buffer. The bound surface proteins were released by the addition of 50 mM dithiothreitol and analyzed by SDS-PAGE and Western blotting. Lysates or eluates of surface-labeled proteins were separated on a precast 4–15% Tris-HCl SDS-polyacrylamide gel (Bio-Rad). Proteins were transferred by wet transfer to polyvinylidene fluoride membrane (Roche

Applied Science). Western blots were probed with anti-prestin N20 (Santa Cruz Biotechnology, Santa Cruz, CA) at a 1:500 dilution and then with horseradish peroxidase-conjugated bovine anti-goat secondary antibody (Santa Cruz Biotechnology) at 1:5000 dilution with five washes in TBST between each step. The presence of horseradish peroxidase-conjugated antibody was detected using SuperSignal[®] West Dura extended duration Substrate (Thermo Scientific/Pierce).

Co-immunoprecipitation—Reciprocal immunoprecipitation was done with anti-FLAG (MAP1S-CFP) antibody and anti-Myc (prestin-YFP) antibody using immunoprecipitation kits purchased from Sigma. In brief, membrane-enriched protein lysates were generated 48 h after transfection. 60 μ l of anti-FLAG M2-agarose or 60 μ l of anti-c-Myc-agarose was added to the lysates. The mixtures were incubated with constant agitation for 2 h at 4 °C. Following this binding step, the beads were washed seven times with washing buffer. To elute the FLAG fusion protein (MAP1S) or Myc fusion protein (prestin), 100 μ l of 5 μ g/ml FLAG peptide or c-Myc peptide (Sigma) was added to the resin. The samples were incubated with constant agitation for 30 min at 4 °C and then eluted by centrifugation. The eluted samples were boiled with loading buffer and 6% β -mercaptoethanol for 5 min and then were separated on a precast 4–15% Tris-HCl SDS-polyacrylamide gel (Bio-Rad). Proteins were transferred by wet transfer to polyvinylidene fluoride membrane (Roche Applied Science). Western blots were probed with anti-c-Myc antibody-peroxidase conjugate (1:3000) or anti-FLAG M2 antibody-peroxidase conjugate (1:4000) (Sigma) for 1 h at room temperature. Immunoreactive proteins were detected using SuperSignal[®] West Dura extended duration substrate (Thermo Scientific/Pierce).

Isolation of Individual OHCs from Guinea Pig Cochlea—Hartley albino guinea pigs (~200 g) were sacrificed with halothane (2-bromo-2-chloro-1,1,1-trifluoroethane, Halocarbon Labs, River Edge, NJ), and the temporal bones were dissected in PBS. Four turns of the cochlea were separated and hair cells dislodged by mechanical trituration in PBS and dispersed in Petri dishes to allow cells to settle.

Individual OHCs were captured using a pipette (~30- μ m tip) attached to a micro-manipulator (Scientifica, Uckfield, UK) with the cells visualized using a Nikon Eclipse 600 FN microscope (Nikon, Melville, NY). The tips were silanized with trimethylchlorosilane (Fluka, St. Louis, MO) to prevent cell adhesion to the pipette wall. Cells were aspirated into the pipette using gentle suction. Isolated cells were expelled into Eppendorf tubes and stored in a -80 °C freezer.

Quantitative Immunofluorescence—Quantitative immunofluorescence was done as described previously (50), with modifications. In particular, we used a confocal microscope to obtain images and used the attendant Zeiss LSM software to analyze and extract data. Cochlea were isolated from mice euthanized by CO₂ asphyxiation. Cochlea were dissected from these animals and fixed in 4% paraformaldehyde, PBS for 1 h. The cochlea were washed in PBS (three times) and placed in blocking solution (PBS, 1% bovine serum albumin, 5% horse serum, 0.1% Tween 20). Tissue was incubated in 1:500 anti-prestin antibody in blocking solution overnight (N20 prestin) (Santa Cruz Biotechnology) at 4 °C. After washing in PBS, 0.1% Tween

⁵ S. Bian, manuscript in preparation.

MAP1S Interacts with Prestin

20 (three times), the tissue was incubated with Alexa 648-conjugated horse anti-goat antibody (1:1000) for 1 h at room temperature. The tissue was washed again in wash buffer (three times) and incubated with a 1:50 dilution of mouse anti-MAP1S antibody (Abnova, 00055201B01) for 1 h at room temperature. Alexa 488 goat anti-mouse antibody (1:1000) was added after washing the tissue. The tissue was dissected, and the three turns of the cochlea were separated after a further three washes. Tissue was then mounted using Vectorshield, and viewed using a Zeiss 510 meta confocal microscope. Sixteen bit images were acquired using a 40× water immersion lens (N.A. 1.2), with fixed laser settings, a scan rate of 6.4 μs/pixel, a pinhole aperture of 1.0 Airy units, and fixed detector gain. Regions of interest identified as horizontal sections of circumscribed hair cells in the most basal and apical ends of the cochlea were identified, and fluorescence data were extracted. We established that the fluorescence intensity was within the linear range and used mean fluorescence density as a measure of protein concentration. Surrounding supporting cells, where there is minimal prestin and MAP1S expression, were used to subtract background fluorescence. Cells from four individual cochlea were used for these analyses. The specificity of the antibodies was established by Western blots of cell lysates from cells with the respective constructs. Both antibodies identified bands of the expected size with minimal additional bands.

Single Cell Nested PCR from OHC—cDNAs from each cell were synthesized as described previously in a total volume of 20 μl (51). Nested PCR was performed in two steps. 35 cycles of PCR amplification were performed (94 °C for 30 s, 55 °C for 1 min, and 68 °C for 3 min) using 5 μl of cDNA and MAP1S outer primers (MAP1SOUTF, AACTTCTTCCTGCGTGTGCG; MAP1SOUTR, ATGCGTCTCCTCATAACCTGTG). A second nested PCR amplification was then done using 5 μl of the initial PCR as template. This second PCR step involved 30 cycles of amplification using MAP1S inner primers as follows: MAP1SINF, GTGTGCGTGCACTCTGCTAT; MAP1SINR, TCACTGCAGAGTCGAAGGTG. Both steps used Expand High Fidelity PCR enzyme (Roche Applied Science). PCR fragments were analyzed on a 1% agarose gel. These primers spanned an intron of 501 bp. Control PCRs included aliquots from isolated cells to which no reverse transcriptase was added (no cDNA).

Quantitative (q) PCR—Organs of Corti were peeled off of each turn of the cochlea, and total RNA was isolated using the RNAqueous kit (Ambion, Austin, TX) following the manufacturer's instructions. cDNAs was synthesized using oligo(dT) primers and random hexamers as described previously (51). Triplicate qPCR amplifications using 1 μl of cDNA from each turn of the cochlea were performed using the IQ SYBR Green super mix (Bio-Rad). The reaction mixtures were set up in 96-well thin wall plates (Bio-Rad) and run on either C1000 thermal cycler with a CFX96 optical reaction module (Bio-Rad) or Mx3000P QPCR system (Stratagene, La Jolla, CA). The parameters were 95 °C for 30 s, 55 °C for 1 min, and 72 °C for 30 s for 35 cycles. Amplification data were analyzed using CFX Manager software (Bio-Rad) and normalized to 18 S RNA.

The primer sequences were as follows: prestin, PRQ96F, CAG-CAGTTGACTGCCCTGTA, and PRQ276R, ACGTGGTAC-

TTCTGGGTTGC; MAP1S, MAP1Q2945F, GAGTTCTAGC-CCCACACTGC, and MAP1Q3105R, TCTGCCTCTCCAAC-CTGAGT; and 18 S, 18 S344F, AGAAACGGCTCCACATCC-AAG, and 18 S493R, TCAAAGTCCCTCCAATGGTCC.

Electrophysiological Recording—Whole-cell patch clamp recordings were performed at room temperature using an Axon 200B amplifier (Axon Instruments) as described previously (15). Cells were recorded 48 h after transfection to allow for stable measurement of nonlinear capacitance. Ionic blocking solutions were used to isolate capacitive currents. The bath solution contained the following (in mM): tetraethyl ammonium 20, CsCl 20, CoCl₂ 2, MgCl₂ 1.47, Hepes 10, NaCl 99.2, CaCl₂·2H₂O 2, pH 7.2, and the pipette solution contained the following (in mM): CsCl 140, EGTA 10, MgCl₂ 2, Hepes 10, pH 7.2. Osmolarity was adjusted to 300 ± 2 mosM with dextrose. Command delivery and data collections were carried out with a Windows-based whole-cell voltage clamp program, jClamp (Scisoft, CT), using a Digidata 1322A interface (Axon Instruments). Capacitance was evaluated with a continuous high resolution 2-sine wave technique fully described elsewhere (52, 53). Capacitance data were fitted to the first derivative of a two-state Boltzmann function to extract Boltzmann parameters (11); a two-state Boltzmann model adequately describes charge movement of prestin (54, 55) as shown in Equations 1 and 2,

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}} \quad (\text{Eq. 1})$$

where

$$b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right) \quad (\text{Eq. 2})$$

where Q_{\max} is the maximum nonlinear charge transfer; V_h is the voltage at peak capacitance or half-maximal nonlinear charge transfer; V_m is the membrane potential; C_{lin} is linear capacitance; z is the unitary charge movement or valence (also a metric of voltage sensitivity); e is electron charge; k is the Boltzmann constant, and T is absolute temperature. Q_{\max} is reported as Q_{sp} , the specific charge density, *i.e.* total charge moved normalized to linear capacitance. A Student's *t* test was used to evaluate the effects of mutants on the different parameters of NLC.

RESULTS

Yeast Two-hybrid Results Show That Prestin Interacts with MAP1S—In seeking to find binding partners to prestin, we used the C terminus of prestin as bait in a Gal-4-based yeast two-hybrid screen. The Gal-4-based method requires soluble (non-membrane-bound) protein, and we used the intracellular hydrophilic C terminus of prestin for this experiment. We subcloned cDNA encoding amino acids 488–744 of prestin into the pGBK-T7 vector and screened a rat brain cDNA library. Of several clones identified, one encoded the C terminus of MAP1S from amino acids 720–972. The interaction was detectable even in the most stringent conditions. Thus, yeast containing both of these constructs grew in the absence of histidine and adenine and expressed β-galactosidase.

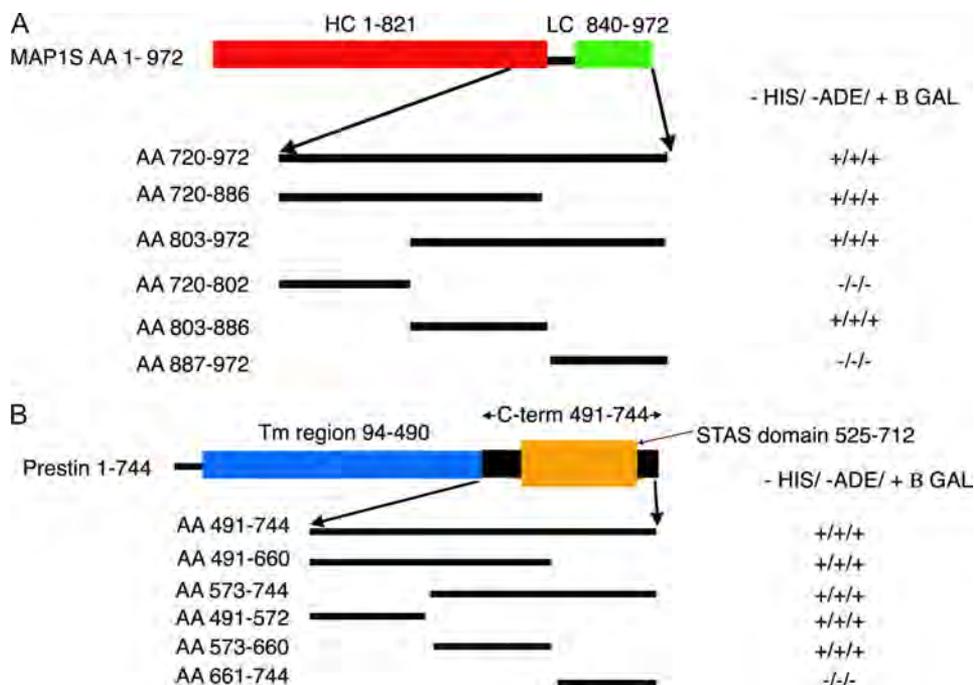

FIGURE 1. Yeast two-hybrid experiments detect interactions between prestin and MAP1S, which is restricted to specific domains. Initial yeast two-hybrid screening using the C terminus of prestin as bait revealed MAP1S as a binding partner. This clone extended from residues 720 to 972. Subsequently, we used several truncations of these constructs in a yeast two-hybrid assay to clarify the specific domains involved in this interaction. *A*, initial screening using three equal parts of the protein revealed the interacting domain to lie within the middle fragment (amino acids (AA) 803–886). Subsequent yeast two-hybrid assays (data not shown) using 15–16-amino acid fragments within this region confirmed that the interaction with prestin was mediated by amino acids 819–835 in MAP1S, which lacks predicted secondary structure, contains a large number of proline residues, and lies between the heavy (HC) and light chains (LC) of the protein. Also indicated are the heavy chain (red) and light chain (green) regions of MAP1S relative to the region in MAP1S identified in the yeast two-hybrid screen. *B*, in a similar approach, we used three equal fragments of the C terminus of prestin in a yeast two-hybrid assay to determine areas that were important in interactions with MAP1S(720–972). We determined that the interacting domains in prestin extended across residues 491–655, which includes parts of the STAS domain and included the entire IVS subdomain within it. We have also shown in schematic form the transmembrane region (blue) of the prestin, its C terminus (black), and the STAS domain (orange) within the C terminus.

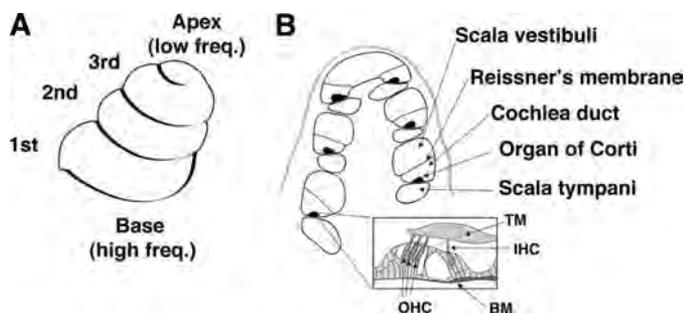

FIGURE 2. Anatomy of the cochlea. OHCs are arranged tonotopically along the three turns of the cochlea. *A*, schematic of the external appearance of the cochlea shows its three turns. Hair cells in these turns are arranged tonotopically with cells at the base responding to high frequency (Freq) sounds and cells at the apex responding to low frequency sound. Notably, hair cells in the 1st, 2nd, and 3rd turns of the cochlea respond to sound of decreasing frequency. *B*, section across the cochlea reveals the organ of Corti to be compartmentalized. An expanded view of the organ of Corti reveals it to contain three rows of OHCs and one row of inner hair cells. TM, transmembrane; IHC, inner hair cell; BM, basilar membrane.

Interactions between MAP1S and Prestin Is Limited to Specific Regions—We attempted to isolate the regions of MAP1S that interacted with prestin (Fig. 1A). We divided the MAP1S amino acid sequence from 720 to 972 into approximately three equal segments and used these three segments (encoding

amino acids 720–802, 803–886, and 887–972) to test if they interacted with prestin using the yeast two-hybrid assay. In this instance, MAP1S cDNA fragments were subcloned into pGADT7 and used in a complementation assay with the C terminus of prestin (amino acids 488–744) in pGBK-T7. Interactions were detected using the middle segment encoding amino acids 802–886. This region was further subdivided into five segments of ~16 amino acids each, and interactions with the C terminus of prestin were assayed using the yeast two-hybrid assay. This third more focused complementation assay (again using MAP1S fragments in pGAD-T7 and amino acids 488–744 of prestin in pGBK-T7) revealed that MAP1S interacted with a short segment limited to amino acids 819–835. These 17 residues are not predicted to contain a specific secondary structure, but rather they contain a large number of proline residues. Moreover, these 17 amino acids lie in a region between the purported heavy and light chains of the protein. The heavy and light chains of the better studied MAP1B has been defined as extending from residues 1 to 2185 and 2210 to 2459, respectively. The corresponding residues in MAP1S

are 1–821 and 840–972. A search using the FingerPRINTScan revealed two other proteins containing a similar sequence, Kv3.3 and Atrophin.

We next attempted to determine the interacting sites within prestin responsible for binding to MAP1S (Fig. 1B). Here too we used a similar strategy of using the yeast two-hybrid assay to ascertain interactions of three equal regions of the C terminus of prestin with amino acids 720–972 of MAP1S. In these experiments, these smaller fragments of cDNA were subcloned into pGBKT7. As shown in Fig. 1B, regions of prestin that are important for interacting with MAP1S extended across amino acids 491–660. This region includes parts of the STAS domain (525–712) and encompasses almost the entirety of the IVS region of the STAS domain.

MAP1S Is Expressed in OHC and Shows a Tonotopic Gradient—To determine whether the interaction between MAP1S and prestin is physiologically significant, we sought to ascertain if MAP1S existed in OHCs from guinea pig cochlea (the species in which there is the most amount of physiological data). A schematic of the guinea pig cochlea along with the tonotopic axis is shown in Fig. 2. We isolated individual OHCs and performed single cell PCRs from these cells. As evident in Fig. 3, OHCs contained MAP1S. Single cell nested PCR from

MAP1S Interacts with Prestin

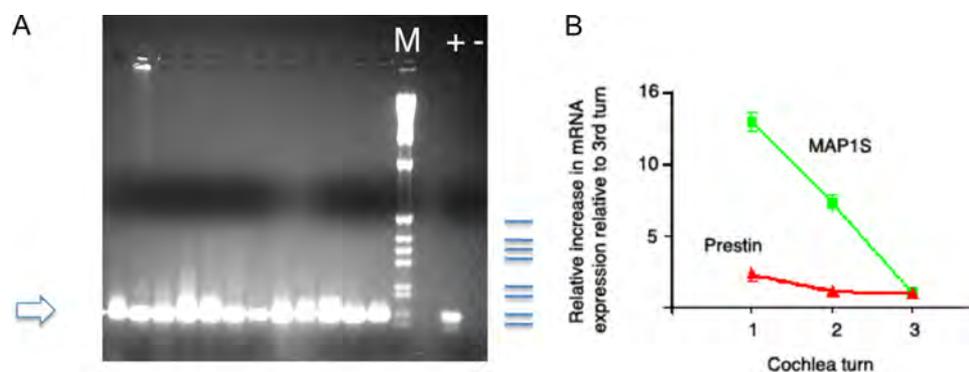

FIGURE 3. MAP1S is expressed in individual hair cells, and its mRNA shows a marked gradient in expression across the tonotopic axis. *A*, MAP1S was detected in 12 individual OHCs by nested PCR using cDNA from single cells. The product of 147 bp is the expected product of the inner primer pair. The products were separated on a 2% agarose gel. Also included are DNA size markers (*M*); a positive control (+, using plasmid containing MAP1S cDNA as template), and negative control (–, no reverse transcriptase). The sizes of the markers indicated in blue are 506, 398, 356, 298, 220, 203, 154, and 134 bp. *B*, shown in graph form are the fold change of prestin and MAP1S mRNA determined by qPCR across the organ of Corti from the three turns of the cochlea compared with the 3rd turn of the cochlea. The expression of each mRNA species was normalized to the expression of the 18 S subunit of ribosomal RNA. As is evident, although prestin shows an almost 3-fold increase in expression from the third to the basal (first) turn of the cochlea, MAP1S shows a more dramatic 13-fold increase in expression from the third to the basal (first) turn of the cochlea. The error bars are \pm S.E., $n = 4$.

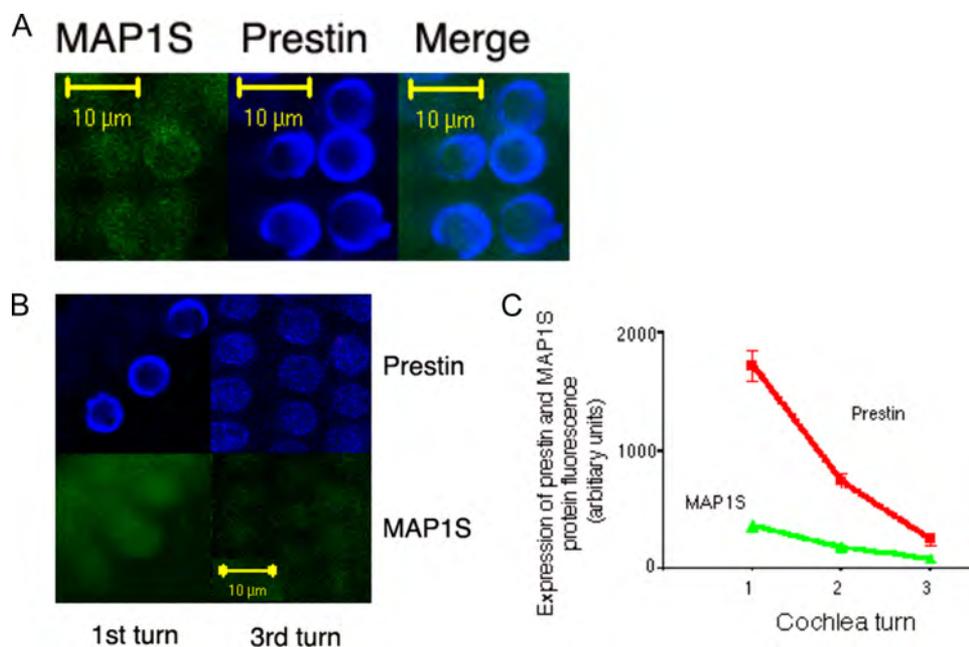

FIGURE 4. MAP1S co-localizes with prestin in mouse OHC and, along with prestin, shows a gradient in expression across the tonotopic axis. *A*, prestin co-localizes with MAP1S. Shown are mouse OHCs labeled consecutively with antibodies against MAP1S (*left*) and prestin (*middle*). There is co-localization of the two proteins in these cells (*right*). *B*, OHCs from the most apical (*left*) and basal (*right*) portions of the mouse cochlea were labeled with antibodies to prestin (*upper*) and MAP1S (*lower*). As is evident, these two proteins are abundant in OHCs of the basal turn. Contrast in the *right* panel was increased post hoc to better show the expression of MAP1S and prestin. *C*, these findings were confirmed using quantitative immunofluorescence. OHCs from the most basal and apical portions of the mouse cochlea together with cells from the midpoint between these two extremes were tested for the expression of prestin and MAP1S. The mean fluorescence density (\pm S.E.) of MAP1S in the apical, mid, and basal hair cells are 88 (± 14 , $n = 6$), 183 (± 28 , $n = 12$), and 371 (± 48 , $n = 6$). Similarly, values for prestin are 257 (± 53 , $n = 6$), 744 (± 60 , $n = 12$), and 1723 (± 130 , $n = 6$). These quantitative data confirm a 7-fold increase in prestin expression and a 3.5-fold increase in MAP1S expression from the most apical to basal ends of the mouse cochlea.

OHCs from the three turns of the cochlea all revealed MAP1S. We then attempted to quantify the expression of MAP1S and prestin across the tonotopic axis using qPCR. As shown in Fig. 3, prestin mRNA expression is increased 1.2-fold in the middle turn compared with the 3rd turn and 2.8-fold in the basal turn

compared with the 3rd turn. In contrast, MAP1S expression is increased 7-fold in the middle turn compared with the third turn and 13-fold in the basal turn compared with the third turn.

We attempted to confirm our protein data using antibodies to these proteins in the guinea pig. However, because of poor antibody recognition of MAP1S in this species, we were unable to confirm or refute our qPCR data. We were able, however, to use mouse cochlea to confirm our PCR data from the guinea pig cochlea. As shown in Fig. 4, mouse OHCs demonstrate co-localization of these two proteins. Moreover, there is an apical to basal gradient in the expression of prestin and MAP1S. Thus, prestin showed a 7-fold increase in expression in the most basal hair cells, whereas MAP1S increased 3.5-fold in these cells compared with those from the apex.

In Vivo Interactions between MAP1S Are Confirmed by Immunoprecipitation—Although the interaction between prestin and MAP1S was suggested by the yeast two-hybrid experiments done under stringent conditions, it is widely believed that the yeast two-hybrid assay can be erroneous, yielding false positives from non-specific interactions. To confirm interactions between prestin and MAP1S, we performed a reciprocal immunoprecipitation using prestin and MAP1S in its entirety tagged with c-Myc and FLAG tags, respectively. FLAG-MAP1S was transfected into cells constitutively expressing prestin-YFP-c-Myc. Immunoprecipitation and wash steps were stringent and included high salt and detergent (0.05% Triton X-100). As shown in Fig. 5, prestin and MAP1S could reciprocally immunoprecipitate the other protein. Together with our showing interactions between prestin

and MAP1S using the yeast two-hybrid system, these data argue for a robust interaction between the two proteins. Interestingly, the form of MAP1S that was immunoprecipitated by prestin was the entire coding sequence and not the heavy chain, although there was evidence of the protein being cleaved into

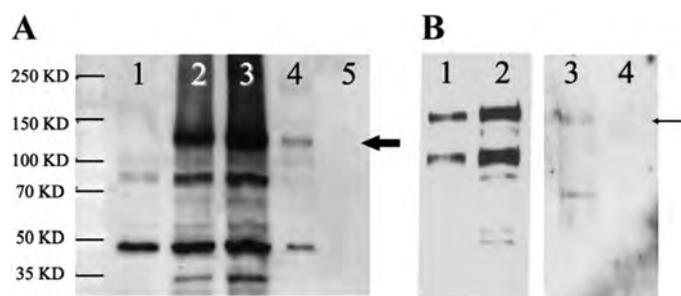

FIGURE 5. Reciprocal immunoprecipitations confirm the interaction between prestin and MAP1S. A permanent cell line expressing prestin-YFP-myc was transfected with FLAG-MAP1S-CFP. A, immunoprecipitations were performed with anti-FLAG (MAP1S) antibody and the presence of prestin in the immunoprecipitate detected on Western blots with anti-Myc antibody. Lanes 1–3 are control crude lysates of untransfected HEK cells, cells expressing prestin-YFP-myc, and cells expressing prestin-YFP-myc and FLAG-MAP1S-CFP, respectively. Lane 4 is an immunoprecipitate with FLAG antibody of lysates from HEK cells expressing prestin-YFP-myc together with FLAG-MAP1S-CFP. Prestin-YFP-myc is indicated by the thick arrow. Lane 5 is an anti-FLAG immunoprecipitate of HEK cells expressing prestin-YFP-myc. The absence of prestin in this lane confirms the specificity of the immunoprecipitating antibody. B, reciprocal experiment was performed to further confirm the interactions. Immunoprecipitation of cell lysates was done using anti-Myc antibody, and the presence of MAP1S in the immunoprecipitate was detected by Western blotting using anti-FLAG antibody. Lanes 1 and 2 are crude cell lysates of HEK cells expressing FLAG-MAP1S-CFP and HEK cells expressing prestin-YFP-myc together with FLAG-MAP1S-CFP, respectively. Lane 3 is the Myc immunoprecipitate of cells expressing prestin-YFP-myc and FLAG-MAP1S-CFP. FLAG-MAP1S-CFP is indicated by the thin arrow. Lane 4 is a Myc immunoprecipitate of cells expressing FLAG-MAP1S-CFP alone. The absence of prestin in lane 4 confirms the specificity of the immunoprecipitating Myc antibody. Although lanes 1–4 were separated on a single gel and transferred to the same blot, lanes 1 and 2 have been separated from lanes 3 and 4 in the figure for reasons of clarity. Lanes 1 and 2 are a shorter exposure and lanes 3 and 4 a longer exposure of the same blot. The experiments were repeated three times.

heavy and light chains in these cells. Consistent with these data, our yeast two-hybrid assay identified the interacting domain within MAP1S as restricted to an area between the heavy and light chains of the protein.

Physiological Interaction between MAP1S Confirmed by Förster Resonance Energy Transfer (FRET)—Our immunoprecipitation data strongly argue for an interaction between prestin and MAP1S. We next sought to determine that such an interaction took place *in vivo* (and prior to cell lysis in the immunoprecipitation assay). We chose to use FRET to demonstrate these interactions. Prestin and MAP1S were tagged at their C termini with YFP and cyan fluorescent protein (CFP). cDNA encoding these two fused proteins were inserted into an internal ribosome entry site vector and expressed in CHO cells. As evident in Fig. 6, cells transfected with this construct and expressing both these fused proteins show FRET. FRET efficiency was measured after acceptor photobleaching and showed values similar to what we have previously found in prestin-prestin interactions (15). FRET efficiency after photobleaching in Prestin-YFP/MAP1S-CFP was $2.8 (\pm 0.9 \text{ S.E.})$ and contrasts with $-36 (\pm 11 \text{ S.E.})$ in prestin-YFP/CFP. In contrast, the FRET efficiency of a construct in which CFP and YFP were in tandem separated by three amino acids was $35 (\pm 10 \text{ S.E.})$. These results argue that the distance between MAP1S and prestin is proximate to that between two molecules of prestin. These results also argue that interactions between prestin and MAP1S are likely physiological.

MAP1S Increases NLC—Having established a likely physiological interaction between prestin and MAP1S, we sought to ascertain if MAP1S affected prestin function. CHO cells were transfected with $0.8 \mu\text{g}$ of prestin and $0.8 \mu\text{g}$ of MAP1S fused to CFP per well in a 24-well plate. The control group was transfected with $0.8 \mu\text{g}$ of prestin and $0.8 \mu\text{g}$ of CFP. We assayed the physiological function of prestin by determining NLC in cells from these two groups. As shown in Fig. 7, cells transfected with prestin and MAP1S showed a 2.7-fold excess in NLC compared with cells that were transfected with prestin and CFP together. Prestin and MAP1S-transfected cells showed Q_{sp} of 6.38 fC/pF , which compared with 2.34 fC/pF in cells transfected with prestin and CFP alone (Table 1). In contrast, MAP1S did not affect other aspects of NLC function. Thus, cells transfected with prestin and MAP1S had mean V_h and z values of -120 mV and $0.63e$ and contrasted with values of -119 mV and $0.6e$ in cells transfected with prestin and CFP alone (Table 1). It should be noted that the Q_{sp} values obtained in these experiments were 50% of those that we normally achieve in CHO cells. Most likely, this results from the use of half the relative amount of prestin plasmid in each transfection that we normally use, necessitated by the need to co-transfect MAP1S at the same time.

MAP1S Increases Surface Expression of Prestin—Our data showing increased charge movement in the membrane of cells expressing MAP1S and prestin could be due to an increased number of molecules delivered to the membrane or as a result of an allosteric effect on each molecule at the surface of the cell. Our estimates of z , the charge carried by individual motors, were unchanged in cells transfected with prestin and MAP1S and argue against an allosteric effect. Rather our electrophysiological data argue for an increased number of motors delivered to the surface of the cell. To test this possibility, we assayed prestin expression in the membrane using a surface biotinylation assay. As shown in Fig. 8, there was a 2.8-fold increase in surface expression of prestin induced by MAP1S. This increase corresponded well with our electrophysiological findings that showed a 2.7-fold increase in specific charge, Q_{sp} . Because MAP1S binds tubulin, and because there is evidence that microtubule-associated mechanisms are important for surface expression of cell surface proteins, we sought to determine whether tubulin disruption affected prestin surface expression. In several experiments, cells were treated with and without $10 \mu\text{M}$ colchicine soon after transfection with prestin-YFP and $10 \mu\text{M}$ colchicine maintained in culture for 48 h. NLC in these cells was assayed at 48 h and showed no difference in the two groups (Table 2).

DISCUSSION

Our data show for the first time an interaction between prestin and MAP1S and evinces a physiological role for this interaction. The initial yeast two-hybrid data showing an interaction between these proteins are substantiated by the immunoprecipitation data. Subsequently, we demonstrate that the interaction is physiological with FRET, and electrophysiological recordings show an enhanced amount of prestin on the surface of the cell in the presence of MAP1S. The latter finding is further confirmed by biochemical means. Finally, we show that

MAP1S Interacts with Prestin

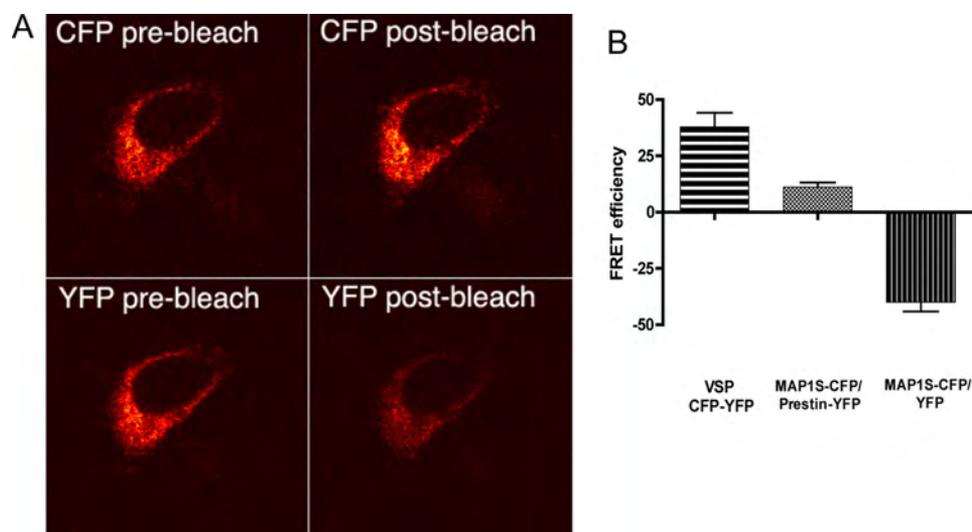

FIGURE 6. FRET experiments using acceptor photobleaching confirm *in vivo* interactions between prestin and MAP1S. *A*, photomicrographs of a CHO cell expressing prestin-YFP and MAP1S-CFP in an internal ribosome entry site vector are shown. The cell was excited with an argon laser at 458 nm, and the CFP emission in the bandwidth from 476 to 485 nm was recorded with a meta detector (upper two panels). The cell was also excited at 514 nm, and YFP emission at 536–545 nm was recorded (lower two panels). YFP was photobleached by continuous excitation at 514 nm for 1 min. Emission of CFP after photobleaching (right upper panel) shows an increase compared with CFP emission before photobleaching (left upper panel). In contrast, YFP emission (left lower panel) shows a decrease after photobleaching (right lower panel) compared with YFP emission before photobleaching (left lower panel). *B*, CFP FRET efficiency was measured after photobleaching as described previously (15). The MAP1S-CFP and prestin-YFP pair shows an increase in FRET efficiency after photobleaching (mean 11.02 ± 2.0 S.E., $n = 8$) and contrasts with MAP1S-CFP and YFP pair that shows a decrease in FRET efficiency (mean -40.0 ± 4.6 S.E., $n = 7$). Also included is a positive control that has CFP and YFP in tandem separated by one amino acid and fused to the C terminus of the membrane-spanning voltage-sensing phosphatase from *Nematostella vectensis*. This construct yielded higher FRET efficiency (mean 37.87 ± 6.26 S.E., $n = 4$).

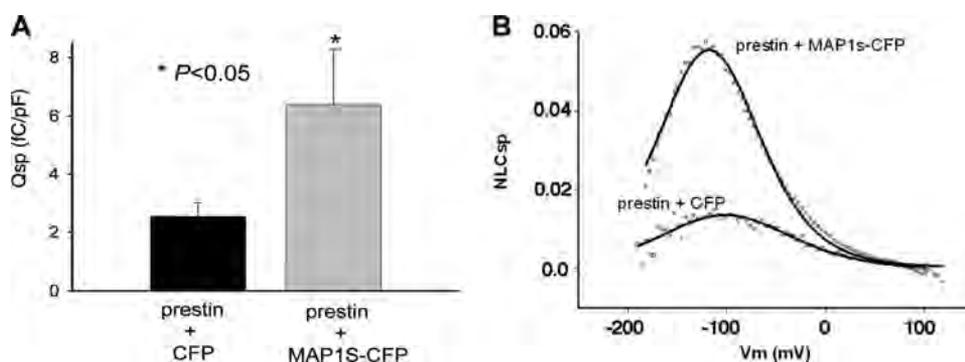

FIGURE 7. MAP1S increases Q_{sp} . *A*, CHO cells transiently transfected with prestin and MAP1S-CFP showed a statistically significant ($p < 0.05$, *t* test) increase in Q_{sp} (mean 6.38 ± 1.89 S.E.) compared with cells transfected with prestin and CFP (mean 2.34 ± 0.47 S.E.). *B*, shown are two representative NLC_{sp} (defined as NLC (pF)/linear capacitance (pF) to correct for effects of cell size) traces from two comparable cells transfected with the combination of plasmids prestin/CFP and prestin/MAP1S-CFP. There is a notable increase in peak NLC_{sp} in the cell transfected with the plasmid combination prestin/MAP1S-CFP compared with the plasmid combination prestin/CFP.

TABLE 1

MAP1S increases Q_{sp} but does not affect other measures of NLC (V_h and z)

Shown are values of NLC in cells transfected with the combination of plasmids prestin/MAP1S-CFP or prestin/CFP. Although Q_{sp} is significantly increased, both the voltage of peak capacitance (V_h) and estimates of the charge carried by a single motor z are comparable.

	Q_{sp}	V_h	z	n
	fC/pF	mV		
0.8 μ g of normal prestin + 0.8 μ g of CFP	2.34 ± 0.47	-119.29 ± 3.17	0.60 ± 0.02	11
0.8 μ g of normal prestin + 0.8 μ g of MAP1S-CFP	6.38 ± 1.89	-120.47 ± 3.61	0.63 ± 0.04	10

there is a gradient in the expression of prestin and MAP1S along the tonotopic axis. This gradient may partially explain the increase in charge density in high frequency OHCs.

Interaction between MAP1S and Prestin Is Restricted to Specific Regions of the Proteins

The interaction between these two proteins occurs in the region between the heavy and light chain in MAP1S and the proximal portion of the STAS domain in prestin. Although it is possible that interactions with prestin may extend into the loops connecting consecutive transmembrane domains, our current approaches limit our exploration of this possibility. To date there has been no evidence that the region between the heavy and light chain of MAP1S is involved in interactions with other proteins (22). Consistent with these results, our immunoprecipitation data show that prestin interacts with the holoprotein and not its component heavy and light chains. The cleavage site between the heavy and light chains of MAP1S lies in the region between them and coincides with the prestin-binding site (22). The light and heavy chains of the molecule have been shown to bind different elements of the cytoskeleton (22). Thus, the N terminus of the light chain binds tubulin, and the more C-terminally placed MH3 domain binds actin. In contrast, the heavy chain interferes with the interaction between the light chain and tubulin. In this respect, our data that show no effect on surface expression of prestin by colchicine is consistent with the result that prestin surface expression is mediated by the holo-

protein, which does not interact with tubulin.

Other data from the yeast two-hybrid experiments show that amino acids involving the STAS domain of prestin are involved in the interaction with MAP1S. Specifically, the sequence extends across the first three β -strands, the first α -helix, and the intervening IVS region of the purported STAS domain in prestin determined by molecular modeling (22, 23). The STAS domain resembles the bacterial SPOIIAA transcription factor, the crystal and NMR structure of which has been determined (24, 25). The SPOIIAA transcription factor is involved in protein-protein interactions with the anti- σ factor SPOIIB. Bind-

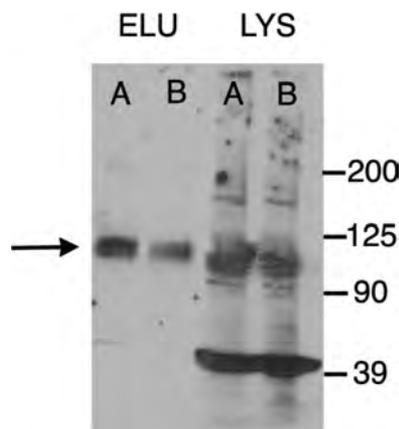

FIGURE 8. MAP1S increases surface expression of prestin. CHO cells were transfected with prestin/MAP1S CFP and separately prestin/CFP plasmids. Proteins on the surface of the cell were labeled with sulfo-succinimidyl-2-(biotinamido)ethyl-1,3-dithiopropionate and isolated using a Neutravidin resin. The surface proteins were eluted using 50 mM dithiothreitol and separated by SDS-PAGE, and the presence of prestin was detected by Western blotting (left two lanes). The amount of surface protein loaded in each lane has been normalized to the total protein in the cell lysate. As is evident, cells expressing prestin and MAP1S-CFP (A) demonstrate an increase (2.8-fold \pm 0.9 S.E., $n = 4$) in surface expression of prestin when compared with cells expressing prestin and CFP (B). The comparable expressions of prestin in the corresponding cell lysates are shown in the two right lanes confirming that the total amounts of prestin in these cells were equivalent. The prestin band is shown by an arrow. The numerous other bands in the lysates (for example, the band at 39 kDa) are nonspecific and detected in untransfected HEK cells probed with the secondary antibody alone (data not shown). ELU, eluate; LYS, lysate.

TABLE 2

Colchicine has no effect on the Q_{sp}

The table shows the effects of treating cells with 10 μ M colchicine for 48 h after transfection. Measures of NLC, including Q_{sp} , V_h , and z , were unchanged by treatment with this drug. It should be noted that because treatment with this drug is cytotoxic, we incorporated in our data analysis only those cells that showed good seal resistance, using it as a surrogate marker for the well being of cells.

	Q_{sp}	V_h	z	n
	fC/pF	mV		
Prestin	7.35 ± 0.42	-110.03 ± 3.00	0.71 ± 0.02	5
Prestin + 10 μ M colchicine	7.33 ± 1.88	-107.70 ± 10.24	0.69 ± 0.03	5

ing of these two proteins results in σ factor release from SPOIIB, which in turn triggers transcription (26–28). Mutations within the STAS domain of SLC26A2, SLC26A3, and SLC26A4 and the *Arabidopsis thaliana* sulfate transporter Sultr 1.2 have been shown to alter anion transport function (29–34). Moreover, the STAS domain in SLC26A3 also interacts with cystic fibrosis transmembrane regulator, and this interaction reciprocally modulates cystic fibrosis transmembrane regulator channel function as well as SLC26A3 transporter function (35). In contrast, cystic fibrosis transmembrane regulator interacts with the STAS domain of SLC26A9 and inhibits Cl^- currents as well as its Cl^- - HCO_3^- exchange (36). Given these data, it was our expectation that MAP1S would modulate NLC. However, we did not note an alteration in measures of prestin “kinetics.” Both V_h and z , reflecting the steady state energy profile and unitary charge movement, were unchanged in cells co-transfected with MAP1S. In contrast, we noted increased delivery of prestin to the surface of the cell. Several mutations in the STAS domain resulted in altered delivery of SLC26A3, a related protein, to the surface of the cell (32). Taken together, these data suggest that modulation of the

STAS domain may affect surface delivery of SLC26 proteins (prestin), in addition to affecting the kinetics of the protein (SLC26A3). Efforts are currently underway in our laboratory to determine how MAP1S affects prestin anion transport (37), especially given the data that mutations in the STAS domain have been shown to affect anion transport in members of the SLC26 family of proteins. Furthermore, given the sequence homology in this region between the different members of the SLC26 family of proteins, and the ubiquitous distribution of MAP1S, we would anticipate that these anion transporters also will interact with MAP1S (38). In this regard, the yeast two-hybrid experiments identifying residues 491–572, which is conserved between prestin and other SLC26 members, could suggest homologous regions from other SLC26 members as also interacting with MAP1S. In contrast, it is possible that residues 573–660, which has little homology in other SLC26 family members, confers specificity to the interactions with prestin.

Increase in Q_{sp} Is Likely Brought About by Increased Amounts of Prestin on the Surface of the Cell—As noted above, our data on measures of NLC show that MAP1S affects Q_{sp} but not other measures of NLC, including z and V_h . Theoretically, Q_{sp} could be increased by increasing the number of functional motors in the membrane or by increasing the net charge carried by each motor. However, given that z , our best estimate of charge carried by an individual motor, was unchanged in the presence of MAP1S, it is most likely that the number of motors delivered to the surface is increased. This conclusion is borne out by our determination of surface expression of prestin in the presence and absence of MAP1S. The biotinylation assay revealed a 2.8-fold increase in surface expression of prestin that compared with a 2.7-fold increase in Q_{sp} . Thus, there was good concordance between our biochemical assays of surface expression and electrophysiological determination of surface expression. How is this increase in surface expression brought about? Three possibilities are suggested as follows: increased delivery of newly synthesized protein to the surface, decreased degradation of the protein, or increased recycling of the protein that is endocytosed from the surface. Although we have no experimental data to discern these possibilities at present, we expect that MAP1S will likely deliver more newly synthesized protein to the surface. Previous experiments in our laboratory indicate that turnover rates of prestin may be slow; in the presence of brefeldin A, a blocker of newly synthesized protein delivery into the surface membrane, OHCs in culture maintained robust NLC for up to 7 days.⁶

MAP1S has been shown to interact with the NR3A *N*-methyl-D-aspartic acid receptor subunit, the fibroblast growth factor-associated protein LRPPRC, the tumor suppressor protein RASSF1A, and the sperm protein VCY2 that has been implicated in azoospermia (39–43). However, in all these instances there were no clearly observed consequences of the interactions. Thus, the functional effect of MAP1S on prestin expression appears to be the first direct demonstration of any functional effect by MAP1S. In the case of the NR3A receptor and MAP1S, there was sharp co-localization of the two proteins in

⁶ E. Navarrete and J. Santos-Sacchi, unpublished data.

MAP1S Interacts with Prestin

dendritic spines that led the authors to speculate that MAP1S was important for localizing NR3A receptors to dendritic spines (41). However, there were no direct tests of this possibility. In the related MAP1B protein, early data suggested that MAP1B was important for targeting γ -aminobutyric acid type C receptors to specific subcellular locales (44). These two proteins co-localize in retinal bipolar cells (44). Heterologous expression of the two proteins in COS cells resulted in an altered distribution of the γ -aminobutyric acid type C receptor. However, subsequent MAP1B knock-out experiments were confounding with normal γ -aminobutyric acid type C clustering in bipolar cells (45).

There are a number of reports suggesting a role for the microtubule-associated motors in directing organelles and proteins to subcellular sites, including dendritic shafts (46–48). Given the known associations between MAP1S and tubulin, an obvious mechanism for prestin delivery to the surface of the cell would be through its association via MAP1S with microtubules and their motors. However, we show that continued disruption of microtubules (after transfection) with 10 μ M colchicine had no effect on Q_{sp} .

Interactions between Prestin and MAP1S Likely Has Physiological Significance—Our data showing a graded tonotopic expression of prestin and MAP1S have bearing on physiological findings in the cochlea. Prior work has compared Q_{sp} in guinea pig OHCs isolated from regions along the tonotopic axis and found an ~5–6-fold increase in Q_{sp} in the lateral membrane of OHC responding to high frequency sound compared with OHC responding to low frequency sound (13). However, prestin mRNA expression increases 1.2-fold from the 3rd turn to the 2nd turn and 2.8-fold from the third turn to the basal turn. Thus, the prestin expression increase in high frequency cells is less than the increase in Q_{sp} . Whether the even greater increase in MAP1S expression that we find contributes to the excess increase in Q_{sp} remains to be investigated. In the mouse where physiological data are unavailable, but antibodies to MAP1S and prestin are available, there is a 7-fold increase in prestin protein expression from the most apical to the most basal hair cells. Similarly, there is also a smaller 3.5-fold increase in protein expression of MAP1S. This is an important issue, because the increase in Q_{sp} in high frequency cells has been proposed to be a mechanism that provides a constant electrical energy to these cells, which may help circumvent the low pass filter effects of the cell membrane (13).

In conclusion, we show for the first time an interaction between prestin and the microtubule-associated protein MAP1S. The interaction is confirmed by immunoprecipitation and FRET. Our data from FRET suggest that the relative distance between MAP1S and prestin is proximate to the distances between two molecules of prestin. The interaction results in an increased amount of prestin on the surface of the cell that accounts for the increase in Q_{sp} brought about by MAP1S. We demonstrate the presence of MAP1S in individual OHCs and confirm a gradient in the expression of prestin and MAP1S along the tonotopic axis. This gradient of both proteins could explain the increase in charge movement density (Q_{sp}) seen in OHCs from higher frequencies.

Acknowledgment—We thank Dr. Fritz Probst for the MAP1S constructs and for critical reading of this manuscript.

ABSTRACT Prestin is a member of the SLC26 family of anion transporters and is responsible for electromotility in outer hair cells, the basis of cochlear amplification in mammals. It is an anion transporting transmembrane protein, possessing nine cysteine residues, which generates voltage-dependent charge movement. We determine the role these cysteine residues play in the voltage sensing capabilities of prestin. Mutations of any single cysteine residue had little or no effect on charge movement. However, using combinatorial substitution mutants, we identified a cysteine residue pair (C415 and either C192 or C196) whose mutation reduced or eliminated charge movement. Furthermore, we show biochemically that surface expression of mutants with markedly reduced functionality can be near normal; however, we identify two monomers of the protein on the surface of the cell, the larger of which correlates with surface charge movement. Because we showed previously by Förster resonance energy transfer that monomer interactions are required for charge movement, we tested whether disulfide interactions were required for dimerization. Using Western blots to detect oligomerization of the protein in which variable numbers of cysteines up to and including all nine cysteine residues were mutated, we show that disulfide bond formation is not essential for dimer formation. Taken together, we believe these data indicate that intramembranous cysteines are constrained, possibly via disulfide bond formation, to ensure structural features of prestin required for normal voltage sensing and mechanical activity.

INTRODUCTION

Prestin (SLC26A5) is a member of the SLC26 family of anion transporters (1). It is now well established that this protein is responsible for electromotility in mammalian outer hair cells (OHC), which are believed to be responsible for cochlear amplification (2–5). Prestin is a membrane protein of 744 amino acids (1). A large central core of the protein is predicted to traverse the membrane multiple times based on hydrophobicity analysis (1,6). The number of predicted transmembrane regions varies (10 or 12), and is dependent on the different prediction paradigms (1,6–8). It also has a small N-terminus and a larger C-terminus that are thought to be intracellular (6,9). Prestin has piezoelectric properties; membrane voltage controls its conformation (10–13). Its voltage sensitivity arises from voltage sensor charge movement within the membrane that can be measured as a nonlinear capacitance (NLC) (14–16).

Prestin contains nine cysteine residues (1). Of these nine residues, six (C192, C196, C260, C381, C395, and C415) lie in areas that are potential transmembrane regions (1,6,7). Of the remaining three, two (C52 and C679) are located in the intracellular N- and C-termini, respectively, whereas the remaining cysteine (C124) residue lies in a loop connecting two potential transmembrane regions (Fig. 1). Cysteine residues, because of their ability to form disulfide bonds, can play a number of roles in a protein's function (17,18).

Disulfide bond formation is a covalent posttranslational modification that occurs concurrent with translation. Disulfide bonds can be structural, catalytic, or allosteric (17–19). Structural bonds stabilize the structure of the protein by decreasing the entropy of the unfolded (denatured) protein (18). Catalytic disulfide bonds help in catalyzing enzyme reactions. The best known of these is found in oxidoreductases where a catalytic disulfide bond is found in its thioredoxin-like fold. Allosteric disulfide bonds, in contrast, modulate a protein's function (19). Cleavage of allosteric disulfide bonds results in a change in the protein's tertiary or quaternary structure and its function (19).

Tests for disulfide bond formation often involve functional assays of proteins, for example, membrane transport (20). In native OHCs, measures of NLC or mechanical activity have been used (21,22). Preliminary exploration of disulfide bonds in the structure and function of prestin has provided a number of insights. It has been reported that mutation of individual cysteine residues did not adversely affect its charge movement (23,24). Other work has implicated disulfide bonds formed by one or more cysteine residues in the transmembrane regions of prestin as important for dimerization of the protein (25). Here, we systematically mutated cysteine residues individually and in combination, and then determined how mutations affect characteristics of NLC (see **Materials and Methods**). These characteristics include the density of voltage sensor charge (Q_{sp}), the voltage at peak capacitance (V_h), and unitary charge valence (z). Q_{sp} is an estimate of functional motors within a unit membrane surface area, V_h is a metric of the steady-state

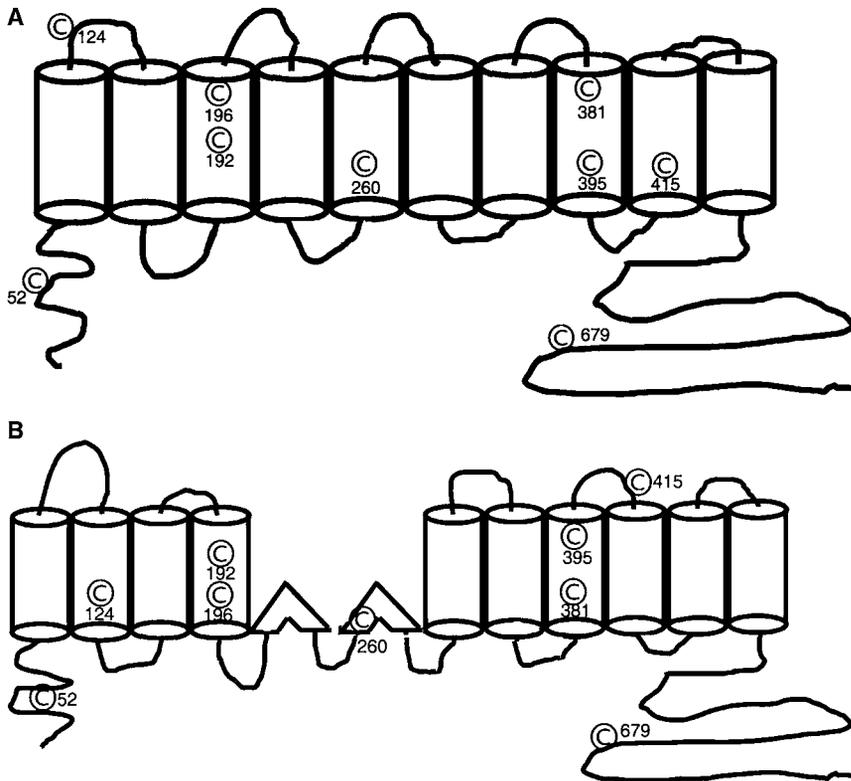

FIGURE 1 Nine cysteine residues are distributed throughout the protein. A cartoon of the two different transmembrane models are shown along with the position of individual cysteine residues in these two models. (A) Ten transmembrane model. (B) Twelve transmembrane model. Six of these residues (C192, C196, C260, C381, C395, C415) lie within hydrophobic transmembrane regions of the protein. Two residues (C52 and C679) lie in the predicted intracellular amino and carboxy termini of the protein, respectively, and the last residue (C124) lies in a loop connecting two transmembrane regions in the 10 transmembrane model.

energy profile, and z is an estimate of charge moved within an individual motor. We also explored the role of these cysteine residues in the formation of prestin multimers. Our data show that mutation of individual cysteine residues has little or no effect on the function of prestin. However, our combinatorial data show profound changes in the function of prestin, providing evidence that cysteine residues (namely, C415 and either C192 or C196) in prestin potentially form disulfide bonds. Finally, we show that disulfide bond formation is not necessary for the formation of prestin multimers.

MATERIALS AND METHODS

cDNA constructs and generation of mutants

Single or multiple amino acid substitutions were generated using QuickChange II or QuickChange II Multi site-directed mutagenesis kits (Stratagene, La Jolla, CA) with a gerbil prestin-YFP in pEYFPN1 vector (Clontech, Mountain View, CA) as a template. All mutations were confirmed by DNA sequencing, including the entire coding region.

Transient transfections in Chinese hamster ovary cells

For electrophysiological recordings 100,000 Chinese hamster ovary (CHO) cells were transfected in 24-well plates with the cysteine mutants using Lipofectamine (Invitrogen, Carlsbad, CA) as described previously (7).

Electrophysiological recording

Cells were recorded by whole-cell patch clamp configuration at room temperature using an Axon 200B amplifier (Axon Instruments, Sunnyvale,

CA), as described previously (7). Cells were recorded 24–48 h after transfection to allow for stable measurement of NLC. Ionic blocking solutions were used to isolate capacitive currents. The bath solution contained (in mM): TEA 20, CsCl 20, CoCl₂ 2, MgCl₂ 1.47, Hepes 10, NaCl 99.2, CaCl₂·2H₂O 2, pH 7.2, and the pipette solution contained (in mM): CsCl 140, EGTA 10, MgCl₂ 2, Hepes 10, pH 7.2. Osmolarity was adjusted to 300 ± 2 mOsm with dextrose. Command delivery and data collections were carried out with a Windows-based whole-cell voltage clamp program, jClamp (Sciosoft, Ridgefield, CT), using a Digidata 1322A interface (Axon Instruments).

Capacitance was evaluated using a continuous high-resolution 2-sine wave technique, fully described elsewhere (26,27). Capacitance data were fitted to the first derivative of a two-state Boltzmann function (16):

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}},$$

where

$$b = \exp\left(\frac{-ze(V - V_{\text{pkCm}})}{kT}\right).$$

Q_{\max} is the maximum nonlinear charge transfer, V_h the voltage at peak capacitance or half-maximal nonlinear charge transfer, V_m the membrane potential, C_{lin} linear capacitance, z the valence (a metric of voltage sensitivity), e the electron charge, k the Boltzmann constant, and T the absolute temperature. Q_{\max} is reported as Q_{sp} the specific charge density, i.e., total charge moved normalized to linear capacitance. Where necessary we increased the range of voltage commands to test mutants in which V_h was extreme. A Student's t -test was used to evaluate the effects of mutants on the different parameters of NLC. In mutants where Q_{sp} was immeasurable, namely zero, we state, for presentation purposes, that the significance of differences with prestin that had NLC was <0.01 , although the probability of a difference between these data would be infinitely small.

It should be noted that measures of Q_{sp} , V_h , and z in CHO cells are in line with our previous work. Measures of Q_{sp} in CHO cells are in the lower range

of that recorded in HEK cells. However, V_h in CHO cells (-120 to -100 mV) is significantly negative compared to prestin expressed in HEK cells (-50 to -70 mV).

Western blots

Crude lysates were generated from transiently transfected CHO cells after 24–48 h. Lysates were separated on a precast 4–15% Tris-HCl SDS-PAGE gel (Bio-Rad, Hercules, CA) or a 5–8% urea-SDS PAGE containing 6 M urea. Samples were incubated with and without reducing agents where indicated. Two reducing agents, β -mercaptoethanol and ethanedithiol (EDT), were added to the samples at final concentrations of 200 mM and 600 mM, respectively. Proteins were transferred by wet transfer to polyvinylidene fluoride membrane (Roche, Indianapolis, IN). Western blots were probed with anti-prestin-N20 (Santa Cruz, Santa Cruz, CA) at a 1:500 dilution and then with horseradish peroxidase (HRP) conjugated bovine anti-goat secondary antibody (Santa Cruz) at 1:5000 dilution with TBST washing ($\times 5$) in between. The presence of HRP conjugated antibody was detected using SuperSignal West Dura Extended Duration Substrate (ThermoScientific/Pierce, Rockford, IL). Where indicated, the blots were stripped using Restore plus Western stripping buffer and reprobed with prestin C-16 antibody (Santa Cruz) at a 1:500 dilution and HRP conjugated bovine anti-goat secondary antibody at a 1:5000 dilution.

Prestin surface expression

Surface expression of prestin was determined using a surface biotinylation assay (ThermoScientific/Pierce). Transiently transfected CHO cells were analyzed 24 h after transfection. These cells were washed with PBS, and incubated in the presence of sulfo-NHS-biotin for 30 min at 4°C. Free sulfo-NHS-biotin was quenched by washing cells in 140 mM Tris-Cl, and the cells lysed in lysis buffer containing (mM): Tris 20, pH 8.0, NaCl 137, NaEDTA 5, NaEGTA 5, 10% glycerol, 0.5% Triton X-100, PMSF 0.2, NaF 50, benzamidine 20. The lysates were cleared by centrifugation, and its protein concentration assayed (Bio-Rad) and equalized. Streptavidin agarose was added in the mixtures, incubated 1 h at room temperature with constant agitation. After centrifugation at $1000 \times g$ the beads were washed with washing buffer. The bound surface proteins were released by addition of 50 mM dithiothreitol and analyzed by SDS-PAGE and Western blotting as described above. In several experiments we also sorted cells by fluorescent activated cell sorting and determined that there was no consistent difference in transfection efficiency between different mutants. Similarly, there was no difference in the ratio between the upper to lower monomer within a given mutant irrespective of whether or not cells were sorted before labeling of cell surface proteins.

RESULTS

Substitution of single cysteine residues did not abolish NLC

To ascertain which cysteine residues are important for the structure and function of prestin, we substituted each of the nine individual cysteine residues with a serine residue. We reasoned that substituting cysteine with a serine residue, which has the identical side chain length (thereby minimizing confounding effects from side chain interactions), was a good method to determine the role of disulfide bonds in the function of the protein. NLC characteristics of three single point cysteine mutations differed significantly from wild-type prestin (Table 1). These were C415S which had a significant change in Q_{sp} (2.45 ± 0.81 fC/pF vs. 7.88 ± 1.26 fC/pF),

TABLE 1 Mean NLC parameters of single cysteine to serine mutations and number of cells recorded for each mutant

Single mutants	NLC parameter			n
	Q_{sp}	V_h	z	
Wild-type prestin	7.88 ± 1.26	-111.30 ± 2.94	0.72 ± 0.01	25
C52S	6.49 ± 0.92	-111.03 ± 4.31	0.70 ± 0.05	5
C124S	10.18 ± 4.03	-111.05 ± 4.30	0.68 ± 0.03	6
C192S	5.87 ± 0.74	-109.72 ± 6.41	0.70 ± 0.02	6
C196S	6.50 ± 1.00	$-130.14 \pm 3.22^*$	0.68 ± 0.01	8
C260S	4.16 ± 0.49	-110.11 ± 5.43	0.68 ± 0.05	4
C381S	8.72 ± 1.06	-97.07 ± 7.39	0.66 ± 0.03	5
C395S	5.37 ± 0.82	$-58.51 \pm 4.68^*$	0.66 ± 0.03	7
C415S	$2.45 \pm 0.81^*$	-117.11 ± 9.47	0.71 ± 0.06	7
C679S	7.64 ± 1.54	-107.78 ± 9.57	0.73 ± 0.03	5

Values that show statistically significant differences from wild-type prestin are indicated.

and C196S and C395S that had changes in V_h (-130.14 ± 3.22 mV and -58.51 ± 4.68 mV, respectively, versus -111.30 ± 2.94 mV in control).

Substitution of two or more cysteine residues does not alter prestin surface expression, but rather folding of monomers with adverse affects on Q_{sp}

Our data that mutations of individual cysteine residues do not eliminate NLC suggest several possibilities. First, there may be no disulfide bonds. Second, disulfide bonds are not crucial for the generation of NLC. Third, one disulfide bond is able to compensate for the loss of another disulfide bond. Our experiments thus far are unable to rule out the first two possibilities. Attempts in our lab to purify adequate amounts of prestin expressed in mammalian expression systems for analysis by mass spectrometry have not been successful. To test the third possibility, we mutated cysteine residues in varying combinations and determined their effects on NLC (Fig. 2 and Table 2). These data show that mutation of more than one cysteine residue in the nontransmembrane regions had no effect on NLC. Thus, the combination of mutations C52S, C124S, and C679S has preserved NLC (namely, no significant changes in Q_{sp} , and z, although there were some significant effects on V_h). In contrast, several combinations of two or more transmembrane cysteine mutations could abolish NLC.

Two opposing transmembrane models for prestin exist for which structural data are of insufficient resolution to choose between (6–8,28). Interestingly, our observations on transmembrane cysteine mutations might help to choose between models, because the 10- and 12-transmembrane models predict potential physical approximations of different cysteine residues, with the implication that they could more likely form disulfide bonds (Fig. 1). An attempt to rationalize our

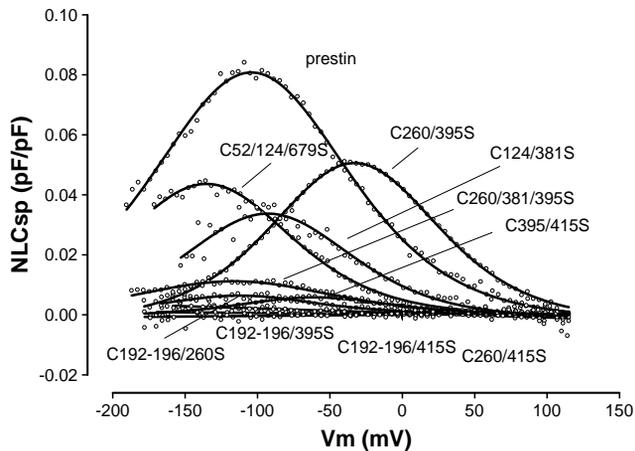

FIGURE 2 Representative NLC traces of wild-type prestin and several combinatorial cysteine mutants. These individual combinations are representative of the variable effects on different aspects of NLC produced by these mutants. Only select combinations were able to markedly reduce NLC (see text and Table 2 for details).

data given the constraints of either model was not definitive, however, and we expect that higher resolution structural studies will be needed to answer this question.

We also used our mutational data to model the formation of disulfide bonds removed from the spatial constraints of the two transmembrane models. Thus, the combinations C260S/C415S and C192S–C196S/C395S that both lost NLC raised the possibility that residue C260 could form a disulfide bond with C192–C196 or C395, and C415 form a second disulfide bond with the remaining cysteine residue (either C192–C196 or C395). To test this hypothesis we made the following combination of mutants: C260S/C395S, C395S/C415S, C192S–C196S/C260S and C192S–196S/C415S. Of these combinations, only the latter abolished NLC. This result is consistent with the possible formation of disulfide bonds between C415 and C395, and separately C192–C196 and C260. However, the preserved NLC in C260S/C395S (and reduced NLC in C192S–C196S/260S, and separately, C395S/C415S) rules out this possibility.

We reasoned that the loss of NLC in prestin mutants could result from inadequate surface expression of the mutated protein, subtle alterations in structure in a protein adequately expressed on the surface of the cell, or a combination thereof. We used a surface biotinylation assay to determine surface expression of prestin in wt prestin and several mutants that showed variation in Q_{sp} . In this procedure, prestin or individual mutants of prestin were expressed transiently in CHO cells, and surface proteins labeled using Sulfo-NHS-SS-Biotin, a cell impermeable cleavable biotinylation reagent. Surface labeled proteins were isolated from the lysed cells and the presence of prestin detected by Western blot (Fig. 3). Wild-type prestin contained dimeric protein and two forms of monomeric protein with the larger form of the monomer dominating. In contrast, all the mutants that had reduced Q_{sp}

showed both monomers with the smaller form dominating in those mutants where Q_{sp} was most decreased. Indeed, in mutants that lacked NLC there was a profound decrease in the larger monomeric form. Moreover, there was a linear relationship between Q_{sp} of individual mutants and their respective ratios of the upper monomeric form to the lower monomeric form (Fig. 3). Both monomers were detected with antibodies to the N-terminus of prestin and after stripping and reprobing with antibodies to the C-terminus of prestin (data not shown), suggesting that the smaller form of the protein was misfolded, not truncated. Importantly, when we used fluorescence activated cell sorting to isolate transfected cells we noted no difference in prestin expression determined by YFP fluorescence between mutants with reduced or absent NLC and wt-prestin (data not shown). Moreover, there were similar levels of prestin expression on the membrane of mutants with reduced NLC (Fig. 3). The remarkable difference in these mutants, as noted above, was that they predominantly expressed the smaller monomer. Together these data suggest a subtle misfolding of the protein, but not inadequate surface expression, as a cause for reduced Q_{sp} in these mutants.

Line scan maps suggest the presence of three dimers (potentially from upper monomer–upper monomer, upper monomer–lower monomer, and lower monomer–lower monomer). However, although there was an impression that the ratio of the three different dimers in the different mutants related to that of the two monomers, the gels had insufficient resolution to consistently separate the different bands with three distinct peaks. We are therefore unable to quantify the expression of different prestin dimers and their relationship to Q_{sp} . This is unfortunate because other work indicates that dimers form the functional motor subunit of the protein (7,29).

Cysteine 192 substitutes for cysteine 196, suggesting the formation of disulfide bonds

The two residues C192 and C196 lie in an α helix and would therefore be predicted to lie in close proximity to one another in 3D space. We therefore hypothesized that C192 could substitute for C196 (and vice-versa) in forming disulfide bonds. NLC in C192S/C395S and C196S/C395S mutants (as pointed out above C192S–C196S/C395S lacked NLC) was assayed. As shown in Fig. 4, mutation of C395S with either C192S or C196S resulted in a recovery in NLC. Similarly, there was recovery of NLC when C381S was mutated with either C192S or C196S; in contrast, C381S/C192S–C196S had severely decreased NLC (Table 2). In keeping with this pattern, two other combinations of mutants (C192S–C196S/C260S and C192S–C196S/C415S) that had reduced or absent NLC, showed recovery in Q_{sp} when mutated with either C192 or C196, alone. Thus C192S/C260S, C196S/C260S, C192S/C415S, C196S/C415S all restored Q_{sp} (Fig. 4). We interpret these data to signify the formation of disulfide bonds by either C192 or C196. C192S–C196S was the only mutant that showed significant

TABLE 2 Mean NLC parameters of the different combinatorial cysteine mutants and number of cells recorded for each mutant

Mutants	NLC parameter			<i>n</i>

In mutants where the percentage of transfected cells that showed NLC was <90%, the fraction of cells with demonstrable NLC is shown. Values that show statistically significant differences from wild-type prestin are indicated. Because z the estimated charge carried by a single motor is not significantly changed, the reduction in Q_{sp} (representing the total charge carried by all the motors per unit area of membrane) suggests that the total number of functional motors on the surface is reduced.

* $p < 0.05$.

[†] $p < 0.01$.

alteration in Q_{sp} , V_h , and z . Moreover, any combinatorial mutation that included C192S–C196S showed absent or significantly reduced Q_{sp} . These data reinforce our conclusion that either residue C192 or C196 forms a disulfide bond.

Cysteine 415 likely forms a disulfide bond

The only single cysteine mutation that resulted in a significant reduction in Q_{sp} was C415S. In this regard, C415S was similar to the single mutation equivalent of C192S–C196S, and suggested that C415 should be as influential as the C192–C196 pair. As suspected, mutation of C415S in combination with another cysteine residue posited to lie within the transmembrane segments also resulted in a loss or near loss of NLC. These include C192S–C196S/C415S, C260S/C415S, C381S/C415S (abolished NLC), and C395S/C415S (greatly reduced NLC). One possibility was that C415 formed a disulfide bond that was critical in maintaining tertiary structure of the protein important for generating NLC. Alternatively, because disulfide bonded cysteine resi-

dues are sterically constrained by the bond, in contrast to the side chain of an unbonded serine residue, we hypothesized that changes in NLC were because the more freely mobile serine residue interfered with prestin function. To test this possibility we mutated C415 to alanine, which has a shorter side chain and would be predicted to minimally disrupt secondary structure, and tested NLC of this mutant. Additionally, C415A was mutated in combination with each of the following substitutions: C192S–C196S, C260S, C381S, and C395S. The C415A mutant alone or in combination with the other cysteine mutations resulted in significant NLC (Fig. 5). Taken together these data argue that C415 forms a disulfide bond.

Substitution of all nine cysteine residues did not hinder dimerization of the protein

Our data suggest that cysteine residues are important for the generation of NLC. In addition, there is compelling indirect evidence that cysteine residues in prestin form disulfide

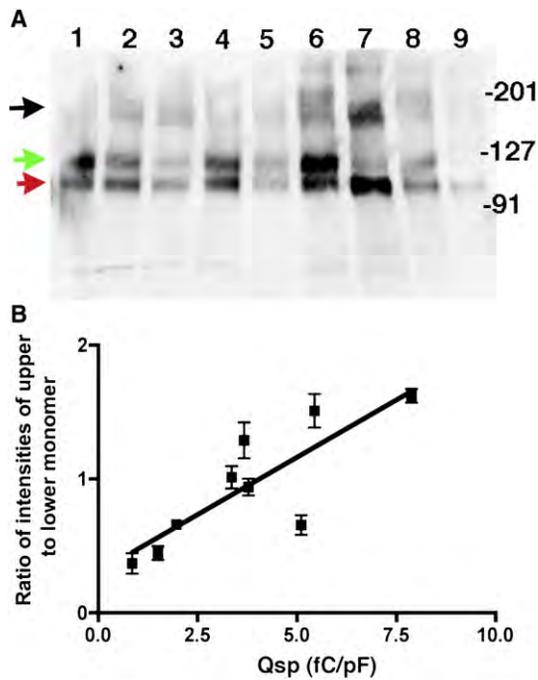

FIGURE 3 Prestin and nonfunctional cysteine mutants of prestin are expressed on the surface of the cell. (A) To ascertain if mutations in cysteine residues allowed surface expression, we assayed prestin expressed on the surface of the cell using a surface biotinylation assay. CHO cells were transiently transfected with prestin-YFP constructs. Plasma membrane proteins in these cells were labeled using the cell impermeable amino reactive agent, Sulfo-NHS-SS-Biotin. Surface proteins were isolated using avidin Sepharose beads and the avidin bound protein released by cleavage with dithiothreitol. The released surface proteins were separated by SDS-PAGE and the presence of prestin detected by Western blots using an antibody to an epitope in prestin's N-terminus (and separately to its C-terminus; data not shown). The total protein loaded on each column was the same. The lanes from left to right along with their respective Q_{sp} values and ratios of upper to lower monomer intensities \pm SE ($n = 3$) are: 1), wt-prestin (7.88 fC/pF; 1.62 ± 0.09); 2), C192S/C381S (5.11 fC/pF; 0.67 ± 0.12); 3), C192S/C196S (1.97 fC/pF, 0.66 ± 0.04); 4), C260S/C381S (3.36 fC/pF, 1.01 ± 0.14); 5), C192S/ C260S (3.78 fC/pF, 0.94 ± 0.1); 6), C260S/C395S (5.44 fC/pF, 1.51 ± 0.22); 7), C395S/C415S (0.86 fC/pF, 0.37 ± 0.13); 8), C395S/C415A (3.67 fC/pF, 1.28 ± 0.23), and 9), C192S/C196S/C260S (1.5 fC/pF, 0.447 ± 0.09). The positions of the molecular weight markers are indicated on the right. As is evident, there are two monomeric forms of prestin-YFP at ~ 120 kD in wild-type prestin and the multiple cysteine mutants, although the relative proportions between the two monomeric forms varied in the different cysteine mutants. The upper functional monomer is indicated by a green arrow, whereas the lower nonfunctional monomer is indicated by the red arrow. Prestin dimers shown in black (at ~ 250 kD) were present in all the mutants. Furthermore, the total amount of prestin monomers and dimers on the surface of the cell were similar, suggesting that there were no deficiencies in trafficking to the surface. (B) Plot of the relationship between Q_{sp} of individual mutants and the ratio between the upper and lower monomers. The intensities of the different bands were quantified using a BioRad ChemiDoc XRS imaging system. The ratios represent the average of three experiments.

bonds. Given the importance of multimerization in prestin function (7), we then sought to determine if any of these cysteine residues were important in multimerization of the protein. Work by Zheng et al. (25) showed that the addition

of the hydrophobic reducing agent EDT resulted in a reduction in the amount of dimeric prestin relative to its monomeric form. Data hitherto mutating several cysteine residues in combination had no effect on dimerization (Fig. 3). We also assayed dimerization in prestin-YFP in which all nine cysteine residues were mutated to serine (ALL9). Cell lysates from this mutant and from wt-prestin-YFP were separated by SDS-PAGE. Prestin was detected by Western blotting using an antibody to its N terminus (Fig. 6). Two features of the mutant were evident. First, dimers of prestin were evident in both wt-prestin as well as prestin in which all nine cysteine residues were mutated. Second, removal of all nine cysteine residues resulted in a notable apparent reduction in molecular weight of prestin monomers (and dimers). Because disulfide bonds were not necessary for prestin dimerization we then separated the protein using Urea-SDS gels, attempting to disrupt potential hydrophobic interactions between monomers of the protein. As is evident in Fig. 6 this approach also failed to disrupt dimer formation. Unexpectedly, monomers of prestin were seen to separate into several closely interspersed discrete bands. These bands were detected on Western blots using antibodies to the N-terminus of prestin, and after stripping and reprobing with antibodies to YFP (because YFP was fused to the C-terminus of prestin), suggesting that the smaller forms of prestin were not due to significant proteolytic cleavage (data not shown). Finally, we note that higher multimers of prestin are likely not detected because we did not boil our preparations before running gels.

DISCUSSION

Prestin is a protein that underlies cochlea amplification, in turn responsible for the high sensitivity of mammalian hearing (2,4). It is an anion transporter (SLC26a5) that is voltage-dependent, as well (14). Intrinsic charged residues are displaced during membrane voltage perturbations to effect conformational changes that drive a robust somatic motility that provides a boost in signal to the sensory inner hair cells within the cochlea (16,31). We showed previously that monomer interactions determined by FRET were required for normal voltage sensing, because very short truncations of the N-terminus, but not the C-terminus, abolished FRET and NLC, the electrical signature of OHC electromotility (7). Additionally, sulfhydryl reagents have been shown to significantly alter NLC and mechanical activity in native OHCs (21,22). These data raised the possibility that voltage sensing and multimerization in prestin require disulfide bond formation.

Combinatorial cysteine substitutions reveal critical residues for voltage sensing and are likely involved in disulfide bond formation

We have attempted to discern the role of cysteine residues in prestin by mutating these residues both individually and in

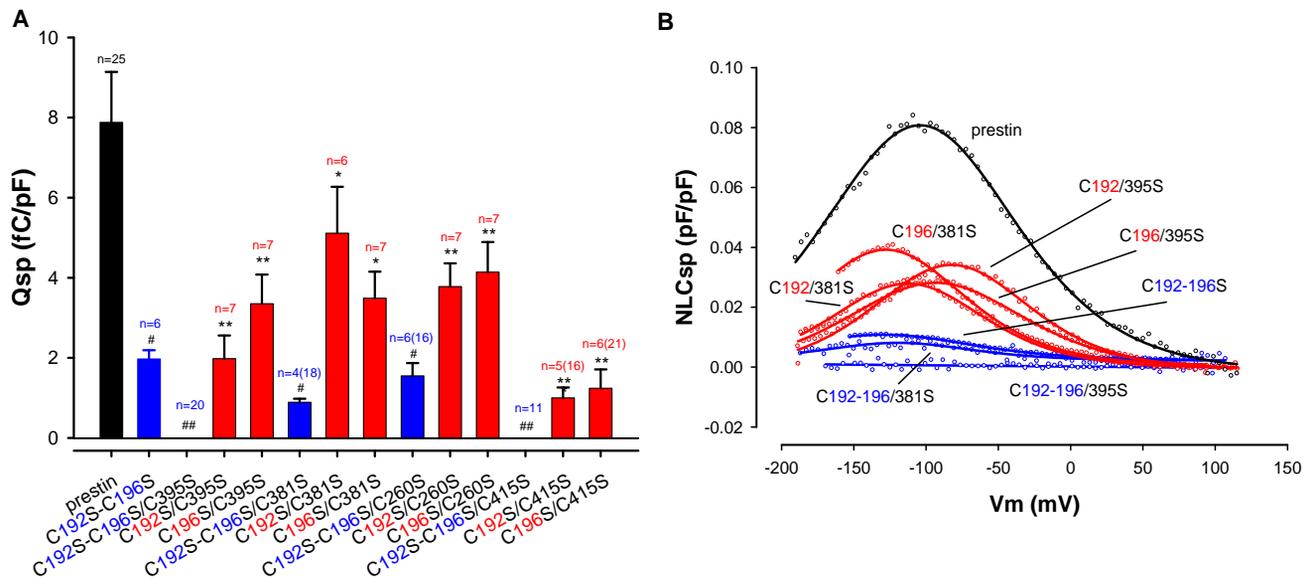

FIGURE 4 C192 and/or C196 play a key role in generating NLC. (A) Q_{sp} values of C192S–C196S related mutants are shown. Mutating C192S–C196S together markedly decreases Q_{sp} compared to control. Moreover, mutating them in combination with other transmembrane cysteine to serine residues reduces Q_{sp} even further (blue). Separate back mutation, either S192C or S196C (red), recovers Q_{sp} , suggesting that C192 and C196 are able to compensate for each other. For instance, C192S–C196S/C395S and C192S–C196S/C415S (blue) fully abolish NLC. Nevertheless, C395S (or C415S) in combination with either C192S or C196S alone (red) partially recovers Q_{sp} . Similar patterns were found in C260S combined with C192S and/or C196S, and C381S combined with C192S and/or C196S, although C192S–C196S/C260S and C192S–C196S/C381S decrease (but do not abolish) Q_{sp} . Reduction of Q_{sp} in these C192S–C196S mutants were statistically significantly different from wild-type prestin ($^{\#}p < 0.05$; $^{\#\#}p < 0.01$). Similarly, recovery of Q_{sp} with back mutation of either S192C or S196C alone was also statistically significant ($^*p < 0.05$; $^{**}p < 0.01$). n is number of cells that evidenced NLC and were used for statistics; parentheses enclose the total number of cells recorded. (B) Representative NLC traces from wild-type prestin and mutants.

combination, and then determining their effects on NLC. Earlier work had shown that individual mutations only slightly affected measures of NLC, in line with our results. However, Zheng et al. (25) raised the possibility that disulfide bonds between cysteine residues in the transmembrane domains were important for oligomer formation. Disulfide bond prediction programs, which use a host of algorithms, largely predict an absence of cysteine bonding (A. Surguchev and D. S. Navaratnam, unpublished observation). However, two caveats apply to these programs; they are based largely on soluble proteins, and a number of them rely on empirically established cysteine residue interactions in homologous proteins (17). Thus, the use of these algorithms for prestin analysis is limited, because six of the nine cysteine residues reside in predicted hydrophobic transmembrane regions. Moreover, there is scarce literature on cysteine residue interactions in prestin homologs.

Our data provide indirect evidence that residues C415 and either C192 or C196 are involved in disulfide bond formation. Our reasoning for imputing the formation of disulfide bonds for each differs. In the case of C192–C196, the formation of disulfide bonds by one of these residues is indicated by the two residues being able to substitute for one another. In the case of C415, bond formation is indicated based on the ability of alanine substitution to rescue effects produced by C415S. We hypothesize that the unconstrained side chain of the serine residue interferes with prestin function.

In contrast, the naturally occurring cysteine residue, with an identical side chain length, is disulfide bonded and therefore sterically constrained. We reason that this sterically constrained side chain is unable to interfere with NLC. Similarly, we reason that the shortened side chain in C415A is incapable of interfering with prestin function.

It might be argued that differences in hydrophobicity of alanine, cysteine, and serine, rather than disulfide bond formation promote NLC generation. However, it is not clear that hydrophobicity differences between cysteine and the two substitutes are significant. In fact, the differences between the hydrophobicity of serine, cysteine, and alanine are small (32). Of the >30 tabulations of hydrophobicity the placement of these residues by relative hydrophobicity are interchangeable. In part, this is because cysteine residues form disulfide bonds and are prone to lie on the internal surface of the protein. Some tabulations use position of the residue on 3D structure as a measure of hydrophobicity. However, others that use only the physical/chemical properties of the amino acid find it to be less hydrophobic. Furthermore, the relevance of an amino acid’s hydrophobicity to structure is questionable (33). To reiterate, we suggest that disulfide bond formation constrains C415 and allows for NLC generation.

An obvious pairing would be for C415 to form a disulfide bond with C192 or C196. However, individual mutations of these residues do not produce mirror effects on measures of

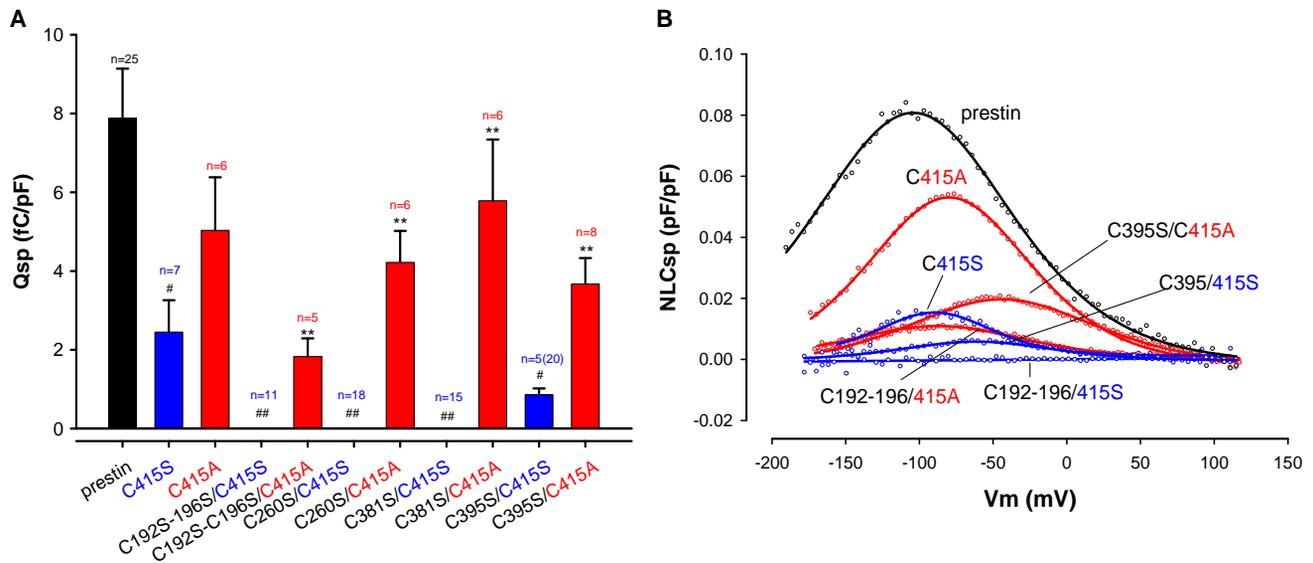

FIGURE 5 C415S plays a key role in generating NLC. (A) Q_{sp} values of C415S related mutants are shown. C415S (blue) alone markedly decreases Q_{sp} . In addition, C415S in combination with other transmembrane cysteine mutants reduces Q_{sp} even further. In contrast, the back mutation C415A alone or in combination with other cysteine mutants evidenced recovery of Q_{sp} (red). Thus, C192S–C196S/C415S, C260S/C415S, and C381S/C415S completely eliminate NLC, and C395S/C415S markedly reduced NLC. In contrast, C192S–C196S/C415A, C260S/C415A, C381S/C415A, and C395S/C415A all showed significantly improved or recovered Q_{sp} . Residue side chain length and spatial constraint may underlie these differences (see text for details). Q_{sp} in C415S mutants was statistically significantly different from wild-type prestin ($^{\#}p < 0.05$; $^{\#\#}p < 0.01$). Similarly, recovery of Q_{sp} with back mutation of S415A was statistically significant ($*p < 0.05$; $**p < 0.01$). n is number of cells that evidenced NLC and were used for statistics; parentheses enclose the total number of cells recorded. (B) Representative NLC traces from wild-type prestin and mutants.

NLC (V_h , Q_{sp} , and z), as might be expected. The reason for this could be due to C192 substituting for C196, with mutation of both residues (C192 and C196) producing additional effects on measures of NLC. Should there be formation of disulfide bonds between C415 and C192 or C196, we would anticipate a physical approximation of the two residues, a feature not especially obvious in the current transmembrane models of the protein. Other data indicate that a disulfide bond between C415 and C192 (or C196) is unlikely. For instance, Q_{sp} was significantly decreased when C415S (or C192S–C196S) was combined with other transmembrane cysteine residues, but not when combined with nontransmembrane cysteine residues (C52S, C124S, and C679S). Thus, given that intra membranous disulfide bonds are formed in these cases, the occurrence of a bond between C415 and C192 or C196 is unfeasible.

Evolutionarily new cysteine residues are among those residues critical for NLC generation

Of the nine cysteine residues four, C52, C381, C395, and C679, are conserved between nonmammalian vertebrates and eutherian mammals (34). In contrast, cysteines in positions 124, 192, 196, 260, and 415 are not conserved. Cysteine residues could be important for determining electromotility, a feature of mammalian prestin but not its nonmammalian counterparts (35,36). It could be reasoned that these nonconserved, and evolutionarily newly acquired,

cysteine residues would be more important than cysteine residues that are conserved between prestin from mammals and nonmammalian vertebrates. It is interesting that both C415 and C192–C196 are not found in prestin from nonmammalian vertebrates, reinforcing the view that these newly acquired cysteine residues are important for the structural features in prestin responsible for generating characteristics of gating charge movement that underlie electromotility. The data suggesting that these residues are involved in disulfide bond formation lead us to predict that these disulfide bonds are structural (instead of allosteric or catalytic disulfide bonds). The increased amounts of misfolded protein on the surface of the cell where these cysteines have been modified corroborate this prediction. It should be noted that the removal of cysteines does not predicate misfolding of the protein but rather increases the probability of misfolding suggested by a fraction of wt-prestin that is also misfolded (albeit to a smaller degree).

Alterations in Q_{sp} produced by different cysteine mutants is due to subtle alteration in folding and not due to reduced surface expression

The effects of cysteine mutations on prestin could be due to inadequate surface expression, changes in tertiary/quaternary structure or a combination of the two. There was no relationship between transfection and expression efficiencies of the different mutants and its effects on Q_{sp} . Both the expression

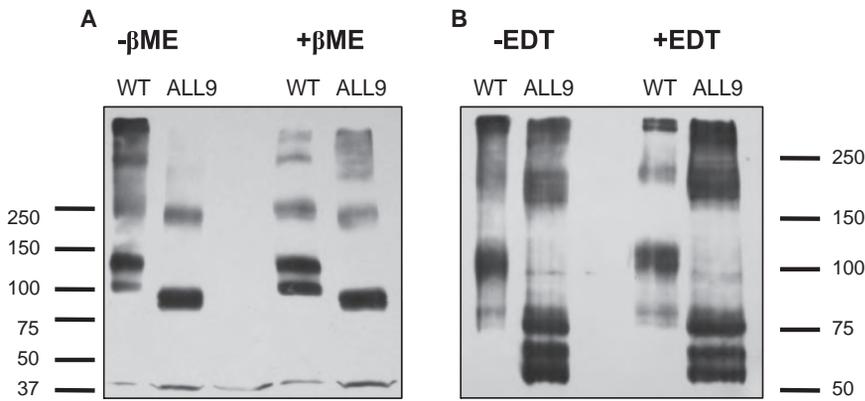

FIGURE 6 Prestin dimerization does not require cysteine residues. Cell lysates of CHO cells transiently transfected with prestin-YFP or prestin-YFP where all nine cysteine residues were mutated to serine (ALL9) were separated by SDS-PAGE and prestin was detected by Western blotting using an antibody to its N-terminus. The position of molecular weight markers is shown. (A) The absence of all nine cysteine residues does not influence the formation of prestin dimers (~250 kD) in lysates separated by standard SDS-PAGE in the presence or absence of 5% β -mercaptoethanol. Prestin monomers and dimers were apparently smaller in the ALL9 cysteine mutants. (B) Separation on SDS-PAGE gels containing 6 M urea before Western blotting did not alter the identification of dimers. Prestin dimers in both wild-type

prestins and ALL9 mutants were still detectable in the presence of 6 M urea (and 600 mM EDT), signifying that the formation of dimers did not require disulfide bonds and resulted from strong hydrophobic bonds. Moreover, the smaller prestin monomers and dimers in the ALL9 mutant were resolved into several discrete bands. These bands were also detected after stripping and reprobing the blots with antibodies to tagged YFP (data not shown) indicating that altered folding rather than proteolytic cleavage was responsible for the observed difference in molecular weight between prestin and the ALL9 mutant.

of YFP tagged protein in the cell determined by fluorescent activated cell sorting and the total expression of prestin on the surface of the cell determined by surface biotinylation had no relationship to Q_{sp} , the electrophysiological measure of functional prestin on the surface of the cell. Rather, a linear correlation between the ratio of the upper monomer to lower monomer and Q_{sp} suggests that the cell expresses a functional monomer and that Q_{sp} is a measure of this functional monomer. Why does the ratio of upper to lower monomer correlate with Q_{sp} ? We reason that the misfolded lower band interferes with prestin function, in a dominant negative manner, possibly during dimerization of the two forms. In this way, the absolute amount of upper band monomer may not necessarily correlate with prestin function.

Although it is known that SLC26A3 can be cleaved at its N-terminus to produce two bands detectable with C-terminal antibodies on Western blotting (17), we conclude that the observed differences in prestin monomers are due to changes in folding because the two monomers are detected with antibodies to both the N- and C-terminus of prestin. An alternate possibility that the lower molecular form represents a nonglycosylated protein is unlikely. For one, both forms of the protein would have been exposed to the glycosylation machinery before insertion into the plasma membrane. For another, prior experiments have shown absent glycosylation of prestin in CHO cells (7). Moreover, removal of glycosylation results in a functional protein. Importantly, these data question the use of prestin surface expression determined by fluorescence as a measure of adequate surface delivery, as has been done by many groups including ours. Our data suggest an alternative and more accurate test—adequate surface delivery of properly folded protein. Conversely, we believe the data in this study substantiate the idea that Q_{sp} , in the absence of significant changes in z , to be a good measure of functional protein on the surface of the cell.

Dimer formation is a result of strong van der Waals forces and does not require disulfide bonds

Previous experiments by Zheng et al. (25) suggested that disulfide bonds were important in the formation of prestin dimers. However, the formation of prestin dimers in the absence of all nine cysteine residues leads us to conclude that disulfide bonds are not essential for the formation of prestin dimers, in line with another recent study (29). The presence of prestin dimers in multiple cysteine mutations involving different cysteine residues further validates our reasoning. We think it unlikely the alternative explanation that mutation of all nine cysteines resulted in a misfolding of the protein that then led to dimerization of this misfolded protein through interactions of novel exposed hydrophobic surfaces. On the other hand, although not essential for dimer formation, we are unable to confirm if disulfide bonds contribute to prestin dimer maintenance. For instance, disulfide bonds stabilize dimers in the enzyme acetylcholinesterase, but are not required for their formation (37). In any case, the presence of dimers in 6 M urea in mutants lacking all nine cysteine residues implies very strong hydrophobic interactions between prestin monomers. In the absence of evidence showing intermolecular disulfide bond formation in prestin, we posit that cysteine residues are constrained by intramolecular disulfide bonds that are important for normal voltage sensing and mechanical activity in prestin.

Prestin in the lateral membrane of outer hair cells, is responsible for electromotility (EM) and a corresponding nonlinear capacitance (NLC). Prestin's voltage sensitivity is influenced by intracellular chloride. A regulator of intracellular chloride is a stretch-sensitive, non-selective conductance within the lateral membrane, G_{metL} . We determine that prestin itself possesses a stretch-sensitive, non-selective conductance that is largest in the presence of thiocyanate ions. This conductance is independent of the anion transporter mechanism. Prestin has been modeled, based on structural data from related anion transporters (SLC26Dg and UraA), to have a 7 + 7 inverted repeat structure with anion transport initiated by chloride binding at the intracellular cleft. Mutation of residues that bind intracellular chloride, and salicylate treatment which prevents chloride binding, have no effect on thiocyanate conductance. In contrast, other mutations reduce the conductance while preserving NLC. When superimposed on prestin's structure, the location of these mutations indicates that the ion permeation pathway lies between the core and gate ring of helices, distinct from the transporter pathway. The uncoupled current is reminiscent of an omega current in voltage-gated ion channels. We suggest that prestin itself is the main regulator of intracellular chloride concentration via a route distinct from its transporter pathway.

Outer hair cell (OHC) electromotility is at the heart of cochlear amplification, a mechanism responsible for the mammal's ability to hear sounds of extremely low intensity^{1,2}. Prestin is a member of the SLC26 anion transporter family that now includes 10 members, and was initially identified in a search for the OHC lateral membrane motor³⁻⁵. Subsequent experiments have confirmed that prestin (SLC26a5) is required for electromotility and has all the properties including electromotility (EM) and non-linear capacitance (NLC) of the voltage-driven motor in OHCs⁶⁻⁹, expanding and contracting up to several thousand Hz¹⁰. Recent modeling and experimental data have established that it most likely has a structure similar to the distantly related bacterial uracil transporter UraA^{11,12}, and this is now corroborated by the crystal structure of the more closely related bacterial homologue SLC26Dg¹³. This modeling experiment, that shows prestin with a 7 + 7 inverted repeat structure, supersedes previous models suggesting similarity of the SLC26 family to the ClC bacterial chloride transporter/ion channel family^{12,14,15}.

Intracellular chloride anions play a critical role in prestin's function¹⁶, setting, in an allosteric-like manner, its operating voltage range and affecting transition rates between expanded and contracted states^{17,18}. How intracellular chloride levels are regulated in OHCs remains largely unknown. A dominant stretch-sensitive, non-selective conductance, G_{metL} , has been observed in the lateral membrane of OHCs, and awaits molecular identification¹⁹. An obvious candidate would be prestin itself, although its ability to transport anions has been controversial. An initial model suggested a complete absence of transmembrane ion flux; instead, chloride movement in a truncated cycle of transport was hypothesized to act as the protein's voltage sensor¹⁶. Many subsequent observations have challenged this hypothesis^{17,19-24}. Additionally, experiments have shown formate and oxalate uptake based on isotopic flux²⁰ (although one report failed to do so²⁵), and $\text{HCO}_3^-/\text{Cl}^-$ exchange at a 2:1 ratio generating small

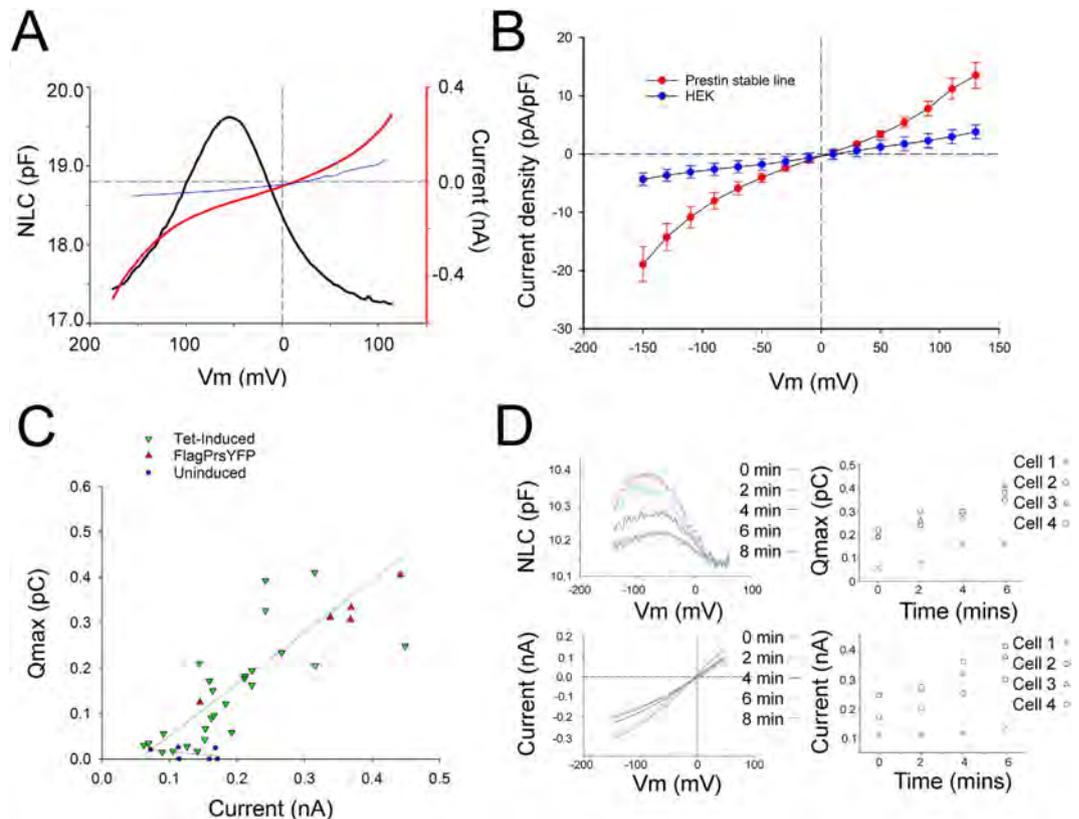

Figure 1. Prestin expression induces a current. (A) Voltage dependence of gating charge (NLC) and current, recorded in the presence of Cl⁻ after tetracycline induction of prestin expression in a HEK cell. There is a large non-linear capacitance (left axis, with a Q_{\max} of 302 fC, z of 0.81e) accompanied by a voltage dependent current (right axis, current, in red, of 0.64 nA for voltage range of -160 mV to 110 mV. In blue is the current of a control cell). (B) I-V relationship of average currents of cells after tetracycline induced prestin expression ($n = 16$) is compared to native HEK cells ($n = 10$). Prestin expression is associated with a significant increase in voltage dependent current ($p < 0.001$, mixed model analysis for correlated measures). Pipette solution contained 100 mM KCl, 20 mM TEACl, 20 mM CsCl, 2 mM CoCl₂, 2 mM MgCl₂, 5 mM Hepes, pH 7.2 and the bath solution contained 100 mM NaCl, 20 mM CsCl, 5 mM EGTA, 2 mM MgCl₂, 10 mM Hepes, pH 7.2. Error bars are standard error. (C) There is a linear relationship between size of prestin induced currents and NLC. The difference in current at 110 mV and -150 mV is plotted against total charge movement (Q_{\max}) of individual cells. Green triangles are cells after tetracycline induction ($n = 27$), red triangles are from cells stably expressing high levels of prestin ($n = 5$) and circles are currents from untransfected HEK cells ($n = 6$). The line represents a simple linear regression in tetracycline induced cells ($R = 0.78$, $n = 27$). (D) Increased surface expression of prestin after Golgi release is temporally associated with an increase in current. Inducible cell lines were maintained at 22 °C for 24 hours to allow accumulation of prestin in the Golgi immediately after tetracycline induction. Cells were then continuously recorded using a two-sine protocol and the bath temperature raised to 37 °C. There is increasing prestin expression on the surface of the cell evidenced by time dependent increase in NLC (upper left, single cell; upper right, four cells) that is correlated with increasing currents (lower left, single cell; lower right, four cells).

transporter currents²⁶. Interestingly, large currents associated with prestin expression arise in the presence of the pseudohalide thiocyanate, similar to uncoupled currents in SLC26a6 and SLC26a3^{14,15,27}. In this paper we show that prestin itself has a tension-sensitive, non-selective leakage conductance similar to G_{metl} that operates independently of its putative transporter pathway.

Results

Schänzler and Fahlke²⁷ demonstrated an uncoupled conductance for SCN⁻ ions that correlates with the expression of prestin. We find that expression of prestin induces currents in the absence of SCN⁻, as well. In the presence of Cl⁻, we observed a current in tet-inducible, prestin expressing HEK cells²⁸, which is significantly larger than currents in untransfected or uninduced HEK cells (Fig. 1A,B). The current, several hundred pA per cell in symmetrical chloride solutions, shows a non-linear voltage dependence, similar to the non-selective current (I_{metl}) observed within the lateral membrane of OHCs²⁹. The size of the current correlates with the magnitude of prestin-associated, voltage-dependent NLC, the electrical signature of OHC mechanical activity, indicating that the current is associated with prestin successfully expressed on the surface of the HEK cell (Fig. 1C). Further evidence that prestin carries this current is shown by the parallel increases of current and NLC magnitudes upon

delivery of prestin to the plasma membrane after release of low-temperature Golgi block (Fig. 1D)³⁰. This effect was clearly demonstrated in 8 cells (four cells are shown in Fig. 1D).

Absence of ion selectivity of the conductance was shown by substitution of anions and cations in both the intracellular and extracellular solutions; no substitutions resulted in clear change in the size of these currents, except for the large cation NMDG⁺ (Fig. 2A, B). Moreover, there was no change in the I-V relationships (Fig. 2A, B). The anion substitution data also suggest that the current was uncoupled: extracellular substitution of Cl⁻ with the anion malate did not affect the size of the current or its reversal potential (Fig. 2A). A similar effect was seen with oxalate, IO₃⁻, and methanesulfonate (data not shown). Each of these ion replacements is known to cause a shift of up to 50 mV in the NLC voltage operating range¹⁷. Similarly, substitutions of intracellular and extracellular K⁺ and Na⁺ with other ions (Na⁺, K⁺ or Tris⁺) did not affect the size of the current or its reversal potential (Fig. 2B). In contrast, when extracellular Na⁺ was replaced with NMDG⁺, we note a significant decrease in the size of the current (Fig. 2B). NMDG⁺ substitution affected both outward and inward currents, as might be expected from a pore-block mechanism. Further confirming the non-selective nature of the conductance, we observed a decrease in the size of the current at both depolarizing and hyperpolarizing voltages when extracellular KCl was decreased from 140 to 14 mM (the pipette solution contained 140 mM KCl, setting the intracellular concentrations) while 300 mOsm extracellular osmolarity was maintained with sucrose. The reversal potential shifted by -15 mV + /- 2 mV with 14 mM extracellular KCl, and is consistent with a calculated permeability ratio of 0.45 for Cl⁻ relative to K⁺ (2C,D). Consistent with the current being carried by a non-selective "open pore", we note that cells expressing prestin show significant depolarization, relative to controls, in resting membrane potential, determined immediately after establishing the whole cell configuration under current clamp (Fig. 2E).

Similar to the Schänzler and Fahlke observation²⁷, we find larger uncoupled currents (nA magnitude) in prestin-expressing cells in the presence of thiocyanate (Fig. 2F), also akin to the effect observed in Slc26a3 and Slc26a6^{14,15,27}. As expected for a current predominantly carried by SCN⁻, the current was directed outward with extracellular thiocyanate and inward with intracellular thiocyanate. The reversal potential with extracellular SCN⁻ (in millimolar: 100 SCN⁻ and 44 Cl⁻ in the bath; 122 Cl⁻ in the pipette with Na⁺ as the counterion in the pipette and bath solutions), was -29 ± 2 mV. We calculate a permeability ratio of 0.27 for Na⁺ and 0.11 for Cl⁻ relative to SCN⁻. These permeability ratios are underestimates, and most probably they are discordant due to the background conductances that are also seen in control HEK cells (Fig. 2).

In the presence of thiocyanate, voltage step-induced currents were instantaneous in onset and showed no deactivation (Fig. 2F, inset). We observe a similar instantaneous onset with no deactivation with Cl⁻ substitution (data not shown). The shape of the I-V relationship is similar to that observed with Cl⁻ as the dominant intra and extracellular anion, with increasing slope upon both depolarization and hyperpolarization. This I-V relationship would be expected from a channel having a large central energy barrier and whose currents are sufficiently small to exclude diffusion limitation. A symmetrical, single-barrier channel model, which yields a hyperbolic sine I-V relationship, fits the data well (Fig. 3) but with a reduced voltage dependence, obtained by setting the valence to 0.75 instead of unity. This effect could arise from a broadened central barrier, or from the presence of barriers at slightly different locations for different ion species and polarities. According to the fitted model with external SCN⁻ and internal Cl⁻ the ratio of permeabilities $P \approx 6$.

As shown in Figs 2 and 4, a similar but smaller whole-cell current was observed when cyanate replaced thiocyanate. These anion substitutions were notable for effects on the Boltzmann parameter V_h of NLC: while small shifts in V_h were noted when switching from chloride to thiocyanate, much larger effects on V_h were found with cyanate; on the other hand, significant effects on Qmax were found with both anions (Fig. 4B, Table 1).

Notably, currents in the presence of thiocyanate and extracellular Cl⁻ were unaffected by application of salicylate that, however, eliminated NLC (Fig. 4C,D, and Supplementary Figure 1). These data argue against a transporter mechanism as the origin of the current since salicylate binds to the intracellular Cl⁻ binding site and has been shown to reduce transporter currents³¹ and inhibit NLC^{32,33}. Consistent with this observation, the use of 1 mM DIDS, the well-established blocker of anion transport³⁴⁻³⁶, did not affect the size of these currents in the presence of thiocyanate, nor did it affect NLC (Fig. 4C,D). Application of membrane tension by exposing the cell to a fluid jet of extracellular solution resulted in a decrease in the size of the current in the presence of thiocyanate and an increase in the size of the current in the presence of chloride and cyanate (Fig. 4E,F, for comparison see Supplementary Figure 2 for the size of effects of pressure on currents of HEK cells not expressing prestin). We observed a similar effect in guinea pig OHCs with large outward currents in the presence of extracellular thiocyanate that decreased in size in the presence of fluid jet stimulation (data not shown).

An estimate of the unitary current of a prestin-associated channel can be obtained as the whole-cell current normalized by the number of prestin molecules. This number can be derived from the magnitude of NLC³⁷. In this way we estimate that at +50 mV the unitary currents are 0.010 fA and 0.062 fA with extracellular Cl⁻ and thiocyanate, respectively.

Another approach to determining the size of unitary currents is fluctuation analysis. Schänzler and Fahlke²⁷ observed fluctuations in thiocyanate currents having a 1/f spectral density in whole-cell recordings. Because, however, the variance of the fluctuations had no clear relationship to the mean current, they concluded that the unitary currents were too small to be estimated with any reliability. We chose instead to record currents in excised patches to obtain higher sensitivity. Individual patch experiments (with patches of 1-2 mm²) from prestin expressing cells demonstrate an increase in average current of +11.94 pA (+50 mV) and -12.56 pA (-50 mV), and +7.73 pA (+50 mV) and -10.36 pA (+50 mV) over HEK cells in the presence of thiocyanate and chloride, respectively.

In the presence of Cl⁻ and SCN⁻ we also observed fluctuations with a power-law frequency dependence, approximately 1/f, whose magnitude clearly depended on membrane potential (Fig. 5A,C). The variance of the fluctuations was computed in two steps. First, the spectral density at 0 mV applied potential was taken to be the background spectrum, and was subtracted from spectra obtained at +50 mV or -50 mV (Fig. 5B,D). The

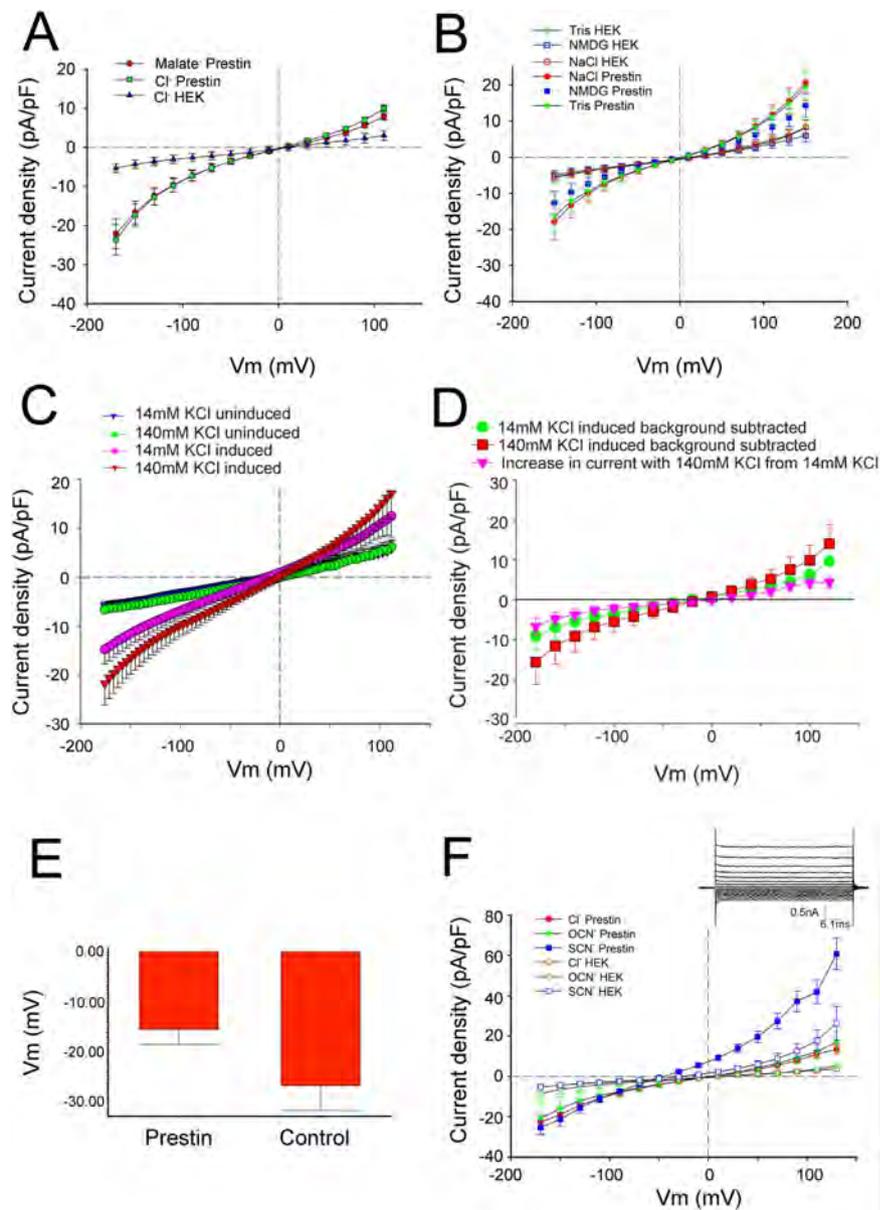

Figure 2. Prestin expression is associated with a non-selective current that is augmented with thiocyanate. (A) Substitution of extracellular NaCl with NaMalate did not affect the size of the current ($P > 0.05$, $n = 7$) or affect the reversal potential. (B) Extracellular substitution of Na^+ with NMDG $^+$ significantly reduced the size of the currents ($P < 0.001$, $n = 10$). In contrast, substitution with Tris^+ did not affect the current size or shift reversal potential. (C) Prestin associated currents are non-selective. In prestin expressing cells the substitution of 14 mM extracellular KCL with 140 mM KCL, while maintaining pipette (intracellular) KCL at 140 mM, results in an increase in the size of the whole-cell current at both depolarizing and hyperpolarizing voltages ($p < 0.05$, $n = 7$; $+/-$ SEM). In induced cells the reversal potential is 1.2 mV ($+/-$ 3.6, $n = 7$) with symmetrical 140 mM KCl and -14.7 mV ($+/-$ 3.9, $n = 7$) with 14 mM extracellular KCl. These data are consistent with permeability ratios for $\text{K}^+ : \text{Cl}^-$ of 1: 0.45. (D) Subtraction of baseline currents in uninduced cells from currents after prestin induction confirms the non-selective nature of the prestin associated current. (E) Resting membrane potentials recorded in current clamp mode immediately after achieving the whole cell configuration show significant depolarization in prestin expressing cells to -15.4 mV ($+/-$ 2.9 SE, $n = 11$) compared to -26 mV ($+/-$ 4.8 SE $n = 7$) in uninduced HEK cells ($p < 0.05$, students t test). (F) I-V relationships show a non-linear voltage dependent current with cyanate and thiocyanate. Average currents corrected for the size of the cell after induced expression of prestin in HEK cells are compared with currents in uninduced HEK cells before and after perfusion with 100 mM NaOCN, and 100 mM NaSCN ($+/-$ SE). Currents increase significantly in prestin expressing cells compared to HEK cells in the presence of extracellular Cl^- ($P < 0.001$, $n = 16$ prestin, $n = 5$ HEK), OCN^- ($p < 0.001$, $n = 3$ prestin, $n = 5$ HEK) and SCN^- ($p < 0.001$, $n = 17$ prestin, $n = 5$ HEK) with the largest effects seen with SCN^- . Inset: Thiocyanate current activates instantaneously and shows no deactivation. Prestin currents were recorded in a cell perfused with 100 mM NaSCN (holding at 0 mV, -150 to $+150$ mV with 20 mV steps of 50 ms duration).

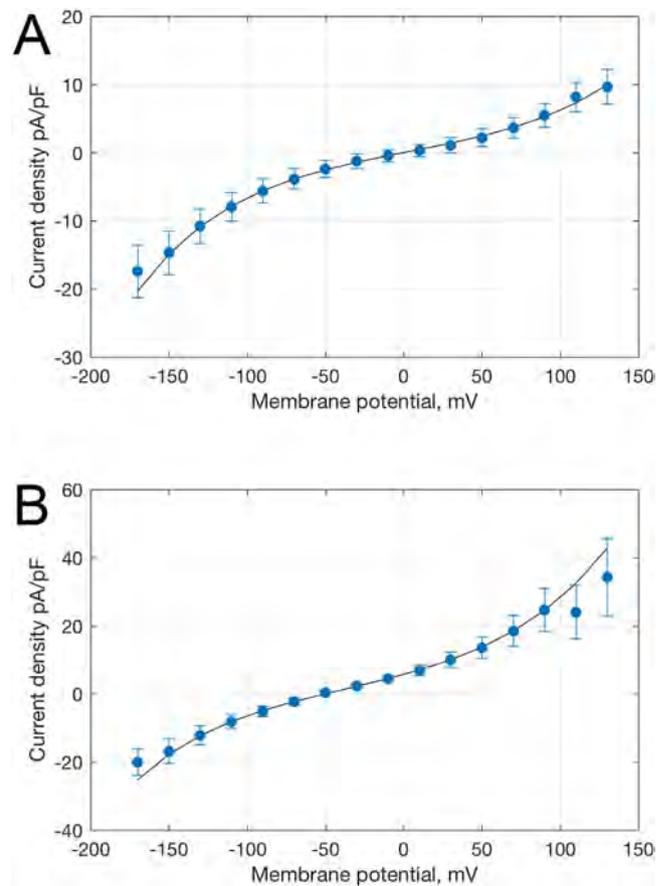

Figure 3. Single-barrier model I-V fits. Plotted is whole-cell current density in prestin-induced cells ($n = 19$) after subtraction of the corresponding current in control HEK cells ($n = 19$) in (A) symmetrical 140 mM KCl⁻ or (B) with extracellular SCN⁻ replacing Cl⁻ (+/-SEM). Curves are fitted with a single-barrier current-voltage relationship.

variance was then calculated as the integral of the subtracted spectrum over the frequency bandwidth of 0.1 to 1000 Hz. Very rough estimates of the unitary current can be made from the ratio of the variance to the mean current, yielding values of about ± 2 fA at ± 50 mV driving force in chloride solutions, and about 5 fA for outward current carried by SCN⁻ at +50 mV (Table 2).

This simple estimation of the elementary current magnitude is very approximate because it is based on several assumptions. First, it assumes switching between open and closed states, with a low probability of the open state. Second it is assumed that the fluctuations are approximately confined to the 0.1 to 1000 Hz frequency band. Finally, the use of the spectral density at 0 mV as the background estimate is not strictly correct for currents having a nonzero reversal potential. However, as the variance depends quadratically on the current, which is small at 0 mV, the error from this approximation is probably smaller than the errors arising from the other assumptions.

The power spectrum of current fluctuations in well-behaved transporters and gated ion channels typically shows one or more Lorentzian components^{38–43}. A power-law decay, like the one observed here over a range of four orders of magnitude in frequency, is instead consistent with fluctuations having a broad distribution of relaxation times. The estimated unitary currents are far too small to be visible in patch recordings, and consistent with this, no channel events were visible in the traces recorded at ± 50 mV. However, at large voltages such as +120 mV, channel-like activity could be seen (Fig. 5E). We assume that these very large currents arise from different channels than those under study here.

To date there are scant structural data on eukaryotic Slc26 transporters. However, recently, prestin was modeled, with confirmatory molecular dynamics simulations and experimental evidence, to closely fit the crystal structure of a bacterial uracil transporter, UraA, that is distantly related to the SLC26 family^{11,12}. A recent paper has observed an almost identical 7 + 7 inverted repeat structure in the more closely related bacterial homologue SLC26Dg, a facilitator of proton-coupled fumarate symport from *Deinococcus geothermalis*¹³. For our analyses, we use the 3D crystal structure of UraA as the template (see Supplementary Figure 3 for the sequence alignment using HHpred), as there are better structure-function correlates in UraA than in SLC26Dg. Several key residues in UraA that bind to uracil and are critical for transport are conserved in prestin, including S398 and F137 based on hidden Markov model homology (HHpred). Of these residues E290 in UraA, corresponding to S398 in prestin, is modeled to bind to uracil close to its intracellular cleft. Similarly, F73 in UraA, corresponding to F137 in prestin, binds to uracil and acts as a barrier for its escape to the periplasmic surface¹². We reasoned that mutation of these residues in prestin would reduce the easily measurable thiocyanate currents if prestin were to mediate

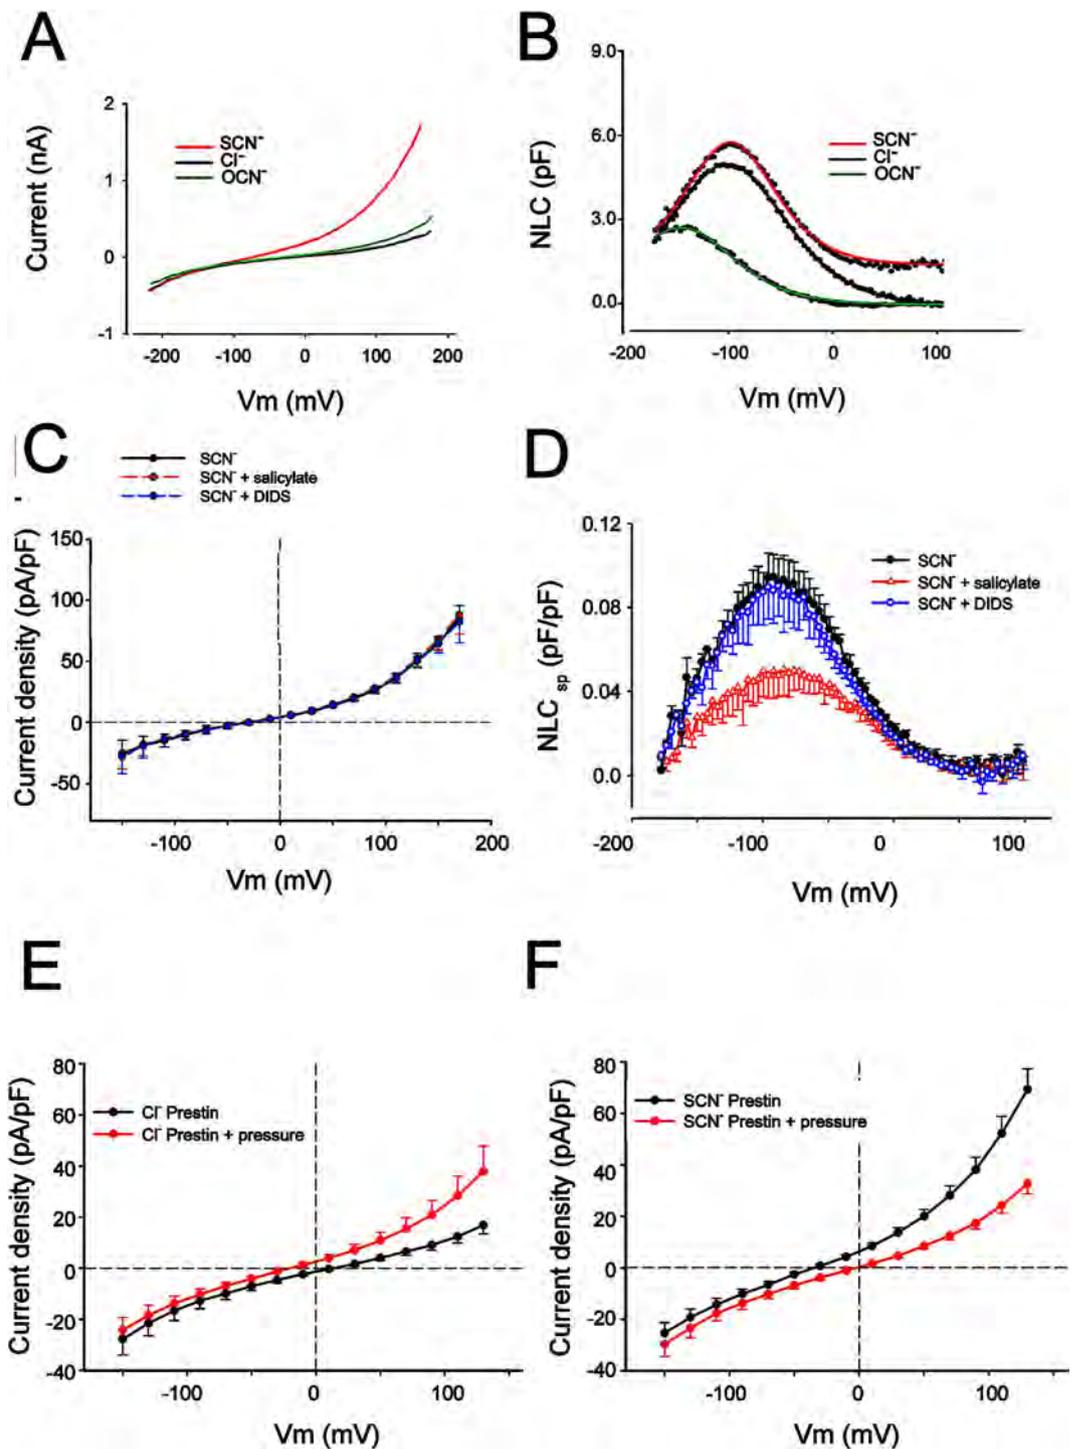

Figure 4. Currents and NLC associated with prestin are separable. (A,B). Shown are NLC (A) and currents (B) in a single cell perfused with extracellular Cl⁻, OCN⁻ and SCN⁻. SCN⁻ increases current significantly and affects gating charge, while OCN⁻ causes a slight increase in current while causing a hyperpolarizing shift in V_h. (C,D) Extracellular salicylate (20 mM) has no effect on currents (C) in the presence of extracellular SCN⁻, while reducing NLC (D). 1 mM DIDS does not affect NLC or SCN⁻ current. Shown are average tracings from three cells (+/-SEM). (E,F) The effects of fluid-jet pressure on the size of the current are dependent on the conducting anion. With Cl⁻ in the bath solution there is an increase in the size of the current with exposure of the cell to a fluid jet (E). In contrast, in the presence of extracellular SCN⁻, the size of the current decreases with exposure to a fluid jet (F). Shown are average tracings from 10 cells (+/-SEM).

these currents via its transporter pathway. However, mutation of these residues to alanine had little effect on the size of thiocyanate currents but they did shift V_h of NLC (F137A did not have detectable NLC likely since V_h was so shifted; membrane targeting was confirmed by confocal microscopy (Supplementary Figure 4)). We interpret

Prestin stable line	Q_{sp} (fC/pF)	V_h (mV)	z	n
extracellular Cl^-	20.32+/-2.21	-96.26+/-3.37	0.74+/-0.02	19
extracellular SCN^-	15.32+/-1.68	-101.34+/-2.49	0.81+/-0.02	19
extracellular OCN^-	9.08+/-1.74	-141.72+/-3.94	0.76+/-0.02	6

Table 1. Effects of extracellular substitution with the pseudohalides OCN^- and SCN^- on parameters of NLC in tetracycline inducible HEK cell line. Specific capacitance was reduced by both extracellular OCN^- and SCN^- with V_h shifted to more hyperpolarizing voltages. The effects were more pronounced with OCN^- . Additionally, SCN^- also increased estimates of single charge movement (z).

these data as consistent with a model of Na^+ , Cl^- and thiocyanate movement through the protein independent of its transporter pathway (Fig. 6A). We note that mutation of F137A did produce a positive shift in SCN^- reversal potential, although an increase SCN^- conductance is not borne out in the size of SCN^- currents at -130 mV. One possible explanation for the shift in reversal potential is of a decrease in cation conductance in the presence of thiocyanate.

In contrast to the absence of effects on thiocyanate or chloride currents from mutation of residues corresponding to those in the UraA binding pocket, we note marked reductions in SCN^- currents with charge neutralizing mutations of several charged residues in prestin's transmembrane domains (Fig. 6B). The side chains of these residues reside at the interface between the core and gate domain (Fig. 6D–F). These mutations (K227Q, K359Q and D485N) in three widely separated alpha helical transmembrane domains 5, 8 and 14, preserved NLC (Table 3, Fig. 6C), thus confirming surface expression of functional molecules. Examining the modeled structure of prestin reveals a potential accessory pathway, which links these widely separated residues that lie in physical proximity in its tertiary structure, independent of the suspected substrate binding site between the alpha-helical regions of TM3 and 10. Indeed, this pathway allows access to the inner membrane surface while access to the external surface is partially obstructed by a loop linking transmembrane domains 3 and 4. Significantly, an additional mutation, R463Q, that also reduced SCN^- currents, lies in an unstructured loop linking transmembrane domains 12 and 13. It lies at the intracellular cleft of the transporter and is in a potential pathway linking the extracellular medium and the envisaged accessory pathway. Note however, that our model is based on the structure of UraA and SLC26dg both of which capture a single state, namely an inside open conformation. Determining the exact pathway of the non-selective conductance will require more structural data particularly of the outside open and other intermediary conformations.

Discussion

Prestin has evolved to facilitate hearing in mammals by enhancing auditory thresholds by up to 1000 fold, through cochlear amplification^{1,2}. Since it is a member of the SLC26 anion transporter family, it is no surprise that anions, chiefly intracellular chloride, control many of its biophysical characteristics^{16–18}. It is paramount that intracellular chloride homeostasis be understood, since chloride manipulations have been shown to reversibly abolish cochlear amplification⁴⁴. Here we present evidence that prestin, itself, provides a stretch-sensitive leakage pathway for anions that is independent of its transporter pathway, thereby providing a potential feedback system driven by the protein's voltage-induced mechanical activity. A similar non-selective current, GmetL, has been observed along the lateral wall of outer hair cells¹⁹. Initially, we believed these currents were independent of prestin since the current in outer hair cells had different voltage sensitivity than NLC^{17,29}. However, our new data require that we reexamine the role of prestin in the non-selective currents observed along the lateral wall of outer hair cells^{19,29}.

Previous studies have characterized an ionic conductance in the SLC26 transporter family in the presence of SCN^- . In prestin, we find that this conductance is also demonstrable in the presence of Cl^- as the main anion. Our major findings can be summarized as follows. First, there is clear evidence to associate this conductance with prestin: 1) in individual cells the conductance increases with prestin expression and is proportional to NLC. 2) the conductance appears with the same time course as NLC upon release of Golgi block. 3) Mutations in prestin affect the current. An alternative possibility that a prestin associated protein contributes to the current could account for the first two observations. However, the third observation strongly suggests that the current is carried by prestin itself. Moreover, two other SLC26 family members have been demonstrated to have an uncoupled current in the presence of SCN^- ^{14,15}.

Our second major finding is that the conductance is carried by a pathway different from the Cl^- transport pathway in prestin. Evidence for this is: 1) mutation of residues that are modeled to bind intracellular Cl^- , the first essential step in the transporter cycle, do not affect the size of the current. 2) salicylate, which in non-mammalian homologs has been shown to block the transporter current while simultaneously blocking NLC, has no effect on the size of the current. 3) single point mutations have effects on the size of the current or on NLC but not both. Since mutation of F137, that we speculate based on homology to UraA to be involved in the transporter cycle, changed the reversal potential in the presence of SCN^- , it is possible that the alternative leakage pathway shares some commonality with the transporter pathway. In this context, owing to data that prestin and many similar transporter proteins form dimers and since the charge mutations that affected current are in proximity to its dimer interface, it is possible that the leakage pathway may in fact lie within the dimer interface^{45–50}.

The unusual current-voltage relationship can be explained by a channel having a high central energy barrier to ion transport. Consistent with this possibility we note small unitary currents in the fA range. We conclude that prestin forms at least part of an independent pathway for ions to cross the membrane. Mutations suggest that the pathway is located between the core and gate domains of the 7 + 7 inverted repeat structure. In this way

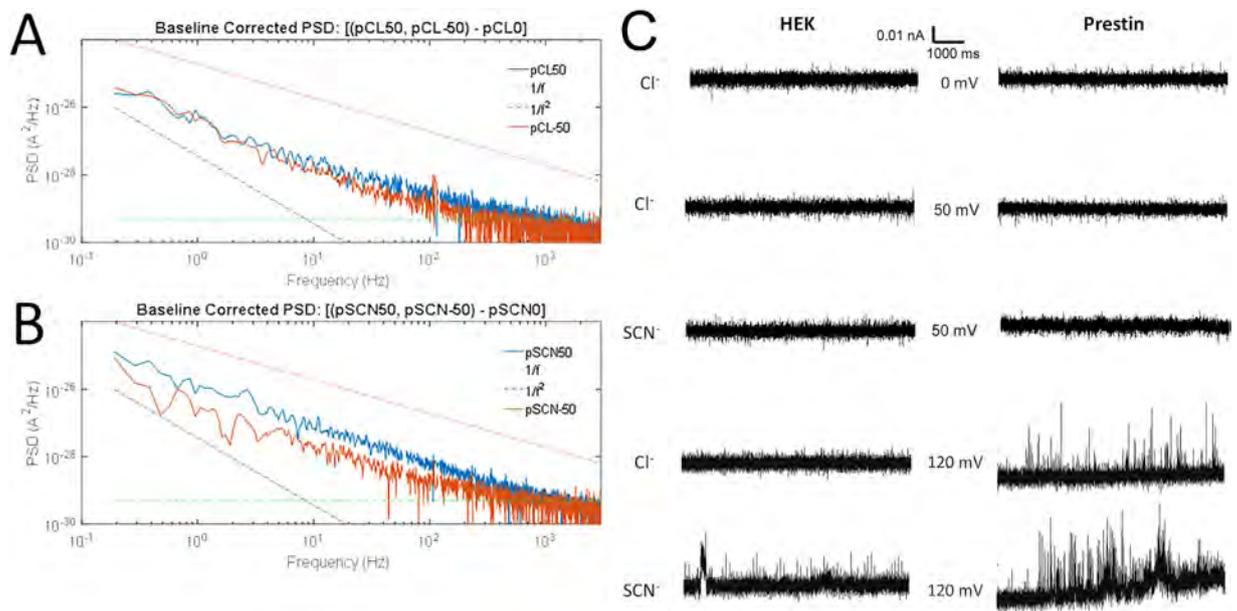

Figure 5. Noise analysis of currents in prestin expressing cells. (A) Currents in inside-out patches from prestin-expressing cells were recorded in symmetrical 140 mM Cl^- solutions at -50 mV (red line), 0 mV and $+50$ mV (blue line) for 10 seconds. Spectra from 11 patches were averaged. Spectra are plotted after subtraction of the 0 mV background spectrum. The frequency dependence is well described by a power-law decay plus a shot-noise (constant, green dotted lines) component with no apparent Lorentzian components. (B) Corresponding averaged, subtracted spectra obtained from same inside-out patches with 100 mM NaSCN on the intracellular side. As expected, noise is larger for currents at $+50$ mV where, by convention, the movement of SCN^- current is inward, although the size of the mean patch current at $+50$ mV (Table 2) is similar to that at -50 mV (Table 2). Reference lines of $1/f$ and $1/f^2$ slopes accompany data plots as visual aids. (C) Consistent with the small unitary currents estimated from the noise variance, no ion-channel events were visible except at extreme potentials such as $+120$ mV. Representative recordings are shown from excised inside out patches of HEK cells (left) and HEK cells with prestin expression (right) held at 0, 50 and 120 mV in the presence of 140 mM Cl^- and 100 mM $\text{SCN}^-/40\text{mMCl}^-$.

	Variance, σ^2 (A^2)	Mean patch current, $\langle I \rangle$ (pA)	Estimate of single channel current $\sigma^2/\langle I \rangle$ (fA)	n
-50 mV Cl^-/Cl^-	$1.66\text{e-}26$	-11.9 ± 5.5	-1.40	11
$+50$ mV Cl^-/Cl^-	$2.40\text{e-}26$	12.6 ± 5.6	1.91	11
-50 mV Cl^-/SCN^-	$1.58\text{e-}26$	-16.3 ± 5.4	-0.97	11
$+50$ mV Cl^-/SCN^-	$7.19\text{e-}26$	14.8 ± 5.3	4.87	11

Table 2. Noise analysis of inside out patches demonstrate increased variance with SCN^- during depolarization. Inside out patches from induced HEK cells expressing prestin were recorded for 10 seconds in each condition. The table lists variance of currents, σ^2 (A^2) with symmetrical Cl^- and after perfusing with SCN^- (with Cl^- inside the electrode) at -50 mV and $+50$ mV. Also shown are mean currents, $\langle I \rangle$ (re: 0 mV), and estimates ($\sigma^2/\langle I \rangle$) of single channel currents in each of the conditions.

the pathway is reminiscent of the omega current pathway in voltage gated channels. There a nonselective cation current is carried by voltage-sensor domains, in a structure entirely separate from the ion-selective pore of these channels.

Our whole cell and patch analyses provide disparate estimates of unitary currents. One explanation could be that only a fraction of prestin molecules show a leakage conductance, as our whole-cell estimates are based on normalization with the total population of prestin molecules derived from NLC. By contrast, the noise analysis provides estimates solely from active channels within a patch (without normalization to NLC as above). We also note that the relative conductances for Cl^- and SCN^- differed between whole cell recordings and excised patches. These discrepancies between recording approaches could very well be explained by the effects of an increase in membrane tension in excised patches, given the conductance's tension dependence (Fig. 4E and F).

The non-selective nature of the prestin associated currents and its small size is somewhat at odds given our current understanding of the selectivity filters in ion channels. Perhaps the mechanical model gleaned from structural data of the unrelated EAAT transporter that has a similar leakage conductance (albeit limited to anions) has

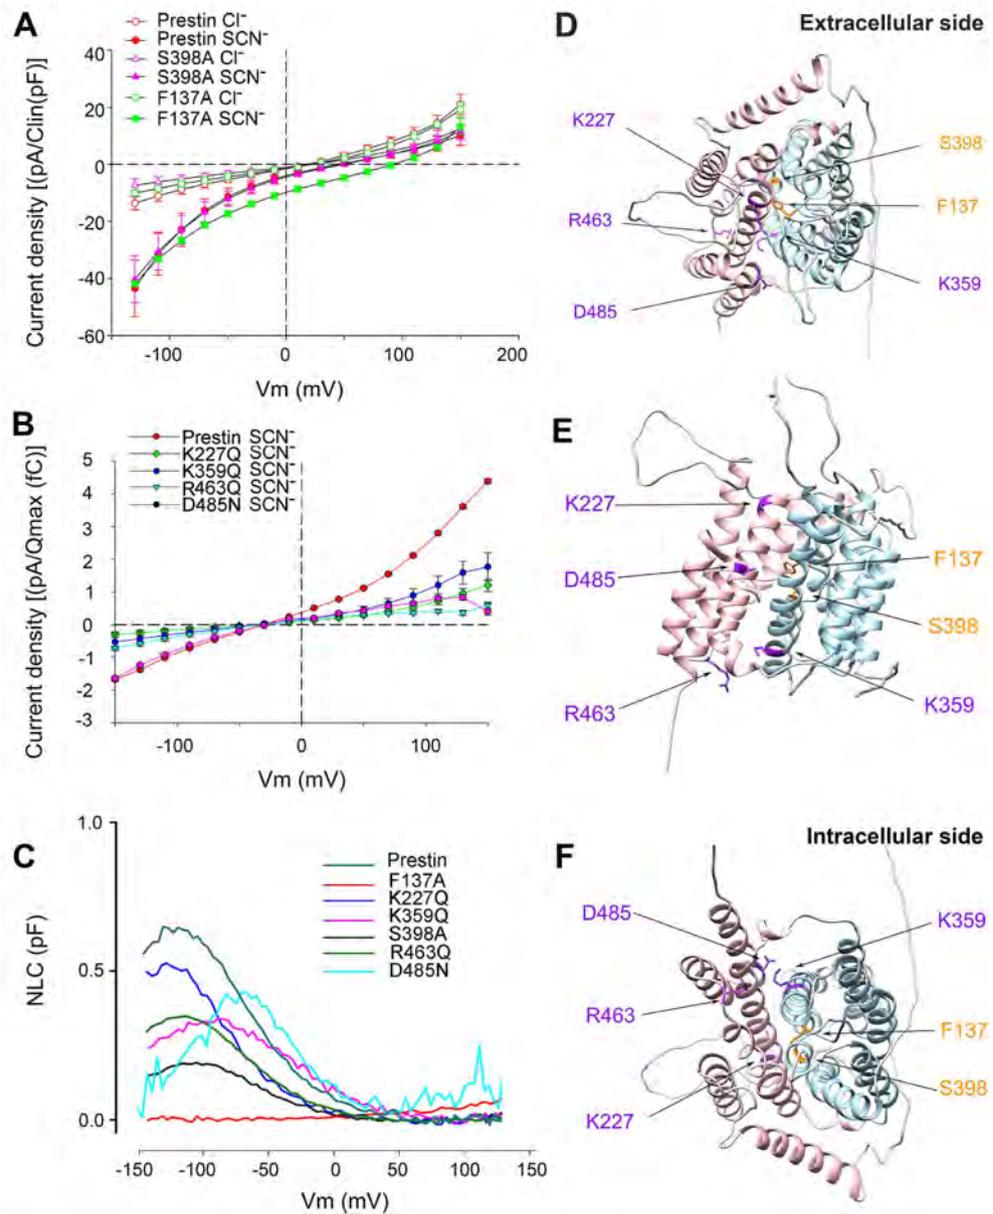

Figure 6. SCN^- currents in prestin suggest an ancillary pathway independent of the transporter pathway.

(A) Mutation of residues critical for Cl^- binding, the first step in transport, has no effects on SCN^- currents. Average currents of CHO cells expressing prestin ($n = 5$), F137A ($n = 4$) and S398A ($n = 7$) show no differences (\pm SEM). Currents, after correction for background currents, were divided by linear capacitance to correct for differences in cell size and plotted against voltage (F137A did not have easily measurable NLC, so the more rigorous normalization to NLC was not possible). Cells show large inward currents in the presence of intracellular SCN^- (100 mM) at depolarizing voltages. Intracellular SCN^- was used since the residue corresponding to S398 lies closer to the inner cleft of the transporter pathway and binds to intracellular uracil in UraA; the residue corresponding to F137 acts as a barrier to the diffusion of uracil to the exterior surface. (B) Neutralization of charged residues lying outside the transporter pathway reduce SCN^- currents. Average currents of CHO cells expressing K227Q ($n = 7$), K359Q ($n = 7$), R463Q ($n = 9$), and D485N ($n = 18$) show significantly reduced currents in the presence of extracellular SCN^- ($p < 0.001$). To account for variations in expression, current averages for each mutant construct, after correction of average background currents, were normalized by the NLC charge Q_{max} and plotted against voltage. (C) NLC traces from residues (K227Q, K359Q, R463Q and D485N) where mutation affected SCN^- currents but had measurable NLC, and of mutations in the transporter pathway (F137A and S398A). (D–F) The location of residues that line a potential accessory pathway are shown on the structure of prestin modeled on the crystal structure of the bacterial uracil transporter UraA rendered with Chimera^{11,12}. The core domains are colored blue and the gate domains colored in pink. (D–F) are the molecule viewed from above, the side and below respectively. In the potential accessory pathway lined by alpha helices 5, 8 and 14, the contained amino acids K227, K359 and D485, and R463, that lies in the loop connecting helices 12 and 13, are colored purple. Residues modeled to bind intracellular chloride (F137 and S398) are colored orange.

	Q_{sp} (fC/pF)	V_h (mV)	z	n
Prestin (wt)	8.79+/-2.28	-127.69+/-6.31	0.70+/-0.02	8
S398A	4.99+/-0.90	-107.73+/-2.21	0.71+/-0.008	9
F137A	—	—	—	5
K227Q	13.08+/-5.32	-146.12+/-6.27	0.67+/-0.03	7
K359Q	5.76+/-0.47	-98.01+/-3.71	0.57+/-0.02	7
R463Q	7.61+/-1.50	-114.32+/-5.62	0.70+/-0.03	9
D485N	6.3+/-1.4	-63.06+/-7.6	1.00+/-0.06	21

Table 3. Effects of neutralizing charge substitutions along a potential accessory pathway on gating charge parameters on transiently transfected CHO cells. Almost all these mutations decreased Q_{sp} (except K227Q) and affected the direction of V_h variably. Effects on unitary z were variable and consistent with previous data²⁰.

bearing⁵¹. In this transporter, the anion leakage pathway is not evident in the crystal structures of the many permutations of the transporter cycle including inside open, outside open and several intermediate states. Molecular dynamics simulations, however, show a conductance pathway that opens several 100s of nanoseconds after application of voltage. Experimental observations confirm such a pathway. The absence of an anion leakage pathway in the many conformations of the transporter cycle of EAAT crystal structures suggests that the pathway is a transient opening. In prestin, as well, the even smaller size of unitary currents may represent much briefer openings in the leakage pathway. In this respect, the block of the non-selective current in prestin by charge neutralization of both positive and negatively charged residues may result from reduced hydrophilicity, preventing water movement that is modeled to precede ionic movements in EAAT.

Our data suggest that currents carried by prestin's leakage conductance could affect Cl^- in OHCs. A similar conductance in the lateral membrane of OHCs has been demonstrated, and Cl^- ions have been shown to affect the voltage sensitivity and affect the speed of transitions from expanded to contracted states of prestin. Although the current carried by individual molecules of prestin is small, the presence of large numbers of prestin in the lateral membrane of OHCs (estimated to be upwards of 10^6 per OHC) likely makes this current important. Consistent with this possibility, expression of prestin at high levels in HEK cells has a major effect on its resting potential. A similar role has been established in the leakage conductance of EAAT1/2 in glial cells in the cerebellum, that show developmental expression, reducing intracellular chloride⁵².

Methods

Cell culture. Chinese hamster ovary (CHO) cells were cultured in Hams-F12 medium (high glucose), containing 50 U/ml each of penicillin and streptomycin, 10% fetal bovine serum, 2 mM L-glutamine at 37 °C in a CO_2 incubator (5%).

HEK293 cells were cultured in Dulbecco's modified Eagle's medium (DMEM, high glucose) containing 50 U/ml each of penicillin and streptomycin, 10% fetal bovine serum at 37 °C in a CO_2 incubator (5%).

The tetracycline-inducible, highly-expressing monoclonal prestin HEK 293 cell lines were reported previously²⁸. Cells were cultured in modified DMEM mentioned above. In addition, 4 μ g/ml of blasticidin and 130 μ g/ml of zeocin were supplemented in the growth media to maintain prestin expression. Tetracycline (1 μ g/ml) was added to the cell growth medium to induce prestin expression. Cells were recorded after 24 to 72 h after tetracycline-induction.

Mutagenesis. Single amino acid substitutions were generated using QuickChange II site-directed mutagenesis kit (Stratagene, La Jolla, CA) with a gerbil prestin (genbank AF230376³)-YFP in pEYFPN1 vector (Clontech, Mountain View, CA) as a template. All mutations were confirmed by DNA sequencing.

Transient transfection in CHO cells. Transfection of constructs into CHO cells (CHO-K1.ATCC[®] CCL-61[™]) was done using Fugene 6 (Promega, Madison, WI) according to the manufacturer's instructions, in 24-well plates. Cells were recorded 24–72 h after transfection.

Electrophysiological Recording. Prestin stably expressed in a tetracycline inducible HEK line or transiently transfected into CHO cells were recorded using a whole-cell configuration at room temperature using an Axon 200B amplifier (Molecular Devices, Sunnyvale, CA), as described previously²⁸. Cells were recorded 24–72 h after tetracycline induction or transfection to allow for stable measurement of current and NLC. A series of bath solutions with different anions/cations were used. The standard base solution components were (in mM): TEACl 20, CsCl 20, $CoCl_2$ 2, $MgCl_2$ 2, Hepes 5, pH 7.2. In addition, for anion substitutions the following were added (separately) to the base solution (in mM): NaCl 100, NaSCN 100, NaOCN 100, $NaIO_3$ 100, Na Methanesulfonate 100, Na_2 Malate 60, or Na_2 Oxalate 60. Similarly, for cation substitutions the following were added separately to the base solution (in mM): KCl 100, NMDG-Cl 100, or Tris-Cl 100, separately. The pipette solution contains (in mM): NaCl 100/NaSCN 100, CsCl 20, EGTA 5, $MgCl_2$ 2, Hepes 10, pH 7.2. Osmolarity was adjusted to 300 ± 2 mOsm with dextrose. After whole cell configuration was achieved in extracellular NaCl and a ramp protocol recorded to confirm baseline NLC and currents. Extracellular anion and cation substitutions were then made by local extracellular perfusion of each individual cell followed by recording a ramp protocol.

Command delivery and data collections were carried out with a Windows-based whole-cell voltage clamp program, jClamp (Scisoft, Ridgefield, CT), using a Digidata 1322A (Axon Instruments).

A continuous high-resolution 2-sine voltage command was used, cell capacitance and current being extracted synchronously. Capacitance data were fitted to the first derivative of a two-state Boltzmann function:

$$C_m = Q_{max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin} \quad (1)$$

where

$$b = \exp \left(-\frac{ze(V_m - V_{vh})}{kT} \right) \quad (2)$$

Q_{max} is the maximum nonlinear charge transfer, V_h the voltage at peak capacitance or half-maximal nonlinear charge transfer, V_m the membrane potential, C_{lin} linear capacitance, z the unitary charge (a metric of voltage sensitivity), e the electron charge, k the Boltzmann constant, and T the absolute temperature. Q_{sp} the specific charge density, is the total charge moved (Q_{max}) normalized to linear capacitance. Capacitive currents (Icap) generated by our ramp protocol were removed to reveal ionic currents. In order to estimate Icap (from both linear and NLC), we modelled the patch clamp-cell in Matlab and extracted membrane capacitive currents arising from averaged values of linear capacitance and NLC. In all figures, individual I-V plots were corrected based on averages from the inclusive cells. Reversal potentials, thus, arise from ionic current contributions only. Separately, in specific experiments currents were also determined after voltage steps (50 ms duration) from -150 mV to 150 mV, with 20 mV step increments. Where cations and anions were substituted, local perfusion of the cells were estimated to give rise to small junctional potentials (JPCalc function in pClampEx). These varied from $+1.1$ mV (SCN⁻) to -5.4 mV (Methanesulfonate) with anion substitutions. Cation substitutions also were estimated to give rise to small junctional potentials varying from -0.8 mV (KCl) to $+6.8$ mV (NMDG⁺). Since these numbers were small no corrections were made to the IV plots. For fluid jet experiments we used a QMM perfusion system (ALA Scientific, Instruments, Westbury, NY). The manifold's output tip was $200 \mu\text{m}$ placed 1 mm from the cell, and the flow rate increased by an applied pressure of approximately 20 kPa. Significance of the size of currents at different voltage steps from experimental perturbations were determined using a mixed model analysis of correlated measures (MMACM). Statistical analysis was done with SAS software (SAS Institute Inc, NC).

Inside-out patch recording (noise analysis). Thick wall glass pipettes were pulled using same puller as described above, and coated with sylgard. The initial resistances of the pipettes are 13 – 15 M Ω . Pipette solution contains (in mM): NaCl 100, CsCl 20, EGTA 5, MgCl₂ 2, Hepes 10, pH 7.2. Bath solution contains (in mM): NaCl/NaSCN 100, TEACl 20, CsCl 20, CoCl₂ 2, MgCl₂ 2, Hepes 5, pH 7.2. Osmolarity was adjusted to 300 ± 2 mOsm with dextrose. Inside-out patches were obtained from control HEK cells or the tetracycline-induced prestin stable line. Data acquisition was done with the same interface and amplifier described above. Continuous 10 second commands at desired holding potentials were delivered during recording.

Noise analysis. PSD analyses of excised patch currents from prestin transfected cells, filtered with a 10 kHz, 4 pole Bessel filter and Hamming windowed, were derived from 10 second recordings held at -50 , 0 , and $+50$ mV potentials. In some cases, voltages up to ± 120 mV were analyzed. Some patch records were excluded because of seal loss during recording. Number of patches from separate cells: 11 for symmetrical chloride condition; and 11 for chloride/SCN⁻ conditions 5 for symmetrical chloride of HEK cells and 5 for chloride/SCN⁻ conditions in HEK cells. Spectra were taken for each individual patch recording (1,061,306 pts at $10 \mu\text{s}$ sampling, with a frequency resolution of 0.095 Hz), averaged and plotted out to 3 kHz. Data are presented following subtraction of baseline spectra at 0 mV. Variance was determined by integration of spectra between 0.1 Hz and 1 kHz after subtraction of calculated shot noise ($2ie_0$). Analyses were made with a custom written MATLAB application.

$$I = g \frac{kT}{q[(P-1)\delta + 1]} \left[P \exp\left(\frac{q\delta E}{kT}\right) - \exp\left(\frac{-q(1-\delta)E}{kT}\right) \right] \quad (3)$$

where g is the slope conductance at $E = 0$, q is the apparent charge, is the electrical distance of the barrier, and P is the relative permeability of ions carrying outward current compared to those carrying inward current; if the current were entirely anion selective P would be the permeability ratio P_{SCN^-}/P_{Cl^-} . For Cl⁻ as the external anion the values were $P = 1$, $\delta = 0.467$, $q(e_0) = 0.75$ and g (pS/pF) = 46.3 . For SCN⁻ as the anion the values were $P = 6.18$, $\delta = 0.339$, $q(e_0) = 0.75$ and g (pS/pF) = 92.8 . The values that differ for the two anion species, and the value of q smaller than the elementary charge, are consistent with a distribution of barrier locations, for example distinct barrier locations for anions and cations.

Abstract

Prestin, the transmembrane motor protein is a novel protein underlying the motility of the outer hair cells. Nonlinear capacitance (NLC) or gating charge current, which can be observed in both auditory and transfected non-auditory cells, is the electrical signature of prestin's electromechanical activity. To test the functional role of the C-terminus of prestin, several charged residue clusters were reversed en-block by site-directed mutagenesis. They are D/E to K at 516, 518, 522, 524, 527, 528 and 531 (*cluster a*); R/K to D at 571, 572, 573, 576, 577 and 580 (*cluster b*); R to D at 571; and E/D to K at 608, 609, 610, 611, 612 and 613 (*cluster c*). These constructs were transfected into Chinese hamster ovary cells (CHO) and NLC recordings were performed to evaluate the effects of these charge substitutions. All of the mutants showed NLC. Charge *cluster a* reversal significantly reduced the maximum charge movement (Q_{max}). All but one mutation (charge *cluster c* reversal) shifted V_h , indicative of the operating voltage range, in the depolarizing direction. None of the mutations affected unitary charge movement (z). These data suggest that the C-terminus of prestin lies outside the membrane voltage field, and may play an important role in controlling the operating voltage range through control of the protein's conformational energy profile via allosteric means.

Keywords: Capacitance; Outer hair cell; Prestin; SLC26

Two types of receptor cells populate the mammalian organ of Corti, the inner hair cell (IHC) and the outer hair cell (OHC). IHCs serve only as sensory receptors by transducing basilar membrane vibrations into electrical signals. However, OHCs function both as receptors and effectors, possessing both electro-mechanical and mechano-electrical activities, thereby enabling amplification of the auditory stimulus to the IHCs [2,5,21]. Voltage-dependent mechanical activity of the OHC is detectable by whole-cell patch clamp recording as a nonlinear capacitance (NLC), or equivalently, a gating charge current [3,25]. Recently, the motor protein, prestin, which resides in the OHC lateral membrane [4], was found to underlie OHC electro-mechanical activity and mammalian cochlear amplification [12,31,24]. Transfection of the gene into non-auditory cells results in electro-mechanical characteristics similar to that observed in the native outer hair cell [15,26,31]. Topology studies of this 744 amino acid protein, a member of the anion

transporter family SLC26, show that its C- and N-termini reside within the cytoplasm [6,15,16,18,30]. Interestingly, intracellular chloride was found to play a key role in influencing NLC in both OHCs and prestin-transfected cells, but whether chloride itself is an intrinsic voltage sensor or an allosteric modulator is still debated [18,20]. We have found that removal of intracellular chloride by substitution with other anions causes shifts in prestin's operating voltage range, in addition to altering the protein's nonlinear charge transfer or NLC, indicating that anions modulate energy barriers controlling prestin's conformational state [20,27]. Additionally, we recently observed prestin–prestins interactions via their intracellular termini [17]. Such results may indicate that charged residues within prestin may interact with intracellular anions or influence interactions with other proteins. Many charged residues within the putative transmembrane regions of prestin have been manipulated [18]; however, little data are available on the role played by charged residues found within the cytoplasmic termini, structures which are unlikely to house the molecule's voltage sensor. Here we evaluate the effects of several C-terminal charge cluster reversals on prestin's electromechanical activity in order to gauge

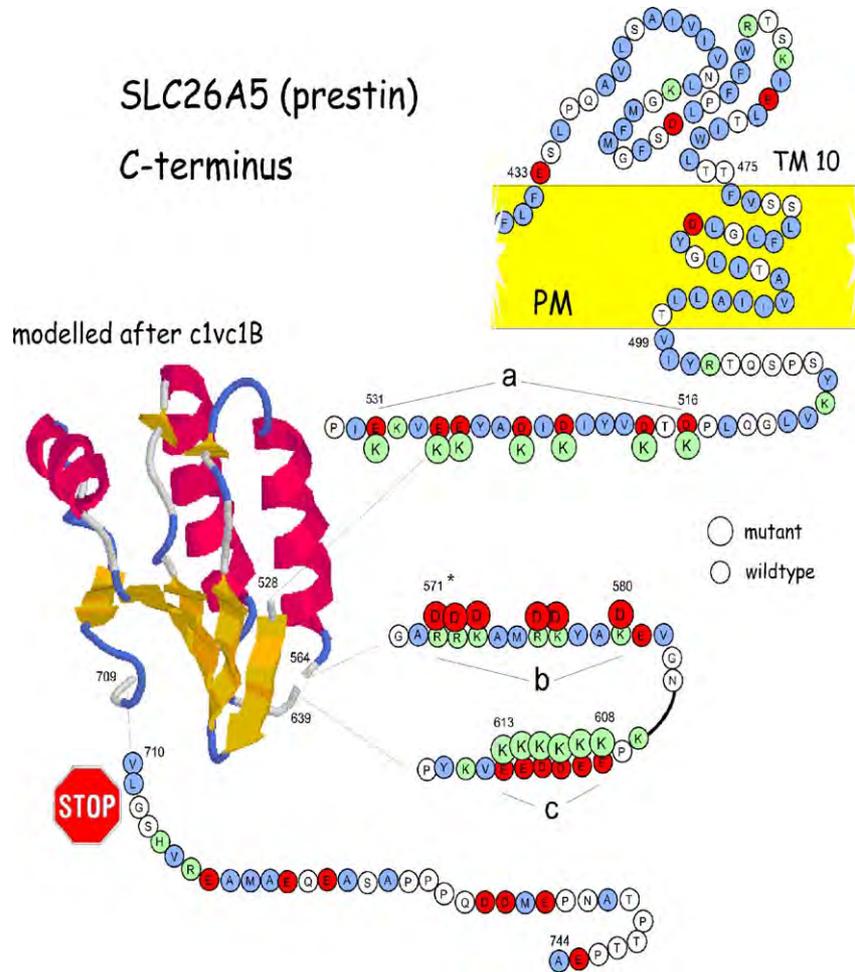

Fig. 1. C-terminal cartoon of gerbil prestin. Indicated are the charged clusters (a–c) which were mutated to residues of opposite polarity (large circles). The final transmembrane domain from the topology model of Navaratnam et al. [18] is shown along with the intracellular residues that were not captured in the model based on 3D structure of the sequence of c1vc1B, the putative anti-sigma factor antagonist tm1442. The model gives an excellent prediction of prestin’s C-terminal structure, but nearly all of the charged clusters we mutated reside in regions with no clear secondary structure. The residues 569–617 though present in prestin, are absent in c1vc1B. Parameters of the model fit: 19% i.d., 100% precision and a 6.4e-7 E value. The stop indicates the position (709) of the C-terminal truncation that results in a loss in NLC [18].

the C-terminal contribution to allosteric modulation of motor function.

The gerbil prestin sequence [31] was submitted to Quick Phyre (<http://www.sbg.bio.ic.ac.uk/~phyre/>) fold facility for 3D structural modeling and the C-terminal region of prestin was best fit with the structure encoded by the putative anti-sigma factor antagonist tm1442 (PDBcode: 1vc1_B; characteristic of the STAS domain [1]), at 19% i.d., 100% precision and a 6.4e-7 E value. The structure is shown in Fig. 1 along with noted mutations that we made in the prestin sequence. Though the STAS domain stretches from 525–711, the model is more limited.

We changed two negatively charged clusters to positive (residues 516–531 and 608–613; designated as charge clusters a and c, respectively), and changed one positively charged cluster to negative (571–580; cluster b). Additionally, a single site charge substitution was made at residue 571, denoted by “*” in Fig. 1. Charged amino acids were mutated en-block using the megaprimer PCR amplification method. Amplification by PCR was done using Hi-Fidelity DNA polymerase (Roche). The parameters were: 10 cycles of 94 °C for 40 s, 55 °C for 2 min,

68 °C for 6 min; 30 cycles of 94 °C for 40 s, 55 °C for 2 min, 68 °C for 6 min with 20 s extension for every cycle. A clone of gerbil prestin served as the template (courtesy of Zheng et al. [31]). Amplified products were purified, and ligated into PCDNA 3.1. Each of the clones generated were sequenced to exclude the possibility of PCR generated errors. Transient co-transfection with EGFP into Chinese hamster ovary cells (CHO) was achieved with Lipofectamine in accordance with the manufacturer’s recommendations. The ratio of prestin to EGFP plasmid (2:1) was kept constant in all the experimental groups. All cells showing NLC were included in our analyses.

Cells were recorded by whole-cell patch clamp configuration at room temperature using an Axon 200A amplifier (Axon Instruments, CA, USA), as described previously [25]. Expression levels, as evidenced by NLC measures, were stable from 24–72 h after transfection in control group. All statistical analyses of the mutants were performed at the 48 h time period following transfection. The bath solution contained (in mM): TEA 20, CsCl 20, CoCl₂ 2, MgCl₂ 1.47, Hepes 10, NaCl 99.2, CaCl₂·2H₂O 2, pH 7.2, and the pipette solution contained (in

mM): CsCl 140, EGTA 10, MgCl₂ 2, Hepes 10, pH 7.2. These conditions ensured that prestin-chloride interactions were maximal [18,20]. Osmolarity was adjusted to 300 ± 2 mOsm with dextrose. Command delivery and data collections were carried out with a Windows-based whole-cell voltage clamp program, jClamp (Scisoft, CT, USA), using a NI PCI 6052E interface (National Instruments Co., USA).

Capacitance was evaluated with a continuous high-resolution 2-sine wave technique fully described elsewhere [22,25]. Capacitance data were fitted to the first derivative of a two-state Boltzmann function:

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}} \quad (1)$$

where

$$b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right)$$

Q_{\max} is the maximum nonlinear charge transfer, V_h the voltage at peak capacitance or half-maximal nonlinear charge transfer, V_m the membrane potential, C_{lin} linear capacitance, z the valence (a metric of voltage sensitivity), e the electron charge, k the Boltzmann's constant and T the absolute temperature. Q_{\max} is reported as Q_{sp} the specific charge density, i.e. total charge moved normalized to linear capacitance. A student's t -test was used to evaluate the effects of mutations on the different parameters of NLC.

FACS analysis of the different mutants and prestin were done to determine levels of surface expression exclusively [17]. Two antibodies to prestin peptides (aa 274–290 and 359–375) that we model to lie on the outer surface of the membrane were used to live stain transfected CHO cells [17]. Staining was performed as previously described except that the secondary antibody used was an Alexa 488 labeled goat anti-rabbit antibody. There was good concordance between the two antibodies used to separately stain transfected cells, results that internally validated our data (see Fig. 4). We have previously established that prestin surface expression in CHO cells were unchanged between 24–72 h after transfection by both FACS analysis and measurement of NLC [17]. The percentage of cells expressing prestin on its surface and the magnitude in NLC in CHO cells are similar to that obtained by other investigators [17,18].

Fig. 1 depicts the structural features of prestin's C-terminus. Large circles indicate the charge reversals that were made and confirmed by sequencing. All charge substitution mutants displayed NLC, and did not affect unitary charge movement z . Q_{\max} , was significantly different only with mutation of residues 516–531 (charge cluster *a*), which reduced Q_{\max} . Fig. 2 shows an example of a NLC capacitance function obtained from this mutation and a control cell. For presentation purposes, we averaged fitted Boltzmann parameters, presented in Table 1, and constructed average NLC functions of each mutation based on their average values (Fig. 3). The mutation of cluster *a* had a significant decrease of Q_{\max} , but unitary charge movement (z) remained normal, indicating that the mutated protein's voltage sensor remained unaltered, and only the number of functional proteins decreased. We confirmed that the levels of prestin surface expression in this (and other) mutant(s) were similar to

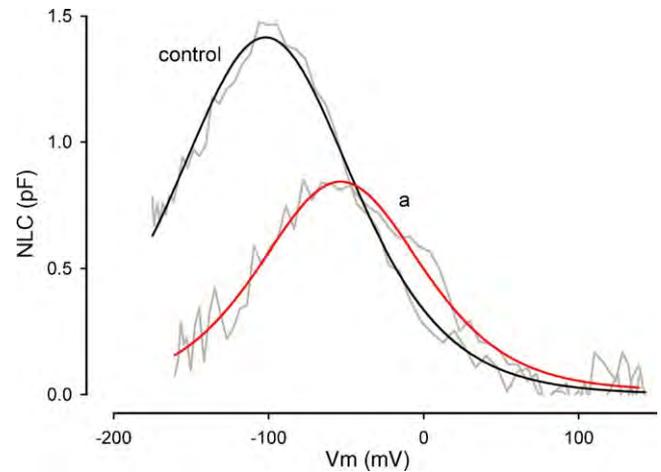

Fig. 2. NLC traces from prestin transfected CHO cells. CHO cells were transfected with constructs containing normal prestin (control) or the reversal of charge cluster *a* as indicated in Fig. 1. The solid traces are fitted curves. V_h of the reversal mutation shifts in the depolarizing direction along the voltage axis, and Q_{\max} significantly decreases.

Table 1
Average fitted Boltzmann parameters

	Q_{sp} (fC/pF) ± S.E.	z ± S.E.	V_h (mV) ± S.E.
Control ($n=15$)	6.15 ± 0.71	0.58 ± 0.03	-99.85 ± 2.51
Cluster <i>a</i> ($n=5$)	2.90 ± 0.58	0.53 ± 0.04	-57.41 ± 5.51
Cluster <i>b</i> ($n=6$)	6.23 ± 1.50	0.52 ± 0.04	-67.93 ± 1.73
Cluster <i>c</i> ($n=5$)	5.10 ± 0.38	0.71 ± 0.01	-108.20 ± 6.45
Residue 571 ($n=7$)	4.86 ± 0.63	0.65 ± 0.05	-90.19 ± 0.97

controls by FACS analysis (Fig. 4). z (and Q_{\max}) remained stable in the other mutations too, confirming that these residues, as expected, do not serve as charge carriers through the membrane. Some substitutions significantly affected V_h , with opposite charge substitutions changing V_h in the same depolarizing direction. For example, a change of negative charge in cluster *a* to

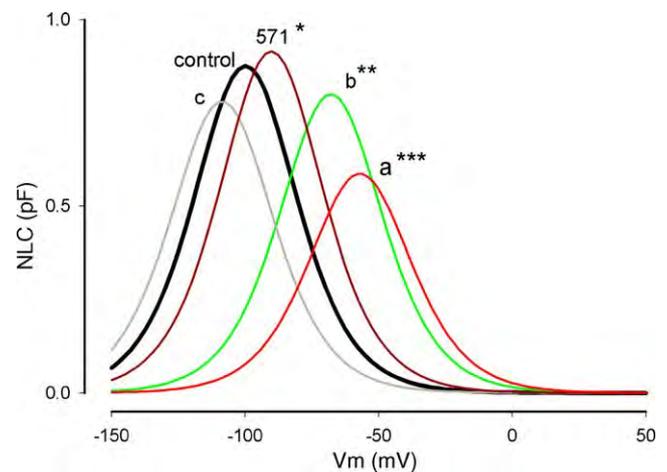

Fig. 3. C-terminal charge reversals predominately alter prestin's operating voltage range. For visual clarity, we averaged fitted parameters from each mutation, presented in Table 1, and constructed NLC functions of each based on their average values. Traces from each mutation are indicated as *a*, *b*, *c* and 571, and show some significant differences from control NLC, namely, for V_h and Q_{sp} (* $P_{V_h} < 0.05$; ** $P_{V_h} < 0.05$; *** $P_{V_h} < 0.05$; $P_{Q_{\text{sp}}} < 0.05$, respectively. The trace from control cells is the heavy black line.

positive, and a change in positive charge in *cluster b* to negative resulted in a depolarizing shift in V_h to -57.41 ± 5.51 ($n = 5$) and -67.93 ± 1.73 mV ($n = 6$), respectively. These effects on prestin activity are likely due to changes in the steady state energy profile of prestin, i.e. an allosteric effect possibly through interference with interacting proteins or anions (see discussion). Interestingly, mutation of charge *cluster c* within the most distal charged cluster, showed little difference from controls. Finally, the single charge substitution at residue 571 showed only minor changes.

The topology of prestin (SLC26A5) has received much attention, as has that of the other family members of SLC26

[6,13–19,30]. Initial efforts indicated that the protein consists of 12 transmembrane domains (TM), with both C- and N-terminal regions residing intracellularly [6,15,16,18,29,30]. Though the location of these termini are fairly certain, various prediction programs provide a confusing profile of TM domains. Even so, epitope tagging and the putative location of reactive residues have narrowed our view. One of the popular maps places two N-glycosylation sites on the second extracellular loop [16], but we have since observed that this site may not reside extracellularly, but instead intracellularly [17]. Though our new model flips the protein within the plane of the membrane, while conserving the

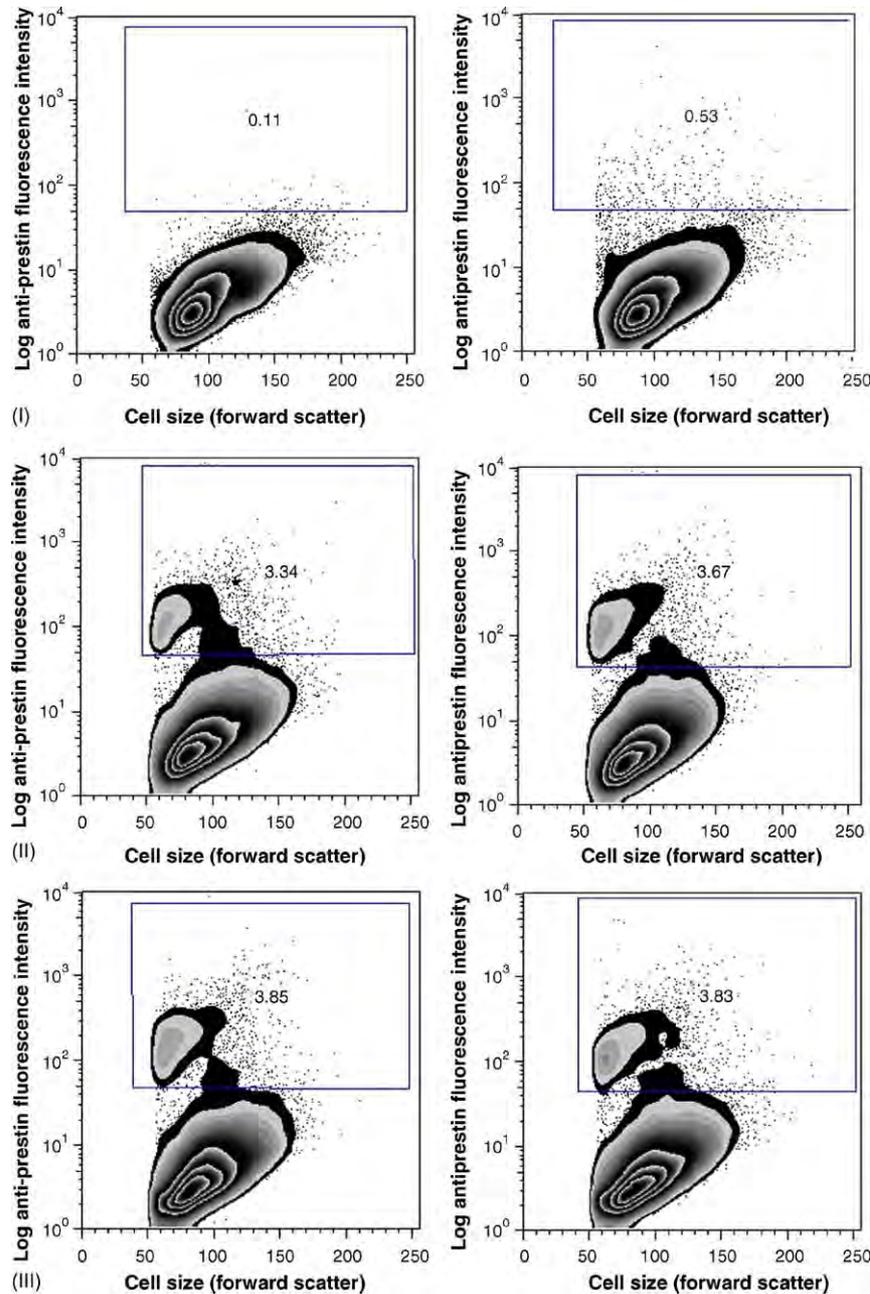

Fig. 4. Surface expression of cells transfected with normal prestin and mutant prestin were similar. Shown above are FACS plots of cells transfected with empty vector (I), normal prestin (II), charge cluster reversal a (III), charge cluster reversal b (IV) and charge cluster reversal c (V). The cells were live-stained with two antibodies against two peptides that we model to lie on the outer surface of the cell [18]. The percentage of cells with prestin surface expression (boxed area) reflecting efficiencies of transfection (inset) varied from 3.5 to 8.0% and are in line with results obtained by other groups (Oliver and Zheng, personal communication, see also [18]). The intensities of fluorescence between the different groups were similar confirming similar levels of surface expression.

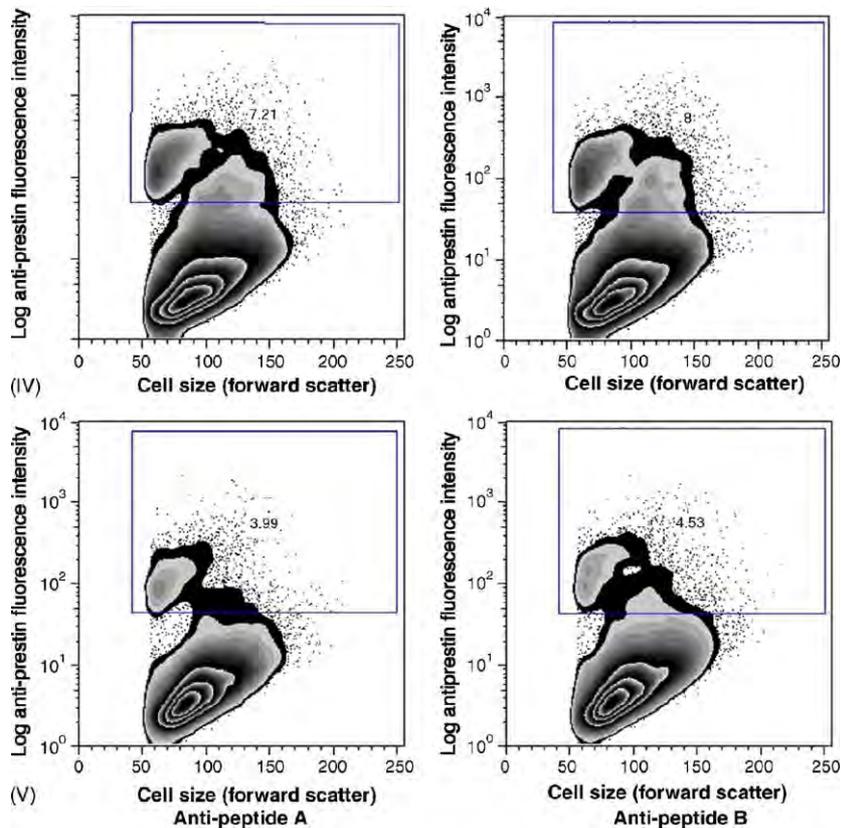

Fig. 4. (Continued).

intracellular termini and reversing the resident milieu of the non membrane bound loops, it maintains the intracellular location of a cGMP phosphorylation site proposed by Dallos and coworkers [6]; their modified model required a reentrant loop to intracellularly expose their previously predicted extracellular location of the site. Our model predicts simple TM transits. Clearly, the controversy over prestin's membrane topology indicates a complex interaction with the plasma membrane, which structural studies must finally divulge.

More germane to the present work, despite the seemingly clear localization of the C-terminus intracellularly, there are some observations which indicate that this domain is not simply accessible to attempted perturbations made intracellularly, outside the lipid bilayer. For example, the lack of an effect of intracellular trypsin or pronase treatment on OHC and transfected cell NLC indicates that prestin's termini are somehow protected [7–9,28]. We would therefore expect that deletion of either the C- or N-terminus would abolish NLC, a view that has been confirmed by mutational analysis (see Fig. 1); [17,29]. Interestingly, in channel forming bacterial colicins an intracellular hydrophilic group of residues (or even larger appended tags) can be moved across the membrane in response to changes in voltage [10,11], a mechanism that could also operate in prestin since these charged clusters may be constrained close to the PM within the restricted sub-plasmalemmal space bounded by the subsurface cisternae. Indeed, this type of mechanism that colicin employs has been offered as a possible mechanism to account for area changes evoked by prestin activation [23]. Thus, we

have no direct empiric evidence that the C-terminus of prestin is statically placed outside the bilayer. Nevertheless, our current work bears on this issue, since mutating charged residues in prestin that do not reside within the membrane field should not directly alter unitary charge movement. We found with our charge reversal mutations that, in no case, was the unitary charge of prestin's voltage altered, implying that these residues lie outside the membrane field. However, clear effects on voltage sensing were observed, with three mutations, *a*, *b* and *R571D* showing significant changes in V_h . We interpreted these results to indicate a shift in the steady state energy profile of the protein. Since both mutations of *cluster a* and *b* (which have opposite charge) shift V_h in the same direction, it is possible that simultaneous mutations of both could produce an augmented shift. Additionally, one mutant (*charge cluster a* that is most proximal to the membrane) shows a significant decrease in the total charge moved. We interpret this to mean that the number of functional motors in this mutant has decreased. This view is additionally supported by similar levels of surface targeting of prestin determined by FACS in cells transfected with this mutant compared to normal prestin. Moreover, this observation is also in line with our previous work on truncations at the most distal section of the C-terminus, where the number of functional motors within the membrane decreased as stop codons were successively placed within the residue range of 715 to 710. Truncations at residues more proximal to 710 produced non-functional motors despite proper membrane targeting. We additionally showed in that work that homo-multimerization occurs among prestin molecules, and

hypothesized that obligate interactions underlie prestin's motive force. It may be that our charge reversals also interfere with interactions of other proteins at the C-terminus.

One other possibility arises. It is known that Cl^- interactions with intracellular moieties of prestin are crucial for prestin function, and we have proposed that, in contrast to models suggesting extrinsic voltage sensing by Cl^- , Cl^- serves as an allosteric modulator of prestin. For this reason, it may be that anions might interact with the C-terminal charge clusters, at least with those two clusters which reside most proximal to the membrane (*clusters a, b*), since only those showed substantial shifts in voltage sensing. Recently, manipulation of the STAS domain, which is conserved within the C-terminus among SLC26 transporter family members has been shown to inhibit sulfate transport in SULTR1.2 [19]. This was observed in the presence of normal membrane targeting. We are currently investigating whether our charge reversal mutants alter multimerization and Cl^- sensitivity in prestin.

In sum, we hypothesize that the C-terminal charged clusters of prestin, while not interacting with the membrane field to alter unitary charge movements in prestin, may work by intracellular interactions with either other proteins or anions, namely via allosteric means.

Bian S, Koo BW, Kelleher S, Santos-Sacchi J, Navaratnam DS. A highly expressing Tet-inducible cell line recapitulates in situ developmental changes in prestin's Boltzmann characteristics and reveals early maturational events. *Am J Physiol Cell Physiol* 299: C828–C835, 2010. First published July 14, 2010; doi:10.1152/ajpcell.00182.2010.—Prestin is the motor protein within the lateral membrane of outer hair cells (OHCs), and it is required for mammalian cochlear amplification. Expression of prestin precedes the onset of hearing in mice, and it has been suggested that prestin undergoes a functional maturation within the membrane coincident with the onset of hearing. We have developed a tetracycline-inducible prestin-expressing cell line that we have used to model prestin's functional maturation. We used prestin's voltage-dependent nonlinear charge movement (or nonlinear capacitance) as a test of function and correlated it to biochemical measures of prestin expressed on the cell surface. An initial stage of slow growth in charge density is accompanied by a rapid increase in our estimate of charge carried by an individual motor. A rapid growth in charge density follows and strongly correlates with an increasing ratio between an apparently larger and smaller monomer, suggesting that the latter exerts a dominant-negative effect on function. Finally, there is a gradual depolarizing shift in the voltage of peak capacitance, similar to that observed in developing OHCs. This inducible system offers many opportunities for detailed studies of prestin.

development; prestin; cell lines

MAMMALIAN OUTER HAIR CELLS (OHCs) are electromotile, and this property is believed to underlie cochlear amplification, a process that enhances mammalian frequency tuning and sensitivity (4, 5, 16). Prestin, a member of the SLC26 anion transporter family, has been identified as the protein responsible for electromotility (15, 20). In these and other studies, voltage-dependent charge movement of prestin's voltage sensor, detected as a nonlinear capacitance (NLC), has been shown to strongly correlate with electromotility. Thus, NLC can be used as a proxy measure of electromotility. The Boltzmann characteristics of NLC include the density of voltage sensor charge (Q_{sp}), the voltage at peak capacitance (V_h), and unitary charge valence (z). Q_{sp} is an estimate of the number of functional motors within a unit area of surface membrane, V_h is a metric of the steady-state energy profile, and z is an estimate of charge moved within an individual motor. Both electromotility and NLC show a developmental maturation in the OHCs (1, 2, 7, 13). In gerbils, electromotility is first detected at postnatal day P8 and P7 in OHCs from the apical

and basal turns, respectively; thereafter it stabilizes at P17–P19 (7), coincident with maturation of hearing (11). In contrast, NLC can be detected as early as P0 in OHCs from the rat apical turn (13). In that study, specific NLC was found to stabilize at P11 well before maturation of hearing in rats (3). However, in mice, linear capacitance (an indicator of both cell surface area and prestin deposition into the membrane) and prestin RNA levels asymptote at about P10, whereas specific NLC continued to increase until P18 (1), which coincides with maturation in hearing (17). The results of Abe et al. (1) strongly suggest a maturation process for the motor protein itself, although the nature of this maturation has yet to be determined. To gain insight into the possible mechanisms underlying this phenomenon, we used a tetracycline-inducible, prestin-expressing stable cell line of human embryonic kidney (HEK) cells to study aspects of NLC as they relate to expression of prestin. Our results demonstrate that maturation following induction involves an increasing incorporation of two monomeric forms of prestin into the cell membrane, with one form exerting a dominant-negative effect on the other. Functional correlates of maturation show early and prolonged time course components following induction, with z increasing during the first few hours, and both Q_{sp} and V_h changing over tens of hours. These data substantiate observations about the maturation of electromotility in OHCs. They also provide insights that cannot be gleaned from OHC measures alone and underscore the utility of this inducible cell line.

MATERIALS AND METHODS

Prestin gene constructs. Plasmid pcDNA6/TR is from Invitrogen with selective antibiotic blasticidin. This construct codes for a tetracycline operon (TO) repressor that works with the second plasmid, pcDNA4/TO/*myc*-HisC, to create a tetracycline-inducible system for protein expression. pcDNA4/TO/*myc*-HisC is also from Invitrogen and is selective by antibiotic zeocin. The gerbil prestin gene (a gift from J. Zheng and P. Dallos) tagged with enhanced yellow fluorescent protein (EYFP) was inserted into the multiple cloning site of pcDNA4/TO/*myc*-HisC. This construct (gPrestin-YFP4TOMycHisC) contains a 2× tetracycline operon that works with the first construct to create inducible prestin expression. When tetracycline is absent, the repressor binds to the tetracycline operon, keeping the gene downstream from being expressed. When tetracycline is present, it binds to the repressor, releasing the tetracycline operon and allowing the prestin gene to be expressed. The *myc*-His tags in the construct are for detection and purification purposes. pEYFP-N1 vector (Clontech) was used to construct the noninducible prestin-YFP-expressing vector with a Flag tag added to the NH₂ terminus. This vector uses antibiotic G418 for selecting stable cell lines.

Cell culture and transfection. HEK293 cells (American Type Culture Collection ATCC, Manassas, VA) were cultured in Dulbecco's modified Eagle's medium (DMEM, high glucose) medium containing 50 U/ml each of penicillin and streptomycin, 10% fetal bovine serum at 37°C in a CO₂ incubator (5%). Transfection of constructs into these cells was done using Superfect reagent (Qiagen) according to the manufacturer's instructions for stable transfection. To produce inducible prestin cell lines, pcDNA6/TR was first transfected and selected with 8 µg/ml blasticidin for monoclonal stable cell lines (293-pcDNA6/TR). Then the gPrestin-YFP4TomyHisC construct was transfected to stabilized 293-pcDNA6/TR cells, and selected with 280 µg/ml zeocin. Stabilized monoclonal prestin-YFP-mycHis expression was initially screened by using fluorescence microscopy 1 or 2 days after addition of 1 µg/ml tetracycline to the growth medium. Culturing of these cell lines (293-TRxST-gPrestin-YFP4TomyHisC) was in DMEM base medium supplemented with 4 µg/ml blasticidin and 130 µg/ml zeocin. Selection of the Flag-prestin-YFP-N1 construct was done by adding 1,200 µg/ml G418 (geneticin) to these cells. G418 concentration in the growth medium was reduced to 600 µg/ml for stable cell lines.

Patch-clamp electrophysiology. Intracellular solution (pipette solution) contained (in mM) 136 KCl, 1 CaCl₂, 1 MgCl₂, 10 HEPES buffer, and 5 EGTA, pH 7.28. Osmolarity was adjusted to 299 ± 2 mosM using glucose for all solutions. Extracellular solution (bath solution) contained (in mM) 20 TEA, 20 CsCl, 2 CoCl₂, 1.47 MgCl₂, 10 HEPES buffer, 99.2 NaCl, 2 CaCl₂, and 2 BaCl₂, pH 7.28. Glass pipettes were pulled using a P-2000 laser-heating pipette puller (Sutter Instruments). All pipettes have initial resistances of about 2.5 MΩ. All patches were made on single cells growing on a coverslip at different time points after tetracycline induction. A Nikon Eclipse FNI upright microscope equipped with a ×40 water immersion lens and a green fluorescent protein (GFP) UV light filter was used for cell observation,

and an EXFO motorized manipulator by Burleigh (PCS-6000) was used for pipette manipulation. Data acquisition was done with a Digidata 1322A A/D converter and an Axonpatch 200B Integrating Patch clamp (Axon Instruments). Cell capacitance was measured under whole cell configuration using the jClamp software (<http://www.scisoftco.com/>). For time course studies with tetracycline-inducible cell lines, 4–11 cells were averaged for each time point. NLC from two inducible cell lines was measured separately, and the results are comparable. Only one is presented in this study.

The NLC traces show the change of membrane capacitance C_m in response to voltage across the membrane V_m . Each trace can be fitted according to Eq. 1 using four parameters:

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}}$$

where

$$b = \exp \left[\frac{-ze(V_m - V_h)}{kT} \right] \quad (1)$$

Q_{\max} is maximum nonlinear charge transfer, V_h is voltage at peak capacitance or half-maximal nonlinear charge transfer, V_m is membrane potential, C_{lin} is linear capacitance proportional to cell surface area, z is valence (a metric of voltage sensitivity), e is electron charge, k is Boltzmann's constant, and T is absolute temperature. Q_{\max} is reported as Q_{sp} , the specific charge density, i.e., total charge moved normalized to linear capacitance. Similarly, specific nonlinear capacitance NLC_{sp} refers to $(C_m - C_{\text{lin}})/C_{\text{lin}}$.

Confocal fluorescence imaging. Tetracycline (1 µg/ml) was added to the cell growth medium 1 day after the cells were plated on coverslips. After incubation for 24 to 48 h for tetracycline-induced

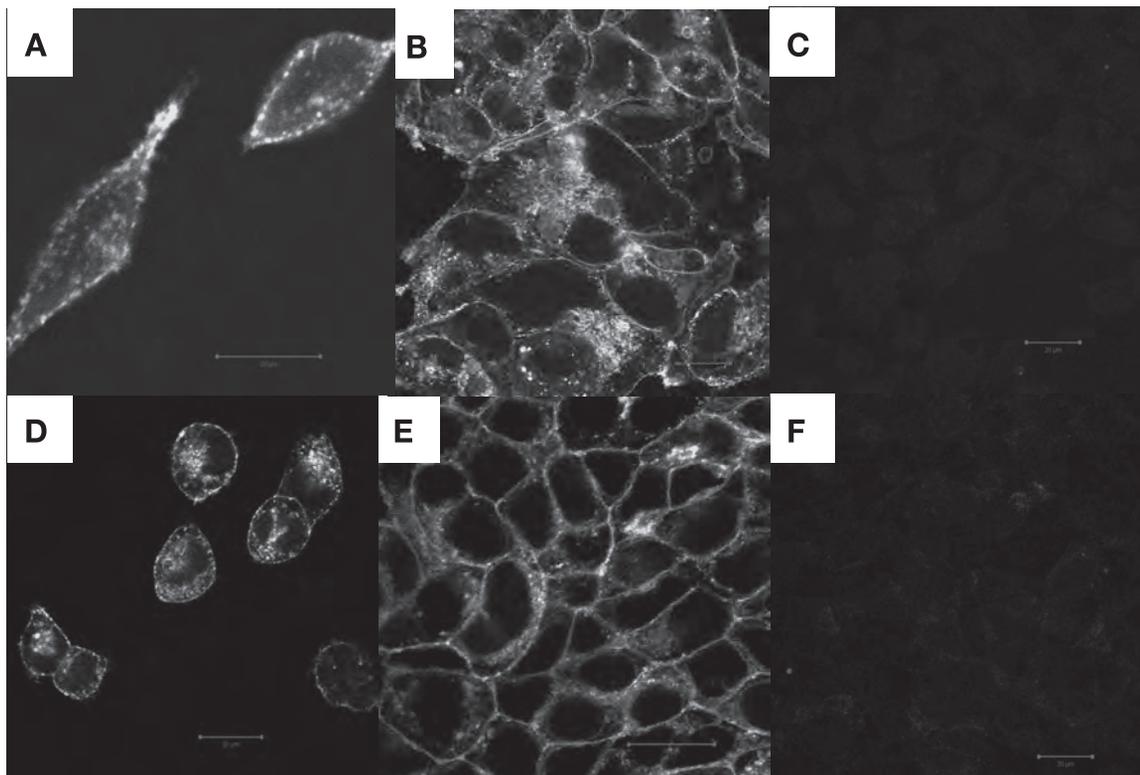

Fig. 1. Prestin-yellow fluorescent protein (YFP) is localized to the membrane. Prestin-YFP expression in human embryonic kidney (HEK) 293 cell lines characterized by confocal imaging of YFP fluorescence is shown. *A* and *B*: a HEK293 cell line stably expressing a Flag-tagged prestin-YFP construct. *C*: untransfected HEK293 cells as negative control. *D–F*: a tetracycline-inducible HEK293 cell line expressing prestin-YFP with a mycHis6 tag at its COOH terminus. *D* and *E*: 24 h after addition of 1 µg/ml tetracycline to the growth media. *F*: no tetracycline added as negative control. Scale bar, 20 µm.

expression of prestin-YFP, cells were washed briefly with PBS, then fixed in 3% formaldehyde in PBS for 20 min at room temperature. Following a wash in PBS, cells were mounted with VectaShield mounting media for confocal microscope observation. All confocal experiments were done on a Zeiss LSM 510 Meta confocal microscope using a 514 nm laser line. Image analysis was done using LSM Image browser.

To analyze fluorescence intensity of cell surface prestin versus total prestin expression using YFP fluorescence imaging, individual cells from the 293-Flag-prestin-YFP cell line were analyzed using Photoshop's histogram utility. The integrated fluorescence intensity is the product of mean pixel intensity, after subtracting mean background intensity, times total pixel numbers in the region of interest (ROI). By demarcating the outer edge of the whole cell as the ROI, we obtained total integrated pixel intensity. We then obtained intracellular intensity by applying the same algorithm defining the ROI within the inner aspect of the cell membrane. Surface intensity was obtained by subtracting the intracellular intensity from the total cell intensity.

Electron microscopy of nanogold-labeled prestin-YFP. Electron microscopy immunohistochemistry was done at the Yale Center for Cell and Molecular Imaging using a Tecnai 12 Bio Twin Transmission Electron Microscope. All images were taken at the same calibrated magnification ($\times 43,000$). Fifty images were taken randomly from HEK cells expressing prestin-YFP, as well as 20 images from a control sample (untransfected HEK cells) for quantification and statistics. For all images included in this analysis, the anti-GFP primary antibody conjugated with 10-nm nanogold was used at a 1:50 dilution for maximum labeling efficiency. Background labeling as seen in

mitochondria and nucleus was very low. Quantification of surface prestin and total prestin expression was done by counting the nanogold particles either on plasmic membrane only or everywhere in the cell.

Surface protein labeling. Cell surface protein labeling was done according to the manufacturer's instructions (Pierce Biotech, EZ-link Sulfo-NHS-SS-Biotin surface protein isolation kit). Briefly, cells grew on 10-cm culture plates, and 1 $\mu\text{g/ml}$ tetracycline was added at different time points to give different incubation times at harvest. Cell surface proteins were labeled after a brief wash in cold PBS at 4°C on a flat shaker. The reaction was quenched using quenching solution after 30 min, and cells harvested by using a scraper. Cells were spun down and briefly washed in Tris-buffered saline before addition of lysis buffer supplemented with protease inhibitors (Roche Complete protease inhibitors). Cells were lysed at 4°C for 30 min with end-to-end rotation, and total protein was quantified using Bio-Rad Protein Assay kit (500-0006); 2,500 μg of total protein from each sample was mixed with 250 μl NeutrAvidin Gel and incubated for 1 h at room temperature. Following steps of washing and centrifugation, plasma membrane proteins were purified and eluted from the gel using SDS sample buffer with 100 mM DTT. Two microliters of each eluted surface protein was loaded onto a Bio-Rad 4-15% Tris-glycine gradient gel. Lysate loading was also quantified to have 0.75 μg of total protein for each lane. In total, three rounds of surface labeling were done, each followed by Western blot and densitometry measurements, and the results were averaged. To avoid signal saturation on the film, and to minimize the subjectivity in assigning the boundaries between the bands, different exposures that gave clearly identifiable

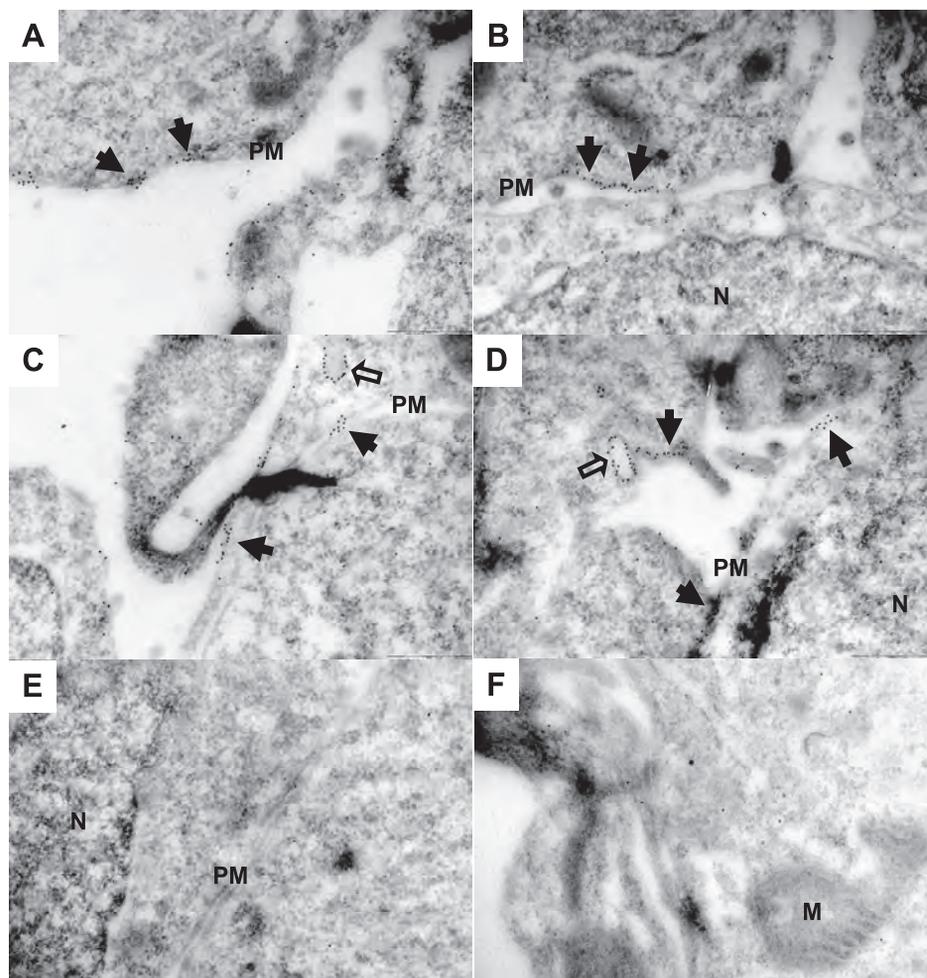

Fig. 2. Immunogold labeling localizes prestin to the plasma membrane. Electron microscopy (EM) images of a HEK293 cell line expressing Flag-tagged prestin-YFP are shown. Cells were grown to a monolayer in culture dishes, fixed, embedded, thin-sectioned, labeled with anti-green fluorescent protein (GFP) antibody (that cross-reacts with YFP) conjugated with 10 nm nanogold particles, stained, and imaged using a Tecnai 12 Bio Twin transmission electron microscope. *A–D*: samples from cells expressing prestin-YFP. Nanogold labeling is clearly seen on the plasma membrane (filled arrows), indicating proper trafficking and targeting of prestin molecules to the cell membrane. Notice also scattered labeling in the cytoplasm and on some intracellular vesicles as pointed out by hollow arrows. *E* and *F*: in the untransfected HEK293 cells, very small amount of labeling was observed. N, nucleus; PM, plasma membrane; M, mitochondria. Scale bar, 250 nm.

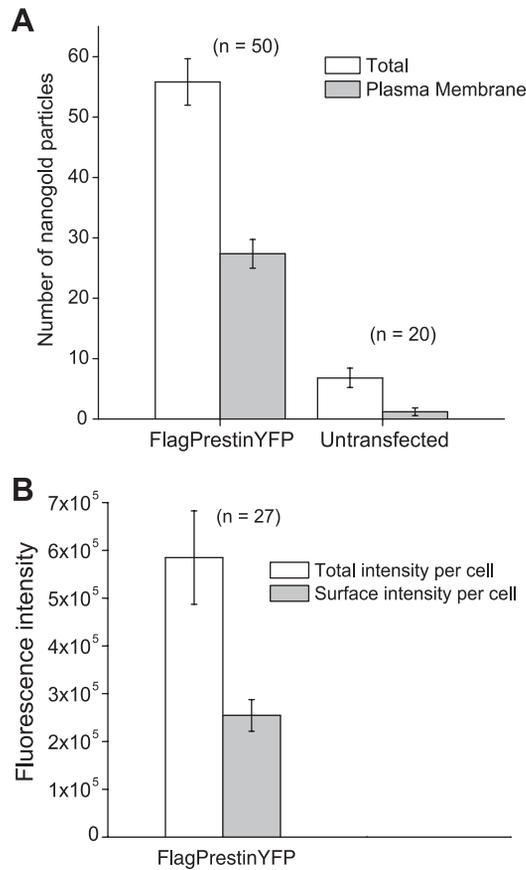

Fig. 3. Equivalent amounts of prestin are found in the plasma membrane and cytoplasm. Quantitative analysis on the distribution of prestin molecules in a Flag-tagged prestin-YFP stable cell line is shown. *A*: nanogold particle counting from EM images. Individual particles were counted from each micrograph, and the particles on the plasma membrane were subtracted from the total. As shown here, on average there are 56 gold particles in each micrograph of transfected cells, out of which 27 are localized on the cell membrane ($\sim 50.6 \pm 2.5\%$). *B*: the intensity of fluorescence was assayed on Flag-tagged prestin-YFP-expressing cells. The localization of YFP fluorescence was quantified in the plasma membranes of these cells. The plasma membranes of these cells contained $48.6 \pm 1.9\%$ of the total fluorescence signal (\pm SE).

and separate bands were used. To allow comparison between different exposures, data were normalized to several bands in the middle lanes with expression levels that were intermediate.

RESULTS

We have established several inducible and noninducible HEK cell lines stably expressing the motor protein prestin. When making these cell lines, we used a number of prestin constructs where prestin was variably tagged to YFP, and the c-myc and FLAG epitopes. We have studied the distribution of prestin expression in these cells by electron microscopic immunogold labeling and confocal imaging. Using our tetracycline-inducible cell line, we investigated the development of the motor protein by measuring NLC and correlated these data with biochemical measures of prestin surface expression in these cells.

Prestin is targeted to the surface membrane in HEK cells. With both inducible and noninducible cell lines expressing prestin-YFP, we observed that YFP fluorescence was localized to the plasma membrane, but significant amounts remained

intracellularly (Fig. 1). In inducible cell lines, YFP was observed at very low levels before induction (Fig. 1*F*) but showed a dramatic increase after induction (Fig. 1, *D* and *E*).

We also attempted to better localize prestin in these cell lines by using nanogold labeling with an antibody to GFP that also recognizes YFP with high fidelity (Fig. 2). In these experiments, we noted that nanogold particles were localized on the plasma membrane and within the cell. A quantitative morphometric analysis where individual particles were counted in 50 photomicrographs revealed that about half of the particles were on the surface membrane of the cell (Fig. 3*A*). These data are congruent with measurement of fluorescence in YFP-tagged prestin-expressing cells. In these cells, $\sim 50\%$ of the fluorescence signal was localized to the surface of the cell (Fig. 3*B*).

Nonlinear capacitance characterization of stable cell lines. Fluorescence measurements indicate that our stable cell lines have high levels of prestin-YFP located in the cell plasma membrane. We then tested these cell lines for functional expression of prestin, by determining NLC in several representative cells from each cell line.

Under whole cell voltage-clamp configuration, we were able to record large NLC in most of our HEK cell lines expressing prestin (Fig. 4). For example, a Flag-tagged noninducible cell line (termed G) exhibits a peak NLC of 3.7 pF (Fig. 4, *top* trace), while the tetracycline-inducible line (termed 16c) has a peak NLC of 2.8 pF (*bottom* trace). NLC values of these cell lines are summarized in Table 1. These typical values are higher than values seen in transiently transfected Chinese hamster ovary cells, which exhibit peak capacitance of about 1 pF; expression levels in these lines are also higher than other stable prestin cell lines (9).

Development of NLC in a tetracycline-inducible prestin cell line. We used tetracycline-inducible cell lines to analyze time-dependent changes in NLC. Typical traces of NLC from different time points after addition of tetracycline to the growth

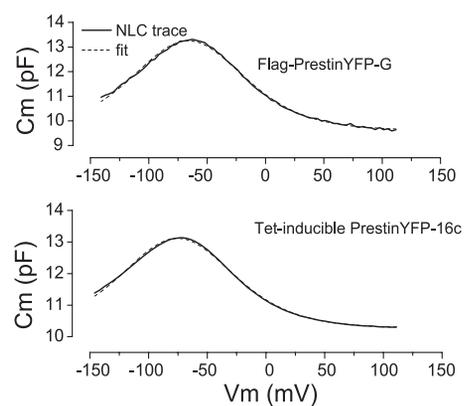

Fig. 4. Large nonlinear capacitance (NLC) is generated in cell lines expressing prestin. Shown are typical traces of NLC from two stable cell lines expressing prestin-YFP. The data were fitted according to Eq. 1. *Top*: trace from a noninducible HEK293 cell line (termed G) expressing Flag-tagged prestin-YFP. The fitting parameters were as follows: peak capacitance voltage (V_h) = -66.1 mV, unitary charge valence (z) = 0.801, maximum nonlinear charge (Q_{max}) = 0.468 pC, and linear capacitance (C_{lin}) = 9.61 pF. C_m , membrane capacitance. *Bottom*: NLC trace from a tetracycline (Tet)-inducible HEK293 cell line expressing prestin-YFP tagged with mycHis6. Tetracycline (1 μ g/ml) was added to the growth media, and NLC was measured 34 h after tetracycline induction. Fitting parameters were as follows: V_h = -75.3 mV, z = 0.804, Q_{max} = 0.365 pC, and C_{lin} = 10.3 pF. V_m , cell membrane potential.

Table 1. Nonlinear capacitance parameters from representative prestin cell lines

Cell Line	Q_{sp} , fC/pF	V_h , mV	z	n	Notes

HEK transiently transfected cells (18)	$\sim 11 \pm 4$	-70 ± 18	0.82	10	
CHO cell line (8)	~ 6	-75			

Values are means \pm SE of nonlinear capacitance parameters in one noninducible (*) and two tetracycline (Tet)-inducible (†) monoclonal cell lines we have developed. For inducible cell lines 15b and 16c, values were chosen from specific time points after induction, since their specific charge density (Q_{sp}) as well as unitary charge valence (z) and voltage at peak capacitance (V_h) change with time of incubation. These cells have a range of Q_{sp} values, all of which are higher than either typical transiently transfected human embryonic kidney (HEK) cells or other stable cell lines developed previously. YFP, yellow fluorescent protein; CHO, Chinese hamster ovary cells. Reference numbers are in parentheses.

media are shown in Fig. 5. When no tetracycline is added, little or no NLC is observed. With 1 μ g/ml tetracycline, NLC becomes readily measurable as early as 2 h after addition.

We also assayed three different parameters of NLC, Q_{sp} , z , and V_h , to further delineate prestin function. Q_{sp} , charge movement per unit of membrane surface, increases with time in a sigmoidal manner (Fig. 6A). The inset in Fig. 6A shows the growth phase in the first 6 h after addition of tetracycline. This phase was characterized by a steady, yet slow increase of Q_{sp} , to about one-tenth of the asymptotic value. This is followed by a rapid increase in Q_{sp} from 6 h to about 20 h after tetracycline induction, where Q_{sp} increases to $\sim 60\%$ of the asymptotic value. Following this rapid increase there is again a phase of slow increase in Q_{sp} to its mature level over a further period of 72–96 h.

In contrast to Q_{sp} , which takes over 60 h to reach its asymptotic level, z , an estimate of charge carried by an individual motor, reaches a maximum level of $0.8e$ 6 h after induction (Fig. 6B).

We also looked at changes in V_h over the time course of prestin expression. As shown in Fig. 6C, even though V_h values fluctuate, there was a general trend for these values to reach

more depolarized potentials with time. V_h settles near -80 mV at ~ 30 h after tetracycline induction.

Development of surface prestin expression in a tetracycline-inducible cell line. We undertook quantitative surface protein labeling experiments using a tetracycline-inducible cell line to determine the expression of prestin on the cell surface. We used a cell surface protein labeling method with cleavable water-soluble Sulfo-NHS-SS-Biotin reagent that then allows for the isolation of surface-labeled protein through its binding to avidin-Sepharose beads. The amount of prestin in these surface-labeled preparations was then determined using Western blotting.

Prestin expressed on the cell surface reaches an asymptotic level at 18–20 h (Fig. 7, B and D). In contrast, the total amount of prestin in the cell continues to increase throughout the sampling period after induction, albeit more slowly after 22 h (Fig. 7, A and C). In these experiments, we observed two major monomeric forms of prestin in both total cell lysate and the cell surface components. The upper monomer has a molecular mass of ~ 125 kDa, and the lower monomer a mass of ~ 100 kDa. There is also a broad multimeric form of prestin, which was first detected at ~ 4 h after induction. The upper monomeric form is the predominant component in both cell lysates and plasma membranes. When plotting Q_{sp} against the intensity of the upper monomer alone, we obtained a linear correlation (adjusted $R^2 = 0.83$). However, this relationship was attenuated at higher Q_{sp} values, when the amount of upper monomer remained stable with continued increase in Q_{sp} (Figs. 7D and 8A). At higher Q_{sp} values, there was a decrease in the lower monomer (Fig. 7D). Concordant with these data, we observed a strong linear relationship (with adjusted $R^2 = 0.92$, Fig. 8A), when we plotted Q_{sp} against the ratio of the upper to lower monomer. These results corroborate our previous assertion (9) that the lower monomer has a dominant-negative effect on the upper monomer. Interestingly, there is also a linear correlation between the initial rapid rise in z and the shift toward more depolarizing voltages in V_h (Fig. 8B). We note that this particular correlation was not an artifact of different initial fitting parameters. That is, we tested a range of voltages used to bracket NLC and established that V_h was not changed by the limits of the voltage range set when establishing a fit.

DISCUSSION

We have developed and used an inducible HEK cell line as a model system to understand prestin's maturation that has been observed in OHCs (1, 13). We used a combination of imaging, electrophysiological recording, and protein labeling

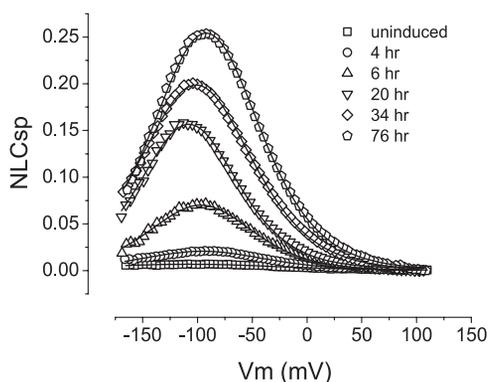

Fig. 5. NLC increases as a function of time in inducible cell lines expressing prestin. Shown are representative NLC curves from a tetracycline-inducible HEK293 cell line (16c). Specific NLC (NLC_{sp}) was used as a means to normalize data to cell size [$NLC_{sp} = (C_m - C_{lin})/C_{lin}$]. Without tetracycline added to the growth media (uninduced), prestin expression is repressed, resulting in minimal measurement of NLC. As the incubation time with tetracycline lengthens, the cells develop higher NLC as a result of either more prestin expression and/or prestin maturation on the cell membrane. Fitting parameters according to Eq. 1 were the following: for 4 h, V_h (mV) = -93.8 , $z = 0.697$, Q_{max} (pC) = 0.045 , C_{lin} (pF) = 18.0 ; for 6 h, $V_h = -97.3$, $z = 0.799$, $Q_{max} = 0.213$, $C_{lin} = 23.7$; for 20 h, $V_h = -108$, $z = 0.855$, $Q_{max} = 0.270$, $C_{lin} = 14.6$; for 34 h, $V_h = -101$, $z = 0.753$, $Q_{max} = 0.528$, $C_{lin} = 19.5$; and for 76 h, $V_h = -92.2$, $z = 0.780$, $Q_{max} = 0.548$, $C_{lin} = 16.5$.

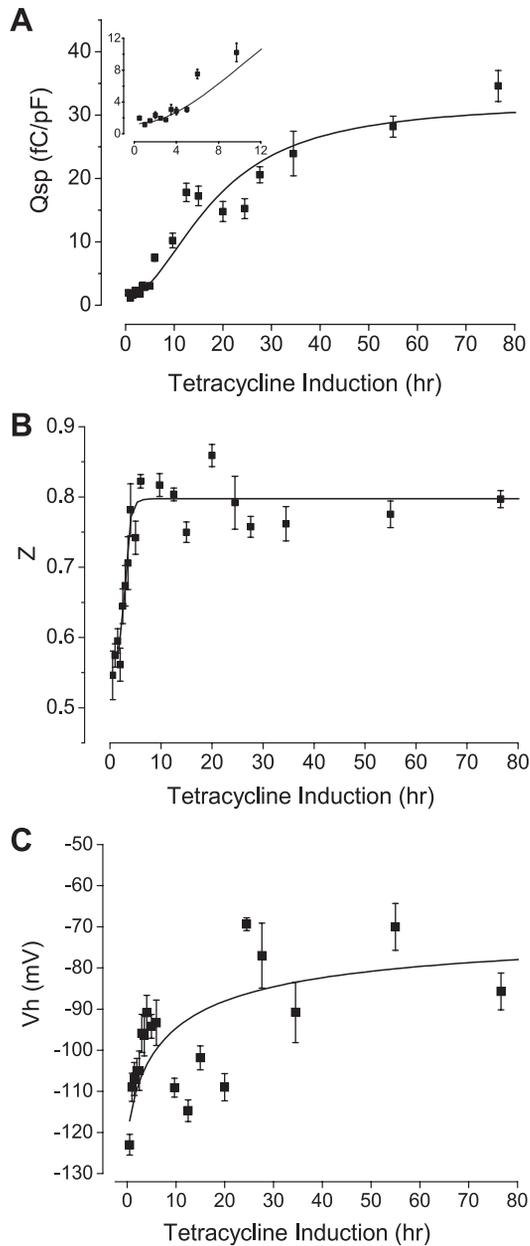

Fig. 6. NLC parameters change as a function of time after induction. *A*: development of specific charge density (Q_{sp}) after induction in a representative tetracycline-inducible prestin cell line (16c) with time. Q_{sp} increase shows a sigmoidal pattern with time and stabilizes at 30+ h. The number of cells patched for each point ranged from 4 to 11. Error bars are \pm SE. Data were fitted to a Hill equation [$y = \text{start} + (\text{end} - \text{start}) \times x^n / (k^n + x^n)$] with the following parameters: start = 1.23; end = 32.0; $k = 18.3$; $n = 2.0$. *B*: development of unitary charge valence (z) in a tetracycline-inducible cell line as a function of time after induction. z shows a rapid increase over several hours to reach its plateau at 6–8 h. z values did not change significantly, remaining stable after this time point. Fitting parameters were as follows: start = 0.58; end = 0.80; $k = 3.0$; $n = 6.8$. *C*: development of voltage dependence of peak NLC (V_h) as a function of time after induction. While there was considerable variation in V_h values, there was a clear trend in the development of V_h values toward more depolarizing voltages with time. Fitting parameters were as follows: start = -123 ; end = -69.4 ; $k = 8.6$; $n = 0.74$.

to ascertain aspects of prestin's development. Both confocal fluorescence and electron microscopy techniques show prestin to be efficiently targeted to the surface of the cell, with approximately half of the expressed prestin found on the cell

surface. Immunogold labeling and fluorescence quantifications were equivalent.

We also observed a relationship between aspects of prestin biochemistry and function. Increase in Q_{sp} , which corresponds to electromotility, clearly correlates to an increase in the level of prestin expression on cell surface (Fig. 8A). Moreover, consistent with our prior data in transiently transfected cells (9), we observed a strong linear relationship between Q_{sp} and the ratio of the upper and lower forms of prestin monomer. These data indicate that the lower prestin monomer has a dominant-negative effect on the upper monomer. It also means that the lower monomer is a less functional or nonfunctional variant of prestin. Moreover, because they imply interactions between upper and lower forms, these data are indirect evidence that the functional unit of the protein is a dimer, in line with previous suggestions (6, 12, 14, 19).

Our data raise questions as to the nature of the two monomers of prestin that we identified. Three scenarios are conceivable. First, it may be that the two monomers are differentially folded forms of the protein, with the smaller being misfolded and migrating faster on SDS-PAGE. This possibility is supported by our previous data showing increasing amounts of the lower monomer with cysteine mutants that are likely important for the structural integrity of the protein (9). The second scenario, that the lower monomer represents proteolytic cleavage of the protein, is untenable since antibodies to both NH₂- and COOH-terminal tags of the protein identify both monomers (data not shown). Lastly, it is also possible that these two monomers represent effects of differential glycosylation (10) with the upper and lower monomer representing glycosylated and unglycosylated forms of the protein, respectively. However, since we and others have previously shown that wild-type prestin and prestin in which the two potential *N*-glycosylation sites (N163 and N166) were mutated differ minimally in function (10, 12), this possibility will not explain the dominant-negative effect of the lower monomer on prestin function (Fig. 8A).

Our hypothesis that the lower monomer represents a misfolded form raises mechanistic questions concerning prestin turnover. Induction results in a continuous production of prestin that continues in time beyond asymptotic measures of prestin activity (Q_{sp}), indicating a mechanism of prestin removal. Since the ratio of upper to lower monomer changes with time until steady state, we reason that the rates of production and/or removal of these two forms of the monomer must be different during the early and late stages following induction. This possibility is substantiated by the differing rates of change in upper and lower monomers that occur over time in total cell lysates versus that in the plasma membrane (Fig. 7, *C* and *D*).

We noted an early increase in z after induction (Fig. 6*B*), indicating that the unitary charge carried by a functional motor changes with time. Since there are data supporting the role of the dimer as the functional unit (6, 12, 14, 19), an obvious possibility is that the increase in z represents a rapid increase of dimers on the cell surface in the initial hours of induction. We were unable to substantiate this possibility owing to technical difficulties in detecting prestin dimer in the very early stages after induction (0–4 h), when z shows its greatest change.

Our detection of a progressive depolarizing shift in V_h is similar to that observed in OHCs (1, 13). It had been suggested

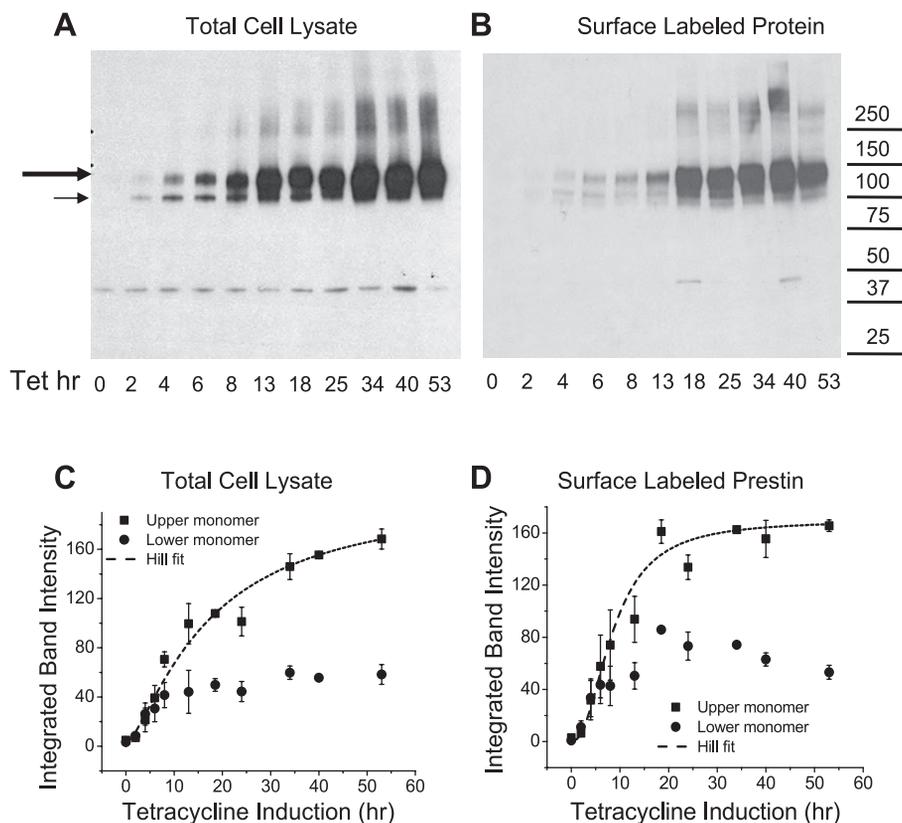

Fig. 7. Two monomers and multimers of prestin develop differentially as a function of time after induction (cell line 16c). *A*: Western blot of total cell lysate probed with anti-prestin N-20 antibody. Each lane has 0.75 μg of total protein as determined by protein assay. The large and small arrows indicate the upper (dominant) and lower monomers of prestin-YFP, respectively. A dimeric form of the protein is identifiable at 250 kDa. Prolonged incubation with tetracycline causes total cell prestin expression to increase steadily. The band at ~ 40 kDa is a nonspecific artifact, because it appears also in untransfected HEK293 cells (data not shown). *B*: Western blot of surface-labeled prestin-YFP obtained from cells at different time points after induction with 1 $\mu\text{g}/\text{ml}$ tetracycline. Each lane has 2 μl of the 250 μl surface-purified eluate from NeutrAvidin beads after binding to 2.7 mg of total protein. Each lane was derived from and corresponds to cell lysates in *A*. As with total cell lysates, prestin has at least two monomers and a broad dimeric form. The monomers in particular are detectable at the earliest time point (2 h) at which NLC is detectable. *C* and *D*: densitometric quantification of monomers of prestin from Western blots reveals a sigmoidal increase in the upper larger monomer of prestin. The surface expression of this monomer, however, stabilizes earlier than the monomer in cell lysates, with an asymptotic value achieved at 20 h after induction. The lower monomer expressed on the surface in contrast shows a small but persistent decrease in the asymptotic value with time. Hill fitting parameters for lysate (*C*) were as follows: start = 1; end = 205; $k = 17.2$; $n = 1.4$. Hill fitting parameters for surface prestin (*D*) were as follows: start = 0; end = 169; $k = 8.6$; $n = 2.2$. Data are averages from three batches of surface labeling experiments. Error bars are \pm SE.

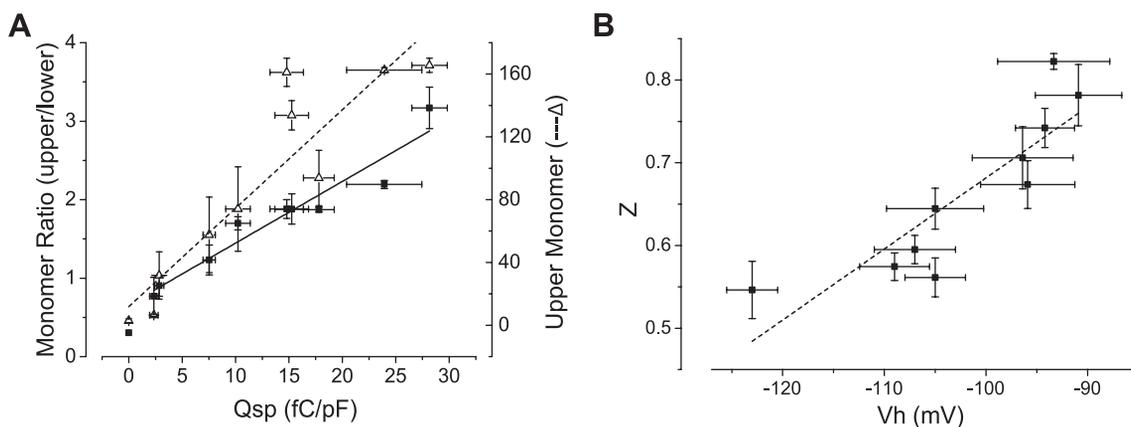

Fig. 8. Prestin's lower monomer exerts a dominant-negative effect on the upper functional monomer. *A*: the relationship between Q_{sp} and the densitometric ratio of the upper to lower prestin monomer expressed on the surface of the cell is linear ($Q_{sp} = -8.35 + 11.12 \times \text{ratio}$; adjusted $R^2 = 0.93$). Data were obtained from cells at variable time points after induction. Taken together, these data would suggest that the lower monomer exerts a dominant-negative effect on the function of the molecule. Also shown is the relationship between the upper monomer intensity and Q_{sp} . There is an initial correlation between the two that decreases with higher Q_{sp} values. *B*: correlation of z and V_h in the initial phase after induction where there is a rapid increase in z that correlates with a change in V_h .

that this shift might represent development of other unique molecular structures within the OHC, such as subsurface cisternae, pillars, and cortical cytoskeleton (1). Since a similar developmental event is unlikely in HEK cells, a more plausible explanation is that this change in V_h represents a maturation process that is intrinsic to the protein. It is interesting that in the first 6 h after induction, this shift in V_h coincides with the rapid increase in z (Fig. 8B). This suggests that charge valence and sensitivity to voltage is coupled in the initial stages of prestin's maturation.

In conclusion, we have developed several stable cell lines that have functional expression of prestin up to four times that of transiently transfected cells and have focused on a tetracycline-inducible line to elucidate the molecular events that underlie the development of prestin's NLC characteristics. Our data suggest that two prestin monomers are expressed on the cell surface, only one form being functional. Our data also suggest that dimerization of prestin may be associated with increases in prestin's voltage sensitivity (z values). Finally, our data suggest that prestin undergoes an intrinsic maturation that results in a shift in its voltage operating range to more depolarizing levels. Clearly, these cell lines will be useful as model systems for studying other aspects of prestin activity, including trafficking and turnover.

Nitric oxide uncouples gap junctions of supporting Deiters cells from Corti's organ

Received: 24 March 2000 / Received after revision: 3 May 2000 / Accepted: 10 May 2000 / Published online: 29 June 2000

Abstract Supporting cells of Corti's organ are electrically coupled via gap junctions. They probably serve to maintain the unique cochlear environment that is required for normal sensory function. In this study we used input capacitance measurements under whole-cell voltage-clamp conditions to evaluate the effects of nitric oxide on gap junctional communication between pairs of isolated supporting Deiters cells. We show that the nitric oxide (NO) donor sodium nitroprusside causes the uncoupling of Deiters cells, and that an NO synthase inhibitor blocks the effect. The cGMP analogue 8-bromo-cGMP also uncouples Deiters cells. With either treatment, the input capacitance of pairs of Deiters cells drops to single-cell levels within minutes of application, indicative of electrical uncoupling. We surmise that the NO/cGMP pathway may serve to modulate normal cochlear homeostasis and possibly plays a role in ototoxic mechanisms.

Key words Calcium · cGMP · Gap junctions · Membrane capacitance · Supporting cells

Introduction

The mammalian organ of Corti is comprised of sensory (inner and outer hair cells) and supporting cells, e.g., Hensen, Deiters, and Pillar cells. The supporting cells are structurally and electrically coupled together by gap junctions, which permit the direct cellular exchange of ions, dyes, and metabolites [5]. Cochlear homeostasis is believed to rely on intercellular coupling [4]. Coupling in the organ can be modulated by changes in intracellular

pH and Ca^{2+} , temperature, membrane voltage (junctional and non-junctional), and membrane tension (e.g., [8]). Recently, free radicals have been shown to uncouple Henson cells [7].

An understanding of nitric oxide's (NO) role in inner ear function is presently limited, but evolving (see [1] for review). The Ca^{2+} -dependent constitutive isoforms of nitric oxide (NO) synthase (NOS), neuronal bNOS (NOS I) and endothelial eNOS (NOS III) are found in the inner ear [2]. More specifically, Hess et al. [2] showed that bNOS is present in Deiters cells and in efferent nerve fibers, while eNOS is found in afferent nerve fibers and synaptic endings. The inducible Ca^{2+} -independent iNOS (NOS II) is a third isoform that has not been found in the cochlea under normal conditions but can be stimulated by bacterial lipopolysaccharides (LPS) and tumor necrosis factor α (TNF- α) [2]. In the present study we investigate the effects of NO on the electrical coupling between supporting cells. We show that the generation of NO can uncouple gap junctions of Deiters cells, and that the effect probably occurs through the NO/cGMP pathway.

Materials and methods

Guinea pigs were killed by decapitation. The organ of Corti was dissected from the temporal bone in Ca^{2+} -free Leibovitz medium (NaCl 142.2 mM, KCl 5.37 mM, MgCl_2 1.48 mM, HEPES 10.0 mM, dextrose 5.0 mM, pH 7.2, 300 mosmol/l). Pairs of Deiters cells were obtained by agitating the organ of Corti in Ca^{2+} -free Leibovitz medium containing 1 mg/ml trypsin for 10 min. The cell-enriched supernatant was then transferred to a 700- μ l perfusion chamber, and the cells were allowed to settle and attach to the untreated glass bottom of the chamber at room temperature for 15 min. An ionic blocking solution [tetraethylammonium (TEA) 20.0 mM, CsCl 20.0 mM, CoCl_2 2.0 mM, MgCl_2 1.47 mM, HEPES 10.0 mM, NaCl 99.2 mM, 2 mM $\text{CaCl}_2 \cdot 2\text{H}_2\text{O}$, pH 7.2, 300 mosmol/l] was used as the normal extracellular perfusate in order to block outward (K) and inward (K, Ca) currents. The use of ionic blocking solutions has no effect on gap junctional coupling in supporting cells [4, 8], and is simply used so that capacitive currents can be evaluated in isolation. Better voltage control is an additional benefit. CaCl_2 was included to facilitate pipette seal formation and cell attachment to the chamber bottom. Before starting an experi-

ment, enzyme and cell debris were removed by perfusing for 15 min. The bath perfusion was continued for the whole of each experiment. Patch electrodes were made from borosilicate glass capillaries. The initial resistance was 3–5 M Ω , corresponding to tip sizes of 1–2 μ m in diameter. The pipette solution was composed of 140 mM CsCl, 1 mM EGTA, 2 mM MgCl₂, 10 mM HEPES, pH 7.2, 300 mosmol/l. In some experiments, 10 mM BAPTA replaced EGTA to more efficiently limit intracellular Ca²⁺ activity. Electrical coupling between isolated pairs of Deiters cells was evaluated by monitoring the input capacitance obtained by the whole-cell voltage clamp of one cell in the pair. This method is a sensitive indicator of junctional coupling [4, 8]. All data collection and analysis were performed with the software program jClamp (www.med.yale.edu/surgery/otolar/santos/jclamp.html).

A 1 mM sodium nitroprusside (SNP) solution (Sigma, St. Louis, Mo., USA) and a 1 mM 8-bromo-guanosine 3', 5'-cyclic monophosphate (cGMP) solution (Calbiochem, La Jolla, Calif., USA) were freshly prepared in the normal medium prior to each experiment. Each solution was locally delivered to the cells via Y-tube microperfusion while the normal bath perfusion continued. This was done to limit the treatment effect to the cell pair under study. NOS activity was blocked by a 500- μ M solution of *S*-methyl-L-thiocitrulline (MTC, Sigma), a competitive NOS inhibitor.

Results and discussion

Deiters cells are intimately associated with outer hair cells, providing a cellular buffer between the outer hair cell and the basilar membrane. Additionally, via their apical processes, they contribute to the formation of the reticular lamina, a boundary between endolymph and perilymph. These cells are strategically placed to support the normal function of the outer hair cell, which serves as the basis of the "cochlear amplifier". Pairs of Deiters cells are readily isolated from Corti's organ, and remain electrically well coupled (Fig. 1). This coupling effectively provides contiguity of the plasma membrane among Deiters cells, as evidenced by measurements of input capacitance. Figure 1A shows the input capacitance of a pair of Deiters cells where octanol is used reversibly to uncouple the cells. Input capacitance decreases to single-cell values during uncoupling and increases during washout with normal solution. Isolated pairs of Hensen cells show similar responses [4], and indeed this supporting cell type has been used to confirm the utility of input capacitance measures in coupling studies. For example, visually confirmed single cells, pairs and triplets have average input capacitances of 31.0, 64.8, and 104 pF, respectively [8]. In the present study, the input capacitance of single Deiters cells was 42.4 \pm 7.4 pF ($n=12$).

In order to evaluate the effects of NO on the coupling of Deiters cells, we perfused solutions containing the NO donor SNP (1 mM) during electrical recording. Figure 2A illustrates that SNP reduces the input capacitance of cell pairs to single-cell levels, indicating that gap junctional communication was disrupted. This type of result was obtained in 11 of 13 cell pairs. For those pairs that uncoupled, the initial input capacitance averaged 101.3 \pm 9.9 pF (mean \pm SE). The time course of effects was variable, but, on average, input capacitance was reduced to 75% after 493 \pm 97 s following the start of SNP perfusion. The minimum input capacitance ultimately

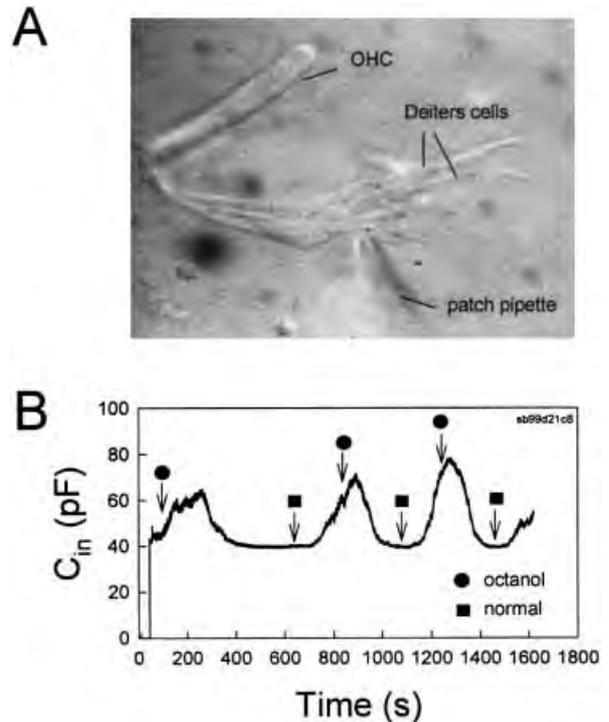

Fig. 1 **A** Digitally captured image of an isolated pair of Deiters cells, one of which is whole-cell voltage clamped. An outer hair cell (OHC) remains attached to the apical processes. **B** Effect of octanol on the input capacitance (C_{in}) of a pair of Deiters cells. After about 30 s, the pipette-membrane seal was ruptured and C_{in} jumped to 43 pF; initially, coupling was slight, but increased over the course of a few minutes, i.e., as C_{in} increased. The application of octanol (\approx 1 mM) via Y-tube perfusion uncoupled the cells as indicated by a drop of capacitance to single-cell levels. After washout of octanol, re-coupling occurred. The effects were repeatable. The absence of an immediate effect upon the initial application of octanol is probably due to perfusion blockage, as subsequently, and in previous studies (e.g. [4]), octanol uncouples supporting cells within tens of seconds

reached was 50.6 \pm 7.4 pF. In some cells, re-coupling occurred following the washout of SNP. In an additional ten pairs, the NOS inhibitor MTC (0.5 mM) was perfused continuously during SNP delivery (Fig. 2B). In eight of ten cells no reduction of input capacitance to single-cell levels was observed; in two cases where input capacitance dropped to single-cell levels, the quality of the cells may have been low since the recordings were made at the end of an experimental session.

Many of the effects of NO are mediated by activation of soluble guanylate cyclase (sGC) and the subsequent action of cyclic guanosine monophosphate (cGMP) [3]. sGC is found in supporting cells, including Deiters cells [1]. We tested the possibility that NO acts via the cGMP pathway by treating coupled Deiters cells with a membrane-permeant form of cGMP (1 mM). Fig. 2C illustrates that 8-bromo cGMP causes Deiters cells to uncouple. As with SNP treatment, input capacitance drops to single-cell levels following treatment. All six cell pairs tested evidenced uncoupling. The initial input capacitance averaged 112.6 \pm 18.2 pF (mean \pm SE). Similar to

Table 1 The input capacitance of a pair of Deiters cells and the effects of altering gap junctional communication between them. (*cGMP* 8-Bromo-guano-sine 3', 5'-cyclic monophosphate, *MTC* S-methyl-L-thiocit-rulline, *SNP* sodium nitroprus-side.) Single-cell values were 42.4 ± 7.4 pF ($n=12$; mean \pm SD)

Treatment	Initial C_{in} (pF)	Time (s) to 75% C_{in}	Ultimate C_{in} (pF)	% decrease
SNP ($n=11$)	101 \pm 9.9	493 \pm 97	50.6 \pm 7.4	50
SNP + MTC ($n=7^*$)	90.6 \pm 20.4	–	79.3 \pm 13.4	88
cGMP ($n=6$)	112 \pm 18	908 \pm 163	46.2 \pm 13.6	41

*Only seven of the eight pairs that did not reduce to single-cell levels were perfused with MTC throughout the recording period. In the other pair, MTC was washed out and subsequently SNP did reduce C_{in} to single-cell levels

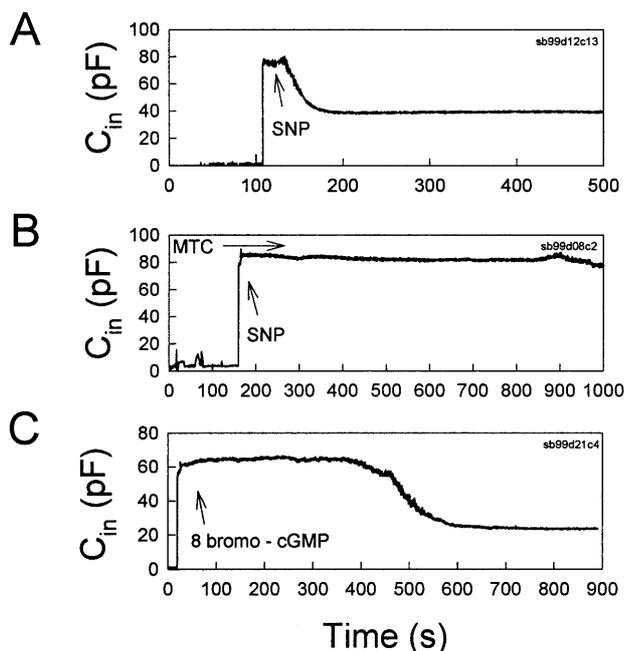

Fig. 2 **A** After about 110 s, the whole-cell configuration was established, indicated by the jump in capacitance (C_{in}). Perfusion of 1 mM sodium nitroprusside (SNP) caused the cell pair to rapidly uncouple, indicated by the drop in capacitance to a single-cell value of 40 pF. **B** Perfusion of the nitric oxide synthase (NOS) inhibitor MTC (0.5 mM) started before the whole-cell configuration was established, and continued during application of SNP. C_{in} remained fairly constant throughout the recording period. **C** Treatment with 8-bromo cGMP (1 mM) uncoupled this pair of Deiters cells after about 7 min

SNP, the time course of effects was variable, but, on average, input capacitance was reduced to 75% after 908 ± 163 s following the start of 8-bromo-cGMP perfusion. The minimum input capacitance ultimately reached was 46.2 ± 13.6 pF. Our results are summarized in Table 1.

The susceptibility of supporting cell gap junctions to intracellular calcium is well documented (see [5]), and, indeed, second messenger mechanisms that elevate intracellular calcium levels, e.g., inositol 1,4,5-trisphosphate or IP_3 , can uncouple supporting cells [6]. In preliminary tests, we found that replacing the patch pipette solution Ca^{2+} chelator EGTA (1 mM) with the more effective chelator BAPTA (10 mM) blocked the effect of SNP on supporting cell coupling (six cell pairs). The enzyme probably responsible for NO generation is one of the Ca^{2+} -dependent constitutive ones, because of the rapidity of the

uncoupling effects. Consequently, it might be that Ca^{2+} sequestration interferes with NO generation. Alternatively, it is conceivable that NO is generated within the adjacent un-patched cell, or other cells within the perfusion area, and that it is the buffering of Ca^{2+} within the immediate vicinity of gap junctions that maintains coupling. BAPTA, based on molecular weight, can traverse gap junctions into adjacent Deiters cells so as to maintain low Ca^{2+} levels within the vicinity of gap junctions. Further studies are required to resolve the mechanism of BAPTA's effects.

Among other possibilities, we have suggested that coupling between supporting cells provides for the spatial buffering of potassium ions within the organ of Corti, which otherwise would compromise the normal activity of hair cell and neural elements [4]. The present results may underscore a mechanism for the physiological control of ionic buffering within the organ of Corti. Additionally, the potential for damage caused by free radicals subsequent to NO generation may have a bearing on the detrimental affects of bacterial toxins [2] and ototoxic drugs [7] on cochlear function.

PART IV: ANIMAL RESEARCH IN PERIPHERAL AUDITORY PHYSIOLOGY

Joseph Santos-Sacchi

BACKGROUND

Cataloging the microanatomy of the auditory end organ provided an important start for understanding the physiology of the peripheral auditory system. These anatomical studies, conducted on a variety of species, began in earnest following the development of the compound light microscope in the 1700s. The detail in some of the original work of such pioneers as Alfonso Corti is remarkable (see Hawkins (2001) and references within), but alas, the microscopic structures were necessarily altered by the decay following extirpation and dissection. As we shall see, this decay had a major impact on our understanding of cochlear physiology as well. Whereas the development of fixatives proved a boon for anatomists, physiologists did not benefit directly, but belatedly profited from histologists' appreciation of the need to preserve the natural state.

The cochlea, we now know, is a remarkable electromechanical device. Prior to the discovery of animal electricity and the means to measure it, only the mechanical components of cochlea function could be investigated. Thus, the microscopic structures in the inner ear were used to deduce the mechanical foundation of cochlea function; for example, Helmholtz postulated his resonance theory based on the changing length (hence mechanical properties) of radial basilar membrane fibers. Clearly, in mammals, the basilar membrane, with its varying dimensions and stiffness, would be a prime candidate for the basis of hearing. Indeed, von Bekesy's (1960) studies confirmed the importance of the basilar membrane's mechanical qualities by demonstrating tuned traveling waves evoked by basilar membrane disturbances. von Bekesy used a variety of animal models, mainly the human temporal bone, but also mouse to elephant, to assess the sharpness of tuning in the cochlea. While the data he obtained contributed immensely to our understanding of cochlea mechanics and won him the Nobel prize in 1961, unforeseen factors worked to stymie an understanding of the true sensitivity and tuning of the mammalian cochlea. These factors were the same that stymied early anatomists, namely the difficult-to-avoid decay of normal cellular structure and function after death. These problems, though acknowledged by von Bekesy, were argued away, so that for many years auditory aficionados were led to believe that his data were gold. In fact, there were serious problems with his experiments, which when ultimately realized and solved, helped elucidate the roles of the two types of hair cells; the inner and outer hair cells, that the early anatomists identified with the aid of improved fixation techniques. To improve on the work of von Bekesy, models other than the human would be required.

WHY DO WE STUDY ANIMAL MODELS?

There are two main reasons for the study of peripheral auditory physiology, namely 1) the quest to understand and cure auditory dysfunction, and 2) simply to understand how our, and other animals', ears work. Clearly, study based on the former rationale would benefit from direct investigations on humans. Unfortunately, though, immense difficulties are associated with human experimentation on the auditory periphery. These problems include limited numbers of specimens, inability to control for pathological effects, and the inevitable problem of tissue destruction caused by delays in getting access to the cochlea (caused by dissection difficulties due to the dense temporal bone and delays in acquisition following death). Thus, for many reasons and regardless of the clinical vs. scientific rationales, animal models are best for studies on cochlear physiology. The major hurdle in rationalizing a particular animal model is its validity and generality. Most investigators believe that a range of small mammals, including the cat, chinchilla, guinea pig, rat, and mouse are appropriate for providing insight into the human condition. Of course, one or another species may prove better for particular experimental questions. In general, however, these small animals are particularly well suited, since the cochlea structures can be easily accessed. This enhanced accessibility (and heightened concern for better physiological status) has led directly to enhancements of the findings of von Bekesy.

BASILAR MEMBRANE TUNING

The data on basilar membrane movement that von Békésy obtained indicated that the response of the basilar membrane was linear, i.e., the magnitude of the displacement response grew linearly with the stimulus level. By extrapolating down to threshold levels, it was argued that basilar membrane movements at the threshold of hearing were a fraction of an atom's width. Tuning of the basilar membrane was also observed to be not as good as psychophysical measures, and von Békésy sought reasons beyond the basilar membrane to explain how we hear so well. With the aid of animal models, these notions would dramatically change.

Using the squirrel monkey, Rhode and colleagues (Rhode 1974; Rhode and Robles 1974) first noticed that, in some animals, a nonlinear growth in basilar membrane motions occurred as stimulation levels were changed. Importantly, this compressive nonlinearity of the basilar membrane response was vulnerable to the animal's status. Only when extreme care was used to maintain a healthy preparation did the response remain nonlinear, otherwise it resembled the data of von Békésy. We know now that tuning on the basilar membrane is far sharper than the data that von Békésy showed, indicating that his human temporal bone preparation and his animal preparations were working in a passive, damaged mode. Of course, the new Mossbauer measurement tool that Rhode and colleagues (Rhode 1974; Rhode and Robles 1974) used helped to record at lower stimulus levels than von Békésy could when using stroboscopic illumination. Today, it is clear that the sharp tuning found in the eighth nerve has its direct counterpart in basilar membrane motion (Narayan et al 1998). This turnaround in the description of basilar membrane tuning highlights the caveat that while animal models have the potential to provide valid data, care must be exercised in order to attain validity.

THE COCHLEA IS ELECTRIC

In the 1700s, electricians (as serious students of electricity were then called) often relied on themselves or acquaintances to serve as subjects. Indeed, Volta perceived a deafening blast as a result of self-inflicted aural electrocution (Piccolino 2000). Despite this early indication, it would be nearly two centuries after the controversial discovery of animal electricity that the electrical nature of audition would be confirmed. The discovery had to wait for the invention of the vacuum tube and oscilloscope, but once in hand, Wever and Bray (1930) demonstrated the "cochlear microphonic", an electrical response of the hair cells (which they mistakenly took as eighth nerve firings) measured from electrodes placed on a decerebrate cat's eighth nerve. The response mimicked the acoustic stimulus, and they confirmed this finding in a number of animal species, including turtles and insects.

The study of the electrical activity of the cochlea took off, and small mammals were perfect models since their cochleae were easily exposed for electrode implantations. Extracellular (from scala media and the perilymphatic scalae) electrical recordings were made of the resting (e.g., endolymphatic potential) and sound-evoked potentials (cochlea microphonic, summing potential, and even action potentials; see Dallos (1973)), but eventually these were usurped by intracellular recording directly from hair cells (Dallos et al 1982; Russell and Sellick 1978) after the high impedance electrode was devised. The clear correspondence of electrical activity within the auditory periphery with hearing capabilities would place this measure above that of histopathologic determination of auditory insult and recovery.

ANIMAL MODELS OF CLINICAL IMPORTANCE

The anatomical identification and characterization of cochlear dysfunction is time-consuming. The classic histological work on otopathology (see Schuknecht 1974), while quite informative, could not be used with high efficiency, simply because the animal or human temporal bone had to be removed and processed after death. The use of electrical measures to determine auditory sensitivity, especially those that were noninvasive (e.g., auditory brainstem response [ABR], compound action potential [CAP]) permitted ongoing and quantitative studies on the effects of noise exposure, ototoxic drug exposure, and hazardous chemicals (e.g., see Henderson et al 1999). As a direct result of animal experimentation, we would no longer have to experience devastation such as that caused by the first uses of the ototoxic antibiotic, dihydrostreptomycin (Shambaugh et al 1959). Nevertheless, while animal models have contributed significantly toward our understanding of pathologies that afflict humans, we must remain cognizant of species-specific differences.

One of the hottest areas of current research is that of hair cell regeneration (see Warchol 2001). Mammalian hair cells do not regenerate following destruction, as do those of some lower vertebrates. Thus, unlike some

tissues that can be interrogated via cell culture, mammalian inner ears must be harvested for each new experiment. Perhaps some day, if the key that controls hair cell production is found, hair cell cultures may reduce the need for animal sacrifice.

In the heyday of electron microscopy, transport of electron-dense markers into various compartments of the inner ear was studied. These studies included, for example, movements of molecules out of the vasculature and into cochlea scalae, thus identifying the blood–labyrinthine barriers (Duvall and Klinkner 1983; Hukee and Duvall 1985; Santos-Sacchi and Marovitz 1980) and movements of molecules across the round window membrane into the scala tympani (Schachern et al 1987). The latter experiments contributed to the scientific basis for the currently popular clinical approach of intratympanic drug delivery, notably used to deliver gentamycin for control of intolerable vertigo. This type of approach heralds a new era where the otologist will successfully treat previously inaccessible structures of the inner ear and will ultimately do so with the new tools of molecular biology. In cochlear implant research, animal models helped in facilitating assessment of the reversibility of deafness-associated changes at the level of the cochlea. The feasibility of using clinical devices in the animal models is a great asset in evaluation and study of such devices in the present and future (Kretzmer et al 2004).

FROM MOLECULES TO EAR

Some very important advances in auditory physiology have been made in recent years using the techniques of molecular biology. Two of them are especially dear to my heart, namely, the determination that mutations of the connexon 26 gene result in nonsyndromic deafness (Kelsell et al 1997) and the identification of the protein responsible for the mechanical activity of the outer hair cell (Zheng et al 2000).

Connexons are proteins that form gap junction channels between adjacent cells, in the ear's case, allowing ionic and metabolic communication between supporting cells (Santos-Sacchi and Dallos 1983). These channels were proposed to aid in the removal of harmful extracellular potassium away from active hair cells (Santos-Sacchi 2000), and this is a likely reason for the mutation's devastation of hearing.

The mammalian outer hair cell has long been known to dance wildly in response to electrical stimulation (Brownell et al 1985; Ashmore 1987; Santos-Sacchi and Dilger 1988); this mechanical activity is believed to promote the sharp tuning and nonlinearity that Rhode and colleagues (Rhode 1974; Rhode and Robles 1974) found in the basilar membrane. Finally, after nearly two decades, the motor responsible for the outer hair cell (OHC) boogie was molecularly identified as the protein, prestin (Zheng et al 2000). The story is a continuing one that is full of twists (Santos-Sacchi 2003), but most recently, a knockout of the prestin gene in the mouse seriously interfered with normal auditory function (Liberman et al 2002), and a mutation of the gene was shown to cause deafness in humans (Liu et al 2003). In the end, it will likely be the mouse model that holds the key to our interests in the ear, as this small prolific rodent is a perfect molecular biology laboratory. But let us not forget the guinea pig, which is a classic model in auditory research; indeed, this animal has helped show that gene transfection (of Math1 transcription factor) into the intact cochlea can induce new hair cell growth (Kawamoto et al 2003). Imagine, the future otologist growing some new hair cells for us hard-of-hearing baby boomers — thanks to animal research.

HERE AND NOW

Well, some 14 years have passed since the short review given above, and one thing remains clear – animal modelling enjoys tremendous popularity in otolaryngological research, especially in auditory physiology. We have not yet made enough progress to understand basic physiological mechanisms so that mathematical models can fully supplant experiment. Importantly, however, experiments on animals and their cells, often are simultaneously accompanied by mathematical models of identified processes, leading the way to limit the use of animals in the future.

What has become of the hope that the otologist could grow and insert new hair cells to alleviate deafness? Well, as I see it, though progress to the bedside has not been as rapid as initially anticipated, things are picking up. One of the promising bases for potential treatments involves manipulating signaling pathways to promote proliferation of stem cells that can then be triggered to differentiate into hair cells – methods that have been established in the mouse (McLean et al., 2017). Several clinical trials are now underway to help regenerate hair cells. Most trials include molecular biological approaches that have directly benefited from animal experiments. Even methods of treatment delivery, e.g., transtympanic or systemic, have been evaluated using animal models.

In the meantime, the cochlear implant remains the prime treatment for severe deafness, but even this established approach is benefiting from animal experiments aimed at prolonging spiral ganglion cell and neurite survival (Jolly et al., 2010). Such experiments often use guinea pigs (because of the large size of the cochlea) to study the effects of drug delivery (e.g., steroids) via the implant.

For the auditory physiologist, the animal model of choice is now clearly the mouse, although the zebrafish is far more amenable to molecular manipulations on a more rapid time scale. To be sure, the zebrafish has been instrumental in understanding certain aspects of auditory and vestibular development, and sensory function (Nicolson, 2005). In fact, the lateral line, in particular, has been a popular model for studying hair cell function, and the ability to now patch clamp from these cells (Ricci et al., 2013) is a boon for the auditory electrophysiologist. However, the usefulness of this species will never surpass the mouse. Below, I touch on a couple of significant observations that have benefited from mouse experimentation.

The elucidation of the molecular nature of the vertebrate hair cell stereociliar transduction channel has been a persistent challenge over the years, with many suggestions made (Corey et al., 2004), but all failing to materialize (Corey, 2006). Recently, however, several investigations have honed in on the TMC protein as being a major component of the channel, and these efforts have benefited from studies in the mouse (Beurg et al., 2018 ; Pan et al., 2018). The Pan et al. experiments showed that single channel characteristics of the stereociliar transduction channel could be manipulated following cysteine mutagenesis of the presumed pore-forming region of TMC1, pointing towards its central role in transduction. However, since such channel characteristics are also altered by membrane lipid modifications of PIP2 (Effertz et al., 2017) in the presence of normal TMC1. This indicates that the mere alteration of single channel characteristics does not guarantee the identification of a pore-forming region in a membrane protein. Thus, expression of the TMC1 protein in heterologous cells is required to fully confirm that it is indeed the transduction channel. Currently, TMC1 is unable to be transfected into non-auditory cells. Nevertheless, we are now closer than ever to solving this puzzle.

Alluded to above, prestin is the identified motor protein that accounts for electromotility and cochlear amplification. This protein exclusively resides in the outer hair cell membrane, and in no other cell type in the organ of Corti. Nevertheless, Chessum et al. (Chessum et al., 2018) have identified a key regulator of OHC maturation (Helios) that dictates the localized expression of prestin, and knockout mice of the gene encoding Helios produces deafness and reduction of prestin expression. Surprisingly, the ectopic expression of this gene regulator in mouse inner hair cell results in prestin expression and electromotility in inner hair cells! I believe that the mouse is truly a molecular laboratory destined to tell us how the ear's works really works.

male was silenced or the subordinate males were deafened, the results were very similar.

A dominant male that was audible to his subordinates devoted less time to fighting and more to courting and, consequently, had a higher rate of copulation. Our study, as well as more detailed studies of female behavior (5), indicates that male chirping does not affect female behavior directly. We conclude that acoustic signals influence male mating success because inaudible males are interrupted by other males more often during courtship than are audible males. The structural similarity in chirps produced during courtship and during aggression may reflect a convergence of function: no matter what the context, male chirps signal an aggressive warning to other males.

The chirps of many species of crickets have a different structure for each of several contexts (13). Most species of field crickets are solitary, and the males produce loud species-specific "calling" songs that attract females from a distance and possibly serve a role in the territorial spacing of neighboring males (3). The less intense "courtship" chirps of solitary males are audible to females in the immediate vicinity, but may not be detectable by other males (5); female field crickets discriminate against males that do not chirp during courtship (4). "Aggressive" chirps usually have yet another structure (13). A gregarious cricket such as *Amphiacusta maya* need not produce a calling song but is very likely to be interrupted during courtship. Thus a male in a gregarious species, at risk of constant interruptions and fights, produces "war propaganda" whenever he chirps.

6. Another gregarious Phalangopsine cricket, *Phaeophilacris spectrum*, communicates with infrasound rather than with audible signals. The same signal is produced during courtship and aggression, but a second signal is added in high-intensity aggressive interactions [M. von Dambach and L. Lichtenstein, *Z. Tierpsychol.* **46**, 14 (1978)].
7. Three marked males were housed in each cage. One female was put in immediately before observations began. Most aggressive interactions occurred in the vicinity of the female, when a male was interrupted during courtship. The interactions varied in intensity from one male antennating the other and displacing him, to fights in which both males stood on their hind legs, hit each other with their front legs, tried to bite, and chirped continuously. All aggressive interactions [described in (5)] and all attempts to copulate were recorded for 0.5 hour. If the female had mated during this period, she was removed; otherwise, she was left in the cage for another 0.5 hour. The ranks of males were assigned on the basis of the number of aggressive interactions that each male won during each observation session. A cage was observed only once per day.
8. Fifty cages each containing three males were observed for one to four sessions each (7). If mating in this species occurs by chance alone, then each male should have achieved approximately 0.33 of the copulations in his cage. To test this hypothesis, one day on which just one copulation occurred was chosen at random for each cage, and the number of times that the dominant or a subordinate male copulated was compared with an expected value of the dominant male copulating in 0.33 of the cases and the subordinates in 0.67. Dominant males copulated in 39 cases and subordinates in 11 ($\chi^2 = 45$, d.f. = 1, $P \ll .001$).
9. Males were silenced by first anesthetizing them with CO₂ or N₂ or restraining them, then waxing the stridulatory file on the underside of the right wing. This allowed them to move their wings normally but they were unable to produce sound. Control males were anesthetized or restrained similarly and in the second experiment a drop of wax was put on their pronota.
10. Seven of 40 copulations in 57 observations were made by silent males.
11. Fisher test, not significant, 14 experimental and 9 control cages.
12. Subordinate males were deafened by tearing the tympana on their prothoracic legs. The dominant males were handled in similar fashion except that the analogous sites on their metathoracic legs were scratched rather than their prothoracic tympana. All of the males walked normally after this operation.

Intracellular Recordings from Cochlear Outer Hair Cells

Abstract. *Intracellular recordings were made from outer hair cells in the third turn of the guinea pig cochlea, and the electrical characteristics of the cells were compared to those of inner hair cells, supporting cells, and extracellular spaces from the same recording region. Outer hair cells have higher membrane potentials than do inner hair cells, but they produce smaller a-c receptor potentials. The frequency response characteristics of both types of hair cells are probably not significantly different. In the frequency region where tuning is optimal, both cell types produce depolarizing d-c receptor potentials, but outer hair cells also generate hyperpolarizing responses at low frequencies.*

The most advanced auditory organs have two morphologically distinct sensory receptors. Electrical characteristics of individual mammalian receptors have been described only for one type, the inner hair cell (1). We now describe results of a 4-year study of cochlear outer hair cells (2). Information from single outer hair cells may explain some central questions of cochlear physiology, such as the role of this receptor cell in hearing and the types of interaction, if any, that occur between outer and inner hair cells.

Anesthetized guinea pigs were maintained at a constant core temperature and their heart rates were monitored; in later experiments, exhaled CO₂ was also measured. To assess the normalcy of the ear, a wire electrode was placed in the scala tympani of the first cochlear turn, and tone-burst-generated compound action potentials were recorded. In preparing for the recording of hair cell potentials a fenestra (~ 0.3 by 0.5 mm) was made in the bone over the stria vas-

cularis in the third turn of the cochlea. Microelectrodes were introduced through the stria and aimed at the organ of Corti. The cochlea was back-lighted with a fiber optics illuminator, so that the shadow of the organ of Corti could be seen through the fenestra. Attempts were made to insert the electrodes so that they would travel parallel with the reticular lamina (3) (Fig. 1A). Electrodes were driven by a motorized microdrive in increments of multiples of 2 μ m (4). Only responses obtained with tone-burst stimuli are presented.

The continuous recording of electrode position and a characteristic sequence of d-c potential changes (Fig. 1B) help identify the location of the electrode tip within the organ of Corti. Cell types may be identified by a combination of recording depth, membrane potential, and response magnitude. In all supporting cell types the membrane potential is high (steady-state values range up to -100 mV) and electrical responses are smaller, at any frequency, than those mea-

sured in scala media or in the extracellular spaces in the organ of Corti. Inner hair cells ($N = 19$ stable recordings) are characterized by low steady-state membrane potentials (median, -20 mV; highest, -47 mV) and large receptor potentials (up to 25 mV, peak to peak). At the best frequency of the cell, these responses can be up to a hundred times larger than the corresponding extracellular response. These findings are in harmony with the observations of Russell and Sellick on first-turn inner hair cells (1). Outer hair cells ($N = 22$) can be recognized from their large steady-state membrane potentials (median, -71 mV; highest, -94 mV) and large receptor potentials (up to 15 mV, peak to peak) (5). The cell's a-c response is between 3 and 15 times greater than the extracellular potential. Response patterns at various electrode locations are shown in Fig. 1C.

We compared observations made among a-c response magnitudes recorded at various locations in the same organ of Corti (Fig. 2A). All functions, except the scala media plot (6), depict bandpass filter characteristics. Around the best frequency there is a relatively sharply tuned tip segment with a high frequency slope of more than 40 dB per octave. The low frequency slope flattens out in a tail section which begins about 10 dB below the maximum at the tip. Direct comparison between the inner and outer hair cells in the same cochlea show that the tuning characteristics are comparable, even though the tip-to-tail ratio tends to be smaller in outer hair cells. This ratio, however, is highly variable among animals, ranging from 0 to 20 dB. Higher ratios probably correspond to better preparations.

When a-c and d-c receptor potentials recorded from an outer hair cell are compared, several striking observations can be made. First, outer hair cells produce both depolarizing and hyperpolarizing d-c responses, whereas the d-c output of inner hair cells is always positive (1). Second, the d-c response of outer hair cells appears to be much more sharply tuned than the a-c component. Third, around the best frequency of the cell, the a-c and d-c response magnitudes are commensurate. The behavior of the d-c receptor potential is similar to the patterns described for the gross summing potential (7), which also undergoes a polarity reversal along the frequency axis. In addition, we have shown that the summing potential is much better tuned than the gross cochlear microphonic (8), further suggesting a similarity between intracellular responses of outer hair cells and the gross cochlear poten-

tials. Both a-c and d-c intracellular responses are largest at the same frequency when measured at low sound levels. With an increase in the magnitude of the stimulus both types of responses saturate, and the a-c response peak shifts to lower frequencies. Thus, for example, at 70 dB (Fig. 2B) the a-c maximum occurs at 600 Hz even though at low sound levels it is at 800 Hz, the same frequency at which the d-c maximum is maintained over the whole range of intensities.

Our results reveal some potentially significant similarities, as well as differences, between the electrical characteristics of inner and outer hair cells. The a-c potential produced by either the inner or outer hair cells peaks at the same frequency which is determined by the cell's location along the cochlear spiral. In other words, there does not appear to be a systematic tuning disparity between the two types of receptors located at the same place. The sharpness of tuning

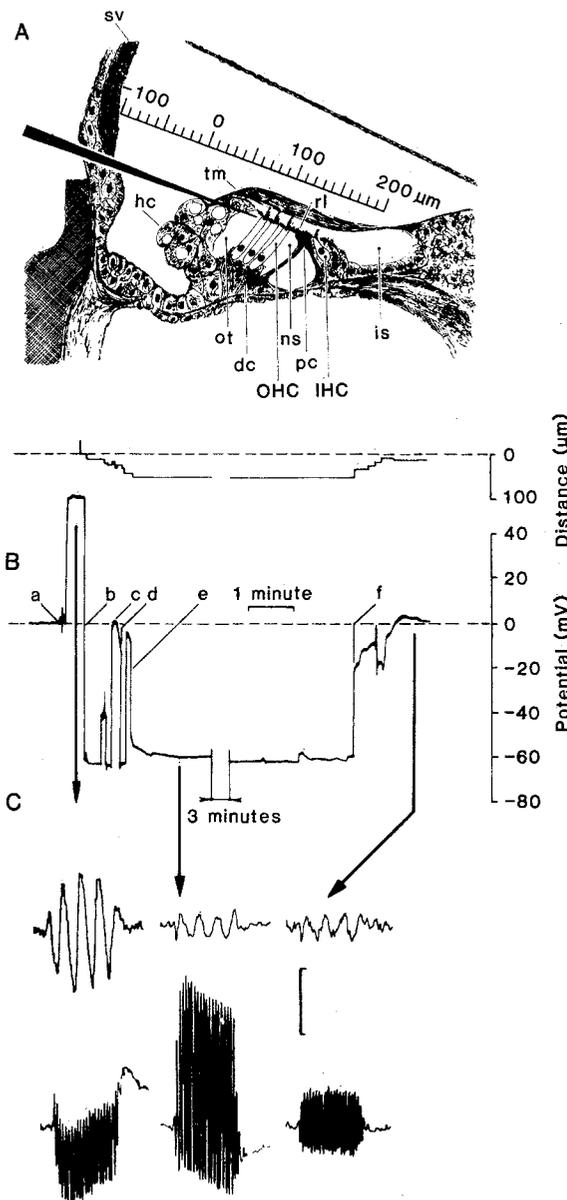

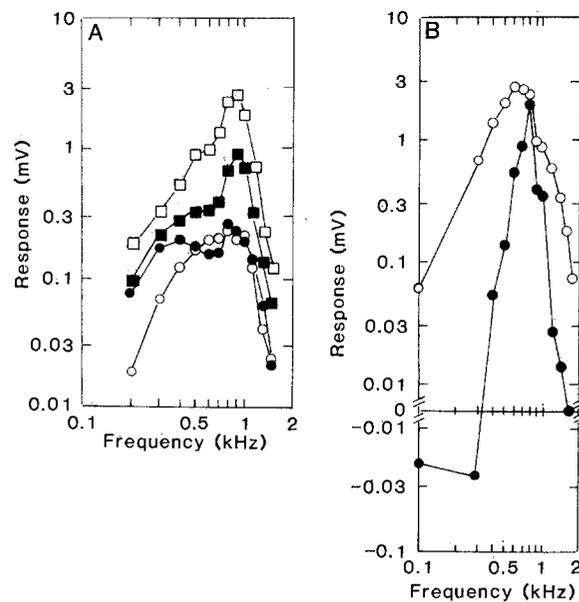

Fig. 1. (A) Cross-section of the third turn of a guinea pig cochlea. The recording electrode was inserted through the stria vascularis by a fenestra in the cochlear bone. The optimal electrode path is parallel to the reticular lamina and situated just below it. OHC, outer hair cell; IHC, inner hair cell; sv, stria vascularis; hc, Hensen's cell; tm, tectorial membrane; rl, reticular lamina; ot, outer tunnel; dc, Deiters' cell; ns, Nuel space; pc, pillar cell; and is, inner sulcus. (B) The d-c potentials measured during a typical electrode track through the cochlear scala. The appearance of a potential can be correlated with the location of the electrode tip with the aid of the distance scale provided. Electrode tip potentials are balanced to zero on the outer surface of the tissue lining the cochlear duct. At point *a* the electrode penetrates the stria vascularis and enters the endolymphatic space. This is signaled by the positive endocochlear potential (EP = 57 mV). After encountering the EP, the electrode travels within the endolymph from 80 to 180 μ m, depending on its position and orientation, before reaching the organ of Corti. Hensen's cells are contacted first, and their penetration is clearly marked by a d-c shift from positive to negative of up to 180 mV (point *b*). A further advance of the electrode traverses the Hensen's cell layer and locates the tip within the outer tunnel of Corti (point *c*). The d-c potential in the outer tunnel or in any fluid space (12) within the spiral organ is zero or slightly negative (less than -10 mV). At electrode location *d* a cell is registered; it is, however, quickly lost. This is probably a third-row outer hair cell. At a depth of 50 μ m another cell is penetrated (point *e*) and held with a stable membrane potential. (The range of holding times for outer hair cells is from 1.2 to 33 minutes; the many cells that were lost before a minute are not considered.) This is another outer hair cell. At marker *f* contact is lost with the hair cell in which the electrode dwelled for 7.5 minutes. A 3 -minute segment of recording is omitted. (C) Averaged responses ($N = 32$) to tone bursts from various electrode locations. Two stimulus frequencies were used (100 and 600 Hz), and all presentations are at the same sound level (70 dB with respect to 20 μ Pa). The vertical bar represents 1 mV, except for the two, top right-hand traces, for which it is 0.2 mV. The recording electronics is a-c coupled with a low frequency cutoff of 1 Hz. Recording electrodes typically possess a bandwidth extending to 1700 Hz (upon optimal capacitance compensation).

Fig. 2. (A) Peak-to-peak a-c response magnitude as a function of stimulus frequency, recorded from various locations within the same organ of Corti. Sound pressure is constant at 40 dB (with respect to 20 μ Pa); at this level the responses are linear. Inner hair cells (\square), outer hair cells (\blacksquare), scala media (\bullet), and organ of Corti fluid space (\circ). (B) Comparison of the frequency dependence of the a-c and d-c receptor potential components from one outer hair cell. Data are obtained from averaged responses with tone-burst stimuli having a constant sound level of 70 dB (with respect to 20 μ Pa); a-c responses are peak-to-peak magnitude, and d-c responses are measured between prestimulus baseline and half the excursion of the a-c waveform; a-c (\circ) and d-c (\bullet).

appears to be similar in both types of cells. Although some evidence suggests that inner hair cells can be better tuned, tuning appears to vary more from animal to animal than from cell to cell in a particular animal. This variation most likely reflects the nonuniformity of physiological conditions among our subjects. We have compared equal intensity response curves with single auditory nerve fiber rate functions obtained at the same sound level from fibers (recorded from chinchillas in our laboratory) for which the best frequency matched those of our hair cells. The range of tuning for these single fibers encompassed our sample, but our best tuned hair cell is not as sharply tuned as the best nerve fiber; it is much better tuned, however, than the poorest one. Since single fiber tuning itself is relatively shallow in the frequency range of interest (600 to 1000 Hz), quantitative comparisons between fiber and hair cell tuning are not particularly revealing. Our data therefore support the suggestion that the sharpness of tuning seen in single fiber discharge patterns is already established at the hair cell level, and the degree of sharpness is probably determined by the mechanical tuning of the basilar membrane-organ of Corti complex (9).

In agreement with work (1) on inner hair cells, we find that the magnitude of a-c and d-c receptor potentials is remarkably large. The responses of inner hair cells appear to be about three times greater than the ones recorded from outer hair cells. There also does not appear to be a systematic difference in sensitivity between the two types of hair cells. Thus schemes that assign different operating regions of sound intensity for outer

and inner hair cells are not supported by these data. At their best frequency the operation of both inner and outer hair cells becomes markedly nonlinear above approximately 50 dB. The nonlinearity is manifested by saturation and production of harmonics and of a d-c component. Although it has been suggested that outer and inner hair cells operate in phase opposition (10), we find no evidence to support such a contention. At the best frequency the a-c receptor potentials produced by the two sensory cell types are approximately in phase, and, as was mentioned above, the d-c receptor potentials are depolarizing. Thus the intrinsic electrical behavior of the two hair cell types is similar around their best frequency.

The most striking difference between the electrical characteristics of outer and inner hair cells is in their resting membrane potentials: the inner hair cells appear to operate at about half the membrane potential of the outer hair cells, and thus resemble supporting cells in this respect. There is no readily evident explanation for this difference in resting potentials. Although the input resistance of our receptor cells is highly variable, the two cell types show overlapping distributions ranging between 10 and 34 megohms (11).

Santos-Sacchi, paper presented at the meeting of the European Inner Ear Biology Workshop, Montpellier, France, September 1981.
3. Initially electrodes filled with aqueous solutions of Niagara sky blue, Procion yellow, or Lucifer yellow were used to mark the cells. Dye injection followed recording and was accomplished by passing a 1 to 5 nA negative current through the cell. After the experiments, the cochleas were perfused with 4 percent glutaraldehyde buffered to pH 7, removed from the animal, and stored in the perfusing solution. Subsequently the ears were dehydrated, embedded in Epon or Spurr, and sectioned in 10- μ m increments. Dye-filled cells were identified under epifluorescent illumination, and 4 inner hair cells, 13 outer hair cells, 28 Deiters' cells, 41 pillar cells, 19 Hensen's cells, and a small assortment of other supporting cell types were recovered. Once the electrical characteristics of various cell types had been clarified, only 3M KCl-filled pipettes (tip, 0.1 μ m in diameter with 120 to 200-megohm resistance) were used for recording.
4. There may be interference with cochlear partition movement when an electrode is introduced into the organ of Corti. It may be questioned if our approach (with an electrode track roughly parallel to the basilar membrane instead of perpendicular to it) compounds the problem. To study this issue we recorded gross receptor potentials from a third turn scala vestibuli electrode during various stages of microelectrode penetration. In most cases no changes were observed in the gross potential, either in its waveform or its spectral content.
5. All organ of Corti cells, including outer hair cells, had negative membrane potentials. This is in contrast to the report of Y. Tanaka, A. Asanuma, and K. Yanagisawa [*Hearing Res.* **2**, 431 (1980)].
6. The observation that in some cases (for example, see Fig. 1C at 100 Hz) the scala media potential can be larger than the intracellular outer hair cell response appears disturbing, since gross potentials are largely produced by outer hair cells [P. Dallos and M. A. Cheatham, *J. Acoust. Soc. Am.* **60**, 510 (1976)]. We have shown that the low frequency lobe of the scala media response function does not represent a locally produced electrical activity. Instead, these responses are conducted from more apical regions of the cochlea which are tuned to the low frequencies and produce much larger potentials. When the fourth turn of the cochlea is amputated, the large, low frequency response disappears, and the scala media function assumes the form of the organ of Corti gross response, without a change in its magnitude at the best frequency.

Fragile X syndrome (FXS) is characterized by hypersensitivity to sensory stimuli, including environmental sounds. We compared the auditory brainstem response (ABR) recorded *in vivo* in mice lacking the gene (*Fmr1*^{-/-}) for fragile X mental retardation protein (FMRP) with that in wild-type animals. We found that ABR wave I, which represents input from the auditory nerve, is reduced in *Fmr1*^{-/-} animals, but only at high sound levels. In contrast, wave IV, which represents the activity of auditory brainstem nuclei is enhanced at all sound levels, suggesting that loss of FMRP alters the central processing of auditory signals. Current-clamp recordings of neurons in the medial nucleus of the trapezoid body in the auditory brainstem revealed that, in contrast to neurons from wild-type animals, sustained depolarization triggers repetitive firing rather than a single action potential. In voltage-clamp recordings, K⁺ currents that activate at positive potentials (“high-threshold” K⁺ currents), which are required for high-frequency firing and are carried primarily by Kv3.1 channels, are elevated in *Fmr1*^{-/-} mice, while K⁺ currents that activate near the resting potential and inhibit repetitive firing are reduced. We therefore tested the effects of AUT2 [((4-({5-[(4R)-4-ethyl-2,5-dioxo-1-imidazolidinyl]-2-pyridinyl}oxy)-2-(1-methylethyl) benzonitrile], a compound that modulates Kv3.1 channels. AUT2 reduced the high-threshold K⁺ current and increased the low-threshold K⁺ currents in neurons from *Fmr1*^{-/-} animals by shifting the activation of the high-threshold current to more negative potentials. This reduced the firing rate and, *in vivo*, restored wave IV of the ABR. Our results from animals of both sexes suggest that the modulation of the Kv3.1 channel may have potential for the treatment of sensory hypersensitivity in patients with FXS.

Key words: auditory brainstem response; AUT2; fragile X; high- and low-threshold potassium channels; medial nucleus of the trapezoid body; potassium channels

Significance Statement

mRNA encoding the Kv3.1 potassium channel was one of the first described targets of the fragile X mental retardation protein (FMRP). Fragile X syndrome is caused by loss of FMRP and, in humans and mice, causes hypersensitivity to auditory stimuli. We found that components of the auditory brain response (ABR) corresponding to auditory brainstem activity are enhanced in mice lacking FMRP. This is accompanied by hyperexcitability and altered potassium currents in auditory brainstem neurons. Treatment with a drug that alters the voltage dependence of Kv3.1 channels normalizes the imbalance of potassium currents, as well as ABR responses *in vivo*, suggesting that such compounds may be effective in treating some symptoms of fragile X syndrome.

Introduction

Fragile X syndrome (FXS) is a genetic disease caused by a silencing mutation of the *FMRI* gene. In the majority of cases, this is

caused by an expansion of the CGG repeats in the promoter region of the *FMRI* gene, which leads to a lack of fragile X mental retardation protein (FMRP; Oberlé et al., 1991; Verkerk et al., 1991). FMRP is a mRNA binding protein that controls the func-

tion and expression level of a variety of proteins including several ion channels (Darnell et al., 2011). Patients with FXS experience multiple symptoms such as hypersensitivity to sensory stimuli, hyperactivity, susceptibility to seizures, intellectual disability, anxiety, and social and memory impairment (Garber et al., 2008; Chonchaiya et al., 2009). Some of these symptoms have been replicated in fragile X mice in which the gene for FMRP has been deleted (*Fmr1*^{-/-} mice; Michalon et al., 2012; Curia et al., 2013; Rotschafer and Razak, 2014; Myrick et al., 2015; Bostrom et al., 2016; Aloisi et al., 2017; Pyronneau et al., 2017; Sinclair et al., 2017). In humans, early intervention, such as drug treatment, speech therapy, schooling, and social integration, are believed to improve cognition in patients with FXS (Lozano et al., 2016). This offers hope that further effective treatments for fragile X symptoms will emerge if the appropriate targets for therapeutic agents can be identified.

One symptom that is relevant to this study is the hypersensitivity of patients with FXS to auditory stimuli (Arinami et al., 1988; Roberts et al., 2005). Physiological levels of sound evoke abnormal elevation of the cortical auditory response in patients with FXS (St Clair et al., 1987; Rojas et al., 2001; Castrén et al., 2003; Van der Molen et al., 2012), and ordinary environmental sounds can become unbearable for patients with FXS. In addition to this hypersensitivity to auditory stimuli, patients with fragile X syndrome have difficulties in discriminating the timing of auditory stimuli, which renders them unable to localize sounds in space (Hall et al., 2009; Rotschafer and Razak, 2014). Both the elevated cortical responses to sound stimuli and the deficits in temporal processing are likely to be influenced by alterations in subcortical networks such as those in the auditory brainstem that compute sound localization. These include the anteroventral cochlear nucleus (AVCN) and the medial nucleus of the trapezoid body (MNTB), as well as the medial and lateral superior olivary nuclei to which the AVCN and MNTB project. This conclusion is supported by the finding that the auditory brainstem response (ABR) recorded *in vivo* is altered in adult *Fmr1*^{-/-} mice, and this may result, in part, from an alteration in the balance of excitation and inhibition (Rotschafer et al., 2015; Garcia-Pino et al., 2017; McCullagh et al., 2017).

The intrinsic excitability of neurons is determined by the ion channels they express. The mRNAs for several ion channels bind FMRP (Darnell et al., 2011), and in several cases the loss of FMRP has been demonstrated to alter levels of ion channel proteins in neurons (Brager and Johnston, 2014; Frick et al., 2017). Moreover, a subset of these ion channel proteins bind FMRP directly, altering the amplitude, gating, or trafficking of the channels (Brown et al., 2010; Zhang et al., 2012; Deng et al., 2013, 2019; Ferron et al., 2014; Myrick et al., 2015; Yang et al., 2018). Previous studies have demonstrated that currents corresponding to some of these ion channels are altered in the auditory brainstem MNTB neurons of *Fmr1*^{-/-} mice (Brown et al., 2010; Strumbos et al., 2010b). We have now analyzed the effects of the loss of FMRP on the intrinsic excitability of auditory brainstem MNTB neurons *in vitro* and compared this to alterations in auditory brainstem responses *in vivo*, in *Fmr1*^{-/-} and wild-type (WT) mice. We have also characterized the actions of a small molecule, AUT2 [(4-({5-[(4R)-4-ethyl-2,5-dioxo-1-imidazolidinyl]-2-pyridinyl}oxy)-2-(1-methylethyl) benzonitrile; Brown et al., 2016], which modulates Kv3.1 potassium channels, and found that this compound was able to normalize both the firing patterns of MNTB neurons and the ABR of *Fmr1*^{-/-} mice.

Materials and Methods

AUT compound. AUT2 (Autifony Therapeutics) is a small molecule modulator of human and rodent Kv3.1 and Kv3.2 channels. Some of the electrophysiological actions of AUT2 have been described previously (Brown et al., 2016). AUT2 is a cell-permeant small molecule, which modulates human recombinant Kv3.1 channels by shifting the voltage dependence of activation and inactivation to negative potentials (EC_{50} , 0.9 μ M; Brown et al., 2016). AUT2 (10 mM stock solution) was dissolved in DMSO (0.1%), and the final concentration used in the recording chamber was 10 μ M for *in vitro* recordings. A 10 μ M concentration of AUT2 has previously been shown to strongly modulate the recombinant Kv3.1 channel, causing a 28 mV leftward shift in the V_{1/2} of activation (Brown et al., 2016). For testing the effects of AUT2 on auditory brainstem response *in vivo*, we prepared a vehicle containing 12.5% of Captisol, mixed with 0.5% HPMC (hydroxypropylmethylcellulose) K15M and 0.5% Tween 80 in sterile water. The AUT2 drug suspension was then prepared by dissolving AUT2 compound in the vehicle solution, which was used at a final concentration of 30 mg/kg and dosed by the intraperitoneal route 20 min before testing. While formal pharmacokinetic studies have not been conducted with this compound in the mouse, a dose of 30 mg/kg AUT2 administered orally to rats gave brain concentrations of ~3500 mg/ml 2 h after dosing (Autifony Therapeutics, unpublished data). Taking into account brain tissue binding, this is expected to be equivalent to a free brain concentration of ~0.5 μ M. The brain concentration of AUT2, 20 min after 30 mg/kg, i.p., administration, might be expected to be in the range of 0.5–1 μ M.

Electrophysiological recordings from MNTB brain slices. Both male and female WT (FVB.129P2-*Pde6b*⁺*Tyr^{c-ctd}*/Ant) and *Fmr1*^{-/-} (FVB.129P2-*Fmr1*^{tm1Cgr/J}) mice were purchased from The Jackson Laboratory. All data represent the mean \pm SE. The number of neurons or animals is represented by “n” or “N” respectively.

All procedures described followed National Institutes of Health guidelines outlined in *Preparation and Maintenance of Higher Animals during Neuroscience Experiments* (publication 91–3207). Procedures were approved by the Institutional Animal Care and Use Committee at the Yale University School of Medicine. The auditory brainstem including the MNTB was extracted from 15-d-old wild-type (Fvbn129) and *Fmr1*^{-/-} mice of either sex. Acute transverse slices of the auditory brainstem were cut to a thickness of 250 μ m using procedures described previously (Yang and Wang, 2006). Recordings were performed in a chamber continuously perfused (1–2 ml/min) with oxygenated and warmed (31–33°C) artificial CSF containing the following (in mM): 124 NaCl, 2.5 KCl, 25 NaHCO₃, 1.25 NaH₂PO₄, 2 MgCl₂, 2 CaCl₂, and 10 glucose. Whole-cell patch-clamp recordings were made from visualized MNTB neurons using an upright Zeiss Axioskop 2 FS microscope with differential interference contrast optics. Patch pipettes (3–5 M Ω) were pulled from borosilicate glass tubing (outer diameter, 2.0 mm; wall thickness, 0.5 mm) and filled with the following intracellular solution (in mM): 32.5 KCl, 97.5 K-gluconate, 5 EGTA, 10 HEPES, and 1 MgCl₂, pH 7.2 (Macica et al., 2003). Voltage-clamp recordings were made using EPC-7 (HEKA Elektronik) or Multiclamp 700B (Molecular Devices) amplifiers. Tetrodotoxin (1 μ M) and CdCl₂ (20 μ M) were used to suppress Na⁺- and Ca²⁺-activated K⁺ channels, respectively. Current-clamp recordings were made in bridge mode using an SEC 05L amplifier (npi electronic). Neurons with resting potentials more positive than –50 mV were discarded, regardless of treatment. The junction potential was not corrected. Uncompensated series resistances were on average 13.12 \pm 0.31 M Ω (n = 77 cells, N = 52 cells). Series resistance was compensated at 50–70%. Access resistance and holding current were continuously monitored for stability; >20% variation led to a rejection of the cell.

Data acquisition and analysis were performed using software that was either custom written in the Igor Pro programming environment (WaveMetrics) or using pCLAMP version 9.2 (Molecular Devices). Conductance values were obtained by dividing the current by the electrochemical driving force, as follows: $I_K/(V_m - E_K)$, where I_K is the K⁺ current, V_m is the membrane potential and E_K is the reversal potential for K⁺ ions. For voltage dependence of activation experiments, normalized conductance–voltage plots were obtained by normalizing conductance

(G) to that measured at +60 mV (G_{+60}) for each recording and fit using the sigmoidal function: $y = A_2 + (A_1 - A_2)/(1 + e^{(x-x_0)/k})$, where A_1 and A_2 represent the initial and final values of the y abscise, respectively; k is the slope factor; and x_0 is the half-maximal value. For the voltage dependence of inactivation, normalized conductance–voltage plots were fitted by normalizing currents to the maximum obtained by stepping from -100 mV and fitted using the same function. These fits were not used to calculate $V_{1/2}$ values, which were instead determined for each cell by direct determination of the potential at which conductance was 0.5 of the maximal value at +60 mV. In current-clamp recordings, input resistance was calculated by applying a train of three hyperpolarizing current pulses (250 pA, 300 ms duration, at 0.3 Hz), and comparing the mean maximal voltage deflection during these pulses to the baseline membrane potential 20 ms before current injections.

ABR. Animals (15 d old) were anesthetized with 480 mg/kg, i.p., chloral hydrate, and all recordings were conducted in a sound-attenuating chamber (Industrial Acoustics). A customized TDT3 system (Tucker-Davis Technologies) was used for ABR recordings. Subdermal needle electrodes (Rochester Electro-Medical) were positioned at the vertex (active, noninverting), the infra-auricular mastoid region (reference, inverting), and the neck region (ground). Differentially recorded scalp potentials were bandpass filtered between 0.05 and 3 kHz over a 15 ms epoch. A total of 400 trials was averaged for each waveform for each stimulus condition.

Symmetrically shaped tone bursts were 3 ms long (1 ms raised cosine on/off ramps and 1 ms plateau). All acoustic stimuli were delivered free field via a speaker (Part FF1 2021, Tucker-Davis Technologies) positioned 10 cm from the vertex. Stimulus levels were calibrated using a 0.5 inch condenser microphone (model 4016, ACO Pacific) positioned at the approximate location of the animal's head during recording sessions and are reported in decibels of sound pressure level (SPL; referenced to 20 μ Pa). Stimuli of alternating polarity were delivered at a rate of \sim 20/s. Tone burst responses were collected in half-octave steps ranging from 32 to 2.0 kHz. The effects of level were determined by decreasing stimulus intensity in 5 or 10 dB steps. A maximum stimulus level of 90 dB SPL was used first to avoid overstimulation. The ABR threshold was defined as the lowest intensity of sound level capable of evoking a reproducible, visually detectable response (Song et al., 2006). Latencies and amplitudes of the initial four ABR peaks were measured from sound stimuli delivered at a rate of 20/s and at a frequency of 11.3 kHz, one of the most sensitive frequency ranges of hearing in mice. The analysis was performed off-line in BioSig (BioSig Technologies) on traces with visible peaks by setting cursors at the maxima and minima of the peaks. Latency was defined as the time from the onset of the stimulus to the peak, while amplitude was measured by taking the mean of the ΔV of the positive and negative deflections of the ABR wave (Tan et al., 2017).

Experimental design and statistical analysis. All data were collected from different littermates and used both males and females. Data analysis was performed using Igor, Clampfit, and BioSig software. For whole-cell voltage-clamp experiments, evoked currents were quantified by measuring the mean current between 50 ms after the onset of a test pulse and 50 ms before the end of the pulse. The interval between each pulse protocol ranged from 3 to 5 min in control conditions. When waiting for drugs to take effect, cells were held at resting membrane potentials for 10–15 min. The analyses used either a paired two-tailed t test (for comparison between $Fmr1^{-/-}$ mice before and after AUT2 treatment) or unpaired two-tailed t test for comparison between wild-type and $Fmr1^{-/-}$ mice (with Welch's correction). In some cases, for example, when a comparison of ABR amplitude and/or latency with genotype (or with AUT2 treatment) across sound level intensity was performed, we used a two-way ANOVA that considered a full set of variances. Similarly, for data comparing the number of action potentials between genotypes across stimulus frequencies or the magnitude of potassium current between genotypes across membrane voltages, we performed a two-way ANOVA followed by a *post hoc* multiple comparison using Bonferroni–Dunn or Holm–Sidak method. A value of $p < 0.05$ was considered significant for all tests. Statistical analysis was conducted using GraphPad Prism 8 and Origin software.

Results

Loss of FMRP alters central processing of auditory information

To investigate how loss of FMRP impacts the processing of auditory information early in development, we compared the *in vivo* ABR of 15-d-old wild-type and $Fmr1^{-/-}$ mice, corresponding to 3–5 d after the onset of hearing. The ABR is characterized by a series of electrical waves, labeled as waves I to V (Jewett and Williston, 1971; Song et al., 2006), representing the progressive transfer of the auditory signal from the periphery to the CNS. Wave I represents the summated response from the spiral ganglion and auditory nerve, while waves II to V represent responses from the ascending auditory pathway (Akil et al., 2016).

We first determined that the threshold for detecting an electrophysiological response (ABR threshold) was not altered in $Fmr1^{-/-}$ mice at all sound frequencies tested from 2 to 32 kHz (Fig. 1A). ABRs were then recorded in response to an 11.3 kHz stimulus lasting 3 ms at intensities up to 90 dB (Fig. 1B). A two-way ANOVA with mean comparison using Bonferroni's test was performed to compare the effects of genotype (WT or $Fmr1^{-/-}$ mice) and of sound levels (from 40 to 90 dB) on the amplitude of the ABR response. We found that the amplitude of wave I was significantly reduced in $Fmr1^{-/-}$ mice compared with WT mice ($F_{(1,353)} = 15.44$, $p = 0.0002$). We also found a significant interaction effect between the genotype and sound level on the amplitude of wave I ($F_{(10,353)} = 2.4$; $p = 0.01$). When this analysis was followed by a simple test effect that corrected for multiple comparisons using Bonferroni–Dunn method, we found that the amplitude of wave I was significantly smaller in $Fmr1^{-/-}$ animals at higher intensities of sound levels (Fig. 1C: 85 dB, $*p = 0.002$; $*90$ dB, $p = 0.0009$).

In contrast, the amplitude of wave IV, which reflects the synchronous activity of the auditory brainstem nuclei including the MNTB, was significantly enhanced in $Fmr1^{-/-}$ mice ($F_{(1,301)} = 30.33$, $p < 0.0001$). The intensity of sound level had a significant effect on the amplitude of wave IV ($F_{(10,301)} = 10.20$, $p < 0.0001$), and the interaction of both genotype and sound levels also had an effect on the amplitude of wave IV ($F_{(10,301)} = 2.23$, $p = 0.01$; Fig. 1C). We thus performed a simple effects test and found that the amplitude of wave IV was significantly higher at 75, 80, 85, and 90 dB ($p = 0.0001$, Bonferroni–Dunn method).

We then analyzed the latency of each wave to investigate any potential changes in the rate of propagation through the nervous system. Although the latency of waves I appeared slightly prolonged in $Fmr1^{-/-}$ mice compared with wild-type mice, this difference was not statistically significant ($F_{(1,340)} = 2.213$, $p = 0.13$). In addition, the latency of wave IV was not significantly different between WT and $Fmr1^{-/-}$ mice ($F_{(10,285)} = 0.3$, $p = 0.98$).

Firing patterns of MNTB neurons are disrupted in $Fmr1^{-/-}$ mice

To determine whether the loss of FMRP alters the firing patterns of MNTB neurons, we performed *in vitro* recordings from principal neurons of the MNTB in brainstem slices from 15-d-old mice. We first used a whole-cell current-clamp configuration to record the response of cells to a series of sustained hyperpolarizing and depolarizing current pulses (200 ms square current pulses, -250 to $+350$ pA). As has been found in previous studies (Wang et al., 1998a), we found that in response to a 250 or 350 pA depolarizing current injection, MNTB neurons from wild-type mice fire only at the onset of the depolarization, and never fire more than one or two action potentials (Fig. 2A). In contrast,

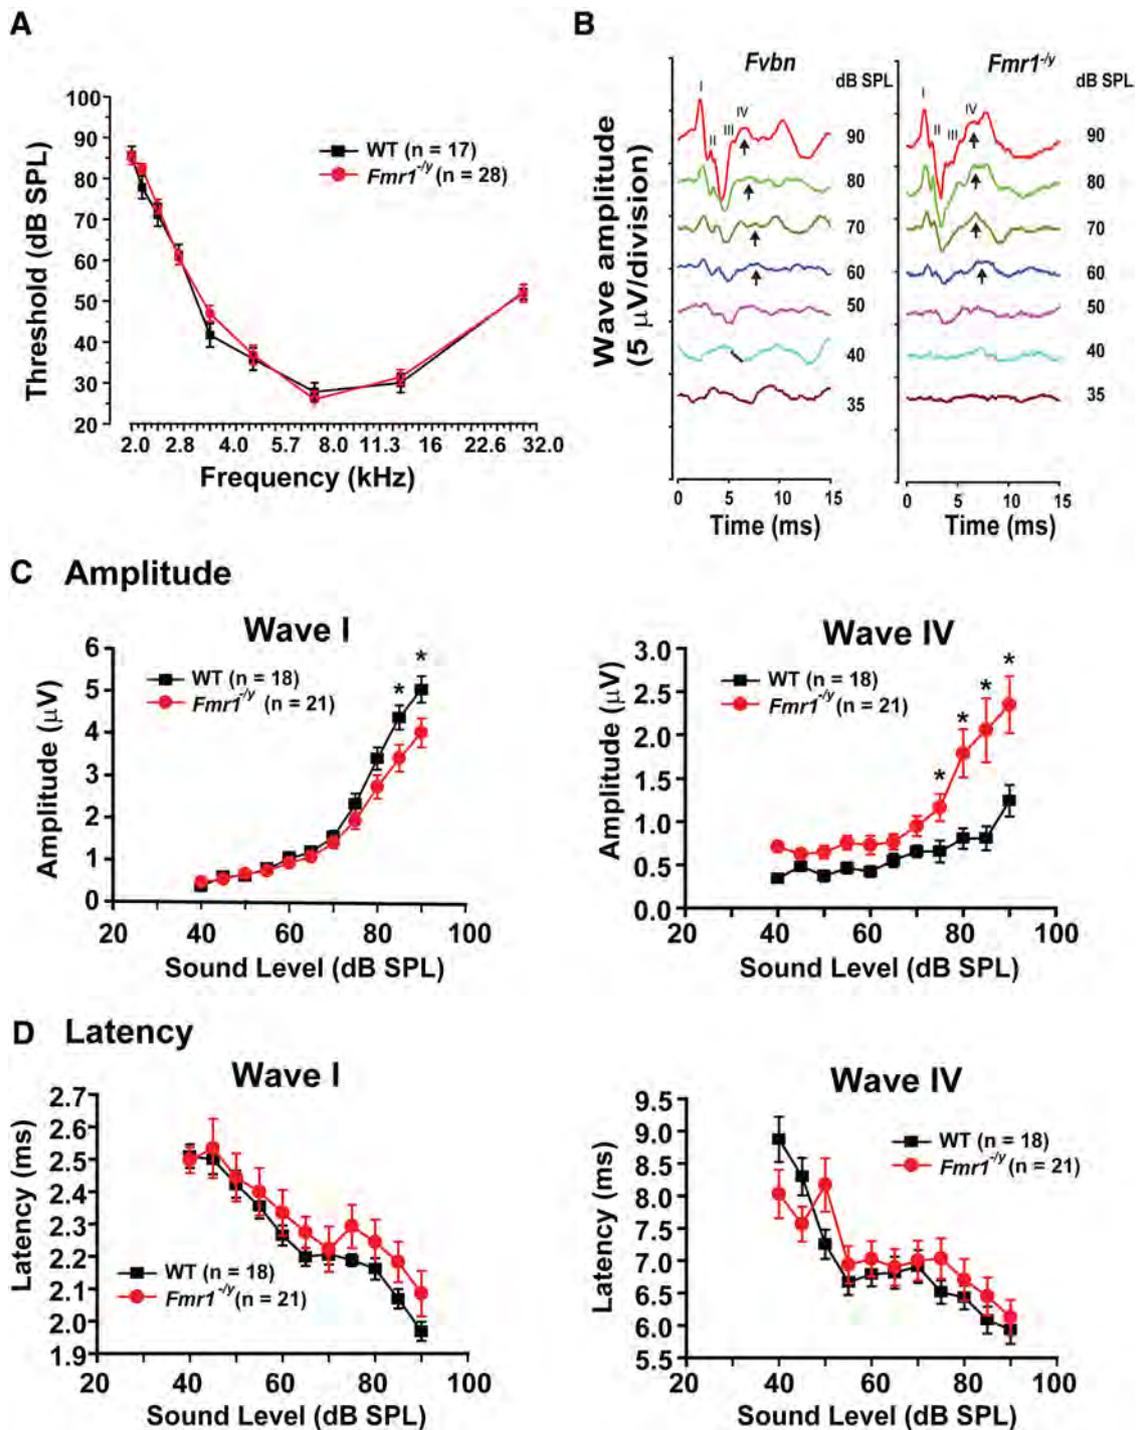

Figure 1. Loss of FMRP alters the central processing of auditory signals. **A**, Plots of the ABR thresholds for wild-type mice ($N = 17$ animals) and *Fmr1*^{-/-} mice ($N = 28$ animals). **B**, ABR wave recordings from WT and *Fmr1*^{-/-} mice stimulated at 11.3 kHz at different sound levels (35–90 dB). Arrows indicate wave IV of the ABR response. **C, D**, Plots of the amplitudes (**C**) and latencies (**D**) of ABR waves I and IV as a function of sound levels (40–90 dB). The magnitude of wave I is decreased for high sound levels ($p = 0.0002$) only, and there is a significant increase in wave IV amplitude in *Fmr1*^{-/-} mice at most sound levels tested ($p < 0.0001$) without significant change in the ABR latencies. Error bars indicate the mean \pm SEM. In **C**, asterisks indicate statistical significance (two-way ANOVA followed by Bonferroni–Dunn post-test).

MNTB neurons from *Fmr1*^{-/-} mice fire repetitively throughout the sustained depolarizations (Fig. 2*A, B*). Overall, the number of action potentials evoked by the 200 ms, 250 pA depolarizing current pulse was significantly greater in neurons from *Fmr1*^{-/-} mice (5.82 ± 1.48 , $n = 27$ cells, $N = 9$ animals; Fig. 2*A, B*) than in those from wild-type animals (0.33 ± 0.11 , $n = 18$ cells, $N = 7$ animals; $p = 0.002$, Student's unpaired t test with Welch's correction; $t = 1.713$, $df = 3.041$).

The input resistances and resting membrane potentials of MNTB neurons from *Fmr1*^{-/-} mice (88.70 ± 5.42 M Ω and -60.76 ± 1.44 mV, $n = 18$, $N = 11$) were not different from those of wild-type mice [90.65 ± 9.67 M Ω and -59.92 ± 0.39 mV, $n = 18$, $N = 15$; $p = 0.23$ for the input resistance comparison (Student's unpaired t test with Welch's correction, $t = 1.239$, $df = 22.76$); and $p = 0.87$ for the resting membrane potential comparison (Student's unpaired t test with Welch's correction

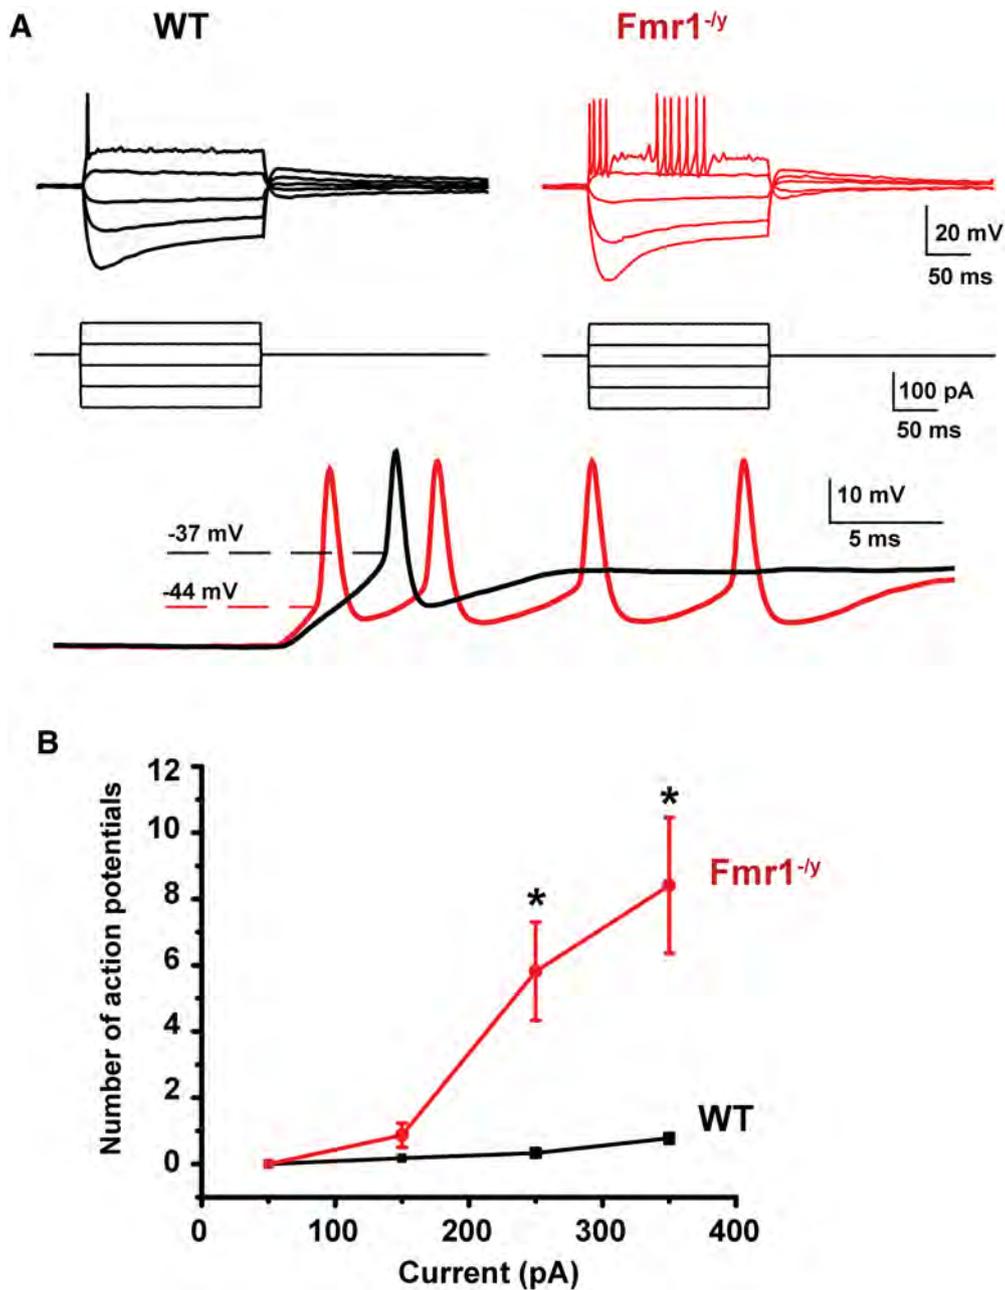

Figure 2. MNTB neurons from *Fmr1*^{-/-} mice are hyperexcitable. **A**, Current-clamp recordings of action potentials in response to a series of sustained hyperpolarizing and depolarizing current pulses (200 ms square current pulses, -250 to +350 pA). Note the repetitive firing and the shorter latency firing of MNTB neurons from *Fmr1*^{-/-} mice compared with the WT mice, which never fired more than one or two action potentials. **B**, Group data showing a significant increase in number of action potentials evoked in neurons from *Fmr1*^{-/-} mice in response to currents of increasing amplitude (Asterisks indicate statistical significance. *p* = 0.002, Student’s unpaired *t* test with Welch’s correction).

Table 1. Electrical parameters of MNTB neurons from wild type and *Fmr1*^{-/-} animals

Condition	Input resistance (MΩ)	Resting membrane potential (mV)	Rheobase (pA)	First action potential latency (ms)	Spike threshold (mV)
Wild type	90.65 ± 9.67 (18)	-59.92 ± 0.39 (18)	450 ± 49.25(18)**	3.67 ± 0.24 (18)	-37.28 ± 1.35(18)**
<i>Fmr1</i> ^{-/-}	88.70 ± 5.42 (18)	-60.76 ± 1.44 (18)	255.55 ± 20.56(18)**	3.48 ± 0.32 (18)	-44.21 ± 1.37(18)**

***p* = 0.001.

(*t* = 0.1649, *df* = 12.7)]. We found, however, a significant difference in the spike threshold between the two groups of mice [wild-type mice: -37.3 ± 1.35 mV, *n* = 18, *N* = 15; vs *Fmr1*^{-/-} mice: -44.2 ± 1.37 mV, *n* = 18, *N* = 11; *p* = 0.001, Student’s unpaired *t* test with Welch’s correction (*t* = 3.59, *df* = 31.92)]. This is consistent with a significant decrease of

the rheobase from 450 ± 49.25 pA in wild-type mice to 255 ± 20.56 pA in *Fmr1*^{-/-} mice (Table 1; *p* = 0.001, Student’s unpaired *t* test, with Welch’s correction; *t* = 3.643, *df* = 21.45). We found, however, no statistical difference in action potential height between the wild-type mice (43.51 ± 3.73 mV, *n* = 18, *N* = 15) and the *Fmr1*^{-/-} mice (42.11 ± 2.57 mV, *n* = 18,

$N = 11$, $p = 0.8$; Student's unpaired t test, with Welch's correction, $t = 0.3085$, $df = 15.63$).

In response to high rates of stimulation, MNTB neurons are capable of locking their action potentials to stimuli at rates of up to several hundred hertz (Macica et al., 2003; Song et al., 2005; Kopp-Scheinflug et al., 2011). We therefore compared the ability of MNTB neurons from wild-type and $Fmr1^{-/-}$ mice to follow repetitive stimuli of brief and subthreshold current pulses (1 nA, 0.3 ms, 20 stimuli) applied at rates from 50 to 600 Hz. Consistent with their enhanced excitability in response to sustained depolarization, we found that MNTB neurons from $Fmr1^{-/-}$ mice fired more action potentials compared with WT mice. For example, at 200 Hz, the number of spikes elicited by a train of 20 stimuli was 14.38 ± 1.43 ($n = 10$, $N = 9$ animals) in $Fmr1^{-/-}$ mice compared with 8.66 ± 1.92 ($n = 13$, $N = 10$ animals) in wild-type mice ($p = 0.04$, Student's unpaired t test with Welch's correction; $t = 2.381$, $df = 10.71$). A two-way ANOVA was further performed to examine changes in the number of spikes in relation to both variables: the genotype of animals (WT or $Fmr1^{-/-}$ mice) and the frequency of stimulation. We found that the genotype had a stronger impact on the number of spikes ($F_{(1,75)} = 16.88$, $p = 0.0001$; Fig. 3A,B). The stimulus frequency also had an effect on the number of evoked spikes ($F_{(3,75)} = 2.81$, $p = 0.04$), but no significant interaction effect was found between the genotype and the stimulus frequency on the number of action potentials ($F_{(3,75)} = 2.81$, $p = 0.3$). *Post hoc* tests that corrected for multiple comparisons showed that this increase in spike number in $Fmr1^{-/-}$ mice was significant for 50, 200, and 400 Hz ($p = 0.0005$, $p = 0.04$, $p = 0.04$) but not for 600 Hz ($p = 0.5$, Holm–Sidak method; Fig. 3B, asterisk).

Multiple potassium currents are altered in MNTB neurons of $Fmr1^{-/-}$ mice.

Several different types of voltage-dependent K^+ currents have been described in MNTB neurons. Some of these activate only at positive potentials and contribute primarily to the rapid repolarization of action potentials. These include currents attributed to the Kv3.1 and Kv2.2 channels (Macica et al., 2003; Steinert et al., 2011). Several other components of K^+ current activate near the resting potential and are required to maintain accurate temporal locking of action potentials to incoming stimuli. These include subunits of the Kv1, Kv11, and K_{Na} subfamilies (Brew and Forsythe, 1995; Grigg et al., 2000; Dodson et al., 2002; Yang et al., 2007; Hardman and Forsythe, 2009; Mathews et al., 2010). To evaluate the effect of loss of FMRP on intrinsic excitability, we performed voltage-clamp experiments using protocols that differentiate between these two components of current in postnatal day 15 wild-type and $Fmr1^{-/-}$ mice. Because several K^+ subunits have a tonotopic distribution in the MNTB (Li et al., 2001; Bhat-tacharjee et al., 2002, 2005; Brew and Forsythe, 2005; Strumbos et al., 2010a), we confined our recordings to cells in the lateral region of the MNTB.

We first recorded K^+ currents that activate at positive potentials by holding the membrane potential at -40 mV for 2 min before applying test pulses between -30 and $+60$ mV in 10 mV increments (Fig. 4A). This holding potential causes the inactivation of most components of K^+ current that activate at more negative potentials, and 80–90% of the current evoked under these conditions represents the Kv3.1 current (Wang et al., 1998a; Macica et al., 2003). The amplitude of these currents at $+60$ mV, which we will term “high-threshold” K^+ currents, was significantly higher in MNTB neurons from $Fmr1^{-/-}$ mice than in wild-type mice (Figs. 4A, 5.90 ± 0.40 vs 3.99 ± 0.66 nA, respectively,

$p = 0.02$; Student's unpaired t test with Welch's correction: $t = 2.493$, $df = 14.87$). A two-way ANOVA test revealed that both the genotype ($F_{(1,150)} = 22.02$, $p < 0.0001$) and the membrane voltage ($F_{(9,150)} = 45.54$, $p < 0.0001$) had a significant impact on the magnitude of high-threshold K^+ currents. Using a *post hoc* test that corrected for multiple comparisons, we found that the high-threshold K^+ currents were significantly increased in neurons from $Fmr1^{-/-}$ mice at 40 mV ($p = 0.01$), 50 mV ($p = 0.003$), and 60 mV ($p = 0.0007$; Fig. 4A).

When the normalized conductance was plotted as a function of membrane voltage (Fig. 4A, right), we found no significant change in the conductance between WT and $Fmr1^{-/-}$ groups of mice. The half-activation potential ($V_{1/2 \text{ max}}$) for the WT group was -1.05 ± 3.8 ($n = 9$, $N = 7$) compared with 6.25 ± 2.2 mV in the $Fmr1^{-/-}$ group ($p = 0.16$, $n = 7$, $N = 7$; Student's unpaired t test with Welch's correction: $t = 1.47$, $df = 12.94$).

For the second protocol, the membrane potential was held at -80 mV, and currents were evoked by potentials between -70 to $+60$ mV in 10 mV increments. This evokes currents that activate near the resting potential and action potential threshold (-60 to -20 mV, low-threshold currents) as well as the high-threshold K^+ currents (Fig. 4B). Under these conditions, the currents recorded at $+60$ mV were significantly lower in MNTB neurons from $Fmr1^{-/-}$ mice: 7.71 ± 0.31 nA ($n = 7$, $N = 7$ animals) than in those from wild-type mice vs 9.51 ± 0.47 nA ($n = 9$, $N = 7$ animals, $p = 0.007$, Student's unpaired t test with Welch's correction: $t = 3.535$, $df = 8.506$). Additional two-way ANOVA revealed a significant main effect of the genotype on the amplitude of low-threshold K^+ current ($F_{(2,139)} = 56.30$, $p < 0.0001$). Using a *post hoc* test that corrected for multiple comparisons, we found that the low-threshold K^+ currents were significantly decreased in $Fmr1^{-/-}$ mice at membrane voltages from -10 to $+60$ mV (-10 mV: $p = 0.006$; 0 mV: $p = 0.0005$; 10 mV: $p = 0.00002$; 20 – 50 mV: $p < 0.0001$; 60 mV: $p < 0.0001$; Fig. 4B).

When the normalized conductance was plotted as a function of membrane voltage (Fig. 4B), there was a significant decrease in the conductance in the $Fmr1^{-/-}$ group of mice. The $V_{1/2 \text{ max}}$ for the WT group was -34.15 ± 1.4 mV compared with -20.12 ± 1.23 mV in the $Fmr1^{-/-}$ group ($p = 0.01$, Student's unpaired t test with Welch's correction; $t = 5.88$, $df = 6.99$).

These findings indicate that the high-threshold and low-threshold K^+ currents are altered in opposite directions by loss of FMRP. Both of these changes are consistent with the increased excitability of MNTB neurons in $Fmr1^{-/-}$ mice. Increased Kv3.1-like high-threshold currents increase the ability of neurons to fire at high rates, while reduced low-threshold K^+ currents, which dominate total current in steps from -80 mV, lower the threshold for action potentials and promote repetitive firing (Gan and Kaczmarek, 1998; Rudy and McBain, 2001; Zhang et al., 2012).

Actions of the Kv3.1 channel modulator AUT2 on K^+ currents in MNTB neurons from $Fmr1^{-/-}$ mice

AUT2 is an imidazolidinedione derivative that modulates Kv3.1 channels (Brown et al., 2016; Fig. 5A). In mammalian cells transfected with human Kv3.1 channels, AUT2 shifts the voltage dependence of activation toward more negative potentials. This may cause Kv3.1 channels to activate at potentials that normally only activate low-threshold K^+ channels. In addition, AUT2 also shifts the voltage dependence of steady-state inactivation to more negative potentials, reducing the amount of current that can be activated by depolarization to positive potentials. We investigated the effects of AUT2 on the high- and low-threshold components of current in MNTB neurons of $Fmr1^{-/-}$ mice.

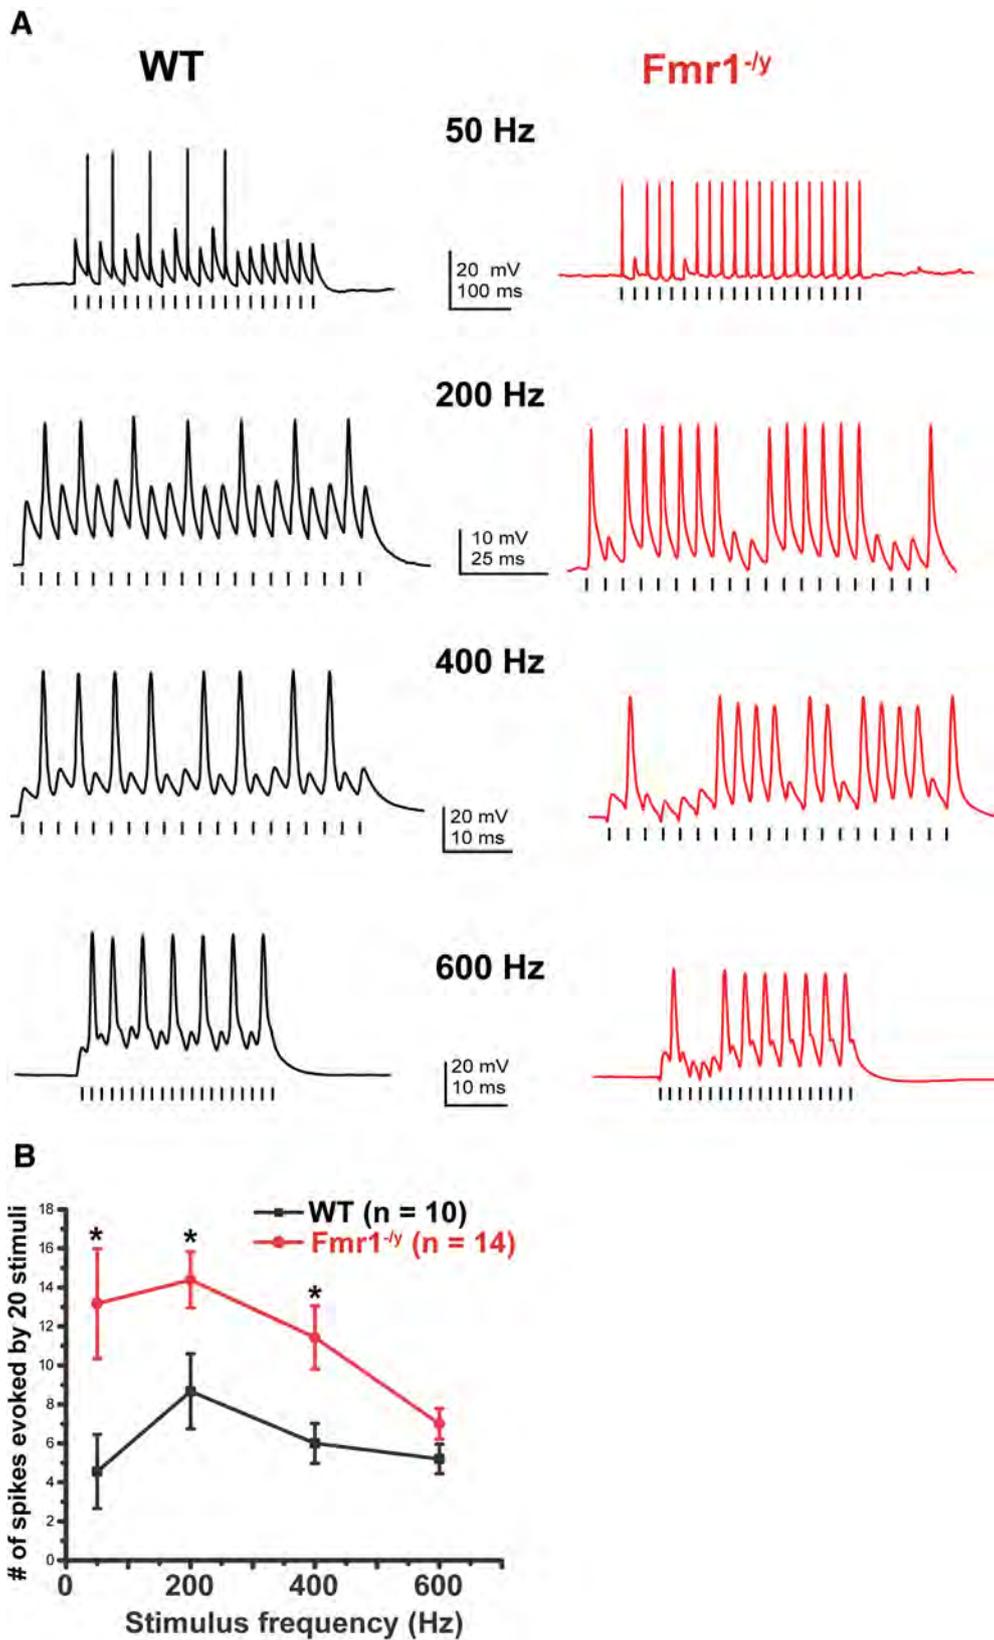

Figure 3. MNTB neurons from *Fmr1*^{-/-} mice fire more action potentials in response to repetitive stimulation. **A**, Current-clamp recordings of action potentials in response to repetitive stimulation with brief current pulses (1 nA, 0.3 ms, 20 stimuli) applied at rates from 50 to 600 Hz. **B**, Group data showing that MNTB neurons from *Fmr1*^{-/-} mice fire more action potentials at all stimulus frequencies up to 400 Hz. Asterisks indicate significant differences (two-way ANOVA followed by Holm–Sidak post-test).

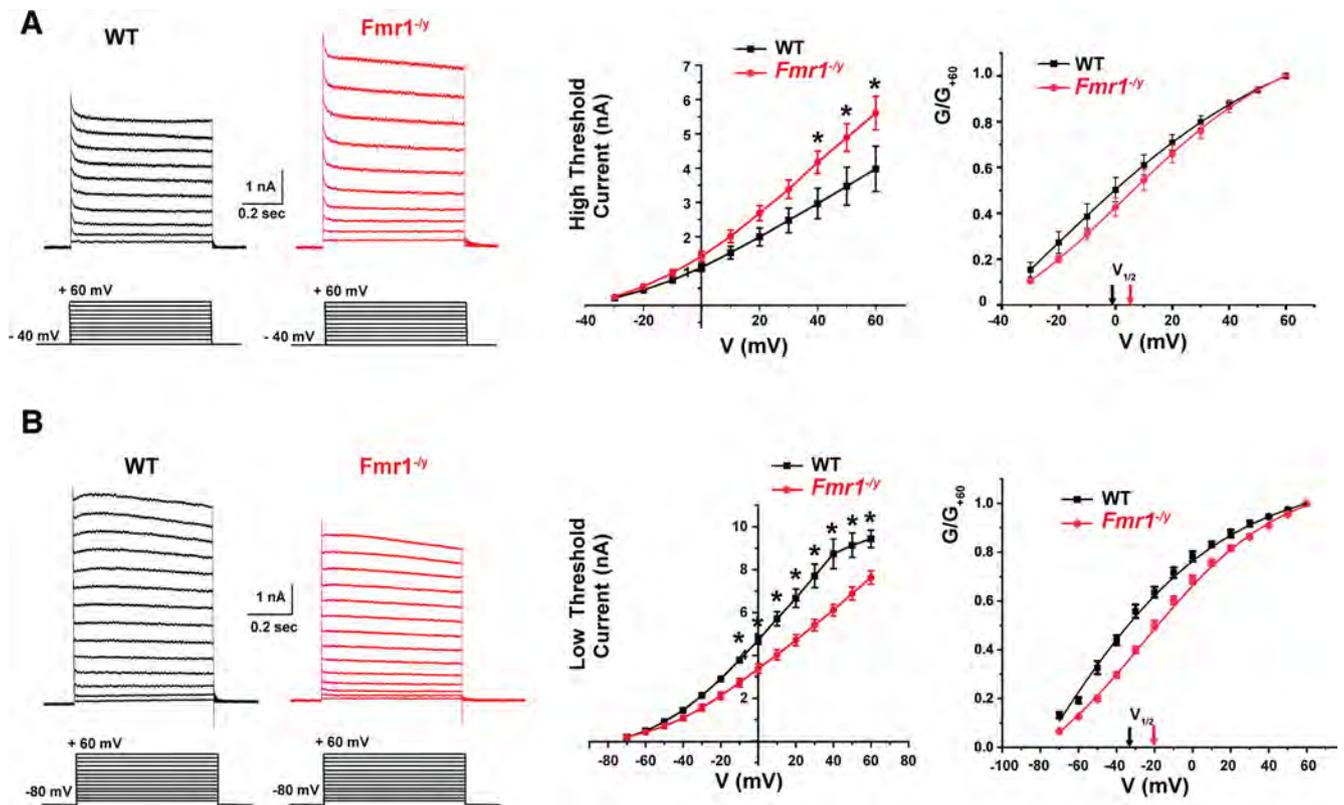

Figure 4. High- and low-threshold potassium currents are altered in MNTB neurons of *Fmr1*^{-/-} mice. **A**, Representative whole-cell patch-clamp recordings of high-threshold potassium current evoked by holding the membrane potential at -40 mV for 2 min before stepping to test potentials between -30 and $+60$ mV in 10 mV increments. Middle, Plot shows that the amplitude of high-potassium current was significantly higher in MNTB neurons from *Fmr1*^{-/-} mice compared with wild-type mice (two-way ANOVA, $p < 0.0001$). Right, Plot shows the corresponding normalized conductance that was not significantly ($p = 0.16$) different between WT and *Fmr1*^{-/-} mice. **B**, Representative whole-cell patch-clamp recordings of low-threshold potassium current by holding the membrane potential at -80 mV before stepping to test potentials from -70 to $+60$ mV in 10 mV increments. Middle, Plots show that the peak amplitude of low-potassium current was significantly reduced in *Fmr1*^{-/-} mice compared with WT mice ($p < 0.0001$, two-way ANOVA). Plot on the right shows a significant shift in voltage dependence of the low-threshold K⁺ conductance in *Fmr1*^{-/-} mice ($p = 0.01$, Student's unpaired *t* test with Welch's correction). In the *I*-*V* plots, asterisks indicate statistical significance in post-test results for multiple comparisons (Holm–Sidak method).

Application of AUT2 reduced the amplitude of the high-threshold component of currents that could be evoked from a holding potential of -40 mV to a test potential of $+60$ mV in MNTB neurons from *Fmr1*^{-/-} mice. At 60 mV, the amplitude of the high-threshold potassium currents decreased from 4.82 ± 0.54 to 2.24 ± 0.22 nA ($n = 4$, $N = 4$ animals, $p = 0.0006$, Student's paired *t* test; Fig. 5A). Using a two-way ANOVA with *post hoc* correction for multiple comparisons, we found that AUT2 had a main effect on high-threshold current ($F_{(1,130)} = 54.66$, $p < 0.0001$). Because we found a significant interaction between AUT2 treatment and membrane voltage on the amplitude of high-threshold potassium currents ($F_{(9,130)} = 3.20$, $p = 0.001$), we then performed a simple effects test and found that the high-threshold K⁺ currents recorded in *Fmr1*^{-/-} mice were significantly decreased by AUT2 treatment at membrane voltages from 20 to 60 mV (20 mV: $p = 0.01$; 30 mV: $p = 0.002$; 40 mV: $p = 0.0001$; 50 and 60 mV; $p < 0.0001$; Fig. 5A).

When the normalized conductance was plotted as a function of membrane voltage (Fig. 5A), we found no significant change in voltage dependence after the addition of AUT2. The $V_{1/2 \max}$ for the *Fmr1*^{-/-} group of mice was 0.67 ± 3.59 mV compared with -2.53 ± 5.72 mV with AUT2 treatment ($p = 0.84$, $n = 4$, $N = 4$ animals; Student's paired *t* test, $t = 0.2$, $df = 6$).

When the holding potential was maintained at -80 mV, allowing for evaluation of combined low-threshold and high-threshold components of evoked K⁺ currents, AUT2 produced a

significant increase in current. For example, the current at $+60$ mV was increased from 6.64 ± 0.57 nA in MNTB neurons from *Fmr1*^{-/-} mice to 8.43 ± 0.4 nA ($p = 0.031$, $n = 4$, $N = 4$ animals Student's paired *t* test; Fig. 5B). Using a two-way ANOVA with *post hoc* correction for multiple comparisons, we found that AUT2 had a main effect on low-threshold current ($F_{(2,209)} = 61.65$, $p < 0.0001$). Because we found a significant interaction between the drug treatment and membrane voltage ($F_{(26,209)} = 2.14$, $p = 0.001$), we performed a simple effects test and found that the increase of low-threshold potassium current by AUT2 was significant at membrane voltages from -20 to $+60$ mV (-20 mV: $p = 0.01$; -10 mV: $p = 0.002$; 0 mV: $p = 0.0004$; 10 – 60 mV: $p < 0.0001$; Fig. 5B).

The voltage dependence of the low-threshold currents was also altered by AUT2. When the normalized conductance was plotted as a function of membrane voltage (Fig. 5B), we found a significant shift of the $V_{1/2 \max}$ toward hyperpolarized potentials after AUT2 treatment. Values of $V_{1/2 \max}$ shifted from 8.42 ± 3.33 mV before AUT2 to -3.82 ± 0.65 mV after AUT2 application ($p = 0.004$, $n = 4$, $N = 4$ animals; Student's paired *t* test, $t = 5$; $df = 5$).

We have previously described that application of AUT2 alters also the voltage dependence of inactivation of Kv3.1 channels when expressed in mammalian cells (Brown et al., 2016). To test further whether the same concentration of AUT2 used previously ($10 \mu\text{M}$) can also change the inactivation curve of the high-

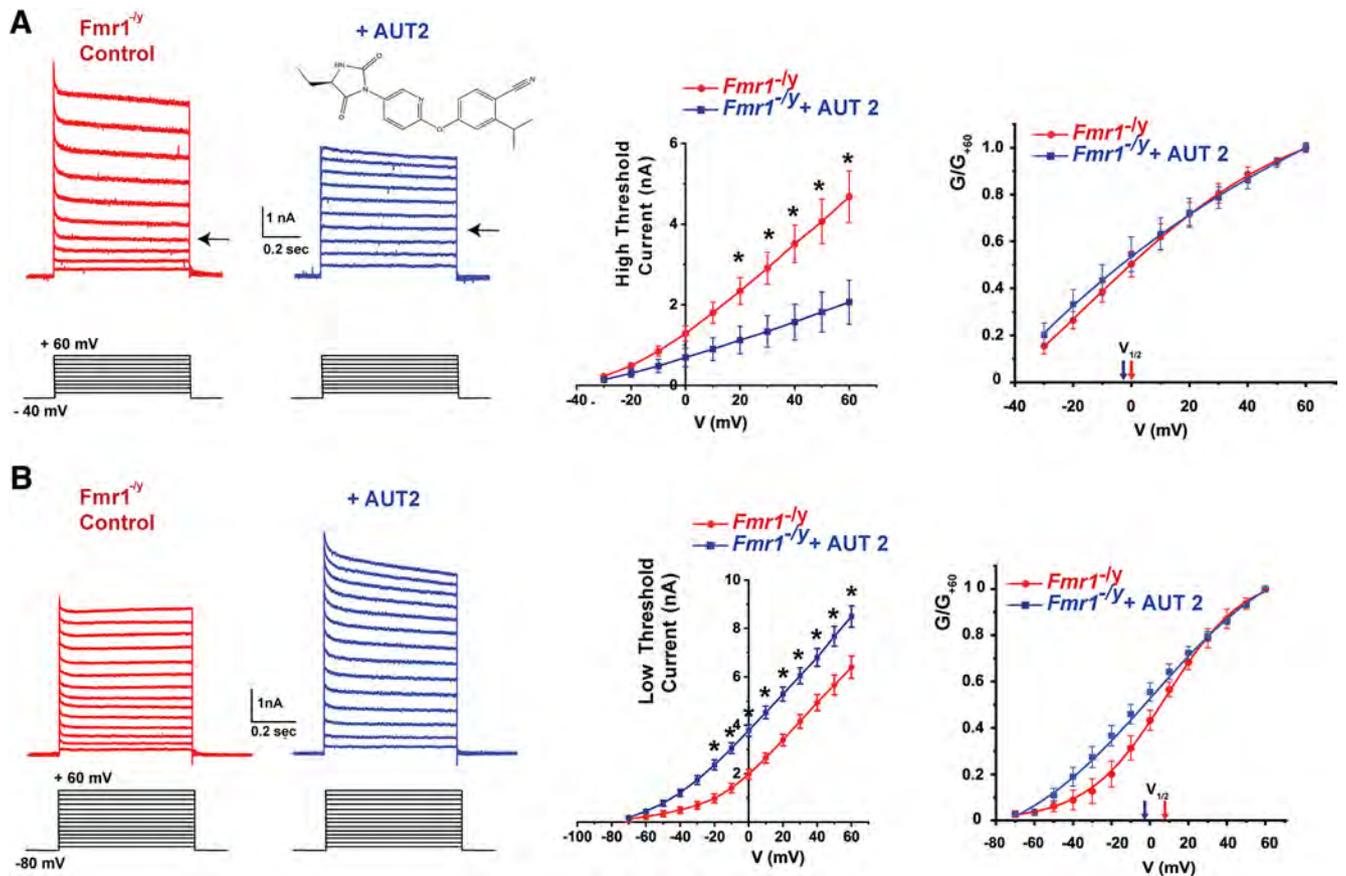

Figure 5. AUT2 decreases high-threshold potassium current and increases low-threshold potassium current of MNTB neurons from *Fmr1*^{-/-} mice. **A**, Representative traces of high-threshold potassium current evoked by holding the membrane potential at -40 mV and stepping to test potentials from -30 and +60 mV in 10 mV increments before and after the addition of 10 μM AUT2. The chemical structure of AUT2 is shown above the right-hand current traces. Middle, Group data for the effects of AUT2 on current amplitude at different voltages. Right, group data for conductance-voltage relations normalized to maximal value at +60 mV (G/G_{+60}), indicating that AUT2 did not produce a significant change of the voltage-dependent activation of high-threshold potassium currents. **B**, Representative whole-cell patch-clamp recordings of low-threshold potassium current evoked by holding the membrane potential at -80 mV and applying test potentials from -70 to +60 mV in 10 mV increments before and after addition of AUT2 (10 μM). Panels at center and right show group data for current amplitudes and conductance-voltage relations, demonstrating that AUT2 significantly increased the low-threshold potassium currents in *Fmr1*^{-/-} mice. Asterisks in **A** and **B** indicate statistical significance in post-test results of the simple effect test for multiple comparison (Holm-Sidak method).

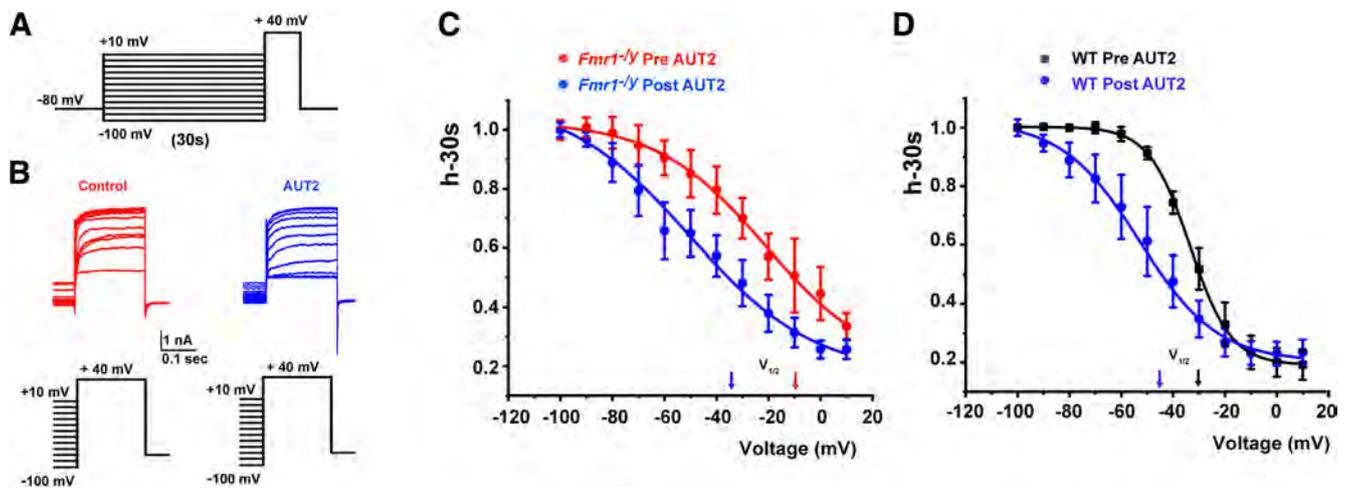

Figure 6. Addition of AUT2 produces a left shift in the voltage dependence of inactivation of high-threshold potassium currents in wild-type and *Fmr1*^{-/-} mice. **A**, Standard voltage-clamp protocol to assess the inactivation of K⁺ currents. Cells were held at potentials between -100 and +10 mV for 30 s before a test pulse to +40 mV. **B**, Representative traces of the outward current recorded in neurons from *Fmr1*^{-/-} mice at a test potential of +40 mV before and after AUT2 (10 μM). **C**, **D**, Plots of steady-state inactivation as a function of a 30 s prepulse to potentials between -100 and +10 mV in *Fmr1*^{-/-} (**C**) and WT (**D**) mice.

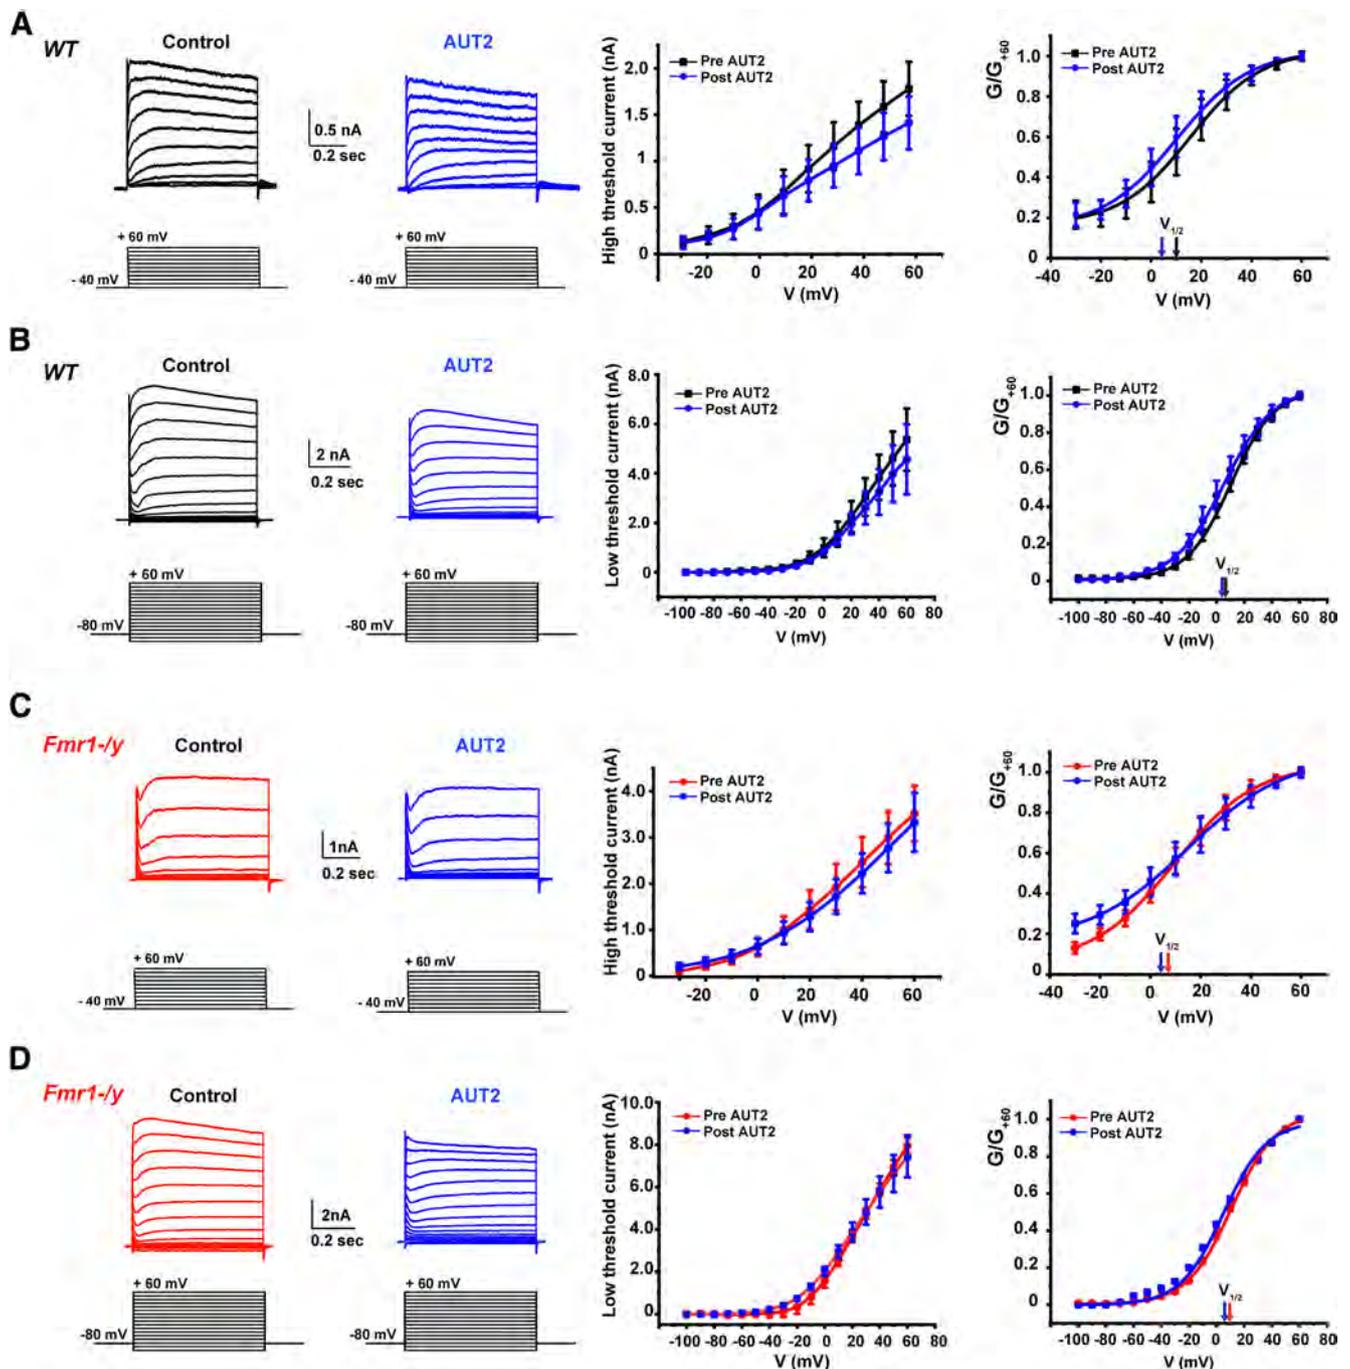

Figure 7. AUT2 fails to alter high- and low-threshold K^+ currents in the presence of the Kv3 channel blocker TEA. **A–D**, Voltage-clamp recordings of the high-threshold (**A, C**) and low-threshold (**B, D**) potassium currents in wild-type and in *Fmr1*^{-/-} mice. Panels on the right show the current–voltage and the conductance–voltage (normalized to maximal value at +60 mV; G/G_{+60}) curves for high- and low-threshold K^+ currents before and after AUT2, in the presence of the Kv3 channels blocker TEA (1 mM). AUT2 failed to alter the magnitude and the conductance of both high- and low-threshold potassium currents in these conditions.

threshold of K^+ currents in MNTB neurons, we used a standard protocol to assess the inactivation of K^+ currents. Neurons were held at potentials between -100 and $+10$ mV for 30 s before a test pulse to $+40$ mV, before and after the application of AUT2 to MNTB neurons from brain slices of either WT or *Fmr1*^{-/-} mice (Fig. 6A). Consistent with our previous results, we found that AUT2 compound produced a significant shift of the half-inactivation potential toward hyperpolarization potentials in both genotypes. In *Fmr1*^{-/-} mice, AUT2 shifted $V_{1/2 \max}$ from -10.17 ± 3.82 to -35.21 ± 3.42 mV ($p = 0.041$, $t_{(5)} = 2.72$, two-tailed paired Student's t test; $n = 5$, $N = 5$ animals; Fig.

6B, C). In WT mice, AUT2 shifted $V_{1/2 \max}$ from -30.51 ± 0.37 to -44.36 ± 1.86 mV ($p = 0.043$, $t_{(4)} = 2.85$; $n = 5$, $N = 5$ animals two-tailed paired Student's t test; Fig. 6D).

To exclude the possibility that AUT2 may have affected other type of channels in MNTB neurons, we repeated the experiments described in Figure 5 in the presence of a low concentration of tetraethylammonium (TEA; 1 mM), which selectively eliminates the component of current carried by Kv3 channels in these cells (Wang et al., 1998a). We found that, in the presence of TEA, AUT2 did not change the magnitude or the voltage dependence of either low- or high-threshold K^+ currents when tested in both

WT and *Fmr1*^{-/-} mice. Using a two-way ANOVA (with Bonferroni's *post hoc*) to analyze the effect of AUT2 on the amplitude of both high- and low-threshold potassium currents, we found no significant effect in WT mice (high *Kv*: $F_{(1,60)} = 2.32$, $p = 0.13$; low *Kv*: $F_{(1,102)} = 4.07$, $p = 0.35$; Figure 7*A,B*, middle panels). AUT2 also failed to change the amplitude of potassium currents in *Fmr1*^{-/-} mice (high *Kv*: $F_{(1,26)} = 0.99$, $p = 0.32$; low *Kv*: $F_{(1,102)} = 1.77$, $p = 0.18$; Figure 7*C,D*, middle panels). When the normalized conductance of the high-threshold currents in WT mice was plotted as a function of membrane voltage, there was no significant shift of the $V_{1/2}$ after AUT2 treatment (10 μM): $V_{1/2}$ was 10.11 ± 6.30 mV and changed to 5.2 ± 5.4 after AUT2 application ($p = 0.42$, $n = 3$, $N = 3$ animals, Student's paired *t* test; Fig. 7*A*, right). Similarly, AUT2 failed to change the voltage dependence of activation of low-threshold K^+ currents in the presence of TEA ($V_{1/2 \text{ max}}$ for WT mice before AUT2 was 8.52 ± 0.8 mV and 5.40 ± 1.07 mV after AUT2 application; $p = 0.09$, $n = 3$, $N = 3$ animals, paired *t* test; Fig. 7*B*, right).

The conductance of both high- and low-threshold potassium currents in *Fmr1*^{-/-} mice, in the presence of TEA, was also unaffected by AUT2 [$V_{1/2 \text{ max}}$ for high-threshold currents: 9.42 ± 0.40 mV before AUT2; 4.82 ± 0.63 mV after AUT2; $p = 0.12$, $n = 4$, $N = 4$ animals, Student's paired *t* test (Fig. 7*C*, right); $V_{1/2 \text{ max}}$ for low-threshold currents: 10.00 ± 1.72 mV before AUT2; 5.16 ± 0.35 mV after AUT2; $p = 0.36$, $n = 4$, $N = 4$ animals, Student's paired *t* test (Fig. 7*D*, right)].

These changes in amplitude and voltage dependence of the high- and low-threshold currents in normal conditions and the absence of these changes in the presence of the selective inhibitor of Kv3 channels (TEA) are entirely consistent with that expected from the effects of AUT2 observed on recombinant human Kv3.1 currents in transfected cells (Brown et al., 2016). A shift in steady-state inactivation to more negative potentials would be expected to reduce maximal currents evoked by the high-threshold voltage protocol. With the more negative holding potential, however, the shift in activation of Kv3.1 to more negative potentials would be expected to increase evoked currents, particularly at those negative test potentials where Kv3.1 channels are not normally activated.

AUT2 reduces the hyperexcitability of MNTB neurons in *Fmr1*^{-/-} mice

The effects of AUT2 on high- and low-threshold components of K^+ currents are directly opposite to those produced by loss of FMRP (Fig. 4). In particular, the increase in current that activates close to the resting potential would be expected to limit the generation of action potentials by increasing spike threshold. We therefore performed current-clamp recordings of MNTB neurons from *Fmr1*^{-/-} mice to determine the effects of AUT2 on their firing patterns evoked by repetitive stimulation with brief current pulses (1 nA, 0.3 ms, 20 stimuli) applied at rates from 50 to 300 Hz (Fig. 8). We found that AUT2 (10 μM) decreased the number of action potentials of MNTB neurons at all frequencies tested. Using two-way ANOVA and the Holm-Sidak method for *post hoc* correction, we found that the effect of AUT2 treatment was significant ($F_{(1,14)} = 29.32$, $p < 0.0001$) and that AUT2 decreased the number of spikes at all stimulus frequencies tested (50 Hz: $p = 0.002$; 200 Hz: $p = 0.02$; and 300 Hz: $p = 0.0006$, Holm-Sidak method; Fig. 8*A,B*).

AUT2 rescues the ABR of *Fmr1*^{-/-} mice

Because AUT2 reversed some of the effects of loss of FMRP on K^+ currents and firing patterns of MNTB neurons in brainstem

slices, we tested the effects of AUT2 on auditory function in *Fmr1*^{-/-} mice *in vivo*. As shown in Figure 1, the magnitude of wave IV of the ABR of 15-d-old mice was significantly enhanced in *Fmr1*^{-/-} animals compared with wild-type mice of the same age, which is consistent with the increased excitability of MNTB neurons. We found that intraperitoneal administration of AUT2 (30 mg/kg, 20 min before testing) significantly reduced the magnitude of wave IV in five of five mice without changing the magnitude of wave I (Fig. 9*A,B*). For sounds delivered at 80 dB, the amplitude of wave IV decreased from 1.24 ± 0.10 to 0.9 ± 0.07 μV after AUT2 treatment ($p = 0.001$, two-way ANOVA; $N = 5$ *Fmr1*^{-/-} mice) without changing the ABR threshold. The two-way ANOVA revealed no significant interaction between wave IV amplitudes before and after AUT2 treatment with the intensity of sound level ($F_{(5,59)} = 0.478$, $p = 0.8$). We found, however, a significant difference in the effect of sound level on wave IV amplitude before and after AUT2 ($F_{(1,59)} = 11.26$, $p = 0.001$).

AUT2 failed to change the magnitude of wave I ($p = 0.3$, two-way ANOVA). Although AUT2 slightly increased the latency of wave I at 80 and 90 dB, this effect was not statistically significant ($p = 0.1$, two-way ANOVA with multiple comparisons using the Holm-Sidak method; Fig. 9*B*). When the vehicle was administered alone (without AUT2) in another group of mice, the magnitudes of wave I and IV were unchanged. For example, at a sound level of 85 dB, the amplitude of wave IV was 1.78 ± 0.57 μV in *Fmr1*^{-/-} mice before the administration of the vehicle compared with 1.52 ± 0.64 μV 20 min after the vehicle administration ($N = 4$ animals; $p = 0.99$, two-way ANOVA; Fig. 10*A*). At the same sound level, the administration of the vehicle to *Fmr1*^{-/-} mice did not change the amplitude of wave I (before vehicle: 2.00 ± 0.49 μV ; vs after vehicle: 1.90 ± 0.45 μV ; $N = 4$ animals; $p = 0.99$, two-way ANOVA; Fig. 10*A*). Similarly, the latencies of waves I and IV were also unchanged by the administration of the vehicle. At a sound level of 85 dB, the latency of wave I was 2.42 ± 0.28 ms before and 2.55 ± 0.23 ms after vehicle administration and the latency of wave IV was 6.47 ± 0.30 ms before and 6.072 ± 0.238 ms after the administration of vehicle ($N = 4$ animals; $p = 0.98$ and $p = 0.90$, respectively, two-way ANOVA; Fig. 10*A*).

We also tested the effect of AUT2 on wild-type mice and found no significant changes in the amplitude of waves I or IV, perhaps because levels of Kv3.1 are lower in wild-type mice (Fig. 10*B,C*). Together, these data suggest that AUT2 rescues the auditory function of *Fmr1*^{-/-} mice by changing the voltage dependence of Kv3-like, high-threshold K^+ channels, thereby reducing excitability and restoring brainstem responses *in vivo* to those of wild-type animals.

Discussion

Our findings suggest that one mechanism by which the loss of FMRP alters the processing of auditory information is by altering the expression and activity of K^+ channels. Our results with *Fmr1*^{-/-} mice are consistent with the clinical observation that patients with fragile X syndrome experience a hypersensitivity to sound and impairment of auditory processing (St Clair et al., 1987; Arinami et al., 1988; Ferri, 1989; Wisniewski et al., 1991; Rojas et al., 2001; Castrén et al., 2003; Van der Molen et al., 2012; Garcia-Pino et al., 2017). Most of these studies show a prolonged latency of the ABR response in humans, particularly for waves III and V and for interpeak intervals III–V and I–V, suggesting a central, as opposed to a peripheral, dysfunction of auditory pathways (Arinami et al., 1988). Consistent with these findings, the marked increase in the magnitude of wave IV in *Fmr1*^{-/-} mice in

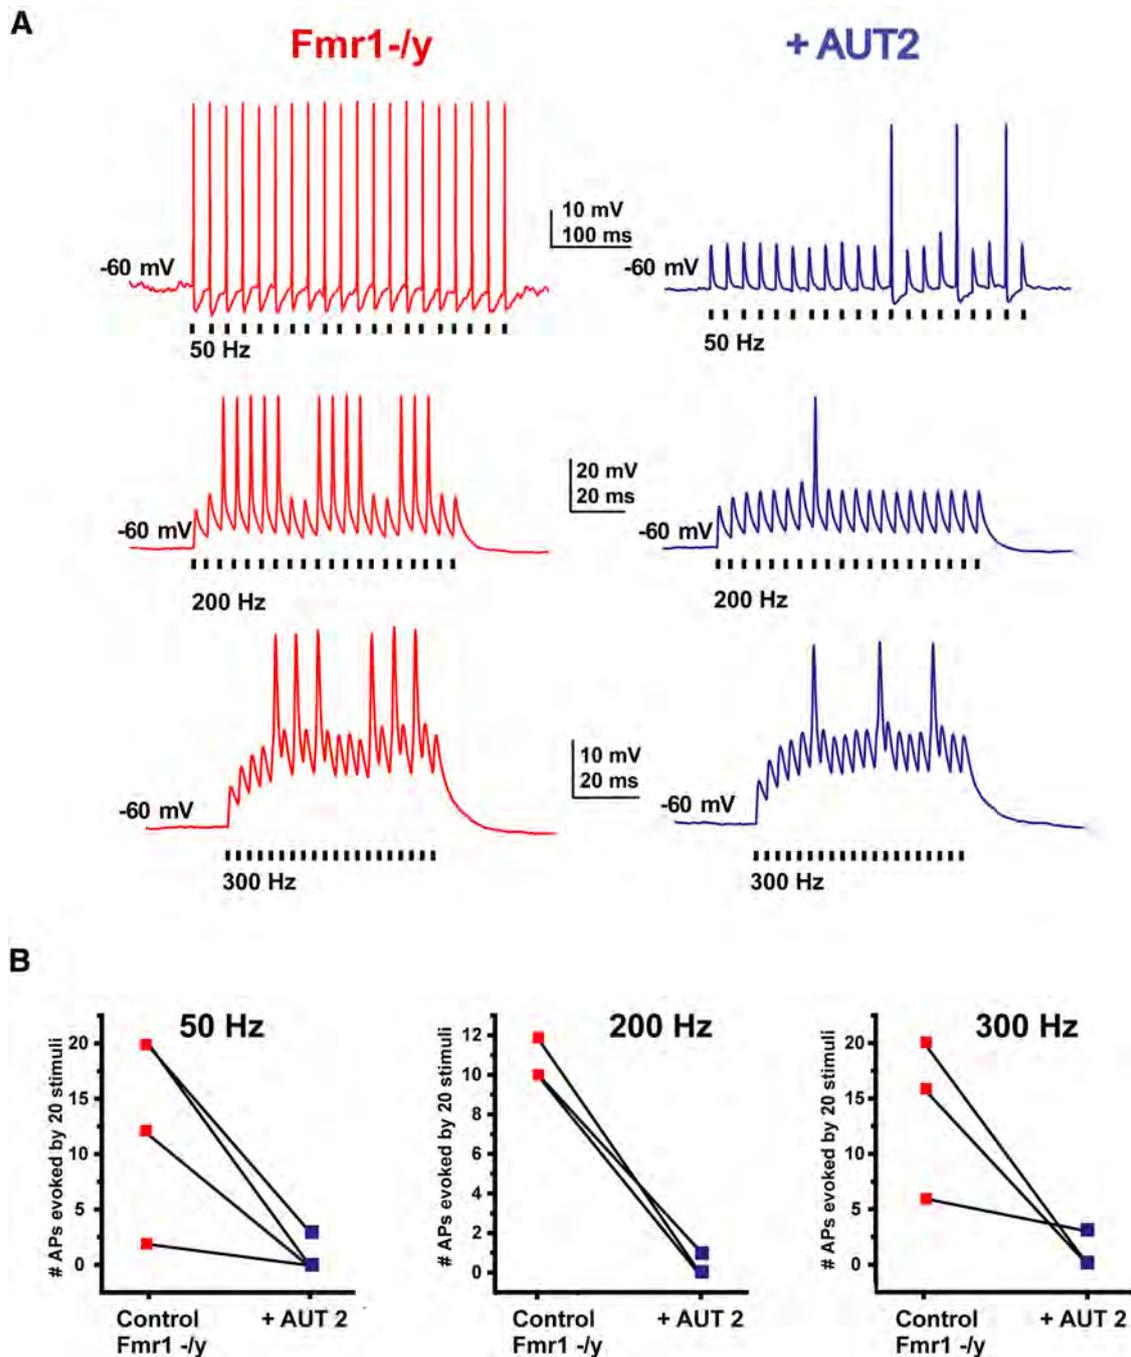

Figure 8. AUT2 reduces the firing rate of MNTB neurons of *Fmr1*^{-/-} mice. **A**, Current-clamp recordings of action potentials evoked by 20 consecutive stimuli of intracellular current pulses (2 nA, 0.3 ms) in MNTB neurons applied at 50, 200, or 300 Hz before and after application of AUT2 (10 μ M). **B**, Plots of the numbers of action potentials evoked by repetitive stimulation at 50, 200, and 300 Hz in different experiments before and after AUT2 application. AUT2 decreased the number of evoked action potentials in MNTB neurons at all frequencies tested ($n = 3$, $N = 3$ animals; $p < 0.0001$, two-way ANOVA followed by Holm–Sidak post-test).

the present study also suggests that changes in the excitability of brainstem nuclei are more pronounced than those in auditory afferents as there is little or no change in wave I amplitude compared with that of wave IV.

We have demonstrated that in neurons of the MNTB in *Fmr1*^{-/-} mice, low-threshold K⁺ currents, which activate near the resting potential, are significantly decreased. The K⁺ channels that contribute to these currents in the MNTB of mice have been identified, and include Kv1.1, Kv1.2, Kv1.6, Kv11.1, Kv11.3, K_{Na}1.1, and K_{Na}1.2 channel subunits (Dodson et al., 2002; Brew et al., 2003; Kopp-Scheinplüg et al., 2003; Yang et al., 2007;

Hardman and Forsythe, 2009; Brown et al., 2010). In the neurons of wild-type mice, these channels, particularly Kv1.1. and Kv1.2, serve to limit the response to sustained depolarization to a single action potential at the onset of the depolarization. A reduction in the low-threshold K⁺ current is therefore consistent with the repetitive firing of MNTB neurons of *Fmr1*^{-/-} mice evoked by depolarization. The mRNA for three of the low-threshold K⁺ subunits are targets of FMRP (Darnell et al., 2011). Moreover, two of these subunits, K_{Na}1.1 (Slack) and Kv1.2, directly bind FMRP itself (Brown et al., 2010; Zhang et al., 2012; Yang et al., 2018). In MNTB neurons, the Slack-FMRP interaction stimulates

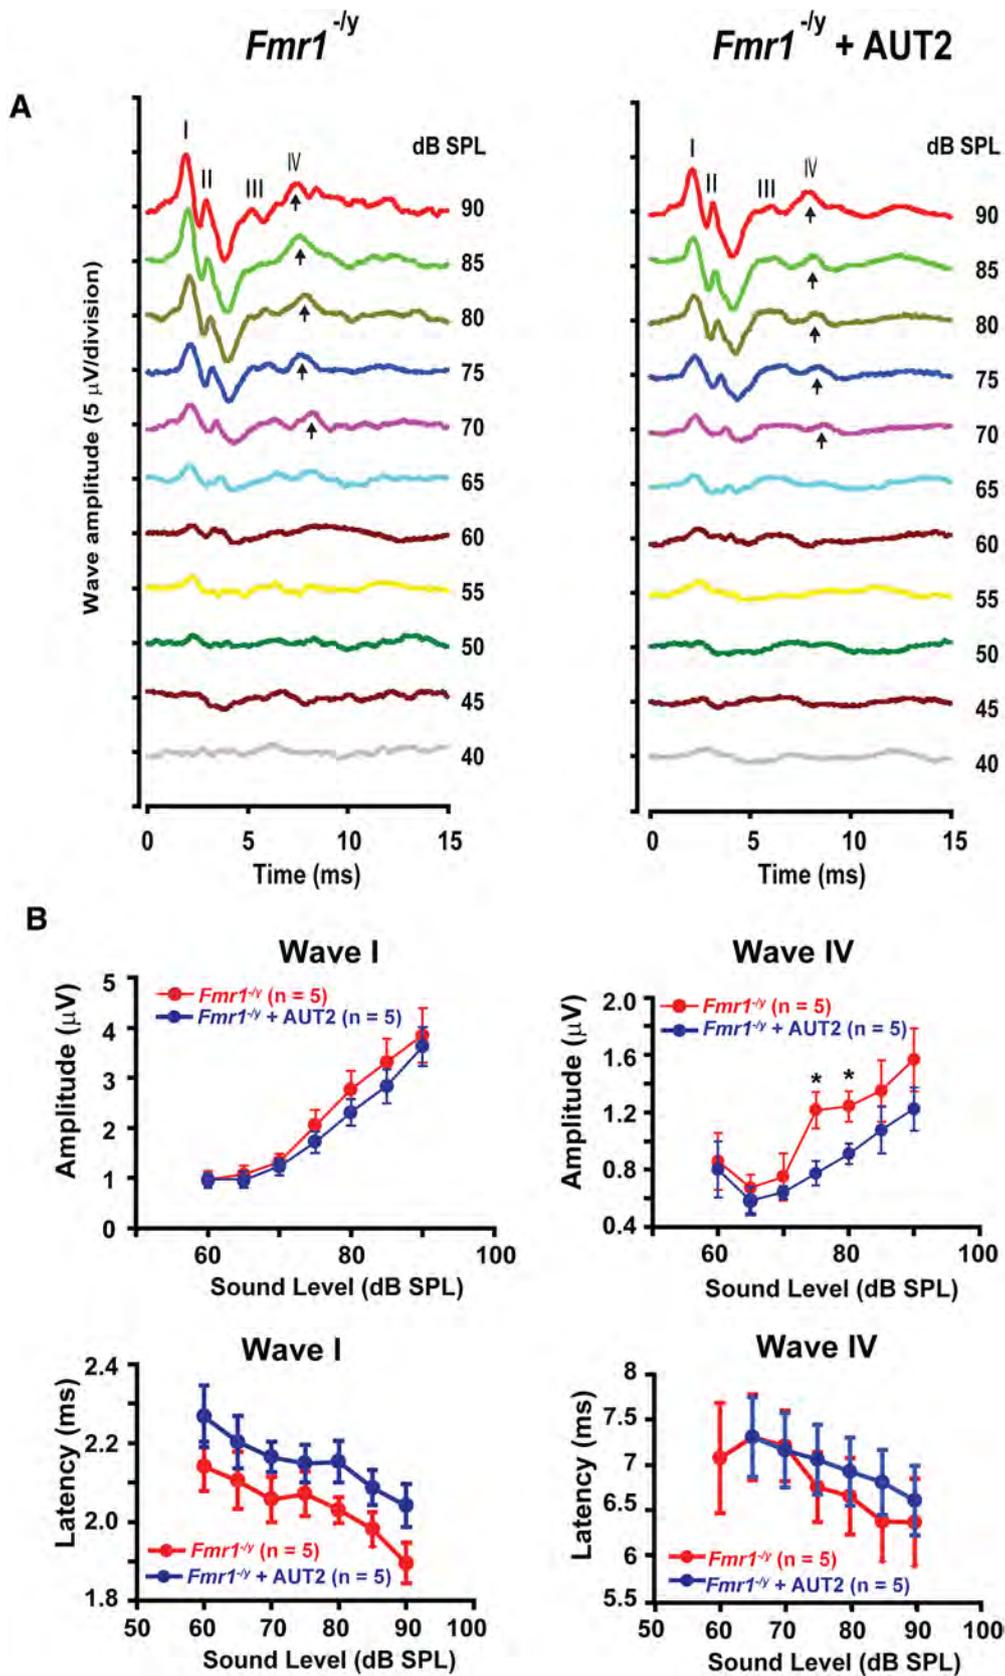

Figure 9. AUT2 rescues the auditory function of *Fmr1*^{-/-} mice. **A**, Representative ABR traces recorded from *Fmr1*^{-/-} mice before and 20 min after intraperitoneal injection of AUT2 (30 mg/kg). Arrows indicate wave IV of the ABR response. **B**, Plots of the amplitudes and latencies of ABR waves I and IV as a function of sound level before and after injection of AUT2. The group data show a significant decrease in the amplitude of ABR wave IV after AUT2 injection ($p = 0.001$) with no change in the amplitude of wave I ($p = 0.3$). In **B**, asterisks indicate statistical significance (two-way ANOVA followed by Holm–Sidak post-test).

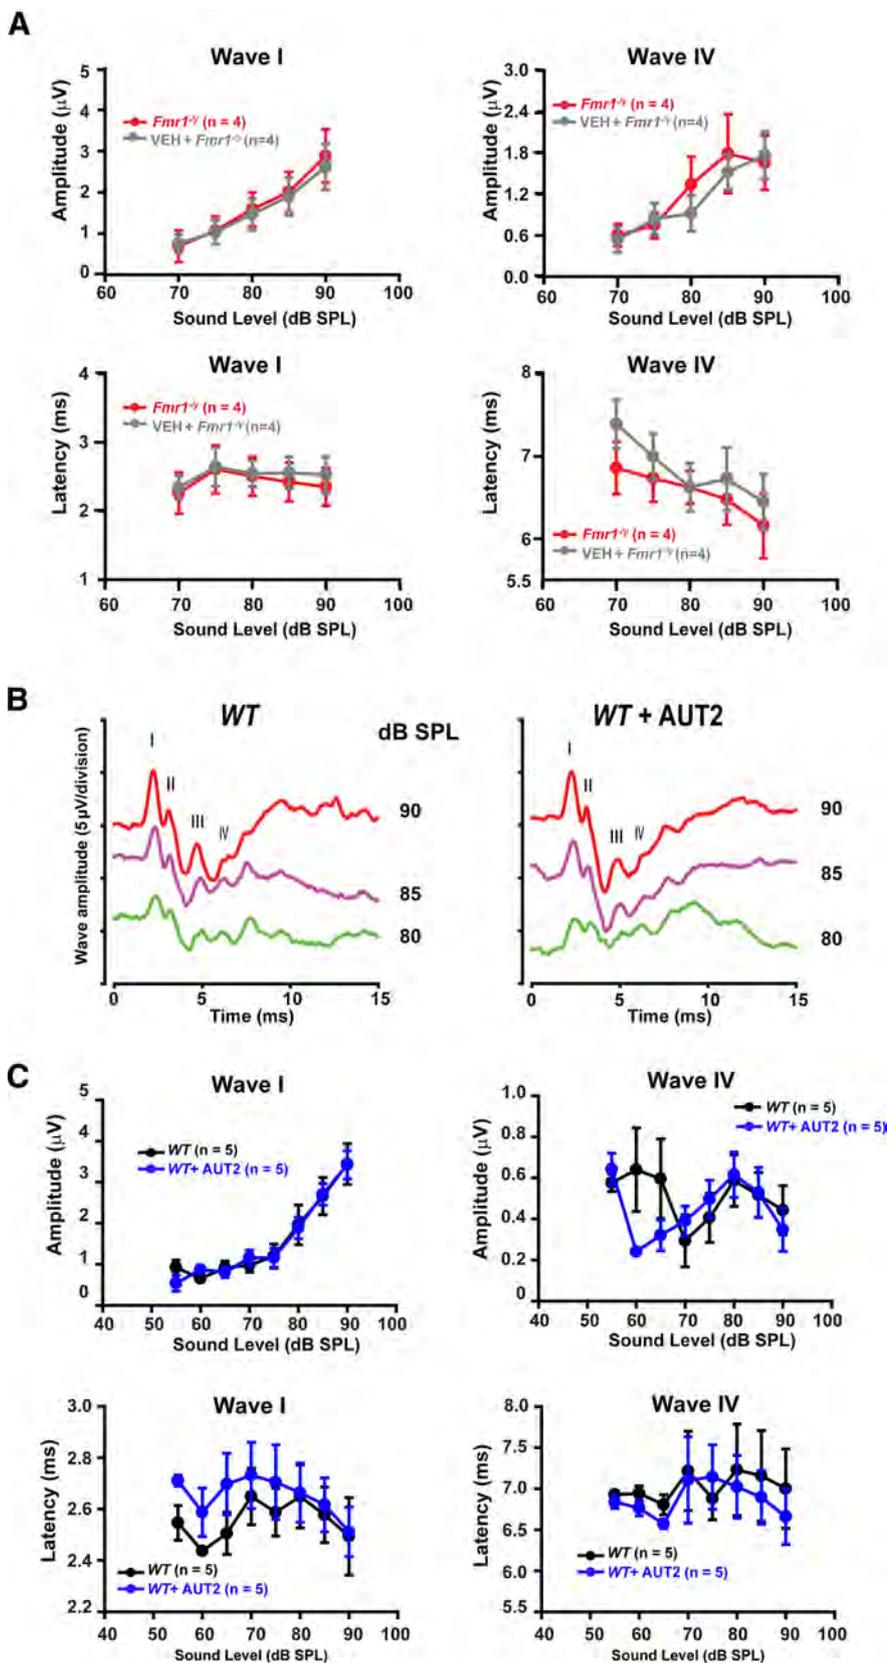

Figure 10. Administration of vehicle does not alter ABR waves in $Fmr1^{-/-}$ mice, and AUT2 does not alter auditory function in wild-type mice. **A**, Plots of the amplitudes and latencies of ABR waves I and IV as a function of sound level before and after the administration of vehicle to $Fmr1^{-/-}$ mice. No statistical differences in the magnitude of wave I and IV ($p = 0.99$ for both) or in the latencies of wave I and IV ($p = 0.98$ and $p = 0.90$, respectively) were found after vehicle injection (two-way ANOVA followed by Holm–Sidak post-test). **B**, Representative ABR traces recorded from WT mice before and 20 min after intraperitoneal injection of AUT2 (30 mg/kg). Traces represent responses to sounds delivered at 80, 85, and 90 dB. **C**, Plots of the amplitudes and latencies of ABR waves I and IV as a function of sound level before and after injection of AUT2. The group data show no significant changes in

channel activity, and the Na^+ -dependent K^+ current is reduced in these neurons in $Fmr1^{-/-}$ mice (Brown et al., 2010). Such a reduction in K_{Na} current is expected to reduce the temporal accuracy of firing (Yang et al., 2007).

Our findings also indicate that, in contrast to the low-threshold currents, high-threshold K^+ currents are enhanced in the MNTB of $Fmr1^{-/-}$ mice relative to those in wild-type animals. The dominant channel responsible for the high-threshold current in MNTB neurons is Kv3.1b , and this current is reduced by >80% in $\text{Kv3.1}^{-/-}$ mice (Wang et al., 1998a; Macica et al., 2003). Our present recordings are also consistent with this identification in that Kv3.1 currents can have a phase of rapid partial inactivation that was also seen in many of the present recordings of high-threshold current. This transient component can be detected in some but not all Kv3.1 -expressing transfected cells and in native neurons (Critz et al., 1993; Kanemasa et al., 1995; Wang et al., 1998b; McCrossan et al., 2003). The transient component, which is regulated by auxiliary subunits, can be attributed, at least in part, to the rapid accumulation of external K^+ ions (Critz et al., 1993; Wang et al., 1998b; McCrossan et al., 2003). Nevertheless, although Kv3.1 appears to be the dominant channel contributing to high-threshold currents, Kv2.2 can become the dominant subunit responsible for action potential repolarization with stimulation at low rates (Steinert et al., 2008, 2011).

Numerous studies have demonstrated that Kv3.1 channels promote the ability of neurons to fire at high rates (Rudy and McBain, 2001; Gu et al., 2012; Kaczmarek and Zhang, 2017). mRNA for Kv3.1 was one of the first mRNAs to be recognized as a target of FMRP (Darnell et al., 2001; Strumbos et al., 2010b; Darnell et al., 2011), and our present findings are consistent with those of previous studies demonstrating that Kv3.1 currents are enhanced in $Fmr1^{-/-}$ mice (Strumbos et al., 2010b). Another possibility is that Kv3.4 channels, which are located both presynaptically and postsynaptically in the brainstem region (Brooke et al., 2004) may contribute to the hyperexcitability of MNTB neurons in $Fmr1^{-/-}$ mice either by

←

the amplitude of ABR waves I and IV ($p = 0.92$, $p = 0.3$ respectively) after AUT2 injection. Similarly, AUT2 did not change the latencies of waves I and IV ($p = 0.8$ and $p = 0.46$, respectively, two-way ANOVA by Holm–Sidak post-test).

speeding the repolarization rate of action potentials or by enhancing glutamatergic synaptic transmission (Muqem et al., 2018).

Our studies were performed using 15-d old mice. This allows a direct comparison of ABR responses *in vivo* with recordings of K^+ currents in MNTB neurons from brainstem slices before the onset of myelination, which hampers patch-clamp recordings at later stages. We found no change in the ABR threshold in the *Fmr1*^{-/-} mice but did find an increase in the magnitude of wave IV, a finding consistent with the increase in the intrinsic excitability of different types of brainstem and midbrain nuclei, particularly the MNTB. ABR recordings reflect the passage of auditory information along diverse anatomical pathways, and the high- and low-threshold potassium channels studied here are widely expressed in cells of the auditory system. Thus, it is possible that changes in the amplitude of wave IV captured in this study may result from increased excitability or synchrony in other nuclei such as the inferior colliculus, and the medial and/or lateral superior olive.

We also found that, in *Fmr1*^{-/-} mice, the magnitude of wave I was decreased at higher sound levels (85–90 dB), further reinforcing the concept that auditory hyperexcitability in fragile X syndrome results from changes in central rather than peripheral pathways. Another study of *Fmr1*^{-/-} mice, which used adult animals, found an imbalance of glutamatergic and GABAergic inputs within the MNTB (Rotschafer et al., 2015; McCullagh et al., 2017). This study, however, also found a different pattern of changes in the ABR, specifically that while the amplitudes of the early waves I and III were reduced, the later waves IV and V were unchanged. This apparent discrepancy may reflect adaptive changes that occur during early life. Both the ABR waveform threshold and latency are subject to changes during development (Song et al., 2006). Moreover, it has been established that, at least for Kv3.1 channels, the maintenance of channel expression is very markedly altered by ongoing auditory activity (von Hehn et al., 2004; Leão et al., 2010; Strumbos et al., 2010a,b). Thus, our present findings are most likely to be relevant to the effects of the loss of FMRP early in development.

We found that the imbalance of low- to high-threshold K^+ currents in MNTB neurons of *Fmr1*^{-/-} mice could, in large part, be corrected by treatment with AUT2, a modulator of Kv3 family channels. AUT2 is one of a number of agents that have been found to shift the voltage dependence of activation of Kv3.1 and Kv3.2 channels to more negative potentials, increasing the amount of K^+ current activated by depolarization to voltages closer to the resting potential (Rosato-Siri et al., 2015; Taskin et al., 2015; Brown et al., 2016; Boddum et al., 2017). AUT2 also produces a negative shift in the voltage dependence of steady-state inactivation, reducing the amount of current activated by depolarizations to more positive membrane potential (e.g., +30 mV). A consequence of this is to reduce high-voltage activated K^+ current. These changes also reduce the firing rate of MNTB neurons in wild-type mice (Brown et al., 2016). Thus, AUT2 appears to reduce the intrinsic excitability of MNTB neurons by increasing the low-threshold component and reducing the high-threshold component of K^+ currents. The finding that AUT2 normalizes ABR responses in *Fmr1*^{-/-} mice *in vivo* is therefore consistent with the suggestion that the enhancement of wave IV in *Fmr1*^{-/-} animals reflects increased intrinsic excitability of auditory brainstem neurons. It is possible, however, that AUT2 has additional biophysical effects that have not been captured in the present analyses.

Increased neuronal excitability is detected in a variety of brain regions in *Fmr1*^{-/-} mice, including the auditory cortex and the lateral superior olive (Kim et al., 2013; Rotschafer and Razak, 2014; Garcia-Pino et al., 2017), as well as the barrel and prefrontal cortex (Zhang et al., 2012, 2014; Gonçalves et al., 2013; Hébert et al., 2014; Kalmbach et al., 2015; Deng and Klyachko, 2016a,b). In some of these areas, alterations in K^+ channels such as Kv1.2, Kv4.2, and $K_{Ca}1.1$ (BK) have been implicated in the hyperexcitability of fragile X mice (Zhang et al., 2014; Kalmbach et al., 2015). The function and/or the expression of these channels is regulated by FMRP either through mRNA binding or through protein–protein interactions with the channels themselves. (Frick et al., 2017). Given the large number of FMRP targets that control multiple aspects of neuronal function, including synaptic transmission, signal transduction, and neuronal development, it is likely that multiple therapeutic strategies will be required to reduce the broad range of symptoms of patients with fragile X syndrome. However, our results suggest that the hypersensitivity to sound observed in a large proportion of patients with FXS may be ameliorated by drugs that modulate Kv3.1 channels.

FAST OUTER HAIR CELL MOTILITY: HOW FAST IS FAST?

J. Santos-Sacchi

*Laboratory of Otolaryngology
New Jersey Medical School, Newark N. J. 07103*

Introduction

Recent experiments have implicated transmembrane voltage as the driving force of OHC motility (Santos-Sacchi and Dilger, 1988a,b; Iwasa and Kachar, 1989). A voltage dependence of OHC motility clearly implies that a charged voltage sensing particle must reside in the OHC membrane, and as was predicted for voltage dependent ionic channels (Hodgkin and Huxley, 1952), particle movement should occur under an applied transmembrane voltage. Gating currents associated with the movement of the presumed voltage sensor in OHCs have been described by Ashmore (1989).

However, two lines of evidence argue against a voltage-dependent motility mechanism in OHCs. The first is the inability of the OHC to faithfully follow a voltage stimulus in time or frequency; i.e., the speed of the movements have been reported to be unrelated to the time course of voltage clamp stimuli (Ashmore, 1987). The second is the poor temperature dependence of the rate of OHC movement (Ashmore and Holley, 1988). If OHC motility is coupled to a voltage-dependent charge movement across the OHC membrane (hence the observed gating currents), then a temperature dependence with a Q_{10} greater than 2 might be expected as occurs for sodium channel gating currents (Bezanilla and Taylor, 1978; Collins and Rojas, 1982).

This work attempts to explain these discrepancies in the voltage dependency hypothesis of OHC motility.

Methods

OHCs were obtained from the apical turns of the guinea pig cochlea by simple mechanical dissociation. Temperature was adjusted with a Peltier device and measured with a probe placed within 500 μm of the cells studied. Voltage step studies were performed with an Axon Instruments A/D and D/A board (Axolab 1100) with associated software (P-Clamp, sampling period down to 3 μs). AC studies were performed using a digital signal processing board with custom software (DSP-16; Ariel Corp., NJ), capable of delivering and analyzing pure tone or swept frequency stimuli. Filtered current records were saved to disk for off-line analysis.

Patch electrodes (flint or borosilicate glass) had initial resistances of 3-6 Mohm. The series resistance, i.e., the actual electrode resistance obtained upon establishment of whole cell configuration, typically ranged from 4 to 12 Mohm, and was reduced further by electronic compensation; care was taken to maintain low series resistance values during recording by delivering transient positive or negative pressure into the electrode to maintain an unobstructed orifice. The resistance values are estimated from current transients initiated at the onset of voltage pulses and are corrected for during analysis, so that actual voltages imposed upon the cell are known (Marty and Neher, 1983). The program Clampex (Axon Instruments) was modified to provide a continuous display of clamp time constant, cell capacitance and resistance, and series resistance between data collections. Pipette solutions were composed of 140 mM CsCl, 10 mM EGTA, 2 mM MgCl₂, and 5 mM HEPES buffered to pH 7.2. Gigohm seals were obtained at the nuclear level of the cell membrane and electrode capacitance was compensated prior to whole cell recording. Generally, single cells were clamped to holding potentials near -70 to -80 mV using a Dagan patch clamp amplifier. OHC gating currents (nonlinear capacitive currents) were measured by averaging current responses elicited by voltage pulses of alternating polarity (40 mV magnitude) about the holding potential of -80 mV, or by using a P/5 protocol at a holding potential of -120 mV.

Fast OHC movements elicited by voltage clamp with short duration or high frequency stimuli (below video detectability) were measured with a differential photodiode onto which the image of the cuticular plate from the microscope was projected. The frequency response of the differential photodiode is flat out to 2 kHz (measured with a light emitting diode or piezoelectric bimorph). Absolute calibration of cell movements is determined by measuring off the video monitor the cell movement in response to a large steady state or low frequency voltage stimulus.

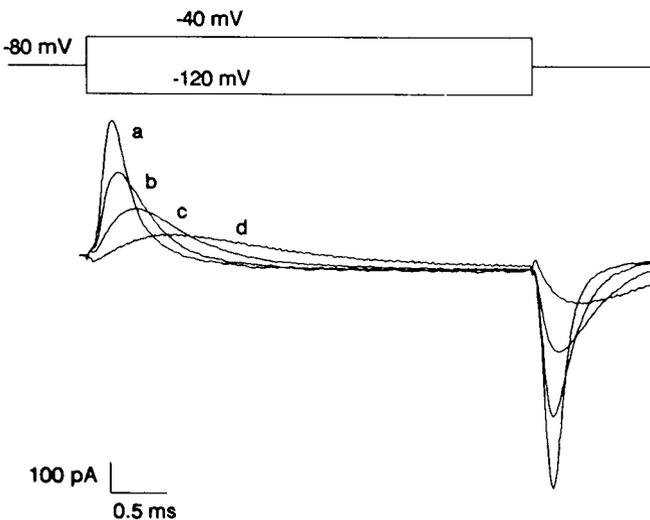

FIGURE 1 Nonlinear capacitive currents generated at the onset and offset of depolarizing voltage step. Linear capacitive currents were removed by averaging 100 X alternating steps of 40 mV above and below a holding level of -80 mV. Cell resistance was 140 Mohm. Charge movement indicates a nonlinear capacitance of 4.5 pF under these conditions. Clamp time constant was varied by adjusting series resistance compensation. Clamp time constant (ms), gate-on time constant (ms): a) 0.08, 1.38, 0.22; b) 0.15, 4.0, 0.37; c) 0.25, 7.83, 0.52; d) 0.36, 11.8, 1.1. Note parallel shift of gating time constant as clamp time constant is changed. Extracellular solution: 10 mM TEA, 300 nM TTX.

Results

OHCs exhibit a nonlinear charge movement which can be seen under voltage clamp as a transient outward current upon depolarization from negative holding potentials, and an inward current upon repolarization (Fig. 1). Charge movement for the cell in Fig. 1 was equal at the onset and offset of the voltage step, being about 185 fC. The time constants associated with the decaying phase of on and off currents differ, with the off tau being of similar magnitude to the clamp time constant, and the on tau being roughly twice in magnitude. Both time constants are directly dependent upon the clamp time constant, indicating that the kinetics of the gating current are faster than the time limitations imposed by the voltage clamp amplifier. Because of the apical OHC's large capacitance (Santos-Sacchi, 1989b), clamp time constants of only around 100 μ s have been achieved.

These results may indicate that the speed of OHC mechanical responses are dependent upon the ability of the clamp amplifier to charge the membrane. This is the case, and is demonstrated in the time domain in Fig. 2. The OHC was induced to contract with depolarizing steps to +40 mV from a holding potential of -80 mV, before and after electronically compensating the series resistance. The attendant changes in the clamp time constant is reflected in the rate of onset of the mechanical response, the slower clamp time constant charging the OHC membrane more slowly than the faster clamp time constant. Hence, it would be expected that the mechanical response of the OHC in the frequency domain will display a similar dependence upon clamp characteristics. Fig. 3 illustrates the mechanical response of two OHCs which have been voltage clamped

FIGURE 2 An OHC was held at a potential of -80 mV and stepped to +40 mV for 5 ms duration. Current and mechanical response records were recorded simultaneously, being averaged 200 X. Collections were made with different clamp time constants: a) clamp tau was 0.4 ms; b) clamp tau was 0.19 ms. Boxed portion of traces are enlarged and fitted with single exponentials (smooth curves). a) fitted tau was 0.37 ms; b) fitted tau was 0.23 ms. Scales refer to traces on right.

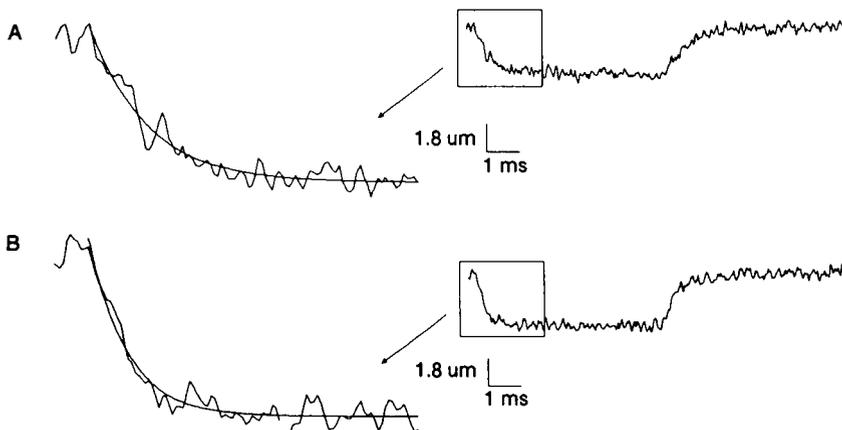

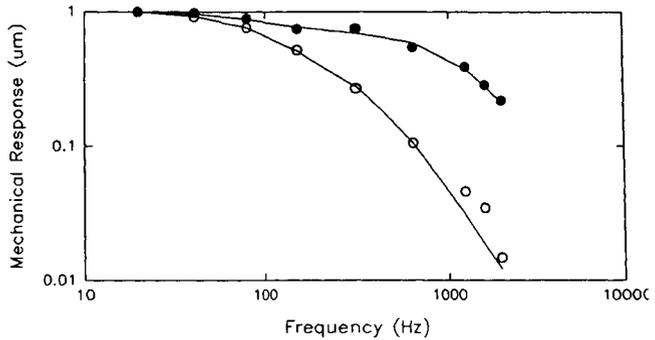

FIGURE 3 Two OHC's were clamped at -80 mV and stimulated with sinusoidal voltage bursts. The fundamental magnitude was obtained by FFT. Open circle (50 mV Pk) data were collected with a clamp tau of 1 ms, and were fit with the sum of two Lorentzians, with time constants of 1.7 and 0.5 ms. Closed circle (40 mV Pk) data clamp tau was 0.2 ms and fit with taus of 1.87 ms and 0.12 ms. Note improved frequency response associated with faster clamp time constant. 20 mM TEA.

at a holding potential of -80 mV and stimulated with superimposed sinusoidal voltages of varying frequency. The clamp time constant dictates the frequency response of each cell's mechanical response. The cell clamped with the poorer time constant displays a precipitous drop in mechanical response as frequency increases. The other cell displays a much better frequency response, the response measuring about 13 dB down at 2 kHz.

The temperature dependence of the gating current time constant was studied in order to determine if it behaves similar to sodium channel gating currents. Figure 4 shows the change in gate-on time constants for two OHCs as the temperature is varied from about 20 to 5°C. At first glance it appears that gating kinetics are slowed down as the temperature is decreased, with a Q₁₀ of about 1.5 (Fig. 4a); however, when one takes into account the dependency of gate time constant upon clamp time constant, no relation is apparent (Fig. 4b).

DISCUSSION

The limitations imposed by the whole cell voltage clamp technique can provide us with a distorted picture of some of the properties of the OHC. The apical OHC has a

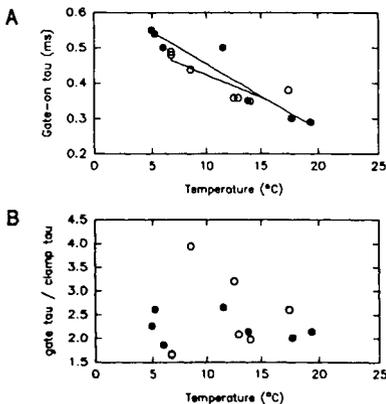

FIGURE 4 Two OHCs were voltage clamped at -80 mV and the single exponential time constant of the non-linear capacitive on current was determined as in Fig. 1. The temperature was varied from about 20 to 5°C and the effects on gate time constant plotted. In Fig. 4a it appears that temperature reduction slows down the kinetics of the gating currents, as is known to occur with sodium channel gating. However, the Q₁₀ is only about 1.5. Fig. 4b demonstrates that when the dependence of gate time constant upon clamp time constant is taken into account the temperature dependence is difficult to observe. It appears that cooling the OHC down to 5°C does not slow the gating kinetics sufficiently to overcome its dependence upon clamp characteristics. 20 mM TEA, 20 mM CsCl, 2 mM CoCl₂, no added calcium.

fairly large capacitance, a substantial portion of which is due to a nonlinear voltage-dependent component. The nonlinear contribution saturates with depolarization at about 30% of the cells' linear capacitance when the P/5 protocol at -120 mV holding potential is used (Santos-Sacchi, 1990). Even at a holding potential near the cell's normal resting potential (-70 mV; Dallos, Santos-Sacchi and Flock, 1982), there is a substantial nonlinear contribution. The OHC's capacitance in conjunction with the series resistance limits the voltage clamp's ability to rapidly alter the cell's transmembrane voltage (Santos-Sacchi, 1989b). The fact that the time and frequency response of OHC motility is dependent upon the clamp's ability to charge the membrane indicates that the actual mechanical capabilities of the OHC have yet to be determined. In this regard it is interesting to note that *in vivo* measures of electrically evoked oto-acoustic emissions, presumably due to the activity of OHCs, have been measured in pass bands up to several kHz (Hubbard and Mountain, 1990). Although these investigators suggest, based on Ashmore's data (1987), that the OHC length changes are too low-pass to account for such high frequency phenomena, the data presented here indicate that this may not be the case.

The fact that the time course of the nonlinear capacitive currents is imposed by those of the voltage clamp, also indicates that the kinetics of charge movement in the OHC membrane are faster than can be observed presently. Indeed, an attempt to slow down this charge movement by cooling to 5°C proved unsuccessful. This may indicate that these currents are artifacts of the technique used to collect the data; however, the clearest evidence against this is that Deiter cells possess no nonlinear capacitance. Lower temperatures are being investigated. Nevertheless, if these charge movements are related to the mechanical responses, then it is clear that clamp time constants down to 80 usec with associated fast gating constants (Fig. 1) still cannot validly investigate OHC mechanical capabilities. Ashmore (1989) reported gate time constants ranging from 1 to 2 ms, which is probably indicative of a large series resistance, with attendant slow clamp time constants. Under such clamp conditions (Ashmore and Holley, 1988), it would be difficult to measure a temperature dependent *increase* from 20 to 37°C in the rate of OHC movement that was due to an effect on the OHC, since the clamp imposes its temporal characteristics.

The OHC appears to alter its length in response to a change in transmembrane voltage. The underlying mechanism may involve the movement of membrane bound molecules bearing charged moieties which is somehow translated into longitudinal forces. This membrane phenomenon can be interfered with, for example, by treatment of the cells with gadolinium ions, which rapidly and reversibly reduce or abolish OHC gating currents and motility (Santos-Sacchi, 1989a; 1990). However, the coupling between membrane phenomena and these longitudinal forces is clearly dependent upon cytosolic volume -- cell turgor. This is demonstrated by several means. Prolonged depolarizations or treatment of OHCs with salicylates produces a slow loss of cell volume, with accompanying reduction of the magnitude of longitudinal motility (Brownell, Shehata, and Imredy, 1989; Brownell, Imredy, and Shehata, 1989; Brownell, 1990). I have observed similar effects during prolonged whole cell voltage clamping, even though cells were maintained at a potential near -70 to -80 mV. In fact, very rapid reversible changes in cell volume can be produced using large tipped patch pipettes. Voltage-dependent longitudinal motility is rapidly abolished during loss of cell turgor

and is restored upon cell volume replacement (Santos-Sacchi, 1990). In sum, the capability of OHCs to mechanically follow transmembrane voltage alterations may be limited by a number of factors including the strength of hydrodynamic coupling between membrane phenomena and longitudinal displacement. As yet, an estimate of this limit is difficult to make with the presently used technology, and it must be concluded that OHC motility is faster than has been reported.

Abstract—Prestin (SLC26a5) is an integral membrane motor protein in outer hair cells (OHC) that underlies cochlear amplification. As a voltage-dependent protein, it relies on intrinsic sensor charge to respond to transmembrane voltage (receptor potentials), thereby effecting conformational changes. The protein's electromechanical activity is experimentally monitored as a bell-shaped nonlinear capacitance (NLC), whose magnitude peaks at a characteristic voltage, V_h . This voltage denotes the midpoint of prestin's charge–voltage (Q – V) Boltzmann distribution and region of maximum gain of OHC electromotility. It is an important factor in hearing capabilities for mammals. A variety of biophysical forces can influence the distribution of charge, gauged by shifts in V_h , including prior holding voltage or membrane potential. Here we report that the effectiveness of prior voltage augmentations during the delivery of prestin to the membranes in an inducible HEK cell line. The augmentation coincides with an increase in prestin density, maturing at a characteristic membrane areal density of 870 functional prestin units per square micrometer, and is likely indicative of prestin–prestins cooperative interactions. © 2020 IBRO. INTRODUCTION

Prestin (SLC26a5) is a protein (Zheng et al., 2000) that is housed in abundance within the lateral membrane of outer hair cells (OHC) in the organ of Corti. The protein imparts robust electromechanical activity to the cell that is unlike any other form of cellular motility, notably associated with a voltage-dependent, bell-shaped nonlinear capacitance (NLC) that reports on conformational changes in the protein (Ashmore, 1990; Santos-Sacchi, 1991). This mechanical activity, termed electromotility, driven by receptor potentials (Evans and Dallos, 1993), is believed to feed back into the acoustically-driven vibration of the cochlear partition, thereby enhancing the

mechanical stimulus that the inner hair cells (IHC) sense and transmit to the CNS (Ashmore et al., 2010). This process is called cochlear amplification, amounting to 40–60 dB of gain.

One of the interesting features of prestin is the protein's ability to alter its state differentially depending upon initial voltage conditions, i.e., it shows hysteresis. Simply put, the protein's operating voltage range (conveniently characterized by V_h , the voltage at peak NLC, where half of its sensor charge is moved across the membrane field, and where electromotility gain is maximal) shifts depending upon prior holding potentials. This phenomenon has been measured in OHCs and in prestin-transfected cells (Santos-Sacchi et al., 1998, 2001). In OHCs, the voltage at peak capacitance (namely, V_h) differs by about 20 mV between pre-pulse holding potentials of ± 100 mV. Besides magnitude of holding voltage, the shift depends on the polarity direction of voltage prior to the measurement of NLC. Finally, the shift evolves over time in a stretched exponential fashion, ranging from sub-milliseconds to seconds

(Santos-Sacchi et al., 2009); thus, the duration of prior holding potential influences the amplitude of the V_h shift. This phenomenon likely reflects interactions among adjacent prestin molecules within the local membrane environment, just as ion channels show cooperative effects when expressed at high areal densities within the membrane (Molina et al., 2006). Here we denote this phenomenon observed in prestin Boltzmann characteristics as “molecular memory”, realizing that it may not be an intrinsic property of the protein prestin itself, but instead an interaction of prestin with itself and its local microenvironment (lipid, cytoskeletal) within the membrane. In mice, having an appropriate V_h value is critically important for normal hearing. In prestin knock-ins that have altered V_h , or with cochlear perilymphatic alterations of chloride that alter V_h , profound deafness ensues, the latter in a reversible manner (Santos-Sacchi et al., 2006; Dallos et al., 2008).

The development of prestin function has been studied in immature hair cells and in prestin-transfected cells (Oliver and Fakler, 1999; Abe et al., 2007; Bian et al., 2010, 2013; Seymour et al., 2016; Bai et al., 2019). We recently established a HEK cell line where prestin expression is tetracycline-inducible (Bian et al., 2010). We have already reported on some component Boltzmann characteristics of NLC maturation over hours following induction, and during the first few minutes following release of membrane trafficking block from low temperature (Bian et al., 2013). Prestin insertion into the membrane followed a sigmoidal function of time following induction. Here we utilize our model system to follow the maturation of prestin’s molecular memory as prestin density increases post-induction. We find that mature function arises after about 12 h following induction, that is, when prestin charge density is greater than 11.1 fC/pF, or equivalently about 870 functional prestin units/ μm^2 . We suggest that protein–protein interactions are optimized at and above this molecular density, such that negative cooperative effects among prestin units are maximized.

EXPERIMENTAL PROCEDURES

Experiments were performed on OHCs and HEK cells. Full details on OHC measurements have been reported previously (Santos-Sacchi et al., 2009). Full details on cell culture and induction of our tetracycline-inducible, highly-expressing monoclonal prestin HEK 293 cell lines have been reported previously (Bian et al., 2010, 2013). Briefly, cells were cultured in Dulbecco’s modified Eagle’s medium (DMEM) containing 50 U/ml each of penicillin and streptomycin, 10% fetal bovine serum at 37 °C in a 5% CO₂ incubator. 4 $\mu\text{g}/\text{ml}$ of blasticidin and 130 $\mu\text{g}/\text{ml}$ of zeocin were supplemented in the growth media. Induction was begun by treating with 1.0 $\mu\text{g}/\text{ml}$ tetracycline. At time point 2, 4, 6, 10 and 24 h, coverslips of grown cells were transferred to recording media (see below).

Whole cell patch-clamp measurements were made with an Axopatch 200B patch clamp amplifier (Axon Instruments) and a Digidata 1322A digitizer, with sampling rates of 10 μs . Experiments were performed at room temperature. Blocking solutions were used to remove ionic currents, limiting confounding effects on

NLC determination and voltage delivery under voltage clamp (Santos-Sacchi, 1991; Santos-Sacchi and Song, 2016). Extracellular solution was (in mM): NaCl 100, TEA-Cl 20, CsCl 20, CoCl₂ 2, MgCl₂ 1, CaCl₂ 1, Hepes 10. Intracellular solution was (in mM): CsCl 140, MgCl₂ 2, Hepes 10 and EGTA 10. All chemicals were purchased from Sigma-Aldrich.

Pipettes had initial resistances of about 2.5 M Ω . Stray capacitance was compensated with amplifier controls prior to whole-cell establishment. Corrections for series resistance were made post-hoc. For our HEK cell studies, following establishment of whole-cell recording conditions, cells were held at 0 mV. Thirty second pre-pulse holding potential steps to -100 or $+50$ mV preceded NLC collections. Whole cell recordings were made on single cells growing on a coverslip at 2 h, 4 h, 6 h, 10 h and 24 h after tetracycline induction. The number of cells recorded for each time point was 9, 9, 10, 10 and 9, respectively.

Membrane capacitance was measured with jClamp software (Scisoft, CT; www.SciSoftCo.com) using a continuous high resolution (2.56 ms sampling) two-sine stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz) superimposed onto the voltage ramp (Santos-Sacchi et al., 1998; Santos-Sacchi, 2004). Briefly, real and imaginary components of membrane current at harmonic frequencies were determined by FFT in jClamp, corrected for the roll-off of recording system admittance (Gillis, 1995). R_s , R_m and C_m were extracted using the dual-sine, 3-parameter solution of the standard patch clamp model (Santos-Sacchi et al., 1998; Santos-Sacchi, 2004), based on the original single sine solution (Pusch and Neher, 1988). In order to extract Boltzmann parameters, capacitance–voltage data were fit to the first derivative of a two-state Boltzmann function.

$$C_m = NLC + C_{sa} + C_{lin} = Q_{max} \frac{ze}{k_B T} \frac{b}{(1+b)^2} + C_{sa} + C_{lin}$$

$$\text{where } b = \exp\left(-ze \frac{V_m - V_h}{k_B T}\right), C_{sa} = \frac{\Delta C_{sa}}{(1+b^{-1})}$$

Q_{max} is the maximum nonlinear charge moved, V_h is voltage at peak capacitance or equivalently, at half-maximum charge transfer, V_m is R_s -corrected membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k_B is Boltzmann’s constant, and T is absolute temperature. C_{sa} is a component of capacitance that characterizes sigmoidal changes in specific membrane capacitance (Santos-Sacchi and Navarrete, 2002; Santos-Sacchi and Song, 2014). ΔC_{sa} is the total sum of unitary changes per prestin motor protein. Q_{sp} denotes charge density, namely Q_{max}/C_{lin} .

The time-dependent change in Q_{sp} in Fig. 3B is fit by a sigmoidal function, $f = a/(1 + \exp(-(x - x0)/b))$, as we have done previously (Bian et al., 2010), where x is time, $x0$ is the midpoint, b is the slope indicator, and a is the asymptotic value. Two parameter exponential fits were made using the formula $f = a*(1 - \exp(-b * x))$, where x is time for Fig. 3A, and x is Q_{sp} for Fig. 4. The parameter a denotes the asymptotic value of either Q_{sp} or ΔV_h (see plots). The parameter $1/b$ is the characteristic “time constant” to achieve the final value a . For Fig. 4, to estimate

charge density at “steady state”, we use the value reached at five times the “time constant”.

RESULTS

The voltage range over which prestin works is not fixed, but shifts depending on previous state of the protein/membrane environment set by holding voltage. This is most apparent in native isolated OHCs. Fig. 1 illustrates the effect of prior holding voltage on prestin’s state/charge distribution as revealed through capacitance measures in the guinea pig OHC. In this case, dual sine stimuli were superimposed on a slow sinusoidal holding voltage (Fig. 1b), which spanned from -150 to $+150$ mV. The direction of holding potential change over time influences the position of V_h along the voltage axis (Fig. 1a); in the hyperpolarizing direction (blue lines), V_h is shifted towards depolarized voltages and vice versa (red lines). Steady state pre-pulse voltages can likewise cause shifts in V_h .

Our HEK cell line allows us to monitor NLC characteristics over the course of prestin insertion into the membrane. Thirty seconds holding potential pre-pulses to either -100 or $+50$ mV were used to gauge the molecular memory of prestin in our HEK cell line. Following these pre-pulses, NLC was measured. Fig. 2 illustrates the dependence of V_h on post-induction time. Here we average our voltage protocol-generated currents prior to C_m determination. Clear differences are found between 2 and 24 h post-induction. Analysis of cells on an individual basis allowed statistical comparisons. At 2 h post induction, the average difference in V_h between 2 and 24 h pre-pulse protocols

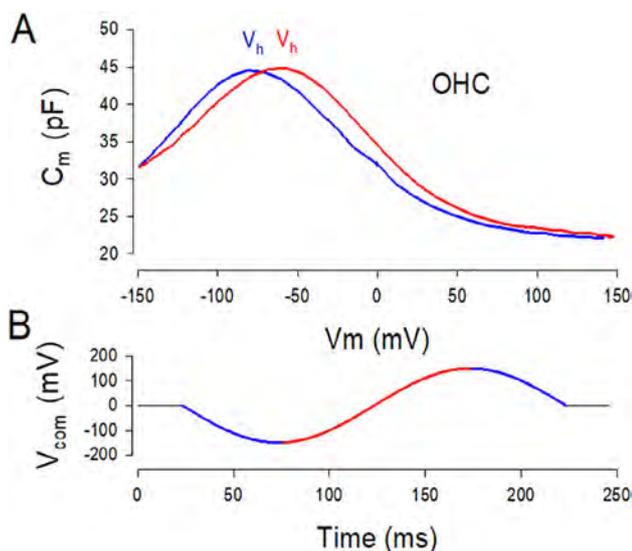

Fig. 1. Prestin state memory. **(A)** NLC functions in a guinea pig OHC measured during hyperpolarizing direction (blue) and depolarizing direction (red) of sinusoidal change in holding potential. Prior hyperpolarizations cause movements of V_h in the opposite direction. The shift in voltage at peak capacitance (V_h) indicates redistribution of charge as a function of prior voltage. **(B)** Holding potential sinusoid. Two sine stimuli have been removed. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

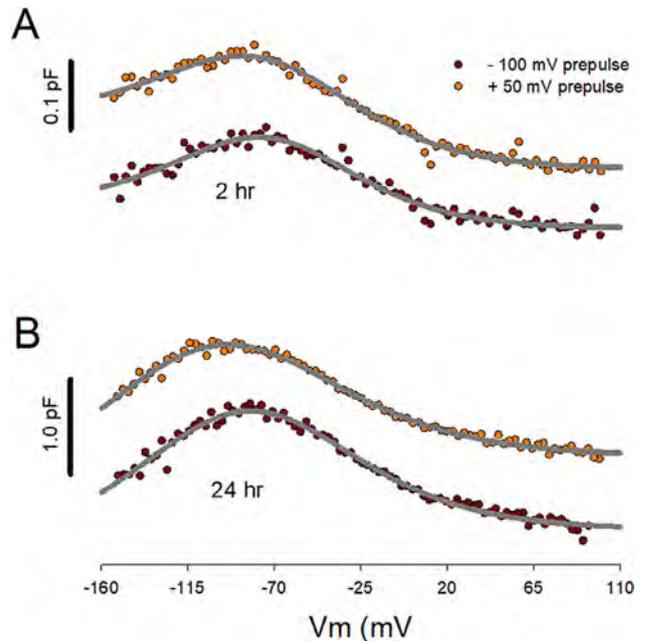

Fig. 2. Illustration of post-induction time dependence of V_h on steady state holding potential. Individual cell currents were averaged prior to C_m determination from averaged currents. **(A)** At 2 h post tetracycline induction, 0.5 min prepulse to -100 or $+50$ mV has smaller effects on V_h than at 24 h post induction **(B)**. V_h for fits at 2 h, -100 mV prepulse: -73.3 mV; $+50$ mV prepulse: -76.4 mV. Fits at 24 h, -100 mV prepulse: -84.7 mV; $+50$ mV prepulse: -102.3 mV. Traces offset for visual clarity.

(ΔV_h) is smaller than that measured after 24 h post induction (unpaired t -test, $p = 0.02$). The average difference (mean \pm SEM) at 2 h was 7.39 ± 1.32 mV ($n = 9$) and that at 24 h was 12.97 ± 1.70 mV ($n = 9$). Fig. 3A plots results for 2, 4, 6, 12, and 24 h post induction (mean \pm SEM). ΔV_h rises exponentially over induction time, with a time constant of 2.2 h. Along with the growth of molecular memory, the density of prestin, gauged as Q_{sp} , increases more slowly in a sigmoidal fashion (Fig. 3B), with a time at half magnitude of 7.3 h and reaching an asymptotic value of 16.0 fC/ μm^2 based on the fit. This is in line with our previous observations over this time course (Bian et al., 2010). Clearly, while the density of prestin continues to rise, ΔV_h asymptotes during the early phase of prestin delivery to the membrane. The Boltzmann parameter, z , on the other hand is stable after 4 h post induction near 0.8 (Fig. 3C).

In order to relate prestin density and ΔV_h , we plot the two against each other in Fig. 4. The relation shows an exponential growth in ΔV_h as density increases, reaching at five times the characteristic “time constant”, $1/b$ ($5 * 2.2$ fC/pF = 11.1 fC/pF), the value of 12.6 mV. The number of prestin units per square micrometer is determined by $Q_{sp}/(z * e)$, where e is electron charge. Taking the classical value for linear membrane capacitance of $1 \mu\text{F}/\text{cm}^2$ (Hille, 1992), $1 \text{ pF} = 100 \mu\text{m}^2$, and based on 11.1 fC/pF, we estimate that beyond a critical density of about 870 functional units of prestin per square micrometer, ΔV_h has matured. The nonlinear relationship between charge density and ΔV_h we take to

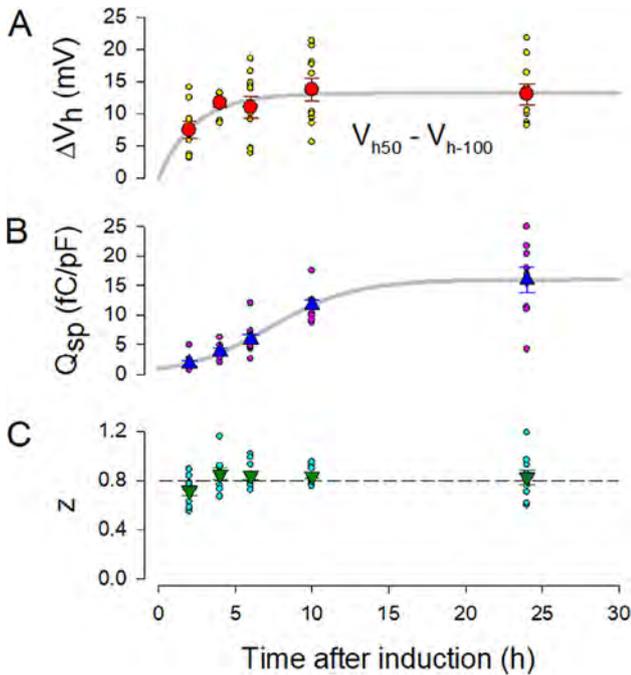

Fig. 3. Prestin behavior alters over post-induction time. **(A)** The magnitude of V_h change (ΔV_h) increases in an exponential manner over time. Fitted exponential parameters: $a = 12.6$ mV, $1/b = 1.9$ h (see Experimental procedures). R^2 : (correlation coefficient of variation): 0.89. **(B)** Prestin charge density also increases in an exponential manner. Fitted exponential parameters: $a = 20.1$ fC/pF, $1/b = 14.9$ h (see Methods). R^2 : 0.99. **(C)** On the other hand, the Boltzmann parameter z , which increases very early following induction (Bian et al., 2010), is stable after 4 h. Error bars are SEM.

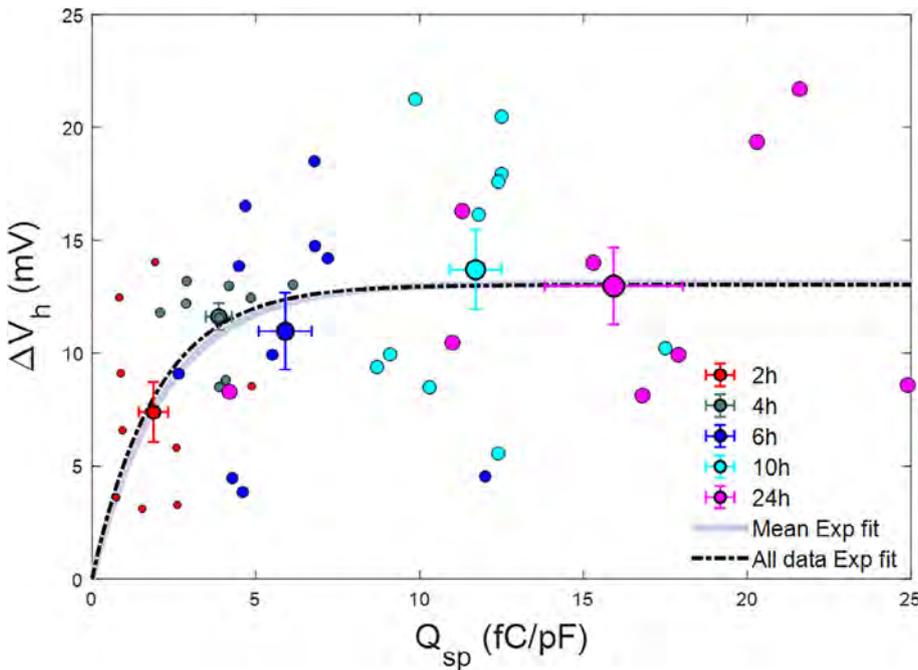

Fig. 4. Relationship between susceptibility to voltage pre-pulse (ΔV_h) versus prestin charge density (Q_{sp}). ΔV_h increases exponentially with charge density, reaching at 11.1 fC/pF at five times $1/b$, the characteristic “time constant”. Fitted exponential parameters of the mean data points: $a = 13.11$ mV, $1/b = 2.2$ fC/pF (see Experimental procedures). R^2 : 0.89. Error bars are SEM. All data points were used for an exponential fit, as well. Fitted exponential parameters are similar: $a = 13.02$ mV, $1/b = 2.0$ fC/pF.

mean that above this critical density, interactions among prestin molecules are likely.

DISCUSSION

All hair cells utilize apical membrane components (stereocilia) for forward transduction of sound into receptor potentials that evoke neurotransmitter release onto afferent nerve fibers (Flock, 1965). However, in addition, the OHC has evolved special lateral membrane components to reverse transduce those receptor potentials into mechanical energy, a process called electromotility (Evans and Dallos, 1993).

The responsible molecular motor was identified in 2000 (Zheng et al., 2000), and remarkably was found to be a solute carrier of the SLC26 family. Named as prestin, for its presumed fast kinetics (electromotility was measured beyond 80 kHz (Frank et al., 1999)), the protein has been studied extensively. Recently, this ultrafast capability of electromechanical activity has been challenged (Santos-Sacchi and Tan, 2018; Santos-Sacchi, 2019; Santos-Sacchi et al., 2019). Regardless, prestin is a voltage-dependent protein (Santos-Sacchi and Dilger, 1988) that has been successfully modelled with modifications of a two-state Boltzmann process, where motors are either in an expanded or compact state. Displacement currents or correspondingly a NLC arises from these conformational changes (Ashmore, 1990; Santos-Sacchi, 1990, 1991). Based on these measures, membrane density of the motor in the OHC lateral membrane has been estimated to be up to $11000/\mu\text{m}^2$ (Huang and Santos-Sacchi, 1993; Gale and Ashmore, 1997; Mahendrasingam et al., 2010; Santos-Sacchi and Tan, 2020). Specific membrane sensor charge correlates well with biochemical measures of membrane content (Bian et al., 2010; Seymour et al., 2016). Interestingly, as might be expected of an anion solute carrier, anion binding plays a pivotal role in its function (Oliver et al., 2001; Rybalchenko and Santos-Sacchi, 2003), though it likely does not work solely as an extrinsic voltage sensor (Song and Santos-Sacchi, 2010; Santos-Sacchi and Song, 2016). Concerning our present work, we have previously shown that chloride effects on prestin do not underlie its molecular memory (Santos-Sacchi et al., 2009).

In our current experiments we have employed our tetracycline-inducible prestin cell line which provides specific nonlinear charge (sensor charge/linear capacitance) values of up to 20 fC/pF after 24 h, far greater than transient transfection can provide (Bian et al., 2010). This efficiency allows

us to monitor characteristics of NLC resulting during prestin delivery and insertion into the plasma membrane. Specifically, we used this approach to study the development of prestin's ability to respond to its prior state, established by pre-pulse holding voltage. We find that ΔV_h , a metric for prestin's molecular memory, increases as post-induction time and the number of membrane-bound prestin molecules increase. The correspondence between areal density and ΔV_h indicates that at a critical density of prestin within the membrane, namely, about 870 functional prestin units per square micrometer, molecular memory matures. If maturation were simply a consequence of time spent within the membrane, we would not have expected asymptotic behavior, because insertion of new proteins into the membrane continues well beyond the observed maturation. The exponential fit of ΔV_h as charge density increases is simply used to provide an estimate of the asymptotic behavior; earlier time point measures of this phenomenon could reveal non-exponential behavior, just as charge density itself matures in a sigmoidal fashion (Fig. 2B) (Bian et al., 2010). Nevertheless, the identification of asymptotic behavior within our evaluated time points would not be changed by including earlier time points of ΔV_h , which would be exceedingly difficult to measure. Interestingly, we recently have found that prestin kinetics augments, that is, the frequency response of NLC increases, during early development of mouse OHCs in organ explants (Bai et al., 2019). However, it is unlikely that development of prestin density may be a controlling factor in prestin's ability to alter conformation at kilohertz rates. In that study, the estimated frequency cut-off (F_c) was found to asymptote beyond postnatal day p17–18, where charge density has also matured – a density well beyond maturation of molecular memory. Of course, for OHCs, other factors beyond prestin kinetics could be at play. For example, not only intrinsic (e.g., membrane components or cytoskeleton) but also extrinsic (e.g., viscoelastic interactions with supporting cells within the organ) mechanical loads could influence our frequency response measures, as we have recently observed (Santos-Sacchi et al., 2019). These mechanical impediments to charge movement have as their basis prestin's piezoelectric-like behavior, where load can influence prestin's state (Iwasa, 1993; Gale and Ashmore, 1994; Kakehata and Santos-Sacchi, 1995).

The piezoelectric-like mechanical sensitivity of prestin may also underlie its molecular memory, and result from interactions among functional prestin units within the membrane. Indeed, we previously modelled molecular memory as resulting from such behavior (Santos-Sacchi et al., 1998), where the voltage-induced conformational changes in one unit could directly affect those of adjacent units through the viscoelastic plasma membrane. We reasoned that when prestin moves from an extended state to a compact state, forces generated within the plane of the membrane will influence the state in adjacent molecules, as lipid redistributes around compact prestin and acts on neighbors. Recapitulation of experimental data with the model was successful (Santos-Sacchi et al., 1998). Of course, the effectiveness of such negative cooperativ-

ity will depend upon intermolecular distances. At a critical density of about 870 functional units per square micrometer, intermolecular distances would be on the order of 34 nm, assuming a uniform distribution. Physiological evidence for dimerization has been obtained for prestin (Navaratnam et al., 2005; Detro-Dassen et al., 2008), and recent cryo-EM observations on SLC26a9, a family member of prestin, also suggests dimerization. Given that the widest dimension of a prestin dimer within the membrane may be 10 nm based on SLC26a9 cryo-EM structure, the closest proximity of adjacent molecular edges would be 17 nm. Of course, this is founded on a uniform distribution, but local, restricted diffusion cannot be discounted (Santos-Sacchi and Zhao, 2003; Organ and Raphael, 2007; Yamashita et al., 2015), nor can subsequent clustering be ignored. To be sure, in our cell line prestin-fused YFP often presents as visible fluorescent patches within the membrane. Modelling of ion channels indicates that at areal densities greater than $10^3/\mu\text{m}^2$, close to our observed critical prestin density, cooperative viscoelastic interactions are possible (Ursell et al., 2007). Indeed, clustering in a variety of ion channels can impact on channel activity (see (Molina et al., 2006)). Thus, for the OHC, where densities of prestin are up to 11,000/ μm^2 (Huang and Santos-Sacchi, 1993; Gale and Ashmore, 1997; Mahendrasingam et al., 2010; Santos-Sacchi and Tan, 2020), the ensemble might be considered one huge cluster permitting negative cooperativity among molecules spanning across several molecular distances. These interactions are expected to impact OHC influence on cochlear amplification and hearing, since those resulting V_h shifts may be viewed as amplificatory in nature (Santos-Sacchi et al., 2009).

ABSTRACT

There are known differences in the properties of hair cells along the tonotopic axis of the avian auditory epithelium, the basilar papilla (BP). To determine the genetic basis of these differences, we compared gene expression between the high- (HF), middle-, and low-frequency (LF) thirds of 0-day-old chick auditory epithelia. RNA amplified from each sample was hybridized to whole-genome chicken arrays and GeneSpring software was used to identify differentially expressed genes. Two thousand six hundred sixty-three genes were found to be differentially expressed between the HF and LF segments, using a fold-change cutoff of 2 and a *p* value of 0.05. Many ion channel genes were differentially expressed between the HF and LF regions of the BP, an expression pattern that was previously established for some but not all of these genes. Quantitative PCR was used to verify tonotopic expression of 15 genes, including *KCNMA1* (Slo) and its alternatively spliced

STREX exon. Gene set enrichment analyses (GSEA) were performed on the microarray data and revealed many microRNA gene sets significantly enriched in the HF relative to the LF end, suggesting a tonotopic activity gradient. GSEA also suggested differential activity of the kinases protein kinase C and protein kinase A at the HF and LF ends, an interesting corollary to the observation that there is tonotopic expression of the STREX exon that confers on Slo sensitivity to the activity of kinases. Taken together, these results suggest mechanisms of induction and maintenance of tonotopicity and enhance our understanding of the complex nature of proximal–distal gene expression gradients in the chicken BP.

INTRODUCTION

The basilar papilla (BP), the chicken auditory epithelium, is tonotopically organized much like its mammalian counterpart the organ of Corti. Hair cells residing at specific locations along the apical-basal axis are maximally responsive to sounds at a particular frequency. In non-mammalian vertebrates such as turtles (Crawford

and Fettiplace 1981) and birds (Fuchs et al. 1988), this tuning seems to be largely mediated by intrinsic electrical resonance properties of hair cells. Electrical resonance in these cells is mediated by interplay between a depolarizing voltage-gated calcium current through calcium channels and a hyperpolarizing calcium-sensitive potassium current through BK channels.

Both hair cell physiological activity and gene expression are known to vary along the tonotopic axis of auditory epithelia. There are also differences in the properties of the transduction apparatus along the tonotopic axis. The mechanotransduction channels at the HF end of the turtle BP pass more current per channel than those in the LF end, allowing for faster adaptation (Ricci et al. 2003). As another example, there are changes in the electrical tuning apparatus along the length of the BP. Both models and data confirm the expression of inward and delayed rectifying potassium channels in hair cells in the low-frequency portion of the sensory epithelium, while BK channels and L-type calcium channels are present in higher density in hair cells in the high-frequency region (Art et al. 1995; Wu et al. 1995; Samaranayake et al. 2004). Differences in the density and properties of these channels are believed to give rise to the higher resonant frequency of cells in the HF end of the BP (Navaratnam et al. 1997; Rosenblatt et al. 1997; Samaranayake et al. 2004). Specifically, the higher resonant frequency of HF hair cells seems to be partly due to an increase in calcium influx and an increase in potassium efflux through an increased number of potassium and calcium channels (Art et al. 1995; Wu et al. 1995; Tucker et al. 1996).

In light of what is known about tonotopic gradients of gene expression and hair cell physiology, we endeavored to use a genome-wide comparison of gene expression between the high-frequency (HF), middle-frequency (MF), and low-frequency (LF) segments of the post-hatch chicken BP to identify tonotopically expressed genes. Genes found to have this expression pattern may be functionally significant and may therefore provide new insight into BP structure and function. Specifically, tonotopically expressed genes may represent differences in development, susceptibility to injury, or regenerative capacity along the tonotopic axis. We expected that such a data set would identify gene expression regulators such as transcription factors and microRNAs (miRNA) that are important for the development and/or maintenance of these transcriptional gradients. Affymetrix whole-genome chicken microarrays were therefore used to compare transcription profiles between the HF (basal), MF, and LF (apical) thirds of the post-hatch chicken BP. Many of the genes found to be differentially expressed between the two extreme ends of the epithelium were ion channels, some known to

be tonotopically expressed and others with a previously uncharacterized pattern of expression. Given limitations in sensitivity and specificity of microarrays, gene set enrichment analyses (GSEA) were also performed. These analyses complement the microarray results as they are more specific and are less susceptible to systematic bias from false results. The GSEA results suggested tonotopic gradients of activity of a number of miRNAs and kinases, as well as expression of genes associated with the hematopoietic stem cell phenotype.

METHODS

Basilar papilla tissue preparation

Animals were treated in accordance with policies established by the Yale Institutional Animal Care and Use Committee (protocol number 2007–10439). Cochlear ducts were carefully dissected out of 0-day-old chicks. The tegmentum vasculosum and tectorial membrane were immediately dissected off to expose the auditory epithelium, which was delicately freed from the basement membrane resting on cartilaginous plates using a tuberculin needle. The entire epithelium was then sectioned into even HF, MF, and LF thirds (Fig. 1). Three segments from three different BPs went into each sample to produce a total of three HF samples, three MF samples, and three LF samples. Samples were frozen at -80°C until RNA isolation could be performed.

RNA isolation

Frozen samples were removed from the -80°C freezer and immediately placed in the lysis buffer from the RNAqueous[®] Kit (Ambion, Austin, TX). The tissue was not actively homogenized or disrupted given the small amount of tissue. Total RNA isolation was performed as per the manufacturer's instructions. The quality of each sample was confirmed by gel and Bioanalyzer analysis. All samples had an A260/A280 ratio of at least 1.9, as well as 18S and 28S bands with no obvious evidence of degradation or genomic contamination and RNA integrity numbers (based on 28S/18S ratio and other parameters) of at least 9 on a ten-point scale (Schroeder et al. 2006). Total RNA concentration was determined by measuring absorbance at 260 nm on a spectrophotometer.

Microarray hybridizations

Microarray hybridizations were performed as previously reported (Frucht et al. 2010). Briefly, double-stranded cDNA and biotin-labeled cRNA were synthesized from 1 to 5 μg of total RNA using a two-cycle target labeling kit (Affymetrix 2004). Biotin-labeled cRNA was purified using the GeneChip Cleanup Module prior to fragment-

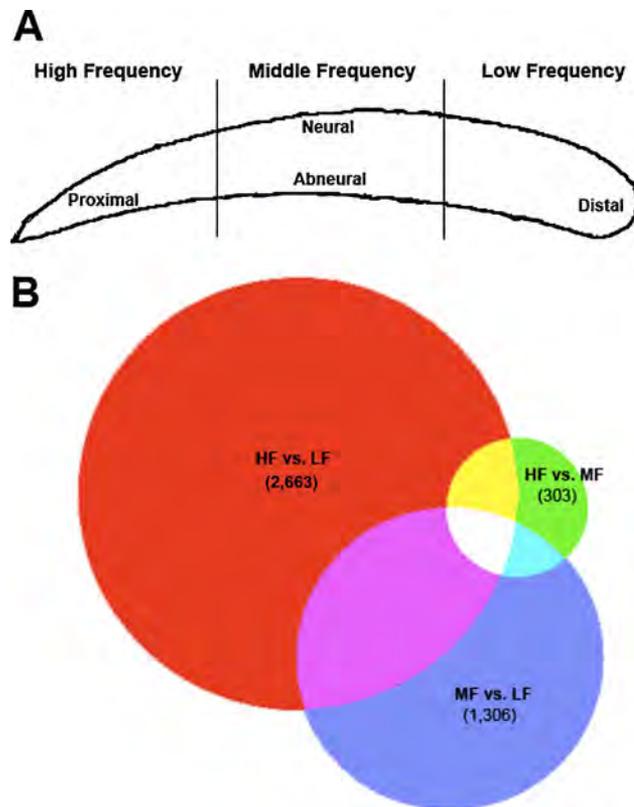

FIG. 1. Shown in panel **A** is a schematic diagram showing the manner in which the auditory epithelia were sectioned. Low-, middle-, and high-frequency segments were pooled as described in the text to allow for comparison of genome-wide expression across the three indicated regions. Shown in panel **B** is a proportional Venn diagram representing overlap of differentially expressed genes for the high- versus low-frequency (HF vs. LF; 2,663), high- versus middle-frequency (HF vs. MF; 303), and middle- versus low-frequency (MF vs. LF; 1,306) comparisons. Far more genes are differentially expressed between the HF and LF segments than either of the middle-frequency comparisons, suggesting that many of the HF vs. LF genes are expressed in a gradient along the tonotopic axis of the basilar papilla.

ing to a size of 35–200 bases. Hybridization of the samples with Affymetrix whole-genome chicken microarrays was then performed at the Yale University Keck Facility according to the manufacturer's protocol (Affymetrix 2009). This array contains many internal controls, including negative hybridization controls that serve to minimize the detection of signals resulting from nonspecific binding to probes. All microarray data is MIAME-compliant and has been uploaded to the EMBL-EBI ArrayExpress database (<http://www.ebi.ac.uk/arrayexpress/>) along with extensive annotations on both experimental and analytical methods as well as all raw and normalized data (accession: E-MEXP-2806).

Differential gene expression analysis

Gene expression analyses were performed using GeneSpring GX 9.0 software (Agilent Technologies,

Santa Clara, CA). After GC-RMA normalization without baseline transformation, the microarray data were then filtered by expression (20–100% in at least one of the three samples from each segment of the BP) to exclude genes expressed only at very low levels in all samples. In cases of probeset redundancy, median expression values were used. Differentially expressed genes were identified by using a fold-change cutoff of 2 and then performing an unpaired *t* test ($p < 0.05$) after Benjamini–Hochberg correction for multiple comparisons. R version 2.10.1 (www.r-project.org) was used to generate a heat map using the HeatPlus add-on in the Bioconductor package.

Quantitative PCR validation of microarray expression data

In order to validate the microarray data, quantitative PCR was performed on 15 detected genes. Six of these genes were upregulated in the HF relative to the LF region, and nine were upregulated in the LF relative to the HF region. The differentially expressed genes validated by quantitative PCR (qPCR) were highly expressed in at least one region and chosen to span a range in fold-change differences between the HF and LF regions, from 2.33 to 30.61.

The 15 genes that were validated are brain-derived neurotrophic factor, glutamate receptor 2, medium neurofilament, aquaporin 5, chordin-like 1, docking protein 7, ret proto-oncogene, SLIT, and NTRK-like family member 4, wnt inhibitory factor 1, integrin A1, potassium large conductance calcium-activated channel, subfamily M, alpha member 1 (KCNMA1, Slo; total and STREX exon), potassium voltage-gated channel, shaker-related subfamily, beta member 1 (KCNAB1), potassium voltage-gated channel, shaker-related subfamily, beta member 2 (KCNAB2), transient receptor potential cation channel, subfamily C, member 1 (TRPC1), and sodium channel, voltage-gated, type II, alpha subunit (SCN2A). The RNA samples were the same ones used for microarray analysis for all genes except KCNMA1 (total and STREX containing only) and TRPC1. Total Slo (KCNMA1) expression and expression of the Slo exon STREX were determined in the HF, MF, and LF segments of the BP to assess for expression gradients. At least three samples, each comprised of three BP segments, were used. Expression of the 18S ribosomal subunit was also assessed to allow for normalization of total RNA levels between samples using the $2^{-\Delta\Delta C_T}$ method (Schmittgen and Livak 2008). Primer 3 (Rozen and Skaletsky 2000) was used to design intron spanning primer pairs that were validated by melting curve analysis.

Five micrograms of RNA was isolated from each sample as described above and used to create first-strand cDNA using oligo-dT primers. Because exten-

sive genomic contamination was made unlikely by the use of oligo-dT primers and confirmed not to be present by Bioanalyzer measurements, RNA samples were not treated with DNase. qPCR was performed using the SYBR Green Supermix reagent (Bio-Rad, Hercules, CA) on an iCycler system (Bio-Rad, Hercules, CA). To establish the sensitivity of our qPCR methodology, reactions were run with serial dilutions of amplified 18S cDNA of known concentrations to ensure that the correct product (i.e., by band size and melting temperature) could be amplified with only several copies in a well. Each reaction was run in triplicate, and the data was averaged for each cDNA sample and primer pair combination. Only those fold-changes with a 95% confidence interval that did not include the value 1 were considered significant. A fold-change of 1 between two conditions would indicate that the expression level is exactly the same in both conditions, the null hypothesis of this test. Therefore, one can conclude with 95% certainty that a fold-change interval that does not overlap with a value of 1 represents a real change in gene expression.

Gene set descriptions

GSEA was performed to gain insights into the functional relevance of tonotopic gene expression gradients using GSEA version 2 software (Subramanian et al. 2005). In a GSEA, genes are first ranked by their association with the class distinction of the comparison being made (e.g., HF versus LF). In other words, the genes most consistently overexpressed in the HF samples were ranked at one end of the list, and those most overexpressed in the LF samples were ranked at the other end. GSEA asks whether the genes that make up a particular gene set are overrepresented at either end of the list, rather than randomly distributed throughout. This question was answered by calculating for every gene set a running sum statistic known as the enrichment score (ES). The ES can be thought of as a running tally that is proportional to the number of genes in a set that are upregulated with

a particular manipulation. Each ES was normalized to gene set size to produce a normalized enrichment score (NES). The statistical significance of each NES was determined by comparing that NES to the distribution of ESs generated by randomly permutating the genotype class labels. Both the p value and false discovery rate (FDR, q value) were calculated for each set. Gene sets whose NES had an associated FDR less than 0.25 and a p value less than 0.05 were considered significantly enriched.

The GeneSpring processed data from the 38,535 original probes was collapsed into 13,159 genes based on gene symbols. Some genes were assigned to one or multiple gene sets downloaded with the GSEA package. The mammalian gene set package included 837 gene sets, 50 of which were excluded by gene set size criteria (15–50), leaving 783 to be included in our analysis. One thousand one hundred ninety-seven out of the 1,892 curated gene sets also met this criterion (Table 1). The GSEA parameters used were as follows: metric=signal to noise; permutation number=1,000; gene size minimum=15; gene size maximum=500; enrichment statistic=classic; permutation type=gene set.

Gene set descriptions

Two different gene set packages were used, both of which were downloaded directly from the Broad Institute Website (www.broad.mit.edu/gsea). To assess for tonotopic gradients in miRNA and transcription factor activity in the chicken gene expression data, a GSEA was performed using a gene set package called “c3.all.v2.5.symbols,” which was obtained from the BROAD Institute Website (Xie et al. 2005). This package includes gene sets defined by the presence of transcription factor motifs and predicted miRNA binding sites. Because the genes in each set of this package share regulatory motifs that are conserved across human, mouse, rat, and dog genomes, they will be referred to as the “mammalian gene sets.” The motifs used come from Xie et al. (2005) and the TRANSEAC database and include sets of genes sharing particular 3'-UTR miRNA binding motifs.

TABLE 1

Shown are the number of mammalian and curated gene sets that were significantly enriched ($p < 0.05$ and false discovery rate < 0.25) in the high-frequency (HF), middle-frequency (MF), or low-frequency (LF) segments of the basilar papilla for the HF vs. LF, HF vs. MF, and MF vs. LF comparisons

	<i>HF vs. LF</i>		<i>HF vs. MF</i>		<i>MF vs. LF</i>	
	<i>Up in HF</i>	<i>Up in LF</i>	<i>Up in HF</i>	<i>Up in MF</i>	<i>Up in MF</i>	<i>Up in LF</i>
Mammalian	56/783	18/783	1/783	66/783	163/783	13/783
Curated	293/1,197	82/1,197	170/1,197	123/1,197	231/1,197	91/1,197

There are 783 mammalian gene sets and 1,197 curated gene sets that met the size criteria indicated in the text

To assess the functional relevance of the pattern of differential gene expression, GSEA was performed using a gene set package called “c2.all.v2.5.symbols” which was also downloaded from the BROAD Institute Website. This package defines curated sets of genes based on specific experimental findings from experiments on human and animal model tissue. This package includes both canonical pathways and chemical/genetic perturbations based gene sets. These gene sets will be referred to as the “curated gene sets.” References for all curated gene sets are provided on the BROAD Website.

To ascertain whether any of the tonotopic gene expression gradient is attributable to protein kinase activation, two additional GSEAs were performed by generating gene sets from available data sets. To assess for tonotopic activity of protein kinase A (PKA), a set of genes putatively upregulated with increased PKA activity was used. Specifically, the data used was raw Affymetrix whole-genome microarray data from a previously reported experiment describing gene expression differences in the chicken BP after 24-h exposure to forskolin (100 μ M), an adenylate cyclase activator which increases intracellular cAMP levels and therefore PKA activity (Frucht et al. 2010). These data were processed to generate a list of significantly (fold-change > 2, p value < 0.05) differentially expressed genes. The list of 39 affected genes was used for GSEA. A different data set was processed in the same fashion to produce a set of genes whose expression is putatively affected by protein kinase C (PKC) for use in a GSEA. This particular data set was from a previously reported experiment in which transcription was profiled with and without PMA-induced activation of PKC in human MM6 cells (Yu et al. 2008). The set of 3,456 genes that were differentially expressed (fold-change > 2, p value < 0.05) following PMA activation was used in a GSEA to look for evidence of tonotopic PKC activity.

RESULTS

Gene expression analysis statistics

We report here a systematic comparison of genome-wide expression along the tonotopic axis of the chicken auditory epithelium using Affymetrix whole-genome chicken microarrays. Zero-day-old chickens were used because this developmental time point succeeds the onset of hearing (Gottlieb 1965). The complete data set (included as [Supplemental Data](#)) should therefore be of interest to those studying expression and functional gradients along the tonotopic axis of the inner ear.

To examine gene expression gradients along the tonotopic axis of BPs, cochlear ducts were explanted and sensory epithelia were immediately isolated, microdissected, and sectioned into HF, MF, and LF segments (Fig. 1). Out of the 38,535 probe sets on the Affymetrix chicken array, 2,663 were differentially expressed between the HF and LF segments; 303 were differentially expressed between the HF and MF segments, and 1,306 genes were differentially expressed between the MF and LF segments. The complete list of differentially expressed genes for each of the three comparisons (i.e., HF vs. LF, HF vs. MF, MF vs. LF) are included as [Supplemental Data](#). A proportional Venn diagram clearly indicates that far more genes are differentially expressed between the two extreme ends of the epithelium than between the MF segment and either of the two extremes (Fig. 1). This is consistent with the notion that most genes are being expressed differentially along the tonotopic axis in an apical-to-basal gradient. Gene expression data for all genes on the array (Tables S1, S2, and S3) as well as only the subset of genes identified as differentially expressed (Tables S4, S5, and S6) are included as supplementary material.

qPCR confirms microarray data

qPCR was performed on select genes in order to validate the microarray data. Primers were designed for 15 genes, six of which were upregulated in the HF segment and nine of which were upregulated in the LF segment (Table 2). These genes were selected to span a range of fold-changes in both directions based on their high level of expression in at least one segment of the BP. Some genes were selected because they are specifically known to have an important role in the inner ear and are known to be tonotopically expressed in the BP (e.g., *KCNMA1*). However, most of the genes chosen were selected because their expression pattern in the BP was previously uncharacterized. Out of the 15 genes examined, qPCR confirmed the directionality of all 15. The fold-changes of 12 of these 15 genes (80%) were significantly different from a value of 1 (Table 2), confirming their differential expression as detected by microarray. These findings validate the microarray results, so further analyses were performed on the gene expression data set.

Slo (*KCNMA1*) and its alternatively spliced STREX exon were tested by qPCR in the HF, MF, and LF segments of the BP (Fig. 2). Both showed a clear tonotopic expression gradient with higher expression in the LF than in the MF or HF segments (one-way ANOVA, $p < 0.05$). Slo expression at the HF end was

Shown are qPCR and microarray data for genes selected for qPCR validation

Genes were selected to span a range of fold-change differences between the low- and high-frequency segments of the basilar papilla in both directions. Multiple microarray values represent redundant probe sets for the same gene. Significant fold-changes by qPCR have a 95% confidence interval excluding 1

34.1% of that at the LF end, whereas HF expression of STREX was 10.7% of that at the LF end. These results show a steeper tonotopic gradient for STREX than for Slo, suggesting that the proportion of Slo transcripts including the STREX exon decreases going from the LF to HF segments.

Tonotopic expression of structural proteins

Among the 2,663 genes found to be differentially expressed between the HF and LF segments were some genes known to have important functions in the inner ear, as well as many other genes whose functional significance is unknown (Table 3). As shown in Table 3, there was differential expression of the actin cross-linkers plastin 1 (up in LF) and plastin 2 (up in HF). Interestingly, some myosin transcripts were also tonotopically expressed. Myosin XVa expression was

higher in the LF end of the BP while myosin IIIa transcription was higher in the HF end.

Tonotopic expression of sodium, potassium, and calcium channels

Many sodium, potassium, and calcium channels were differentially transcribed between the HF and LF ends (Table 4). An expression heat map shows that most of these genes are expressed in a gradient along the tonotopic axis (Fig. 3). Interestingly, the expression patterns of most of these channels have not been previously described. Specifically, multiple calcium-gated (i.e., KCNMA1, KCNMB4), voltage-gated (i.e., KCNQ2, KCNG4, KCNF1, KCND2, KCNAB1, KCNAB2), and inward-rectifying (i.e., KCNJ2, KCNJ15) potassium channels were all upregulated in the LF end. There was also differential expression of

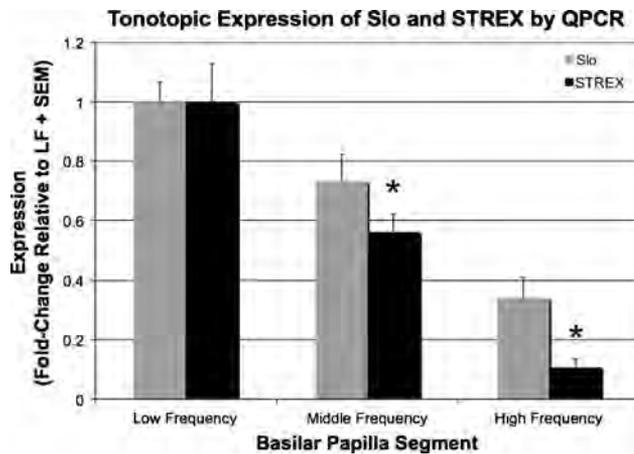

FIG. 2. Slo and the Slo exon STREX are transcribed tonotopically. Shown are the relative expression levels of both Slo and its alternatively spliced STREX exon in the low- (LF, $n=3$), middle- (MF, $n=3$), and high-frequency (HF, $n=4$) segments of the post-hatch chicken basilar papilla as determined by qPCR. Expression levels were normalized first to 18S expression, then respectively to Slo and STREX expression levels in the LF segment. A clear tonotopic gradient can be appreciated for both Slo and STREX with expression that significantly decreased from the LF region to the HF region (one-way ANOVA, $p<0.05$). The fold-change differences of LF versus MF and LF versus HF were significantly different between STREX and Slo, indicating a steeper gradient for STREX than for Slo (t tests, $p<0.05$).

voltage-gated calcium channels (i.e., *CACNA1B* was up in the LF end; *CACNA2D1* was up in the HF end) between the two ends of the BP. Additionally, there were sodium channels found by microarray differentially expressed between the HF and LF segments; *SCN2A* (voltage-gated) and *SCNN1A* (nonvoltage-gated) were up in the HF end of the BP, whereas *SCN3B* (voltage-gated) was up in the LF end. However, *SCN2A* was found by qPCR to not

be differentially expressed. Finally, three transient receptor potential (TRP) channels were found to be tonotopically expressed. *TRPC1* transcription was higher at the LF end, a finding confirmed by qPCR (Table 2). *TRPC3* and *TRPM3* were found by microarray to be upregulated in the HF end, but were undetectable by qPCR. These observations suggest important functional roles for some of these channels in the chicken inner ear.

Gene set enrichment analysis results

In order to determine the large-scale functional significance of differential gene expression, a GSEA was performed using manually curated gene sets downloaded from the Broad Institute Website. This package contains gene sets comprised of genes found by individual experiments to be associated with specific phenotypes in a variety of systems. Of the 1,197 gene sets included in this package, 293 were significantly enriched in the HF end whereas 82 were enriched in the LF end (Table 1). Interestingly, many gene sets comprised of genes associated with hematopoietic stem cells (HSC) are significantly enriched in the HF end of the BP, while only one HSC gene set is enriched in the LF end (Table 5). This finding is suggestive of a subpopulation of cells with HSC-like gene expression patterns in the HF end of the chick BP. GSEA statistics for all curated gene sets are included as supplemental material (Tables S7, S8, and S9).

To determine whether any miRNAs or transcription factors are differentially active between the HF and LF segments, an additional GSEA was performed using a gene set package with gene sets comprised of

KCNK5	Potassium channel, subfamily K, member 5	1/3.86	0.0093
KCNMA1	Potassium large conductance calcium-activated channel, subfamily M, alpha member 1	1/6.82	0.025
KCNMB4	Potassium large conductance calcium-activated channel, subfamily M, beta member 4	1/2.27	0.0045
SCN2A	Sodium channel, voltage-gated, type II, alpha subunit	2.33/1 8.55/1	0.015 0.0027
SCN3B	Sodium channel, voltage-gated, type III, beta	1/3.58	0.020
SCNN1A	Sodium channel, nonvoltage-gated 1 alpha	2.85/1 2.62/1	0.020 0.015
TRPC1	Transient receptor potential cation channel, subfamily C, member 1	1/2.77	0.035
TRPC3	Transient receptor potential cation channel, subfamily C, member 3	3.55	0.022
TRPM3	Transient receptor potential cation channel, subfamily M, member 3	24.24	0.0030

Multiple values are displayed for the probesets with redundancy. Various sodium, potassium, and calcium channels are all differentially expressed along the tonotopic axis of the chick basilar papilla. Three of the genes in this table were also tested by qPCR (KCNAB1, KCNAB2, SCN2A; see Table 2). Of these three genes, two are also found to be differentially expressed by qPCR (fold-change 95% confidence interval does not include 1)

genes containing particular transcription factor and miRNA recognition sites. Fifty-six out of 783 of the gene sets in this set are enriched in the HF end, whereas 18 of the gene sets are significantly upregulated in the LF end (Table 1). Interestingly, many of the differentially expressed gene sets are miRNA ("MIR") gene sets (Table 6). These results suggest tonotopic expression and therefore some functional relevance of these particular miRNAs in the chicken inner ear. GSEA statistics for all of these motif-based gene sets are included as supplemental material (Tables S10, S11, and S12).

GSEA was also performed using a PKC-based gene set and a PKA-based gene set as described in the [Methods](#). A set of genes found to be differentially

expressed following activation of PKC using PMA in human MM6 cells was significantly enriched in the HF end of the BP (Table 5; FDR < 0.001). Additionally, a set of genes differentially expressed in the chicken BP after 24 h of forskolin-induced PKA activation were significantly enriched in the LF end (Table 5; FDR = 0.002). These results suggest differential activation and/or expression of these kinases themselves along the tonotopic axis of the chicken BP.

DISCUSSION

Reported here are 2,663 genes that are differentially expressed between the HF (i.e., proximal) and LF

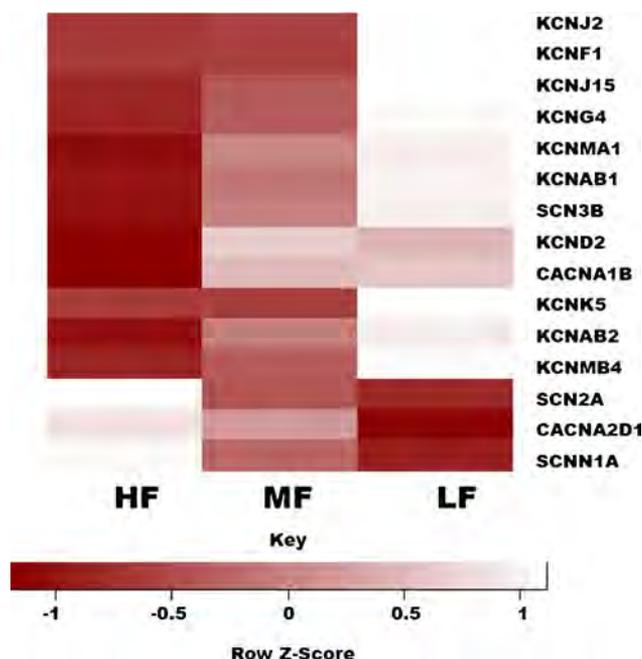

FIG. 3. Many ion channels are expressed in a gradient along the tonotopic axis of the chicken basilar papilla. Shown is a heat map showing normalized expression levels in the high- (HF), middle- (MF), and low-frequency (LF) segments of the basilar papilla for 15 ion channel genes. The depicted expression values are all normalized relative to the average for each row (i.e., the average expression for a particular gene across all three segments). As shown in the color key, *light rectangles* represent higher expression levels than *dark rectangles*. Most of the genes shown appear to be expressed in a gradient along the tonotopic axis.

(i.e., distal) thirds of the BP. Among the list of genes found to be differentially expressed are many that would be predicted to show this pattern, as well as many with a previously uncharacterized pattern of

expression or functional activity in the BP. Our data revealed that two inward-rectifying potassium channels (KCNJ2, KCNJ15) are transcribed at higher levels at the apical end, an interesting observation given that previous work has shown preferential expression of inward-rectifying potassium channels at the LF end of the BP (Fuchs et al. 1990; Fuchs 1992; Navaratnam et al. 1995; Wu et al. 1996). Also suggested by our microarray data is relative upregulation of a number of voltage-gated potassium channels in the LF end (Table 4), confirming physiological data on the presence of voltage-gated potassium currents preferentially found in LF hair cells of the turtle BP (Fuchs et al. 1990; Goodman and Art 1996). KCNMA1 was identified by our microarray data to be upregulated in the LF end of the BP, confirming recently reported results (Miranda-Rottmann et al. 2010). Similarly, there were increased amounts of the sodium channel transcript SCN3B in the LF end and of SCNN1A in the HF end. While sodium channels have not been observed in the chicken, hair cells from the LF end of alligator BP were found to contain TTX-sensitive currents (Evans and Fuchs 1987). Actin was detected by our array but found not to be tonotopically expressed (data not shown), a finding that is intuitive given that the total amount of actin per hair cell does not vary tonotopically in chickens (Tilney and Tilney 1988). The calcium binding protein calbindin was previously found to be expressed at higher levels in basal than in apical hair cells (Navaratnam et al. 1995; Navaratnam et al. 1997; Hiel et al. 2002), a finding that was not confirmed by our microarray data. However, this observation is likely the result of the 3' bias of the Affymetrix chicken array. The NCBI

TABLE 5

Shown are all hematopoietic stem cell (HSC) and protein kinase gene sets that were significantly enriched ($p < 0.05$, false discovery rate {FDR} < 0.25) in the high-frequency (HF) versus low-frequency (LF) curated gene set enrichment analysis

No miRNA gene sets were significantly enriched in the LF end of the basilar papilla. These results suggest that the above miRNAs are upregulated in the LF end, causing downregulation of their targets in the LF end, therefore relative HF upregulation

Module Maker lists all chicken calbindin mRNAs (*Gallus gallus* Build 2.1, Chromosome: 2, Contig: NW_001471651.1) including ESTs, the vast majority of which (24/25) do not contain the sequence targeted by the calbindin probeset on this array. In contrast, previous work showing tonotopicity of calbindin expression used qPCR primers designed to amplify a portion of the transcript that is present in all 25 variants, and these results are therefore much more reliable (Navaratnam et al. 1995, 1997; Hiel et al. 2002). That calbindin was not found by microarray to be tonotopically expressed therefore likely reflects the spatial distribution of an exceedingly rare splice variant. Despite the known limitations of microarrays, these observations and the good correlation with qPCR serve to instill confidence that this data set generally reflects actual gene expression levels.

Among the genes examined here are genes whose products are known components of stereocilia tip-links. For example, the stereocilia tip-link protein protocadherin-15 was found by microarray to be upregulated in the LF end of the BP. However, protocadherin-15 was not detectable by qPCR (data not shown), suggesting that its identification by microarray was likely a false-positive result. Previous work has also shown a temporal but no appreciable spatial gradient of protocadherin-15 in the postnatal mouse organ of Corti (Lelli et al. 2009). The same study showed that protocadherin-15 expression is

relatively high in embryonic mice, but drops to extremely low levels after birth. Our data suggest that protocadherin-15 is expressed at extremely low levels in the post-hatch chicken BP as well. Further work should aim to further characterize the spatiotemporal expression gradient of protocadherin-15 in BPs from animals of different ages to determine whether the pattern mirrors that seen in mammals.

KCNMA1, the transcript encoding the BK calcium-activated potassium channel, was upregulated in the LF end of the BP, confirming recently reported data (Miranda-Rottmann et al. 2010). However, the results from both studies are in apparent disagreement with both protein expression (Samaranayake et al. 2004) and electrophysiological data (Art et al. 1986, 1995) suggesting higher BK protein expression in the HF end of the BP. This discrepancy is likely due to post-transcriptional control of KCNMA1 (Bai et al. 2010, under review). There is precedent for this observation, as previous work has shown dissociation between mRNA expression and protein levels (Gygi et al. 1999; Ghaemmaghami et al. 2003). We have since established that Slo delivery to the surface of the cell is inhibited by beta-1 and beta-4 subunits (Bai et al. 2010, under review), which are expressed at higher levels in LF hair cells (Ramanathan et al. 1999, 2000; Bai et al. 2010, under review).

The TRP channel TRPC1 was found by qPCR to be upregulated in the LF end of the BP by both micro-

array and qPCR. Differential expression of TRP channels along the tonotopic axis is of particular interest given that they are among a small subset of channel families thought to possess the characteristics required of the as yet unidentified mechanoelectrical transduction (MET) channel in the inner ear (reviewed in Fettiplace 2009). Members of the TRP family are known to act as mechanically gated ion channels in a variety of species (reviewed in Christensen and Corey 2007). TRP proteins are capable of forming heteromultimeric channels with conductances that vary with channel composition (Bai et al. 2008; Köttgen et al. 2008). Channel composition may therefore partly give rise to the tonotopic gradient in MET channel conductance that is seen along the BP (Ricci et al. 2003). The present findings suggest closer examination of TRPC1 as a potential component of the transduction apparatus, especially in light of this protein's known expression in the organ of Corti (Cuajungco et al. 2007).

Given the limitations of microarray data sets, GSEA was performed to gain more meaningful insight into the spatial patterns of gene expression in the BP. Previous work has confirmed the utility of using GSEA to identify biologically important players in the BP (Frucht et al. 2010). One advantage of this approach is that gene sets found to be significantly enriched can be interpreted with confidence as they are not systematically biased by false-positives and false-negatives, which serve only to increase background noise in the data and decrease the sensitivity of this computational approach. Therefore, some genes sets that are actually enriched may be missed, but positive GSEA results are likely to reflect real gene expression patterns.

The GSEA results described here shed new light on the intricacy of tonotopicity in the post-hatch chicken BP. Interestingly, many sets of genes associated with HSC were enriched in the HF end of the BP. This finding suggests that there may exist a subpopulation of cells in the BP with properties similar to those of HSCs in the BP. HSCs, much like non-mammalian vertebrate hair cells, are quiescent until stimulated by external cues to divide and differentiate into new hair cells (Ryals and Rubel 1988; Jude et al. 2008; Narbonne and Roy 2008). The tonopocity of this pattern of gene expression is interesting, given that the HF end of the BP is more susceptible than the LF end to death following ototoxic insult (Matz et al. 1965; Johnstone and Boyle 1967). It may be more than merely coincidental that HSC genes are enriched in the HF end of the BP, which is the end of the BP that is most susceptible to damage by ototoxins. In birds, following ototoxic or traumatic injury, the entire auditory sensory epithelium regenerates so that morphology and architecture are almost

completely restored (reviewed in Stone and Cotanche 2007). The present results therefore beg the question, are there as yet unobserved differences in regenerative mechanisms and/or capacity along the tonotopic axis of the BP? Further experimentation will be required to definitively answer this question.

In addition to the HSC gene sets, GSEA revealed that many sets of predicted targets of specific miRNAs were enriched in the HF end of the BP, suggesting upregulation of these miRNAs in the LF end. It is striking that all 22 miRNA gene sets that were significantly enriched showed this directionality. Myriad miRNA have already been shown not only to be expressed in the inner ear (Weston et al. 2006; Sacheli et al. 2009; Wang et al. 2010), but also to play an important role in inner ear development (Friedman et al. 2009; Soukup 2009; Soukup et al. 2009), function (Lewis et al. 2009; Mencia et al. 2009), and hair cell regeneration (Frucht et al. 2010). The present results suggest a tonotopic gradient in activity and accordingly expression in the chicken BP. Tonopocity of miRNA activity in the post-hearing onset chicken suggest a role for these specific miRNAs in inner ear function.

GSEA of tonotopic data were consistent with increased activity of PKA at the low-frequency end of the papilla and PKC activity at the high-frequency end of the BP. These findings have implications for electrical tuning. The primary determinant of changing oscillatory frequency in membrane potential is the changing kinetic properties of the BK channel (Art et al. 1986, 1995). Specifically, deactivation times in response to a step voltage decreases with increase in characteristic frequency (Art et al. 1986, 1995). Thus, the inclusion of the STREX exon, which is preferentially expressed in LF hair cells, prolongs BK channel deactivation times consistent with native BK channels at this location (Art et al. 1986, 1995; Xie and McCobb 1998). Similarly, the presence of increased PKA activity in low-frequency hair cells is consistent with the longer deactivation times produced by addition of PKA (with the STREX exon and the beta-4 subunit) in heterologous expression systems (Petrik and Brenner 2007). The inference that PKC is increased in high-frequency hair cells corroborates the physiological finding of shorter open times in higher-frequency hair cells (Art et al. 1995). PKC has been shown to shorten BK channel open time (Zhou et al. 2010).

It is worth emphasizing that all of these experiments were performed on tissue from 0-day-old chickens. This age was selected for study because, unlike in mammals, there is much evidence that, in chickens, this time point is preceded by both acquisition and maturation of hearing. This observation is confirmed by behavioral (i.e., whole animal), physiological, and molecular evidence. For example, not

only do chickens at embryonic day 19 have evoked cochlear nuclei responses (Saunders et al. 1973, 1974), but the frequency tuning and threshold levels of embryonic chickens resemble those of adult animals (Rebillard and Rubel 1981). Furthermore, acquisition of BK currents necessary for electrical tuning is measurable in embryonic chickens and is coincident with hearing onset (Sokolowski et al. 1993). Interestingly, recent work suggests that part of this maturation process may involve developmental switching in the splice variants of BK channel subunit transcripts (Kim et al. 2010). Moreover, work in our lab has confirmed an identical spatial expression pattern of transcripts encoding KCNMA1 and its related proteins between 0-day-old and 14-day-old chickens (Bai and Navaratnam, unpublished observations). It therefore seems unlikely that genes found to be differentially expressed here represent transient developmental changes rather than true stable tonotopic expression, but this possibility cannot be definitively excluded. Future work should therefore aim to characterize these expression gradients in more mature BPs as well. An additional point that requires consideration is that, as was likely the case with calbindin, the microarray probesets may only be detecting a specific transcript variant when in reality there may be many additional variants in this tissue, perhaps some of which are tonotopically expressed. Therefore, in addition to the well-known methodological limitations of microarrays, there are also biological implications to the sensitivity of the approach.

In summary, the present results suggest that 2,663 genes are differentially expressed between the HF and LF thirds of the post-hatch chicken BP. While many of these genes likely reflect tonotopic differences in hair cells, which are known to have varying properties, some of these genes may reflect tonotopic differences in non-sensory supporting cells as well. Among those genes identified as differentially expressed were many potassium, calcium, and sodium channels, the inner ear expression patterns of which have not been previously described. Given the large number of genes found to be differentially expressed between the HF and LF ends of the BP, there must be gene expression regulatory mechanisms underlying this expression pattern. The present results point to specific miRNA and transcription factors that may play an important role in the maintenance of these gene expression gradients. Because the frequency selectivity properties of hair cells in non-mammalian vertebrates seem to be attributable more to the physiological properties of individual cells than to physical properties of the basilar membrane, it would be interesting to eventually determine whether transfection with pre-miRNAs and/or transcription factors can alter the tonotopic axis.

ACKNOWLEDGMENTS

This work is part of a dissertation submitted to fulfill in part the requirements for the degree of Doctor of Philosophy at Yale University.

ABSTRACT

Specialized sensory-transducing hair cells regenerate in response to injury in non-mammalian vertebrates such as birds and fish but not in mammals. Previous work has shown that overexpression of microRNA181a (miR181a) in cultured chicken basilar papillae, the avian counterpart of the cochlea, is sufficient to stimulate proliferation with production of new hair cells. The present study investigates the role of miR181a in hair cell regeneration after injury in explants of chicken auditory epithelia. Basilar papillae were explanted from 0-day-old chickens and transfected with either anti-miR181a, which knocks down endogenous miR181a, or a non-targeting miRNA and cultured with streptomycin to eliminate all hair cells from the epithelium. Labeling with BrdU was used to quantify proliferation. Explants exposed to streptomycin and transfected with anti-miR181a had significantly fewer BrdU positive cells than basilar papillae treated with streptomycin and transfected with a non-targeting miRNA. Activated caspase-3 and myosin VI labeling were used to show that the pattern of hair cell death and loss, respectively, were not affected by anti-miR181a transfection. MiR181a downregulation therefore seems to diminish the proliferative component of hair cell regeneration rather than prevent hair cell death following ototoxic injury.

Auditory hair cells are highly specialized mechanosensitive sensory cells in the inner ear that respond to acoustic stimulation. These cells can be damaged or lost as a result of infection, chemical insult, aging, acoustic trauma, or genetic causes. These cells cannot regenerate in the mammalian organ of Corti, where hearing impairment resulting from their loss is irreversible. In contrast, non-mammalian vertebrates such as birds are able to regenerate hair cells after injury [22] by both mitotic [6,19,23] and non-mitotic mechanisms [1,3,18,2,17,24,7]. As yet, little is known about the molecular signals that underlie this phenomenon. A better understanding of the cellular signals for regeneration in the avian ear might point to rational targets for reversing sensorineural hearing loss in humans.

Previous work has shown that many genes are differentially expressed between proliferating and quiescent cultured chicken auditory epithelia [10]. Given this observation, a computational approach called gene set enrichment analysis was used to identify regulatory molecules and events that might be responsible for the complex changes in transcriptional profile that occur with proliferation and new hair cell production. This analysis identified myriad microRNAs (miRNA) that were predicted to play a role in this process. One particular miRNA, miR181a, was selected for functional studies and was found to stimulate proliferation and produce new hair cells when overexpressed in undamaged chicken auditory epithelia *in vitro*.

The present study addresses the question of whether endogenous miR181a plays a role in auditory hair cell regeneration after injury in the chicken inner ear. Cochlear ducts containing the basilar papilla (BP), the avian counterpart of the cochlea, were explanted from 0-day-old chickens and immediately transfected with either a nontargeting miRNA or anti-miR181a, which knocks down endogenous miR181a. The explants were then cultured with streptomycin to eradicate all hair cells and the thymidine analog BrdU to assay for proliferation. The tissue was then fixed and labeled for BrdU. BPs transfected with anti-miR181a had signif-

icantly fewer BrdU positive cells than tissue transfected with a nontargeting miRNA, indicating that endogenous miR181a is necessary for the proliferative component of hair cell regeneration after injury in the chicken inner ear. Additionally, the pattern of hair cell loss is unaffected by anti-miR181a transfection, so the decreased rate of BrdU labeling seems to represent direct inhibition of proliferation rather than cytoprotection. Quantitative PCR (qPCR) was used to measure expression of miR181a, which did not increase after exposure to streptomycin, suggesting that the functional effect of miR181a in hair cell regeneration is not primarily mediated by expression level, but rather by regulation of its activity.

Animals were treated in accordance with policies set forth by the Yale Institutional Animal Care and Use Committee (protocol number 2007-10439). Cochlear ducts containing the BPs were explanted from 0-day-old chicks and then transfected with either anti-miR181a or a non-targeting miRNA (Ambion, Austin, TX) as described below. Explants were then cultured for 48 h with or without streptomycin (78 μ M) and BrdU (0.01%, to allow for quantification of proliferation) in DMEM with 10% FBS at 37 °C with 5% CO₂. BPs were then transfected again with either anti-miR181a or a non-targeting miRNA (pre-miR negative control #1, Ambion), and then cultured for an additional 48 h with BrdU but no streptomycin to allow recovery. The anti- and non-targeting miRNAs were transfected at a final concentration of 100 nM using the lipid-based X-tremeGENE SiRNA Transfection Reagent (Roche, Indianapolis, IN). This, and all subsequent reagent kits were used per the manufacturer's instructions. The efficacy of this transfection reagent in the chicken auditory epithelium has been previously established [10].

BPs were fixed in 4% PFA in PBS for 30 min. Between each step three 5-min PBS washes were performed. All BrdU labeling steps were performed at room temperature. The tissue was blocked and permeabilized using a solution of PBS with FBS (10%) and Triton-X (0.1%) for 1 h. Each BP was then incubated with mouse anti-BrdU antibodies (1:40, BD, Franklin Lakes, NJ) in PBS for 1 h. Alkaline phosphatase-conjugated goat anti-mouse IgG (1:400, Santa Cruz, Santa Cruz, CA) in PBS with Triton-X (0.1%) was applied for 1 h. Alkaline phosphatase substrate was produced using the NBT/BCIP Reagent Kit (Invitrogen, Carlsbad, CA) and then added to the tissue for approximately 5 min.

BPs immunohistochemically labeled for BrdU were viewed using brightfield microscopy and were analyzed following digitization. The borders of the sensory epithelium were easily appreciated by direct microscopy. Only those nuclei that were clearly within the epithelium were counted. Unpaired Student's *t*-tests were performed to determine the statistical significance of the comparisons discussed in the text using a cut-off of $p < 0.05$.

Explanted BPs cultured with or without streptomycin (78 μ M) for 48 h. These conditions cause a complete loss of hair cells in the proximal (i.e., high frequency) segment of the BP [20]. The CaspaTag kit (Millipore, Billerica, MA) was then used to label for activated caspase-3. The BPs were then fixed, permeabilized and incubated with rabbit anti-myosin VI (1:350, Proteus, Ramona, CA) in blocking solution for 1 h and then incubated in Alexa Fluor 546 conjugated anti-rabbit secondary antibodies (1:1,000, Invitrogen, Carlsbad, CA) with Alexa Fluor 633-conjugated phalloidin (1:100, Invitrogen, Carlsbad, CA) for 1 h. Sections were mounted on glass slides in Vectashield fluorescent mounting medium (Vector Laboratories, Burlingame, CA). Images were captured using a Zeiss LSM 510 confocal microscope.

Some BPs were microdissected after 24, 48, or 72 h in culture with or without 78 μ M streptomycin. Total plus small RNA isolation was performed using the MiRNEasy kit (Qiagen, Duesseldorf, Germany). Reverse transcription and qPCR were performed using the TaqMan MicroRNA Reverse Transcription Kit and Taq-

Man MicroRNA Assay for miR181a (Applied Biosystems, Foster City, CA).

Amplification was performed using the SYBR Green Supermix kit (Bio-Rad, Hercules, CA) on an iCycler system (Bio-Rad, Hercules, CA). Expression levels were normalized to the total RNA concentration. Three replicates were performed and the data averaged for each cDNA sample and primer pair combination. Those fold-changes with a 95% confidence interval excluding a fold-change of one (which would represent no change) were considered significant.

To determine miR181a's role in hair cell regeneration in the post-hatch chicken inner ear, BPs were cultured for 48 h with streptomycin to cause hair cell death, and then for an additional 48 h recovery period without streptomycin [20]. The explanted tissue was also transfected with either anti-miR181a, to knock down endogenous miR181a, or a nontargeting miRNA at 0 and 48 h of exposure to streptomycin. Also present in the culture medium was BrdU, a thymidine analog that is incorporated into the nuclei of cells entering S-phase. At the end of the entire 4-day culture duration, BPs were fixed and labeled for BrdU to quantify proliferation.

BPs injured with streptomycin and transfected with the nontargeting miRNA had an average of 353.1 (\pm SEM = 56.5) BrdU positive cells (Fig. 1). In contrast, anti-miR181a transfection and subsequent culture alone apparently does not cause much injury to the epithelium, as these BPs had on average 5.3 (\pm SEM = 2.6) BrdU positive cells. Similarly, BPs that were neither transfected nor exposed to streptomycin all had fewer than 10 BrdU positive cells per epithelium (data not shown). Explants that were cultured with streptomycin and transfected with anti-miR181a had on average 149.9 (\pm SEM = 14.5) BrdU positive cells per epithelium, significantly fewer than epithelia exposed to streptomycin and transfected with the non-targeting miRNA ($p < 0.01$).

The BrdU labeling data suggest that endogenous miR181a plays a crucial role in the post-injury proliferative response in the chicken auditory epithelium but does not exclude the possibility that anti-miR181a transfection simply prevents cell death. To address this issue it was necessary to compare the patterns of hair cell loss after streptomycin exposure with and without prior anti-miR181a transfection. BPs were therefore transfected with either anti-miR181a or a non-targeting miRNA and then cultured for 48 h with 78 μ M streptomycin, before fixation and labeling for the apoptosis marker activated caspase-3 [11], the hair cell marker myosin VI, and the major hair bundle component actin (Fig. 2). Streptomycin treatment causes complete hair cell loss at the high frequency segment of the BP (Fig. 2). Accordingly there are many activated caspase-3 positive cells in BPs exposed to streptomycin, but not in those cultured without streptomycin. This pattern of cell death and hair cell loss is consistent regardless of anti-miR181a transfection, where there is still hair cell loss and caspase-3 activation at the high frequency end of the BP. At the low frequency end, there is less of a loss of hair cells and accordingly less caspase-3 activation (data not shown). This pattern is also independent of anti-miR181a transfection, mirroring the data from the high frequency BP segment. It therefore appears as though the reduction in BrdU labeling with anti-miR181a transfection of streptomycin treated BPs is due to direct inhibition of the regenerative response, rather than cytoprotection with a resulting decrease in the number of cells damaged by streptomycin.

QPCR was used to ascertain whether expression of mature miR181a increases following exposure to streptomycin. BPs were cultured in streptomycin for 24, 48 or 72 h, at which point the sensory epithelium was isolated by microdissection. After RNA isolation, first-strand-synthesis and qPCR was performed using primers for miR181a. At none of these time points were there significant miR181a expression level differences (Fig. 3). Therefore, while knocking down endogenous miR181a interferes with post-

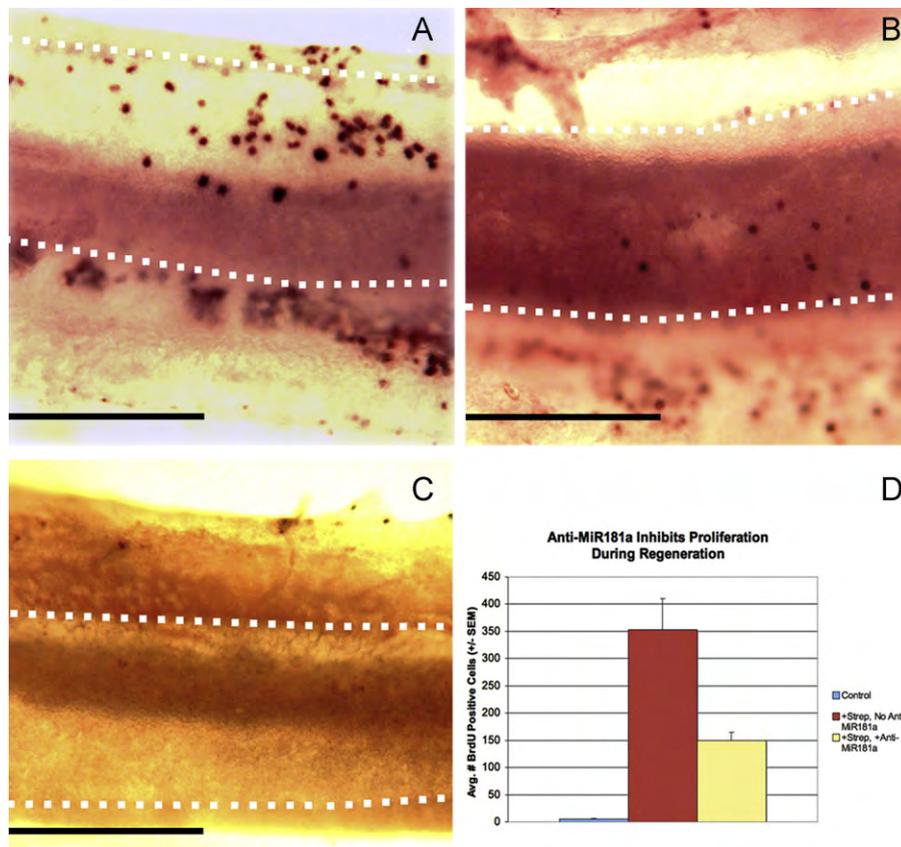

Fig. 1. Suppression of endogenous miR181a expression with anti-miR181a blunts proliferation during hair cell regeneration after streptomycin exposure. Basilar papillae from 0-day-old post-hatch chickens were transfected with either anti-miR181a or a non-targeting miRNA and then cultured with BrdU and streptomycin (78 μ M) or in drug-free medium ($n = 7$) as described in the text. There were a total of 7 BPs in each condition. After culture, explants were immunolabeled for BrdU to assay for proliferation. Panels A–C show basilar papillae labeled for BrdU, with the sensory epithelia outlined with dotted white lines. The neural edges of the epithelia are toward the bottom, and the proximal ends are to the left. Epithelia exposed to streptomycin exhibit far more proliferation when transfected with a non-targeting miRNA (A) than anti-miR181a (B). Epithelia transfected with a non-targeting miRNA and cultured in the absence of streptomycin typically have very few BrdU positive cells (C). Shown in D is the average number of BrdU positive cells per epithelium in each condition. All pair wise comparisons are statistically significant (t -test, $p < 0.05$). Scale bars in A–C = 0.2 mm.

injury hair cell regeneration, it appears as though an increase of activity rather than expression level mediates this miRNA's role in regeneration.

Presented here is the first direct functional biological evidence for the role of a specific miRNA in auditory hair cell regeneration after injury. Previously, there was limited, indirect evidence that the let-7 family of miRNA play a role in hair cell regeneration in the newt inner ear [25]. The present observation that transfection with anti-miR181a results in a markedly blunted regenerative response suggests that miR181a plays a key role in hair cell regeneration in the chicken inner ear. This finding agrees with a previous study showing that miR181a overexpression in the uninjured chicken BP can stimulate proliferation with the production of new hair cells [10]. Additionally, miR181a has a pro-proliferative role in cultured human myeloid leukemia cells that seems to be mediated at least partly by repressing expression of the cell cycle inhibitor p27 [26]. This is worth pointing out given that p27 is thought to represent a significant barrier to regeneration in the mammalian inner ear [15,12]. Further experiments will be necessary to determine whether miR181a's ability to stimulate proliferation in the chicken inner ear involves targeted downregulation of p27 expression.

The observation that miR181a expression does not increase during regeneration despite its clear role in this process suggests regulation of its activity mediates this effect. It is possible that upregulation of miR181a occurs earlier than 24 h after onset of exposure, or transiently between 24, 48 or 72 h, but these possibilities seem unlikely given the sustained nature of the regenerative

response. Our understanding of the mechanisms of control of miRNA biogenesis is more detailed than that of the ways in which miRNA biological activity is controlled [5]. miRNA activity can be modulated by different mechanisms including association with RNA-binding factors that influence miRNA-target interactions [4]. Unfortunately, there are presently no methods for directly assaying miRNA activity. One indirect method would be to look at changes in expression of predicted miR181a targets with exposure to streptomycin once such targets have been validated in chickens. Future studies on changes in expression of predicted miR181a targets in regeneration may be helpful in elucidating the precise mechanism of this miRNA's role in hair cell regeneration.

It also bears mentioning that miR181a is not the only miR181 family miRNA expressed in chickens. MiR181b is also expressed in chickens, and its sequence differs from that of miR181a by 4 bases. (www.mirbase.org). It is theoretically possible that the anti-miR181a may also cause downregulation of miR181b, but this seems highly unlikely given evidence that there is a significant decrease in anti-miRNA activity with just one mismatch and a complete lack of activity with as few as three mismatches [8]. Once there are known, biologically validated targets of both miR181a and miR181b in chickens, experiments should aim to confirm the predicted specificity of anti-miR181a.

Though presented here is the first functional evidence for a role for a specific miRNA in hair cell regeneration, previous work has shown that certain miRNAs are not only expressed in the mammalian inner ear [28,27], but are also important for the proper

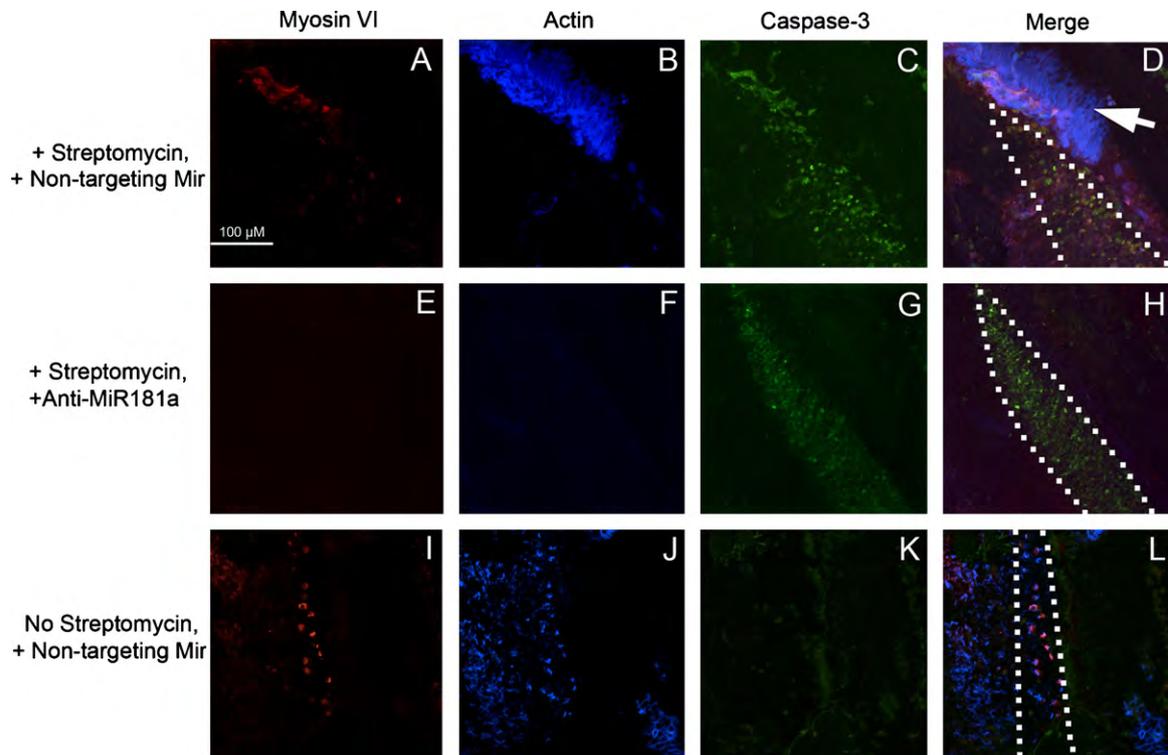

Fig. 2. Anti-miR181a transfection does not prevent hair cell death after streptomycin exposure. Basilar papillae were cultured with streptomycin for 48 h following transfection with either a non-targeting miRNA (A–D) or anti-miR181a (E–H). Whole-mounts were then labeled for the hair cell marker myosin VI, stereocilia bundle component actin, and the early cell death marker caspase-3. Hair cells were completely eliminated from the high frequency segment of basilar papillae exposed to streptomycin, regardless of transfection with anti-miR181a (A, B, E and F). Further, streptomycin exposure triggers extensive cell death with or without anti-miR181a transfection (C and G). In contrast, epithelia transfected with a non-targeting miRNA and unexposed to streptomycin retain hair cells (I and J) and do not show extensive apoptosis (K). The neural edge is to the right of each panel, and the proximal segment is to the top. The arrow in panel D shows what are likely homogeneous cells remaining after microdissection. The scale bar in A also applies to B–L.

function and/or development of this structure. For example, conditional *Dicer* knockout mouse embryos that are depleted of all inner ear miRNA develop grossly malformed inner ears [21]. Similarly, mice with conditionally silenced *Dicer* expression in hair cells only are deaf and have markedly aberrant hair cell morphology [9]. Interestingly, mutations in the target-defining seed region of miR96 cause a progressive hearing loss in both mice [13] and humans [16]. These results suggest inter-species similarities in ear miRNA function, at least within the class of mammals and therefore raise hopes that insights into the role of miRNA in hair cell regeneration in birds may shed light on why the mammalian auditory epithelium lacks regenerative capacity.

There are as yet very few studies that have directly examined the role of specific miRNAs in development, function, or regeneration of the inner ear. The miR183 family (miR96, miR182, miR183) have been examined closely following the observation that miR96 mutations are associated with progressive hearing loss. Specifically, miR183 is expressed in mammalian hair cells and spiral and vestibular ganglia [28]. Interestingly, overexpression of miR96 or miR182 causes production of ectopic hair cells in the zebrafish embryo [14]. In light of existing expression and functional data, it is clear that the miR183 family is important for inner ear development across species. These observations affirm that miRNA may prove to be suitable targets for rational therapies to reverse hearing loss.

In addition to miR181a, other miRNAs have been identified whose roles in hair cell regeneration warrant further investigation [10]. Increasing evidence suggests this is a promising avenue of investigation for those interested in developing rational therapies for sensorineural hearing loss. It is attractive to consider the possibility of miRNA based therapeutics, specifically, in light of the

transient nature of their overexpression which may result in side effect profiles that are more favorable than those of hypothetical DNA-based gene therapies for hearing loss. Further functional studies are necessary to test the hypothesis that miRNA transfection, perhaps with a carefully chosen combination of miRNA, can result in the production of new hair cells in the mammalian inner ear, and may therefore result in alleviation of sensorineural hearing loss.

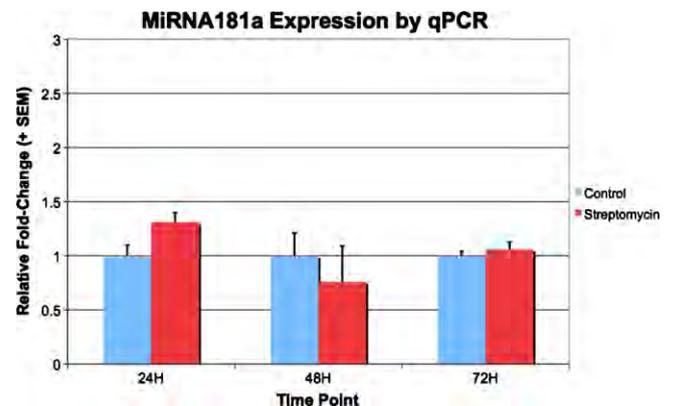

Fig. 3. MiR181a expression does not increase after exposure to streptomycin for 24, 48 or 72 h. Basilar papillae were cultured with 78 μ M streptomycin for 24, 48, or 72 h, and sensory epithelia were isolated by microdissection ($n = 3$ in each condition). Shown are relative fold-changes of miR181a expression with exposure to streptomycin, as detected by qPCR. The fold-changes shown are relative to expression in untreated controls. There was no significant difference in miR181a expression between the basilar papillae that were and were not treated with streptomycin at any of the three time points (t -test, $p < 0.05$).

Abstract

Background: Auditory hair cells spontaneously regenerate following injury in birds but not mammals. A better understanding of the molecular events underlying hair cell regeneration in birds may allow for identification and eventually manipulation of relevant pathways in mammals to stimulate regeneration and restore hearing in deaf patients.

Methodology/Principal Findings: Gene expression was profiled in forskolin treated (i.e., proliferating) and quiescent control auditory epithelia of post-hatch chicks using an Affymetrix whole-genome chicken array after 24 (n = 6), 48 (n = 6), and 72 (n = 12) hours in culture. In the forskolin-treated epithelia there was significant (p < 0.05; > two-fold change) upregulation of many genes thought to be relevant to cell cycle control and inner ear development. Gene set enrichment analysis was performed on the data and identified myriad microRNAs that are likely to be upregulated in the regenerating tissue, including microRNA181a (miR181a), which is known to mediate proliferation in other systems. Functional experiments showed that miR181a overexpression is sufficient to stimulate proliferation within the basilar papilla, as assayed by BrdU incorporation. Further, some of the newly produced cells express the early hair cell marker myosin VI, suggesting that miR181a transfection can result in the production of new hair cells.

Conclusions/Significance: These studies have identified a single microRNA, miR181a, that can cause proliferation in the chicken auditory epithelium with production of new hair cells.

Introduction

Sensorineural hearing loss represents a major public health concern. Approximately 300 million people worldwide have moderate to profound hearing loss in both ears [1]. Loss of inner ear hair cells, which serve to transduce sound into neural impulses, is responsible for the majority of hearing loss. In humans, and other mammals, loss of hair cells is permanent since these organisms have no capacity for hair cell regeneration. In contrast, other non-mammalian vertebrates such as birds, reptiles, amphibian and fish are able to replace lost hair cells.

The basilar papilla, the avian auditory epithelium, is able to regenerate hair cells in response to hair cell loss (reviewed in [2]). However, the auditory epithelium shows no mitotic activity normally, a feature that is reminiscent of the mammalian auditory

epithelium, and contrasts with the chick vestibular epithelium which shows continuous mitotic activity [3]. Thus, the avian auditory epithelium can be viewed as an intermediary in the evolution from the fish to the mammal, and we reason that the study of this epithelium will provide insight into why the mammalian auditory epithelium shows mitotic quiescence at rest (similar to the avian auditory epithelium), but is unable to proliferate in response to damage (in contrast to the avian auditory epithelium).

The basilar papilla is comprised of both sensory transducing hair cells and supporting cells. Following injury, it is the supporting cells which give rise to new hair cells [4,5]. For example, exposure of birds to intense noise causes some supporting cells to leave growth-arrest, re-enter the cell cycle and ultimately differentiate into hair cells [6,7,8,9]. New hair cells are first seen 4–5 days after the onset of

exposure to an intense sound [6,10] and undergo maturation so that by 20–28 days after stimulus onset they are virtually indistinguishable from unaffected cells [11]. In addition, some new hair cells arise from direct differentiation of supporting cells without an intervening mitotic step [12,13,14,15,16,17,18,19]. After acoustic or ototoxic insult, birds initially have increased hearing thresholds, which eventually return nearly to baseline confirming that newly produced hair cells are functional [20]. It is believed that this recovery of function results from both regeneration of new hair cells as well as repair of those that have survived [21].

Though the intracellular pathways required for hair cell regeneration have not yet been fully elucidated, various pathways and signaling cascades have been implicated in this process. For example, it has been shown that treatment of the chick basilar papilla with forskolin, a potent adenylate cyclase activator that increases intracellular cAMP levels, causes a robust and widespread proliferation of supporting cells, leading to the production of new hair cells [22]. This effect is first seen after 72 hours in culture, occurs without upregulation of markers of apoptosis, and is significantly blocked by protein kinase A inhibitors. It therefore appears as though activation of this pathway can stimulate growth of new hair cells with limited cell injury. Forskolin also appears to have a mitogenic effect in the mammalian vestibular system, in which brief treatment with this compound results in an increase in supporting cell S-phase entry [23]. Moreover, the same study found that this effect is blocked by brief treatment with forskolin in the presence of monensin or bafilomycin, which inhibit recycling of membrane receptors. Increased cAMP levels may therefore lead to proliferation by causing upregulation of tyrosine kinase growth factor receptors. With age-related hearing loss in humans there is a substantial loss of hair cells within the organ of Corti [24], so it is likely that a robust proliferative process that produces new hair cells is what will ultimately lead to maximal recovery of function in hearing impaired patients. In the present study, microarrays were used to analyze gene expression in forskolin treated basilar papillae given the robustness of this effect.

In other systems, microarray analysis of differing phenotypes has revealed complex differences in mRNA expression. These complex differences are likely brought about by the combined activity of transcription factors and microRNAs (miRNAs) that regulate expression of multiple genes and specific genetic programs. In fact, a study of transcription factor expression in regenerating versus non-regenerating chicken basilar papillae revealed a number of transcription factors that were differentially expressed [25].

MiRNAs are a species of small regulatory RNA that bind to complementary sequences in mRNA and decrease gene expression by increasing degradation and blocking translation (reviewed in [26]). Though each miRNA binds a specific sequence, these molecules are promiscuous in that their complementary sequences are found in a number of different mRNAs [27]. As a result, miRNA expression may represent a way in which cells can rapidly and in a coordinated fashion up- or downregulate a large number of genes. Some miRNAs are known to be important for inner ear development [28,29,30,31] and may play a role in hair cell regeneration, where there is presumably some reiteration of developmental events. However there have been few published studies on the role of miRNAs in auditory hair cell regeneration, specifically. One study revealed that the *let-7* family of miRNA are downregulated in the newt inner ear after hair cell injury [32]. This particular study underscores the importance of examining more closely the role of miRNA in hair cell regeneration.

In order to gain insight into the molecular events which underlie auditory hair cell regeneration in chicken, we compared gene

expression in forskolin treated (i.e., proliferating) and control (i.e., quiescent) auditory epithelia using Affymetrix whole genome chicken microarrays. The microarray data were validated by quantitative PCR. Gene set enrichment analyses were performed to identify miRNAs and transcription factors that may be important for hair cell regeneration. Many sets of genes representing predicted targets of specific miRNAs were found to be significantly enriched among genes downregulated in the forskolin-treated sensory epithelia after 72 hours, suggesting that these miRNAs were likely upregulated in the proliferating tissue. One of these microRNAs, miR181a, was selected for functional experiments given its role in proliferation and suppression of the cell cycle inhibitor p27 in human myeloid leukemia cells [33]. P27 is thought to represent a key barrier to hair cell regeneration in the mammalian inner ear [34,35]. Basilar papillae transfected with a miR181a precursor had increased numbers of BrdU positive cells than epithelia that were transfected with a non-targeting miRNA. Some cells labeling for BrdU also expressed the early hair cell marker myosin VI, indicating that overexpression of miR181a is capable of producing proliferation with production of new hair cells.

Materials and Methods

Basilar papilla explant cultures

Animals were treated in accordance with policies set forth by the Yale Institutional Animal Care and Use Committee (protocol number 2007-10439). Under sterile conditions, cochlear ducts containing the basilar papillae were carefully dissected out of 0-day-old chicks and then individually cultured in DMEM with 10% fetal bovine serum with or without forskolin (final concentration 100 μ M, delivered in 1% DMSO) for either 24, 48, or 72 hours at 37°C with 5% CO₂. Control samples received DMSO at 1% as a vehicle control. At the end of 72 hours, the tegmentum vasculosum was dissected off to expose the auditory epithelium, which was delicately freed from the underlying cartilaginous plates. All explants were kept in culture for 72 hours because new hair cells are first seen in basilar papillae treated with forskolin after ~72 hours of exposure to the small molecule [22]. Therefore, at even earlier time points in culture the molecular events that underlie hair cell proliferation are well underway. Each sample was comprised of three auditory epithelia from three different chicks and were put in 100 μ L of DMEM and then immediately frozen at –80°C until RNA isolation could be performed. There were a total of 24 samples in this experiment: three 24-hour forskolin, three 24-hour control, three 48-hour forskolin, three 48-hour control, six 72-hour forskolin and six 72-hour control.

RNA isolation

Immediately upon removal of the frozen epithelia samples from the –80°C freezer, the lysis buffer from the RNAqueous® Kit (Ambion, Austin, TX) was added. Given the small amount of tissue and relatively large surface area to size ratio, no measures to actively disrupt or homogenize the tissue in each sample were necessary. Total RNA isolation then proceeded as directed by the RNAqueous® Kit manual. Sample quality was confirmed by gel analysis.

Microarray experiments

Double-stranded cDNA and biotin-labeled cRNA were synthesized from 1 to 5 μ g of total RNA using a two-cycle target labeling kit [36]. Biotin-labeled cRNA was purified using the GeneChip Cleanup Module prior to fragmenting to a size of 35–200 bases by

incubating at 94°C for 35 minutes in fragmentation buffer (40 mM Tris-acetate, pH 8.1, 100 mM potassium acetate, 30 mM magnesium acetate). Hybridization of the samples with Affymetrix chicken arrays was then performed at the Yale University Keck Facility according to the manufacturer's protocol [37]. All microarray data is MIAME compliant and has been uploaded to MIAMEExpress (ArrayExpress accession: E-MEXP-2642, username = Reviewer_E-MEXP-2642, password = 1269882335242).

Differential gene expression analysis

The microarray gene expression analysis was performed using GeneSpring GX 9.0 software (Agilent Technologies, Santa Clara, CA). The data were GC-RMA normalized without baseline transformation, and then filtered by expression (20%–100% in at least one of the six or twelve samples at each time point) to exclude genes expressed only at very low levels in all samples. Median expression values were used for redundant probe sets. Genes differentially expressed were identified by using a fold-change cutoff of 2 and then performing an unpaired t-test after Benjamini-Hochberg correction for multiple comparisons ($p < 0.05$). Heat maps were generated using R version 2.10.1 (www.r-project.org) using the HeatPlus add-on in the Bioconductor package.

Quantitative PCR validation of microarray gene expression data

In order to validate the microarray data, twelve genes were selected to be verified by qPCR. Seven of the genes selected were upregulated and five were downregulated in the forskolin condition. The upregulated genes validated by qPCR were highly expressed in at least one condition and chosen to span a range in fold-change differences between the two experimental conditions at 72 hours, from 2.0 to 64.3. The 12 genes that were validated are BECN1, CCNI, CDKN1B (p27), CDKN2B, DPM1, EME1, FBXO8, ITGA4, NLGN1, OCM, PIGW, SNX1. Additionally, expression of the 18S ribosomal subunit was also assessed to allow for normalization of total RNA levels between samples using the $2^{-\Delta\Delta C_T}$ method [38]. Primers were designed using MacVector (MacVector, Cary, NC) software and Primer 3 [39] and were validated by melting curve analysis. 5 μ g of RNA was isolated from each sample as described above and was used to create first-strand cDNA using random hexamers and reverse transcriptase (Superscript II; Invitrogen, Carlsbad, CA), according to the manufacturer's instructions. Amplification was performed using the SYBR Green Supermix kit (Bio-Rad, Hercules, CA) on an iCycler system (Bio-Rad, Hercules, CA). Three replicates were performed and the data averaged for each cDNA sample and primer pair combination. Those fold-changes with a 95% confidence interval excluding one were considered significant.

Gene sets used for enrichment analyses

Gene set enrichment analysis (GSEA) was performed to analyze the pattern of differential gene expression between forskolin treated and control basilar papillae using GSEA version 2 software [40]. Three different gene set packages were used, two of which were downloaded directly from the Broad institute website (www.broad.mit.edu/gsea).

To identify transcription factors which may be important for hair cell regeneration, a GSEA was performed using a gene set package called “c3.all.v2.5.symbols,” which was obtained from the BROAD Institute website. This package contains a series of gene sets defined by the presence of transcription factor motifs and predicted miRNA binding sites. The genes in each set of this package therefore share a *cis*-regulatory motif that is conserved across human, mouse, rat, and

dog genomes and will be referred to hereafter as the “mammalian gene sets.” The motifs used come from Xie et al. (2005) and the TRANSFAC database and include sets of genes sharing a 3'-UTR miRNA binding motif [41]. Even though these gene sets are not based on the chicken genome, we reasoned that these results would be of interest given the known conservation of miRNA targets among mammals [42]. We further surmised that if the conservation of miRNA targets is poorly conserved between mammals and non-mammalian vertebrates then an enrichment analysis might produce no statistically significant results. Any significant findings, however, would warrant further examination.

In order to validate the GSEA results from the analyses performed using the mammalian gene sets, GSEA was also run using a gene set package that was generated by scanning the portions of the chicken genome that are conserved with frog (*Xenopus tropicalis*) to identify gene sets sharing particular transcription factor motifs defined in the TRANSFAC database. These gene sets will hereafter be referred to as the “chicken/frog conservation gene sets.” Only conserved regions were used to reduce the number of false positives, as there is evidence to suggest that transcription factor recognition sites tend to be enriched in conserved portions of the genome [43]. However, recent genome-wide studies have demonstrated that many transcription factor binding sites are not conserved [44,45] and are also found outside of the proximal promoter region [44,46]. Thus, our approach should be considered to be conservative in the sense that some true binding sites may be overlooked, but those that are identified have a higher likelihood of being functional. The frog genome in particular was used in light of this organism's close evolutionary relationship to chickens. The use of conservation between more distantly related organisms, such as chicken and mammals, would be very strict and would result in the omission of many potentially significant positive results. To create these gene sets we downloaded the transcription start site for all chicken RefSeq genes, defined by the May 2008 RefGene table [47] using the UCSC Genome Bioinformatics site (genome.ucsc.edu). The region 2 kilobases around each transcription start site was identified within the May 2006 genome-wide multiple alignment of 6 vertebrate species to the chicken genome [48], also available through UCSC Genome Bioinformatics site. In order to identify putative transcription factor binding sites, the chicken sequences, along with aligned regions from frog, were analyzed using the TRANSFAC MATCH algorithm with a cutoff chosen to minimize the sum of false positives and false negatives [49]. The analysis was performed for all vertebrate transcription factor matrices in the 2009.1 release of TRANSFAC [50], and putative binding sites were considered to be evolutionarily conserved if matches were also found at the aligned positions in both chicken and frog sequences and had no gaps present in the multiple alignment of these species.

To assess the functional relevance of the pattern of differentially expressed genes across a variety of organisms and systems, GSEA was performed using a gene set package called “c2.all.v2.5.symbols” which was also downloaded from the BROAD Institute website. This package defines curated sets of genes based on specific experimental findings from experiments on human and model animal tissue, which includes canonical pathways and chemical/genetic perturbations based gene sets. These gene sets will hereafter be referred to as the “curated gene sets.” The relevant reference is given on the BROAD website for each curated gene set for assessment of relevance.

Gene set enrichment analysis

The GeneSpring processed data from the 38,535 original probes was collapsed into 13,159 genes based on gene symbols. Some genes were assigned to one or multiple gene sets

downloaded with the GSEA package. There are a total of 837 gene sets in the mammalian gene sets package, 50 of which were excluded by gene set size criteria (15–50), leaving 783 to be included in our analysis. 359 of the 566 chicken/frog conservation gene sets met this size threshold criterion, as did 1,197 out of the 1,892 curated gene sets (Table 1).

Genes were first ranked by their signal-to-noise ratio between the forskolin and control groups. In other words, the genes most consistently overexpressed in the forskolin samples were ranked at one end of the list and those most underexpressed in this group were ranked at the other end. GSEA asks whether the genes that make up a particular gene set are randomly distributed throughout the ranked list of genes, or whether they have a tendency to cluster at the top or bottom of the list. This question was answered by calculating for every gene set a running sum statistic, the maximum of which is referred to as the enrichment score (ES). Each ES is then normalized to the size of its corresponding gene set to produce a normalized enrichment score (NES). Statistical significance of each NES is determined by comparing that NES to the distribution of ESs generated by randomly permutating the genotype class labels of the data set. Therefore, the null hypothesis of a GSEA is that the distribution of a gene set throughout the ranked list of genes is random with regards to the two treatment conditions being compared. The alternative hypothesis is that location of genes in a set is associated with the treatment conditions. Both the p-value and false discovery rate (FDR; q-value) were calculated for each set. Gene sets with a FDR less than 0.25 and a p-value less than 0.05 were considered differentially expressed. The GSEA parameters used were as follows: metric = signal to noise; permutation number = 1,000; gene size minimum = 15; gene size maximum = 500; enrichment statistic = classic; permutation type = phenotype. One GSEA was performed using the 24-hour control data and 72-hour control data to negatively control for gene expression changes occurring with culture duration, as well as false positives not reflective of the treatment condition.

Pre-microRNA181a and anti-microRNA181a transfection

For functional miR181a experiments, basilar papilla explants from 0-day-old chicks were cultured with or without forskolin for 72 hours as described above. Basilar papillae from both conditions were also transfected with either a miR181a precursor (Ambion, Austin, TX) or a non-targeting miRNA which served as a negative

control (Ambion, Austin, TX) at a final concentration of 100 nM. Transfections were performed for six hours in serum-free medium which was eventually replaced with regular medium. BrdU was present at a concentration of 0.01% for the entire culture duration, except for the six-hour transfection. Some basilar papillae were also cultured for 24 hours with forskolin as described above and then transfected with anti-miR181a (Ambion, Austin, TX) to suppress endogenous miR181a. Transfections were performed using the lipid-based X-tremeGENE SiRNA Transfection Reagent (Roche, Indianapolis, IN) per the manufacturer's instructions.

Antibody labeling

After 72 hours in culture basilar papillae were fixed in 4% PFA in PBS for 30 minutes. All fixative was removed by three 5-minute washes in PBS. The tissue was blocked and permeabilized using a solution of PBS with FBS (10%) and Triton-X (0.1%) for one hour. Each basilar papilla was then incubated with mouse anti-BrdU antibodies (1:40, BD, Franklin Lakes, NJ) in PBS for one hour. After washing with PBS, alkaline phosphatase-conjugated goat anti-mouse IgG (1:400, Santa Cruz, Santa Cruz, CA) in PBS with Triton-X (0.1%) was added for one hour. After washing in PBS, alkaline phosphatase substrate was produced using the NBT/BCIP Reagent Kit (Invitrogen, Carlsbad, CA) per the manufacturer's instructions and then added to the tissue for approximately five minutes. All substrate was then thoroughly washed with PBS.

Statistics

Basilar papillae immunohistochemically labeled for BrdU were viewed using brightfield microscopy and were imaged using a digital camera attached to a Zeiss Stemi SV 11 stereoscope. The borders of the sensory epithelium were easily viewed both by direct microscopy and in the captured images. The intraepithelial location of BrdU positive nuclei was confirmed through focal plane adjustments. Only those nuclei which were clearly within the epithelium were counted. Unpaired Student's t-tests were performed to determine the statistical significance of the comparisons discussed in the text using a cut-off of $p < 0.05$.

Co-labeling experiments

To determine whether any newly produced BrdU positive cells express the early hair cell marker myosin VI, some basilar papillae were transfected with pre-miR181a as described above and

Table 1. Gene set enrichment analysis results.

Gene Set Package	Statistic Description	24H FSK	24H CTL	48H FSK	48H CTL	72H FSK	72H CTL

The number of mammalian miRNA/transcription factor motif based ("Mammalian"), chicken/frog conservation transcription factor motif based gene sets ("Conservation"), and curated gene sets from the BROAD Institute ("Curated") meeting the criteria $p < 0.05$ and q (false discovery rate) < 0.25 for forskolin (FSK) and control (CTL) samples after 24, 48, or 72 hours in culture.

doi:10.1371/journal.pone.0011502.t001

cultured for 72 hours. At the end of the culture duration, the tegmentum vasculosum and tectorial membranes were removed prior to fixation in 4% PFA for 30 minutes. Basilar papillae were cryoprotected overnight in 30% sucrose and then embedded in PBS with 1% low melting point agarose and 18% sucrose. The tissue was cryosectioned at 10 μ m and then blocked and permeabilized as described above. Sections were labeled for both myosin VI and BrdU as previously described [12]. Sections were then incubated with rabbit anti-myosin VI (1:350, Proteus, Ramona, CA) in blocking solution for one hour. After washing, sections were then incubated in Alexa Fluor 546 conjugated anti-rabbit secondary antibodies (1:1,000, Invitrogen, Carlsbad, CA) for one hour. After washing, basilar papilla sections were post-fixed in 4% PFA for one hour. The cryosections were then washed in PBS before 20 minute 2M HCl treatment to expose BrdU. After thorough washing, sections were incubated with mouse anti-BrdU antibodies (1:40, BD, Franklin Lakes, NJ) for one hour. After 3 additional PBS washes, sections were incubated with Alexa Fluor 647 conjugated anti-mouse secondary antibodies (Cell Signaling Technology, Danvers, MA) for one hour. After thorough washing, sections were mounted on glass slides in Vectashield fluorescent mounting medium (Vector Laboratories, Burlingame, CA). Images were captured using a Zeiss LSM 510 confocal microscope.

Results and Discussion

Differential expression of genes in the forskolin and control groups increases as a function of time

We report here a systematic comparison of genome-wide expression between proliferating and non-proliferating chick auditory epithelia using Affymetrix whole genome chicken microarrays. The forskolin-induced proliferation paradigm was chosen for this study given the robustness of the effect, which we reasoned would facilitate identification of the molecular events resulting in the production of new hair cells. RNA was isolated from control and forskolin-treated samples cultured for 24, 48 and 72 hours. BrdU incorporation, a marker for S-phase entry, is seen at 72 hours in the forskolin paradigm. Since S-phase entry is the

criterion that distinguishes the avian epithelium from that in mammals, we have concentrated our analysis on this time point.

The isolated RNA from proliferating and non-proliferating auditory epithelia was amplified, biotinylated, hybridized to Affymetrix chicken arrays and scanned as described. The normalized data were then filtered by expression to exclude all probes that were expressed below 20% of the maximum expression level in at least one of the samples at each time point. This measure was taken to ensure that differential expression of genes expressed at very low levels were not assigned a disproportionate amount of significance. 32,509 out of 38,535 probes in the microarray met this initial criterion in the 72-hour samples (Table 2). Of the 32,509 filtered probes, 5,032 had a corrected p-value less than 0.05 at 72 hours. Of these 5,032 genes, 2,824 had at least a two-fold change in expression, which was used as a criterion for functional significance. The same statistics from the 24- and 48-hour samples are also shown in Table 2. A proportional Venn diagram clearly shows differential expression of far more genes at 72 hours than at 24 or 48 hours, but expression of most of the genes differentially expressed at the two earlier time points are also affected at 72 hours (Figure 1). It is not surprising that far fewer genes are differentially expressed at 24 and 48 hours than at 72 hours, given that there must be some latency following exposure to forskolin before gene expression is affected. A heat map revealed that directionality of fold-changes for specific genes remained fairly consistent at 24, 48, and 72 hours (Figure 2). There also appeared to be a general trend toward larger fold-change differences at the two later time points.

Many genes thought to be related to cellular proliferation and inner ear development were differentially expressed between the two conditions at multiple time points (Table 3). The complete lists of genes differentially expressed between the control and forskolin conditions at 24, 48, and 72 hours are included as Supporting Information (Tables S1, S2, and S3, respectively). Given that cellular proliferation is first observed in the basilar papilla at 72 hours in culture with forskolin, the following discussion will focus on data from this particular time point. One gene that is differentially expressed after 72 hours of exposure to forskolin is cyclin I (CCNI), a cell cycle regulator, which is over three-fold

Table 2. Microarray analysis statistics.

Statistical Filtering	24 H			48 H			72 H		
	Number of Probe Sets	Probe Sets F>C	Probe Sets F<C	Number of Probe Sets	Probe Sets F>C	Probe Sets F<C	Number of Probe Sets	Probe Sets F>C	Probe Sets F<C

^aThe entire gene expression data set was filtered to exclude probes whose expression was not at least 20% in at least one out of the six 24-hour samples (24 H), six 48-hour samples (48 H), or twelve 72-hour samples (72 H). The statistics reported are based only on those probes that met this criterion. Half of the samples from each time point were treated with forskolin (F) and the remainder served as controls (C). Shown in boldface are the statistics for the list of genes defined to be differentially expressed using $p < 0.05$ and fold-change > 2 .

doi:10.1371/journal.pone.0011502.t002

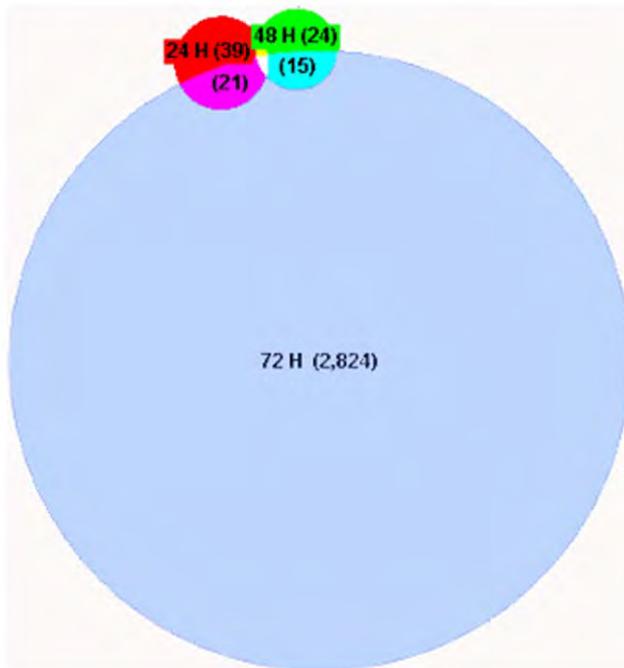

Figure 1. Far more genes were differentially expressed at 72 hours than at 24 or 48 hours of exposure to forskolin. Shown is a proportional Venn diagram indicating the number of genes significantly ($p < 0.05$ and fold change > 2) differentially expressed at 24, 48, and 72 hours of exposure to forskolin. The number of genes in each category is indicated in parentheses. Far more genes are affected at 72 hours than at either of the two earlier time points. A little over half of the genes differentially expressed at 24 or 48 hours are also differentially expressed at 72 hours. Only one gene, AMPH, was affected at all three time points.
doi:10.1371/journal.pone.0011502.g001

underexpressed in the forskolin samples at 72 hours and is downregulated in proliferating murine cardiomyocytes (Table 3) [51]. Wnt5a is underexpressed in regenerating tissue, a noteworthy observation as inactivation of this gene has been linked to cellular proliferation in a particular form of leukemia [52]. Wnt proteins are also thought to play a role in the development of the lateral line in zebrafish (reviewed in [53]) and chicken inner ears [54,55,56]. Frizzled homolog 10, a gene likely to play a role in cellular proliferation, is over 15-fold overexpressed in proliferating versus non-proliferating tissue after 72 hours in culture [57].

Differential gene expression is confirmed by qPCR

Quantitative PCR (qPCR) was performed on select genes in order to validate the microarray data. Primers were designed for twelve genes that were found by microarray to be differentially expressed between the two conditions at 72 hours; seven genes were upregulated and five were downregulated in the forskolin condition. QPCR confirmed the directionality of the microarray findings for nine out of the twelve genes tested (75%). The fold-changes of these nine genes were all significantly different from one (95% confidence interval, data not shown), confirming their differential expression as detected by microarray. These findings validate the initial microarray results, so further analyses were performed on the gene expression data set.

Curated gene set enrichment results

Our initial analysis of expression of individual genes that were differentially expressed revealed that many are known to be

involved in control of the cell cycle and hair cell differentiation. To more systematically identify genes that were correlated with specific phenotypes, we used gene set enrichment analysis (GSEA), a computational method to determine the expression of genes associated with specific empirically determined phenotypes. Gene sets packages were downloaded from the Broad Institute website and were used for GSEAs on the Affymetrix expression data from 24, 48, and 72 hours (Table 1). An additional GSEA was performed comparing the microarray data from the 24-hour control samples to that in the 72-hour control samples to serve as a negative control for changes in gene expression resulting from the culture conditions rather than exposure to forskolin. This GSEA produced no significantly (FDR < 0.25 and p -value < 0.05) enriched gene sets for any of the three gene set packages used (data not shown).

To assess the functional relevance of the genes that were differentially expressed, a GSEA was performed using manually curated gene sets downloaded from the Broad Institute website. This package contains sets of genes found by individual experiments to be associated with specific phenotypes. The complete GSEA results for all utilized gene sets in this and all subsequent GSEAs are included as Supporting Information (Tables S4, S5, S6, S7, S8, S9, S10, S11, S12). Consistent with our observation of individual gene expression, the GSEA performed using curated gene sets showed that in forskolin treated basilar papillae many gene sets associated with cell cycle control are significantly enriched at various time points. For example, at 24, 48, and 72 hours there is enrichment of the following gene sets: SERUM_FIBROBLAST_CELL_CYCLE [58], HSA04110_CELL_CYCLE [59], [60,61], CELL_CYCLE [62], CELL_CYCLE_KEGG [59,60,61], GOLDRATH_CELL_CYCLE [63], CELL_CYCLE_CHECKPOINT, G1_TO_S_CELL_CYCLE_REACTOME [64], and BRENTANI_CELL_CYCLE [65] in explants exposed to forskolin (Table 4). The enrichment statistics for all gene sets used in this GSEA are included as Supporting Information (Tables S4, S5, S6). These findings are expected and instill confidence about the rest of the enrichment analysis results, given that forskolin treatment is known to stimulate S-phase entry in normally quiescent cells [22,23].

The GSEA based on the curated gene sets also revealed that targets of E2F1, a transcription factor known to be important for cell cycle control, in human primary fibroblast cells identified by ChIP analysis (REN_E2F1_TARGETS [66]) are enriched in the proliferating auditory epithelia at both 48 and 72 hours. Further, a set of genes in the retinoblastoma pathway identified by microarray analysis in human cell lines (VERNELL_PRB_CLSTR1 [67]) was found to be significantly enriched after 24, 48, and 72 hours in culture with forskolin. These findings further underscore the potentially important role of the E2F1 transcription factor and the retinoblastoma protein pathway in auditory hair cell regeneration.

A particularly interesting result of the GSEA using the curated gene sets is the observation that a set of genes found to be upregulated in mouse embryonic, neural and hematopoietic stem cells (HSC) relative to differentiated brain and bone marrow cells (STEMCELL_COMMON_UP [68]) is also enriched in the basilar papilla after culture with forskolin for 24, 48, or 72 hours. Further, a set of genes found to be downregulated in stem cells (STEMCELL_COMMON_DN [68]) in the same study were also enriched in the quiescent tissue relative to proliferating tissue after 48 or 72 hours in culture, suggesting that genes downregulated in stem cells are also downregulated in the proliferating basilar papilla.

Though not widely accepted, there is evidence for the existence of stem cells within the postnatal organ of Corti [69]. Additionally, approximately 4% of supporting cells show stem cell-like behavior

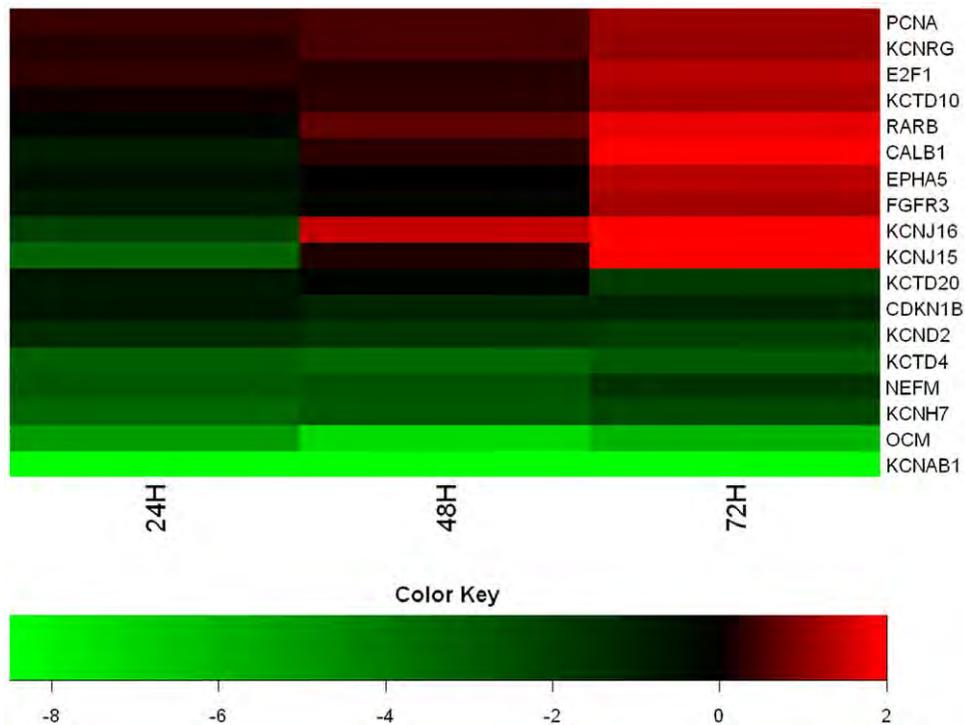

Figure 2. Fold-change differences of selected genes of interest remain stable at 24, 48, and 72 hours. Shown is a heat map depicting fold-changes between the forskolin and control conditions for a set of genes of interest the three time points indicated. The genes shown were selected because of their known expression in the inner ear (i.e., RARB, CALB1, OCM), ion channel identity (e.g., KCNAB1, KCNJ15), or relevance to the present study (i.e., E2F1). The genes span a range of fold-changes and are both up and downregulated with forskolin treatment. Fold-changes are given as $\log_2(\text{expression in forskolin}/\text{expression in control})$. The directionality of fold-changes was fairly consistent across time points, but there was a slight general trend toward increasing fold-change values from 24 to 72 hours. doi:10.1371/journal.pone.0011502.g002

in that they undergo multiple rounds of division [70]. Recent work has shown that murine embryonic and induced pluripotent stem cells retain the capacity to differentiate into mechanosensitive cells which resemble immature hair cells [71]. It is interesting that genes found to be upregulated in HSCs specifically are also upregulated in proliferating basilar papillae given that HSCs are thought to remain in a state of quiescence until stimulated to proliferate by external signals [72,73]. The chick basilar papilla is also quiescent until injury stimulates regeneration of hair cells by signals that have not yet been identified. It is therefore very interesting that proliferating basilar papillae overexpress genes that are also overexpressed in HSCs [68]. If the basilar papilla does in fact possess stem cells that share some properties with HSCs then it may be possible to stimulate the production of new hair cells using signals known to induce normally quiescent HSCs to proliferate. These results are consistent with the hypothesis that in forskolin treated basilar papillae some supporting cells are stimulated to dedifferentiate and express stem cell markers, prior to division and production of new hair cells.

It is worth noting that at 24 and 48 hours after exposure to forskolin, there is enrichment of the following curated gene sets, all of which are associated with cell death and/or apoptosis: BRENTANI_DEATH [65], HSA04210_APOPTOSIS [59,60,61], APOPTOSIS [64], APOPTOSIS_GENMAPP [64]. There is also enrichment of the gene set PASSERINI_APOPTOSIS [74] after 48 hours of exposure to forskolin. It is believed that forskolin induces proliferation in the inner ear without injury and subsequent regeneration, but this has never been definitively proven. However, the proliferation that is seen in the basilar papilla following exposure to forskolin is more

robust than that seen following exposure to gentamicin, which causes hair cell death and regeneration [22]. Unpublished experiments performed for the same paper also did not show a qualitative loss of hair cells at 24, 48, or 72 hours, whereas hair cell ejection from the basilar papilla is seen as early as 30 hours following subcutaneous administration of gentamicin [75]. Markers of cell death in avian hair cells can appear even earlier following injury and begin with TIAR translocation as early as 12 hours after injury, before caspase activation which can occur as early as 30 hours after injury [76,2]. Our gene expression data do not show differential expression of key markers of hair cell death such as caspase-3 and caspase-9 [76]. Regardless, the GSEA results suggest a possible contribution of apoptosis in forskolin induced proliferation in the avian inner ear. As the aim of the present study was to identify novel genes and pathways important for the production of new hair cells in deafened animals, the reported findings are of considerable interest regardless of a possible contribution of injury with subsequent regeneration in the forskolin-induced proliferation model of hair cell regeneration. Additional work will be needed to determine just how much, if any, of this proliferation is in fact the result of injury to the auditory epithelium.

Mammalian gene set enrichment results

To determine which miRNAs were likely upregulated to give rise to the observed pattern of differential gene expression detected by microarray, an additional GSEA was performed using the mammalian gene sets which are based on genomic conservation between the human, rat, mouse, and dog genomes. These gene sets were used on our chicken gene expression data because they included not only transcription factor binding site, but also

QPCR and microarray data for individual genes of interest and genes selected for qPCR validation as described in the text. Multiple microarray values represent different probe sets for the same gene.

doi:10.1371/journal.pone.0011502.t003

miRNA binding sites, which are fairly well conserved between species [42]. Using these mammalian gene sets and a false discovery rate cut-off of 0.25 as suggested by [40], 210 out of 783 gene sets were significantly enriched in the control condition and 37 in the forskolin condition at 72 hours (Table 1). As a negative control, enrichment of predicted targets of the transcription factor PAX6 was examined, given its known role in retinal development [77,78] and absence of expression in the developing chicken inner ear [79]. That a pathway thought not to be important in the inner ear was not activated by forskolin exposure underscores that significantly enriched gene sets reflect real changes in gene expression (Supporting Information).

The difference in the number of gene sets associated with the control and forskolin conditions is striking, and it is worth pointing

out that many of the gene sets associated with the control condition are miRNA gene sets, each of which represents a group of genes that are predicted targets of a specific miRNA. The association of these sets with the control condition implies that the miRNA target genes are down-regulated following forskolin treatment. Thus, we hypothesize that these miRNAs are upregulated in the forskolin group. We put forward this entire set of miRNAs as candidates whose role in hair cell regeneration and cellular proliferation warrants further investigation. Specific miRNAs and transcription factors of interest based on our analysis using the mammalian gene sets are presented in Table 5. A complete list of all significantly enriched gene sets from this analysis are included in the Supporting Information section (Tables S7, S8, S9).

Shown are the curated gene set enrichment analysis results for selected gene sets of interest at 24, 48, and 72 hours. The gene sets shown here were downloaded from the BROAD Institute website and represent empirically defined sets of genes. References for each gene set are provided in the text. Italicized are those gene sets with p-value <0.05 and false discovery rate (FDR) <0.25, which are taken as significant. Gene sets are directly as they appear in the Molecular Signatures Database on the Broad Institute website.

Shown are the mammalian gene set enrichment analysis results for selected gene sets of interest at 24, 48, and 72 hours. Italicized are those gene sets with p-value < 0.05 and false discovery rate (FDR) <0.25, which are taken as significant. Gene sets are directly as they appear in the Molecular Signatures Database on the Broad Institute website.

doi:10.1371/journal.pone.0011502.t005

Some of the miRNAs identified by enrichment analysis are interesting candidates for further study given what is already known about their function. For example, miR141 and miR200a are expressed in the chicken inner ear epithelium, and are important regulators of epithelial-mesenchymal transition [30,80]. It is also interesting that the miR27 family showed up as one of the most significant gene sets in this particular analysis given the known role of this miRNA in cellular proliferation. Specifically, downregulation of this miRNA seems to decrease proliferation in the context of hepatic stellate cell activation, an early event in liver fibrosis [81]. MiR27a is overexpressed in human gastric adenocarcinoma, and inhibition of this miRNA limits proliferation [82]. Another study has also shown that the oncogenic activity of miR27a in human breast cancer cells is likely due to downregulation of genes controlling the G2-M cell-cycle checkpoint [83]. MiR181a is known to be expressed in the mammalian inner ear [28], and has a pro-proliferative role in human leukemia cells, which appears to be mediated by suppression of the cell cycle inhibitor p27 [33]. Given the abundance and nature of evidence for a role of miR181a, miR27a, and miR141/miR200a in cellular proliferation or inner ear development, we put these forward as particularly intriguing candidates for further study within the context of auditory hair cell regeneration.

Chicken/frog gene set enrichment analysis

While the primary goal of the GSEA with the mammalian gene sets was to identify miRNAs that may be important for hair cell regeneration, interestingly some transcription factor gene sets were found to be up- and downregulated in the forskolin condition. This was surprising in light of the fact that these sets were based on portions conserved across only selected mammalian genomes, which were expected to differ significantly from gene sets based on the chicken genome. To verify the up- and downregulation of these gene sets in the chicken inner ear an additional GSEA was performed using gene sets based on scanning the portions of the chicken genome that are conserved with frog (*Xenopus tropicalis*) to look for enrichment of sets of genes sharing particular transcrip-

tion factor recognition sites obtained from the TRANSFAC database. Using a q-value cutoff of 0.25 there were 41 gene sets associated with forskolin treatment, and 331 gene sets associated with forskolin treatment (see Table 1). The enrichment statistics for all gene sets included in this analysis are presented as Supporting Information (Tables S10, S11, S12). Of the six gene sets that were significantly enriched in the forskolin condition, four are sets of genes that share known E2F1 binding sites (Table 6). Additionally, some E2F1 gene sets are significantly enriched in forskolin treated tissue at 24 and 48 hours relative to untreated controls (Table 6), suggesting that upregulation of predicted E2F1 targets occurs early after forskolin treatment and is sustained until 72 hours in culture, when new cells are first seen [22]. Many E2F/E2F1 gene sets are also enriched in the forskolin treated tissue when the mammalian gene sets (Table 5) are used to compare the expression data from forskolin samples fixed after 24 and 72 hours in culture, suggesting agreement between the GSEAs performed using the mammalian gene sets and chicken/frog conservation gene sets. The identification of E2F/E2F1 by both analyses strongly suggests a role for this transcription factor in forskolin induced proliferation in the chicken inner ear.

E2F1 is an intriguing candidate for further study given its known role in cell cycle control (reviewed in [84]) and potential role in inner ear development (reviewed in [85]). E2Fs bind hypophosphorylated pRBs which then sequester these factors. pRBs can be phosphorylated by cyclin-dependent kinases (CDKs), rendering these proteins unable to bind E2Fs thereby releasing these factors which then become transcriptionally active [86,87,88]. Interestingly, overexpression of E2F1 has been shown to induce quiescent REF-52 cells to enter S-phase [89]. E2F1 forms part of an 'activating' E2F complex that can interact with pocket proteins (pRBs) to control the cell cycle [90]. E2F1 exclusively binds the pRB RB1, and peaks in expression during the G1-S checkpoint [90]. Given the central role of E2Fs in cell cycle control, our finding that genes targeted by E2F1 are enriched among the genes that are overexpressed in the proliferating chick inner ear suggests a role for this transcription factor in hair cell regeneration.

Table 6. Conservation gene set enrichment analysis results.

Shown are the results of the conservation gene set enrichment analysis performed on gene expression data from 24, 48, and 72 hours in culture. These analyses were performed using gene sets based on transcription factor motifs in regions conserved between the chicken and frog genomes. The gene sets shown here were downloaded from the BROAD Institute website and represent empirically defined sets of genes. References for each gene set are provided in the text. Italicized are those gene sets with p-value <0.05 and false discovery rate (FDR) <0.25, which are taken as significant. Gene sets are directly as they appear in the Molecular Signatures Database on the Broad Institute website.

doi:10.1371/journal.pone.0011502.t006

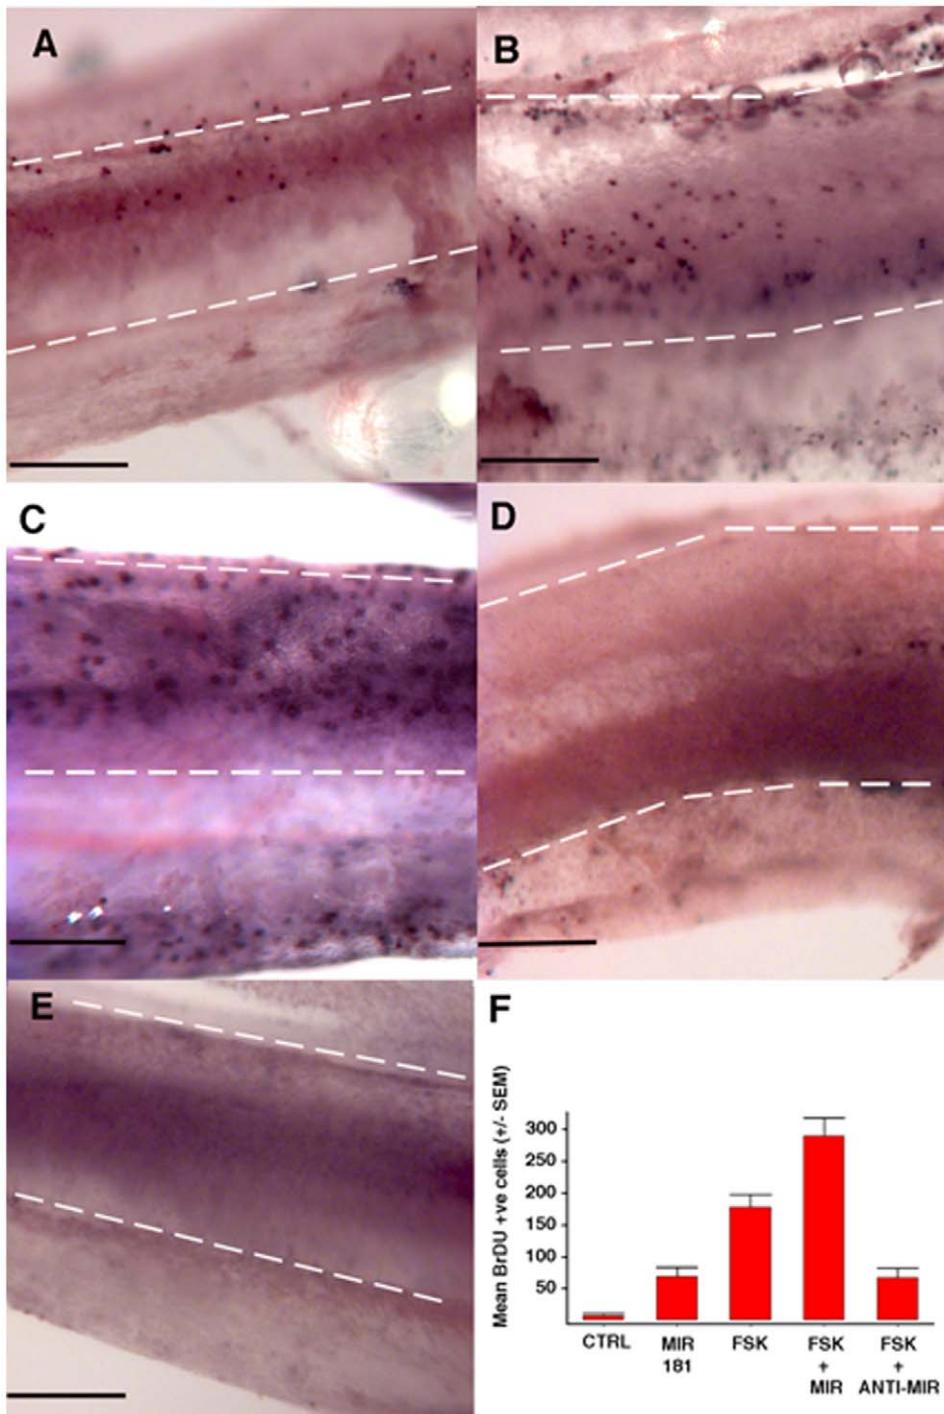

Figure 3. MicroRNA181a overexpression produces proliferation in the chicken basilar papilla. Basilar papillae from 0-day-old chicks were cultured for 72 hours in the presence of BrdU, the nuclear incorporation of which was detected by antibody labeling. In A–E sensory epithelia are outlined with dashed white lines. The neural edge of each epithelium is at the bottom, the abneural edge is at the top, the distal end is to the right and the proximal end is to the left of the image. BrdU-positive (i.e., recently divided) cells are immunohistochemically labeled and appear as purple dots. Individual cochleas were treated with 100 nM pre-miR181a (A), 100 μM forskolin (FSK) (B), FSK + 100 nM pre-miR181a (C), 100 μM FSK + 100 nM anti-miR181a (D), or DMSO as a vector control (E). A pro-proliferative effect of miR181a can be appreciated. Further, knocking down endogenous miR181a appears to have a large suppressive effect on forskolin induced proliferation. Transfection was achieved in the first 24 hours of culture using X-tremeGENE siRNA Transfection Reagent in accordance with the manufacturer's instructions (Roche, Indianapolis, IN). The miRNA containing media was removed after 24 hours and replaced with normal medium. The summary of the average number of BrdU positive cells for the control (n=7), miR181a (n=8), forskolin (n=8), forskolin + miR181a (n=8), and forskolin + anti-miR181a (n=3) conditions. The following comparisons were all statistically significant: control versus miR181a ($p=0.001$), control versus forskolin ($p<0.001$), miR181a versus forskolin ($p<0.001$), forskolin versus forskolin plus anti-miR181a ($p=0.008$) and forskolin versus forskolin plus miR181a ($p=0.005$). Scale bars in panels A–E=0.2 mm. doi:10.1371/journal.pone.0011502.g003

Functional microRNA181a studies

Of all the miRNAs whose predicted targets were significantly enriched in control relative to forskolin treated basilar papillae, miR181a was specifically selected for functional studies in light of its high level of statistical significance, known expression in the developing mammalian inner ear [28], and pro-proliferative role in human leukemia cells, which appears to be mediated by suppression of the cell cycle inhibitor p27 [33]. To test whether miR181a overexpression is sufficient to stimulate proliferation, chick basilar papilla explants were transfected with either pre-miR181a, which is converted to mature miR181a within cells, or a non-targeting negative control miRNA. Incorporation of the thymidine analog BrdU was used to assay proliferation. Basilar papillae transfected with pre-miRNA had on average 68.75 (\pm SEM = 13.54) BrdU positive cells, significantly more than organs transfected with a non-targeting miRNA which averaged only 7.00 (\pm SEM = 10.23) BrdU positive cells ($p < 0.01$, Figure 3). MiR181a overexpression is therefore sufficient to stimulate proliferation in the normally quiescent chick auditory epithelium.

Basilar papillae cultured with forskolin for 72 hours and transfected with a non-targeting miRNA had on average 178.25 (\pm SEM = 19.02) BrdU positive cells, significantly more than is seen with miR181a overexpression ($p < 0.05$) which suggests that miR181a upregulation may account for only a portion of forskolin's mitogenic effect (Figure 3). To determine whether miR181a expression is necessary for forskolin induced proliferation, some basilar papillae were cultured with forskolin for 24 hours, then transfected with anti-miR181a to suppress endogenous miR181a, then cultured with forskolin for an additional 24 hours. Basilar papillae transfected with only anti-miR181a without forskolin treatment had an average of only 14

(\pm SEM = 3.06) BrdU positive cells per epithelium, not significantly different from controls. Basilar papillae exposed to forskolin and transfected with anti-miR181a had an average of 67.33 (\pm SEM = 13.38) BrdU positive cells, significantly less than the basilar papillae that were cultured with forskolin and transfected with a negative control miRNA ($p < 0.01$), suggesting that endogenous miR181a contributes to the pro-proliferative effect of forskolin in the chick inner ear.

To see whether miR181a could enhance the already robust pro-proliferative effect of forskolin, basilar papillae were transfected with pre-miR181a and cultured in the presence of forskolin for 72 hours. These basilar papillae averaged 289.63 (\pm SEM = 28.04) BrdU positive cells per basilar papilla, which is significantly higher than the forskolin effect alone ($p < 0.01$). This observation reaffirms the finding that endogenous miR181a is an important mediator of forskolin induced proliferation in the chick inner ear and is limited in part by the ability of forskolin to stimulate upregulation of miR181a.

Given the observation that miR181a overexpression is sufficient to stimulate proliferation in the chick auditory epithelium, basilar papillae were transfected with pre-miR181a or nontargeting negative control miRNA and then cryosectioned and labeled for BrdU and the early myosin VI to determine whether any of the newly produced BrdU positive cells express the early hair cell marker. As is seen in Figure 4, some cells labeling for BrdU 72 hours after transfection with pre-miR181a are located at the most apical portion of the basilar papilla, an area occupied by only hair cells and thin supporting cell processes. Further, some cells with nuclear BrdU labeling also have cytoplasmic myosin VI labeling. No such co-labeling cells were observed in basilar papillae transfected with a non-targeting miRNA. These results

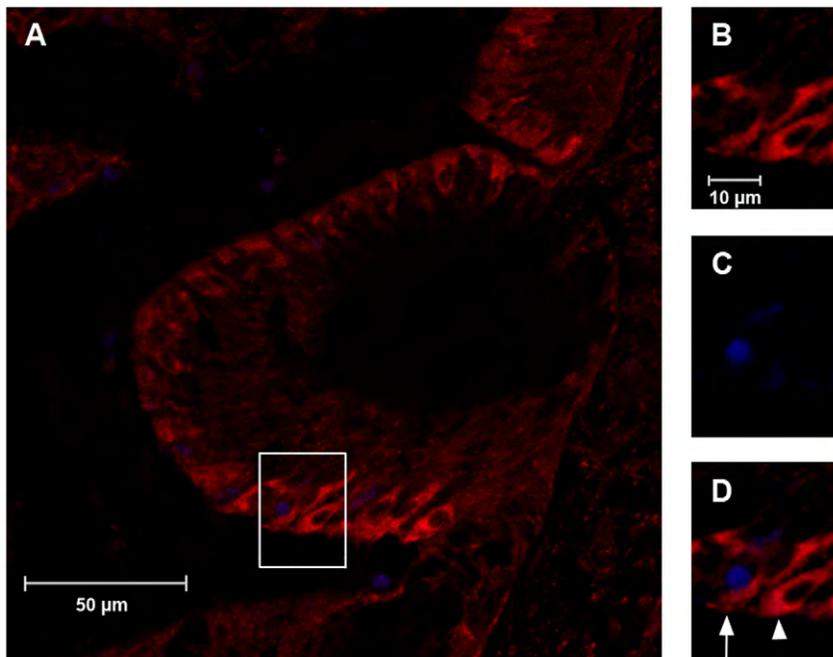

Figure 4. Some new cells produced by miR181a transfection express the early hair cell marker myosin VI. Shown is a confocal image of a basilar papillae that was transfected with pre-miR181a, cultured for 72 hours, then cryosectioned and labeled for BrdU (blue) and the early hair cell marker myosin VI (red) (A). The apical surface of hair cells is to the left of the image and the neural edge of the basilar papillae is toward the bottom. The tectorial membrane has been removed to allow for antibody labeling. The inset of A is also shown in panels B (myosin VI), C (BrdU) and D (merge). The arrow in D shows a cell that expresses myosin VI and has a BrdU positive nucleus, whereas the arrowhead shows a cell that is labeling for myosin VI but not BrdU. The double-labeled cell is one that has been stimulated to divide and subsequently begin differentiating toward a hair cell phenotype. The scale bar in B also applies to C and D. doi:10.1371/journal.pone.0011502.g004

suggest that miR181a overexpression results in the production of new hair cells.

It is not surprising that a single miRNA is able to stimulate S-phase entry in the avian auditory epithelium given the mounting evidence that miRNAs can affect cell cycle regulation in a variety of systems. MiR181a specifically has been shown to have a proliferative effect in human myeloid leukemia cells [33]. Interestingly, this effect appears to be mediated in part by producing downregulation of p27, which may represent a barrier to hair cell regeneration in the mammalian cochlea [34,35,91,92]. There is also evidence that many different miRNAs, including miR181a, are expressed in the developing mouse inner ear [28]. Despite these findings, studies on the role of miRNA in hair cell regeneration are limited in number and scope. One study revealed that the let-7 family of miRNA is downregulated in the regenerating newt auditory epithelium [32]. An interesting translational correlate to this finding is that let-7 reduces tumor growth in a rodent model of lung cancer, providing additional evidence for the antiproliferative effects of this particular family of miRNA [93]. Studies such as these underscore the importance of examining more closely the role of miRNA in hair cell regeneration, as induced underexpression of antiproliferative genes may ultimately allow regeneration of hair cells in mammals.

In summary, we have identified a possible role for miR181a in avian auditory hair cell regeneration. We have further identified additional miRNAs and transcription factors as candidates that warrant further investigation as potential targets for therapeutics aimed at replacing lost hair cells. Presented additionally are results suggestive of the presence of stem cells with properties similar to HSCs in the regenerating chick inner ear. Of all the candidates identified miR181a is specifically put forward for further study in *in-vivo* mammalian models of induced hearing loss in light of its demonstrated proliferative effect in the chicken inner ear as well as the fact that a miRNA based therapeutic could potentially be locally delivered to the middle ear and passively absorbed through the round window. This scenario seems plausible given that small molecules such as gentamicin can be delivered to the inner ear of patients in this fashion [94]. Computational analyses of our gene expression data suggest that the transcription factor E2F1 may also play a role in hair cell regeneration when many normally quiescent supporting cells are stimulated to re-enter the cell cycle and divide prior to differentiating into new hair cells. Additional functional studies will be necessary to ultimately determine what ability, if any, these players have to replace lost hair cells and result in recovery of compromised hearing thresholds in mammals.

Communicated by Frank H. Ruddle, Yale University, New Haven, CT, July 17, 1995

ABSTRACT Myosin VIIa is a newly identified member of the myosin superfamily of actin-based motors. Recently, the myosin VIIa gene was identified as the gene defective in shaker-1, a recessive deafness in mice [Gibson, F., Walsh, J., Mburu, P., Varela, A., Brown, K. A., Antonio, M., Beisel, K. W., Steel, K. P. & Brown, S. D. M. (1995) *Nature (London)* 374, 62–64], and in human Usher syndrome type 1B, an inherited disease characterized by congenital deafness, vestibular dysfunction, and retinitis pigmentosa [Weil, D., Blanchard, S., Kaplan, J., Guilford, P., Gibson, F., Walsh, J., Mburu, P., Varela, A., Leveilliers, J., Weston, M. D., Kelley, P. M., Kimberling, W. J., Wagenaar, M., Levi-Acobas, F., Larget-Piet, D., Munnich, A., Steel, K. P., Brown, S. D. M. & Petit, C. (1995) *Nature (London)* 374, 60–61]. To understand the normal function of myosin VIIa and how it could cause these disease phenotypes when defective, we generated antibodies specific to the tail portion of this unconventional myosin. We found that myosin VIIa was expressed in cochlea, retina, testis, lung, and kidney. In cochlea, myosin VIIa expression was restricted to the inner and outer hair cells, where it was found in the apical stereocilia as well as the cytoplasm. In the eye, myosin VIIa was expressed by the retinal pigmented epithelial cells, where it was enriched within the apical actin-rich domain of this cell type. The cell-specific localization of myosin VIIa suggests that the blindness and deafness associated with Usher syndrome is due to lack of proper myosin VIIa function within the cochlear hair cells and the retinal pigmented epithelial cells.

Myosin VIIa is a newly identified member of the myosin superfamily of actin-based motors (1–3). The gene encoding myosin VIIa is responsible for human Usher syndrome type 1B (USH1B) (4), a disease characterized by sensorineural hearing loss, absence of vestibular function, and a progressive retinal degeneration termed retinitis pigmentosa. It affects ≈4.4 per 100,000 in the total United States population and 3–6% of deaf children (5, 6) and is the most frequent cause of deaf-blindness. Mutations in the myosin VIIa gene are also responsible for a recessive deafness in mice termed shaker-1 (*sh1*) (7). *sh1* mice exhibit hearing loss following early degeneration of the sensory epithelium in the cochlea, and head tossing behavior due to vestibular dysfunction (8). We have cloned a large portion of the human myosin VIIa heavy-chain cDNA** and have generated antibodies specific to a tail domain of myosin VIIa. Myosin VIIa heavy chain is a 240-kDa polypeptide and its expression is restricted to retinal pigmented epithelial (RPE) cells, cochlear hair cells, and certain cells of the testis, lung, and kidney. These results provide compelling evidence that the blindness and deafness phenotypes associated with Usher disease are due to the lack of functional myosin VIIa polypeptide within a specific subset of retinal

and cochlear cells and suggest a role for myosin VIIa heavy chain in the development and maintenance of these sensory organs.

MATERIALS AND METHODS

Isolation of Human and Porcine Myosin VIIa cDNAs. The 130-bp PCR products encoding a portion of myosin VIIa identified from human and porcine cell lines and tissues (ref. 1; EMBL accession nos. L29145 and L29133, respectively) were used to screen a number of cDNA libraries. Screening of a human liver λZAPII cDNA library (provided by James Anderson, Yale Medical School) and a human testis λgt10 cDNA library (Clontech) resulted in nine overlapping clones, one of which, clone 10C, was found to encode the entire N-terminal 1075 aa of human myosin VIIa (GenBank accession no. U34227). Screening of a λgt10 cDNA library prepared from LLC-PK₁ porcine kidney cells (provided by Robert Reilly, Yale Medical School) resulted in two clones, one of which, 14C, encompassed the N terminus of porcine myosin VIIa (aa 1–566; GenBank accession no. U34226).

Preparation of Myosin VIIa-Specific Antibodies. A *HindIII*–*EcoRI* fragment encoding aa 877–1075 of human myosin VIIa was cloned into pGEX2-T (Amrad, Melbourne, Australia) to produce a 49-kDa glutathione S-transferase/myosin VIIa tail fusion protein. This insoluble fusion protein was extracted from the cell pellet with 0.5% (wt/vol) sodium *N*-lauroylsarcosine, diluted 1:10, brought to 1% (vol/vol) Triton X-100, and purified over a glutathione-Sepharose column. Rabbits were immunized with two 300-μg injections of purified fusion protein spaced 3 weeks apart and were bled 10 days after the second injection. To allow for affinity purification of serum, the same *HindIII*–*EcoRI* fragment was cloned into pQE-30 (Qiagen, Chatsworth, CA) and the resultant His₆-tagged myosin VIIa tail peptide was purified over a nickel-agarose column (Qiagen). The His₆-tagged myosin VIIa peptide was dialyzed into carbonate buffer containing 0.1% SDS and coupled to cyanogen bromide-activated Sepharose (Pharmacia). Rabbit serum was applied to the myosin-VIIa-tail affinity column and bound antibodies were eluted with low pH and dialyzed into phosphate-buffered saline (PBS: 10 mM sodium phosphate/137 mM NaCl, pH 7.4).

Immunoblot Analysis. Protein samples were homogenized in 5% (wt/vol) trichloroacetic acid and standardized for protein concentration by quantitation in the bicinchoninic acid (BCA) assay (Pierce). The trichloroacetic acid precipitation pellet was washed once with water before reconstitution in boiling 5× SDS/PAGE sample buffer to a final protein concentration of 0.9 mg/ml. After SDS/PAGE separation, proteins were transferred to poly(vinylidene difluoride) membrane and incubated with affinity-purified myosin-VIIa anti-

**The sequences reported in this paper have been deposited in the GenBank data base (accession nos. U34226 and U34227).

bodies, and the bound antibodies were visualized with a chemiluminescence kit (Boehringer Mannheim).

Immunolocalization Studies. Guinea pig temporal bones were rapidly removed into PBS containing 50 mM EGTA (PBS/EGTA). The round window membrane and stapes footplate were removed, and a small fenestra was made in the apical cochlear bony capsule in order to rapidly and directly perfuse the cochlear scalae with 4% paraformaldehyde in PBS/EGTA. After 5 min of initial perfusion, the remaining bony capsule was chipped away, the spiral ligament and stria vascularis were peeled away, and the cochlea were immersed in fixative for an additional 15 min. Half-turns of the cochlea spiral were cut free, and nonspecific binding sites were blocked in PBS/EGTA/5% bovine serum albumin for 20 min. Affinity-purified anti-myosin-VIIa or control nonimmune IgG was added at a concentration of 10 μ g/ml in PBS/EGTA/0.1% bovine serum albumin/1% normal goat serum for 1 hr at room temperature. Samples were washed with PBS/EGTA for 20 min before incubation for 1 hr at room temperature with a 1:150 dilution of rhodamine-conjugated goat anti-rabbit antibodies (Cappel) and 40 nM fluorescein-labeled phalloidin (Molecular Probes) in PBS/EGTA/0.1% bovine serum albumin/5% normal goat serum. Samples were washed with PBS/EGTA and placed in PBS/glycerol mounting medium (Citifluor, Kent, England). Samples were observed with a Bio-Rad MRC600 laser scanning confocal microscope.

Rat retina was excised and fixed for 5 min on ice in 4% paraformaldehyde in PBS/EGTA. Samples were quenched, cryoprotected, embedded for frozen sectioning, and prepared for immunostaining as described (9). Antibody incubations were as described above but were done for 20 min. Mounted slides were observed with a Nikon Diaphot 300 light microscope equipped with epifluorescence and differential interference contrast (DIC) imaging.

RESULTS

A 130-bp PCR fragment encoding a portion of the motor domain of human myosin VIIa near the ATP binding site (1) was successfully used to screen a human testis λ gt10 cDNA library. The isolated 3.5-kb cDNA encodes a myosin-like molecule (GenBank accession no. U34227) that has a 730-aa N-terminal motor domain, a 130-aa neck domain containing five light-chain binding repeats ("IQ" motifs; ref. 10), and a 210-aa tail. This tail is made up of two domains, a region of \approx 70 aa predicted to form an α -helical coiled coil (11) and a unique C-terminal globular domain. The human myosin VIIa testis cDNA is 99% identical at the nucleotide level to the 1547-nt fragment of human myosin VIIa cDNA (ref. 4; GenBank accession no. U17180). The testis cDNA sequence differs from the U17180 sequence at 11 sites (Fig. 1), reflecting a frameshift (nt 1433–1440; U17180) and three single-base-pair discrepancies. These differences in the human myosin VIIa cDNA result in changes in the predicted amino acid sequence that match the murine ortholog at those sites (7). Human myosin VIIa is 96% identical to cloned portions of both mouse (7) and porcine (GenBank accession no. U34226) myosin VIIa at the amino acid level and is 83% identical to the frog homolog (2) (Fig. 1). By comparison, human myosin VIIa is only 25–40% identical to the motor domain of members of other unconventional myosin classes. In particular, the N-terminal 100 aa and the C-terminal tail of myosin VIIa are unique to this motor.

Repeated attempts to isolate the entire tail domain of myosin VIIa have been unsuccessful. Since the known portion of the myosin VIIa tail domain is novel, we generated antibodies directed against a bacterially expressed fusion protein containing the available myosin VIIa tail. These

affinity-purified antibodies were used in immunoblot studies to analyze the expression profile of this protein. A 240-kDa polypeptide was detected in rat retina, kidney, temporal bone, and testis, while a 200-kDa polypeptide was detected in lung (Fig. 2). No expression was observed in rat liver, muscle, intestine, stomach, or brain. This finding is consistent with the mRNA expression data of Gibson *et al.* (7), which showed a 9.5-kb transcript in mouse kidney and testis and a slightly smaller species in lung. The antibodies did not recognize myosins II, I, or VI, all of which are known to be expressed within these tissues and which exhibit molecular weights different from that seen with the myosin VIIa-specific antibodies.

PCR evidence suggests that another member of the myosin VIIa family is expressed in humans, myosin VIIb (1). Myosin VIIb has not been cloned, so we cannot specifically compare it with myosin VIIa. Several lines of evidence suggest that myosin VIIa-specific probes do not recognize myosin VIIb. cDNA probes directed against either the conserved motor domain or the novel tail domains of myosin VIIa recognize a single mRNA of \approx 9.5 kb in human testis by Northern blot analysis (data not shown). Screening of additional human and porcine cDNA libraries derived from liver, lung, small intestine, testis, and kidney tissues did not identify myosin VIIb clones when either motor- or tail-specific probes for myosin VIIa were used. When the 3.5-kb myosin VIIa cDNA clone was used as a probe for fluorescence *in situ* hybridization, it hybridized specifically to human chromosome 11q13–15, the position of *USH1B*, but not to additional loci (N. Mokady, T.H., and D. Ward, unpublished data). These examples of lack of cross-hybridization suggest that myosin VIIa and myosin VIIb are not highly homologous at the nucleotide level. The antibodies to myosin VIIa recognize appropriately sized polypeptides only in tissues known to express this motor as judged by Northern blot analysis (7) and by reverse transcription-PCR analysis (4) in human and mouse tissues. Taken together, these results suggest that myosin VIIa-directed probes are specific for this motor and do not recognize myosin VIIb.

An indirect-immunofluorescence study was undertaken to determine the cell-specific localization of myosin VIIa within the cochlea. Half-turns of guinea pig cochlear tissue were double-labeled with antibodies to myosin VIIa and with fluorescein-conjugated phalloidin and visualized as a whole mount by laser scanning confocal microscopy. Optical sections through the organ of Corti showed that myosin VIIa was concentrated within the outer and inner hair cells of the sensory epithelium (Fig. 3). It was detected within the stereocilia at the apex of the hair cell (Fig. 3 *a* and *b*) and within the cuticular plate which anchors the bases of the stereocilia (Fig. 3 *c* and *d*). Myosin VIIa was also present within the cytoplasm of the hair cells (Fig. 3 *e* and *f*), although this region is not enriched in F-actin. No myosin VIIa was detected within Hensen's cells or the pillar cells, two cell types within the organ of Corti that are enriched in F-actin. Nonimmune control experiments indicated that the staining of the stereocilia was not simply due to bleedthrough of the phalloidin signal. Also, no bleedthrough was seen from the bright phalloidin staining of the actin ring at the zona adherens (Fig. 3 *a* and *b*) or staining of the Hensen's cells and pillar cells (Fig. 3 *c–f*). Similar results were obtained with frozen sections of isolated cochlea and whole temporal bone (data not shown), indicating that this staining pattern was not dependent on the method of staining. No myosin VIIa-specific labeling was observed within any supporting cells or nerve cells within the cochlea. Similarly, no myosin VIIa-specific staining of the stria vascularis or other vascular tissue was seen. The image shown in Fig. 3 reflects the pattern of myosin VIIa expression along the entire length of the cochlea, with the staining intensity higher in inner hair cells than in outer hair cells. Labeling was not brighter at the tips

DISCUSSION

Our data establish that myosin VIIa is present within the hair cells of the cochlea and the pigmented epithelium cells of the retina, two tissues known to be affected in Usher disease. Some patients with Usher disease exhibit abnormal sperm cells (13) and defects in bronchial function (14); in keeping with this, myosin VIIa was also found to be expressed in the testis and lung. Myosin VIIa is also expressed in the kidney, but kidney problems have not been reported in Usher patients. The kidney, and in particular the proximal-tubule epithelial cells contains a number of myosins, including two myosins II, at least four myosins I, and myosin VI (reviewed in ref. 9). In addition, at least six other unconventional myosins are expressed within this cell type (1). Perhaps these myosins serve overlapping functions in the kidney, masking the loss of myosin VIIa in Usher patients and *sh1* mice.

sh1 mice exhibit degeneration of the organ of Corti and the afferent spiral ganglion neurons in the first few weeks after birth, at a time when the organ of Corti is normally still developing (8). Hair cells are first detectably abnormal within 3 days after birth. Spiral ganglion neurons are also abnormal at 3 days. Little is known of the histopathology of type 1 Usher patients, as existing studies are apparently on usher types 2 or 3. Given the restricted localization of myosin VIIa to the hair cells, we suggest that the defect lies within this cell type and that the degeneration of the afferent neurons is secondary.

Usher syndrome type 1 is also characterized by absence of vestibular function. Although we have not located myosin VIIa

in the vestibular system, amphibian myosin VIIa was identified in the sensory epithelium of the bullfrog sacculus (2), suggesting that myosin VIIa may be expressed in mammalian vestibular hair cells as well. Gillespie *et al.* (15) identified three myosin-like proteins in bullfrog saccular stereocilia by photoaffinity labeling with uridine nucleotides; one of them had an apparent molecular mass of 230 kDa. In addition, Walker *et al.* (16) identified a 240-kDa calmodulin-binding protein in saccular hair bundles which may be the same protein and, perhaps, myosin VIIa. The neck domain sequence of myosin VIIa has five light-chain-binding IQ repeats. These repeats have been shown to bind calmodulin in other unconventional myosins (10).

The primary cause of the retinal degeneration observed in Usher disease is not known. The problem could lie in the photoreceptors themselves or in the RPE cells, which support the photoreceptors and function in photoreceptor renewal by phagocytosing disks shed by the rod outer segments (17). Myosin VIIa expression is restricted to the pigmented epithelium, suggesting that defects in these cells are the cause of the retinitis pigmentosa in Usher type 1B. One animal model of retinitis pigmentosa, the RCS rat, provides supportive evidence. In these animals, the RPE layer is defective in phagocytosis (18). Cellular debris accumulates in the intercellular space between the outer segments and the RPE layer, leading to photoreceptor cell death. The genetic defect in the RCS rat is not known, but studies in chimeric animals have determined that the cellular defect lies in the RPE layer itself (19).

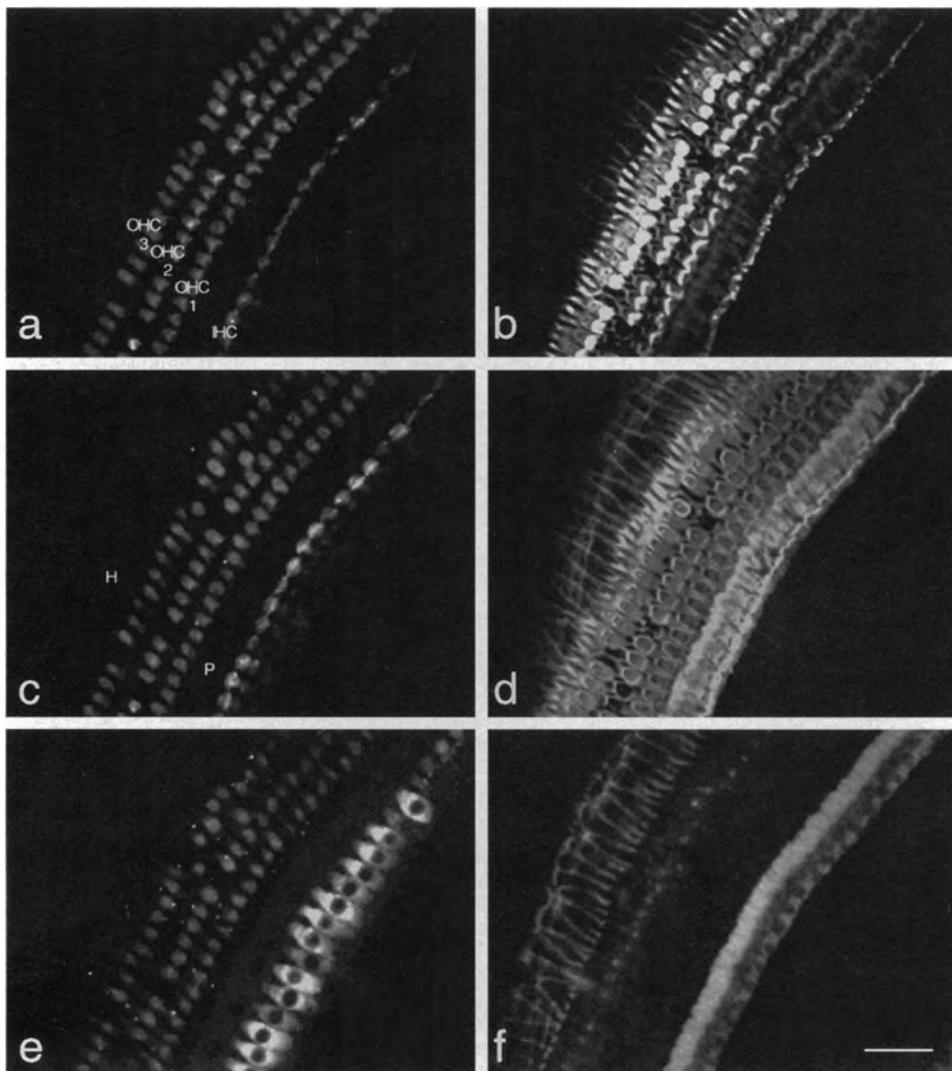

FIG. 3. Localization of myosin VIIa and F-actin in guinea pig cochlea. Immunofluorescence micrographs show optical sections through the organ of Corti perpendicular to the cochlear axis stained for myosin VIIa (*a*, *c*, and *e*) and F-actin (*b*, *d*, and *f*). (*a* and *b*) Apical domain of the organ of Corti. The locations of the inner hair cell (IHC) and three outer hair cell (OHC) rows are marked. The stereocilia are clearly visible as V-shaped, brightly stained bundles in the OHC and as a row of brightly stained material in the IHC. (*c* and *d*) Optical section 2.4 μm lower, at the level of the cuticular plate. The location of the actin-rich pillar cells (P) and Hensen's cells (H) are shown. (*e* and *f*) Optical section 7.8 μm lower, at the level of the IHC nuclei. (Bar = 50 μm .)

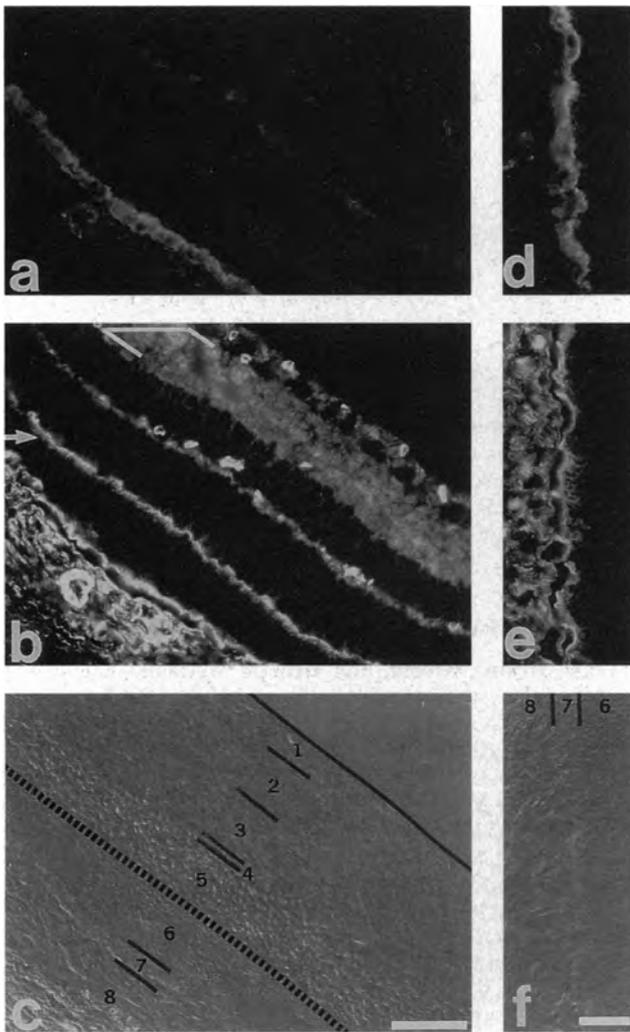

FIG. 4. Adult rat retina stained with myosin VIIa (*a* and *d*) and F-actin (*b* and *e*) and visualized by DIC optics (*c* and *f*). Retinal layers (demarcated in *c* and *f*) are as follows: solid line, inner limiting membrane; broken line, external limiting membrane; 1, ganglion cell layer; 2, inner plexiform layer; 3, inner nuclear layer; 4, outer plexiform layer; 5, outer nuclear layer; 6, rod and cone outer segments; 7, pigmented epithelium; 8, choroid layer. In *b*, the external limiting membrane is marked by an arrow, and the inner plexiform layer by a bracket. (Bar in *c* = 50 μ m; bar in *f* = 25 μ m.)

sh1 mice do not exhibit retinitis pigmentosa. As discussed by Weil *et al.* (4), this may reflect the type of myosin VIIa mutation observed within the *sh1* mice. The three *sh1* mutations identified by Gibson *et al.* (7) reflected two different single amino acid changes and a 10-aa deletion. All mutants expressed myosin VIIa at the mRNA level and therefore may express the mutant protein (7). A human recessive nonsyndromic deafness locus (*DFNB2*) also maps to 11q13 (20). Perhaps this human deafness is more closely related to *sh1*. Alternatively, another unconventional myosin could be compensating for the lack of myosin VIIa in the *sh1* retina.

Unconventional myosins have been shown to be associated with numerous actin-based motilities, such as phagocytosis, endocytosis, chemotactic movement, and vesicular transport (21, 22). Perhaps myosin VIIa serves a similar role in membrane movements in sensory hair cells and in the RPE cells. Both cell types undergo continuous and essential membrane movements—specifically, phagocytosis in the retina and re-

lease of transmitter-containing vesicles at the afferent hair-cell synapses (17, 23). Outer hair cells exhibit a much lower level of constitutive transmitter release than inner hair cells (24), consistent with the differential levels of expression of myosin VIIa between these two hair-cell types. Our results, showing a specific location of myosin VIIa within the cochlea and retina, should allow for an enhanced understanding of the molecular causes of blindness and deafness in Usher patients.

We thank N. Mokady and D. C. Ward for mapping the human myosin VIIa gene and we thank Spyridon Artavanis-Tsakonas for the use of his confocal microscope. Meena Ramakrishnan and Marc Schwartz provided excellent technical help in cloning and sequencing myosin VIIa. This work was supported by Grant PF-3659 from the American Cancer Society (T.H.), National Institutes of Health Program Project Grant DK38979 (T.H. and M.S.M.), and National Institutes of Health Grant DK25387, a basic research grant from the Muscular Dystrophy Association, and Yale Liver Center Pilot Project Grant DK34989 (M.S.M.). J.S.-S. and D.P.C. were supported by National Institute on Deafness and Other Communication Disorders Grants DC00273 and DC02281, respectively. D.P.C. is an Associate Investigator of the Howard Hughes Medical Institute.

From Basilar to Plasma Membrane

Over 40 years ago the auditory community rejoiced that frequency tuning in the auditory periphery had been understood, and was proud that von Békésy received the Nobel Prize for showing us how the basilar membrane (BM) traveling wave provides for mechanical Fourier analysis (von Békésy, 1960). However, as soon as new techniques were devised to measure smaller movements of the BM than Békésy could imagine, curious incongruities arose concerning the significance of Békésy's measurements. Von Békésy made much of his measures on preparations that were compromised in a way unknown to him. Thus, the linear extrapolations from his high-intensity measures, which put auditory threshold movements below the diameter of an atom, were becoming unraveled. The problem turns out to be an inherent nonlinearity in the motion of the basilar membrane that is lost upon the slightest insult to the organ of Corti, that sensory epithelium of hair cells which is stimulated by BM movements. This remarkable observation of a compressive nonlinearity was made by Rhode (Rhode, 1971; Rhode & Robles, 1974), and has revolutionized our thinking on the micro mechanics of the inner ear. We now know that BM vibration is as sharply tuned to frequency as the eighth nerve fiber activity it evokes (Narayan et al., 1998). But what drives this nonlinearity? Why is it so vulnerable to insult? The answer is that it depends on the proper functioning of a particularly fragile cell

type within the organ, the outer hair cell (OHC) (Dallos & Harris, 1978; Ryan & Dallo, 1975).

The OHC is one of the two types of hair cells present in the organ of Corti. The other hair cell type is the inner hair cell (IHC) which receives up to 95% of the auditory nerve's afferent innervation (Spoendlin, 1988), but is fewer in number than OHCs by a factor of 3–4. Two decades ago, Brownell (Brownell, 1984; Brownell et al., 1985; Kachar et al., 1986) discovered that OHCs are capable of electrically evoked mechanical activity. Again, a revolution in our thinking began. The bottom line, after years of study, is that though both inner and outer hair cells respond to sound by generating receptor potentials (Russell & Sellick, 1978; Dallos, Santos-Sacchi & Flock, 1982), the OHCs alone are both receptor and effector – incredibly fast, at that. (You can view a movie of the OHC dance at www.YaleEarLab.org). Currently, the consensus is that OHCs provide a frequency-dependent boost to BM motion, which enhances the mechanical input to IHCs, thereby promoting enhanced tuning and amplification. Indeed, the term “cochlear amplifier” is commonly used to describe the work of the OHC (Davis, 1983). This review will summarize much of what we know about the OHC's electro-mechanical capabilities — phenomena which largely result from properties intrinsic to its plasma membrane (PM) and associated structures.

OHC Somatic Electromotility and Its Electrical Signature

The OHC is a cylindrically shaped cell whose length varies from short (~10–20 μm) to long (> 80 μm)

Correspondence to: J. Santos-Sacchi; email: joseph.santos-sacchi@yale.edu

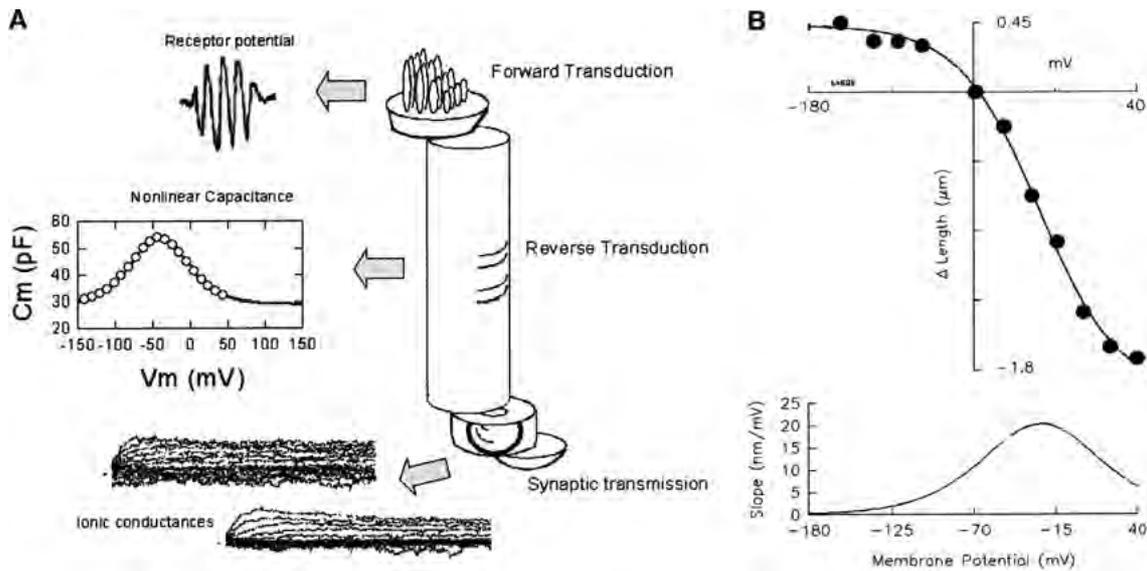

Fig. 1. (A) The OHC has a highly partitioned membrane. Apical, lateral and basal membranes possess characteristic integral membrane constituents with measurable electrical correlates. The apical stereocilia channels work to produce receptor potentials; the basal membrane houses the voltage-dependent ion channels; the lateral membrane houses the molecular motors (prestin), whose electrical signature is a nonlinear, voltage-dependent capacitance (NLC). Fits of the capacitance with the first derivative of a two-state Boltzmann provides information on the motors' operating range (characterized by $V_{1/2}$, the voltage at peak capacitance) and the sensitivity of the motors to voltage (an estimate of elementary motor charge, typically about 0.75). (B) The mechanical response (filled circles) of the OHC can also be fit by a two-state Boltzmann function. The first derivative defines the mechanical gain of the cell at a particular resting potential.

along the length of the basilar membrane, with short cells residing at the basal high-frequency regions of the cochlear spiral. While initial investigations did not identify OHC electrically evoked length changes as resulting from voltage or current flow across the PM, it soon became clear that this robust mechanical response, amounting to about 5% of the cell length, was evoked by voltage. This was indicated by the persistence of mechanical responses in spite of the block of a variety of membrane conductances, and the identification of gating-like currents or a nonlinear capacitance (NLC), which is characteristic of voltage-sensor activity that underlies membrane-based voltage-dependent processes. Consequently, OHCs contract with depolarization and elongate with hyperpolarization (Santos-Sacchi and Dilger 1988; Santos-Sacchi, 1990, 1991; Ashmore, 1989, 1990) Significantly, in isolated OHCs contraction/expansion cycles can be elicited by ciliary displacement (Evans & Dallos, 1993). OHC electromotility is independent of ATP, calcium, and the microtubule or actin system (Brownell et al., 1985; Kachar et al., 1986; Ashmore, 1987; Holley & Ashmore 1988b; Santos-Sacchi 1989; Kalinec et al., 1992). Motile responses can be seen at very high frequencies (Dallos and Evans 1995; Gale & Ashmore 1997; Frank, Hemmert & Gummer 1999). The mechanical response is sigmoidal and corresponds inextricably with those characteristics of the nonlinear charge movement (Fig. 1). Both the mechanical response

and its associated charge movement can be fit well with simple two-state Boltzmann functions and each share indistinguishable fitted parameters; namely, slope factors are near 30 mV per e-fold changes in charge or mechanical response, and operating voltage ranges have their midpoints ($V_{1/2}$) near negative 30–40 mV. Maximum charge movement in OHCs ranges up to about 3 pC, and early on it was observed that treatments that reduce this charge transfer or shift its operating voltage range correspondingly affect the mechanical response amplitude and its voltage activation range (Santos-Sacchi, 1991; Wu & Santos-Sacchi, 1998; Kakehata and Santos-Sacchi, 1995, 1996). Most investigators study charge movement in OHCs by measuring the NLC, which is bell-shaped (the first derivative of charge movement) with respect to voltage. Peak NLC can be greater than the cell's linear capacitance, the latter corresponding to the cell's surface area.

There are several perturbations that can influence the OHC motor mechanism, including membrane tension, temperature, and initial (resting) voltage conditions (Iwasa, 1993; Gale & Ashmore, 1994; Takahashi and Santos-Sacchi, 2001; Zhao and Santos-Sacchi 1998; Kakehata & Santos-Sacchi, 1995). In addition, lanthanides and salicylate can block to some extent NLC and somatic electromotility (Tunstall, Gale & Ashmore 1995; Kakehata & Santos-Sacchi 1996; Santos-Sacchi, 1991). The most

common effect on motor activity is a shift of the operating voltage range, indicative of a shift in the state probability of motor molecules residing in a contracted or expanded state. Additionally, maximum charge movement is also susceptible to external perturbations (*see* Santos-Sacchi, 2003, for a more detailed review). It was the electro-mechanical characteristics of the OHC motor that ultimately enabled the identification of the protein responsible for the unique function of the OHC.

The OHC Motor Protein Prestin

Although the existence of a unique motor protein embedded in the OHC's PM was proposed as early as 1992 (Kalinec et al., 1992), it was not until five years ago that the molecular nature of the OHC motor was revealed (Zheng et al., 2000). The basic strategy of this identification was based on the fact that inner hair cells IHCs do not show somatic electromotility but share many similarities with OHCs. An OHC-IHC subtracted cDNA library was created aiming to isolate the OHC-specific genes that are abundantly expressed only in OHCs and not in IHCs (Zheng et al., 2002a). The OHC motor protein was identified in this library and named prestin. Prestin is localized to the PM where the motor was known to be located (Hallworth, Evans & Dallos, 1993; Huang & Santos-Sacchi, 1993, 1994). When prestin was heterologously expressed in several cell lines, the transfected cells exhibited behaviors that are normally observed only in OHCs: voltage-dependent NLC and shape changes (Zheng et al., 2000); electro-mechanical reciprocity (Santos-Sacchi et al., 2001; Dong & Iwasa, 2004); temperature sensitivity (Meltzer & Santos-Sacchi, 2001), and mechanical force generation with constant amplitude and phase up to a stimulating frequency of at least 20 kHz (Ludwig et al., 2001). Ontogenic expressions of the *prestin* gene (Zheng et al., 2000) and prestin protein (Belyantseva et al., 2000a) are the same as that of electromotility (He, Evans & Dallos, 1994). In addition, the electromotile responses in prestin-transfected kidney cells can be blocked by salicylate (Zheng et al., Oliver et al., 2001), an inhibitor of somatic electromotility in OHCs (Shehata, Brownell & Dieler, 1991; Tunstall et al., 1995; Kakehata & Santos-Sacchi, 1996). Furthermore, OHCs from prestin-null mice lack somatic electromotility, and those mice also lose 40–60 dB of hearing sensitivity (Liberman et al., 2002) and lack frequency selectivity (Cheatham et al., 2004). A splicing mutation in *prestin* gene causes non-syndromic deafness (Liu et al., 2003). Collectively, these results are consistent with the idea that prestin is the motor protein of cochlear OHCs.

Prestin's Gene and Its Expression

Prestin belongs to a distinct anion transporter family called solute carrier protein 26 (SLC26) (Zheng et al., 2002b). At present, eleven members of this family have been identified (Mount & Romero 2004). Several proteins in this family, including prestin, are involved in human diseases (for review, *see* Dawson and Markovich, 2005). The human Prestin gene contains 21 exons crossing more than 90 kb in chromosome 7q22 (Liu et al., 2003), a location near to those of other important SLC26 members, such as PDS (SLC26A4) (Everett et al., 1997) and DRA (SLC26A3) (Haila et al., 1998). The mouse Prestin gene has 20 exons spanning nearly 55 kb in chromosome 5 (Zheng et al., 2003). Eighteen of these exons code for prestin amino acids in both hPrestin and mPrestin. Among coding exons, 12 exons are exactly the same sizes as in other members of the SLC26 family, such as Pendrin, DRA and CFEX (Zheng et al., 2003), indicating high homologies among these genes. Several prestin isoforms have also been found in different stages of human cochlear development (Liu et al., 2003). However, these isoforms were not found in mature mouse cochleae (Zheng and colleagues, *unpublished data*). The function of these predicted human prestin isoforms was not further studied. Prestin mRNA was also found in testis, brain and vestibular system through either RT-PCR or in situ experiments (Adler et al., 2003; Zheng et al., 2003). Anti-prestin labeling was found in the cytoplasm of vestibular hair cells, but not in the PM (Adler et al., 2003). The behavior endowed by prestin, somatic motile activity, was never found in vestibular hair cells (Adler et al., 2003). Overall, prestin is abundantly expressed only in OHCs, where somatic motile activity is observed. The time course of prestin mRNA and protein synthesis in OHCs corresponds to the emergence of somatic motile activity in OHCs (Belyantseva et al., 2000a; Zheng et al., 2000). Furthermore, a prominent longitudinal and radial gradient of prestin expression, ranging from base-to-apex and first-to-third row of OHCs, was also observed (Judice et al., 2002). Such tight regulation of prestin mRNA expression is not fully understood. Thyroid hormone was reported to regulate prestin mRNA expression (Weber et al., 2002). In spite of the fact that prestin's promoter and other regulating regions have not been precisely identified (Weber et al., 2002; Zheng, Richter & Cheatham 2003), the prestin gene has been modified to create transgenic mice that are useful for studying hair-cell-specific gene targeting (Tian et al., 2004).

Prestin is a highly conserved protein among different mammalian species. So far, the full-length prestin protein has been identified from four species including gerbil (Zheng et al., 2000), mouse (Adler et al., 2003; Zheng et al., 2003), rat (Ludwig et al.,

2001) and human (Liu et al., 2003). Among these four, 92.7 % of amino acids are identical and 6% show some similarity. Only 10 amino acids (1.3%) were different as determined by the CLUSTALW multiple alignment analysis (Thompson, Higgins & Gibson 1994). Prestin-related SLC26 proteins were also reported in non-mammalian vertebrates and insects (Weber et al., 2002). The closest one (AY278118) related to mammalian prestin was found in the Zebrafish's auditory organ. This prestin-related gene has ~ 15 exons with 49.8% amino acids identical to mammalian prestin. The function of Zebrafish prestin is not fully investigated. The key question, whether zPrestin demonstrates somatic motile activity, has not been answered yet. Therefore, whether non-mammalian prestin has a similar function and role in non-mammalian hearing needs further investigation.

Prestin Protein's Structure and Its Modification

Prestin appears to share the overall structure and specific protein domains of the SLC26 family: a highly conserved central core of hydrophobic amino acids (~ 400 amino acids) predicted to form 10–12 transmembrane domains according to the topology prediction programs chosen for the analysis (Oliver et al., 2001; Zheng et al., 2001; Deak et al., 2005; Navaratnam et al., 2005b). It is generally agreed that Prestin can be divided into three domains: N-terminus (~100 a.a.), hydrophobic core (~400 a.a.) interacting with lipids of the PM, and C-terminus domain (~240 a.a.) as shown in Fig. 2. Through immunofluorescence experiments, the N- and C-termini were shown to be located on the cytoplasmic side of the PM (Ludwig et al., 2001; Zheng et al., 2001). The "sulfate transporter signature" is present in the hydrophobic core, while a STAS (sulfate transporter and antisigma-factor antagonist) motif (Aravind & Koonin, 2000) is located in the C-terminus (a.a. 634–710). There are two predicted N-glycosylation sites in the hydrophobic core region: N163 and N166. While two sets of experiments suggest that these two sites are glycosylated, indicating that prestin is a glycoprotein (Matsuda et al., 2004; Iida et al., 2003), there are contrary data (Navaratnam et al., 2005b).

Aside from possible glycosylation, prestin can also be phosphorylated by cGMP-dependent kinase at S238 and T560 (Deak et al., 2005). Phosphorylation at these sites not only affects the operating voltage range of prestin's NLC (such as S238A), but also significantly changes the slope of voltage dependence (S238D) (Deak et al., 2005). There are several other phosphorylation sites affecting prestin's function, such as PKC-dependent phosphorylation (Matsuda et al., 2003). How these different phosphorylation sites cooperate with each other to

regulate motor function *in vivo* needs further investigation.

Prestin has 744 amino acids. The estimated size of a prestin monomer is too small to form the 10-nm particle originally found in the OHC's lateral membrane (Gulley & Reese 1977; Kalinec et al., 1992; Santos-Sacchi et al., 1998). Hence, the possibility of prestin's oligomerization has been studied through both genetic, biophysical and biochemical methods. Data from FRET and FRAP experiments obtained by several groups demonstrated that prestin can bind to itself (Kural et al., 2004; Greeson, Organ & Raphael 2005; Navaratnam et al., 2005b). In order to investigate the possibility of higher-order oligomers, we examined the quaternary structures of prestin by LDS/PAGE, PFO/PAGE, a membrane-based yeast two-hybrid system, and chemical cross-linker experiments. Our data suggest that prestin forms a high-order oligomer such as tetramer in OHCs (Zheng et al., 2005b). Using a protein density calculation method described by Fischer et al., (Fischer, Polikarpov and Craievich 2004), we estimate a tetramer of prestin transmembrane domains to be on the order of ~11 nm in diameter. Furthermore, 8–13 nm particles (likely to be prestin) were observed through atomic force microscopy in prestin-transfected CHO cells (Murakoshi, 2005). This size is consistent with the motor protein complex observed in the lateral membrane of OHCs (Gulley & Reese 1977; Kalinec et al., 1992; Santos-Sacchi et al., 1998). How prestin forms tetramers and what amino acids are involved in the formation of these structures is still unknown, though N-terminal-based interactions of prestin appear required for such homomeric relations (Navaratnam et al., 2005b).

Molecular Mechanism of Prestin Function

Prestin shows the greatest sequence similarity to PAT1 (putative anion exchanger 1, SLC26A6) (Dallos & Fakler, 2002). Based on early indications that no anion transport was associated with prestin function (Dallos & Fakler 2002), prestin was thought to behave as an incomplete anion transporter. Thus, although prestin demonstrates voltage-dependent charge transfer manifest as NLC, other members of the SLC26A family, such as SLC26A4 and SLC26A6, do not show NLC under similar conditions (Zheng et al., 2000; Oliver et al., 2001). How membrane potential changes across the OHC membrane result in conformational changes in prestin, corresponding to its motor function, is not understood. In order to find the voltage sensor of prestin, the nonconserved charged amino acids (R, K, D and E) between prestin and SLC26A6 in the hydrophobic core region were changed to neutral amino acids as shown in Fig. 2. However, all mutants continued to show NLC even

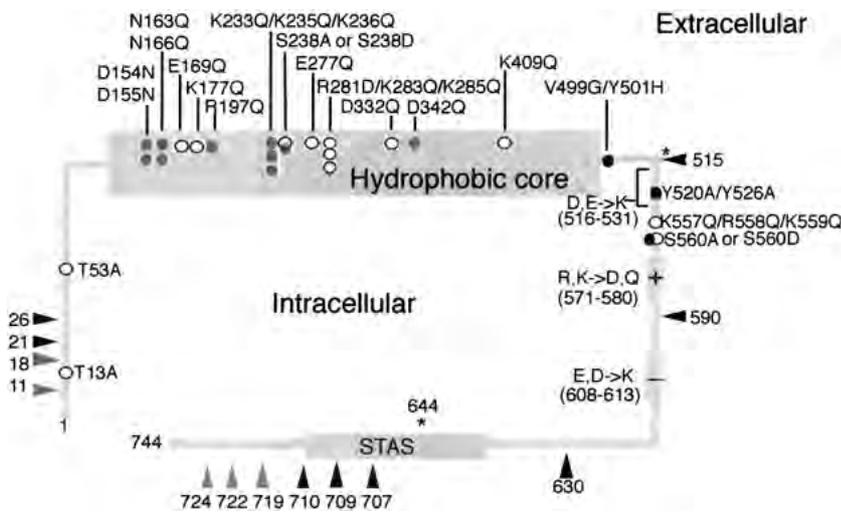

Fig. 2. Effects of mutated amino acids in prestin sequence on prestin's NLC function. *Open circles* are the point mutants that maintain prestin's normal function. *Black dots* are point mutants that produce total loss of prestin's function. *Grey dots* are point mutants that maintain NLC but with significant changes in properties such as voltage dependence. *Grey arrows* indicate truncation mutants (deleted at either the N-terminus or C-terminus end) that maintain prestin's NLC function. *Black arrows* are truncation mutants without NLC. *Asterisks* mark positions where prestin-pendrin, and prestin-pat1 chimeras were switched.

though the parameter values in some mutants were changed (Oliver et al., 2001; Bai et al., 2003). For example, mutant D154N (*grey dot*) has $V_{1/2}$ at -146.7 mV in contrast to -70 mV in wild-type prestin. There are also negative and positive charge clusters in prestin's C-terminus, as shown in Fig. 2. Changing charged amino acids in the C-terminus to either the opposite charge (R, K \rightarrow D, E, D \rightarrow K) or a neutral amino acid (Q), does not abolish NLC function either (Oliver et al., 2001; Bai et al., 2003). It thus appears that these charged amino acids in prestin do not play a primary role as voltage sensors. Subsequent experiments suggested that intracellular anions play a crucial role either as extrinsic voltage sensors (Oliver et al., 2001) or allosteric modulators of the voltage sensor (Oliver et al., 2001; Rybalchenko & Santos-Sacchi 2003). Chloride, in particular, has profound effects on NLC and the motor's operating voltage range (Oliver et al., 2001; Song, Seeger & Santos-Sacchi, 2005; Rybalchenko & Santos-Sacchi, 2003). Most recently, prestin transfected into CHO cells has been shown to exchange extracellular C^{14} formate for intracellular chloride; this transport, which is blocked by salicylate and DIDS, is competitively inhibited by extracellular malate and chloride, but not sulfate (Navaratnam et al., 2005a). Additionally, there is evidence that prestin also provides electrogenic transport of bicarbonate and chloride, and to transport sugar (Chambard & Ashmore, 2003; Ashmore, 2005). This recently observed capability of prestin to transport anions, and the ineffectiveness of anion valence to alter the elementary charge movement underlying NLC (Rybalchenko & Santos-Sacchi, 2003), seriously challenges the extrinsic voltage sensor model (Oliver et al., 2001), and suggests that the effect of anions on prestin activity results from allosteric modulation of the protein's conformation within the lateral membrane. The identity of the charged voltage sensor, however, remains elusive.

Amino acids in the hydrophobic core are near 100% identical among human, mouse, rat and gerbil prestin (only one amino acid is different). Since the function of prestin is directly associated with an increase and decrease of PM area (Kalinec et al., 1992; Santos-Sacchi, 1993; Iwasa, 1994; Santos-Sacchi & Navarrete, 2002), it is logical to assume that the hydrophobic core (embedded in the membrane) is more important for NLC than either the N- and C-termini, since it alone should sense the membrane field. Nevertheless, deletion of N- and C-terminus sections has been shown to be lethal for prestin's function. In fact, deletions of more than 21 amino acids at the N-terminus, or more than 32 amino acids at the C-terminus result in loss of prestin function (*filled arrow* in Fig. 2) (Navaratnam et al., 2005b). There is conflicting evidence whether the loss of function in truncated proteins is due to a lack of membrane insertion (Zheng et al., 2005c) or other causes (Navaratnam et al., 2005b). Replacing the C-terminus of prestin (at position 515 or 644 indicated as "*" in Fig. 2) with the analogous C-terminus portion of one of two closely related SLC26A proteins, Pendrin or PAT1, does not rescue the electrophysiological function of prestin. However, these chimera mutants are not delivered into the PM (Zheng et al., 2005c). In addition, mutating some of the non-charged amino acids in the C-terminus results in loss of electrophysiological function. Some of these mutants, e.g., Y520A/Y52A shown in Fig. 2, lose the ability to reach the PM. Other mutants, e.g., V499G/Y501H, can reach the PM; yet still lose function (Zheng et al., 2005c). These data suggest that the C-terminus plays an important role in both regulating membrane targeting and overall prestin function (Zheng et al., 2005c). Similar results are also found for the N-terminus (Navaratnam et al., 2005b). Together, these data suggest that both N- and C-termini play critical roles for the motor protein's function.

Prestin-Associated Proteins

The PM of OHCs is enriched with protein components. There is also a complicated structural network underlying the PM, including a cortical lattice and cisternal membranes. Although prestin is the key player in somatic electromotility, evidence suggests that other proteins are involved in modifying OHC electromotility. The neurotransmitter acetylcholine (Dallos et al., 1997; Kalinec et al., 2000) and secondary messengers such as cyclic GMP, can modify OHC motor function (Szonyi et al., 1999). An aquaporin-like protein has also been linked to OHC motor function (Belyantseva et al., 2000b). Sugar carrier Glut5 is associated with OHC length changes in a voltage-dependent fashion (Geleoc et al., 1999). Interestingly, Glut5 protein is absent in OHCs of prestin knockout mice (Wu, 2004). The relationship between prestin and Glut5 is still being investigated.

It is of interest to identify the prestin-associated proteins. Several groups used the yeast two-hybrid system to screen prestin-associated proteins. In this system, the C-terminus of prestin was used as “bait” to identify prestin-associated proteins. Couplin was first suggested as a novel protein that binds to both prestin and actin (Dougherty et al., 2003). A transcriptional repressor, promyelocytic leukemia zinc-finger protein (PLZF) was also identified as a protein interacting with prestin in OHCs (Nagy et al., 2005). PLZF gene produces a POZ/domain Kruppel-type zinc-finger transcription factor reported to have pro-apoptotic and anti-proliferative function. Currently, it is not clear how and where PLZF may affect prestin’s function. Other interacting proteins include VCY2-IP1, whose sequence shows homology to MAP1A and MAP1B, and the Na/K ATPase beta 1 subunit (Navaratnam et al., 2005c). Cystic fibrosis transmembrane conductance regulator (CFTR) was reported to activate several of the SLC26 family membrane proteins including DRA, Pendrin and PAT1 via interaction between the STAS domain of SLC26 and the R domain of CFTR (Ko et al., 2004). Prestin contains the conserved STAS domain like other SLC26 family members. Preliminary data also suggest that co-expressing CFTR with prestin in TSA cells could enhance prestin’s function (Zheng et al., 2005a). These observations indicate that the motor does not normally act in isolation in the intact OHC and indeed there are elaborate structural details within the sub-membrane spaces. To be sure, the motor must work in concert with these structures.

Development of Structural and Mechanical Characteristics of the OHC

The OHC lateral wall is a unique trilaminar structure consisting of the PM, the cortical lattice, and

subsurface cisternae. Like the PM of other cell types, the OHC PM has three main components: the lipids, the proteins, and the glycocalyx. A high density of integral membrane proteins in the lateral PM is one of the distinguishing features of OHCs. When the membrane bilayer is fractured using the freeze fracture technique, a dense array of particles can be seen on the inner surface of the cytoplasmic leaflet (Gulley & Reese 1977). The particles are about 10 nm in diameter and the packing density has been estimated to be from 2500–3000/μm² (Saito, 1983; Kalinec et al., 1992; Santos-Sacchi et al., 1998) to as much as 7000/μm² (Forge, 1991; Koppl, Forge & Manley, 2004). These values are much higher than those of inner hair cells (1900–2800/μm², (Koppl et al., 2004)), non-mammalian hair cells (1880–2360/μm², (Koppl et al., 2004)) and axolemma of peripheral myelinated fibers (1300–2500/μm²). The density of cochlear apical and basal turn cells appears to be the same (Forge & Richardson 1993). These particles in OHCs may include many of the normal membrane proteins, such as non-voltage-dependent ion channels and structural links with the cytoskeleton. However, it was suggested the motor protein might account for a major fraction (Kalinec et al., 1992), and as noted above, it is likely that prestin multimers comprise these structures. Indeed, when the PM of gerbil OHCs between 2 and 16 days after birth (DAB) is examined using replicas of the freeze fracture, the particles are found to be present at low density at 2 DAB and increased in density from 2200/μm² at 2 DAB to 4131/μm² at 8 DAB, and continue to increase in density until mature values are attained at 16 DAB (Souter, Nevill & Forge 1995). The increase in density of the particles during this time period matches the appearance and development of OHC motility in the same species (He et al., 1994). Since OHC somatic motility is required for normal hearing, it might be expected that development of motility would correspond in time to the development of hearing. Both measures of OHC length changes and NLC have been used to get at this issue.

To date, OHC motor development has been studied in three species, namely, rat, gerbil and mouse (He et al., 1994; Oliver & Fakler 1999; Belyantseva et al., 2000a; Abe et al., 2005). In these species, slight differences in the development of hearing are found. Hearing onset and maturation in mouse are observed at P10–12 and P18, respectively (Ehret, 1976; Steel & Bock, 1980). In rats and gerbils, these periods are somewhat extended, onset being P12 and P12–14, and maturation being P25 and P21 for rats and gerbils, respectively. He et al., (1994) reported that the electromotile response elicited using a whole-cell microchamber technique was detectable at P7 in cells from the basal cochlear turn and at P8 from the apical turn. All OHCs tested showed detectable responses at P12 and the threshold of detectable response reached

adult levels at about P12. Percentage ratios of maximal response amplitudes and cell lengths reached adult levels of 1.3% at P15 in the basal turn and at P17 apically. On the other hand, OHC cell length of the apical turn continued to elongate until P17 with decreasing cell width, while in basal cells only minimal changes were found. In apical OHCs, voltage-induced length change increased as the cell length elongated. These results suggest that the density of the motor in the longitudinal direction continued to increase until maturation of somatic motility.

In the rat, NLC is detectable as early as P0 in apical turn OHCs (Oliver & Fakler 1999). Oliver and Fakler measured NLC from P0 to P14, demonstrating that NLC increased up to P14, the oldest day they measured, while linear capacitance (C_{lin}) showed saturation between P3 and P11, but suddenly increased from P13. Thus, the calculated value of charge density displayed saturation after P11 because C_{lin} continued to increase after P11. The authors concluded that motor protein density matured at P11 and that the increase in NLC after P11 was due to an increase in membrane area containing the same density of motor proteins. They further concluded that characteristics of the OHC motor reach adult level at the onset of hearing, P12, substantially before the maturation of the hearing of P25 in rat. On the contrary, the developmental time course of NLC and intensity of immunolabeling of rat OHC lateral wall with anti-prestin antibodies correlates well and matures at P17 (Belyantseva et al., 2000a).

Marcotti and Kros (1999) studied somatic motility and capacitance of the OHCs from Swiss CD-1 mice. They measured capacitance at a fixed membrane voltage of -84 mV, and therefore could not detect linear and nonlinear capacitance separately. Total capacitance saturated beyond P16. All the cells tested showed detectable motile response at P12 (they recorded somatic electromotility at P6, 8, 9 and 12). In C57BL/6J mice, Abe and coworkers measured NLC to investigate the development of motor protein activity of apical OHCs each postnatal day from P5 to P18 (Abe et al., 2005). It was found that surface area or C_{lin} of OHCs mature at p10, whereas prestin activity – gauged as NLC – increased until p18. These and other data (prestin qPCR) were interpreted as evidence for a completed population of prestin molecules within the PM early on, whereas prestin function continues to mature, possibly through heteromeric formations, changing chloride sensitivity, establishment of other protein interactions or phosphorylation effects. Such maturation may correspond to ultrastructural particle formation in the PM, as noted above. Of course, it should be noted that the attainment of adult cochlear function undoubtedly profits from a concerted developmental contribution from a variety of cellular and acellular structures that work with the motors.

OHC Stiffness, Forces and Lateral Wall Structure

Little is known of the lipid content of the PM in OHCs, but it seems to include high levels of cholesterol that may reduce its flexibility and fluidity (Forge, 1991). Lipid lateral diffusion in the OHC PM is a function of transmembrane potential and bathing medium osmolality. Cell depolarization, hyposmotic challenge, and amphipathic drugs reduce membrane fluidity (Oghalai et al., 2000). The dynamic changes in membrane fluidity may represent the modulation of membrane tension by lipid-protein interactions. This and the high protein content should mean that the PM is relatively stiff. Indeed, the relatively high stiffness of the PM is important for the expression of somatic motility (Holley & Ashmore, 1988a; Tolomeo, Steele & Holley, 1996; He, Jia & Dallos 2003).

About 25 nm beneath the PM there is an elaborate and highly structured cortical network called the cortical lattice. The cortical lattice appears to be composed of two distinct types of filament (Holley & Ashmore 1990b; Holley, Kalinec & Kachar 1992). The most obvious of these is the 6–7-nm diameter actin filaments that follow a circumferential path around the cell. Adjacent circumferential filaments are from 30 to 80 nm apart, and they are held in parallel arrays by thinner cross-links (2–3 nm in diameter) that may appear single or branched. These thinner cross-links appear to be spectrin (Holley & Ashmore, 1990b). These arrays form discrete domains that vary from just a few parallel filaments only 200 nm long to at least 10 filaments of up to 1 μ m long. Their mean angle to the transverse axis of the cell is about 5° – 15° with significant variability ((Kalinec & Kachar 1995; Holley et al., 1992; Holley & Ashmore, 1990a). This wide range of orientations suggests that the mechanical response of the OHC lateral wall could be locally modulated. In this regard, the OHC motor appears to be able to be modulated by local stresses and conditions (Santos-Sacchi, 2002). The Young's modulus of the circumferential filamentous components of the lattice were calculated to be 1×10^7 N/m². The axial cross-links, believed to be a form of spectrin, were calculated to have a Young's modulus of 3×10^6 N/m² (Tolomeo et al., 1996). The lattice is sufficient to retain the shape of the cell following demembranization and mechanical deformation. The structure of the lattice allows it to be described as a coiled helical spring but with longitudinal stiffness primarily determined by the crosslinks. The axial and circumferential stiffness moduli for the cortical lattice measured in OHCs without PM are 5×10^{-4} N/m and 3×10^{-3} N/m, respectively (Tolomeo et al., 1996). Thus the cortical lattice is a highly orthotropic structure. Its axial stiffness is small compared with that of the intact cell, but its circumferential stiffness is within the same

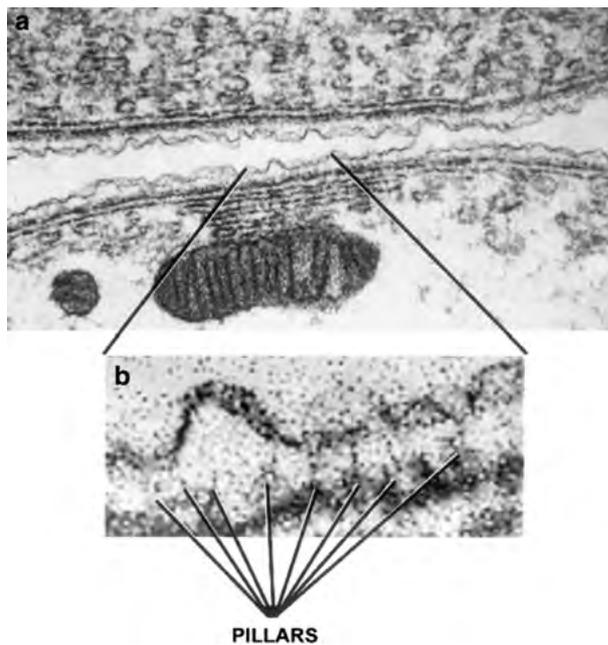

Fig. 3. (a) An electron micrograph of a section of a guinea pig organ of Corti showing two neighboring OHCs (separated by the Nuel space), showing a “rippled” plasma membrane. Beneath the PM is the continuous first sheet of subsurface cisternae. In places where the pillars look intact, the PM appears to be flat, whereas its bending is pronounced in regions where the pillars are disrupted (b). Note the variability in appearance and number of cytoplasmic cisterna, adjacent to the mitochondrion.

order of magnitude. Direct measurements of longitudinal stiffness indicate that the lattice contributes only a fraction of the overall stiffness of OHCs (Holley & Ashmore, 1988a; Tolomeo et al., 1996; He et al., 2003). These measurements support the theory that the cortical cytoskeleton directs electrically driven length changes along the longitudinal axis of the cell. The cortical lattice is connected to the PM by electron-dense “pillars” 7–10 nm in diameter and 25 nm long (Flock, Flock & Ulfendahl, 1986; Arima et al., 1991) that are attached specifically to the circumferential filaments at intervals of about 30 nm (Holley et al., 1992).

The lateral cisternae are a specialized and substantial fraction of the endoplasmic membrane within the OHC (Gulley & Reese, 1977; Saito, 1983). They form multiple, highly ordered layers that line the lateral cytoplasmic surface of the PM (Gulley & Reese, 1977). The number of layers and the morphology of these membranes vary considerably among different mammals, and between apical and basal turn OHCs, and even at different regions of the same cell (Fig. 3). In the guinea pig, as many as 12 layers have been reported (Evans, 1990; Forge et al., 1993), whereas in rats, only one layer is found in the apical turn OHCs (Raphael & Wroblewski, 1986). Modeling work suggests that the subsurface cisterna may influence the electrical properties of OHCs (Halter

et al., 1997) A reduction in the width of the extracisternal space decreases the whole-cell conductance and capacitance. It is unclear whether the lateral cisternae play an important role in the mechanism of somatic motility (beyond that of structural maintenance). Indeed, SSC are not required for normal prestin activity, since disruption of the cisternae with intracellular enzymatic treatments or expression into cells lacking the SSC, shows unmodified NLC (Huang & Santos-Sacchi, 1994; Zheng et al., 2000). Nevertheless, developmental studies show that the appearance of the first layer of the cisternae (Pujol et al., 1991; He, 1997) occurs at the same time when neonatal OHCs begin to exhibit somatic electromotility. The stiffness of the structurally irregular lateral cisternae is very unlikely to contribute significantly to that of the intact OHCs.

Under the influence of the cell’s turgor pressure, the PM, the cortical lattice, and the subsurface cisternae contribute to the global axial stiffness of OHCs. The static axial stiffness of OHCs has been measured by compressing the cell with a fine, vibrating glass probe of known stiffness. The stiffness value obtained by different studies from guinea pig OHCs varies from 0.5 to 5 mN/m (Holley & Ashmore, 1990a; Zenner et al., 1992; Gitter, Rudert & Zenner, 1993; Hallworth 1995, 1997; Iwasa & Adachi 1997; Ulfendahl et al., 1998; He & Dallos, 2000). Although the axial stiffness of OHCs varies significantly among different studies, stiffness of short OHCs from the basal turn is found to be much greater than that of long OHCs from the apical turn (Holley & Ashmore, 1988a; Hallworth, 1995; Russell & Schauz, 1996). OHCs are capable of producing an average maximum axial isometric (stall) force of ~ 5 nN (He & Dallos 2000; Iwasa & Adachi, 1997). From the number of molecules producing this force it can be estimated that the individual molecular stall force is on the order of 2.4 pN. In comparison, the stall force of kinesin is 5–6 pN (Svoboda & Block, 1994). The force generated per mV of command at the cell membrane is estimated to be around 0.1 nN/mV (Hallworth, 1995; Iwasa & Adachi, 1997).

Static stiffness and force of OHCs can also be manipulated by various means (Hallworth, 1997). Axial stiffness and electromotile forces are reduced by 65% when 5 mM salicylate is applied to the cell (Russell & Schauz, 1996). Dallos et al. (1997) demonstrated that delivery of the OHC’s efferent neurotransmitter acetylcholine (ACh) to the cell’s synaptic pole also decreases the axial stiffness. Quinine at 5.0 mM concentration can also substantially affect the cell mechanics and decrease active force generation in isolated OHCs (Jarboe & Hallworth 1999).

While the axial stiffness of OHCs has been studied, relative stiffness of the lateral wall components is still somewhat controversial. Some studies suggest that the PM appears to be relatively stiff and may be the

dominant contributor to the axial stiffness of intact cells (Holley & Ashmore 1990a; Tolomeo et al., 1996; He & Dallos 1999; He et al., 2003), while a study by Oghalai et al., (1998) indicates that the cortical lattice may account for ~70% of the axial stiffness. In addition, Adachi and Iwasa (1997) also show that diamide can reduce the axial stiffness of OHCs by 65%. Diamide presumably affects spectrin in the cortical lattice. Functionally, the stiffness of the PM must be at least within the same order of magnitude as that of the rest of the cell cortex. If it were not sufficiently stiff, most of the energy associated with conformational change of the motor protein would be stored in the PM itself as strain energy, whereas a stiffer cell cortex would resist the deformation. With the PM dominating the lateral wall stiffness, one hypothesis to explain OHC force coupling is the cytoskeletal spring model proposed by Holley and Ashmore (1988). In this model the molecular motors rest within the PM, and the cortical lattice is less stiff than the PM. When the motors change in dimensions, they push against themselves and their surrounding phospholipids, summing their forces and creating cell length changes. Hence, by this model, force coupling occurs within the PM because the PM has a high stiffness. An alternative possibility, suggested by Iwasa (1994) and further discussed by Tolomeo et al. (1996), is that motors in the PM transmit their force down the pillars to the cortical lattice, which then orients the forces. Because an equal and opposite force would be required to hold the motors in place within the PM, the PM must be stiffer than the cortical lattice in this theory, as well.

He and Dallos (1999, 2000) discovered that the axial stiffness of isolated OHCs is also voltage-dependent. They showed that cell stiffness increases upon hyperpolarization and decreases when the cell is depolarized. The stiffness change can be quite large — on the order of 100%. The stiffness change and somatic electromotility appear to co-vary if manipulated (He & Dallos, 2000). The general covariance of stiffness and length changes suggests that they may arise from a common mechanism, the motor protein (He et al., 2003). Existing standard area models (Iwasa, 1994, 2000) of OHC somatic electromotility do not automatically yield stiffness changes of the type that He and Dallos (1999, 2000) observed. Two generic models (Dallos & He, 2000) have been proposed to explain both phenomena via a single mechanism. The first model assumes that molecular motors change both their axial dimension and stiffness upon a voltage-dependent conformational shift. In the second model, only a stiffness change is associated with elementary motors. Corresponding cell-length change is obtained if the quiescent cell is preloaded so that in its resting state it is shorter than its natural length. This model suggests that somatic motility may simply be a consequence of stiffness change. This would then render voltage-dependent stiffness the primary

mechanism, with length change being an epiphenomenon (He & Dallos, 1999).

Honing in on the Role of the Cortical Actin-Spectrin Cytoskeleton in OHC Somatic Motility

A well-known paradigm establishes that even the simplest support system must be adapted to resist tension, compression and bending, three very different kinds of forces (Wainwright et al., 1982). The relative amount of each type of force, together with its intended function, will determine the particular support system for a given cell type. Cell's shape, in turn, will largely be an expression of this mechanical support system. Cochlear OHCs are a unique example of this paradigm.

OHCs possess a hydraulic support system consisting of a fluid under pressure (the cytoplasm), which acts as a compression-resisting component, and the container, which only resists tension (Brownell, 1990). Like OHCs, organisms with a fluid support system are either cylindrical or subcylindrical (Wainwright et al., 1982). However, while the walls of plant cells are rigid enough to support the cylinder at zero pressure, animal hydrostats are flabby and collapse without a positive internal pressure (Wainwright et al., 1982). For a cylindrical vessel closed at its ends — like an OHC — the stress in the longitudinal direction is

$$\sigma_L = pR/2t \quad (t = \text{membrane thickness}; \\ p = \text{external cell radius}).$$

The stress in the circumferential direction, in turn, is

$$\sigma_H = pR/t = 2\sigma_L$$

This means that if slight increases in internal pressure are not to cause disproportionate increase in body diameter, the cylinder wall must be reinforced in order to control the change of shape with changes in pressure. Because of that, lateral walls in pressurized cells are usually reinforced by helically oriented fibers. This is precisely the case in OHCs.

As noted above, OHCs possess a membrane skeleton — the cortical lattice (CL) — composed of relatively long, helically oriented actin filaments cross-linked by spectrin tetramers (Holley & Ashmore 1990a; Holley et al., 1992; Holley, 1996). The cortical actin-spectrin cytoskeleton is a structure common to every known cell population, although its molecular organization, extension and function are cell-specific.

Red blood cells (RBCs) and OHCs, in particular, expose two extreme cases of the functional adaptation of this structure. RBCs, like OHCs, possess a very well developed cortical actin-spectrin cytoskeleton (Bennett, 1990; Matsuoka, Li & Bennet, 2000; Bennet & Gilligan 1993). However, because of the particular

mechanical requirements in each case, they are structurally different. Healthy RBCs are highly deformable, a crucial requirement for cells that need to flow smoothly along very narrow capillary vessels. Consequently, the cytoskeleton is composed of five or six spectrin molecules linked to very short actin filaments, forming a highly flexible “spider-web” sheet underlying the plasma membrane. This arrangement ensures that any stress, in any direction, will actually be resisted by the highly deformable spectrin molecules rather than the practically inextensible actin filaments. In OHCs, in contrast, the cytoskeleton must primarily provide mechanical stability to the cells, and deformations are desirable only in the longitudinal direction and in a controlled way. This is provided by orienting the very long actin filaments in a near circular pattern and the spectrin molecules near parallel to the OHC’s longitudinal axis, facilitating the cell’s changes in length while maintaining the cylindrical shape. Interestingly, the connection between spectrin abundance, localization and particular spatial orientation in OHCs and one of the non-structural functions of these molecules has not been explored yet. Spectrin molecules have been described as “protein-sorting machines” that sort the proteins to be incorporated in plasma membranes (Beck & Nelson 1996), as well as “protein accumulators” because they can trap and stabilize particular protein species at specific points on cell surfaces (Hammarlund, Davis & Jorgensen, 2000; Moorthy, Chen & Bennet, 2000; Dubreuil et al., 2000). Thus, spectrin could be involved in the sorting, accumulation and organization of prestin molecules in the lateral plasma membrane of OHCs and, consequently, in the genesis of the OHC’s motor action.

The orientation and mechanical properties of the circumferential filaments and their cross-links could determine the nature of the shape changes observed in isolated cells (Holley and Ashmore 1988a). Wainwright and co-workers (Wainwright et al., 1982) mentioned as one of the “design principles for biological structural systems” that: “*Thin-walled cylinders are most effectively reinforced against explosion and buckling by crossed-helicallly wound fibers. As the cylinder changes shape, the fiber angle changes. For instance, if the cylinder becomes short and fat the angle increases, and vice-versa.*” In a closed, fiber-wound cylinder like an OHC, the circumferential and longitudinal stresses will be balanced when the fiber angle is $35^{\circ} 16'$ with respect to the transversal axis of the cell ($55^{\circ} 44'$ with respect to the longitudinal axis (Clark & Cowey 1958; Wainwright et al., 1982)

$$\sigma_H/\sigma_L = 2 = [\tan^2(35^{\circ}16')]^{-1}$$

For angles smaller than $35^{\circ}16'$, a given increase in pressure would produce an even larger increase in σ_H than in σ_L . For angles bigger than $35^{\circ} 16'$, the opposite will be true. Interestingly, cell volume would

be maximum for a fiber angle of $35^{\circ} 16'$, and would decrease for smaller or larger angles (Clark & Cowey, 1958; Wainwright et al., 1982). Therefore, the near inextensible actin filaments should be forming an angle smaller than 35° with the transversal axis of the cell in order to keep the cell cylindrical. It should be noted that a mechanism capable of controlling the angle of the helically oriented actin filaments could preserve the OHC’s cylindrical shape and at the same time modulate the amplitude of OHC motility by regulating the longitudinal component of the membrane-generated forces, cell stiffness, and membrane tension.

The question, of course, is which could be the mechanism capable of dynamically controlling the angle of actin filaments in the OHC cortical cytoskeleton. The answer could be in the modular organization of this structure.

The pillars have an important role in the recently proposed “membrane bending model of outer hair cell motility” (Raphael, Popel & Brownell 2000; Oghalai et al., 2000; Brownell et al., 2001; Morimoto et al., 2002). This model is based on the following three considerations (Raphael et al., 2000):

1. Membranes are thin structures in which bending deformations play a pivotal role in the response to external forces.
2. Membranes are liquid crystals and exhibit flexoelectricity.
3. The plasma membrane and the cytoskeleton are tightly associated.

Clearly, consideration number 3 is absolutely dependent on the presence as well as the structural and functional properties of the pillars. In addition, there are two points that, in our opinion, deserve a more detailed discussion. The first and third considerations should always be put in the context of the molecular scale of the OHC lateral wall. In many publications, either the membrane is represented thinner than the CL and/or the separation between the pillars is exaggerated. Although a conventional lipid bilayer may be modeled as ~ 8 nm-thick, a normal plasma membrane also includes a high concentration of integral membrane proteins and glycoproteins — with entire hydrophilic regions protruding from both surfaces of the bilayer — as well as plenty of extrinsic proteins adsorbed to the cytoplasmic side of the bilayer with strong interactions with plasma membrane lipids, proteins or both. Without considering the membrane glycocalyx — which in OHCs could be at least 100–200 nm thick — the actual thickness of a typical plasma membrane should be realistically assumed to be ~ 25 nm. This value is more than twice the pillar’s diameter, thrice the CL thickness, and nearly identical to the average separation between pillars along the actin filaments! From that point of

view, plasma membranes are hardly “thin structures”, and membrane bending would not be an easy task.

However, a significant increase in the distance between pillars — together with a positive cell turgor — could make a significant difference in the mechanical properties of the OHC lateral wall. For instance, as already emphasized by Brownell and coworkers, electron microscopy images of the OHC lateral wall frequently show a plasma membrane “rippling” (Fig. 3 *a*). A careful study of this membrane rippling, however, suggests that it is associated with regions of the lateral wall where the pillar-mediated connection between the CL and the plasma membrane is disrupted (Fig. 3*b*). Moreover, experiments with activators and inhibitors of Rho GTPases, which control the dynamics of the cytoskeleton, indicate that the extension and size of membrane rippling is correlated to the integrity of the pillar system (Kalinec et al., *unpublished*). Thus, not only the transmission but even the generation of forces in the OHC plasma membrane by prestin molecules and/or flexoelectricity could be somewhat regulated by the association between the plasma membrane and the CL via pillars.

It is clear, then, that some data suggest that the structure of the CL, the orientation of actin and spectrin molecules, and the integrity of the pillars could be important for the OHC electromotile response. We did not mention, however, how the CL structure, actin and spectrin molecular orientation, and pillar-mediated PM-CL connection — and consequently OHC somatic motility — could be regulated. From numerous studies in other cellular systems, it is currently accepted that the organization and dynamics of the cytoskeleton and associated molecules is mainly regulated by small GTPases of the Rho family (Van Aelst & D’Souza-Schorey, 1997; Hall, 1998). The existence of a cellular mechanism of homeostatic control of OHC motility involving small GTPases of the Rho family and Rho-mediated cytoskeletal changes has been already suggested (Kalinec et al., 2000). It has also been demonstrated that the molecular machinery underlying this mechanical homeostatic process requires the activation of Rho-Kinases (ROCK) as well as ROCK-dependent and ROCK-independent signaling pathways downstream RhoA and Rac1 (Zhang et al., 2003).

A potential problem with experiments aimed at elucidating the role of the cytoskeleton in the regulation of OHC somatic electromotility is that the results could be “contaminated” with slow, prestin-independent motile responses. For example, since electromotile amplitude is proportional to OHC total length, changes in the performance of the prestin-dependent mechanism could be exacerbated — or masked — by changes in total cell length. Recently reported studies, however, described a simple approach — based on continuous measurement of changes in cell length and longitudinal section area —

to evaluate the individual contribution of prestin-dependent and prestin-independent mechanisms to the total motile response of OHCs (Matsumoto & Kalinec, 2005). It was demonstrated that if the relative change in OHC length (L) during the motile response is expressed as $L = A^2 \times V^{-1}$ (with A and V being the relative changes in longitudinal section area and volume, respectively), A^2 will describe the contribution of the prestin-dependent, while V^{-1} will describe the contribution of the prestin-independent mechanisms. Thus, relative changes in any two of these cellular morphological parameters (L , A or V) would be necessary and sufficient for characterizing any OHC motile response. This simple approach may become an important tool for increasing our understanding of the cellular and molecular mechanisms of OHC somatic motility.

Putting the OHC into Action

It is certain that the evolution of the OHC was designed to enhance basilar membrane motion in order to amplify the mechanical input to the IHC, thereby providing improved hearing capabilities for mammals, which must register high-frequency sounds. The apparent voltage-dependent nature of OHC somatic electromotility necessarily encumbers the effectiveness of the presumed stimulus — voltage — in driving high-frequency mechanical activity. This conundrum derives from the low-pass filter effect of the cell’s plasma membrane (Santos-Sacchi, 1992; Santos-Sacchi, 1989). Consequently, receptor potentials generated by stereociliary transduction elements will be reduced at high acoustic frequency, resulting in diminished feedback into the basilar membrane. In addition to the several proposals advanced to explain how the OHC might deal with this difficulty (Santos-Sacchi et al., 1998; Kakehata and Santos-Sacchi, 1995; Dallos & Evans, 1995; Spector et al., 2003), a stretch-and voltage-activated conductance in the lateral membrane of the OHC, G_{metL} , was recently shown to be permeable to chloride anions (Song et al., 2005; Rybalchenko & Santos-Sacchi, 2003). Because the state of prestin is sensitive to the concentration of chloride near the inner leaflet aspect of prestin, chloride itself by fluctuating across the membrane could “gate” motor activity in a manner which circumvents the low-pass membrane characteristic (Rybalchenko & Santos-Sacchi, 2003; Santos-Sacchi, 2003). Whether such a scheme works in vivo remains to be determined. Nevertheless, we have recently found that modulating extracellular chloride levels in the perilymph bathing OHCs in the living animal (or other manipulations that alter the chloride gradient across the OHC membrane) can drastically alter cochlear amplification in a reversible manner (Nuttall, Zheng

& Santos-Sacchi 2005, Santos-Sacchi et al., 2006). Because intracellular chloride activity is below 10 mM (Santos-Sacchi & Song 2005), and perilymph is about 140 mM, modulation of the chloride gradient could alter the gain of the cochlear amplifier. In fact, changes in intracellular chloride concentration (Song et al., 2005) shift the operating voltage range of somatic electromotility. However, independent of how modulation occurs, it is clear that anions play a powerful physiological role in vivo.

Summary

In an attempt to expand on the pioneering work of the latter part of the last century, a feverish quest continues to uncover the events that lead to cochlear amplification in mammals. The role of the OHC is certainly paramount, and we now have identified many of its membrane constituents that form the basis of the cell's unique contribution. As this review intimates, the motor protein prestin and its interaction with other players within and beneath the plasma membrane drive the cell's augmentation of mammalian hearing acuity. Nevertheless, we are far from understanding the full complement of cellular elaborations that define the cell's mechanical capabilities. Surely, the next quarter century will tell more.

This work was supported by grants NIDCD DC006412 (JZ), NIDCD DC 006496 (DZZH), NIDCD DC05220 and House Ear Institute (FK), Grants-in-Aid for Scientific Research from the Ministry of Education, Culture, Sports, Science and Technology of Japan (SK), NIDCD DC00273 (JSS). We thank Peter Dallos and MaryAnn Cheatham for their comments on manuscript.

Mapping the Distribution of the Outer Hair Cell Motility Voltage Sensor by Electrical Amputation

Guojie Huang and J. Santos-Sacchi

Sections of Otolaryngology and Neurobiology, Yale University School of Medicine, New Haven, Connecticut 06510 USA

ABSTRACT The outer hair cell (OHC) possesses a nonlinear charge movement whose characteristics indicate that it represents the voltage sensor responsible for OHC mechanical activity. OHC mechanical activity is known to exist along a restricted extent of the cell's length. We have used a simultaneous partitioning microchamber and whole cell voltage clamp technique to electrically isolate sections of the OHC membrane and find that the nonlinear charge movement is also restricted along the cell's length. Apical and basal portions of the OHC are devoid of voltage sensors, corresponding to regions of the cell where the subsurface cisternae and/or the mechanical responses are absent. We conclude that the physical domain of the motility voltage sensor corresponds to that of the mechanical effector and speculate that sensor and effector reside within one intra-membranous molecular species, perhaps an evolved nonconducting or poorly conducting voltage-dependent ion channel.

INTRODUCTION

The peripheral auditory system is responsible for the initial decoding of spectral information within acoustic stimuli. In the mammal, frequency selectivity and sensitivity afforded by Bekesy's basilar membrane traveling wave is enhanced by a metabolically labile process which involves one of the two types of sensory cells which populate the organ of Corti, the outer hair cells (OHC). Following the discovery of electrically induced OHC motility (Brownell et al., 1985), evidence has accumulated that the mechanical activity of the OHC alters basilar membrane motion in such a way as to enhance the tuning characteristics of inner hair cells and eight nerve fibers (Ruggero, 1992).

OHC motility is transmembrane voltage-dependent (Santos-Sacchi and Dilger, 1988; Iwasa and Kachar, 1989). Hyperpolarization elongates and depolarization shortens the cylindrically shaped cell. The mechanism underlying this shape change which can occur at acoustic frequencies is unknown. However, it is not based on typical cellular mechanisms of motility (Kachar et al., 1986; Santos-Sacchi and Dilger, 1988; Holley and Ashmore, 1988). In fact, recent evidence indicates that the force generating mechanism may reside within the plasma membrane itself, possibly corresponding to 8–10-nm intramembranous particles observed ultrastructurally in the lateral plasmalemma (Kalinec et al., 1992).

Nonlinear charge movement in the OHC, which is believed to be indicative of a motility voltage sensor, has been studied (Ashmore, 1989, 1992; Santos-Sacchi, 1990, 1991a, 1992), and many characteristics of the mechanical response and charge movement coincide. Recently, Dallos et al. (1991) have utilized a partitioning microchamber to map the distribution of the mechanical response along the length of the cylindrical OHC, and found that it resides within a central

region, roughly corresponding to the extent of the subsurface cisternae, an intracellular membranous system lying beneath the plasma membrane. Ashmore (1992) presented preliminary evidence that the nonlinear charge movement measured in cell-attached patches exists on the lateral portion of the cell, but is absent on the basal end. We have evaluated the extent of the motility voltage sensor using a combined microchamber and whole cell voltage clamp technique which enables us to electrically amputate portions of the OHC. We conclude that the distribution of the motility voltage sensor corresponds to the extent of the mechanical responses observed with the partitioning microchamber (Dallos et al., 1991), that is, that sensor and effector mechanisms colocalize.

A preliminary account of this work has been presented (Santos-Sacchi and Huang, 1993).

MATERIALS AND METHODS

General

Guinea pigs were overdosed with halothane. The temporal bones were removed, the apical two turns of the organ of Corti were microdissected free, and OHCs were isolated enzymatically with collagenase (0.3 mg/ml for 10 min followed by gentle reflux through a tapered polyethylene pipette tip) in Medium 199 with Hanks' salts (GIBCO). The cell-enriched supernatant was then transferred to a 700- μ l perfusion chamber, and the cells were permitted to settle onto the cover glass bottom. All experiments were performed at room temperature (\sim 23°C). A Nikon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical recording. Experiments were videotaped. A modified Leibovitz medium (100 mM NaCl, 5.37 mM KCl, 2.0 mM CoCl₂, 1.48 mM MgCl₂, 20 mM tetra ethyl ammonium, 2 μ M tetrodotoxin, 20 mM CsCl, 5.0 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid, 5.0 mM dextrose, pH 7.2) was used in order to block ionic conductances (outward and inward K⁺, Ca²⁺, Na⁺) which might otherwise interfere with capacitive current measures. OHCs maintained normal appearance in this solution for up to an hour. Osmolarity was adjusted to 300 mOsm with dextrose.

Electrical Recording

OHCs were whole cell voltage-clamped with a Dagan 8900 patch clamp amplifier at a holding potential of -80 mV, similar to the potential recorded

Received for publication 26 April 1993 and in final form 26 July 1993.

in vivo (Dallos et al., 1982). Pipette solutions were composed of 140 mM CsCl, 10 mM EGTA, 5 mM tetra ethyl ammonium, 2 mM MgCl₂, and 5 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid buffered to pH 7.2. Osmolarity was adjusted to 300 mOsm with dextrose. Gigohm seals were obtained either at the nuclear level of the cell membrane or just beneath the cuticular plate depending upon experimental intent; electrode capacitance and series resistance were compensated prior to whole cell recording. A modified version of Clampex (Axon Instruments, CA) utilizing the Labmaster board was used to collect data which were saved to disk for off-line analysis. Current was filtered at 5 kHz with an eight-pole Bessel filter.

Determination of nonlinear capacitance

The electrical characteristics of the voltage-clamped OHC when ionic conductances are blocked can be modeled most simply as an electrode resistance (access resistance, R_s) in series with a parallel combination of a membrane resistance (R_m), a linear membrane capacitance (C_{lin}), and a voltage-dependent membrane capacitance (C_v) (Fig. 1 A). The total membrane capacitance (C_m) at any given voltage is the sum of the linear and nonlinear capacitances,

$$C_m = C_v + C_{lin}, \quad (1)$$

where C_v , which results from the nonlinear charge movement associated with the motility voltage sensor, is defined as the first derivative of the two-state Boltzmann function ($Q_v = Q_{max}/(1 + \exp(-ze(V_m - V_h)/kT))$) which has been shown to adequately relate OHC nonlinear charge movement and membrane voltage ($C_v = dQ_v/dV_m$; see Santos-Sacchi (1991a)). Thus,

$$C_v = \frac{\left(Q_{max} \frac{ze}{kT} \right)}{\exp\left(\frac{ze}{kT} (V_m - V_h) \right) \left[1 + \exp\left(\frac{-ze}{kT} (V_m - V_h) \right) \right]^2}, \quad (2)$$

where V_m is the membrane potential, V_h is voltage at half-maximal nonlinear charge transfer, e is electron charge, k is Boltzmann's constant, T is absolute temperature, z is the valence, and Q_{max} is maximum nonlinear charge transfer. Fits of the measured capacitance data with this equation permit the estimation of nonlinear charge characteristics, similar to measures of these characteristics determined by subtraction techniques (e.g., *P/-4*) which have been utilized previously (Santos-Sacchi, 1991a).

The method employed to estimate membrane capacitance (C_m) and series resistance (R_s) is based on a linearized circuit at small excitation voltage steps (V_c). It is robust despite filter settings and accurately takes into account the effects of series resistance on capacitance measures (Santos-Sacchi, 1993).

For each response at a given step voltage (Fig. 1, *b* and *c*; see Appendix),

$$C_m = \left(\frac{R_{in}}{R_m} \right)^2 \frac{Q}{V_c} \quad (3)$$

$$R_s = \frac{R_m \tau V_c}{Q R_{in} + \tau V_c}, \quad (4)$$

where

$$R_{in} = R_m + R_s, \quad (5)$$

the input resistance readily obtained at steady state. V_c is the raw command voltage. The time constant (τ) is a single exponential fit to the decaying capacitive current induced by the voltage step, and the charge (Q) is obtained by integration (Fig. 1 D). Eq. 3 had been identified and used by Mathias et al. (1981) to evaluate alternative explanations of nonlinear gating charge movement. It is the proper evaluation of cell capacitance for the cell model when the ratio of R_s and R_m does not approach zero. In this report, voltage and charge were corrected for residual series resistance effects. Furthermore, to account for voltage step size, the voltages used in the fits of the capacitance data to Eq. 1 were taken to be the corrected voltage prior to the step plus one-half the corrected step voltage, i.e., the average voltage,

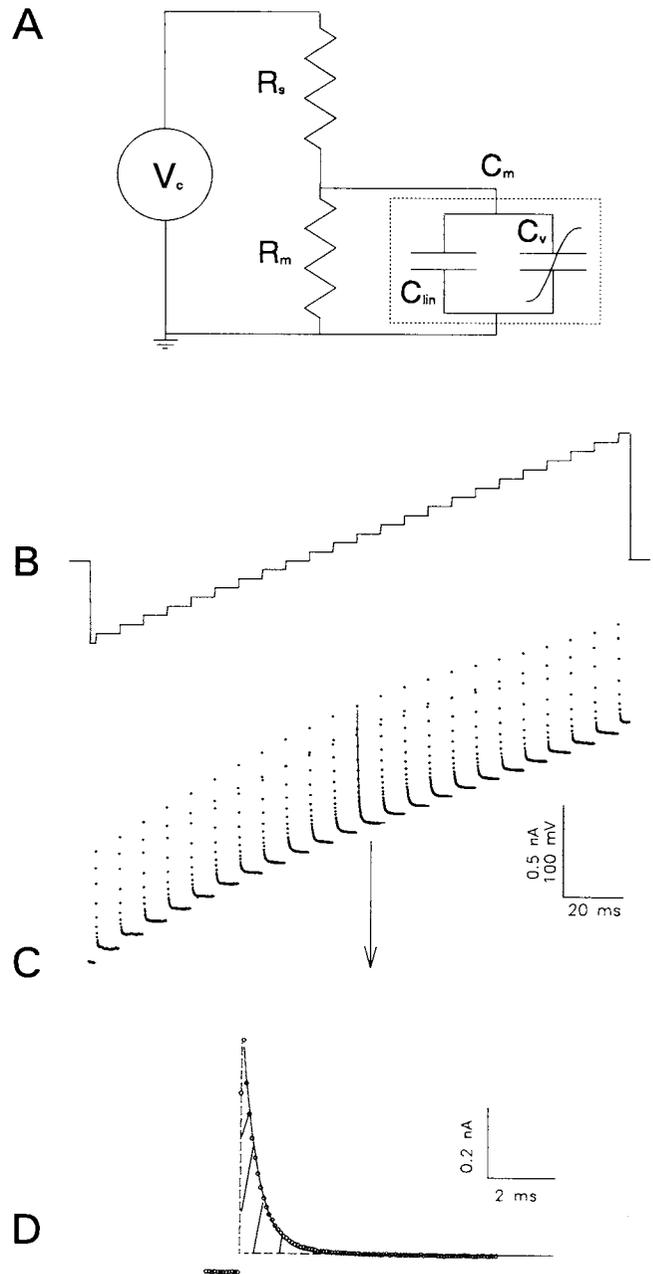

FIGURE 1 (A) Schematic of the OHC under voltage clamp. Charge was determined by integration of the shaded region.

as is predicted through modeling. All data analysis was performed with the software package MATLAB (Mathworks, Natick, MA). Fits of the data to Eq. 1 were made with the Nelder-Mead simplex algorithm.

The voltage protocol was a stair stimulus (2048 pts) whose nominal step size was 10 mV (Fig. 1 B), and whose step length was automatically adjusted to 10 times the previously determined time constant at the holding potential of -80 mV. Current records are averages of 20 collections. Since the time constant at each step potential is influenced by the OHC's nonlinear capacitance and any residual nonlinear leakage conductance, it was impossible

to guarantee that the decaying current trace would reach steady state for each step potential (Fig. 1 C). In order to overcome this limitation, the length of the exponential fit was extended to 10 times the fitted time constant and the fit was used for Q determination. The exponential fit was not extended back to zero onset time but only to peak current time. However, integration was performed back to zero onset time, utilizing pre-peak data points (Fig. 1 D). The position of peak current is due to the filtering effects of the clamp amplifier, and, as such, charge should be redistributed in time but not reduced.

RESULTS

OHCs possess a membrane capacitance which depends upon transmembrane voltage. In addition, despite efforts to block nonlinear voltage-dependent conductances, a residual nonlinearity remains. Fig. 2 illustrates the voltage dependence of the membrane capacitance and demonstrates the necessity of correcting for series resistance effects. In this example, a cell was chosen for which the series resistance and membrane resistance were relatively high, 27 and 281 Mohm, respectively (ratio of 0.096). Consequently, the time constants of the capacitive current decay are very large at potentials where the voltage-dependent capacitance is greatest. The series resistance-corrected membrane capacitance (Fig. 2, *solid downward triangles*) is plotted as a function of membrane voltage and fitted (*solid line*) with Eq. 1. The open downward triangles represent apparent capacitance estimates (Q/V_c), i.e., no series resistance corrections were made. Note the large differences in magnitude and voltage dependence between membrane and apparent capacitance. For comparison, the upward triangles represents a model simulation (that of Fig. 1 A) utilizing the parameters obtained from the fit to the corrected membrane capacitance data and a linear average membrane resistance. It is clear that the membrane capacitance estimates of the model and the data superimpose, how-

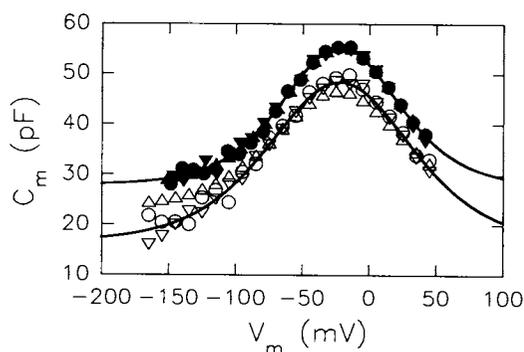

FIGURE 2 voltage-dependent capacitance of guinea pig OHC. Closed symbols indicate the membrane capacitance at each voltage step after correction for series resistance effects. Biophysical data (*downward triangles*), electrical model using fitted parameters of the biophysical data and a linear membrane resistance (*upward triangles*), model incorporating residual nonlinear membrane resistance of the biophysical data (*circles*). The solid line through these data points is a fit with Eq. 1 of the biophysical data (V_h , -27.33 mV; z , 0.829 ; Q_{max} , 2.66 pC; C_{lin} , 23.24 pF). The open symbols depict the apparent capacitance (Q/V_c) at each step, i.e., no series resistance corrections were made. The solid line through these data points is a fit with Eq. 1 of the biophysical data (V_h , -23.97 mV; z , 0.667 ; Q_{max} , 3.89 pC; C_{lin} , 14.75 pF). Note the requirement for series resistance correction in order to obtain correct estimates of the membrane capacitance.

ever, apparent capacitance estimates differ somewhat. Finally, the circles illustrate results when the nonlinear leakage conductance found in the biophysical data is included. Again the corrected capacitance data closely corresponds to the biophysical data, but now the apparent capacitance does as well. Simply modeling the cell with only a nonlinear leakage conductance does not generate an artifactual voltage-dependent capacitance. This exercise demonstrates that the method for estimating membrane capacitance (*filled symbols* in Fig. 2) is robust despite the existence of residual nonlinear leakage conductance and indicates that the correction for series resistance is required to obtain accurate estimates of membrane capacitance.

An additional 12 cells were recorded from in which the ratio of series resistance to average membrane resistance was fairly low, namely 0.057. Fits to the data indicate that the average maximum nonlinear charge transfer (Q_{max}) is 2.4 pC per cell, with a valence (z) of 0.92 . This corresponds to a peak nonlinear capacitance of 21.55 pF at -34.8 mV, riding upon a linear capacitance of 22.7 pF. The linear capacitance corresponds to the estimated whole cell surface area (based on a cylindrical model of the OHC) with the ratio of about 0.01 pF/ μm^2 (Fig. 3; however, see Discussion). It should be noted that nonlinear charge movement similar to that representing the motility voltage sensor is not demonstrable in supporting cells and is measurable in OHCs from species other than the guinea pig, e.g., mouse (Fig. 4).

In order to determine whether the motility voltage sensor is distributed within a restricted region of the OHC, a double voltage clamp protocol using two independent clamp amplifiers was employed. That is, utilizing the partitioning microchamber of Evans et al. (1989), in combination with whole cell voltage clamp we are able to electrically amputate that portion of the OHC housed within the chamber (Fig. 5). When identical voltage clamp stimuli are simultaneously delivered to the microchamber and the cell interior, only that portion of the membrane outside the chamber is excited.

The efficiency of this amputation technique is dependent upon the seal (shunt resistance, R_{sh}) which the microchamber makes with the OHC. This is illustrated in Fig. 6, where an

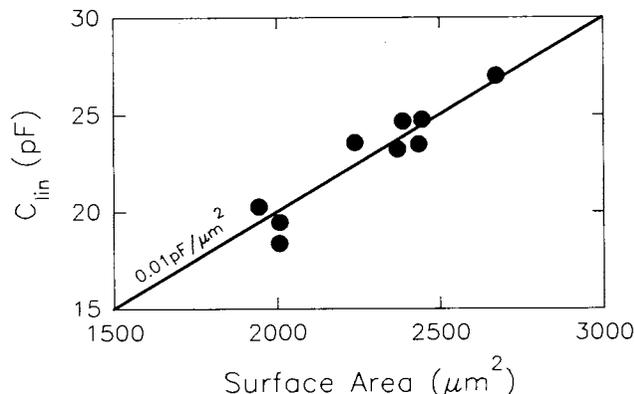

FIGURE 3 Linear capacitance (C_{lin}) versus estimated surface area of OHCs for nine cells.

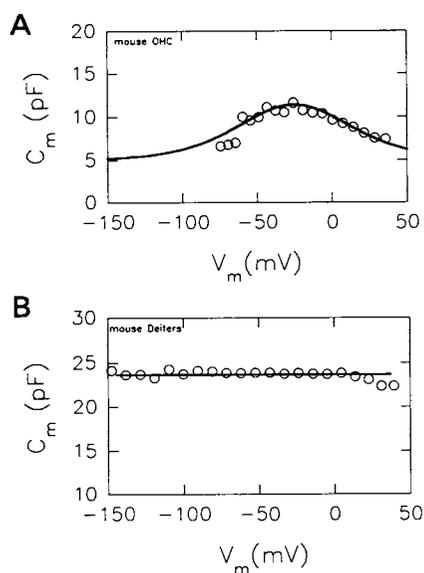

FIGURE 4 (A) Nonlinear membrane capacitance of a mouse OHC as a function of membrane potential. Mechanical responses were observed as well. (B) Membrane capacitance of a mouse Deiters cell demonstrates no voltage dependence.

electrical model of the double voltage clamp is evaluated with a model cell partitioned half-way. It is shown that when the shunt resistance is zero (or the chamber voltage is clamped to zero, i.e., ground), the system performs as a simple whole cell voltage clamp, measuring the parallel combination of the internal and external membrane capacitance. A shunt resistance above 5–10 Mohm, which is typical with the technique, provides good estimates of only the external membrane capacitance. By altering the partitioning of an OHC, it is possible to measure changes in linear and nonlinear capacitance utilizing the voltage stair protocol.

Fig. 7 presents the results from an individual OHC for which it was possible to obtain capacitance measures under three partitioning conditions and the whole cell condition. As the cell is extruded from the chamber, both the linear and nonlinear capacitance increase, because increasingly more membrane is exposed to the voltage stimulus (Fig. 7 A). Under the assumption that the change in linear capacitance and nonlinear charge (or nonlinear capacitance) is colinear as a function of cell extrusion, that is, that the voltage sensors are evenly distributed within the membrane, a linear fit to the partition data points provides evidence for the existence of a restricted, voltage-sensing region within the OHC (Fig. 7 B). The motility data of Dallos et al. (1991) indicates that the motor elements are evenly distributed along the length of the cell. It is likely, therefore, that motility voltage sensors are as well. The linear fit indicates that when the nonlinear charge movement (Q_{max}) reaches zero, linear capacitance is still measurable. That is, as the extent of cell inclusion is increased, a point is reached where nonlinear capacitance is absent, but linear capacitance exists and would continue to decrease with further inclusion. Similarly, as the cell is extruded, Q_{max} reaches a maximum but linear capacitance con-

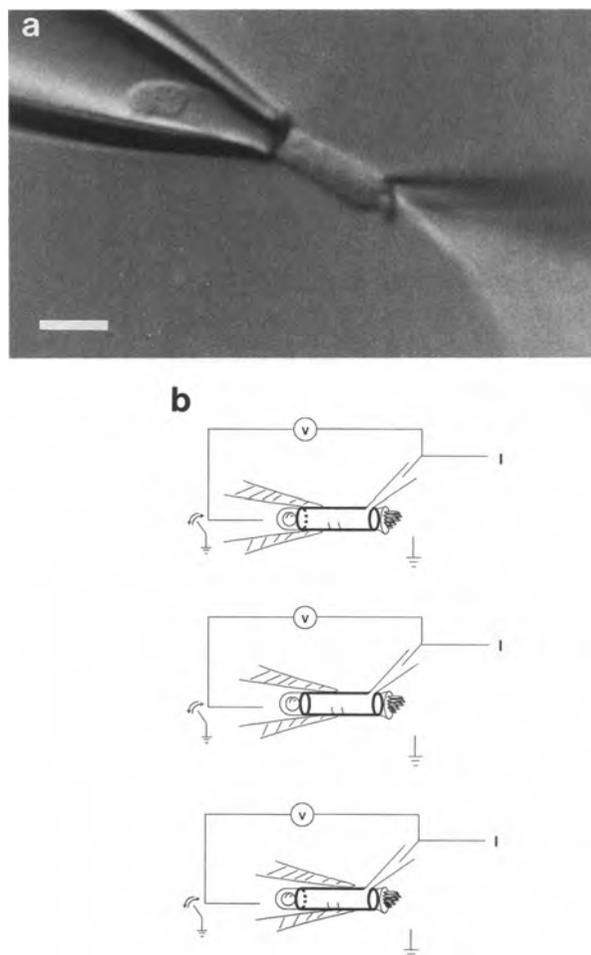

FIGURE 5 (A) Photomicrograph of a guinea pig OHC under double voltage clamp condition. Basal region of cell is within microchamber, and whole cell recording is established at the apical region. Scale is 20 μm . (B) Diagrammatic representation of the double voltage clamp with the OHC under three different conditions of cell extrusion.

tinues to increase with further extrusion. The slope of the fitted line indicates a charge density of $12,373 e^-/0.01 \text{ pF}$ within the voltage-sensing region. As expected, the portion of the cell within the microchamber which experiences no transmembrane voltage drop demonstrates no mechanical response, whereas the portion outside the chamber does (data not shown). However, upon grounding the chamber voltage, mechanical responses of that portion of the cell within the chamber are evident. Thus, the amputation technique also confirms the distributed nature of the mechanical effector (Dallos et al., 1991).

It is extremely difficult to maintain the preparation during changes in partitioning. Nevertheless, it was possible to obtain data on six additional OHCs where at least two partitioning conditions and the whole cell condition were achieved. The average linear capacitance in the apical region of the cells ($n = 7$) where no voltage sensors exist was 4.38 pF. In the base the average was 1.85 pF. The average charge density of the voltage-sensing region for these cells was $10,669 e^-/0.01 \text{ pF}$. The average R_s/R_m ratio for these cells was 0.24.

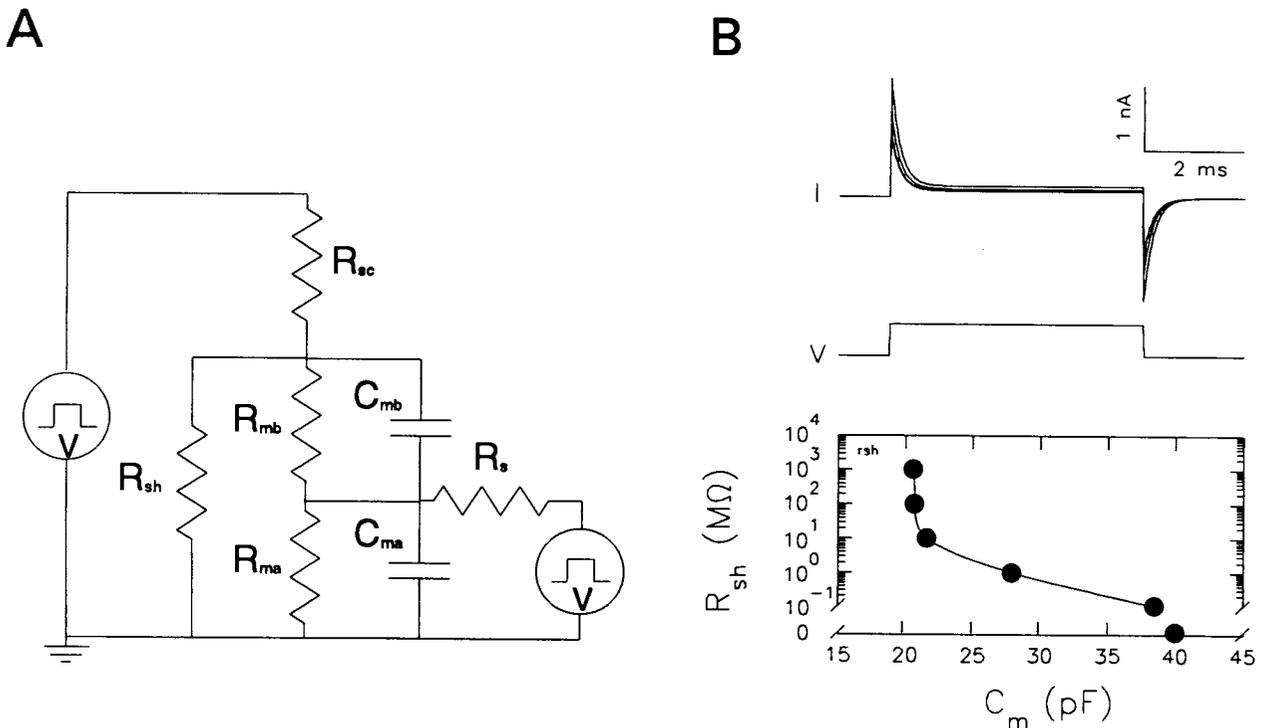

FIGURE 6 (A) Electrical model of double voltage clamp. R_{sc} , chamber series resistance; R_s , patch electrode series resistance; R_{sh} , shunt resistance between chamber electrode and ground; R_{mb} , membrane resistance of inserted portion of cell; C_{mb} , membrane capacitance of inserted portion of cell; R_{ma} , membrane resistance of extruded portion of cell; C_{ma} , membrane capacitance of extruded portion of cell. (B) The above model was numerically evaluated with parameters representing a cell inserted half way into the chamber, and the shunt resistance was varied to observe the effects on the efficiency of electrical amputation of the inserted portion. R_{sc} , 0.5 $M\Omega$; R_s , 5 $M\Omega$; R_{mb} and R_{ma} , 100 $M\Omega$; C_{mb} and C_{ma} , 20 pF. Current traces (I) in response to a 10 mV (V) step were used to determine input capacitance (see Methods) as a function of R_{sh} . When R_{sh} is zero the system functions as a simple whole cell voltage clamp, indicating a capacitance of 40 pF. Above 5–10 $M\Omega$, the system provides good indications of that capacitance of the extruded portion of the cell, 20 pF.

DISCUSSION

Several lines of evidence indicate that the mechanical response of the OHC is voltage-dependent (Santos-Sacchi and Dilger, 1988; Iwasa and Kachar, 1989; Ashmore, 1989; Santos-Sacchi, 1991a, 1992). The nonlinear charge movement, which presents itself as a voltage-dependent capacitance, is believed to represent the activity of the OHC's motility voltage sensor. Indeed, many of the characteristics of the nonlinear charge movement correspond to those of the OHC mechanical response, including extent and slope of voltage dependence, kinetics (which have yet to be fully described due to the limitations of the clamp time constant), block by gadolinium ions, and susceptibility to charge screening (Ashmore, 1992; Santos-Sacchi, 1991a, 1992). The present results indicate that the OHC nonlinear capacitance is restricted along the length of the cell, just as the mechanical response is restricted (Dallos et al., 1991).

Estimation of membrane capacitance and nonlinear charge

Under whole cell voltage clamp, OHCs from the apical turn of the cochlea possess a fairly low membrane resistance. Original estimates were between 20 to 40 $M\Omega$ (Ashmore and Meech, 1986). More recent average estimates are between 75

and 100 $M\Omega$ (Santos-Sacchi and Dilger, 1988; Housley and Ashmore, 1992). Because the ratio of series resistance to membrane resistance under whole cell voltage clamp is not ideal, i.e., zero, it is necessary to correct for series resistance effects. In the present report, membrane capacitance measures were corrected for such effects, and the efficacy of the correction procedure was verified through modeling. Corrections were especially important for those cells partitioned with the microchamber, where the membrane resistance was low (and the R_s/R_m ratio high) as a result of the physical trauma necessarily imposed upon the cell. Eq. 3 indicates that not only corrections to steady state voltage ($V_c \times R_m/R_{in}$) are required, but also corrections to charge magnitude ($Q \times R_{in}/R_m$) are required. In a previous study by Santos-Sacchi (1991), steady state voltage corrections were used to correct voltage dependence measures of nonlinear charge movement; however, corresponding corrections to the charge magnitudes were not made. In that study, average maximum charge movement (2 pC) was probably underestimated. The average Q_{max} in the present study was 2.59 pC ($n = 19$).

Area of OHC devoid of voltage sensors

A linear fit to the partition data points provided average estimates of linear capacitance in the sensor-devoid basal and

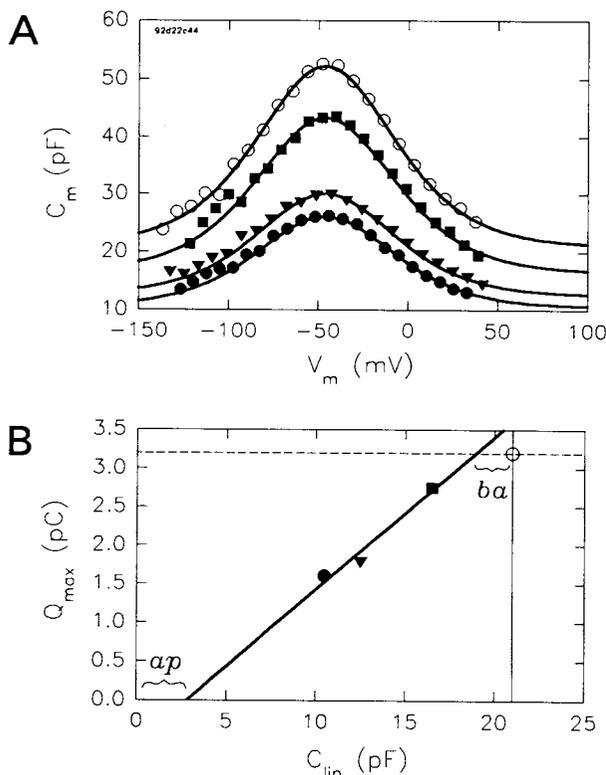

FIGURE 7 (A) The voltage-dependent membrane capacitance of a single OHC was evaluated at three levels of partitioning (*closed symbols*) and the whole cell condition (*open symbols*). Linear and nonlinear capacitance decrease as the cell inclusion is increased. The whole cell data were fit using the Nelder-Mead simplex algorithm. Partition data were fit by eye while holding z constant and varying Q_{\max} : z : 1. V_h of whole cell data: -46 mV, others shifted to coincide; filled squares, triangles, and circles were -51 , -53 , and -48 mV, respectively. (B) Relation between C_{lin} and Q_{\max} determined from above fits for the different levels of partitioning. Linear fit to the partition points indicates the extent of the OHC motility voltage sensor along the length of the cell. The vertical line indicates whole cell linear capacitance; the horizontal dotted line indicates whole cell Q_{\max} . Linear capacitance denoted by *ap* (2.65 pF) represents the area of the apical portion of the cell devoid of voltage sensors; that denoted by *ba* (2.06 pF) represents the area of the basal portion of the cell devoid of voltage sensors. Slope of fitted line indicates a charge density of $12,373 e^-/0.01$ pF within the sensing region. Ratio of R_s to R_m : 0.19.

apical regions of the OHC. The values were 1.85 and 4.38 pF, respectively. The actual membrane surface area of the OHC is greater than that estimated with light microscopy by a factor of about 1.3 (due to lateral membrane surface crenulation; see Dallos (1983)). This indicates that the linear specific capacitance measures obtained in the present study should be corrected¹ to a value of about 0.008 pF/ μm^2 . Consequently, the above capacitance values translate to areas of 231 and 547 μm^2 , respectively. It is possible to compare

these results with the surface areas of OHC plasmalemma which lack adjacent subsurface cisternae and/or mechanical responses.

Microchamber analysis of OHC motility demonstrates that a mechanical response is absent in the cell's most basal region (7 μm in length (B. Evans, personal communication)). The subsurface cisternae are poorly developed or absent in this region, as well. By modeling this basal region of the OHC as a half sphere of 5 - μm radius, with a 2 - μm cylindrical extension, an area of 220 μm^2 is obtained. This compares favorably with the present estimate of basal surface area lacking voltage sensors. At the apical region of the cell, substantial amounts of subsurface cisternae do not arise until about 5 μm from the top of the cell (Ades and Engstrom, 1974; Saito, 1983). The apical region of the OHC is oddly shaped (Fig. 5 *a*); however, if this portion is modeled as a simple single-ended cylinder (which is likely to underestimate its actual area) with a radius of 5 μm and length of 5 μm , then the calculated surface area is 236 μm^2 . Accounting for stereociliar surface area² (average of 50 per cell, with a radius of 0.15 μm and length of 6 μm ; B. Evans, personal communication), the total apical area increases to 518 μm^2 , which is similar to the present estimate of apical surface area lacking voltage sensors. These calculations provide strong support for the notion that the regions of the OHC which lack motility voltage sensors correspond to those which lack subsurface cisternae and/or voltage-dependent mechanical responses. Ultrastructural studies also indicate that only the lateral portion of the OHC plasmalemma possesses dense arrays of intramembranous particles (Saito, 1983; Kalinec et al., 1992).

The correspondence of the nonlinear capacitance with plasmalemmal regions bordering subsurface cisternae may imply some sort of electrical interaction between plasma and subsurface membrane. Such a possibility was considered by Santos-Sacchi (1991a) to account for nonlinear capacitance in this cell. That is, electrical interactions between the two membranous systems might affect capacitance measures, as occurs for input capacitance measures in inner ear supporting cells which are coupled via gap junctions (Santos-Sacchi, 1991b). Recently, however, it has been demonstrated that, following disruption of OHC subsurface structures with intracellularly applied trypsin, mechanical responses of the plasma membrane remain (Kalenic et al., 1992). This indicates that the mechanical effector resides within the plasma membrane. Similar treatments do not abolish the nonlinear capacitance (Huang and Santos-Sacchi, unpublished results), which implies a colocalization of motility voltage sensor and effector within the plane of the plasma membrane. Nevertheless, it is interesting that the subsurface cisternae and voltage sensors coincide, and it is possible that the subsurface

¹The correction is based on the assumption that the linear-specific capacitance is the same in sensor-containing and sensor-devoid membranes. It is possible that the sensor-containing region has a somewhat higher specific capacitance due to a higher dielectric of the protein particles residing therein. The corrected value should be considered approximate.

²While it was often noted that stereocilia were absent in isolated OHCs, it is possible that the isolation procedure caused resorption of the structures. For example, hair cell trauma often causes fusion and clumping of stereocilia (Engstrom, 1983). We never observe isolated stereocilia which may have been sheared off during isolation.

membrane represents a normal molecular turnover route for the motility voltage sensor and/or effector.

Uniform nature of voltage sensors within the OHC

It has previously been noted that some of the nonlinear charge movement in OHCs should be due to gating of voltage-dependent ionic channels (Santos-Sacchi, 1991a). However, while the supporting cells undoubtedly possess channel gating charge, charge movement of the magnitude recorded in OHCs is not seen. It appears that the charge moved by the motility voltage sensor far outweighs that contributed by channel gating, indicating that the characteristics of the nonlinear charge movement in the OHC overwhelmingly reflect that of the motility mechanism. Using similar logic, Fernandez et al. (1983) were able to evaluate characteristics of the membrane bound charge movement produced by the lipophilic molecule DpA^- despite the existence of smaller channel gating charge.

Some aspects of the nature of the voltage sensors along the length of the OHC can be gleaned from the results of the partitioning experiments. That is, it is possible to determine whether sensor characteristics (e.g., voltage sensitivity) along the extent of the active, voltage-sensing region vary from the average obtained under whole cell conditions. The only factor which changed significantly during changes in the degree of partitioning was the value of Q_{max} (except for the linear capacitance, of course). That is, the same nonlinear capacitance function (namely, z kept constant) which fit the whole cell data could adequately describe capacitance measures obtained from increasingly smaller portions of the cell. V_h was seen to vary sometimes, and may be due to charge screening effects, or changes in the metabolic state of cells during the course of the experiments. For example, it is known that phosphorylating agents can shift V_h without altering other parameters of the OHC nonlinear capacitance function (Huang and Santos-Sacchi, 1993). The maintenance of the form of the C_v function during successive amputations indicates that the nature of the voltage sensor along the extent of the OHC is constant, and that partitioning simply alters the number of sensors which are activated. That is, the voltage sensors (and possibly effectors) are probably of one type along their extent.

Density of voltage sensors

The number of independent elementary charges moved per square micrometer has previously been estimated to be about 4000 (Santos-Sacchi, 1991a), based on a Q_{max} of 2 pC and a total surface area of a model OHC of 70- μm length. In the present report, the linear capacitance values obtained in whole cell configuration translate to an average membrane surface area of 2917 μm^2 ($n = 19$). Thus, with the present Q_{max} value of 2.59 pC, an average charge density of 5542 $e^-/\mu\text{m}^2$ is obtained. However, it is now clear that the extent of the OHC motility voltage sensors is restricted along the

length of the cell. It is necessary, therefore, to compute charge density based on surface area estimates for that portion of the OHC which possesses the motility voltage sensors. After removing the average surface area of the OHC devoid of voltage sensors (sum of apex and base: 6.23 pF or 778 μm^2 ($n = 7$)) from the total average surface area, we obtain an average charge density of 7558 $e^-/\mu\text{m}^2$. Since the voltage dependence of the nonlinear charge movement and motility are comparable (z close to 1 (Ashmore, 1992; Santos-Sacchi, 1991a)), it is concluded, based on a two-state model, that about 7500 $e^-/\mu\text{m}^2$ independent elementary charged particles control the mechanical activity of the OHC. It is tempting to attribute the measured charge movement to integral membrane proteins represented by the membrane particles observed in the lateral plasmalemma of the OHC (Gulley and Reese, 1977; Saito, 1983; Forge, 1991; Kalinec et al., 1992). In a similar fashion, Roberts et al., (1990) suggested, based on colocalizing ultrastructural and electrophysiological evidence, that membrane particles located at synaptic areas of the hair cell may represent K^+ and Ca^{2+} channels. One possible interpretation of the colocalization of sensor and effector along the length of the OHC is that the sensor and effector reside within one molecular species, similar to ionic channels where sensor movement in an electrical field is believed to promote gating via a conformational change of the channel protein.

However, the present charge density estimate is no longer in line with the suggestion of Santos-Sacchi (1991a) that the number of elementary charges corresponds to the number of particles observed ultrastructurally in the OHC lateral membrane. Recent estimates of the number of membrane particles indicate about 2500/ μm^2 (Holley et al., 1992). It may be that each membrane particle possesses three charges which must each independently move between two states to effect a mechanical response. An interesting reinterpretation of the OHC charge data may be made by utilizing the electrodiffusion model of Neumcke et al. (1978), in which charge movement is viewed as a multistate phenomenon. For example, using this Langevin type fit to their data, they determined that the valence (z) of Na^+ channel nonlinear charge movement was about three times that of a two-state model. The multistate model more accurately accounted for Na^+ channel gating and conductance characteristics. Drews (1988) reached a similar conclusion. Under such an interpretation, the valence (z) of OHC charge movement would be closer to 3, and this might suggest that three charges correspond to each ultrastructurally observed membrane particle, all charges needing to traverse a characteristic distance across the membrane before a mechanical effect ensues. The multistate model would predict that the onset of the mechanical response would be delayed following a step voltage stimulus, and this type of response has been observed (Ashmore, 1987; Santos-Sacchi, 1992). However, because of the limitations of clamp amplifier speed, the true time course of the OHC mechanical response is not known (Santos-Sacchi, 1992). In addition, a loss of OHC cell turgor (known to interfere with OHC motility (Holley and Ashmore, 1988;

Santos-Sacchi, 1991a)) which necessarily accompanies whole cell voltage clamp configuration, may also contribute to a delayed response. It cannot be judged at this point whether charge movement in the OHC is two-state or multistate.

APPENDIX

For the model (Fig. 1 A), the steady state (I_∞) and instantaneous (I_0) current responses to a voltage step are defined as

$$I_\infty = \frac{V_c}{R_s + R_m}, I_0 = \frac{V_c}{R_s} \quad (6)$$

with the exponentially decaying capacitive current given as

$$I_{C_m} = (I_0 - I_\infty)e^{-\frac{t}{\tau}}, \quad (7)$$

where

$$\tau = R_{||}C_m, \quad (8)$$

$$R_{||} = \frac{R_m R_s}{R_{in}}, \quad (9)$$

and

$$R_{in} = R_m + R_s, \quad (10)$$

the input resistance readily obtained at steady state.

The charge moved is then obtained by integration

$$\int_0^\infty I_{C_m} dt = Q = \frac{C_m R_m^2 V_c}{R_{in}^2}. \quad (11)$$

Solving for C_m ,

$$C_m = \frac{R_{in}^2 Q}{R_m^2 V_c}, \quad (12)$$

and utilizing Eqs. 4 and 8, we obtain

$$R_s = \frac{R_{in} \tau V_c}{QR_{in} + \tau V_c}. \quad (13)$$

The time constant (τ) of the exponentially decaying current, and the charge moved (Q) are little affected by filter settings as low as 2 kHz (eight-pole Bessel).

We thank Frank N. Tilley III for technical assistance. Thanks also to Dr. H. Sontheimer for comments on the manuscript, and Drs. F. Bezanilla and K. Chandler for many helpful discussions.

Motility voltage sensor of the outer hair cell resides within the lateral plasma membrane

Communicated by Jozef J. Zwislocki, August 25, 1994

ABSTRACT The outer hair cell (OHC) from the organ of Corti is believed to be responsible for the mammal's exquisite sense of hearing. A membrane-based motile response of this cell underlies the initial processing of acoustic energy. The voltage-dependent capacitance of the OHC, possibly reflecting charge movement of the motility voltage sensor, was measured in cells during intracellular dialysis of trypsin under whole cell voltage clamp. Within 10 min after dialysis, light and electron microscopic examination revealed that the subplasmalemmal structures, including the cytoskeletal framework and subsurface cisternae, were disrupted and/or detached from adjacent plasma membrane. Dialysis of heat-inactivated trypsin produced no changes in cell structure. Simultaneous measures of linear and nonlinear membrane capacitance revealed minimal changes, indicating that contributions by subsurface structures to the generation of the nonlinear capacitance are unlikely. This study strongly suggests that voltage-dependent charge movement in the OHC reflects properties of the force generator's voltage sensor and that the sensor/motor resides solely within the lateral plasma membrane.

The mammalian outer hair cell (OHC) possesses a unique transmembrane voltage-driven mechanical response that can occur at acoustic frequencies (1–5). This mechanical activity is believed to underlie the enhanced ability of the inner ear to detect and analyze sound (6) and is especially interesting since it is not directly dependent upon Ca^{2+} or metabolic substrates (3, 7, 8). A nonlinear charge movement, or corresponding voltage-dependent capacitance, has been observed in this cell and it probably reflects the activity of the motility voltage sensor, as many of its characteristics and those of the mechanical response coincide (9–12). Recently, the mechanical response and the extent of the nonlinear capacitance have been mapped along the central portion of the cylindrical OHC (13, 14); each corresponds roughly to the extent of subplasmalemmal structures, the cortical network of cytoskeletal filaments, and the subsurface cisternae. It is of interest to determine whether such structures contribute to the motile mechanism or nonlinear charge movement or if the cell's plasma membrane alone is responsible for these phenomena. The experiments of Kalinec *et al.* (15) have shown that intracellular dialysis of trypsin does not abolish OHC membrane movements. However, no electron microscopic analysis of the effects of the trypsin treatment was performed, so it is unclear whether the plasma membrane was totally isolated from intracellular structures in their experiments. We report here that following intracellular trypsin treatments, most of the plasma membrane is isolated from subsurface structures as evidenced electron microscopically. Furthermore, the nonlinear charge movement remains intact during such treatments, indicating that the motility voltage sensor, as well as the motor, reside within the plane of the OHC plasma membrane.

MATERIALS AND METHODS

General. Guinea pigs were euthanized with halothane overdose. The isolated organ of Corti was treated with collagenase (0.3 mg/ml for 10 min) and triturated gently within a polyethylene pipette in medium 199 with Hanks' salts (GIBCO). The OHC-enriched supernatant was then transferred to a 700- μl perfusion chamber. Experiments were performed at room temperature (22°C).

Electrical Recording. OHCs were whole cell voltage clamped with a Dagan 8900 patch clamp amplifier at a holding potential of -80 mV. Cells were bathed in a modified Leibovitz medium (in mM: NaCl 110, KCl 5.37, CoCl_2 2, MgCl_2 1.48, tetraethylammonium chloride 20, CsCl 20, Hepes 5, and dextrose 5; 300 mosM, pH 7.2) in order to block ionic conductances. Pipette solutions were composed of (mM) CsCl 140, EGTA 10, tetraethylammonium chloride 5, MgCl_2 2, and Hepes 5 (300 mosM, pH 7.2). Gigaohm seals were obtained at the middle portion of the lateral wall. In order to introduce trypsin into the cell, relatively large patch pipette tips were used (1.5- to 2- μm inner diameter; series resistance, 2–3 M Ω). For trypsin treatments, 300 μg of trypsin (source: bovine pancreas, M_r 23,281; Calbiochem) was dissolved in 1 ml of pipette solution and the osmolarity and pH were readjusted to 300 mosM and pH 7.2. As a control, heat-inactivated trypsin (enzyme pipette solution heated for 30 min in 56°C water bath) was also used. Electrode capacitance was compensated after gigaohm seal formation, and series resistance compensation was used in whole cell configuration. A modified version of Clampex (Axon Instruments, Burlingame, CA) was used to apply voltage stimuli and collect data that were saved on disk for off-line analysis. Current was filtered at 5 kHz with an eight-pole Bessel filter. All experiments were videotaped.

Three methods were used to evaluate the effects of trypsin treatment on cell capacitance. The first method simply measured cell capacitance near the cell's normal *in vivo* resting potential. The cell was nominally held at -80 mV and a -10 mV step command voltage (4 ms) was applied repeatedly over time. At this potential both linear and a substantial amount of nonlinear capacitance contributes to the generation of a transient capacitive current (12). From averaged ($\times 20$) current records, an on-line analysis of membrane capacitance (C_m), membrane resistance (R_m), and series resistance (R_s) was performed and saved to disk. The transient analysis calculations have been published elsewhere (16).

The second method evaluated the voltage dependence of nonlinear capacitance using a voltage stair protocol. The technique has been fully described elsewhere (14). Briefly, the cell was stair-stepped from a holding potential of -170 mV to voltages between -160 mV and $+50$ mV, in increments of 10 mV. From each step response, C_m , R_m , and R_s were calculated as a function of membrane voltage. The

measured membrane capacitance has two components, a linear one, which is a function of the total cell membrane area, and a nonlinear one, which is a measure of the charge movement of the motility voltage sensor. The total membrane capacitance (C_m) at any given voltage is the sum of the linear (C_{lin}) and nonlinear (C_v) capacitance. The nonlinear capacitance (C_v) can be described as the first derivative of a two-state Boltzmann function relating nonlinear charge movement to voltage, and such a fit provides estimates of the charge characteristics, including the voltage at half-maximal nonlinear charge transfer (V_h), and charge valence (z) (see Fig. 3 and ref. 14 for further details). Measures were made at 1- to 5-min intervals following whole cell configuration.

The third method was used to overcome potential harmful effects of the large voltages of the stair protocol. To estimate maximal nonlinear capacitance, a software tracking protocol using step analysis was developed to monitor peak capacitance by iteratively adjusting the holding potential to maintain the cell at V_h —i.e., the voltage at which nonlinear capacitance is greatest. Should V_h change during an experiment, the tracking technique, utilizing -10 mV steps, will continue to determine peak capacitance.

Electron Microscopy. Following single cell capacitance evaluations, primary fixation was accomplished by slowly perfusing the recording chamber with 0.75% glutaraldehyde in 0.1 M sodium cacodylate buffer with 2 mM CaCl_2 (300 mosM, pH 7.3). The perfusion rate was about 0.05 ml/min in order to minimize distortion of the cell. After perfusion for 30 min, cells were washed with buffer for 10 min and released from recording pipettes by gently breaking the tip on the chamber floor. To continue processing without losing the cell, a microchamber embedding method was devised. A polypropylene disposable pipette (Fisher) was heated and pulled to approximately 20- to 30- μm internal radius and 10- to 15- μm wall thickness. Under a dissecting microscope, the tube was shoed to the tip of a glass pipette. Cells were gently sucked into the microchamber, and the microchamber was affixed to the bottom of a new perfusion dish. Cells were postfixated with 1% OsO_4 in 0.1 M sodium cacodylate buffer (pH 7.3, 300 mosM) for 30 min, followed by dehydration in a graded series of ethanol up to 100%. Cells were stained with 2% uranyl acetate (while in 70% ethanol) for 30 min in the dark.

Poly Bed 812 was prepared according to the Mollenhauer mixture 1 formula (Polyscience). Three changes in graded concentrations of Poly Bed 812 (epoxy resin/ethanol, 1:3, 1:1, 3:1; 4 hr each) were followed by three changes in pure Poly Bed 812 (4 hr each). Polymerization was at 60°C overnight. The plastic microchamber was then cut out and reembedded in an Epon block. Ultrathin sections (70–80 nm) were taken at various points through the cell extent, placed on Formavar-coated 200-mesh copper grids, and stained with uranyl acetate (10 min) and lead citrate (2 min). Sections were observed with a Phillips 300 electron microscope at 60 kV.

RESULTS

During the course of whole cell electrical recording, trypsin enters the OHC and alters the cell's normal cylindrical structure. In a group of 15 OHCs, simultaneous capacitance measures were obtained at a nominal holding potential of -80 mV. Within 3–23 min (10.2 ± 6.7 min; mean \pm SD), these cells were transformed into spherical structures, which appeared at the light microscopic level to have undergone an involution and separation of the cell's subplasmalemmal structures from the plasma membrane. Fig. 1 illustrates the progression of this phenomenon. After the OHCs became fully spherical, the cells were fixed for electron microscopy. However, in some cells that were not fixed, continued dialysis eventually caused dissolution of the nucleus and

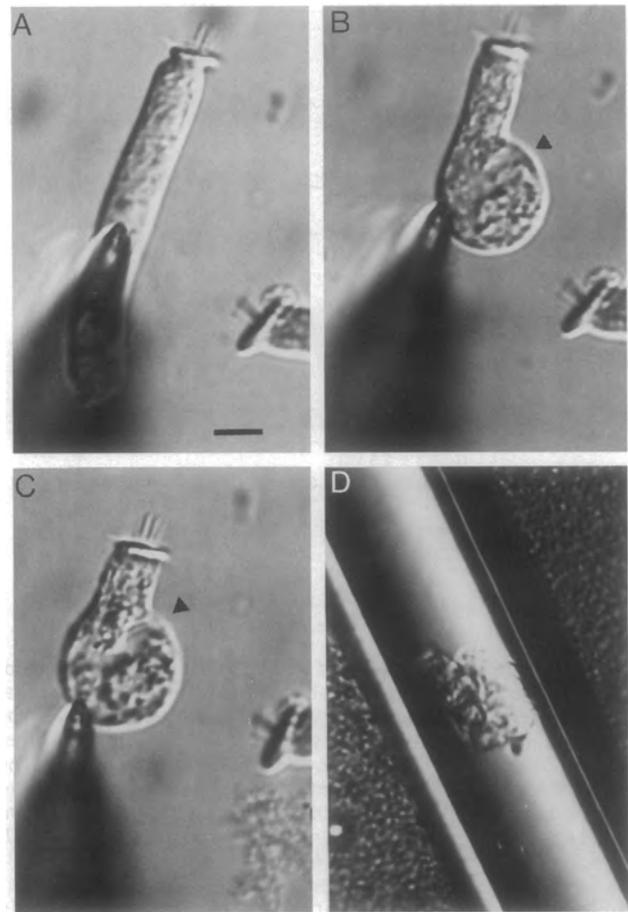

FIG. 1. Light microscopy of an OHC during the course of trypsin treatment and capacitance measurement, illustrating the loss of the cell's cylindrical shape and involution of intracellular cortical structures. (A) Cell 5 min after established whole cell configuration. (B and C) At the 12th and 16th min, respectively. The arrowheads indicate the area where the cortical structures began separation from the plasma membrane. This cell eventually became fully spherical at the 20th min and was then fixed. (D) Cell within a plastic microchamber, prior to embedding. (Bar = 10 μm .)

much of the cuticular plate. Although dramatic alterations in cell structure were observed, C_m at -80 mV did not decrease, as might have been expected if subplasmalemmal structures were requisite for the nonlinear capacitance component. Average data are presented in Fig. 2 and show that C_m actually increased in this sample from an initial value of about 35 pF to 39 pF. R_m decreased during the recording to about 75% of the initial 103 $\text{M}\Omega$ average. The electrode series resistance remained constant at about 6 $\text{M}\Omega$, indicating that efficient dialysis was maintained throughout the recording period.

During capacitance measures obtained at a fixed holding potential, it is possible that either holding potential changed, as a consequence of changes in the ratio of series resistance to membrane resistance (the voltage divider effect), or V_h changed, as a consequence of trypsin treatment. Such occurrences could account for the observed change in total membrane capacitance in Fig. 2. In fact, using the stair-step voltage protocol, it was determined that V_h shifts occurred in some cells. Fig. 3 illustrates the data obtained using the stair protocol. The results from a single cell are presented in Fig. 3 Upper and the average capacitance for 9 cells is presented in Fig. 3 Lower. In each panel, the voltage-dependent capacitance was measured within a minute after cell entry (closed circles) and after the cells had become spherical (open

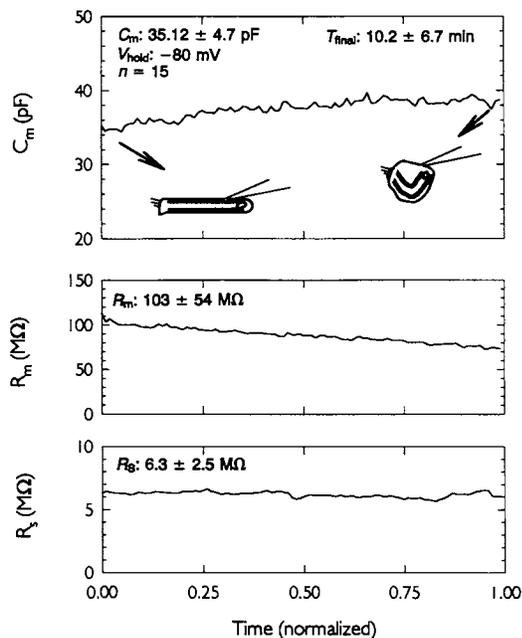

FIG. 2. Average C_m , R_m , and R_s of 15 OHCs during treatment with trypsin. The cells changed shape from cylindrical to spherical during the trypsin treatment, but the time to reach a spherical shape varied among cells, with an average time of 10 ± 6.7 min. Two other cells spontaneously burst at the nuclear pole during recording. The data were normalized by decimation along the time dimension to provide an end point corresponding to the time of sphere formation. Initial values were as follows: C_m , 35.12 ± 4.7 pF; R_m , 103 ± 54 M Ω ; R_s , 6.3 ± 2.5 M Ω . Note a slight increase in C_m .

circles). The data indicate that despite changes in V_h in some cells (average shift of -11 mV; see legend to Fig. 3), voltage-dependent characteristics of the nonlinear capacitance remained near normal, as did peak capacitance values. We have recently observed that a reduction of membrane tension, caused by reduced intracellular pressure, increases nonlinear capacitance and shifts V_h in the negative direction—up to a limiting voltage approaching the membrane potential of OHCs *in vivo*—namely, -70 mV (S. Kakehata and J.S.-S., unpublished observations). We speculate that trypsin treatment reduces tension on the membrane by destroying cortical cytoskeletal interactions with the membrane, causing a negative shift of V_h , and probably accounting for the increase of OHC C_m observed at a holding potential of -80 mV (Fig. 2).

We also confirm the results of Kalinec *et al.* (15), since we observe robust mechanical responses under this voltage protocol despite the fact that the plasma membrane appears divorced from intracellular structures. Nevertheless, the motility that remains in trypsin-treated cells is not the same as in normal cells. This results from the disruption of the cell's normal cytoarchitecture and mechanical properties that provide for the normal longitudinal length changes. Thus, despite the fact that the cell continues to respond to voltage changes by modifying its shape, motility characteristics (e.g., frequency response) may be altered and require further evaluation.

The stair protocol subjects the cells to very large, rapid voltage changes, which, over repeated application, tend to damage the cell or electrode seal. This is especially the case for trypsin-treated cells, which are by definition already compromised. In fact, many spherical cells were lost during such collections. In 19 cells that underwent the stair protocol, the electrode seal was lost in 10 cells, and in another 2 cells the membrane burst at locations remote from the electrode location, near the nuclear pole. Therefore, estimates of peak

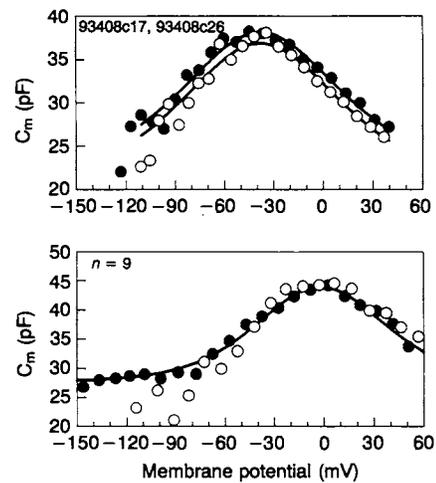

FIG. 3. Voltage-dependent capacitance of OHCs measured with the stair-step protocol during trypsin treatment. The voltage-dependent capacitance rides upon a linear membrane capacitance ($C_m = C_v + C_{lin}$). ●, C_m recorded immediately after the establishment of whole cell configuration; ○, data obtained after the OHCs became spherical. During stimulation, OHCs responded with robust motility, either before or after trypsin effects were evident. (Upper) Results from a single OHC. In this case, the voltage at peak capacitance (V_h) remained constant before and after trypsin treatment. Fits of the data to the first derivative (with respect to membrane voltage) of a two-state Boltzmann function [$Q(v) = Q_{max}/1 + \exp(-ez(V_m - V_h)/kT)$, where e , k , and T have their usual meanings] are indicated by the solid lines, with an additional linear capacitance added (C_{lin}). For the control condition (●), $z = 0.82$, $Q_{max} = 1.97$ pC, $V_h = -38$ mV, and $C_{lin} = 22.4$ pF. The fit through the open circles is the same, with C_{lin} reduced by 1.25 pF. (Lower) Averaged results from nine cells. The voltage at peak capacitance (V_h) was found to vary among cells. To average the capacitance measures from different cells, all functions were shifted along the voltage axis so that V_h resided at 0 mV. Since the actual voltage at each step differed for each cell because of differences in the ratios of R_s to R_m , the data were binned into 10 mV ranges. Both voltages and capacitance values were averaged within bins. Symbols as above. The fit through the closed circles provided average parameters of $z = 0.98$, $Q_{max} = 1.7$ pC, and $C_{lin} = 27.7$ pF. The actual average voltage at peak capacitance (V_h) for the control condition was -15 mV and after trypsin effects were evident, -26 mV. The capacitance values after trypsin treatment (○) are similar (or slightly increased) to the control except at hyperpolarized voltage steps, where it appeared that membrane characteristics became unstable.

capacitance were also obtained by the tracking technique described in *Materials and Methods*. Fig. 4 provides an example of a cell that was monitored during trypsin treatment well beyond the point where it reached a fully spherical shape. Peak capacitance remained relatively constant throughout the recording period ($n = 7$).

Fig. 5 presents a low-power electron micrograph of an OHC after trypsin had caused the cell to become spherical. The striking feature of the trypsin treatment was a separation of the plasmalemma from subsurface cisternae and cortical cytoskeleton. Vast amounts of plasma membrane appeared free of any subsurface interactions. In higher magnification

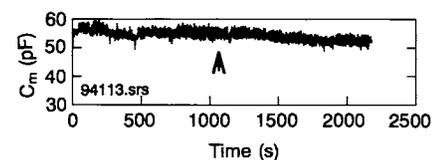

FIG. 4. Peak capacitance (C_m) of an OHC that was monitored with the tracking procedure during trypsin treatment (see text). The arrow indicates the point at which the cell became fully spherical. Note that peak capacitance remains nearly constant in this example.

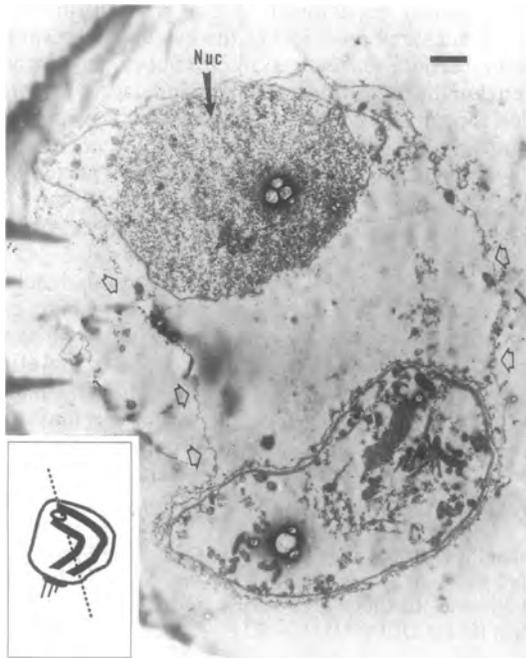

FIG. 5. Low-power electron micrograph of a trypsin-treated OHC within a microchamber. Five minutes after the initiation of recording the cell became spherical and was fixed. Arrows point to the plasmalemma, which is divorced from intracellular structures. (Inset) Schematic illustrating the section orientation through the spherical cell. Note, in the electron micrograph, on one side of the cell the nucleus (Nuc) is sectioned, and on the other side more apical regions are sectioned. (Bar = 1 μm .)

views (Fig. 6), it was apparent that the cytoskeletal attachments between the plasma membrane and subsurface cister-

nae were digested by the enzyme, allowing the cisternae to peel away from the plasma membrane. In five cells successfully recovered for electron microscopy, the bulk of plasma membrane was cleanly isolated, indicating that the capacitance measures reflected simply the intrinsic properties of plasma membrane components.

DISCUSSION

The OHC possesses a unique ability to alter its length in response to electrical stimulation (1). The driving force for this phenomenon is currently considered to be transmembrane voltage (3, 5), and in line with this hypothesis is the demonstration of a gating charge or nonlinear capacitance in the OHC that is associated with the mechanical event (9, 11). The charge displacement may reflect the movement of a proteinaceous motor's voltage sensor, just as voltage sensors of ionic channels demonstrate transient charge movements during channel gating. This contention is based upon similarities between some of the characteristics of the gating charge movement and the mechanical response in the OHC (12, 17). For example, the time course of gating charge movement and OHC motility are similar, and factors affecting the gating charge also are reflected in the motion of the cell. Another indication is that the extent of the charge movement along the length of the cell corresponds to those regions of the cell that are mechanically active (14). Furthermore, both motor activity and nonlinear charge movement are discretely distributed along the cell body and can be activated independently in different regions of the cell (13, 14).

Nevertheless, structural features exist in the OHC that could potentially account for a voltage-dependent charge movement that coincidentally occurs during the mechanical activity of the OHC. The OHC plasmalemma is intimately associated with an adjacent cortical cytoskeleton composed

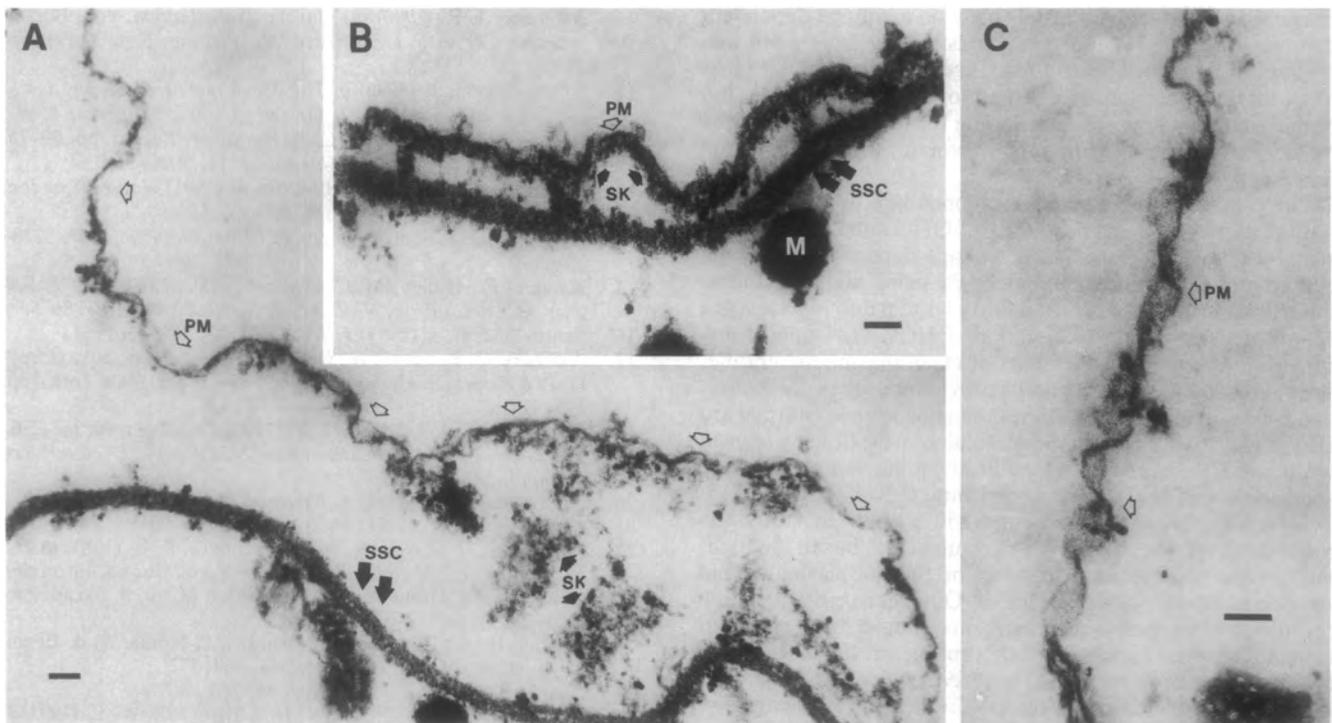

FIG. 6. Higher-magnification view of the same cell as in Fig. 5 at a different level. (A) Area in which the plasma membrane (PM) has peeled away from underlying structures. The subplasmalemmal cytoskeleton (SK) appears digested and has been freed from the intracellular aspect of the plasma membrane. As a result, the subsurface cisternae (SSC) are able to involute into the cell. In some cells there was evidence for cisternal vesiculation. (B) Area where the digestion process is in an early stage. Attachments between the plasma membrane and subsurface cisternae via the cytoskeleton are still visible. (C) At higher magnification, an area of plasma membrane fully clear of intracellular structures. (Bars = 100 nm.)

of circumferential actin filaments, cross-linked by spectrin (18). In addition, filamentous pillar processes extend from the plasma membrane to the circumferential filaments and subsurface cisternae (19), a membranous system whose surface area can be greater than that of the cell's plasma membrane. While the potential electrical interaction between subsurface cisternae and plasmalemma had been initially dismissed based on the observation that OHC capacitance could be accounted for by the linear dielectric properties of the OHC surface plasma membrane (2), subsequent experiments indicated that this was not the case (20). Clearly, it is now known that a portion of OHC capacitance is voltage dependent and can be of the same order of magnitude as the cell's linear capacitance (11, 12). Electrical interactions between two membranous systems could increase input capacitance, just as occurs during alterations of gap junctional communication in inner ear supporting cells (21). It is not inconceivable that the OHC plasma membrane could recruit cisternal membrane in a voltage-dependent manner, either through reversible membrane fusion or through some electrical interaction of the cisternae with the extracellular space, perhaps via the pillar processes spanning the region between plasma membrane and cisternal membrane.

Another potential generator of nonlinear charge movement might exist due to the restrictive subplasmalemma space, resulting in a series resistance between the OHC plasma membrane and axis core (9). For example, it has been suggested that the pillars or spectrin may be associated with the mechanical response in a charge-dependent manner (9, 18). Perhaps movement of these structures or transmembrane ionic flow into the restrictive subplasmalemma space can generate capacitive-like charge movements measurable across the intracellular series resistance. Indeed, a residual nonlinear ionic conductance exists in the OHC even after substantial efforts to block voltage-dependent currents (12, 14). Simple circuits of skeletal muscle membranous systems have been envisioned that theoretically could generate nonlinear charge movement based solely on a voltage-dependent conductance (22). While these possibilities have been dismissed for muscle, because evidence of the molecular basis of excitation-contraction charge movement exists (23), hypotheses of this type are appropriate for the OHC, where the molecular basis of the charge movement remains uncharacterized.

The present experiments were conducted in order to rule out these potential contributions of OHC subplasmalemma structures to the generation of voltage-dependent nonlinear charge movement or capacitance. By using high concentrations of trypsin (300 $\mu\text{g}/\text{ml}$) in fairly large patch pipettes, the subplasmalemma cytoskeleton of OHCs was rapidly disrupted, leaving expansive areas of clean plasma membrane, as evidenced by electron microscopy. Not only is the restrictive space no longer present but the subsurface cisternae are also physically remote to the plasmalemma following trypsin treatment. Despite such treatment, the nonlinear capacitance and motility of the cell remained intact. Kalinec *et al.* (15) used similar trypsin treatments (150 $\mu\text{g}/\text{ml}$) to study the robustness of the motility and concluded based on light microscopy that after disruption of the subplasmalemma structures motility remained intact. Our electron microscopic results confirm that their treatments should have provided isolated plasma membrane. Disruption of the subsurface cisternae has been shown to interfere with the normal longitudinal length changes of the OHC (24, 25). It is clear now, however, that the subplasmalemma structures, while providing structural and other support for the normal OHC, do not contribute directly to the generation of gating currents or the underlying mechanical response of the plasma membrane. The only logical explanation for the persistence of the

OHC's nonlinear capacitance is that it is intrinsic to the lateral plasma membrane, just as the mechanical response is. Furthermore, both sensor and effector appear to be protected from enzymatic digestion, possibly indicating that (i) the complex is proteinaceous and buried within the lipid bilayer, (ii) some sites of the proteinaceous complex are external to the bilayer but lack trypsin cleavage sites, (iii) portions of the complex external to the bilayer are digested but do not contribute significantly to sensor/motor activity, or (iv) the underlying mechanism is somehow lipid based.

Current theories of OHC motility envision molecular motors within the lateral plasma membrane, which change conformation upon sensing alterations in transmembrane voltage (15, 26, 27). The colocalization of sensor and effector, not only along the extent of the OHC's length (13, 14) but also within the plane of the OHC plasma membrane, may indicate that the densely packed intramembranous particles first observed nearly two decades ago (28) ultimately underlie the inner ear's remarkable sensitivity and frequency selectivity.

FIRING UP THE AMPLIFIER: TEMPERATURE, PRESSURE AND VOLTAGE JUMP STUDIES ON OHC MOTOR CAPACITANCE*

JOSEPH SANTOS-SACCHI, LEI SONG, XIANTAO LI

*Yale University School of Medicine
New Haven, Ct 06510, USA*

The outer hair cell (OHC) possesses molecular motors that drive electromotility and cochlear amplification. Here we look at the effects of fast perturbations of biophysical forces that affect the OHC, including voltage, temperature and pressure, on the electrical signature of motor activity, namely nonlinear capacitance (NLC). Under whole cell voltage clamp, we measure changes in NLC at fixed holding voltages following steps in voltage, jumps in temperature induced by ir laser, or jumps in intracellular turgor pressure. In each case we find time dependent changes in NLC resulting from induced shifts of the NLC function across the voltage axis. The time course of these shifts depends on the stimulus, with voltage jumps inducing shifts with fast exponential components less than a millisecond. Those induced by temperature and pressure are within the tens of millisecond ranges and may be limited by cellular and experimental constraints that voltage is able to overcome. The overall observation of time dependent changes to the electromotility function upon stimulation indicates a more complex mechanism than provided by a simple two-state Boltzmann model.

1 Introduction

The outer hair cell (OHC) drives cochlea amplification through a cellular mechanism that works at kilohertz rates [1,2,3,4]. Molecular motors that are housed within the OHC lateral membrane, comprising at least the molecule prestin [5], produce conformational changes in response to voltage which alter the somatic length of the cell [6,7,8]. The deformations of these cells within the organ of Corti feedback energy into the basilar membrane, thus amplifying the auditory stimulus that is delivered to IHC stereocilia [9]. The ultimate effect is a boost in our auditory sensations.

The OHC motor, or prestin transfected into non-auditory cells, produces a signature electrical response analogous to gating currents observed in other voltage dependent membrane bound proteins [2,10,11]. The gating currents, because they are restricted charge movements within the membrane dielectric, can also be measured as a nonlinear capacitance (NLC), bell-shaped as a function of voltage. This charge movement or NLC can be fit most simply by a two-state Boltzmann function, allowing extraction of Boltzmann parameters that provide information on voltage dependence, voltage sensor valence, and maximum charge moved. These steady state parameters do not provide dynamic information about the motor, but the time course of underlying gating charge movements or of shifts in the C-V function can provide hints on the motor's

conformational kinetic properties. Here we report on the effects of fast perturbations of biophysical forces that affect the OHC, including voltage, temperature and pressure, on the electrical signature of motor activity, namely NLC. The occurrence of time dependent changes to the C-V (or equivalently, electromotility) function upon such stimulation indicates a more complex mechanism than provided by a simple two-state Boltzmann model.

2 Methods

Guinea pigs were decapitated following anesthetic overdose with halothane. OHCs were freshly isolated from the guinea pig cochlea using Dispase (1 mg/ml) followed by trituration, and were whole-cell voltage clamped at room temperature using an Axon 200B amplifier. Membrane voltages were corrected for the effects of residual series resistance, which ranged from 3-5 M Ω . Ionic blocking solutions were used to remove voltage-dependent ionic conductances so that capacitive currents could be analyzed in isolation [11]. Extracellular solution: 100mM NaCl, 20mM TEA, 20mM CsCl, 2mM CoCl₂, 1.48mM MgCl₂, 2 mM CaCl₂, 10 mM HEPES, and 5mM dextrose, adjusted to pH 7.2 with NaOH, and adjusted to 300mOsm with dextrose. Pipette solution: 140mM CsCl, 10mM EGTA, 2mM MgCl₂, and 10mM HEPES, adjusted to pH 7.2 with CsOH, and adjusted to 300mOsm with dextrose. In some cases, TEA, CsCl, CoCl₂, CaCl₂, and MgCl₂ were omitted. Also, in some experiments, the extracellular solution was used in patch electrodes. In a few experiments, 50 μ M GdCl₃ was included in the extracellular solution to decrease residual currents. At this concentration, gadolinium has an insignificant affect on OHC capacitance [12]. Additional solution modifications are noted in figure legends.

In order to deliver rapid changes in membrane tension, we used a pressure clamp system from ALA instruments. Pipette tip diameters were increased in size for these experiments (\sim 1 M Ω). In order to deliver rapid changes in temperature a Capella IR laser was used to deliver via fiber optic 5-20 ms light pulses (1850 nm).

OHC capacitance was measured with a continuous high-resolution two-sine voltage stimulus protocol (20mV peak at both f1 and f2; f2=2*f1; f1 ranging up to 3906.3 Hz), and subsequent FFT based admittance analysis [13,14]. These small, high frequency sinusoids were superimposed on voltage steps or ramps that spanned up to \pm 200 mV.

OHC C-V plots were fitted with the function $C_m = C_{lin} + C_v$, where C_{lin} is the voltage-independent (linear surface area component) capacitance of the lipid bilayer, and $C_v = dQ_{nonL}/dV$ is the voltage-dependent component of C_m originating from prestin's voltage-sensor activity. The first derivative with respect to V_m of a two-state Boltzmann function $Q = Q_{max}/(1 + \exp(-ze(V_m - V_{pkCm})/k_B T))$ was used to fit the C-V data [11]. Q_{max} is total charge moved. The measured apparent valence of prestin voltage-sensor (z) is defined as $z = q \cdot d$, where d is a normalized perpendicular projection of distance traveled by the voltage sensor charge (q) within the plasma membrane field. V_{pkCm} is the

membrane potential (V_m) at which prestin molecules are equally distributed between expanded and contracted states. It corresponds to the peak of the C_v function.

All data collection and most analyses were performed with an in-house developed Window's based whole-cell voltage clamp program, **jClamp** (www.scisoftco.com), utilizing a Digidata 1320 board (Axon, CA). Matlab (Natick, MA) or SigmaPlot was used for fitting the C_m data.

3 Results

3.1 Voltage jumps induce time dependent changes in NLC

When OHC voltage is stepped away from the holding potential, a nearly instantaneous change in C_m is observed because membrane capacitance is a bell shaped function of voltage (Fig. 1). However, unlike memory-less systems, the C-V function is not static but

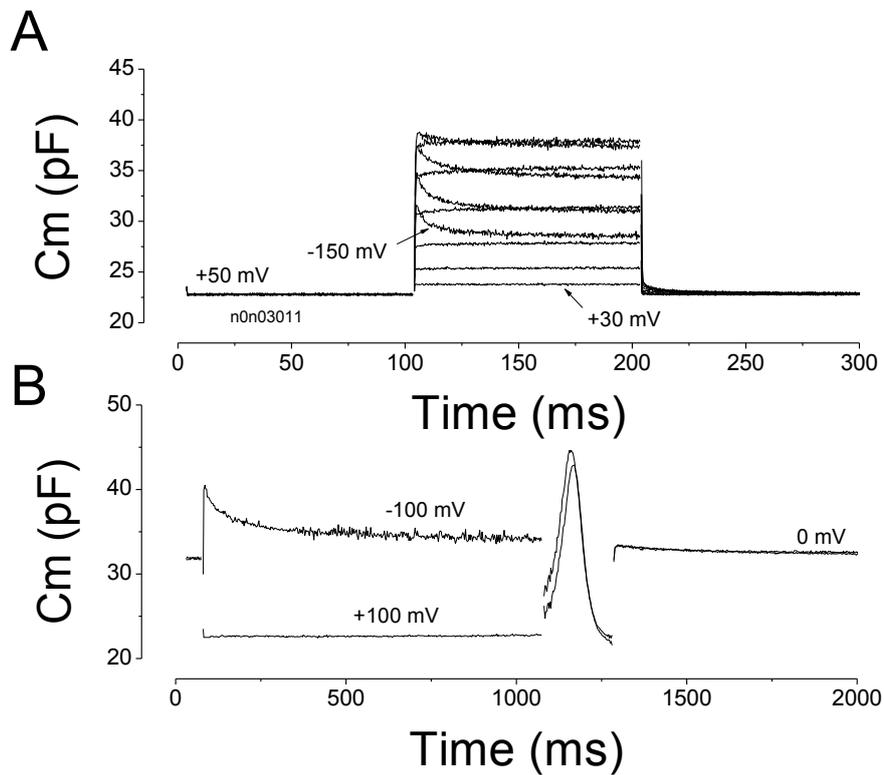

Figure 1 A) An OHC was held under voltage clamp at +50 mV and stepped to 30 (red),10,-10,-30,-50,-70,-90,-110,-130,-150 (blue) for 200 ms. The hyperpolarizing steps induced a time dependent change in C_m , increasing for steps approaching V_{pkcm} , and decreasing for steps beyond V_{pkcm} . B) Another OHC (held at 0 mV) showing that hyperpolarizing steps cause C_m relaxations (red line) due to depolarizing shifts in V_{pkcm} . A ramped voltage from -150 to +150 mV produced the bell shaped C_m response, indicating the rightward shift in V_{pkcm} .

shifts along the stimulus axis to alter C_m over time even though measures are made at a fixed voltage. The change in C_m is multi-exponential. With C_m sampling rates of about 4kHz, we find that the earliest exponential components are below one millisecond, with additional components at order of magnitude intervals.

3.2 Pressure jumps induce time dependent changes in NLC

Fig. 2 shows that rapid changes in membrane tension at a fixed voltage shifts V_{pkcm} in a time dependent manner, mimicking to some extent the C_m changes induced by step voltage changes. The pressure steps produced delayed onset responses because cellular material in the pipette tip obstructed flow. With increasing pressures it can be seen that the pipette unplugged at decreasingly shorter times following onset of the pressure steps (1: 0.8 kPa [fully obstructed], 2: 1.06kPa, 3: 1.33 kPa, and 4: 1.6 kPa). Lower pressures caused an increase in C_m over time, while the largest pressure pulse caused an immediate increase and subsequent relaxation. With this last pressure pulse the cell burst.

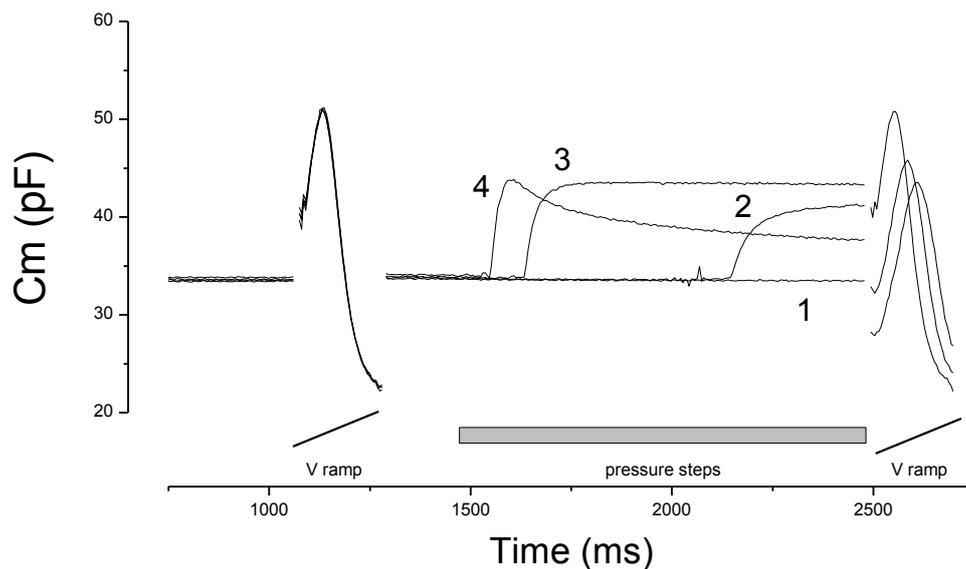

Figure 2 An OHC was held under voltage clamp at 0 mV. A voltage ramp (-100 to +100 mV, 200 ms) was delivered followed by incrementing pressure (1, 2, 3, 4) steps to the patch pipette, and the ramp was repeated (pressure was maintained during the final ramps). 3 sec intervals between traces were allowed for recovery from stimulation. Successful recovery is indicated by overlapping C-V functions. Increments in pressure cause time dependent changes in C_m at the fixed 0 mV holding potential, and occur due to shifts in V_{pkcm} , as the bell shaped C_m functions signify. The final pressure pulse caused the cell to burst; consequently, no C_m ramp data is plotted. In mM: 140 Cl in and out (NaCl 132, MgCl₂ 2, CaCl₂ 2, Hepes 10. Additional 10 EGTA for Intracellular solution)

3.32 Temperature jumps induce time dependent changes in NLC

We have previously shown that the C-V function of OHCs and prestin transfected HEK cells are very temperature sensitive, shifting about 20 mV to the right with a 10 °C increase in temperature [15,16]. Here we find that the effect of temperature jumps induced by IR laser is immediate in onset, followed by relaxation. Unlike steps in voltage and pressure, which could be maintained for unlimited durations, the Capella laser can only deliver up to 20 ms steps. Thus, the time course of C_m changes cannot be attributed to shifts in the C-V function during constant temperature, but could result from return to room temperature. Thus, the shifts in C-V we observed (Fig. 3B) likely correspond to expected changes in temperature as the bath cooled. However, we can glean from these experiments that temperature effects are very rapid, ruling out slow intracellular processes, such as phosphorylation, and likely indicating direct temperature effects on the conformational state of the motor protein prestin.

4 Discussion

By measuring OHC nonlinear membrane capacitance at sub-millisecond resolutions, we have examined the early time course of the OHC motor's dynamic response to jumps in membrane voltage, tension and temperature. We find that the time course of the voltage-induced response is multi-exponential, with the earliest detectable components residing

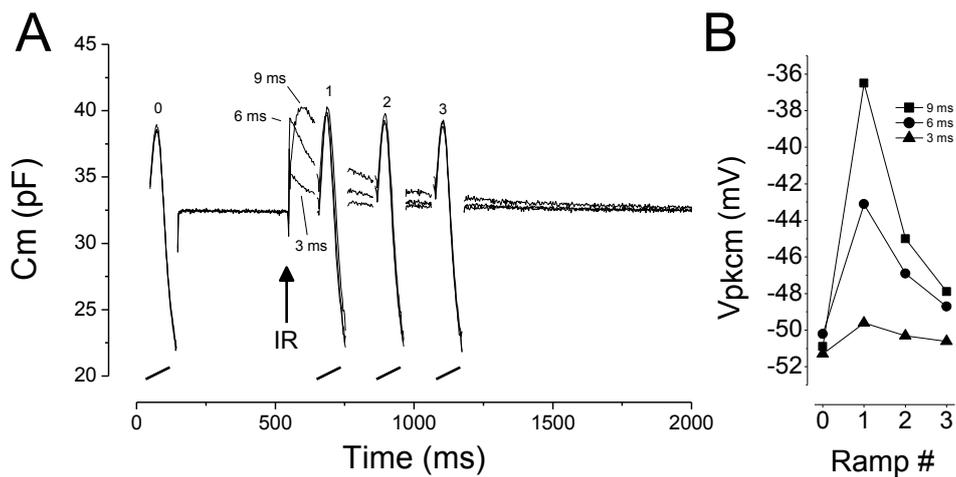

Figure 3 A) An OHC was held under voltage clamp at 0 mV. A voltage ramp (-100 to +100 mV, 200 ms) was delivered (denoted by 0) followed by incrementing temperature step durations to the cell, after which a series of voltage ramps (1, 2, 3) were delivered during the C_m relaxations. 10 sec intervals were used between traces to allow recovery from stimulation. Successful recovery is indicated by overlapping C-V functions. Increments in temperature duration (3, 6, 9 ms) cause time dependent changes in C_m at the fixed 0 mV holding potential, the shifts being plotted in B. Maximal temperature change is estimated to be about 10 °C. In this case the slow relaxations may be due to re-cooling to room temperature after laser stimulation.

in the kilohertz range, thereby establishing the phenomenon's potential significance in peripheral auditory processing of the mammal. These effects actually extend well into the low frequency range, as well; indeed, altering steady state resting potentials can stably set the operating point of electromotility to different points along the voltage axis.

Our data, though measuring whole cell capacitance, actually provide insight into the initial condition-dependent conformational states of the motor protein, prestin. That is, while capacitance may increase or decrease during incremental unidirectional steps in voltage or tension (**Figs. 1 and 2**), both correspond to a unidirectional change in motor state probability, as a conversion of capacitance to gating charge would reveal. Consequently, depolarizing voltages, in addition to causing a near instantaneous redistribution of motors to the compact state, will foster a supplemental recruitment of additional motors into that state, leading to an amplification of the initial response. The same amplification effect holds for hyperpolarizing voltages, where recruitment of motors will be into the expanded state. Tension effects appear to follow these rules, as well. However, because of equipment limitations on laser pulse duration we were unable to deliver long steps, and thus cannot confirm that temperature jumps mimic the effects of the other stimuli. We are attempting to modify the design to allow the further comparison.

Anions play a major role in NLC generation, and we were interested whether our results could reflect underlying interactions of chloride with the motor, since we have shown that V_{pkcm} shifts to the right when chloride is replaced with gluconate or other substitutes [17,18,19]. However, we find that modifying the driving force (changing extracellular chloride concentrations) for chloride movement across the OHC lateral membrane through G_{metL} [18] does not modify the extent or time course of the amplificatory shift (data not shown). It should be noted that although driving force for chloride did not significantly affect the motor's amplificatory shift, the interactions of anions with the motor may still play a role. In this regard, we have recently found that the state probability of prestin influences anion binding affinity (Song and Santos-Sacchi, ARO 2007), and that even if concentrations remain the same at the intracellular binding sites of prestin, changes in binding site affinity, as can occur with allosteric modulation, could alter energy profiles, resulting in V_{pkcm} shifts.

Since the initial observations of Iwasa [20], membrane tension effects on the OHC motor have provided important information on this protein's surprisingly efficient piezoelectric activity [21]. Because membrane tension can shift V_{pkcm} and, indeed, in extreme applications, restrict conformational activity [22], we had modeled the voltage-induced amplificatory shift as resulting from motor induced tension [14]. In the present report we attempted to directly test this by applying rapid changes in membrane tension and seeking C_m relaxations that mimic those induced by voltage steps. Though there are indications of C_m relaxations following rapid tension changes, the time courses of voltage-induced and tension-induced C_m relaxations differ, tension effects being slower. It is possible that during our attempts to alter membrane tension through global changes in OHC structure we may have been restricted by the viscoelastic properties of the whole

cell. For example, Dong and Iwasa [23] found that mechanical relaxations in the OHC have a time constant on the order of 40 s. However, because the fastest C_m relaxation time constants that we found with pressure steps were about 2 orders of magnitude faster than their measured time course, our pressure clamp driver appears to have been quite successful in overcoming this mechanical impediment. We suggest that tension induced by the molecular motors themselves can better bypass this viscoelastic constraint, thereby providing more rapid tensions to evoke fast amplificatory shifts. Thus, we still view motor-derived membrane tension, possibly through alterations of anion binding affinity, to underlie voltage-induced amplificatory shifts [14]. Nevertheless, as we have shown previously, the membrane environment of prestin can have profound effects on the magnitude and time course of the amplificatory shift [24].

In summary, we show remarkably fast changes in the Boltzmann distribution of prestin motor states induced by fast perturbations of the motor. The shifts along the voltage axis represent amplificatory supplementation to the near instantaneous voltage-induced mechanical response of the cell, and it is expected that this phenomenon will impact on high frequency peripheral auditory processing. Finally, it is expected that distortion in the mechanical response will arise, contributing to one of the hallmarks of mammalian cochlear amplification [25].

FIRING UP THE AMPLIFIER: TEMPERATURE, PRESSURE AND VOLTAGE JUMP STUDIES ON OHC MOTOR CAPACITANCE*

JOSEPH SANTOS-SACCHI, LEI SONG, XIANTAO LI

*Yale University School of Medicine
New Haven, Ct 06510, USA*

The outer hair cell (OHC) possesses molecular motors that drive electromotility and cochlear amplification. Here we look at the effects of fast perturbations of biophysical forces that affect the OHC, including voltage, temperature and pressure, on the electrical signature of motor activity, namely nonlinear capacitance (NLC). Under whole cell voltage clamp, we measure changes in NLC at fixed holding voltages following steps in voltage, jumps in temperature induced by ir laser, or jumps in intracellular turgor pressure. In each case we find time dependent changes in NLC resulting from induced shifts of the NLC function across the voltage axis. The time course of these shifts depends on the stimulus, with voltage jumps inducing shifts with fast exponential components less than a millisecond. Those induced by temperature and pressure are within the tens of millisecond ranges and may be limited by cellular and experimental constraints that voltage is able to overcome. The overall observation of time dependent changes to the electromotility function upon stimulation indicates a more complex mechanism than provided by a simple two-state Boltzmann model.

1 Introduction

The outer hair cell (OHC) drives cochlea amplification through a cellular mechanism that works at kilohertz rates [1,2,3,4]. Molecular motors that are housed within the OHC lateral membrane, comprising at least the molecule prestin [5], produce conformational changes in response to voltage which alter the somatic length of the cell [6,7,8]. The deformations of these cells within the organ of Corti feedback energy into the basilar membrane, thus amplifying the auditory stimulus that is delivered to IHC stereocilia [9]. The ultimate effect is a boost in our auditory sensations.

The OHC motor, or prestin transfected into non-auditory cells, produces a signature electrical response analogous to gating currents observed in other voltage dependent membrane bound proteins [2,10,11]. The gating currents, because they are restricted charge movements within the membrane dielectric, can also be measured as a nonlinear capacitance (NLC), bell-shaped as a function of voltage. This charge movement or NLC can be fit most simply by a two-state Boltzmann function, allowing extraction of Boltzmann parameters that provide information on voltage dependence, voltage sensor valence, and maximum charge moved. These steady state parameters do not provide dynamic information about the motor, but the time course of underlying gating charge movements or of shifts in the C-V function can provide hints on the motor's

conformational kinetic properties. Here we report on the effects of fast perturbations of biophysical forces that affect the OHC, including voltage, temperature and pressure, on the electrical signature of motor activity, namely NLC. The occurrence of time dependent changes to the C-V (or equivalently, electromotility) function upon such stimulation indicates a more complex mechanism than provided by a simple two-state Boltzmann model.

2 Methods

Guinea pigs were decapitated following anesthetic overdose with halothane. OHCs were freshly isolated from the guinea pig cochlea using Dispase (1 mg/ml) followed by trituration, and were whole-cell voltage clamped at room temperature using an Axon 200B amplifier. Membrane voltages were corrected for the effects of residual series resistance, which ranged from 3-5 M Ω . Ionic blocking solutions were used to remove voltage-dependent ionic conductances so that capacitive currents could be analyzed in isolation [11]. Extracellular solution: 100mM NaCl, 20mM TEA, 20mM CsCl, 2mM CoCl₂, 1.48mM MgCl₂, 2 mM CaCl₂, 10 mM HEPES, and 5mM dextrose, adjusted to pH 7.2 with NaOH, and adjusted to 300mOsm with dextrose. Pipette solution: 140mM CsCl, 10mM EGTA, 2mM MgCl₂, and 10mM HEPES, adjusted to pH 7.2 with CsOH, and adjusted to 300mOsm with dextrose. In some cases, TEA, CsCl, CoCl₂, CaCl₂, and MgCl₂ were omitted. Also, in some experiments, the extracellular solution was used in patch electrodes. In a few experiments, 50 μ M GdCl₃ was included in the extracellular solution to decrease residual currents. At this concentration, gadolinium has an insignificant affect on OHC capacitance [12]. Additional solution modifications are noted in figure legends.

In order to deliver rapid changes in membrane tension, we used a pressure clamp system from ALA instruments. Pipette tip diameters were increased in size for these experiments (~1 M Ω). In order to deliver rapid changes in temperature a Capella IR laser was used to deliver via fiber optic 5-20 ms light pulses (1850 nm).

OHC capacitance was measured with a continuous high-resolution two-sine voltage stimulus protocol (20mV peak at both f1 and f2; f2=2*f1; f1 ranging up to 3906.3 Hz), and subsequent FFT based admittance analysis [13,14]. These small, high frequency sinusoids were superimposed on voltage steps or ramps that spanned up to +/- 200 mV.

OHC C-V plots were fitted with the function $C_m = C_{lin} + C_v$, where C_{lin} is the voltage-independent (linear surface area component) capacitance of the lipid bilayer, and $C_v = dQ_{nonL}/dV$ is the voltage-dependent component of C_m originating from prestin's voltage-sensor activity. The first derivative with respect to V_m of a two-state Boltzmann function $Q = Q_{max}/(1 + \exp(-ze(V_m - V_{pkCm})/k_B T))$ was used to fit the C-V data [11]. Q_{max} is total charge moved. The measured apparent valence of prestin voltage-sensor (z) is defined as $z = q \cdot d$, where d is a normalized perpendicular projection of distance traveled by the voltage sensor charge (q) within the plasma membrane field. V_{pkCm} is the

membrane potential (V_m) at which prestin molecules are equally distributed between expanded and contracted states. It corresponds to the peak of the C_v function.

All data collection and most analyses were performed with an in-house developed Window's based whole-cell voltage clamp program, **jClamp** (www.scisoftco.com), utilizing a Digidata 1320 board (Axon, CA). Matlab (Natick, MA) or SigmaPlot was used for fitting the C_m data.

3 Results

3.1 Voltage jumps induce time dependent changes in NLC

When OHC voltage is stepped away from the holding potential, a nearly instantaneous change in C_m is observed because membrane capacitance is a bell shaped function of voltage (Fig. 1). However, unlike memory-less systems, the C-V function is not static but

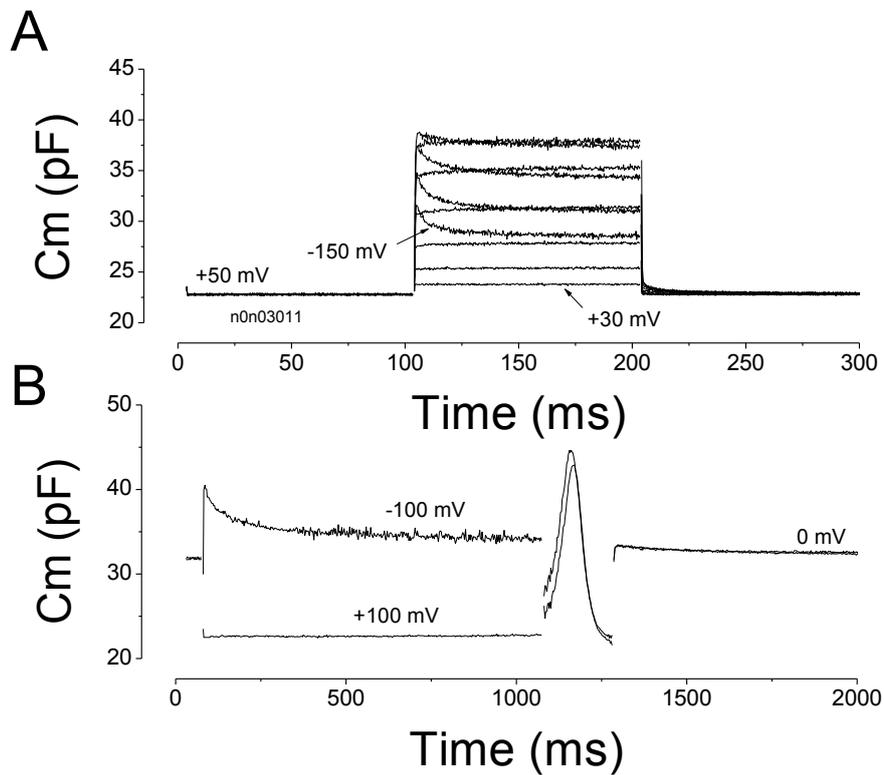

Figure 1 A) An OHC was held under voltage clamp at +50 mV and stepped to 30 (red),10,-10,-30,-50,-70,-90,-110,-130,-150 (blue) for 200 ms. The hyperpolarizing steps induced a time dependent change in C_m , increasing for steps approaching V_{pkcm} , and decreasing for steps beyond V_{pkcm} . B) Another OHC (held at 0 mV) showing that hyperpolarizing steps cause C_m relaxations (red line) due to depolarizing shifts in V_{pkcm} . A ramped voltage from -150 to +150 mV produced the bell shaped C_m response, indicating the rightward shift in V_{pkcm} .

shifts along the stimulus axis to alter C_m over time even though measures are made at a fixed voltage. The change in C_m is multi-exponential. With C_m sampling rates of about 4kHz, we find that the earliest exponential components are below one millisecond, with additional components at order of magnitude intervals.

3.2 Pressure jumps induce time dependent changes in NLC

Fig. 2 shows that rapid changes in membrane tension at a fixed voltage shifts V_{pkcm} in a time dependent manner, mimicking to some extent the C_m changes induced by step voltage changes. The pressure steps produced delayed onset responses because cellular material in the pipette tip obstructed flow. With increasing pressures it can be seen that the pipette unplugged at decreasingly shorter times following onset of the pressure steps (1: 0.8 kPa [fully obstructed], 2: 1.06kPa, 3: 1.33 kPa, and 4: 1.6 kPa). Lower pressures caused an increase in C_m over time, while the largest pressure pulse caused an immediate increase and subsequent relaxation. With this last pressure pulse the cell burst.

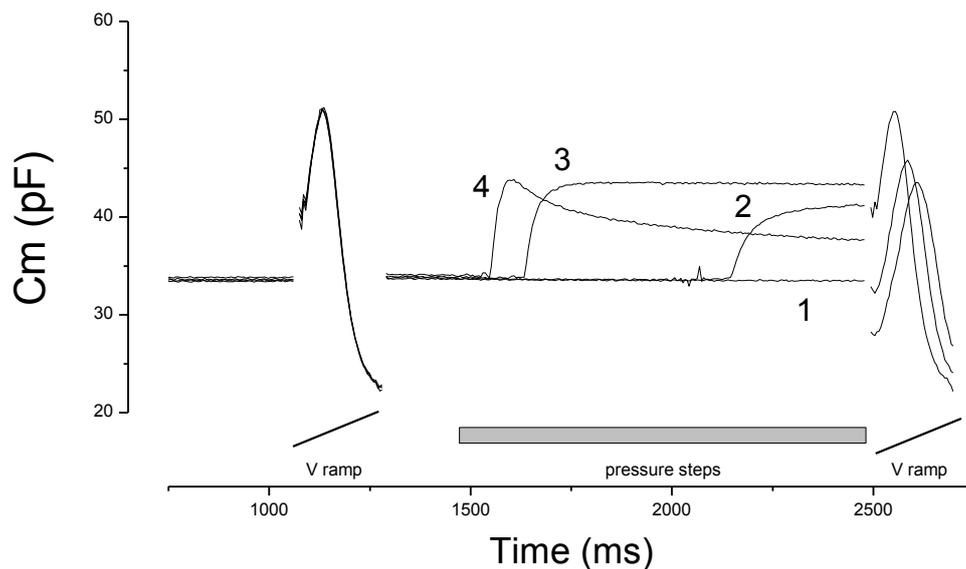

Figure 2 An OHC was held under voltage clamp at 0 mV. A voltage ramp (-100 to +100 mV, 200 ms) was delivered followed by incrementing pressure (1, 2, 3, 4) steps to the patch pipette, and the ramp was repeated (pressure was maintained during the final ramps). 3 sec intervals between traces were allowed for recovery from stimulation. Successful recovery is indicated by overlapping C-V functions. Increments in pressure cause time dependent changes in C_m at the fixed 0 mV holding potential, and occur due to shifts in V_{pkcm} , as the bell shaped C_m functions signify. The final pressure pulse caused the cell to burst; consequently, no C_m ramp data is plotted. In mM: 140 Cl in and out (NaCl 132, MgCl₂ 2, CaCl₂ 2, Hepes 10. Additional 10 EGTA for Intracellular solution)

3.32 Temperature jumps induce time dependent changes in NLC

We have previously shown that the C-V function of OHCs and prestin transfected HEK cells are very temperature sensitive, shifting about 20 mV to the right with a 10 °C increase in temperature [15,16]. Here we find that the effect of temperature jumps induced by IR laser is immediate in onset, followed by relaxation. Unlike steps in voltage and pressure, which could be maintained for unlimited durations, the Capella laser can only deliver up to 20 ms steps. Thus, the time course of C_m changes cannot be attributed to shifts in the C-V function during constant temperature, but could result from return to room temperature. Thus, the shifts in C-V we observed (Fig. 3B) likely correspond to expected changes in temperature as the bath cooled. However, we can glean from these experiments that temperature effects are very rapid, ruling out slow intracellular processes, such as phosphorylation, and likely indicating direct temperature effects on the conformational state of the motor protein prestin.

4 Discussion

By measuring OHC nonlinear membrane capacitance at sub-millisecond resolutions, we have examined the early time course of the OHC motor's dynamic response to jumps in membrane voltage, tension and temperature. We find that the time course of the voltage-induced response is multi-exponential, with the earliest detectable components residing

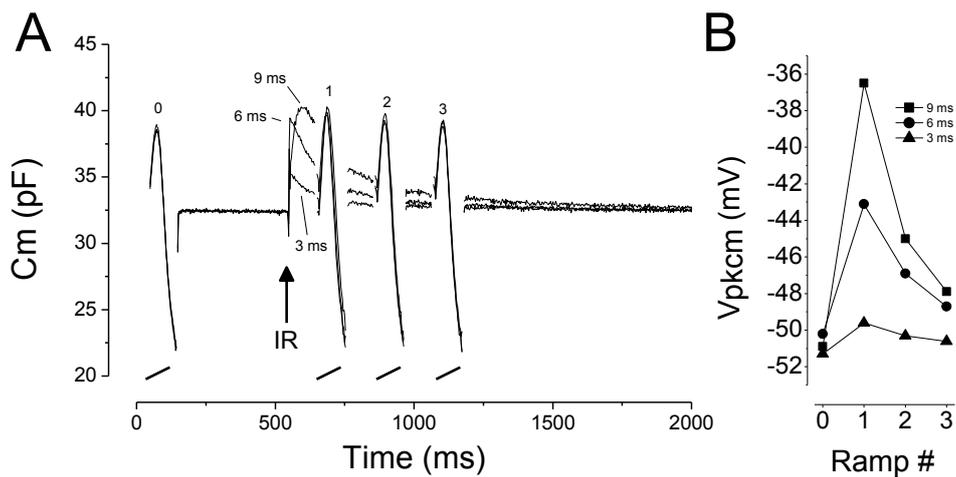

Figure 3 A) An OHC was held under voltage clamp at 0 mV. A voltage ramp (-100 to +100 mV, 200 ms) was delivered (denoted by 0) followed by incrementing temperature step durations to the cell, after which a series of voltage ramps (1, 2, 3) were delivered during the C_m relaxations. 10 sec intervals were used between traces to allow recovery from stimulation. Successful recovery is indicated by overlapping C-V functions. Increments in temperature duration (3, 6, 9 ms) cause time dependent changes in C_m at the fixed 0 mV holding potential, the shifts being plotted in B. Maximal temperature change is estimated to be about 10 °C. In this case the slow relaxations may be due to re-cooling to room temperature after laser stimulation.

in the kilohertz range, thereby establishing the phenomenon's potential significance in peripheral auditory processing of the mammal. These effects actually extend well into the low frequency range, as well; indeed, altering steady state resting potentials can stably set the operating point of electromotility to different points along the voltage axis.

Our data, though measuring whole cell capacitance, actually provide insight into the initial condition-dependent conformational states of the motor protein, prestin. That is, while capacitance may increase or decrease during incremental unidirectional steps in voltage or tension (**Figs. 1 and 2**), both correspond to a unidirectional change in motor state probability, as a conversion of capacitance to gating charge would reveal. Consequently, depolarizing voltages, in addition to causing a near instantaneous redistribution of motors to the compact state, will foster a supplemental recruitment of additional motors into that state, leading to an amplification of the initial response. The same amplification effect holds for hyperpolarizing voltages, where recruitment of motors will be into the expanded state. Tension effects appear to follow these rules, as well. However, because of equipment limitations on laser pulse duration we were unable to deliver long steps, and thus cannot confirm that temperature jumps mimic the effects of the other stimuli. We are attempting to modify the design to allow the further comparison.

Anions play a major role in NLC generation, and we were interested whether our results could reflect underlying interactions of chloride with the motor, since we have shown that V_{pkcm} shifts to the right when chloride is replaced with gluconate or other substitutes [17,18,19]. However, we find that modifying the driving force (changing extracellular chloride concentrations) for chloride movement across the OHC lateral membrane through G_{metL} [18] does not modify the extent or time course of the amplificatory shift (data not shown). It should be noted that although driving force for chloride did not significantly affect the motor's amplificatory shift, the interactions of anions with the motor may still play a role. In this regard, we have recently found that the state probability of prestin influences anion binding affinity (Song and Santos-Sacchi, ARO 2007), and that even if concentrations remain the same at the intracellular binding sites of prestin, changes in binding site affinity, as can occur with allosteric modulation, could alter energy profiles, resulting in V_{pkcm} shifts.

Since the initial observations of Iwasa [20], membrane tension effects on the OHC motor have provided important information on this protein's surprisingly efficient piezoelectric activity [21]. Because membrane tension can shift V_{pkcm} and, indeed, in extreme applications, restrict conformational activity [22], we had modeled the voltage-induced amplificatory shift as resulting from motor induced tension [14]. In the present report we attempted to directly test this by applying rapid changes in membrane tension and seeking C_m relaxations that mimic those induced by voltage steps. Though there are indications of C_m relaxations following rapid tension changes, the time courses of voltage-induced and tension-induced C_m relaxations differ, tension effects being slower. It is possible that during our attempts to alter membrane tension through global changes in OHC structure we may have been restricted by the viscoelastic properties of the whole

cell. For example, Dong and Iwasa [23] found that mechanical relaxations in the OHC have a time constant on the order of 40 s. However, because the fastest C_m relaxation time constants that we found with pressure steps were about 2 orders of magnitude faster than their measured time course, our pressure clamp driver appears to have been quite successful in overcoming this mechanical impediment. We suggest that tension induced by the molecular motors themselves can better bypass this viscoelastic constraint, thereby providing more rapid tensions to evoke fast amplificatory shifts. Thus, we still view motor-derived membrane tension, possibly through alterations of anion binding affinity, to underlie voltage-induced amplificatory shifts [14]. Nevertheless, as we have shown previously, the membrane environment of prestin can have profound effects on the magnitude and time course of the amplificatory shift [24].

In summary, we show remarkably fast changes in the Boltzmann distribution of prestin motor states induced by fast perturbations of the motor. The shifts along the voltage axis represent amplificatory supplementation to the near instantaneous voltage-induced mechanical response of the cell, and it is expected that this phenomenon will impact on high frequency peripheral auditory processing. Finally, it is expected that distortion in the mechanical response will arise, contributing to one of the hallmarks of mammalian cochlear amplification [25].

464 METABOLIC CONTROL OF OHC FUNCTION: PHOSPHORYLATION AND DEPHOSPHORYLATION AGENTS SHIFT THE VOLTAGE DEPENDENCY OF MOTILITY RELATED CAPACITANCE. G-J Huang & J. Santos-Sacchi. Sections of Otolaryngology & Neurobiology, Yale University, School of Medicine, New Haven, CT 06510

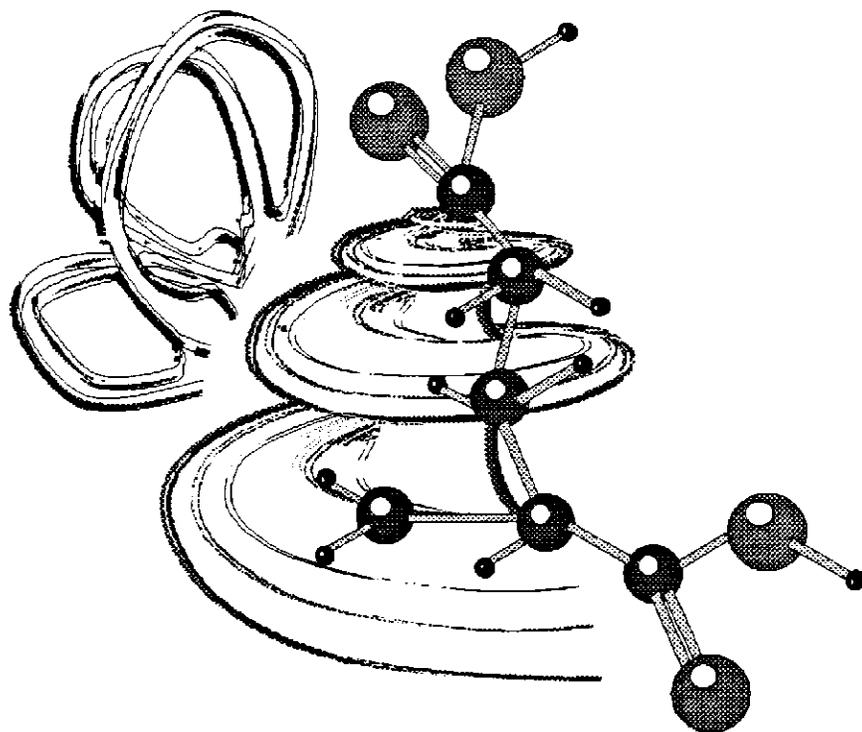

In the latter part of the last decade, it was shown that outer hair cells (OHCs) from the organ of Corti change their length as a function of voltage. Subsequently, a whole cell voltage-dependent capacitance (nonlinear charge movement) was measured in these cells (Ashmore, 1989), and such capacitance changes were shown to be closely co-related to cell length change (Santos-Sacchi, *J Neuroscience* 11:3096, 1991). Although the molecular basis of OHC length and capacitance changes remains to be determined, we explored the phosphorylation modulation on this OHC response.

Voltage-clamp whole cell recording was applied to freshly isolated guinea pig OHC cells. Ionic currents in the cells were blocked and the nonlinear capacitance was measured with transient analysis. Cells were held at -80 mV, and staired voltage steps from -160 to 60 mV were applied. The nonlinear capacitance was fit to the first derivative of a Boltzmann function and the voltage at half-maximal charge movement or peak capacitance (V_h) was calculated. Our preliminary data show that in 33 cells the V_h was -45.3 ± 5.3 mV (mean \pm SE) and the cell resting potential (RP, the zero current potential) was -23.9 ± 4.4 mV. There was a high correlation between V_h and RP ($r=0.838$). In our preparation calcium, sodium and potassium channels were blocked; the mechanism responsible for the RP is under further investigation.

Interestingly, when the cells were locally superfused for 3 minutes with 20 mM 2,3-butanedione monoxime (BDM), a non-specific phosphatase (Wilson & Ginsburg, *Biochem Biophys Acta* 18:168, 1955), the V_h was shifted leftward about -43.3 ± 17.9 mV ($N=6$, mean \pm SD) without changing RP. When these cells were further exposed to 10 mM 8-bromo-cAMP, a membrane permeable phosphorylation-inducing agent, V_h shifted back to the right about 40.8 ± 16.9 mV. If OHCs were pre-treated with 20 mM BDM in the bath for 15 minutes, the V_h of those cells ($n=3$) was around -80 mV, far more negative than non-treated cells; RP was between 0 and -10 mV. BDM does not alter the resting potential of skeletal muscle (Gage et al, *Bri J Pharmacol* 100:467, 1990). These data indicate that OHC nonlinear capacitance undergoes phosphorylation and dephosphorylation regulation, and imply that the auditory effects of metabolic insult in vivo could be due to a shift of the voltage-to-movement function along the voltage axis.

EFFECTS OF PUTATIVE EFFERENT TRANSMITTERS ON THE OHC MOTILITY VOLTAGE SENSOR.

*J. Santos-Sacchi, S. Kakehata, and G. Huang

Yale Medical School, New Haven, CT 06510, USA

We have been evaluating the possible effects of phosphorylating agents, including efferent transmitters, on the voltage dependency of OHC nonlinear capacitance, an indicator of the motility voltage sensor. Evaluations of V_h (voltage at peak capacitance) under whole-cell voltage clamp with ionic blockers were made with a voltage stair step protocol, which has been previously described (Huang and Santos-Sacchi, 1993; Biophysical J.). Evaluations are limited to those cells which maintained a resting membrane resistance of at least 50 M Ω . Application of drugs was accomplished by gravity feed through a four barreled pipette or Y tube, and altered the media around the whole cell. Changes in V_h are relative to that obtained in the first couple of minutes after establishment of recording. Initial studies indicated that BDM (2,3-butandione monoxin), a chemical phosphatase, produces a shift of V_h to hyperpolarizing levels within 3 minutes of application. This agent (20 mM) produced a shift in V_h of -21 ± 4 mV in 10 out of 13 cells. This type of shift might be expected, since it has been shown that phosphorylation of K channels shifts the channel's voltage dependence in the positive direction (Perozo and Bezanilla, 1990). The shift in OHCs was reversible by wash with 10 mM 8-bromo cAMP; however, simply washing the cells also produced a reversal. 8-bromo cAMP (2 mM) alone produced essentially no change in V_h ($n=3$). However, in two cells, intracellular perfusion via the patch pipette with the catalytic subunit of PKA evidenced a shift in V_h greater than -20 mV, opposite that expected for electrostatic effects of phosphorylation. In 6 of 11 cells, carbachol (100 μ M) produced a shift to depolarizing levels of $+13 \pm 5$ mV; a smaller shift to negative potentials was observed in 4 of the remaining cells (-5 ± 3 mV). ACh (100 μ M), on the other hand, produced an initial slight shift to positive potentials ($+2.7$ mV \pm 1.3 mV; $n=4$) immediately after application, but then reversed direction at 2 minutes (-4.7 ± 0.8 mV) during application. This trend continued during a 3 minute wash with a total shift to negative potentials of -13.2 ± 2.3 mV. The data indicate that dephosphorylation tends to shift the nonlinear capacitance function to hyperpolarizing levels. However, efferent transmitters which presumably enhance phosphorylation via protein kinases produce inconsistent results. It is possible that mechanisms subsequent to protein phosphorylation are involved, i.e., perhaps the overall negative voltage shift observed with ACh is related to a positive charge screening potentially provided by an internal Ca^{+2} release working upon lateral plasma membrane voltage sensors. Further experiments are underway. (Supported by NIH grant NIDCD DC-00273).

Membrane Tension Directly Shifts Voltage Dependence of Outer Hair Cell Motility and Associated Gating Charge

Seiji Kakehata and Joseph Santos-Sacchi

Sections of Otolaryngology and Neurobiology, Yale University School of Medicine, New Haven, Connecticut 06510 USA

ABSTRACT The unique electromotility of the outer hair cell (OHC) is believed to promote sharpening of the passive mechanical vibration of the mammalian basilar membrane. The cell also presents a voltage-dependent capacitance, or equivalently, a nonlinear gating current, which correlates well with its mechanical activity, suggesting that membrane-bound voltage sensor-motor elements control OHC length. We report that the voltage dependence of the gating charge and motility are directly related to membrane stress induced by intracellular pressure. A tracking procedure was devised to continuously monitor the voltage at peak capacitance (V_{pkCm}) after obtaining whole cell voltage clamp configuration. In addition, nonlinear capacitance was more fully evaluated with a stair step voltage protocol. Upon whole cell configuration, V_{pkCm} was typically near -20 mV. Negative patch pipette pressure caused a negative shift in V_{pkCm} , which obtained a limiting value near the normal resting potential of the OHC (~ -70 mV) at the point of cell collapse. Positive pressure in the pipette caused a positive shift that could reach values greater than 0 mV. Measures of the mechanical activity of the OHC mirrored those of charge movement. Similar membrane-tension dependent peak shifts were observed after the cortical cytoskeletal network was disrupted by intracellular dialysis of trypsin from the patch pipette. We conclude that unlike stretch receptors, which may sense tension through elastic cytoskeletal elements, the OHC motor senses tension directly. Furthermore, since the voltage dependence of the OHC nonlinear capacitance and motility is directly regulated by intracellular turgor pressure, we speculate that modification of intracellular pressure in vivo provides a mechanism for controlling the gain of the mammalian “cochlear amplifier”.

INTRODUCTION

The term “cochlear amplifier” has been used to describe a physiologically vulnerable process that enhances near-threshold auditory sensitivity (Davis, 1983). In recent years, the outer hair cell (OHC) from the organ of Corti has been acknowledged to play a pivotal role in this process (see Dallos, 1992). The OHC is capable of voltage-dependent mechanical responses that appear to provide feedback into the basilar membrane, thereby sharpening the passive mechanical vibration of the cochlear partition (Brownell et al., 1985; Ashmore, 1987; Santos-Sacchi and Dilger, 1988; Ruggero, 1992). The cell also possesses a nonlinear gating charge movement or equivalently, a voltage-dependent capacitance, which correlates well with its mechanical activity (Ashmore, 1990; Santos-Sacchi, 1990, 1991). The similarity between characteristics of OHC nonlinear capacitance and OHC movement indicates that membrane-bound voltage sensor-motor elements control OHC length (Santos-Sacchi, 1990, 1991, 1993; Ashmore, 1992; Dallos et al., 1991; Iwasa, 1994). Indeed, estimates of the membrane-bound charge density of the OHC responsible for the nonlinear capacitance (7500 e⁻/mm²; Huang and Santos-Sacchi, 1993) coincide fairly well with estimates of the density of OHC intramem-

branous particles, the putative sensor-motor elements, observed electronmicroscopically ($6000/\text{mm}^2$; Forge, 1991).

We have been studying the voltage dependence of the nonlinear capacitance of the OHC and have found that the voltage at peak capacitance (V_{pkCm}), which corresponds to the voltage of maximal motile sensitivity or gain, varies among cells and within single cells during recording under whole cell voltage clamp (Santos-Sacchi et al., 1994). This voltage can range from 0 mV to potentials near the normal resting potential of the OHC in vivo, namely about -70 mV (Dallos et al., 1982). We report here that this variability of the nonlinear capacitance as well as the voltage dependence of OHC movement is directly related to intracellular turgor pressure. Notably, a reduction of turgor pressure induces graded increases in nonlinear capacitance and negative voltage shifts in sensor/motor function. Furthermore, the effects of turgor pressure are not directly mediated through cytoskeletal linkages with the membrane voltage sensor, since digestion of the cortical cytoskeleton with intracellular trypsin does not abolish the effects of turgor pressure-induced membrane tension. A preliminary account of this work has been presented (Santos-Sacchi and Kakehata, 1994).

MATERIALS AND METHODS

OHCs were freshly isolated from the organ of Corti of the guinea pig cochlea (Kakehata et al., 1993), and were whole cell voltage clamped using an Axon 200B amplifier with patch pipettes having initial resistances of $2\text{--}3$ M Ω , corresponding to tip sizes of $1\text{--}2$ μm (Hamill et al., 1981). Residual series resistance (after electronic compensation) ranged from 3 to 7 M Ω . The removal of nonlinear ionic conductances is crucial in evaluating nonlinear capacitive currents. In the presence of nonlinear ionic conductances, voltage-induced currents may possess ionic as well as capacitive components, thereby making extraction of gating charge difficult or impossible.

Therefore, ionic blocking solutions were used to remove voltage-dependent ionic conductances so that capacitive currents could be analyzed in isolation (Santos-Sacchi, 1991; Huang and Santos-Sacchi, 1993). The patch pipette solution contained (in mM): 140 CsCl, 2 MgCl₂, 10 EGTA, and 10 HEPES, with pH 7.2 and osmolarity (adjusted with dextrose) noted in figure legends. The external solution contained (in mM): 100 NaCl, 20 TEA, 20 CsCl, 2 CoCl₂, 1.52 MgCl₂, 10 HEPES, and 5 dextrose, pH 7.2, 300 mOsm. Drugs were applied using the "Y-tube" method (Murase et al., 1990), during simultaneous whole chamber perfusion. Experiments were performed at room temperature.

A tracking procedure was developed to continuously monitor V_{pkCm} after obtaining whole cell configuration. The procedure utilizes a voltage stimulus protocol where equal but opposite polarity voltage pulses are delivered to the cell and the generated currents summed to extract nonlinear gating currents, as originally developed to measure ionic channel gating currents, as originally developed to measure ionic channel gating currents ($\pm P$ protocol, ± 40 mV; Armstrong and Bezanilla, 1973; Keynes and Rojas, 1974). Averages of three to five paired pulses were used. While the term "gating current" is typically applied to nonlinear currents associated with voltage sensor activity during ionic channel gating, we use this term for the motility-related voltage sensor displacement currents to indicate a similar molecular transduction strategy (see Alkon et al., 1993). Fig. 1A is an electrical model simulation of OHC voltage-dependent capacitance showing gating current traces obtained with this protocol. When the holding potential is more hyperpolarized than V_{pkCm} , the gating current consists of an initial upward (outward) transient current followed by a downward (inward) transient at voltage step offset. The polarity of the current reverses when the holding potential is more depolarized than V_{pkCm} . To track V_{pkCm} , holding potential (V_{hold}) was automatically decreased in 2 mV steps until a reversal of gating current polarity was obtained, thereupon V_{hold} was increased in 2 mV steps until polarity reversed again. Thus, V_{hold} was varied to follow gating current reversals, namely, V_{pkCm} . Tracking was always initiated from a holding potential of 0 mV. Since initial voltage conditions do not appear

to alter the voltage dependence of the OHC gating currents and the charge moved demonstrates no immobilization (see Fig. 5; Santos-Sacchi, 1991), the tracking technique should not interfere with V_{pkCm} measures. Fig. 1B presents data from an OHC illustrating the procedure. The program Clampex (Axon Instruments, CA) was modified to perform the V_{pkCm} tracking procedure online, and holding potential was corrected for the effects of residual series resistance. Peak capacitance ($C_{m, pk}$) values were also monitored during the tracking procedure using transient analysis of capacitive currents induced by a -10 mV step. Detailed evaluation of total membrane capacitance was made at different potentials by transient analysis of currents induced by a voltage stair step stimulus, and the capacitance function was fit to the first derivative of a two state Boltzmann function relating nonlinear charge to membrane voltage ($\delta Q/\delta V$; Santos-Sacchi, 1991; Huang and Santos-Sacchi, 1993),

$$C_m = Q_{max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin} \tag{1}$$

where

$$b = \exp\left(\frac{-ze(V - V_{pkCm})}{kT}\right) \tag{2}$$

Q_{max} is the maximum nonlinear charge moved, V_{pkCm} is voltage at peak capacitance or equivalently, at half-maximal nonlinear charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. Series resistance, R_s , was estimated from the decaying time constant and integrated charge of the voltage step-induced current, as fully described elsewhere (Santos-Sacchi, 1993; Huang and Santos-Sacchi, 1993). This technique is relatively insensitive to the effects of data filtering. Membrane resistance, R_m , was evaluated from steady state current. C_{lin} was estimated from the fit to above capacitance (C_m) equation, and indicates the intrinsic linear capacitance of the membrane upon which rides the bell-shaped voltage-dependent capacitance (C_v). All analysis techniques have been previously detailed in Huang and Santos-Sacchi (1993). Pipette pressure was modified with a syringe connected to the Teflon tubing attached to the patch pipette holder. Pressure was monitored via a T-connector to a pressure monitor (WPI, Sarasota, FL). Modifications of intracellular pressure have been shown to modulate OHC membrane tension (Iwasa and Chadwick, 1992; Iwasa, 1993), and as an indicator of pressure-induced membrane stress we present longitudinal strain measures (which are linearly related to membrane stress for small deformations (Iwasa and Chadwick, 1992). All experiments were videotaped using a Matrox (Montreal, Quebec, Canada) video overlay board which combines an enhanced graphics adaptor and video. Measures of voltage-induced (20 mV increments) mechanical responses were made off the video monitor with a differential optoresistor technique (Santos-Sacchi, 1989, 1991). Mechanical data were fit to a two state Boltzmann function to determine the voltage at maximum sensitivity ($V_{SL, max}$). All data analysis was performed with the software package MATLAB (Mathworks, Natick, MA).

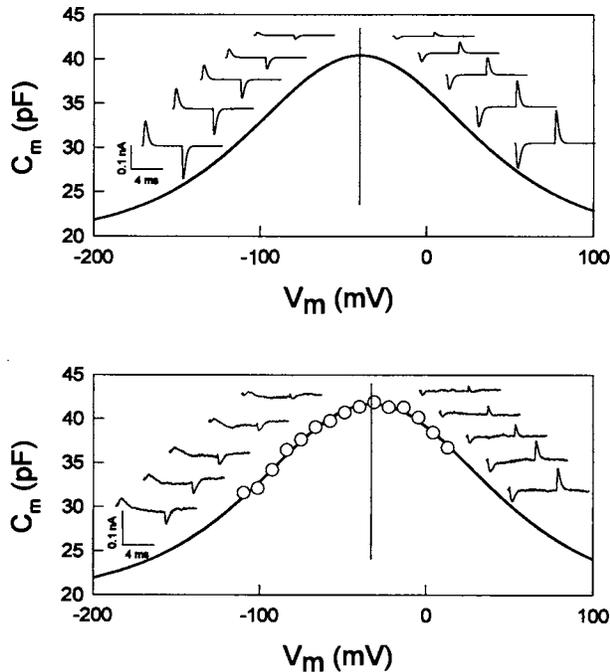

FIGURE 1 Illustration of underlying principle of V_{pkCm} tracking technique. (A) An electrical model simulation of OHC capacitance (that of Huang and Santos-Sacchi, 1993) showing traces obtained with the $\pm P$ protocol (2 mV holding potential alterations about V_{pkCm}). (B) Capacitance of an OHC (measured with the voltage stair step protocol; Huang and Santos-Sacchi, 1993) illustrating the same technique. Note the reversal of gating currents as the holding voltage passes through the region of peak capacitance. Osmolarity of the intracellular solution was 300 mOsm.

RESULTS

The isolated in vitro OHC possesses a positive intracellular turgor pressure of about 1 kPa (Ratnanather et al., 1993; Chertoff and Brownell, 1994). Thus, when a normally cylindrical OHC is under tight-seal whole cell recording, especially with large tipped pipettes, there exists a potential path through the pipette for the release of intracellular pressure, and the cell may depressurize. Fig. 2 illustrates the effect of reducing intracellular pressure during the course of whole cell recording on V_{pkCm} where depressurization of the OHC is assisted by an osmotic imbalance between pipette solution and extracellular media (Δ mOsm = -14). To indicate the effectiveness of pressure changes, longitudinal strain was calculated ($\delta z = (l - L)/L$, where L is initial

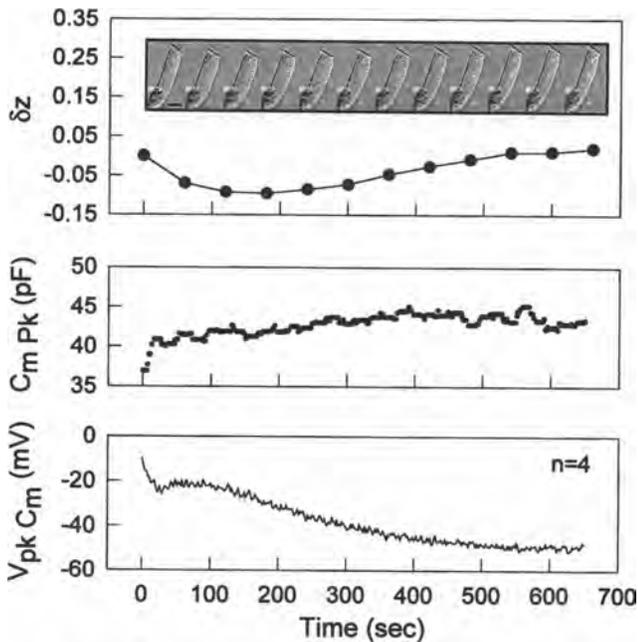

FIGURE 2 Effect of cell turgor reduction on OHC longitudinal strain, δz (top), peak capacitance (middle) and V_{pkCm} (bottom), utilizing the tracking technique, as a function of time after obtaining whole cell voltage clamp configuration (average of four cells; R_s : 7.2 M Ω ; R_m : 177 M Ω). Initial cell length was $55.5 \pm 4.1 \mu\text{m}$ (mean \pm SE). (Inset, top) Video images at 1-min intervals illustrate the shape changes of one of the OHCs. Scale bar 10 μm . Osmolarity of the intracellular and extracellular solutions in these cells was 286 and 300 mOsm, respectively. Whole cell configuration was obtained by electrical "zapping" (see Discussion). Cells did not collapse during the recording period.

length, and l is the length of the cell when deformed), and presented as well. The length of the OHC correlates well with turgor pressure (positive pressure reduces length and increases the radius; Chertoff and Brownell, 1994; Iwasa, 1993). The averaged time course of V_{pkCm} in four cells from the third cochlear turn indicates a shift from an initial value of -21.5 mV to a steady state value of -49.3 mV at 10 min. In addition, $C_{m\text{Pk}}$ increased from an initial value of 40.9 to 43.1 pF. Cell length was reduced immediately after entering the cells, but slowly recovered to initial levels, indicating that over the course of the 10 min recording turgor pressure decreased. During this time the cell did not collapse, and mechanical responses remained robust (however, see below). In four other cells, a more complete analysis of cell capacitance was performed using a voltage stair step protocol (see Materials and Methods). A fit to these capacitance data provided initial/steady state fitted parameters of (mean \pm SE), as follows. Q_{max} : $2.41 \pm 0.18/3.73 \pm 0.3$; V_{pkCm} : $-17.0 \pm 6/-54.5 \pm 3.5$; z : $0.73 \pm 0.04/0.71 \pm 0.02$; C_{lin} : $21.4 \pm 1.5/19.5 \pm 2.3$. Average electrode series resistance and membrane resistance were 4.0 and 315 M Ω , respectively. The slow negative shift in voltage dependence is not due to the dissipation of a diffusion potential at the pipette tip, for the following three reasons. 1) Whereas the time course for osmotic stress effects were on the order of 10 min, diffusion potentials are typically dissipated within 3 min, as the pipette

solution and cell solution equilibrate. Indeed, under current clamp with KCl solutions (140 mM), OHCs that initially have resting potentials greater than -20 mV attain potentials near -70 mV within 20–30 s after whole cell configuration. This is believed to reflect a restoration of intracellular potassium after depletion accompanying OHC isolation (Ashmore and Meech, 1986; Santos-Sacchi and Dilger, 1988). The immediate reduction of cell length noted upon entering whole cell configuration is probably due to clamping the cell at 0 mV at the onset of tracking, and the subsequent rapid exchange of pipette and cell solutions. 2) With small tipped pipettes (10 M Ω ; 0.5 μm tip) containing isoosmolar solutions, although the initial decrease in cell length occurred, no subsequent negative shifts of V_{pkCm} were observed over periods of 30 min or longer. 3) As shown below, pipette pressure changes were as effective as osmotic treatments. Thus, we find an increase in maximum nonlinear charge moved, and a slight decrease in linear capacitance as intracellular pressure and, correspondingly, membrane tension is dissipated. The decrease in linear capacitance might be expected because of a reduced stretch on the plasma membrane.

To investigate the effects of turgor pressure more directly, the intracellular pressure of OHCs was directly modified through the patch pipette. Fig. 3 illustrates the reversible effects of decreasing intracellular pressure on V_{pkCm} and cell capacitance. V_{pkCm} became more negative and the magnitude of peak capacitance grew as the pressure was decreased; subsequently, an increase of pressure reversed the effects. Stable values of V_{pkCm} could be attained with constant pipette pressure, although we do not claim that pipette pressure actually clamps the intracellular pressure. Indeed, during stable pipette pressure, modification of extracellular osmolarity produced results similar to those obtained with pipette pressure changes; namely, hyperosmotic media caused negative

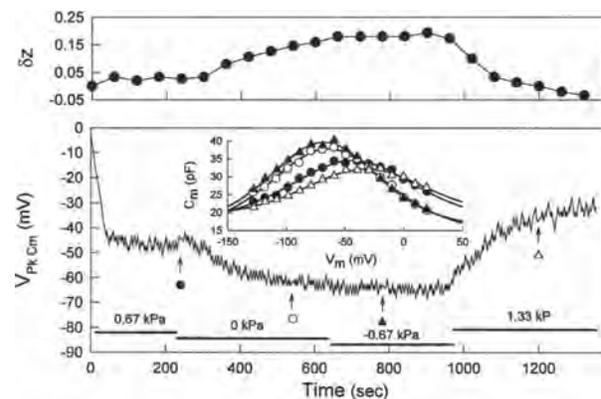

FIGURE 3 OHC longitudinal strain, δz (top), V_{pkCm} (bottom), and nonlinear capacitance (inset) at different pipette pressures. Initial cell length was 38.5 μm . This cell collapsed at -0.67 kPa , and longitudinal mechanical responses stopped. Responses returned upon delivery of positive pressure. R_s : 4.1 M Ω , R_m : 221 M Ω . Fits (insets, solid lines) for capacitance indicate V_{pkCm} , Q_{max} , z , and C_{lin} of -43.6 mV , 2.56 pC, 0.71, and 17.0 pF (@ 0.67 kPa); -64.28 mV , 3.18 pC, 0.76, and 14.2 pF (@ 0 kPa); -68.14 mV , 3.02 pC, 0.82, and 15.6 pF (@ -0.67 kPa); -32.4 mV , 1.95 pC, 0.72, and 18.57 pF (@ 1.33 kPa). Osmolarity of the intracellular solution was 286 mOsm.

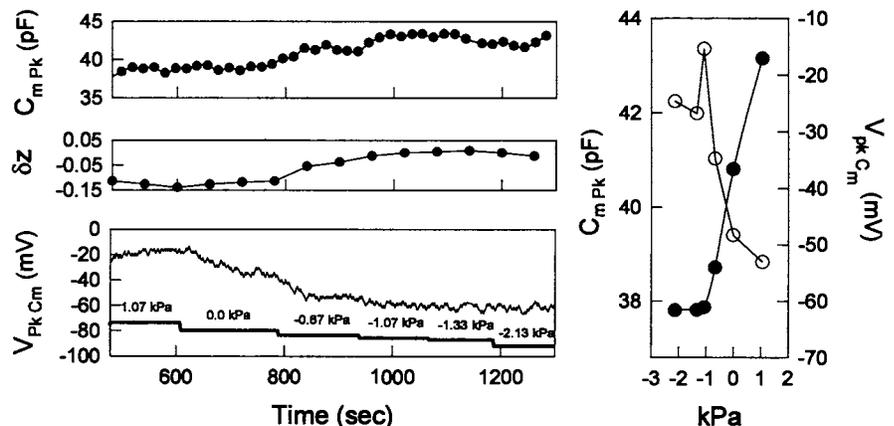

voltage shifts, and hypoosmotic media caused positive voltage shifts (data not shown). OHC δz changes mirrored those of V_{pkCm} . Fig. 4 illustrates, in another cell, that below a critical negative pipette pressure where the OHC just collapses, V_{pkCm} remains constant. This potential is likely to reflect the true voltage dependence of the motility voltage sensor/effector because there is no tension on the membrane motor at the point of cell collapse. In nine cells, this potential was -65.5 ± 1.2 mV (mean \pm SE), which is close to that of the resting potential of OHCs in vivo (Dallos et al., 1982). In some cases where the OHC not only lost its cylindrical shape, but flattened, the magnitude of peak capacitance decreased somewhat ($\sim 10\%$). This may have been due to resultant space clamp problems.

The cylindrical OHC has an elaborate cytoskeletal network linked to the plasma membrane (Holley and Ashmore, 1990; Forge, 1991), and it is conceivable that intracellular pressure works via this network to induce tension on the motility voltage sensors. To evaluate this possibility, we included trypsin (300 $\mu\text{g/ml}$) in the pipette solution (300 mOsm). This treatment is known to digest and/or disrupt the OHC cortical cytoskeleton, and produce a spherical cell whose plasma membrane is essentially free of cytoskeletal attachments, while leaving the voltage sensor fully functional (Huang and Santos-Sacchi, 1994). Fig. 5 illustrates the effect of intracellular pressure on V_{pkCm} and peak membrane capacitance of an OHC during the course of trypsin treatment. In more than 10 cells studied, V_{pkCm} initially shifted to negative potentials after whole cell configuration, but after about 10 min it shifted slowly to positive potentials. This positive shift coincided with the onset of trypsin-induced structural changes and is likely to reflect a growing tension on the membrane as the cell swelled into a sphere. Normally, C_{mPk} remains stable during trypsin treatment (Huang and Santos-Sacchi, 1994). However, in this case, at 14.5 min the electrode and cell were moved to position the cell so that pressure could be delivered without losing the seal. An immediate decrease in peak capacitance was noted, probably because of an induced membrane tension during the manipulation (Fig. 5, bottom). In this particular case, the cell became fully spherical at about 15 min, whereupon positive pipette pressure steps further shifted V_{pkCm} in the positive

direction and reduced peak capacitance, in a reversible manner. Subsequently, negative pressure restored peak capacitance to original levels, and only after the pipette was visibly clear of cellular debris could positive pipette pressure again shift V_{pkCm} to positive values. (In this case, and three others, although C_{mPk} increased with negative pipette pressure, V_{pkCm} did not change. We believe that this occurred because the magnitude of nonlinear charge movement is more susceptible to pressure effects than V_{pkCm} . In Fig. 5, the pipette became plugged with cellular debris upon delivery of negative pressure, and it is likely that the full negative pipette pressure was not delivered to the cell. Upon subsequent delivery of positive pipette pressure, which unplugged the tip, it can be seen that C_{mPk} decreased before a positive shift in V_{pkCm} ensued. Alternatively, it may be possible that the limiting voltage shift of V_{pkCm} became more positive with trypsin treatment. We are currently investigating this possibility.) Finally, the cell burst at a pipette pressure of about 1 kPa and V_{pkCm} of $+8$ mV. From these types of observations, in 10 cells out of 12, we conclude that membrane tension directly modulates the embedded motility voltage sensor.

A correspondence between OHC nonlinear capacitance and motility voltage dependence has been observed (Santos-Sacchi, 1991). Voltage at half maximal charge movement, V_h (or equivalently, V_{pkCm}), corresponds to the voltage where OHC mechanical responses are maximally voltage sensitive, $V_{\delta L, \max}$. We further demonstrate a close relationship between OHC membrane capacitance and movement under different pressure conditions within individual cells. The inset in the bottom panel of Fig. 6 depicts the structure of an OHC under two different pipette pressure conditions, $+0.54$ and -0.19 kPa. Positive pressure caused the cell to shorten, whereas negative pressure caused the cell to lengthen. Fig. 6 shows that the voltage dependence of OHC motility essentially mirrors that of the nonlinear capacitance of the cell. Both shifted to hyperpolarized levels as intracellular pressure was decreased. In three cells, $V_{\delta L, \max}$ was (mean \pm SE) -23.6 ± 2.9 mV and V_{pkCm} was -24.7 ± 4.2 mV for a high pipette pressure condition (0.49 ± 0.1 kPa); a reduced pipette pressure (-0.05 ± 0.07 kPa) shifted these values to -45.7 ± 2.2 mV and -56.5 ± 4.8 mV, respectively. Slight differences may be due to changes in intracellular pressure during the interval

FIGURE 4 Pipette pressure versus V_{pkCm} (bottom left), OHC longitudinal strain, δz (middle left), and peak capacitance (top left). R_s : 7.5 M Ω , R_m : 150 M Ω . Initial cell length was 69.7 μm . In this case, the cell collapsed at -1.33 kPa. Right plot of means of V_{pkCm} (●) and peak capacitance (○) obtained during the last 12 s of pressure durations. Osmolarity of the intracellular and extracellular solutions was 300 mOsm.

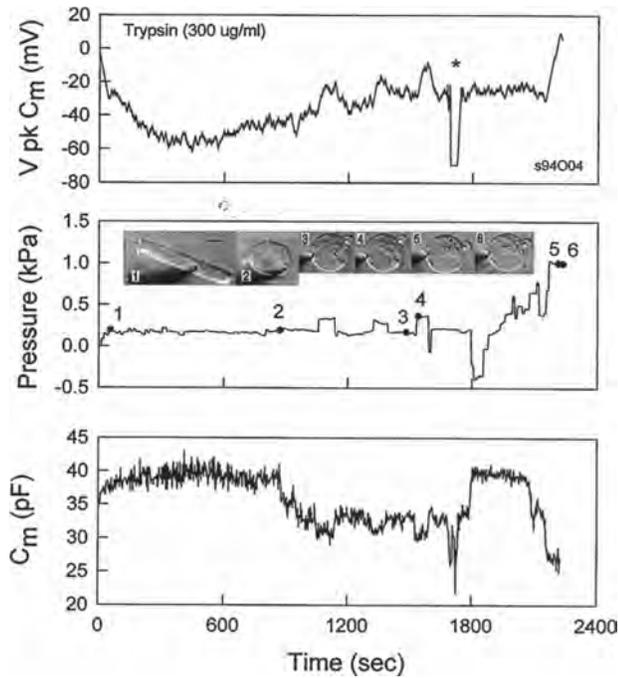

FIGURE 5 Effects of intracellular trypsin treatment on V_{pkCm} (top) and $C_{m, pk}$ (bottom). (middle) Pipette pressure delivered, sampled every 8 s. The numbered inset images are from selected time periods corresponding to the numbered solid circles on the pressure trace. Scale bar is $10 \mu\text{m}$. During constant pipette pressure, V_{pkCm} initially declines but shifts to hyperpolarized levels when cell structural changes ensue, around 10 min. After the OHC reached a spherical shape, positive pipette pressure induced positive voltage shifts and decreases in peak capacitance. At the point indicated by the asterisk, the holding potential was maintained at about ~ 70 mV to evaluate the effect of initial conditions on V_{pkCm} . After the release of holding potential, V_{pkCm} quickly shifted back to its previous value, indicating that holding potential does not influence V_{pkCm} . At 30 min, negative pressure is delivered and $C_{m, pk}$ increased to initial levels, but the electrode subsequently became plugged. Only after considerable attempts to unplug the pipette with positive pressure were we able to observe the release of cellular debris from the tip. At that point V_{pkCm} began to shift to depolarized levels and $C_{m, pk}$ decreased; the cell finally burst after reaching a steady state V_{pkCm} of $+8$ mV for about 20 s.

(~ 1 – 2 min) between nonlinear capacitance measurement (stair step protocol) and mechanical response measures (voltage pulse protocol). The correspondence between voltage dependencies indicates that motor and sensor are either tightly coupled or one entity. The singular identity of motor and sensor is further indicated by the co-localization of the two within a restricted region of the lateral plasma membrane (Dallos et al., 1991; Huang and Santos-Sacchi, 1993, 1994).

Fig. 6 also illustrates that negative pipette pressure reduces the maximum mechanical response of the OHC (Santos-Sacchi, 1991). Despite this reduction, however, the inset in the top panel of Fig. 6 illustrates that the maximum mechanical gain of the cell can remain essentially unaltered. That is, in this example, the maximum gain remained near 20 nm/mV under both pressure conditions.

Interestingly, lanthanides, which interfere with OHC osmotic pressure regulation (Crist et al., 1993; however, see Chertoff and Brownell, 1994), possibly via interaction with

OHC stretch receptors (Yang and Sachs, 1989; Iwasa et al., 1991; Ding et al., 1991) also shifted V_{pkCm} (Fig. 7). Lanthanides have been shown to reversibly block OHC motility and nonlinear gating charge (Santos-Sacchi, 1991). Extracellularly applied lutetium chloride ($100 \mu\text{M}$), one of the lanthanides tested, shifted V_{pkCm} to hyperpolarized levels and decreased peak capacitance only slightly. At a higher concentration (1 mM), however, it apparently shifted V_{pkCm} in the opposite direction but reduced the nonlinear capacitance markedly (Fig. 7, inset). Mechanical responses were fully blocked, as well, without cell collapse. Such a large drop in nonlinear capacitance may invalidate the tracking technique so that the shift to positive potentials is likely artifactual. In all cases of lanthanide treatment where nonlinear capacitance block was not complete, i.e., where V_{pkCm} could be evaluated unequivocally, tracking and full analysis with the voltage stair protocol indicated a V_{pkCm} shift to negative potentials, opposite that of potential charge screening effects. Lanthanides also increased cell length, similar to treatments that reduced turgor pressure. In three cells, 1 mM lutetium increased OHC length about 5% . It was of interest to determine whether lanthanides could interfere with the effects of membrane tension on nonlinear capacitance. Fig. 8 illustrates that turgor pressure changes remained capable of reversibly shifting V_{pkCm} and altering Q_{max} in cells that were treated with both

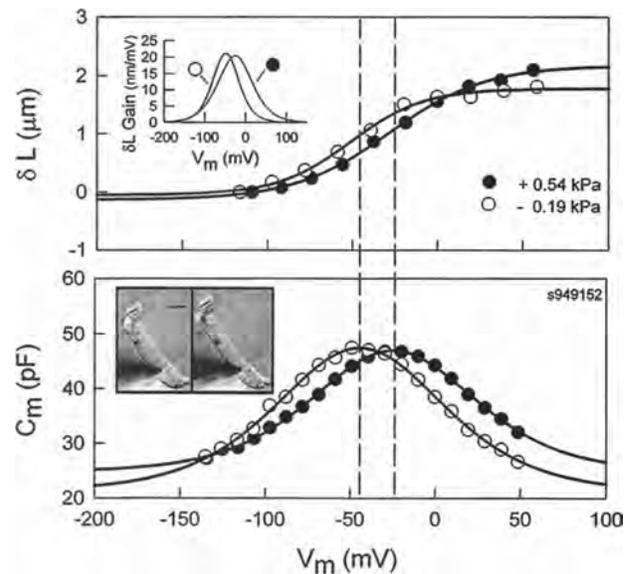

FIGURE 6 Membrane capacitance (bottom) and movement (top) of an OHC under different pressure conditions delivered through the pipette. Length changes induced by 20 mV steps from -140 to $+60$ mV (nominal), but corrected for series resistance effects in figure. R_s : 3.5 M Ω , R_m : 154 M Ω @ 0.54 kPa, and R_s : 2.0 M Ω , R_m : 88 M Ω @ -0.19 kPa. Fits (positive vs. negative pressure) for capacitance indicate V_{pkCm} , Q_{max} , z , and C_{lin} of -24.7 mV, 2.87 pC, 0.79 , and 24.8 pF versus -44.2 mV, 3.47 pC, 0.77 , and 21.3 pF. Fits (positive vs. negative pressure) for mechanical data indicate V_h (voltage midpoint) and z of -28.0 mV and 0.91 versus -51.1 mV and 1.2 . Dotted lines indicate V_{pkCm} under each condition. (Inset, top) First derivative of the fitted mechanical responses, indicating the gain of the mechanical response under the two pressure conditions. (Inset, bottom) Video images of OHC at high (left) and low (right) pressures. Scale bar: $10 \mu\text{m}$. Osmolarity of the intracellular and extracellular solutions was 300 mOsm.

trypsin and lutetium. This indicates that the activity of stretch receptors, which are blocked by low micromolar concentrations of lanthanides, is not responsible for stress-induced effects on OHC membrane capacitance.

DISCUSSION

Treatments that reduce OHC turgor are known to decrease the magnitude of electromotility (Brownell et al., 1989; Shehata et al., 1991). Indeed, we have previously shown that collapsing the OHC with negative pipette pressure produces a rapid and reversible loss of longitudinal motility, but the function of the motility voltage sensor remains intact (Santos-Sacchi, 1991). In fact, we reported that the magnitude of the nonlinear charge movement increased by about 10% under the negative pressure condition, corresponding to the increase in C_{mPK} that we now observe upon reduced cell turgor. Iwasa (1993) first systematically studied the effects of membrane tension on OHC capacitance, and found that increased turgor pressure decreased nonlinear capacitance measured at three fixed holding potentials. He correctly concluded, based on modeling the data, that membrane tension caused a positive shift in V_{pkCm} . More recently, Gale and Ashmore (1994a) showed that V_{pkCm} shifted to a depolarized level and peak capacitance decreased when positive pressure was applied via the patch pipette. However, they further reported that upon collapse of the cell with hyperosmotic extracellular media, V_{pkCm} remained unchanged (-36 ± 11 mV; mean \pm SD), but voltage-dependent capacitance decreased some 60–70%. Other differences are apparent between their results and ours. First, no change in linear capacitance was observed by them during pressure increases, and second, while we find either little change or a slight decrease in z during positive pressure conditions, perusal of their data indicates a marked increase. Notably, Gale and Ashmore (1994a) did not employ ionic channel blockers, and used a phase tracking technique that can be susceptible to changes in electrode and/or membrane resistance. Changes in OHC membrane resistance can be quite large under those conditions, where outward potassium currents can reach several nA.

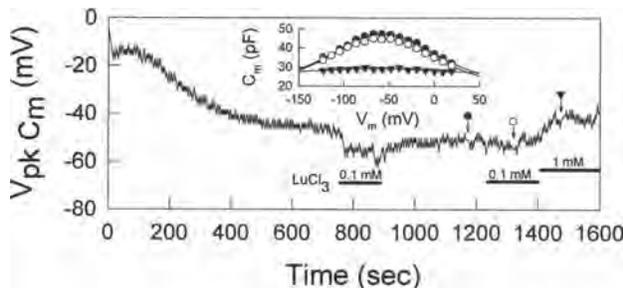

FIGURE 7 Effects of lanthanides on V_{pkCm} and nonlinear capacitance. After V_{pkCm} stabilized, lutetium chloride (1 mM) was applied extracellularly using a Y-tube delivery system. Inset shows voltage-dependent capacitance obtained by the voltage stair step technique (Huang and Santos-Sacchi, 1993). R_s : 6.5 M Ω , R_m : 145 M Ω . Fits (—) to the capacitance data indicate V_{pkCm} , Q_{max} , z , and C_{lin} of -56.9 mV, 4.1 pC, 0.67, and 20.9 pF (●) and -58.9 mV, 4.1 pC, 0.63, and 19.4 pF (○). Data obtained with 1 mM lutetium chloride (▼) could not be fit reliably.

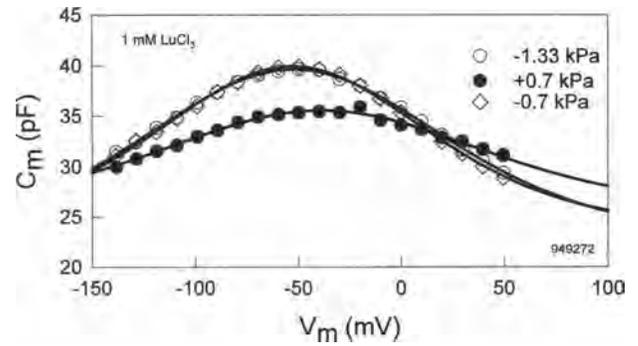

FIGURE 8 Effects of turgor pressure on nonlinear capacitance in a cell treated with intracellular trypsin and extracellular lutetium chloride (1 mM). Initial C_{mPK} was 47.5 pF, and in this cell only a partial block of nonlinear capacitance by lutetium was observed, enabling us to evaluate changes in V_{pkCm} . R_s : 2.5 M Ω , R_m : 300 M Ω . Reversible changes in cell capacitance induced by pressure modification are still observed. Fits (—) to the capacitance data indicate V_{pkCm} , Q_{max} , z , and C_{lin} of -52.0 mV, 3.4 pC, 0.52, and 22.5 pF (○): -1.33 kPa, and -38.6 mV, 2.2 pC, 0.47, and 25.3 pF (●): $+0.7$ kPa, and -52.8 mV, 2.9 pC, 0.57, and 23.6 pF (◇): -0.7 kPa.

Our work indicates that the variability of V_{pkCm} we initially noted (Santos-Sacchi et al., 1994) results from variability in OHC turgor pressure. Upon establishing whole cell configuration, OHC V_{pkCm} and $V_{\delta Lmax}$ are at a potential near -20 mV. Actually, this initial voltage depends on the method of obtaining whole cell configuration. Applying negative pressure to break the membrane patch can cause an immediate loss of cell turgor, whereas electrically breaking through the membrane patch (zapping) can prevent such a loss. The former technique produces a more negative initial V_{pkCm} . Subsequent to whole cell configuration, V_{pkCm} directly follows modifications of intracellular pressure, but shifts to a limiting negative voltage when depressurized. Before cell collapse, V_{pkCm} and correspondingly, $V_{\delta Lmax}$ can attain potentials close to that of the resting potential of OHCs in vivo (Dallos et al., 1982). At this point, mechanical responses are still robust and maximum voltage-dependent movement will exist near normal resting potentials. It should be emphasized that despite the fact that reduced turgor pressure decreases the overall magnitude of the mechanical response (Fig. 6; and see Santos-Sacchi, 1991, Fig. 11), maximum gain or sensitivity is little affected before cell collapse (Fig. 4, inset). Thus, for an OHC at a normal resting potential, reducing turgor pressure effectively increases the mechanical gain at that potential. In fact, another mechanism may aid in aligning the resting potential and $V_{\delta Lmax}$ under normal conditions. It is known that increased turgor can hyperpolarize, and reduced turgor can depolarize the OHC via the action of potassium selective stretch receptors (Iwasa et al., 1991; Harada et al., 1993). Correspondingly, sustained hyperpolarization can increase turgor and depolarization can reduce turgor pressure (Shehata et al., 1991). Thus, lowering turgor pressure may cause $V_{\delta Lmax}$ and membrane potential to approach each other, thereby maximizing the mechanical responsiveness of the OHC to receptor potentials, which presumably drive OHC motility in vivo (Evans and Dallos, 1993).

One problem with the potential role of OHC motility as the basis for the cochlear "amplifier" is that the magnitude of the AC mechanical response induced by receptor potentials in the high frequency region near threshold is calculated to be 20 dB smaller than basilar membrane motion (Santos-Sacchi, 1989, 1992). This is based on prior *in vitro* observations that the mechanical sensitivity of the OHC is not maximal near the normal *in vivo* resting potential of -70 mV. This dilemma has prompted suggestions that other hair cell mechanisms, e.g., stereociliar mechanics, might provide sensory gain (Santos-Sacchi, 1989; Hudspeth and Gillespie, 1994). However, the magnitude of turgor pressure *in vivo* is unknown. If it were close to 0, this might alleviate the apparent disparity between the magnitudes of basilar membrane motion and OHC motion, since the mechanical gain of the OHC would be maximal near the normal resting potential of the cell. It is possible that the high intracellular turgor pressure that is found in isolated OHCs (Ratnanather et al., 1993) is a consequence of the isolation procedures, since it is often noted that OHCs swell because of increased cytoplasmic osmolarity when they are maintained *in vitro* (Chertoff and Brownell, 1994).

Recently, Kalinec et al. (1992) have shown, using light microscopic evaluation, that treatment of the OHC with intracellular trypsin caused the cell to round up, presumably because of digestion of the cytoskeleton of the cell. Interestingly, voltage-dependent mechanical responses were still present. We confirmed by using electronmicroscopy that the cytoskeleton was digested; we also determined that the voltage sensor remained fully functional (Huang and Santos-Sacchi, 1994). In the present study we used trypsin treatment to show that cytoskeletal elements are not responsible for the susceptibility of the voltage sensor to modification of intracellular pressure. Thus, unlike stretch receptors that may sense tension through an elastic cytoskeleton (Sokabe et al., 1991), the OHC voltage sensor appears to respond to tension delivered directly to the plasma membrane. The role of the cortical cytoskeleton in the OHC has been proposed to provide structural constraints that funnel integral membrane motor protein area changes into anisotropic mechanical responses of the whole cell, namely predominant length changes (Kalinec et al., 1992; Santos-Sacchi, 1993). However, we have preliminary evidence that the sensitivity of the membrane motor to changes in turgor pressure increases after destruction of the cortical cytoskeleton. That is, smaller changes in pipette pressure are required to influence nonlinear capacitance after the cytoskeleton is destroyed. Thus, in addition to providing constraints on motility, the cytoskeleton may normally buffer the effects of turgor pressure alterations.

The underlying mechanism responsible for the effects of membrane tension on the nonlinear capacitance of the OHC has been theoretically evaluated by Iwasa (1993, 1994). By supplementing a simple two state Boltzmann model with an elastic energy term, shifts in V_{pkCm} were evidenced upon changes in the elastic energy. However, whereas the voltage shifts are predicted, the changes observed experimentally in

the magnitude of the voltage-dependent capacitance when tension is modified (Fig. 3; Gale and Ashmore, 1994a) are not. The increase in the amount of charge moved as membrane tension is dissipated may represent an increase in the number (N) of voltage sensors/motors capable of conformational change within the membrane. We find that the distance traversed by the sensor in the membrane electric field remains constant, evidenced by a fairly stable z during pressure modifications. Thus, in addition to Iwasa's elastic energy term, perhaps the number of functional sensors is tension-dependent. This possible change in the number of functional sensor/motors might indicate, in turn, that the maximum OHC length change would increase as turgor pressure is dissipated. However, the opposite is the case (Fig. 6; Santos-Sacchi, 1991). One possible explanation for this discrepancy is that coupling of the voltage sensor to the effector is less efficient under reduced tension, resulting in a smaller membrane area change. Alternatively, the membrane area changes thought to be responsible for the overall mechanical response of the cell (Kalinec et al., 1992; Iwasa and Chadwick, 1992; Iwasa, 1993; Santos-Sacchi, 1993) may actually be enhanced, but the translation mechanism funneling area changes into length changes may be compromised. It may be possible to explore this issue by measuring voltage-dependent changes in membrane patch area under conditions of variable tension.

Lanthanides have some effects similar to turgor pressure reductions, including negative shifts of V_{pkCm} and increases in cell length. We initially suggested that lanthanides shifted V_{pkCm} to positive potentials because of charge screening effects on the extracellular aspect of the OHC membrane (Santos-Sacchi, 1991). However, it is now clear that those initial studies were influenced by turgor pressure effects, since in those studies the pipette series resistance was kept low by delivering transient positive and negative pressures. Thus, it is likely that the effects of pipette pressure alterations on OHC turgor masked the true effects of lanthanides. Gale and Ashmore (1994b) have recently presented data indicating that extracellular gadolinium shifts V_{pkCm} in the negative direction, in agreement with our present results. They suggested that gadolinium charge screens from the inner aspect of the OHC membrane; however, it is unlikely that lanthanides enter the cell and charge screen on the intracellular aspect of the membrane, since intracellular EDTA-like calcium chelators, which both they and we used are far more effective (5–10 orders of magnitude) at buffering lanthanides (Kolthoff et al., 1969). While one mechanism of lanthanide action may involve interference with OHC osmo-regulation (Crist et al., 1993), clearly this cannot solely account for the reduction in nonlinear capacitance we observe, since induced turgor pressure changes continue to alter nonlinear capacitance in the presence of lanthanides. It is possible that lanthanides are capable of directly reducing tension on the membrane motors, perhaps via electrostatic effects. Further studies are required to resolve this issue.

In conclusion, our results indicate that OHC turgor pressure directly controls the voltage dependence of the nonlinear

capacitance and mechanical response of the cell, probably through direct induction of tension on the motility voltage sensor/effector. We speculate that modulation of turgor pressure *in vivo*, perhaps via OHC stretch receptor activity, may provide a unique mechanism for gain control of the cochlear “amplifier”.

We thank Sam Khalil for technical help and Dr. Guojie Huang for his comments throughout the study.

Effects of Salicylate and Lanthanides on Outer Hair Cell Motility and Associated Gating Charge

Seiji Kakehata and Joseph Santos-Sacchi

Sections of Otolaryngology and Neurobiology, Yale University School of Medicine, New Haven, Connecticut 06510

Salicylate, one of the most widely used drugs, is known to induce reversible tinnitus and hearing loss. Salicylate interferes with outer hair cells (OHCs), which are believed to underlie normal auditory frequency selectivity and sensitivity. In the present experiments, the effects of salicylate and lanthanides on OHC motility and nonlinear capacitance were investigated by using isolated guinea-pig OHCs while attempting to avoid inadvertent intracellular pressure change, which itself can affect OHC motility and capacitance. Either extracellularly or intracellularly applied salicylate reduced nonlinear peak capacitance ($C_{m_{pk}}$) and shifted the voltage at peak capacitance to depolarized levels. Concentration–response curves for reduction in $C_{m_{pk}}$ by salicylate and $GdCl_3$ revealed a half-maximal concentration and Hill coefficient of 1.6 mM and 1.0, and 0.6 mM and 1.2, respectively. In comparable groups of OHCs, the normal $C_{m_{pk}}$ values of which were near 40 pF, average $C_{m_{pk}}$ de-

creased to 28 and 36 pF for intracellularly and extracellularly applied salicylate, respectively. Salicylate reduced, but did not completely block, the voltage-induced length change. Extracellularly, but not intracellularly, applied lanthanide blocked voltage-induced movement and capacitance almost completely. After intracellular trypsin treatment, salicylate reduced voltage-dependent capacitance reversibly, suggesting that salicylate directly acts on the sensor/motor and not via effects on intracellular structures, such as the subsurface cisternae. The results are consistent with the hypothesis that the dissociated, charged form of salicylate directly interacts with the sensor/motor on the inner aspect of the OHC plasma, whereas lanthanides interact on the outer aspect.

Key words: outer hair cell; salicylate; motility; nonlinear capacitance; gating currents; lanthanides

The outer hair cell (OHC), one of the two receptor cell types in the mammalian organ of Corti, is thought to play a crucial role in hearing by providing a local mechanical feedback into the basilar membrane via its unique voltage-dependent length changes (Brownell et al., 1985; Ashmore, 1987; Santos-Sacchi and Dilger, 1988; Dallos, 1992). This feedback sharpens the passive mechanical vibration of the cochlear partition. Recent studies demonstrate that the OHC has a nonlinear gating charge movement or, equivalently, a voltage-dependent capacitance that presents characteristics similar to those of OHC motility, indicating that membrane-bound voltage sensor/motor elements control OHC length (Ashmore, 1989, 1992; Dallos et al., 1991; Santos-Sacchi, 1991, 1993; Iwasa, 1994).

Salicylate, which is used as an analgesic and anticoagulant, is one of the most widely used drugs. Salicylate is known to produce reversible tinnitus and hearing loss (Myers and Bernstein, 1965; Mongan et al., 1973). Several lines of indirect evidence suggest that salicylate exerts these effects via the OHC (McFadden and Plattsmier, 1984; Long and Tubis, 1988; Puel et al., 1989; Kujawa et al., 1992; Carlyon and Butt, 1993). Indeed, direct studies on the OHC have shown that the nonlinear capacitance and/or motility of the cell can be modified by salicylate (Shehata et al., 1991; Tunstall et al., 1995). Shehata et al. (1991) reported that salicylate reduces OHC turgor pressure and motility. More recently, Tun-

stall et al. (1995) showed that salicylate reduces OHC membrane capacitance and concluded that salicylate is effective in the membrane-permeant uncharged form. Other treatments that are known to affect OHC motility and capacitance include lanthanides and altered turgor pressure, the latter acting via membrane stress (Santos-Sacchi, 1991; Iwasa, 1993; Gale and Ashmore, 1994b; Kakehata and Santos-Sacchi, 1995).

Because whole-cell patch-pipette recording inadvertently can permit changes in OHC turgor pressure (Kakehata and Santos-Sacchi, 1995), we examined the effect of salicylate and lanthanides on OHC nonlinear capacitance and voltage-induced mechanical responses while attempting to avoid such interference. The results suggest that each investigated agent seems to work via a different mechanism on the OHC sensor/motor and that the effects of both agents are independent of turgor pressure. Furthermore, the data indicate that the dissociated, charged form of salicylate interacts with the sensor/motor on the inner aspect of the plasma membrane, whereas lanthanides interact with the sensor/motor on the outer aspect.

MATERIALS AND METHODS

OHCs were freshly isolated from the organ of Corti of the guinea-pig cochlea (Kakehata et al., 1993) and were whole-cell voltage-clamped by an Axon 200 amplifier with patch pipettes having initial resistances of 2–3 M Ω or \sim 10 M Ω , corresponding to tip sizes of 1–2 μ m or \sim 0.5 μ m, respectively (Hamill et al., 1981). Residual series resistance (R_s ; after electronic compensation) ranged from 3 to 7 M Ω and from 20 to 30 M Ω , respectively. Ionic blocking solutions were used to remove voltage-dependent ionic conductances so that capacitive currents could be analyzed in isolation (Santos-Sacchi, 1991; Huang and Santos-Sacchi, 1993). The patch-pipette solution contained (in mM): 140 CsCl, 2 MgCl₂, 10 EGTA, and 10 HEPES, pH 7.2; osmolarity was adjusted with dextrose to 300 mOsm. The external solution contained (in mM): 100 NaCl, 20 TEA,

20 CsCl, 2 CoCl₂, 1.52 MgCl₂, 10 HEPES, and 5 dextrose, pH 7.2, at 300 mOsm. In some experiments, extracellular CaCl₂ (2 mM) was included, without any effect. Drugs were applied by using the Y-tube method (Murase et al., 1990) during simultaneous whole-chamber perfusion. Experiments were performed at room temperature.

A tracking procedure was used to monitor continuously the voltage at peak nonlinear capacitance (V_{pkCm}) after obtaining whole-cell configuration (Kakehata and Santos-Sacchi, 1995). The program Clampex (Axon Instruments, Foster City, CA) was modified to perform the V_{pkCm} tracking procedure on-line, and membrane potential was corrected for the effects of residual series resistance. Peak capacitance (Cm_{pk}) values also were monitored during the tracking procedure by using transient analysis of capacitive currents induced by a -10 mV step.

Detailed, corroborative evaluation of membrane capacitance was made at different potentials by transient analysis of currents induced by a voltage stair-step stimulus, and the capacitance function was fit to the first derivative of a two-state Boltzmann function relating nonlinear charge to membrane voltage (dQ/dV ; Santos-Sacchi, 1991; Huang and Santos-Sacchi, 1993):

$$C_m = Q_{max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin},$$

in which

$$b = \exp\left(\frac{-ze(V - V_{pkCm})}{kT}\right).$$

Q_{max} is the maximum nonlinear charge moved, V_{pkCm} is voltage at peak capacitance or, equivalently, at half-maximal nonlinear charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. Pipette pressure was modified with a syringe connected to the Teflon tubing attached to the patch-pipette holder. Pressure was monitored via a T-connector to a pressure monitor (World Precision Instruments, Sarasota, FL). An in-house pipette pressure clamp was used to maintain constant pipette pressure when required. This device provided positive or negative pressure into the pipette via a motor-driven, gas-tight syringe by using feedback from the pressure monitor.

Previously, we have found that when recording with large-tipped patch pipettes (1.5–3 M Ω , 1.5 μ m tip) containing iso-osmolar solutions, V_{pkCm} shifts to hyperpolarized levels over the course of 10 min after patch membrane rupture (Kakehata and Santos-Sacchi, 1995). This occurs because of a decrease in OHC intracellular pressure. In the present set of experiments, three conditions were used to dismiss potential effects of uncontrolled, recording-induced intracellular pressure change during evaluation of salicylate and lanthanides on OHC capacitance and motility. First, the use of small-tipped pipettes provides for stable intracellular pressures, because no negative shifts of V_{pkCm} are observed over periods of 30 min or longer. Under this condition, the potential effects of exogenous agents on intracellular pressure are unhampered. Second, with large-tipped pipettes, maintenance of constant pipette pressure provides for stable intracellular pressures, because V_{pkCm} can be maintained constant. Third, with large-tipped pipettes after intracellular pressure dissipation (~ 10 min), intracellular pressure is stable, because V_{pkCm} remains constant. The drugs were evaluated under each condition.

All experiments were video taped with a Matrox (Montreal, Canada) video overlay board that combines EGA and video. Measures of voltage-induced (20 mV increments) mechanical responses were made from the video monitor with a differential optoresistor technique (Santos-Sacchi, 1989, 1991). Mechanical data were fit to a two-state Boltzmann function to determine the voltage at maximum sensitivity (V_{sLmax}).

Dose–response data were averaged and are given as mean \pm SE. A continuous theoretical curve was drawn according to a modified Michaelis–Menten equation with the use of a least-squares fitting routine after normalization of the response,

$$\Delta C = C_{max} \left(\frac{C^n}{C^n + K_D^n} \right),$$

in which ΔC is the observed reduction of capacitance, C is the drug concentration, K_D is the dissociation constant, and n is the Hill coefficient. All data analysis was performed with the software package MATLAB (Mathworks, Natick, MA).

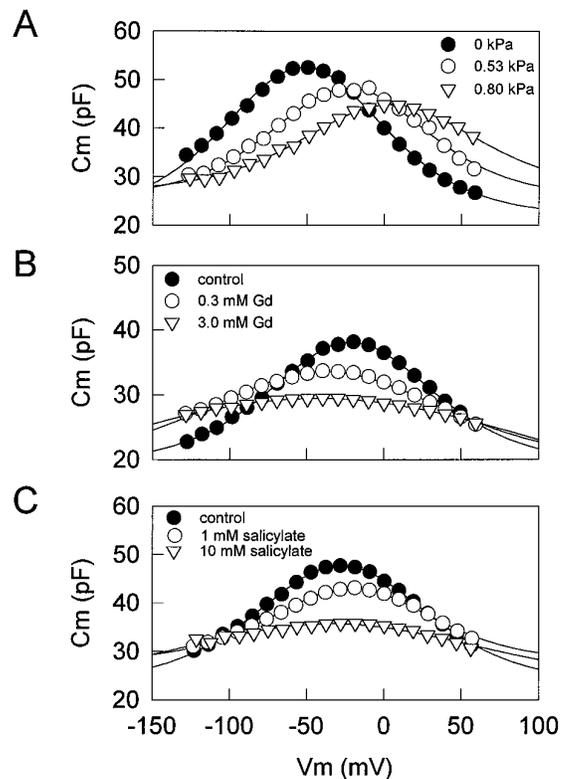

Figure 1. Effects of intracellular pressure (*A*), lanthanides (*B*), and salicylate (*C*) on C_m . Voltage-dependent capacitance was obtained by the voltage stair-step technique. *A*, After V_{pkCm} stabilized after intracellular pressure dissipation (~ 10 min), an increasing intracellular pressure caused a positive shift in the V_{pkCm} with decreasing peak capacitance (Cm_{pk}). R_s (series resistance), 1.9 M Ω (pipette tip, ~ 1.5 μ m); R_m (membrane resistance), 139 M Ω . The initial cell length was 75 μ m; the cell length was reduced to 73% when intracellular pressure was increased to 0.8 kPa. *B*, In another cell, after V_{pkCm} stabilized, GdCl₃ was applied extracellularly by a Y-tube delivery system. GdCl₃ caused a negative shift in V_{pkCm} with decreasing Cm_{pk} . R_s , 2.8 M Ω (pipette tip, ~ 1 μ m); R_m , 220 M Ω . The initial cell length was 50 μ m; the cell length elongated to 107%. *C*, In another cell, with the use of a small-tipped pipette to maintain initial intracellular turgor pressure, extracellularly applied salicylate caused a positive shift in V_{pkCm} with decreasing Cm_{pk} . R_s , 27.2 M Ω ; R_m , 350 M Ω . The initial cell length was 65 μ m; the cell length was reduced to 78%. All treatments were done after V_{pkCm} stabilized.

RESULTS

Effects of salicylate, lanthanides, and pressure on OHC nonlinear capacitance

Figures 1 and 2 illustrate the effects of intracellular pressure changes and extracellularly applied salicylate and lanthanides on OHC nonlinear capacitance. Positive changes in intracellular pressure consistently and reversibly shifted V_{pkCm} to depolarized levels and reduced Cm_{pk} (Figs. 1*A*, 2*A*). Lanthanides such as GdCl₃, LuCl₃, and CeCl₃ consistently, but not always reversibly, shifted V_{pkCm} to hyperpolarized levels and reduced Cm_{pk} (Figs. 1*B*, 2*B*). However, whereas salicylate consistently and reversibly shifted V_{pkCm} and reduced Cm_{pk} , the direction of the shift could be to either depolarized or hyperpolarized levels (Figs. 1*C*, 2*C,D*). About two-thirds of the cells tested exhibited a shift in the depolarized direction (Fig. 2*C*). Residual ionic conductance (leakage) remained unaffected by salicylate or intracellular pressure changes, but lanthanides suppressed it. These results suggest that lanthanides and salicylate do not exert their effects simply via a

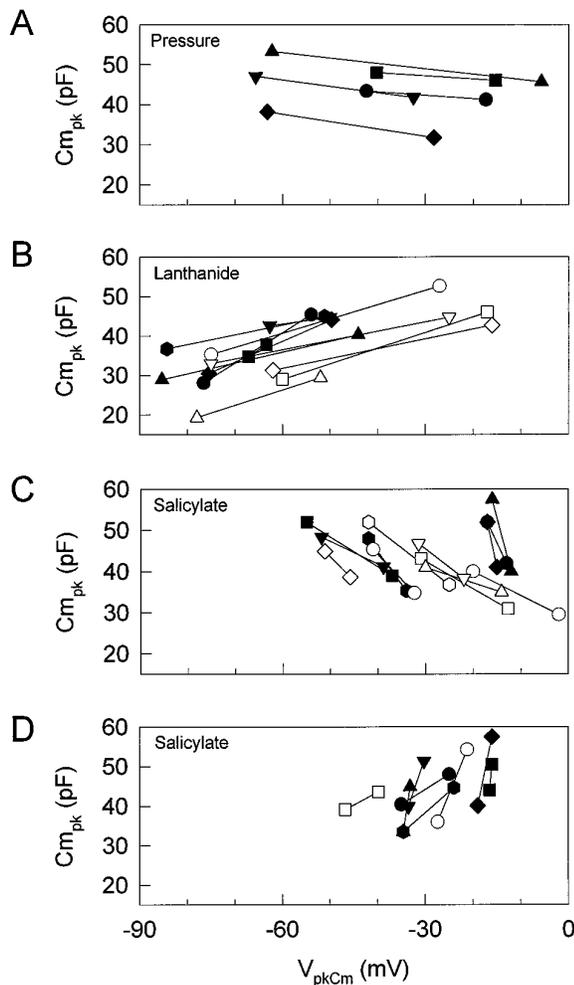

Figure 2. Effects of intracellular pressure (*A*), lanthanides (*B*), and salicylate (*C, D*) on the relationship between V_{pkCm} and Cm_{pk} . Each point shows the relationship between V_{pkCm} and Cm_{pk} . Increasing pressure, extracellularly applied lanthanides, or salicylate reduces Cm_{pk} . *A*, Cm_{pk} and V_{pkCm} under two pressure conditions, -0.41 ± 0.26 (mean \pm SE) and 0.64 ± 0.23 kPa. Increasing pressure caused a positive shift in V_{pkCm} . *B*, Cm_{pk} and V_{pkCm} before and during application of lanthanides (3 or 10 mM $GdCl_3$, $n = 7$; 1 mM $LuCl_3$, $n = 3$; 1 mM $CeCl_3$, $n = 1$). Extracellularly applied lanthanides caused a negative shift in V_{pkCm} with decreasing Cm_{pk} in all cells tested ($n = 11$). Reversibility was dependent on concentration. *C, D*, Cm_{pk} and V_{pkCm} before and during application of 10 mM salicylate. Extracellularly applied salicylate reduced Cm_{pk} , although the direction of the shift in V_{pkCm} was variable. The data are plotted in separate graphs for clarity. Of 21 cells tested, 13 showed a positive shift in V_{pkCm} (*C*), and 8 cells showed a negative shift (*D*). Each symbol indicates a different cell. All treatments were done after V_{pkCm} stabilized.

mechanism similar to that of turgor pressure change, which is believed to act via alterations in membrane stress (Iwasa, 1994; Kakehata and Santos-Sacchi, 1995).

The response time course of extracellularly applied salicylate was examined by using a tracking procedure to follow changes in V_{pkCm} and Cm_{pk} (Kakehata and Santos-Sacchi, 1995). One millimolar salicylate reversibly reduced Cm_{pk} and shifted V_{pkCm} to depolarized levels (Fig. 3*A*). These effects reached steady state in ~ 60 sec in this cell. An increase in the salicylate concentration accelerated the response (Fig. 3*B*). The reduction of Cm_{pk} was well fit with a single exponential. Tau of salicylate-induced reduction in Cm_{pk} was 19.2 ± 3.7 sec (mean \pm SE; $n = 5$) and $11.4 \pm$

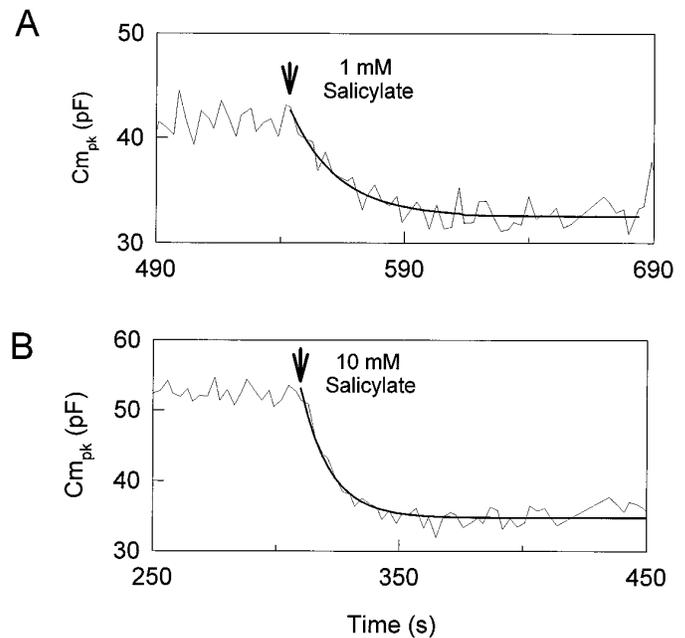

Figure 3. Effects of extracellularly applied salicylate on OHC capacitance. The effective time course of extracellularly applied salicylate was examined by using a tracking procedure. A small-tipped pipette was used to permit any turgor pressure change that salicylate may cause. Salicylate was applied after V_{pkCm} and Cm_{pk} reached steady state. *A*, Effects of 1 mM salicylate. Peak capacitance is shown as a function of time. The reduction of Cm_{pk} is well fit by using a single exponential curve fit. Tau is 19 sec. R_s , 27.1 M Ω ; R_m , 255 M Ω . *B*, Effects of 10 mM salicylate in a different cell. Tau is 12 sec. R_s , 26.6 M Ω ; R_m , 292 M Ω .

2.4 sec ($n = 8$) for 1 and 10 mM salicylate, respectively. With the use of fitted steady-state values, the average reduction of Cm_{pk} and average shift of V_{pkCm} (mean \pm SE) were 6.82 ± 1.48 pF and 4.6 ± 2.2 mV (1 mM; $n = 5$), and 10.63 ± 1.51 pF and 16.7 ± 2.2 mV (10 mM; $n = 7$). Nonlinear capacitance was evaluated more fully by using stair-step stimuli applied at least 120 sec after treatment. With this technique, average Cm_{pk} was 46.86 ± 1.25 ($n = 11$) and 36.75 ± 0.92 pF before and during application of 10 mM salicylate, respectively. The average reduction of Cm_{pk} was 10.11 ± 1.26 pF, which is comparable to the value of 10.63 ± 1.51 pF obtained by the tracking technique.

Concentration–response curves for salicylate and gadolinium

Concentration–response curves for reduction in Cm_{pk} by salicylate were obtained with the V_{pkCm} tracking technique. Salicylate was applied by Y-tube in increasing concentrations, without intermittent washing, until a steady-state response was achieved. Pipette pressure was kept slightly positive (up to approximately +0.07 kPa), to prevent turgor dissipation. Figure 4*A* shows a representative example. The effects of salicylate were just detectable at a concentration of $\sim 300 \mu M$. The reduction increased sigmoidally as the salicylate concentration increased to 10 mM, above which the response was saturated. The half-maximal concentration ($K_{1/2}$) and the Hill coefficient (n) were 1.6 mM and 1.0, respectively. V_{pkCm} shifted to depolarized levels at a concentration of >1 mM.

Concentration–response curves for $GdCl_3$ were obtained in a similar manner. Pipette pressure was kept positive (up to approximately +0.14 kPa) to prevent turgor dissipation. Compared with salicylate, longer perfusion times were required to reach steady-

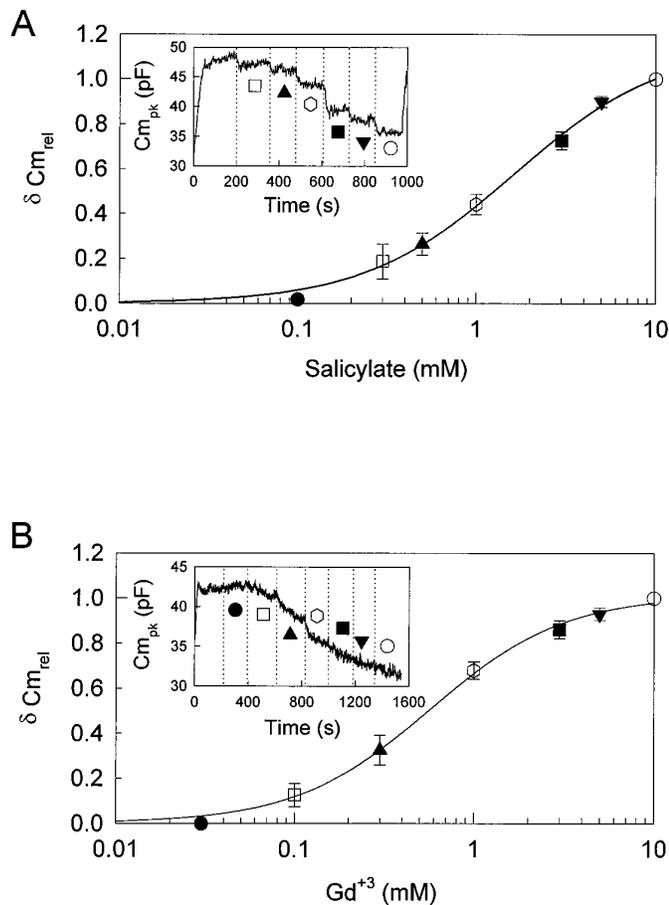

Figure 4. Concentration–response curve for reduction in Cm_{pk} by salicylate and $GdCl_3$. *A*, The concentration–response curve for salicylate. The inset shows the effect on the Cm_{pk} by various concentrations of salicylate in a representative example. R_s , 5.5 M Ω ; R_m , 450 M Ω . Pipette pressure was kept at 0 kPa. Reductions of Cm_{pk} induced by various concentrations were normalized to the reduction induced by 10 mM salicylate. Each point is the mean \pm SE of five cells. *B*, The concentration–response curve for $GdCl_3$. The inset shows the effect on the Cm_{pk} by various concentrations of $GdCl_3$ in a representative example. R_s , 6.5 M Ω ; R_m , 400 M Ω . Pipette pressure was kept at 0.11 kPa. Reductions of Cm_{pk} induced by various concentrations were normalized to the reduction induced by 10 mM $GdCl_3$. Each point is the mean \pm SE of five cells determined at the end of each perfusion.

state levels (Fig. 4*B*). The effects of $GdCl_3$ were detectable at a concentration of 100 μ M. $GdCl_3$ reduced Cm_{pk} in a concentration-dependent manner, and at 10 mM a near-maximal response was obtained. $K_{1/2}$ and n were 0.6 mM and 1.2, respectively. V_{pkCm} shifted to hyperpolarized levels and reached very negative potentials of -67.4 ± 3.9 mV ($n = 5$). Two of the treated cells collapsed during data collection.

Effects of intracellularly applied salicylate

Recent evidence indicates that salicylate is highly permeable through the OHC membrane (Tunstall et al., 1995; Zhi et al., 1996). However, the precise site in which salicylate acts on the OHC motility voltage sensor remains unknown. To investigate possible sites of salicylate effects, we applied salicylate intracellularly through patch pipettes and compared results with those obtained by extracellular application. Large-tipped pipettes were used, with pipette pressure clamped near zero. Tracking of Cm_{pk}

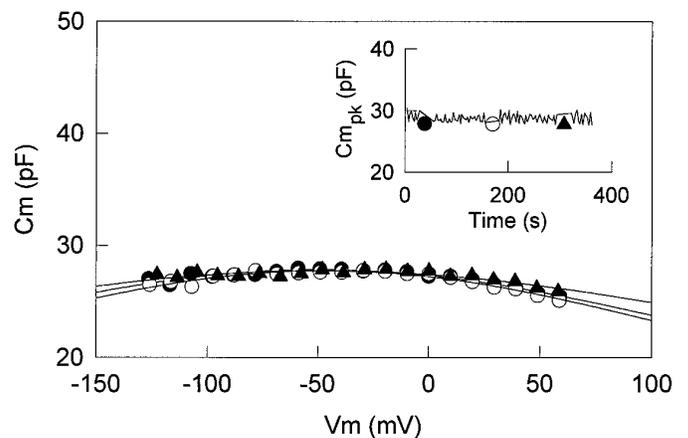

Figure 5. Effects of intracellularly applied salicylate on OHC capacitance. The OHC was dialyzed with a pipette solution containing 10 mM salicylate. The inset shows peak capacitance as a function of time, measured with the tracking procedure (solid line) or stair-step protocol (symbols) at 30, 160, and 300 sec. R_s , 6.01 M Ω ; R_m , 270 M Ω . Capacitance drops to low levels immediately after obtaining whole-cell configuration. This figure is representative of 20 cells tested.

and V_{pkCm} was started immediately after whole-cell configuration was obtained. In addition, stair-step stimuli in a wide voltage range (-150 to $+150$ mV) were applied periodically. Figure 5 shows the immediate effect of intracellularly applied salicylate on voltage-dependent capacitance. In OHCs dialyzed with 5 mM salicylate, stair-step analysis revealed that reduction of Cm_{pk} and the shift of V_{pkCm} were time-dependent (data not shown). In two cells, the exponential time constant of Cm_{pk} reduction was 11.25 and 6.89 sec. With 10 mM salicylate, Cm_{pk} was reduced to a steady level of <30 pF within, at most, 5 sec after whole-cell configuration was obtained (Fig. 5).

Because the effects of intracellularly applied salicylate are so rapid, it is impossible to obtain the initial normal capacitance value of the cell for comparison. Instead, we compared groups of intracellularly untreated and treated (10 mM) cells, the average cell length of which was 56.7 ± 3.1 ($n = 11$) and 58.5 ± 3.4 μ m ($n = 11$), respectively. OHC length correlates well with the membrane capacitance of the cell; thus, valid comparisons can be made between these groups. Average Cm_{pk} was 46.87 ± 1.25 and 28.20 ± 0.67 pF in untreated and treated groups, respectively. In those control OHCs subsequently treated with extracellular 10 mM salicylate, the average Cm_{pk} dropped to 36.75 ± 0.92 pF. This value differs significantly from the value of 28.20 ± 0.67 pF in the OHCs dialyzed with 10 mM salicylate (Student's t test < 0.001). These results indicate that salicylate works more effectively when applied intracellularly.

Voltage-induced OHC movement and voltage-dependent capacitance share many characteristics (Santos-Sacchi, 1991; Ashmore, 1992). OHC voltage-dependent movement as well as voltage-dependent capacitance were reduced in a concentration-dependent manner by intracellular salicylate treatment (Fig. 6). In the absence of salicylate, voltage-induced length changes saturate at positive voltages. The voltage in which saturation initiates depends on OHC turgor pressure, because $V_{\delta Lmax}$ shifts with turgor pressure (Kakehata and Santos-Sacchi, 1995). The maximum mechanical gain of the OHC, however, can remain fairly constant. Thus, to avoid the possible effect of turgor pressure on measures of OHC movement, we compared maximum mechanical

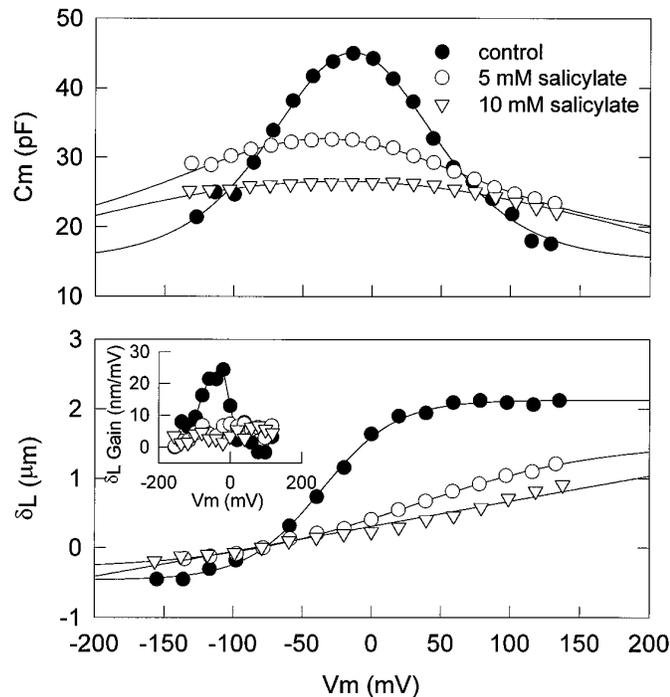

Figure 6. Effects of intracellularly applied salicylate on OHC capacitance and movement. Voltage-dependent capacitance and voltage-induced length change were measured 3–4 min after whole-cell configuration in three different cells. As the concentration of salicylate increased, voltage-dependent capacitance and nonlinearity of voltage-induced length change were reduced correspondingly. Length changes were induced by 20 mV steps from -150 to $+150$ mV at a V_{hold} of -80 mV. R_s , 3.38 M Ω and R_m , 66.5 M Ω (closed circles); R_s , 3.68 M Ω and R_m , 34.7 M Ω (open circles); R_s , 6.57 M Ω and R_m , 240 M Ω (open triangles). Fits (solid lines) for capacitance indicate V_{pkCm} , Q_{max} , and z of -14.3 mV, 4.74 pC, and 0.650 (open circles); -38.2 mV, 5.09 pC, and 0.317 (closed circles); -28.7 mV, 36.54 pC, and 0.111 (open triangles). Fits for the mechanical data indicate V_{hold} and z of -36.4 mV and 0.955 (closed circles), 2.89 mV and 0.376 (open circles), and 6.43 mV and 0.039 (open triangles). The inset shows the first derivative of the mechanical responses, indicating the gain of the mechanical response with different concentrations of salicylate. See text for details.

gain of OHCs in the absence and presence of intracellular salicylate. The average gain was 19.53 ± 1.98 nm/mV ($n = 3$) in the absence of salicylate, which is in line with previous measures (Ashmore, 1987; Santos-Sacchi and Dilger, 1988). In the presence of 10 mM salicylate, voltage-induced length change did not saturate, and the movement function appeared linear within the voltage range of -150 to 150 mV. The average cell-length change obtained by a voltage step from a holding potential of -80 to 150 mV was 1.03 ± 0.06 μm ($n = 7$). The average maximum mechanical gain was 5.17 ± 0.43 nm/mV ($n = 9$), which is about one-fourth of the average gain in the absence of salicylate.

Comparison of effects between salicylate and lanthanide on OHC capacitance and movement

The effect of salicylate on OHC nonlinear capacitance is similar to that of lanthanides, which are known to block voltage-dependent OHC movement and capacitance (Santos-Sacchi, 1991; Kakehata and Santos-Sacchi, 1995). However, significant differences exist between the effects of the two drugs and are revealed via dual-treatment experiments. In OHCs dialyzed with 10 mM salicylate, simultaneous measures of capacitance and voltage-dependent movements were made before and during extracellular applica-

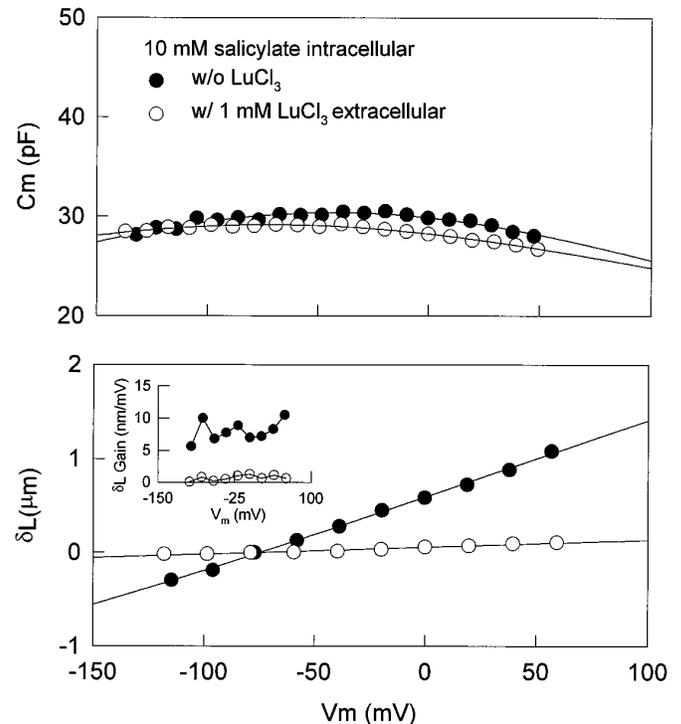

Figure 7. Comparison of effects between salicylate and lanthanide on OHC capacitance and movement. Voltage-dependent capacitance and voltage-induced length change were measured before and during extracellularly applied LuCl_3 (1 mM) in an OHC with intracellularly applied salicylate (10 mM). Length changes were induced by 20 mV steps from -20 to $+60$ mV at a V_{hold} of -80 mV. R_s , 4.75 M Ω and R_m , 89.2 M Ω (closed circles); R_s , 4.39 M Ω and R_m , 261 M Ω (open circles). Fits (solid lines) for capacitance indicate V_{pkCm} , Q_{max} , and z of -42.3 mV, 9.152 pC, and 0.205 (open circles); -71.3 mV, 7.35 pC, and 0.191 (closed circles). Fitting such depressed capacitance functions may not be reliable because of the limited voltage range that can be applied. The mechanical data could not be fit reliably with a two-state Boltzmann. Note that lanthanides, although changing the capacitance function minimally, effectively block mechanical responses. The inset shows mechanical gain of the cell under each condition.

tion of 1 mM LuCl_3 . An example is shown in Figure 7. At 4 min after whole-cell configuration, $C_{\text{m, pk}}$ was 30.4 pF, and z was 0.205 . Extracellularly applied LuCl_3 further reduced $C_{\text{m, pk}}$ and z to a small extent, namely, 29.2 pF and 0.191 , respectively. On the other hand, the effect elicited by LuCl_3 on the cell movement was significant. Voltage-induced movement was blocked almost completely; i.e., maximum mechanical gain was reduced from 8.04 to 0.70 nm/mV.

The effect of intracellularly applied lanthanide also was examined. Because EDTA-like calcium buffers are powerful lanthanide chelators, GdCl_3 (5 mM) was added to patch pipettes that did not include EGTA. Intracellularly applied GdCl_3 neither abolished the voltage-induced movement nor reduced nonlinear capacitance in all cells tested (data not shown; $n = 4$). This result suggests that lanthanides work exclusively from the extracellular side of the OHC membrane.

Effects of salicylate on the limiting value of V_{pkCm}

As OHC intracellular pressure is reduced, V_{pkCm} shifts in the negative direction until it reaches a limiting value that occurs when the cell collapses (Kakehata and Santos-Sacchi, 1995). Figure 8 illustrates the effects of salicylate on this limiting value.

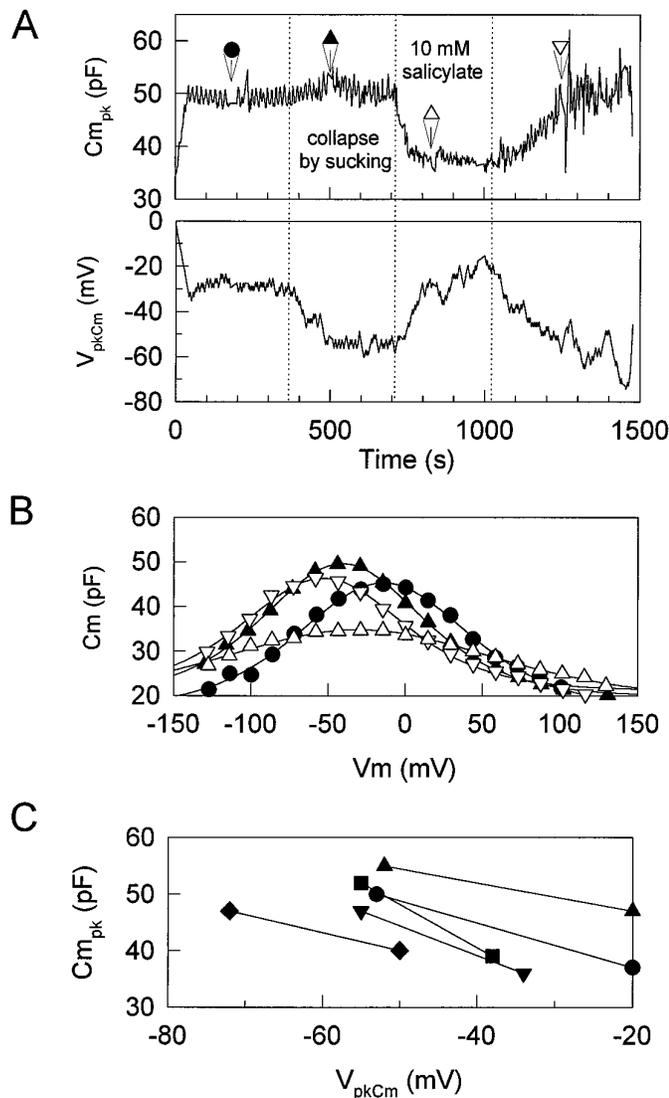

Figure 8. Effects of salicylate on the limited value of V_{pkCm} . Intracellular pressure of the OHC was reduced directly through the patch pipette to collapse the cell. *A*, The cell was maintained in collapse after the point indicated by the first dotted line. As expected, collapsing the cell caused Cm_{pk} to increase and V_{pkCm} to shift to a limiting negative value (Kakehata and Santos-Sacchi, 1995). At the second dotted line, 10 mM salicylate was applied extracellularly. V_{pkCm} shifted in the positive direction with a decrease in Cm_{pk} . Washout at the third dotted line caused recovery. *B*, Capacitance function determined by the stair-step protocol for the same cell. Fits (solid lines) to the capacitance data indicate V_{pkCm} , Q_{max} , and z of -14.3 mV, 4.74 pC, and 0.650 (closed circles, control); -41.0 mV, 4.09 pC, and 0.743 (closed triangles, after collapse); -32.3 mV, 3.86 pC, and 0.418 (open triangles, during application of salicylate); -53.6 mV, 3.54 pC, and 0.728 (closed triangles, after wash). *C*, Data from five cells showing consistent positive shift of V_{pkCm} and decrease in Cm_{pk} in collapsed cells after 10 mM salicylate treatment.

Intracellular pressure was reduced directly through the patch pipette. This treatment increased Cm_{pk} and shifted V_{pkCm} in the negative direction. In this case, V_{pkCm} reached a limiting value of -55 mV when the OHC collapsed. After treatment with 10 mM salicylate extracellularly, the limiting value consistently moved in the positive direction while the OHC remained collapsed ($n = 5$). The effect was reversible. This result further suggests that salicylate does not act via turgor pressure but affects the voltage

dependence of the voltage sensor directly. It also may indicate that the minority of cells in which salicylate shifted V_{pkCm} to negative potentials simultaneously may have experienced inadvertent changes in turgor pressure.

Effects of salicylate on V_{pkCm} and Cm_{pk} of trypsin-treated cells

It has been demonstrated that salicylate alters the structure of the OHC subsurface cisternae (Dieler et al., 1991). To investigate whether normal subsurface cisternae are required for the effects of salicylate on the voltage sensor, we disrupted subsurface cisternal architecture by destroying the cortical cytoskeleton of the cell with intracellular trypsin. This treatment causes the OHC to become spherical and the subsurface cisternae to vesiculate and peel away from the plasmalemma (Huang and Santos-Sacchi, 1994). Neither voltage-sensor gating charge movement nor the sensitivity of the sensor to intracellular pressure change is altered with this treatment (Kakehata and Santos-Sacchi, 1995). Figure 9 illustrates the persisting, reversible effects of salicylate on trypsin-treated OHCs. After the cell became fully spherical at ~ 13 min, 10 mM salicylate was applied extracellularly. Detailed measures of voltage-dependent capacitance also were made by using stair-step stimuli before, during, and after application of salicylate. Salicylate consistently and reversibly reduced voltage-dependent capacitance ($n = 3$), suggesting that salicylate acts directly on the membrane-bound motor/sensor and not via the subsurface cisternae.

DISCUSSION

Previously, we demonstrated that intracellular pressure directly shifts the voltage dependence of membrane capacitance and motility in OHCs (Kakehata and Santos-Sacchi, 1995). Increasing pressure shifts V_{pkCm} and $V_{\delta Lmax}$ to positive potentials while simultaneously suppressing Cm_{pk} ; decreasing pressure has the opposite effects. In addition, even with iso-osmolar intra- and extracellular solutions, V_{pkCm} slowly moves to more hyperpolarized voltages after whole-cell configuration is established. This phenomenon is believed to underlie the variability of V_{pkCm} in isolated OHCs. Thus, in evaluating OHC voltage-dependent movement and membrane capacitance, the effects of intracellular pressure have to be taken into account. In the present study, we used techniques to minimize or control for the effects of intracellular pressure. Under such conditions, it is clear that salicylate and lanthanides exert their effects independent of turgor pressure.

Two other reports have investigated the effects of salicylate on motility or membrane capacitance by the use of whole-cell voltage clamp (Shehata et al., 1991; Tunstall et al., 1995). Neither controlled for pipette-mediated intracellular pressure changes, because large-tipped pipettes were used ($2-5$ M Ω , $1.5-3$ μ m). Reduction of electromotility because of loss of turgidity by extracellularly applied salicylate was reported (Shehata et al., 1991), and disruption of subsurface cisternae was thought to be related to this phenomenon (Dieler et al., 1991). However, our data do not support their conclusions. First, salicylate suppresses Cm_{pk} and shifts V_{pkCm} to depolarized potentials—opposite the effects of decreasing turgor pressure. Second, extracellular salicylate application for up to 300 sec induced an apparent collapse of only one OHC ($n = 11$) in whole-cell configuration with clamped, positive pressure. No unpatched, isolated cells showed any detectable collapse when 10 mM salicylate was applied extracellularly for >10 min, which is in accord with previous findings (Shehata et al., 1991). In addition, only 2 of 11 OHCs tested with internal 10 mM

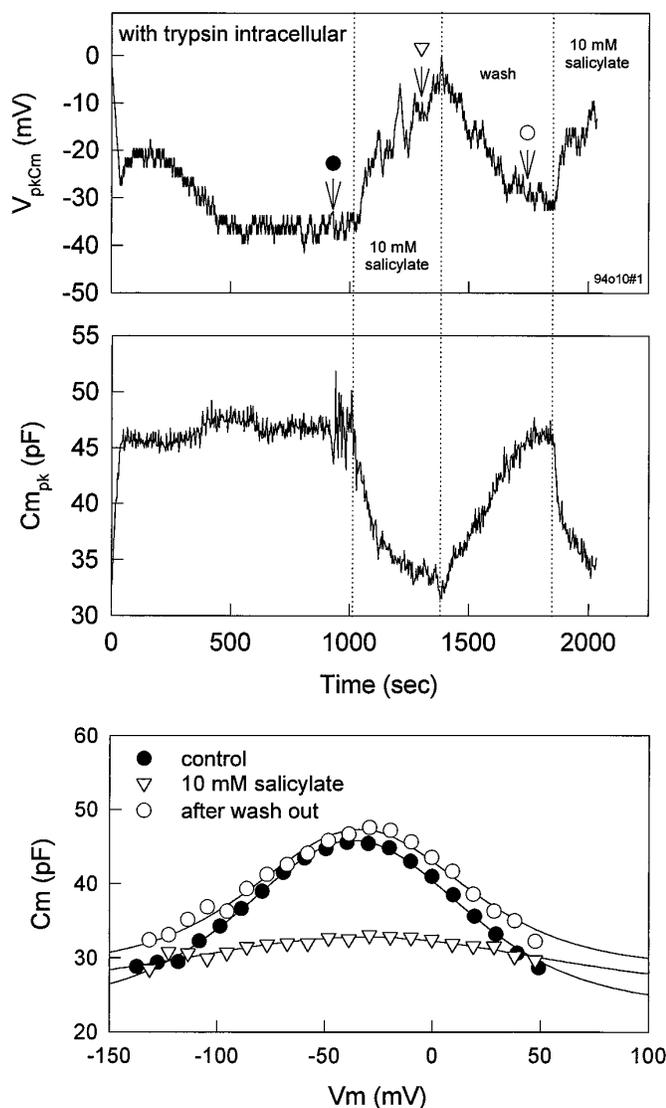

Figure 9. Effects of salicylate on V_{pkCm} and Cm_{pk} of a trypsin-treated cell. Trypsin (300 g/ml) was included in the patch pipette. After the cell became fully spherical at ~13 min, 10 mM salicylate was applied extracellularly. Voltage-dependent capacitance was measured before, during, and after application of salicylate. Salicylate reduced voltage-dependent capacitance reversibly, despite permanent disruption of the subsurface cisternae. Fits (solid lines) for capacitance indicate V_{pkCm} , Q_{max} , and z of -36.6 mV, 3.04 pC, and 0.757 (closed circles); -32.0 mV, 1.69 pC, and 0.450 (open triangles). The fit to open triangles is unreliable because of the shallowness of the function.

salicylate collapsed after 3 min. These time periods are far longer than necessary for the effects we observe on the sensor/motor. Third, in the OHCs treated with trypsin, in which the normal arrangement between membrane and subsurface cisternae is disrupted, effects of salicylate on the membrane voltage sensor remained. Thus, it is likely that the mechanisms of salicylate effects on the membrane sensor/motor and the subsurface cisternae are different and that the action of salicylate on the membrane sensor/motor is faster than that on the subsurface cisternae, which requires >10 min for detectable effects (Dieler et al., 1991).

Tunstall et al. (1995) reported values of the Hill coefficient (n) and half-maximal concentration ($K_{1/2}$) for salicylate of 3.40 and

3.95 mM, respectively. From these data they deduced that the sensor/motor within the OHC membrane is a tetramer, as originally suggested by Kalinec et al. (1992). Our results indicate an n of 1.0 and $K_{1/2}$ of 1.6 mM. These apparent differences can be accounted for. Tunstall et al. obtained their dose-response curve at a fixed voltage of -50 mV, but they did not attempt to keep intracellular pressure constant. Measured capacitance at a fixed voltage may be subject to fluctuation induced by inadvertent turgor pressure change. Nevertheless, one cell was evaluated at four different membrane potentials with similar results, and data collection was rapid, indicating that pressure changes in their cells may not have been significantly influential. More importantly, however, their dose-response curves were obtained with a perfusion technique (monitoring the drug concentration increase near the cell after the start of a continuous flow of 10 mM salicylate), which presented salicylate for too short a period of time at low concentrations to allow Cm levels to reach steady state. As we demonstrated in this paper, tau of salicylate-induced reduction in Cm_{pk} was 19.2 ± 3.7 and 11.4 ± 2.4 sec for 1 and 10 mM salicylate, respectively (see also Fig. 5 in Tunstall et al., 1995; tau of 5 mM salicylate-induced reduction in Cm is ~15 sec). Their Figure 8 indicates that exposure time at each measured concentration below 10 mM was no more than a few seconds, total perfusion time from 0 to 10 mM being 30 sec. Such short application times would make their dose-response curve steeper and $K_{1/2}$ larger than actual and also would account for the nonsymmetrical shape of their data.

In the present experiments, we obtained the concentration-response curve by measuring changes in the maximum capacitance of the cell (Cm_{pk}), and various concentrations of salicylate were applied for at least 120 sec, allowing steady levels to be reached. In addition, we attempted to control for the effects of inadvertent intracellular pressure change. Although the $K_{1/2}$ we observed was 1.6 mM, effects on the sensor/motor were observed in the hundred micromolar range. It has been shown that the perilymphatic salicylate concentration, which induces tinnitus and hearing loss in the rat, is near $400 \mu M$ (Jastreboff et al., 1986). Therefore, the data we obtain *in vitro* are in accord with *in vivo* results. The value of the Hill coefficient for salicylate obtained in this experiment is 1.0, which indicates that there is one binding site per sensor/motor molecule for salicylate. This type of information is not sufficient to speculate on the number of sensor/motor subunits but simply points to a lack of cooperativity.

Our data permit us to speculate on the site and mechanism of salicylate action. Salicylic acid, transported in the undissociated or unionized form, is highly permeable across lipid bilayers (Gutknecht and Tosteson, 1973) and human red cell membranes (Joy and Cutler, 1987). When salicylic acid enters a cell, dissociation to salicylate occurs, with the final concentration of the dissociated form being dependent on intracellular pH (pHi). Because pHi decreases on application of extracellular salicylate under whole-cell recording conditions (Tunstall et al., 1995), the resulting level of intracellular salicylate at equilibrium is less than that of extracellular salicylate. Given the pKa of salicylic acid (3.0), it can be calculated from the Henderson-Hasselbalch equation that $0.6 \mu M$ salicylic acid will exist as the undissociated form at a 10 mM extracellular concentration of salicylate anion. Assuming that extracellularly applied 10 mM salicylate causes pHi to shift from 7.2 to 6.9, then the concentration of salicylate inside the cell would be 5 mM at equilibrium. The actual pHi change would depend on the efficacy of the patch solution buffer. The relatively slow time

course of salicylate action by extracellular perfusion may correspond to the time taken for salicylate to form intracellularly. In fact, Tunstall et al. (1995) showed that pHi changed from 7.2 to 6.9 in 30 sec. This time course should reflect directly the dissociation of H⁺ from salicylic acid. Because they also showed that pHi itself is not the main cause of capacitance decrease, we conclude that the change in capacitance that we note with extracellular salicylate is attributable to the production of the dissociated form. On the other hand, when 10 mM sodium salicylate solution buffered to pH 7.2 is introduced intracellularly, the effect is almost immediate and more pronounced, presumably because the dissociated form is delivered directly and at higher concentrations. It should be emphasized that, for either intracellular or extracellular application, the concentration of salicylic acid would be the same (0.6 μ M). That is, the residence of the uncharged form within the membrane probably does not interfere with the sensor/motor. Thus, our data, which demonstrate that salicylate acts faster and to a greater extent when dialyzed into the OHC, suggest that salicylate works on the sensor/motor in the dissociated, charged form. The ability of the dissociated, charged form of salicylate to interact with the sensor/motor on the inner aspect of the plasma membrane may underlie the voltage dependence shifts that we observe in the capacitance functions. Although salicylate is effective on the intracellular aspect of the lateral plasma membrane, we show that lanthanides function exclusively on the outer aspect. These results are contrary to those reported by Gale and Ashmore (1994a).

The comparison between mechanical movements and charge movements in treated cells indicates that, whereas charge movement is suppressed to nearly the same extent by salicylate and lanthanides, motility is not. Mechanical responses remain substantial after salicylate treatment, but the motility function becomes linear between the range of -150 and $+150$ mV. It should be noted, however, that in both cases residual nonlinear capacitance remains. The difference between mechanical responses obtained with the two treatments may relate to differential changes in the axial stiffness of the cell under each condition. It has been found that extracellularly applied salicylate reversibly reduces axial stiffness of isolated OHCs of guinea pig (Russell et al., 1995), which may be related to the demonstration of a reversible decrease in OHC lateral wall stiffness (Lue et al., 1996). Under such conditions, the residual charge movement may correspond to conformational changes of the motor molecule that are capable of driving an unloaded cell with reduced axial stiffness. Lanthanide treatment, on the other hand, may increase axial stiffness. This may be indicated by the elongation and apparent stiffening of the OHC noted with lanthanide treatments (Santos-Sacchi, 1991; Kakehata and Santos-Sacchi, 1995). Under conditions of increased axial stiffness, the conformation change of the motor, indicated by the residual charge movement, may be unable to effect mechanical responses.

In conclusion, we show that salicylate and lanthanides do not work via mechanisms similar to changes in intracellular turgor pressure. The effects seem to be a result of direct action on the motility sensor/motor: lanthanides working on the external aspect of the lateral membrane and salicylates working on the intracellular aspect. It is interesting to note that simple modifications to the salicylate molecule, which would limit its entry into the OHC, are predicted to eliminate the attendant tinnitus and hearing loss associated with the ingestion of the drug.

Li X, Surguchev A, Bian S, Navaratnam D, Santos-Sacchi J. Extracellular chloride regulation of Kv2.1, contributor to the major outward Kv current in mammalian outer hair cells. *Am J Physiol Cell Physiol* 302: C296–C306, 2012. First published September 21, 2011; doi:10.1152/ajpcell.00177.2011.—Outer hair cells (OHC) function as both receptors and effectors in providing a boost to auditory reception. Amplification is driven by the motor protein prestin, which is under anionic control. Interestingly, we now find that the major, 4-AP-sensitive, outward K⁺ current of the OHC (I_K) is also sensitive to Cl⁻, although, in contrast to prestin, extracellularly. I_K is inhibited by reducing extracellular Cl⁻ levels, with a linear dependence of 0.4%/mM. Other voltage-dependent K⁺ (Kv) channel conductances in supporting cells, such as Hensen and Deiters' cells, are not affected by reduced extracellular Cl⁻. To elucidate the molecular basis of this Cl⁻-sensitive I_K , we looked at potential molecular candidates based on Cl⁻ sensitivity and/or similarities in kinetics. For I_K , we identified three different Ca²⁺-independent components of I_K based on the time constant of inactivation: a fast, transient outward current, a rapidly activating, slowly inactivating current (I_{K1}), and a slowly inactivating current (I_{K2}). Extracellular Cl⁻ differentially affects these components. Because the inactivation time constants of I_{K1} and I_{K2} are similar to those of Kv1.5 and Kv2.1, we transiently transfected these constructs into CHO cells and found that low extracellular Cl⁻ inhibited both channels with linear current reductions of 0.38%/mM and 0.49%/mM, respectively. We also tested heterologously expressed Slick and Slack conductances, two intracellularly Cl⁻-sensitive K⁺ channels, but found no extracellular Cl⁻ sensitivity. The Cl⁻ sensitivity of Kv2.1 and its robust expression within OHCs verified by single-cell RT-PCR indicate that these channels underlie the OHC's extracellular Cl⁻ sensitivity.

voltage-dependent potassium ion channels; chloride; outer hair cells

THE OUTER HAIR CELL (OHC) is both a receptor and an effector, possessing a distinct ensemble of membrane proteins, e.g., prestin (54), the α_9 - and α_{10} -nicotinic ACh receptor subunits (7, 8), and the unidentified transduction channel (5), which underlie these processes.

Concerning the effector role of OHCs, recent studies suggest that prestin activity is highly dependent on intracellular Cl⁻ anions (36, 38, 44, 46). Modulating intracellular Cl⁻ alters the motor's nonlinear charge movement (or nonlinear capacitance), thereby affecting the voltage sensitivity of OHC electromotility. The mechanism whereby anions work on prestin remains controversial; however, much evidence points to an allosteric mechanism (38, 45), similar to the way in which Ca²⁺ modulate the voltage sensitivity of large-conductance Ca²⁺-activated K⁺ (BK) channels (15, 53).

Address for reprint requests and other correspondence: J. Santos-Sacchi, Otolaryngology, Neurobiology, and Cellular and Molecular Physiology, Yale Univ. School of Medicine, BML 224, 333 Cedar St., New Haven, CT 06511 (e-mail: joseph.santos-sacchi@yale.edu).

Concerning the sensory role of the OHC, receptor potentials that drive neurotransmitter release and electromotility are subject to the shaping effects of the cell's basolateral voltage-dependent membrane conductances (17). The dominant conductances of the adult OHC are K⁺ conductances, with two types having been distinguished based on voltage dependence and pharmacological properties: a K⁺ current in OHC activated at negative potential ($I_{K,n}$) and the outward K⁺ current of the OHC (I_K) (16, 27, 42). $I_{K,n}$ is half-activated at -92 mV and likely helps to set the resting membrane potential of the OHC. I_K activates more positive to -40 mV. Because this voltage is depolarized sufficiently from the normal in vivo resting potential [approximately -70 mV (6)], it might be expected that only large suprathreshold receptor potentials could activate I_K to shape the cell's response (12).

Although the effects of Cl⁻ on prestin result from intracellular interactions with the protein, we have shown that extracellular Cl⁻ can modulate the motor via flux through a tension- and voltage-dependent Cl⁻ conductance, termed G_{metL} (38, 46). Indeed, manipulation of extracellular perilymphatic Cl⁻ was shown to reversibly and profoundly alter cochlear amplification in vivo (44).

In our quest to study the permeation characteristics of G_{metL} , we found that extracellular Cl⁻ has an unusual effect on I_K in OHCs. Reduction of extracellular Cl⁻ reduces the outward current in a concentration-dependent manner. We find that this effect is due, in part, to a selective action on the inactivation kinetics of the voltage-dependent K⁺ (Kv) conductance of the OHC alone, with Kv conductances of other inner ear cells being unaffected. The growing impact of anions in the auditory periphery is remarkable.

METHODS

Tissue preparation for electrophysiology. The experiments were performed in accordance with an approved protocol from Yale University's animal use and care committee. Hartley albino guinea pigs (150–200 g) were anesthetized with halothane, and temporal bones were excised rapidly. The top two turns of the organ of Corti were dissected and incubated for 10–12 min with neutral protease (0.5 mg/ml; Worthington) in a nominally Ca²⁺-free solution containing (in mM): 140 NaCl and 5 KCl. Subsequently, the tissue was triturated with a glass pipette for ~1 min with the above solution plus 2 mM Ca²⁺. Drops of the cell suspension were transferred into a small recording chamber mounted on the stage of a Nikon inverted microscope, and cells (OHCs, Hensen cells, and Deiters' cells) were allowed to settle onto the chamber bottom.

Electrophysiological recording. Patch-clamp experiments were performed in the whole cell configuration using pipettes pulled from borosilicate glass capillaries. The pipette resistance ranged between 1.5 and 3 M Ω and was <5–10 M Ω after whole cell establishment. Clamp tau values were <100–200 μ s, orders of magnitude less than measured current tau values. Pipette solution contained (in mM): 150

KCl, 2 MgCl₂, 5 EGTA, and 5 HEPES. The absence of Ca²⁺ intracellularly removes the influence of BK and small-conductance Ca²⁺-activated K⁺ (SK) channel conductances. We did not add ATP or other metabolites to the pipette solution so that currents dependent on these metabolites would be eliminated from our evaluations of Cl⁻ effects. The bath solution contained (in mM): 145 NaCl, 5 KCl, 1 MgCl₂, 2 CaCl₂, and 5 HEPES. The use of intra- and extracellular HEPES obviates the potential effect of pH alterations during changes in Cl⁻. Bath and pipette solutions were adjusted to ~300 mosmol/kg with dextrose and to pH 7.3. The liquid junction potential was around 1–3 mV with 3 M KCl salt bridges. Whole cell currents were recorded at room temperature using an Axon 200B amplifier (Axon Instruments), Digidata 1321 board (Axon Instruments), and the software program jClamp (Sciosoft).

Concentration-response curves were obtained by substituting gluconate for Cl⁻. Extracellular Cl⁻ concentrations of 5, 30, 70, 100, 125, and 150 mM were tested. Responses were plotted relative to the 150 mM Cl⁻ condition. Currents were averaged from the final 100 ms of a 200-ms test step to +50 mV from a holding potential of -40 mV. Attempts were made to fit the response function to the Hill equation, but fits were inadequate. Instead, data were fit to a linear equation to obtain slopes.

Isolation of individual OHCs for RT-PCR. Guinea pig temporal bones were dissected in PBS. Turns two to four of the cochleae were mechanically triturated separately in PBS and suspended in petri dishes to allow cells to settle. Silanized pipettes (trimethyl-chlorosilan; Fluka, St. Louis, MO) with a pore diameter of ~30 μm were used to pick up individual OHCs. Following capture of individual OHCs, the contents of the pipettes were expelled into Eppendorf tubes and stored at -80°C.

Single cell nested PCR from OHC. cDNAs from each isolated cell were synthesized as previously described (30). Nested PCR was performed in two steps. First, 35 cycles of PCR were run (94°C for 30 s, 55°C for 1 min, 68°C for 3 min) using 5 μl of each cDNA and corresponding Kv outer primers. Second, 5 μl of each reaction from the first step were used for another 35 cycles of amplification using Kv inner primers. Both steps used the Expand High Fidelity PCR System (Roche, Indianapolis, IN). Fragments were analyzed on 2% agarose resolute GPG gel (American Bioanalytical, Natick, MA). To confirm the presence of a correct Kv channel, the PCR products were purified from the gel using a gel purification kit (Qiagen, Valencia, CA) and sequenced using the corresponding amplification primers by Yale's Keck sequencing facility. The primers were designed to straddle an intron of at least 1,000 bp. The primers were as follows: Kv1.5 outer, Kv1.5FOT GACACTAGC-

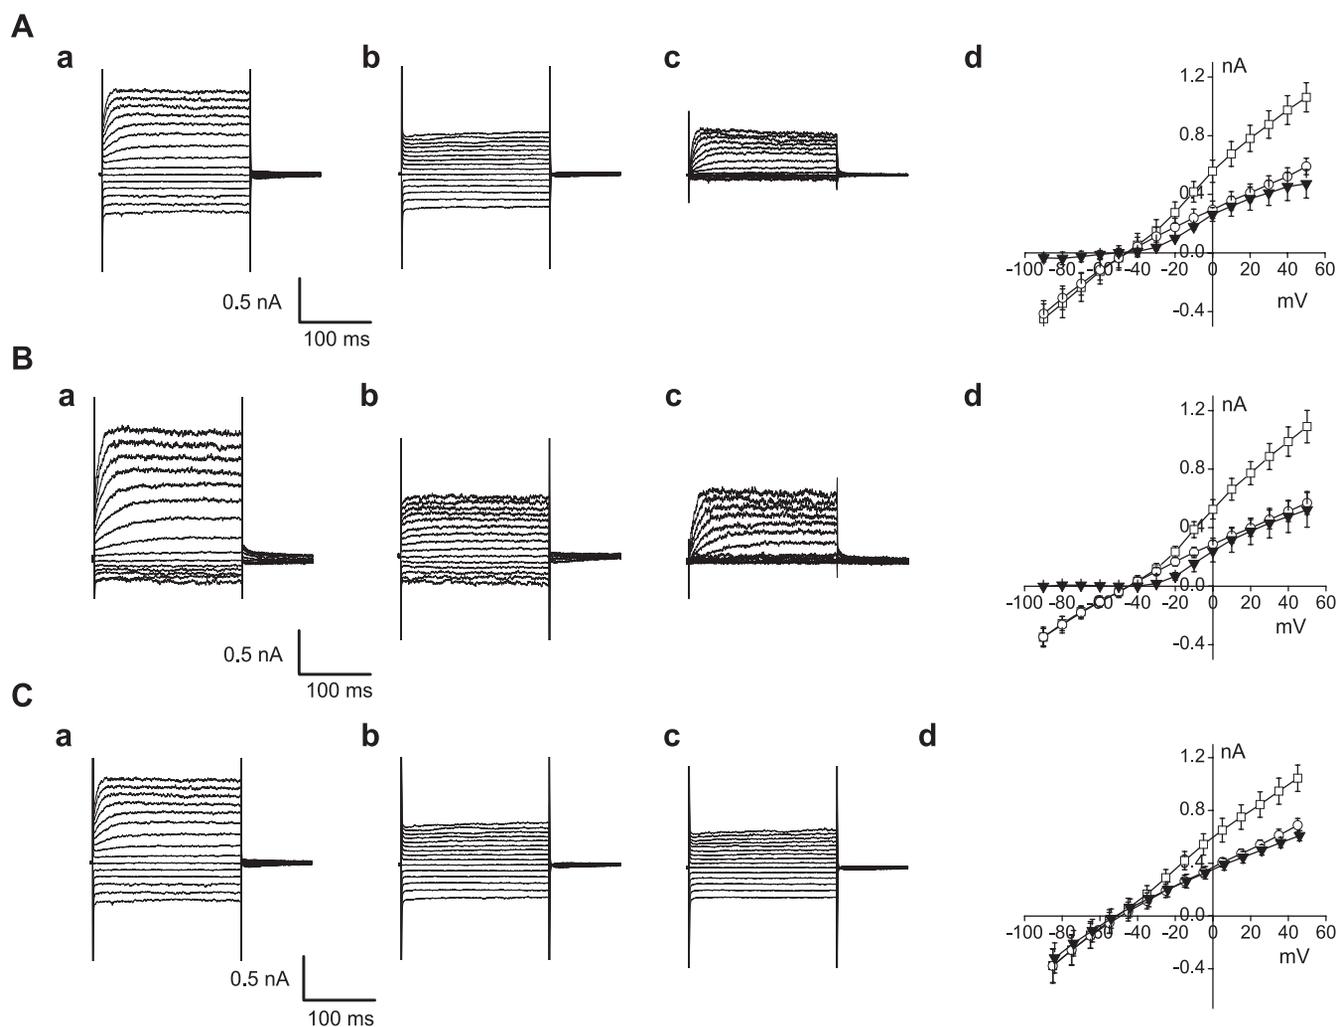

Fig. 1. Inhibition of outward K⁺ current of the outer hair cells (I_K) by 4-AP and low extracellular Cl⁻. Membrane current was recorded with 200-ms pulses to potentials between -90 and 50 mV from a holding potential of -40 mV. The waveforms of the 4-AP- and Cl⁻-sensitive currents were determined by subtraction of control currents. *A*: *a*, control; *b*, 100 μM 4-AP; *c*, 100 μM 4-AP-sensitive current; *d*, current-voltage relationship of I_K for control (□), 100 μM 4-AP (○), and 100 μM 4-AP-sensitive current (▼) ($n = 3$). *B*: *a*, control; *b*, 5 mM Cl⁻; *c*, 5 mM Cl⁻-sensitive current; *d*, current-voltage relationship of I_K for control (□), 5 mM Cl⁻ (○) and 5 mM Cl⁻-sensitive current (▼) ($n = 5$). *C*: *a*, control; *b*, 100 μM 4-AP; *c*, 100 μM 4-AP + 5 mM Cl⁻; *d*, current-voltage relationship of I_K for control (□), 100 μM 4-AP (◇), and 100 μM 4-AP + 5 mM Cl⁻ (▼) ($n = 3$).

CGGGAAACAGA and Kv1.5ROT GGTGACCCTGGTGTATGG; Kv1.5 inner, Kv1.5FIN TCAAGGCAGACTTGCAACAG and Kv1.5RIN GAAGTTAGAGGGCAGGAGGG; Kv2.1, Kv2.1FOT CAAAAGAAGGAGCAGATGAACGAG and Kv2.1ROT TTGAGTGACAGGGCAATGGTG; Kv4.2 outer, Kv4.2FOT: GCCTTCGTAGCAAATCTGG and Kv4.2ROT ACACATTGGCATTGGGATT; Kv4.2 inner, Kv4.2FIN TCACTGCCTGGAGAAAACC and Kv4.2RIN AGCAAGTGCTGGTGACTCCT; Kv4.3 outer, Kv4.3FOT GGCTACACCCTGAAGAGCTG and Kv4.3ROT AGTTGGTGACTATGACGGGG; and Kv4.3 inner, Kv4.3FIN CATGGCCATCATCTTTG and Kv4.3RIN GCCAAATATCTTCCAGCAA.

To investigate whether the pore residue 356 in Kv2.1 has an effect on extracellular Cl^- sensitivity (see RESULTS and DISCUSSION), K356G mutants were generated using QuickChange II or QuickChange Lightning site-directed mutagenesis kits (Stratagene, La Jolla, CA) with rat Kv2.1 as a template. Mutations were confirmed by DNA sequencing, including the entire coding region. The following primers were used: Kv2.1K356GF: GATGAGGACGACACCGGGTTCAAAGCATCCCC and Kv2.1K356GR GGGGATGCTTTGAACCCGGTGTCGCTCATC.

Analysis and statistics. For current-voltage (I - V) analysis, peak currents at each test potential were measured as the difference between the maximal outward current amplitudes and the zero current level. The waveforms of the 4-AP and Cl^- -sensitive currents were determined by subtraction of control currents (recorded in the absence of 4-AP and the presence of 150 mM Cl^-). The decay phases of the currents evoked during long (5.0 s) depolarizing voltage steps to test potentials from a holding potential of -80 mV were fitted by a single or the sum of two exponentials using one of the following expressions:

$$f(t) = A_1 \exp(-t/\tau_1) + A_{ss}$$

$$f(t) = A_1 \exp(-t/\tau_1) + A_2 \exp(-t/\tau_2) + A_{ss} \quad (1)$$

where t is time, τ_1 and τ_2 are the time constants of decay of the inactivating I_K currents, A_1 and A_2 are the amplitudes of the inactivating current components, and A_{ss} is the amplitude of the steady-state, noninactivating component of the total outward current. In the manuscript, control currents refer to those obtained in the presence of 150 mM extracellular Cl^- .

For the steady-state inactivation curve, the current amplitude during each test pulse was normalized to maximal current (I/I_{\max}) and plotted against the voltage during the conditioning prepulse. These data were fitted by a Boltzmann equation:

$$I/I_{\max} = 1/[1 + \exp(V_{1/2} - V_m)/k] \quad (2)$$

where $V_{1/2}$ is the conditioning potential that gives $I/I_{\max} = 0.5$, V_m is the conditioning potential, and k describes the steepness of the curve.

Data are reported as means \pm SE. Statistical significance was calculated using Student's t -test. All experiments were carried out at room temperature (22°C).

RESULTS

I_K in OHCs is sensitive to 4-AP and extracellular Cl^- . Outward currents were recorded routinely during depolarizing voltage steps to potentials more positive than the holding potential of -40 mV (Fig. 1). At this holding potential, $I_{K,n}$ is not further activated upon depolarization (16), thus allowing study of I_K in isolation following linear current subtractions (see DISCUSSION for details). These outward currents (I_K) did not decay appreciably during the 200-ms voltage steps, as previously observed (16, 27, 42). 4-AP ($100 \mu\text{M}$) strongly inhibits outward I_K in OHCs (Fig. 1A). Surprisingly, however, extracellular Cl^- can also modulate I_K of OHCs. Switching from a high- Cl^- solution to a 5 mM Cl^- solution strongly inhibits the

outward current (Fig. 1B). The effect was reversible ($68.5 \pm 16.7\%$ reversibility, $n = 3$). Comparison of the $100 \mu\text{M}$ 4-AP and Cl^- -sensitive currents indicates that they are similar in two ways: each has similar waveform and reversal potential (-70 mV). An initial perfusion of $100 \mu\text{M}$ 4-AP can abolish the subsequent effects of 5 mM Cl^- on I_K (Fig. 1C). These results suggest that Cl^- reduction inhibited the same I_K current that was specifically blocked by 4-AP. The average ($n = 6$) dose-response curve for extracellular Cl^- on I_K was not well fit by a sigmoidal Hill equation. Instead, the K^+ current appeared linear with Cl^- concentration, with a dependence of $0.4\%/m\text{M}$ (Fig. 2). This type of behavior may be related to actions on surface charges at the pore of channels (20) and is further explored below. Changes in intracellular Cl^- were ineffective (data not shown).

I_K of supporting cells is not sensitive to extracellular Cl^- . Prominent depolarization-activated outward K^+ currents (I_K) are recorded from supporting cells, such as Deiters' and Hensen cells (31, 40, 41, 47). We tested to determine whether these currents were also Cl^- sensitive. Figure 3A shows the macroscopic current from a Deiters' cell. Similar to the OHC, there is a rapid activation and slow inactivation elicited by depolarized potentials. For control Cl^- conditions, the peak amplitude was 2.47 ± 0.35 nA at $+50$ mV, and it was 2.33 ± 0.32 nA when extracellular Cl^- was reduced to 5 mM ($n = 3$, $P > 0.05$). The average I - V curve indicates no significant difference between the two conditions. A similar outward current was elicited from Hensen cells (Fig. 3B). The peak amplitude of the control was 1.41 ± 0.28 nA at $+50$ mV, and it was 1.32 ± 0.25 nA with 5 mM Cl^- ($n = 4$, $P > 0.05$). Again, the average I - V curve indicates no differences. We conclude that the I_K current of supporting cells is not sensitive to extracellular Cl^- changes.

Slick and slack channels are not sensitive to extracellular Cl^- . The molecular identity of outward I_K in the OHC is not clear. It is known that the sodium-activated K^+ channels Slick (Slo2.1) and Slack (Slo2.2), which are prominent in brain stem auditory pathways, are sensitive to intracellular Cl^- , but it is not known whether those channels are also sensitive to extracellular Cl^- (2) (Kaczmarek, personal communication). Whole

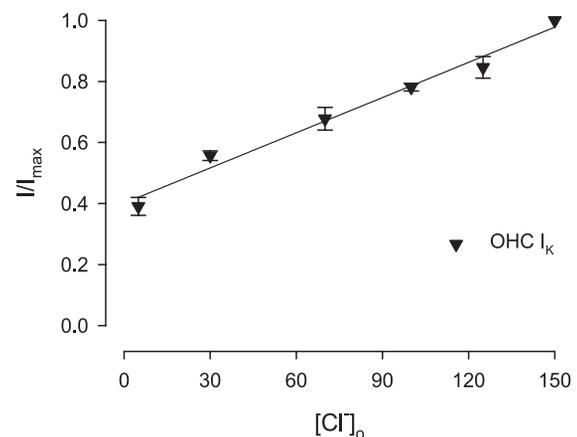

Fig. 2. Concentration-response curve of external Cl^- on magnitude of I_K . Functions were obtained by substituting gluconate for Cl^- . A linear fit (solid line) indicates an I_K change of $0.4\%/m\text{M}$ Cl^- . I/I_{\max} , the current amplitude during each test pulse normalized to maximal current; $[\text{Cl}^-]_o$, extracellular Cl^- concentration; OHC, outer hair cells.

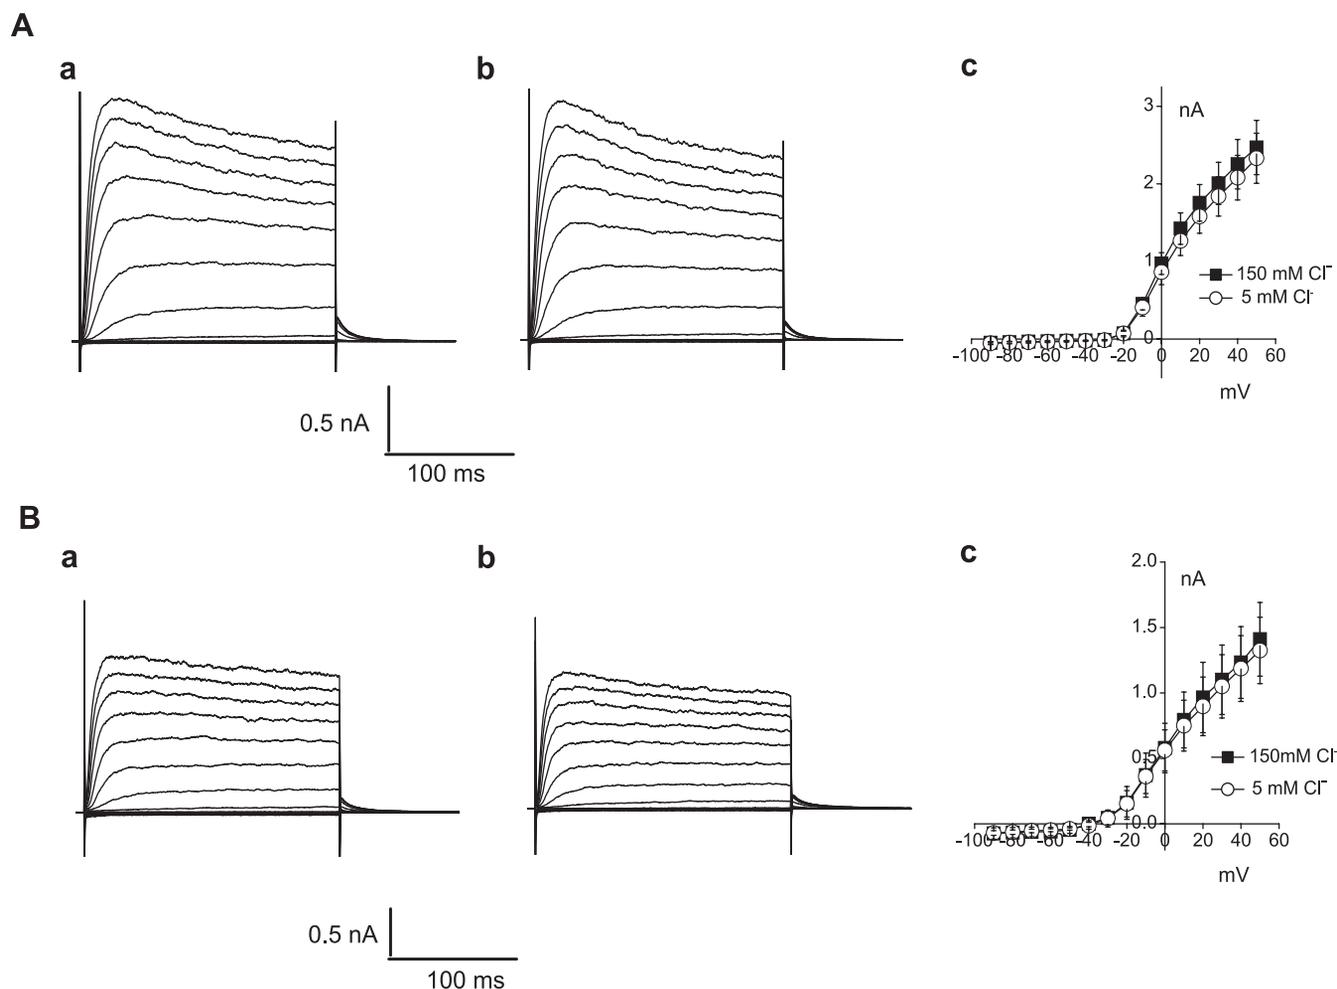

Fig. 3. Deiters' and Hensen cell K^+ currents are insensitive to extracellular Cl^- . Current traces obtained with 500-ms steps from -90 to 50 mV from a -40 -mV holding potential. *A*: *a*, 150 mM Cl^- control current of Deiters' cell; *b*, 5 mM Cl^- ; *c*, current-voltage relationship of I_K of Deiters' cell for control (\blacksquare) and 5 mM Cl^- (\circ). *B*: *a*, 150 mM Cl^- control current of Hensen cell; *b*, 5 mM Cl^- ; *c*, current-voltage relationship of I_K in Hensen cell for control (\blacksquare) and 5 mM Cl^- (\circ).

cell recording of transfected cells was employed to examine the sensitivity of Slick and Slack currents to extracellular Cl^- . Figure 4A shows Slack whole cell currents. The last 50-ms average current amplitude was 2.72 ± 0.79 nA at $+50$ mV (Fig. 4Aa). Upon changing extracellular Cl^- from 150 to 5 mM, the current amplitude was 2.76 ± 0.93 nA and was not different from control ($n = 4$, $P > 0.05$, Fig. 4Ab). The last 50-ms average current amplitude of Slick was 1.14 ± 0.11 nA at $+50$ mV (Fig. 4Ba). Upon changing extracellular Cl^- from 150 to 5 mM, the current amplitude was 1.17 ± 0.09 nA and was not different from control ($n = 4$, $P > 0.05$, Fig. 4Bb). These results show that Slick and Slack channels are not sensitive to extracellular Cl^- , indicating that they do not underlie OHC I_K .

Three components in outward I_K . Outward K^+ currents in other tissues have been characterized in terms of kinetic components (52). To further study the mechanism of inhibition by Cl^- on I_K of the OHC, we performed a similar analysis. Currents were elicited by a 5-s depolarizing step to a potential of $+40$ mV from a holding potential of -80 mV. Outward K^+ currents in all cells activated rapidly, and the decay phases of the currents were somewhat variable among cells (Table 1 and

Fig. 5). One group of cells exhibited only a single exponential decay phase, termed I_{to} (Fig. 5A). We used a dual exponential fit (see METHODS) for two additional populations of cells that each possessed the very fast component (I_{to}) and one of two additional slower second components, termed I_{K1} and I_{K2} (Fig. 5, B and C). Thus exponential fits revealed three inactivating components with decay time constants of 78.4 ± 6.3 ms ($n = 5$), 685.4 ± 61.3 ms ($n = 10$), and $1,504.4 \pm 104.6$ ms ($n = 10$), corresponding to I_{to} , I_{K1} , and I_{K2} , respectively. Of the cells studied, 14.3% had I_{to} alone, 48.6% had I_{to} and I_{K1} , and 37.1% had I_{to} and I_{K2} . The variance in the second term fits of each population was quite small and validates our initial separation into two second component populations. Figure 5D plots the relative distribution of the different current components, and Table 1 summarizes the data. Subsequent experiments were focused on characterizing the Cl^- sensitivity of these depolarization-activated K^+ current components.

Cl^- affects components of I_K in different ways. The voltage dependence of steady-state inactivation of I_{to} was examined using depolarizing voltage steps to $+40$ mV following 5-s conditioning prepulses to potentials between -100 and 0 mV (Fig. 6); the protocol is shown below the current records in Fig. 6C. Such

robust inactivation of the outward I_K in OHCs has never been observed before, simply because such long-duration protocols have never been used. The amplitudes of I_{to} during each test pulse to +40 mV were measured as the difference between peak outward current and the current remaining at the end of

Table 1. Three distinct outward potassium currents in guinea pig outer hair cells

	I_{to}	I_{K1}	I_{K2}	I_{ss}
I_{to} ($n = 5$)				
τ_{decay} , ms	64.8 ± 12.7			
I_{peak} , %	49.3 ± 7.0			50.7 ± 7.0
$I_{to} + I_{K1}$ ($n = 10$)

I_{to} , transient outward K^+ currents; I_{K1} , K^+ currents of slow component 1; I_{K2} , K^+ currents of slow component 2; I_{ss} , steady-state currents. Currents were determined from analyses of records obtained on depolarization to +40 mV from a holding potential of -70 mV.

the depolarizing pulse [steady-state current (I_{ss})]. The amplitudes of I_{to} evoked from each conditioning potential were then normalized to maximal current amplitudes (in the same cell). For example, in the control condition (Fig. 6A), the amplitude of the peak current at the conditioning potential of -40 mV was 0.219 nA. When extracellular Cl^- was changed from 150 to 5 mM, the amplitude was reduced to 0.059 nA (Fig. 6B). The mean ± SE normalized I_{to} amplitudes are plotted as a function of conditioning potential in Fig. 6D; the continuous lines represent the best Boltzmann fits to the averaged data. The steady-state inactivation data for I_{to} in 150 mM Cl^- are well described by a single Boltzmann with a $V_{1/2}$ of -50 mV. Reducing extracellular Cl^- caused the inactivation curve of I_{to} to shift to the left (Fig. 6D), with 5 mM Cl^- producing an 8-mV hyperpolarizing shift.

Because we have no specific blockers for the identified kinetic components of I_{K1} , an analysis of the two additional components was performed by fitting two exponential functions to determine the amplitude and inactivation time constant of each component, I_{K1} and I_{K2} . The effects of Cl^- were analyzed with the simplified voltage protocol depicted in Figs. 7 and 8. In Figs. 7A and 8A, depolarization-induced outward currents are depicted

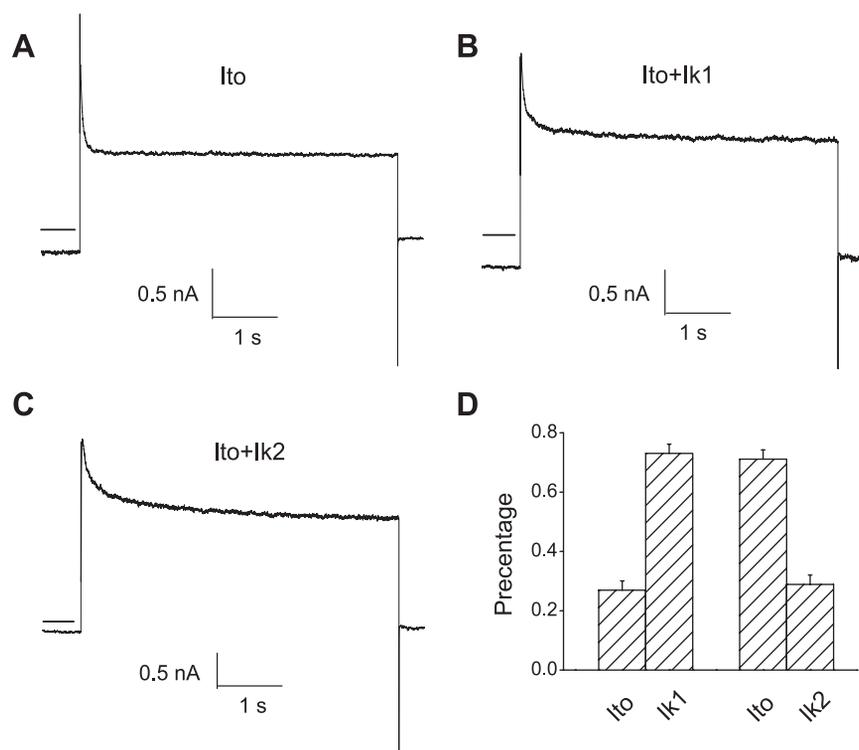

Fig. 5. Three kinetic components of outer hair cell (OHC) outward I_K are identified. Cells were held at -80 mV and stepped up to $+40$ mV for 5 s. *A*: only fast component, transient outward K^+ current (I_{to}). *B*: $I_{to} + I_{k1}$ (K^+ current of slow component 1) components. *C*: $I_{to} + I_{k2}$ (K^+ current of slow component 2) components. *D*: the ratio of different components of I_K . before (traces on top) and after (traces on bottom) switching to 5 mM Cl^- . The bar plots in Figs. 7 and 8 show that, while the time constant of I_{to} remained unaffected, the magnitudes of all components decreased, and the inactivation time constants of I_{k1} and I_{k2} shortened. The inhibitory effect of Cl^- was time dependent on the scale of minutes. From these analyses, we conclude that lowering extracellular Cl^- inhibited I_K in OHCs by shifting the inactivation curve to the left and/or reducing the current amplitude.

Extracellular Cl^- inhibits Kv1.5 and Kv2.1 in CHO cells. The inactivation time constants of I_{k1} and I_{k2} are similar to those of the cardiac current in atrial myocytes that activates ultrarapidly but with no inactivation (I_{kur}) and the delayed-rectifier K^+ current in myocytes that slowly activates and deactivates, with a single channel conductance of 3–5 pS ($I_{k,slow}$), respectively (33, 34, 52). Kv1.5 and Kv2.1 contribute to I_{kur} and $I_{k,slow}$. To determine whether these subtypes contribute to OHC I_K , we transiently transfected Kv1.5 and Kv2.1

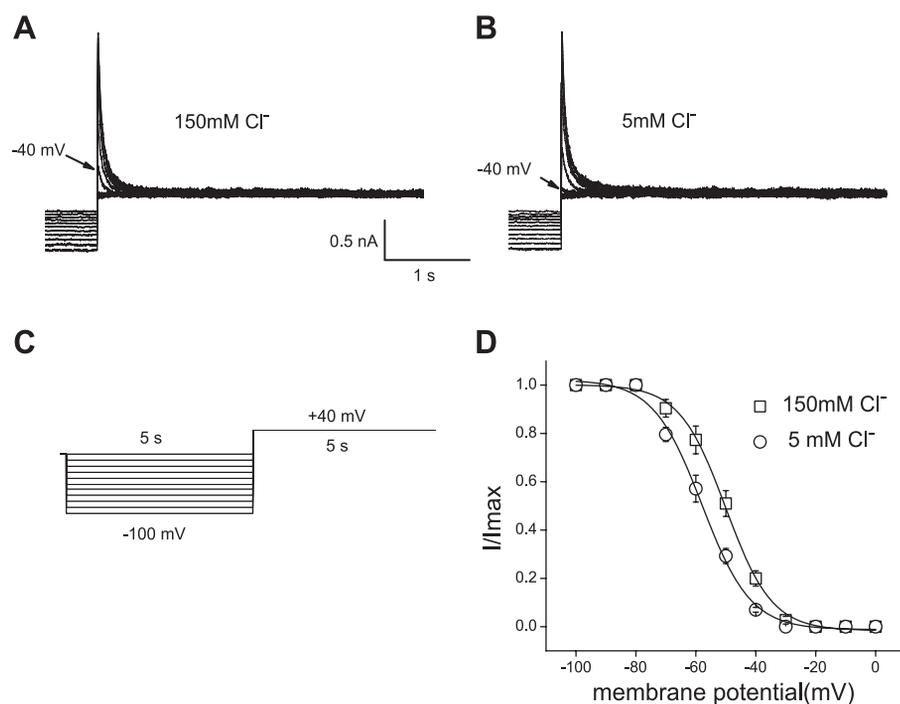

Fig. 6. Inhibition of I_{to} by external Cl^- . *A* and *B*: measurement of voltage dependence of inactivation. into CHO cells and tested the Cl^- sensitivity of the channels. Control macroscopic current of Kv1.5 is depicted in Fig. 9A, where peak amplitude at +50 mV is 3.65 ± 0.13 nA ($n = 4$). A switch to 5 mM extracellular Cl^- reduced the current amplitude to 2.00 ± 0.11 nA (Fig. 9B). Similar results were found with Kv2.1. In the control condition (Fig. 9C), the current amplitude is 8.52 ± 1.87 nA, and it is reduced to 6.15 ± 1.35 nA following the switch to 5 mM extracellular Cl^- ($n = 3$, Fig. 9D). Similar to OHC I_K , the dependence of Kv1.5 and Kv2.1 currents on extracellular Cl^- was not fit well by a sigmoidal Hill equation. Linear regression fits gave 0.38%/mM ($n = 6$) and 0.49%/mM ($n = 5$), respectively (Fig. 9E), similar to results in OHCs.

Kv2.1 and Kv1.5 as well as Kv4.2 and Kv4.3 are expressed in guinea pig OHCs. We sought to determine whether these Kv channels that have properties of the Cl^- -sensitive channel(s) in

the OHC are actually present in OHCs. We opted to use a single-cell RT-PCR strategy using primers that spanned introns to ascertain the presence of transcripts encoding Kv1.5 and Kv2.1 channels in the OHC. For comparison, we also tested for Kv4.2 and Kv4.3 transcripts. OHCs were isolated from different turns of the cochlea, and cDNA was made from these individual cells. Single-cell PCR amplifications were done, and the PCR products of the expected size were isolated and sequenced to confirm their identity. As shown in Fig. 10, Kv 2.1 was present in all nine OHCs and was detected after one round of amplification. In contrast, Kv1.5, Kv4.2, and Kv4.3 required two rounds of nested PCR amplification to be detected. Taken together, these data indicate that these channels are present in OHCs, with Kv2.1 predominating, and likely are responsible for its sensitivity to extracellular Cl^- .

Because the Cl^- dependence of these channels is linear, and such behavior may arise from charge screening effects at the mouth of channels (20), we investigated the mutation of residue K356G at the mouth of the Kv2.1 channel. This mutation has been shown to alter channel conductance by interfering with a K^+ -selective interaction with that site (4). We speculated that Cl^- might be modulating this interaction. However, no statistical difference was observed in the ability of low Cl^- to reduce K^+ currents [I_K 5/150 mM Cl^- : 0.521 ± 0.089 for WT ($n = 8$); 0.387 ± 0.059 for K356G ($n = 12$); $P > 0.05$].

DISCUSSION

There are two major voltage-dependent K^+ currents in OHC, $I_{K,n}$ and I_K , whose pharmacological sensitivities have been well studied (16, 27, 42). Both conductances are largely restricted to the basal pole of the OHC (43). Despite this wealth of knowledge, much remains to be learned about these channels; for example, we have recently shown that capsaicin can block OHC outward I_K and $I_{K,n}$ (51). The molecular entity underlying $I_{K,n}$ is believed to comprise KCNQ4 subunits (3, 14, 28). On the other hand, the molecular identity of I_K has not been suggested previously. In the present work, we identify I_K as a current sensitive to extracellular Cl^- and utilize this sensitivity and its kinetics to hone in on its molecular identity.

Sensitivity of OHC I_K to extracellular Cl^- and its significance. We found that OHC I_K , but neither I_K of Deiters nor Hensen cells, is decreased by reduction of extracellular Cl^- with a sensitivity of 0.4%/mM, indicating a significant sensitivity to Cl^- change over a wide range of extracellular levels. It is not known whether physiological fluctuations of Cl^- occur that could significantly modulate I_K . However, it may be possible that the restricted extracellular space between the Deiters cell and OHC base, where OHC voltage-dependent conductances reside (43), could support functionally significant fluctuations in ion concentrations, in the face of small transmembrane ion fluxes. Such a scenario is well established for intracellular compartmentalization (35).

To estimate the Cl^- concentration change made by a small flux of Cl^- ions at the base of the OHC, we assessed the volume within which Cl^- concentration may change from published electron microscopy descriptions (9, 22, 29, 39). As an example, we evaluate a typical mature OHC in the apical region, which has a diameter of ~ 7 μm . The distance from just above the nucleus to the bottom round end of the OHC, where

Fig. 8. most of the Kv channels concentrate (43), is $\sim 13 \mu\text{m}$. This region resides in the cup formed by the Deiters' cell. An average of 15 afferent nerve terminals and 8 efferent terminals form close contact with the OHC (and with each other) through specialized synaptic structures, with a rather uniform gap of $0.04 \mu\text{m}$. This gap is similar to the reported intercellular space between the type I hair cell and its calyx ending in the vestibular system (10, 11). We assume a cylindrical OHC with hemispherical base and a Deiters' cell cup shaped like an inverted cone, whose height is $8.5 \mu\text{m}$ and base diameter the same as the OHCs. Next, the minimal volume in which the Kv channels can "see" a Cl^- fluctuation is the above-mentioned gap region, which is $\sim 11 \mu\text{m}^3$. If we assume the Kv channels have access to the whole cup region (no nerve ending present), then that volume is $\sim 27 \mu\text{m}^3$. Next, we estimate the Cl^- flux. One typical Cl^- channel with 25 pS conductance releases $\sim 10^6 \text{Cl}^-$ ions per second around resting potential (−60 mV). That translates into a 1.5 mM Cl^- concentration change in the minimal volume and 0.6 mM Cl^- concentration change in the maximal volume. If there are 10 Cl^- channels open simultaneously for 1 s, Kv channels will see anywhere between 6 and 15 mM Cl^- concentration change, which translates to 2.4–6% change in K^+ current magnitude. Specific ion accumulation in a very restricted space has been proposed to influence synaptic transmission, as reported recently in a very detailed work by Lim and colleagues (23) in their study of K^+ accumulation between type I hair cells and calyx terminals in mouse crista. They found that responses to a depolarizing voltage step in embedded, but not isolated, hair cells resulted in a >40-mV shift of the K^+ equilibrium potential and a rise in effective K^+ concentration of >50 mM in the intercellular space. These results strengthen our predictions for extracellular Cl^- fluctuation at the OHC/Deiters' cell interface.

The existence of the GABAergic efferent synapse at the basal pole, with associated conductances and transporters, could contribute to such fluctuations in local Cl^- levels (25). Although the demonstration of functional GABA effects on isolated OHCs has been variable (possibly because of inappropriate pipette Cl^- levels; see Ref. 44), recent knockout experiments clearly establish the efferent receptor's importance (26). Interestingly, an involvement of Cl^- in the efferent response of vestibular hair cells has been proposed, and one of the suggested mechanisms was a Cl^- dependence of the SK conductance known to be activated subsequent to ACh application (13). Perhaps efferent effects in the mammalian cochlea somehow involve Cl^- modulation of I_{K} ; in this case, the voltage activation range of the conductance would indicate that effects may only occur at suprathreshold acoustic levels where large receptor potentials could activate I_{K} (6, 12). Such suprathreshold GABAergic effects may not be observable by standard measures of efferent activity (26).

We have recently found that manipulations of perilymphatic Cl^- can impact on prestin-dependent cochlear amplification on the basilar membrane near threshold and concluded that intracellular Cl^- was being modified via the activity of G_{metL} , an OHC lateral membrane conductance for Cl^- (44). Could I_{K} modulation have played a role in those Cl^- effects? It is unlikely since, in that study, other agents, including salicylate and tributyltin (a Cl^- ionophore), were effective in the presence of normal, unperturbed extracellular Cl^- . Additionally, it has been shown that 4-AP, which blocks I_{K} , does not interfere with threshold cochlear function when perfused via perilymph (18).

Could BK or $I_{K,n}$ OHC conductances have contributed to the Cl^- -sensitive I_{K} that we identify? BK or Ca^{2+} -activated K^+ channel has been measured in OHCs (e.g., see Ref. 49) and

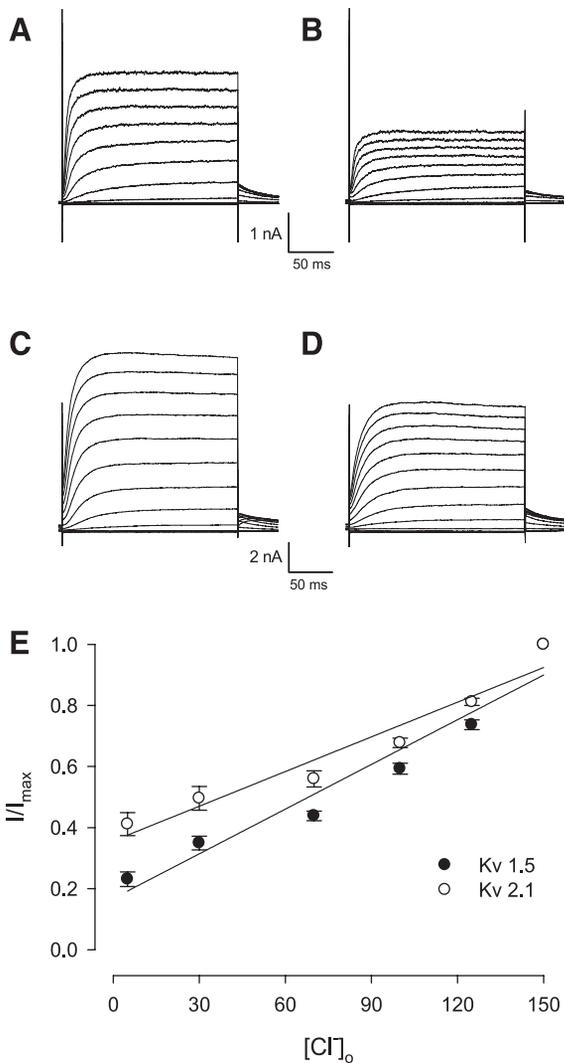

Fig. 9. Extracellular Cl⁻ inhibited voltage-dependent K⁺ (Kv) 1.5 and Kv2.1 in transfected CHO cells. *A*: whole cell current of Kv1.5 in 150 mM Cl⁻. *B*: 5 mM Cl⁻ inhibited the Kv1.5 current. *C*: whole cell current of Kv2.1 in 150 mM Cl⁻. *D*: 5 mM Cl⁻ inhibited the Kv2.1 current. *E*: concentration-response curve of external Cl⁻ on magnitude of Kv1.5 and Kv2.1.

potentially could contribute to the Cl⁻-sensitive K⁺ conductance that we identify. However, we think this is not the case, based on several observations. First, full rundown of Ca²⁺ current (*I*_{Ca}), which may supply Ca²⁺ for BK activation, likely has occurred in our cells, since this is known to happen in guinea pig OHCs whether or not ATP or GTP is included in the patch pipette (24). Thus, given the very low intracellular Ca²⁺ that we have intracellularly (estimated to be <1 nM) and the classic sensitivity of BK to Ca²⁺ (1), BK cannot significantly contribute to our measured *I*_K. Indeed, Wersinger et al. (49), even with a very high Ca²⁺ pipette solution, observed insignificant BK current (iberiotoxin sensitive) in apical OHC.

*I*_{K,n} is a major conductance near the resting potential of OHCs and potentially could have contributed to our measures. We think not, however, based on several observations. Housley and Ashmore (16) showed that resting OHC conductance varies with the length of the cell, decreasing dramatically with increases in length; consequently, *I*_{K,n} is expected to be quite small compared with *I*_K in our long OHC population from

low-frequency regions. Indeed, in this population, we previously found that *I*_{K,n} is not observable in about one-half of the cells (43). Nenov et al. (32) confirmed the above observations. Thus, we expect that relative contamination of the *I*_K we measure by *I*_{K,n} will be small. Interestingly, Wersinger et al. (49) found that linopirdine at 100–200 μM was able to substantially block outward K⁺ currents in apical OHCs and suggested that KCNQ4 channels underlie the major component of the outward *I*_K. It must be emphasized, however, that this drug will block both Kv2.1 [IC₃₀ ~100 μM (50)] and Kv4.3 [IC₅₀ 86 μM (48)], two channels we find transcripts for in OHCs.

Two other factors lead us to dismiss substantial KCNQ4 contributions to our measurements. Our holding protocol at

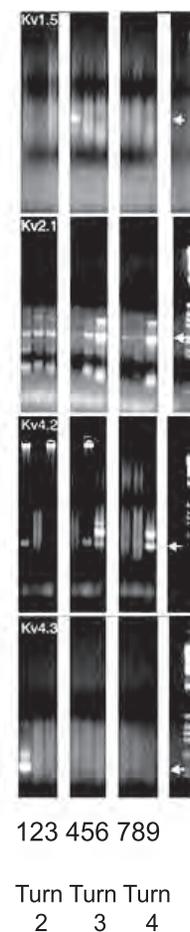

Fig. 10. Kv2.1, Kv1.5, Kv4.2, and Kv4.3 are present in guinea pig OHCs by single-cell RT-PCR. The figure shows single-cell PCR of individual Kv channels. Nine individual OHC were isolated as described in the METHODS, and cDNA was synthesized using Moloney murine leukemia virus reverse transcriptase (Superscript II). A fixed amount of cDNA from these cells was then used as template for amplifying Kv channels. The PCR products were separated on a 2% agarose gel, and the products were detected by ethidium bromide staining. Kv2.1 was present in all the cells and was detected after one round of amplification (35 cycles). In contrast, Kv1.5, Kv4.2, and Kv4.3 were present in only a fraction of cells and required two rounds of nested amplification. The amplification products of each Kv channel are shown in sequence (Kv1.5, Kv2.1, Kv4.2, and Kv4.3 from top to bottom). PCR products from individual cells from turns 2–4 are aligned. We analyzed three cells from each turn. The correct PCR product is indicated by an arrow and was confirmed by sequencing. Also shown are the negative controls and 1-kb markers (lanes 10 and 11, respectively).

−40 mV ensures that $I_{K,n}$ is fully activated, with no further activation upon depolarizations that we used to evoke I_K . Thus, similar to $I_{K,L}$ in vestibular type I hair cells [a conductance analogous to $I_{K,n}$ (37)], when depolarized from potentials where the conductance is fully activated, time-independent, instantaneous currents result and consequently are amenable to simple current subtractions that expose embedded voltage- and time-dependent currents. Thus, the time- and voltage-dependent Cl^- -sensitive current, I_K , is readily isolated from KCNQ4 contributions. Of course, we cannot dismiss that KCNQ4 channels are Cl^- sensitive, since our methods do not permit this evaluation. We would have to block I_K independently, and observe Cl^- effects on $I_{K,n}$. Such sensitivity, if it exists, would be very significant.

How might Cl^- alter I_K ? The linear dependence of I_K on extracellular Cl^- concentration may indicate that fixed charges at the mouth of the channel are screened, thereby altering the local concentration of K^+ available for permeation (20) or interfering with K^+ -specific interactions with the channel. It has been established that residue K356 at the extracellular mouth of Kv2.1 significantly controls K^+ permeation by interacting with K^+ (4), and we reasoned that this residue might be the target of Cl^- . However, we found that mutations of this residue were without effect on Cl^- sensitivity, possibly indicating that other charged residues underlie Cl^- sensitivity.

Molecular substrate of I_K . The K^+ channels Slick and Slack, which are highly expressed in central auditory neurons, are known to be sensitive to internal Cl^- (2) but had not been tested for extracellular Cl^- sensitivity. Here we show that they are unaffected by changes in extracellular Cl^- and therefore do not underlie OHC I_K .

To identify other molecular candidates of channels contributing to OHC I_K , we characterized the differing temporal components of I_K , as has been done previously (52). The distinct inactivation time constants of I_{K1} and I_{K2} are similar to those of $I_{K,cur}$ and $I_{K,slow}$ found in cardiac myocytes (33, 34, 52), and it is believed that Kv1.5 and Kv2.1 contribute to $I_{K,cur}$ and $I_{K,slow}$. Our experiments revealed that these two channels, when expressed in CHO cells, have extracellular Cl^- sensitivity similar to that in the native OHC. This result and similar channel blocker sensitivities between these channels and OHC I_K (24, 32, 42) led us to undertake verification of the channels' presence in OHCs. Our PCR amplification data suggest that Kv2.1 was the predominant form of Kv channel present in the OHC. Transcripts encoding this channel were present in all OHCs tested and moreover required only one round of amplification for detection. In contrast, Kv1.5 required two rounds of amplification and was present in only one cell of nine tested.

Extracellular Cl^- modulates the transient outward K^+ current (I_{to}) in rat ventricular myocytes (19, 21). Replacement of Cl^- with gluconate resulted in a leftward shift (−12 mV) of the steady-state inactivation curve (19), which was comparable to an OHC I_K shift of −8 mV. Interestingly, both Kv4.2 and Kv4.3 contribute to cardiac I_{to} , and, although we did not have these constructs available to us to test for Cl^- effects, we did detect transcripts for these channels in OHCs with RT-PCR, indicating that they may contribute to the Cl^- -sensitive I_K of OHCs.

Although expression level differences by PCR amplification in single cells may be difficult to quantify, the differences in detectability using PCR amplification between Kv2.1 and the

other channels were extreme. The presence of the Kv2.1 transcript in all single cells tested, its detection with only one round of amplification, and the channel's similar Cl^- sensitivity compared with that of OHC I_K strongly suggest that Kv2.1 is the dominant contributor to the Cl^- -dependent I_K in OHCs.

ACKNOWLEDGMENTS

We thank Dr. Len Kaczmarek for providing Kv channel plasmids and Dr. Lei Song for isolating OHCs for single cell PCR.

In Brief

Synaptic ribbons are features of the auditory, vestibular, and visual systems that hold vesicles close to release sites in sensory cells. Lv et al. now find that genetic reduction of Ribeye levels in zebrafish results in the disruption of synaptic ribbon localization and morphology with minor effects on kinetics or levels of vesicle exocytosis.

Highlights

- Ribeye is needed for electron density to form at hair cell synaptic ribbons
- Ribeye mutants have smaller synaptic vesicles and mislocalized ribbons
- Ribeye is required for synaptic ribbon association with calcium channels
- Continuous exocytosis is enhanced in ribeye mutants despite ribbon mislocalization

Synaptic Ribbons Require Ribeye for Electron Density, Proper Synaptic Localization, and Recruitment of Calcium Channels

SUMMARY

Synaptic ribbons are structures made largely of the protein Ribeye that hold synaptic vesicles near release sites in non-spiking cells in some sensory systems. Here, we introduce frameshift mutations in the two zebrafish genes encoding for Ribeye and thus remove Ribeye protein from neuromast hair cells. Despite Ribeye depletion, vesicles collect around ribbon-like structures that lack electron density, which we term “ghost ribbons.” Ghost ribbons are smaller in size but possess a similar number of smaller vesicles and are poorly localized to synapses and calcium channels. These hair cells exhibit enhanced exocytosis, as measured by capacitance, and recordings from afferent neurons post-synaptic to hair cells show no significant difference in spike rates. Our results suggest that Ribeye makes up most of the synaptic ribbon density in neuromast hair cells and is necessary for proper localization of calcium channels and synaptic ribbons.

INTRODUCTION

Primary sensory cells of the auditory, vestibular, and visual systems encode sensory information as graded changes in voltage that lead to graded changes in glutamate release. These non-spiking cells use synaptic ribbons, which hold a dense array of synaptic vesicles in active zones near release sites. Because these cells exhibit tonic and graded signaling in response to sensory stimuli, it has largely been assumed that the synaptic ribbon is necessary to carry out this task (Matthews and Fuchs, 2010). Indeed, ribbon-synapse-containing cells have been demonstrated to exhibit a sustained phase of exocytosis in response to prolonged stimuli (Lagnado et al., 1996; Parsons et al.,

1994; Moser and Beutner, 2000; Edmonds et al., 2004; Bartoletti et al., 2010), and optical studies have revealed that vesicles are immobilized to and move along the ribbon in response to stimuli (Vaithianathan et al., 2016; Zenisek, 2008; Zenisek et al., 2000; Midorikawa et al., 2007).

The most abundant protein in the synaptic ribbon is Ribeye, a protein arising from an alternative start site at the gene encoding for the CtBP2 transcriptional co-repressor (Schmitz et al., 2000). Ribeye can be subdivided into two domains, a ribbon-specific A-domain and a B-domain, which is nearly identical to CtBP2 (Schmitz et al., 2000).

Genetic deletion of mouse Ribeye leads to a loss of synaptic ribbons in the retina, which is accompanied by a reduction in synaptic transmission from bipolar cells without observable changes in the kinetic features of release (Maxeiner et al., 2016), whereas morpholino-oligonucleotide (MO)-driven knock-down of Ribeye expression leads to the mislocalization of calcium channels (Sheets et al., 2011; Lv et al., 2012) and a reduction of spiking rates in afferent neurons postsynaptic to zebrafish hair cells (Sheets et al., 2011).

To better understand the function of Ribeye and the synaptic ribbon, we used genome editing to introduce frameshifting mutations in the A-domain of both zebrafish Ribeye-encoding genes and used light and electron microscopy (EM), whole-cell capacitance measurements, and recordings from afferent neurons to measure the effects on neuromast hair cells. The resultant double-homozygous mutant animals exhibited dramatically reduced Ribeye levels in hair cells, leading to a loss of electron density from hair cell ribbons, shrinkage of ribbon size, mislocalization of ribbon-like structures, and disruption in the association of calcium channels with the ribbon. Despite these changes, the continuous phase of exocytosis is enhanced, and we could not detect differences in afferent neuron response in mutant animals. These results indicate that Ribeye likely makes up the electron-dense portion of the ribbon and recruits calcium channels to release sites in zebrafish hair cells but is not required for vesicle binding, transport, or maintaining continuous release.

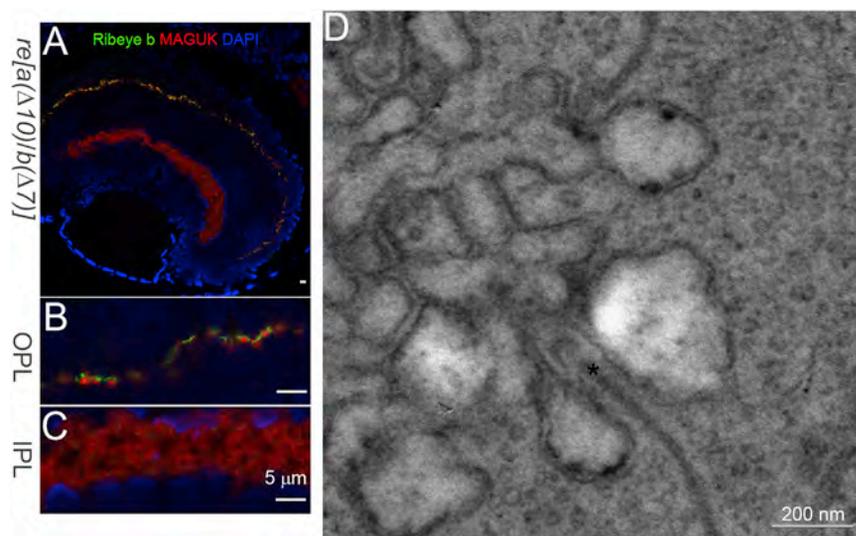

Figure 1. Ribeye and Synaptic Ribbons Remain in the Retina of *ribeye a(Δ10)/ribeye b(Δ7)* (*re[a(Δ10)/b(Δ7)]*) double homozygous mutants.

RESULTS

Generation of Targeted Zebrafish *ribeye* Mutants

To study Ribeye function, we first generated a line of zebrafish harboring mutations in the ribbon-synapse-specific A-domain of Ribeye a that leads to frameshifts resulting in a premature stop codon using zinc finger nucleases (ZFNs) (Supplemental Experimental Procedures; Figure S1). One such mutant that led to a 10-bp deletion (*ribeye a(Δ10)*) was bred to homozygosity for further experiments. Figure S2 shows immunostaining of retinal sections of wild-type (WT) and *ribeye a(Δ10)* homozygous fish with antibodies against Ribeye a or Ribeye b or with a CtBP antibody that labels CtBP1, CtBP2, and all isoforms of Ribeye. As expected, CtBP and Ribeye b staining was still evident in the *ribeye a(Δ10)* homozygous animals, due to expression of Ribeye b. Note that, while the CtBP expression level is greatly reduced in the inner plexiform layer (IPL), the CtBP staining in the outer plexiform layer (OPL) is similar in the *ribeye a(Δ10)* homozygous and WT animals, consistent with stronger expression of Ribeye b in photoreceptor terminals and higher expression of Ribeye a in bipolar cells. EM images revealed normal-appearing ribbons in both the retina and lateral line of *ribeye a(Δ10)* homozygous animals (data not shown). We found that animals homozygous for these mutations are viable and do not exert obvious sensory phenotypes.

Next, we targeted *ribeye b* using CRISPR/Cas9 (clustered regularly interspaced short palindromic repeats/CRISPR-associated protein 9)-based constructs. Using this strategy, we generated eight lines of fish harboring mutations in this region of *ribeye b*, which led to premature stop codons (Figure S1C). As with the ZFN-generated mutations of *ribeye a*, the mutations introduced into *ribeye b* are expected to cause a truncation of the sequence in the A-domain, with no effect on CtBP2 expression.

Characterization of *ribeye a(Δ10)/ribeye b(Δ7)* Homozygous Zebrafish

Next, we characterized the *ribeye a(Δ10)/ribeye b(Δ7)* (herein after termed *re[a(Δ10)/b(Δ7)]*) double-homozygous mutants at

the level of light and EM in the retina and in hair cells of the lateral line. Surprisingly, double-homozygous mutants were

immunopositive for CtBP and Ribeye b in the OPL of the retina, indicating that at least some Ribeye continues to be expressed, despite the mutations (Figure 1). Consistent with Ribeye expression, EM revealed that synaptic ribbons were also present in the OPL of *re[a(Δ10)/b(Δ7)]* fish (Figure 1D).

In contrast to the retina findings, Ribeye was found to be dramatically reduced in the hair cells of zebrafish neuromasts at 5 days postfertilization (dpf) (Figure 2). Figures 2A and 2B show results from neuromasts that are labeled for Ribeye a (Figure 2A) or Ribeye b (Figure 2B) with pan-MAGUK, a marker for post-synaptic densities that labels afferent post-synaptic structures in afferent fiber terminals (Sheets et al., 2011; Meyer et al., 2005). In WT animals, pan-MAGUK staining was found to colocalize near bright spots immunopositive for Ribeye a (Figure 2A, left) and Ribeye b (Figure 2B, left). By contrast, *re[a(Δ10)/b(Δ7)]* double homozygotes exhibit little staining for Ribeye a (Figure 2A, right) but continued to exhibit staining for pan-MAGUK (Figures 2A and 2B, right). Some residual fluorescent spots remained in double-homozygous mutant animals. The Ribeye a puncta were reduced in number from 2.5 ± 0.18 in WT fish to 1.5 ± 0.3 in double homozygotes (Figure 2D), and in intensity from $15,728 \pm 1,517$ to $6,369 \pm 1,021$ (Figure 2E). Ribeye b was not detectable (Figure 2B). Though the number of pan-MAGUK spots in double homozygotes was unchanged (Figure 2D), the puncta intensity was significantly reduced (Figure 2E).

Next, we tested whether overall CtBP levels were also reduced from synaptic sites by staining with an antibody that recognizes Ribeye a, Ribeye b, CtBP1, and CtBP2. As with the Ribeye a staining, we found fewer and dimmer CtBP puncta than in control animals. On average, puncta in double homozygotes had an integrated intensity of 17% of WT fish.

Lastly, to determine whether the Ribeye a immunofluorescent (IF) spots properly localized near post-synaptic structures, we measured the distance of the centroid of each Ribeye a spot to its nearest pan-MAGUK spot. Figure 2F plots the results as a cumulative histogram. As can be seen in the figure, spots in mutant animals were found further away from

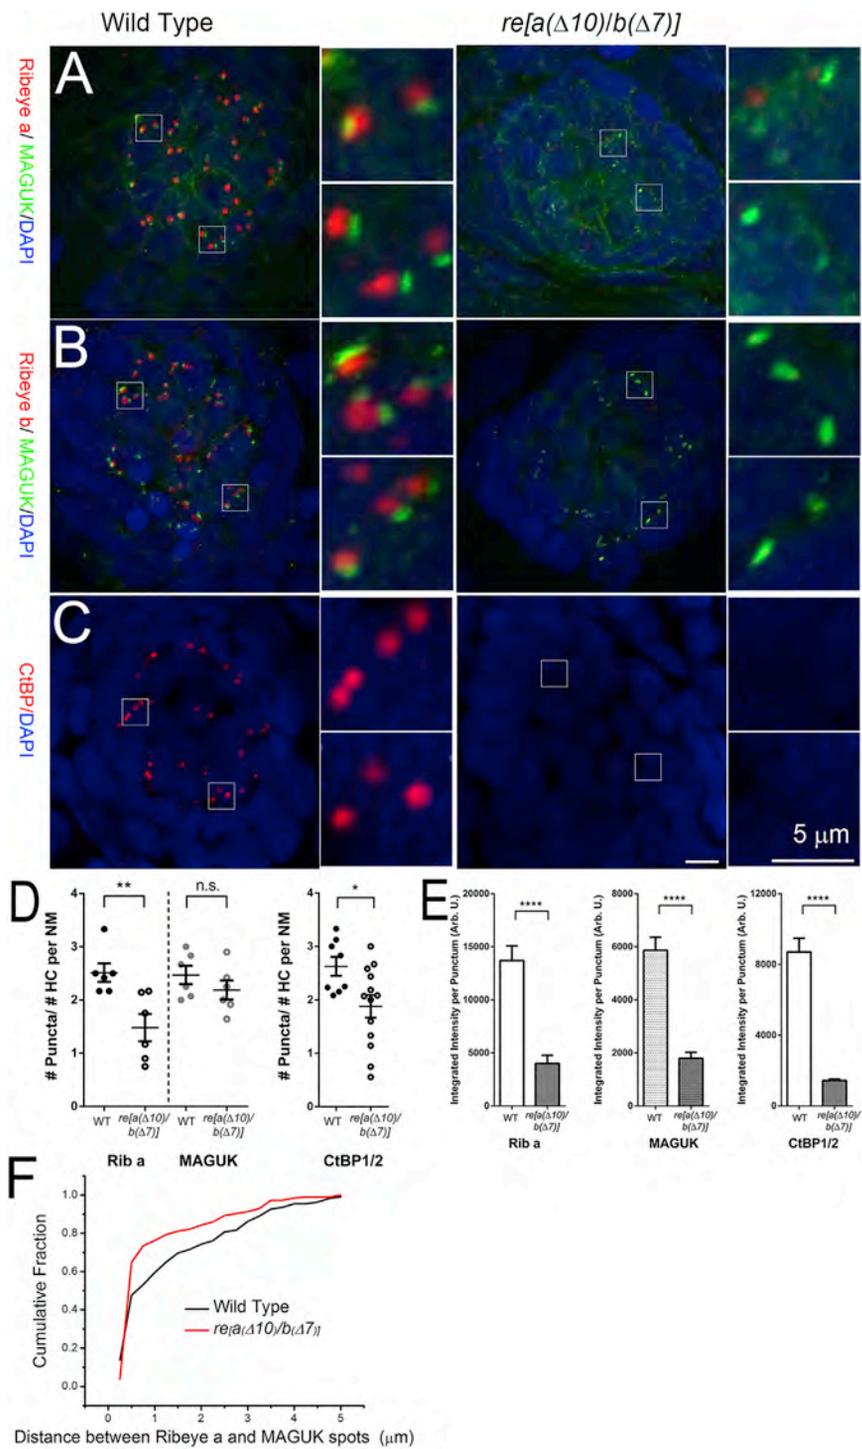

Figure 2. Ribeye Is Dramatically Reduced from Neuromast Hair Cells of *re[a(Δ10)/b(Δ7)]* Double Homozygous Mutants 5 dpf

(A) Confocal images of Ribeye A (red) and post-synaptic density marker pan-MAGUK (green) staining 5 dpf in WT (left) and *re[a(Δ10)/b(Δ7)]* homozygous mutant (right) neuromast. Insets show magnified images centered around synapses. Note the close apposition of Ribeye a and pan-MAGUK in WT animals, whereas little Ribeye a staining is found near pan-MAGUK in the *re[a(Δ10)/b(Δ7)]* double-homozygous mutants.

(B) Ribeye b (red) and pan-MAGUK (green) antibody staining in 5-dpf WT (left) and *re[a(Δ10)/b(Δ7)]* homozygous mutant (right) neuromast.

(C) CtBP antibody staining (green) in 5-dpf WT (left) and *re[a(Δ10)/b(Δ7)]* homozygous mutant (right) neuromast. DAPI (blue) stains nucleus. Scale bars, 5 μm.

(D) The number of Ribeye a, MAGUK, or CtBP1 immunolabeled puncta per hair cell in 5- to 6-dpf WT and *re[a(Δ10)/b(Δ7)]* mutants. Each circle represents an individual neuromast (NM) within a larva. The number of puncta per hair cell was approximated by dividing the number of Ribeye puncta within an NM by the number of hair cells in the NM. Error bars indicate SEM. Unpaired t test; **p = 0.0075; *p = 0.0226; n.s., not significant.

(E) Integrated intensities per punctum of Ribeye a, MAGUK, and CtBP1. Bars represent the means; error bars indicate SEM. Mann-Whitney U test; ***p < 0.0001, for both mutant alleles.

(F) Cumulative histogram of distances between Ribeye a spots to their nearest pan-MAGUK spot in confocal micrographs for WT (red) and *re[a(Δ10)/b(Δ7)]* double-homozygous mutants (black).

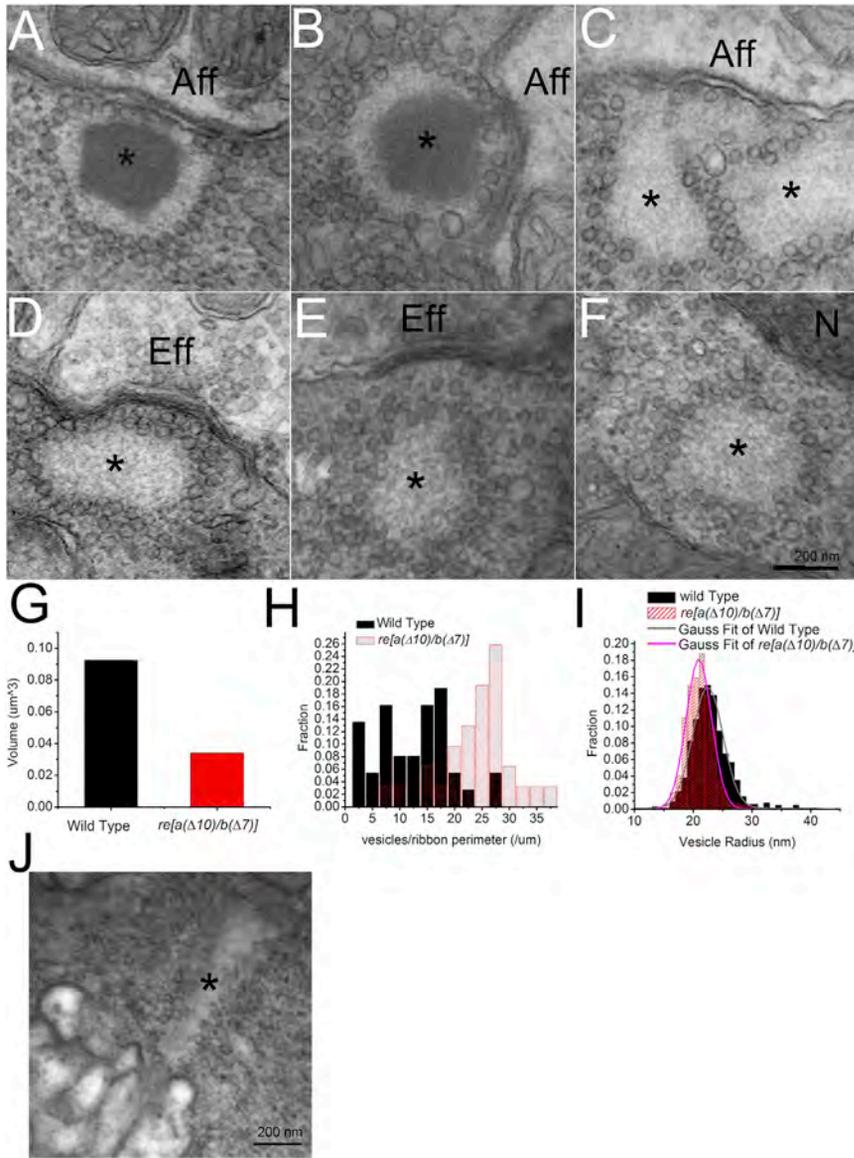

afferent fibers (Obholzer et al., 2008). Similarly, we found that EM sections of neuromasts in WT fish exhibited electron-dense synaptic ribbons (n > 20 fish). Figures 3A and 3B show typical electron micrographs of a synaptic ribbon from a WT hair cell, which were localized near afferent neurons separated by two cell membranes. Afferent neurons were identified in electron micrographs by their reduced density, lack of synaptic vesicles, and mitochondria. In WT fish, we found that 41 of 41 ribbons were localized within 70 nm of a visible plasma membrane opposite an afferent neuron. By contrast, we found no ribbons with typical electron-dense centers in *re[a(Δ10)/b(Δ7)]* double homozygotes. Instead, 5-dpf embryos of *re[a(Δ10)/b(Δ7)]* double homozygotes exhibited ribbon-like structures that lacked electron densities but maintained an organized collection of synaptic vesicles in a spherical array (Figures 3C–3F), which we have named “ghost ribbons.” While some ghost ribbons appeared to localize adjacent to afferent neurons (Figure 3C; n = 14 of 41 ghost ribbons), most were not found near

post-synaptic densities, suggesting defects in their ability to localize to synapses.

Morphology of Hair Cell Synaptic Ribbons in *re[a(Δ10)/b(Δ7)]* Homozygous Mutants

Neuromast hair cells of WT embryos at 5 dpf exhibit spherical synaptic ribbons that localize near the plasma membrane near

b(Δ7) double homozygotes. Instead, 5-dpf embryos of *re[a(Δ10)/b(Δ7)]* double homozygotes exhibited ribbon-like structures that lacked electron densities but maintained an organized collection of synaptic vesicles in a spherical array (Figures 3C–3F), which we have named “ghost ribbons.” While some ghost ribbons appeared to localize adjacent to afferent neurons (Figure 3C; n = 14 of 41 ghost ribbons), most were not found near

identifiable afferent fibers. Figure 3 shows examples of ghost ribbons near efferent neurons (Figure 3D), away from the cell membrane (Figure 3E), and in the center of cell (Figure 3F). By contrast, ribbons of the retina of *re[a(Δ10)/b(Δ7)]* double homozygotes were found to be largely normal; however, we found two examples of structures within photoreceptors of *re[a(Δ10)/b(Δ7)]* double homozygotes that resembled the hair cell ghost ribbons but took on the elongated shape of a photoreceptor ribbon (Figure 3J). These results indicate that Ribeye is necessary for the maintaining the electron density of the ribbon and plays a critical role in localizing ribbons to proper synaptic locations.

Next, we quantified and compared the morphological properties of ghost ribbons in *re[a(Δ10)/b(Δ7)]* double homozygotes to ribbons in WT animals. In WT hair cells ($n = 45$ ribbons, 18 fish), the area of the region beneath the vesicles, including both the electron density and the surrounding light space (e.g.,

Figures 3A and 3B), was, on average, $0.163 \mu\text{m}^2$. If we assume that the ribbons are roughly spherical and that each image represents a random cross-section of that sphere, WT ribbons would have a cross-section of $0.244 \mu\text{m}^2$ at their equator, which yields a spherical ribbon with a diameter of 560 nm and a volume of $0.091 \mu\text{m}^3$. The density occupied about 43% of WT ribbons. By contrast, ghost ribbons lacking the density were much smaller ($n = 32$ ribbons; ten fish), with an estimated cross-sectional area of $0.119 \mu\text{m}^2$, equivalent to a 390-nm diameter sphere and a volume of $0.031 \mu\text{m}^3$. Hence, when one does not factor in the vesicle volume, the volume of ghost ribbons is only 34% of the volume of WT ribbons, less than the 57% that one would predict if ribbons only lost the density but similar to a previous estimate of the contribution of Ribeye to ribbon volume in retinal bipolar cells using a ribbon-binding peptide (Zenisek et al., 2004).

To analyze the vesicles associated with ribbons and ghost ribbons, we counted the number of vesicles within one vesicle diameter of the ribbon. Despite the smaller area of the ghost ribbons, we observed more vesicles per section associated with ghost ribbons in mutant animals (21.8 ± 1.3) than with ribbons in WT cells (15.7 ± 2.0). To measure the density of vesicles on ribbons, we divided the number of vesicles by the length of the perimeter of the ribbon in each section. On average, we found

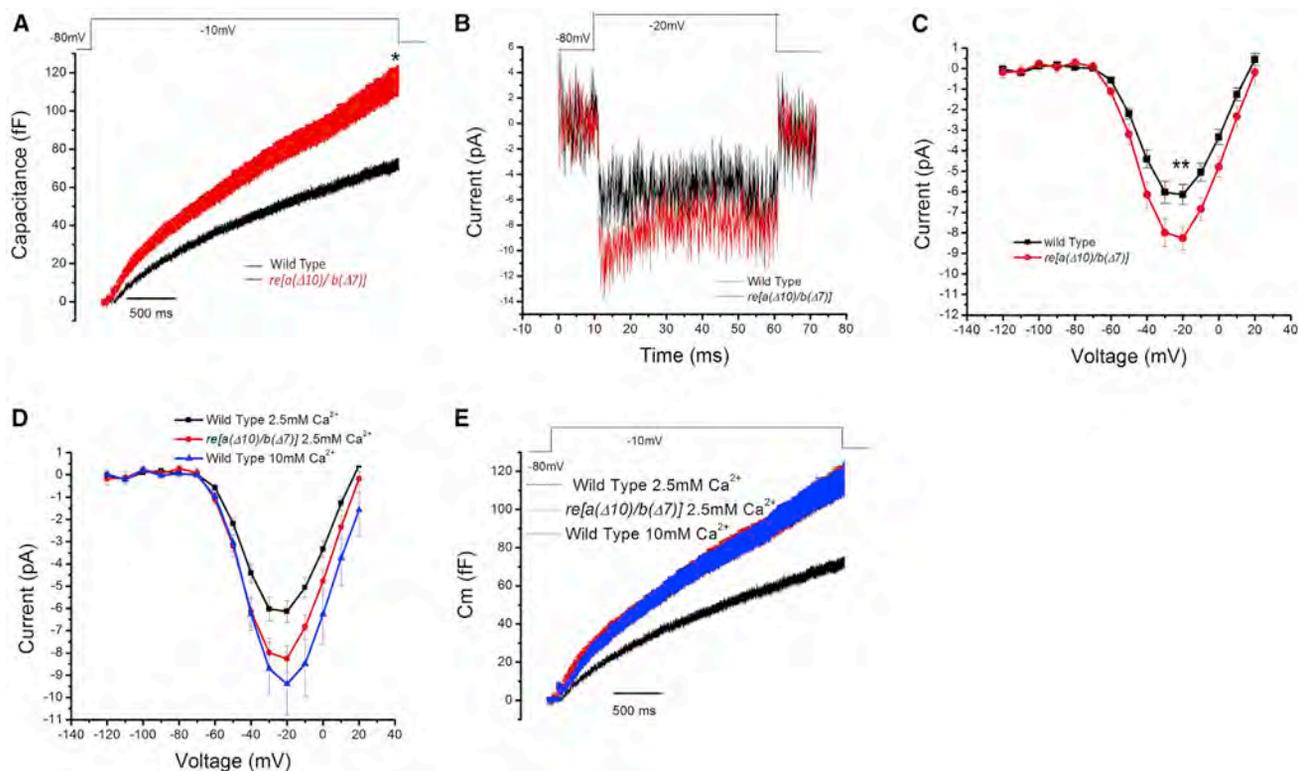

Figure 4. Results from Whole-Cell Voltage-Clamp Recordings from WT and *re[a(Δ10)/b(Δ7)]* Homozygous Mutant Neuromast Hair Cells
 (A) Average whole-cell capacitance measurements of WT (black, n = 11) and *re[a(Δ10)/b(Δ7)]* homozygous mutants (red, n = 12) neuromast hair cells in response to 3-s step-depolarizations. Note that all traces include error bars denoting SEM for each condition. The average capacitance increase at the end of the 3-s depolarization (averaged over 100 ms) was 67.8 ± 5.0 fF for the WT hair cells and was 106.1 ± 13.6 fF in the mutants. $p = 0.018$.
 (B) Averaged calcium current trace of WT (black) and *re[a(Δ10)/b(Δ7)]* homozygous (red) mutants in response to a -20 -mV step depolarization.
 (C) Plot of current-voltage relationship for WT fish NM hair cells (black, n = 15) and *re[a(Δ10)/b(Δ7)]* homozygous mutant neuromast hair cells (red, n = 17). At -20 mV, the average current in WT cells was -6.1 ± 0.5 pA, and mutant fish cells was -8.3 ± 0.6 pA. $p = 0.010$. The fish recorded were between 5 and 8 days old, and the neuromasts recorded were P3 and P4.
 (D) Capacitance recording of WT fish at 2.8 mM Ca^{2+} (black) and 10 mM Ca^{2+} (blue) external solution and double-mutant fish at 2.8 mM Ca^{2+} external solution (red) in response to a 3-s step depolarization. The average capacitance increase at the end of the 3-s depolarization (averaged over 100 ms) was 105.09 ± 13.74 fF for the WT hair cells at 10 mM Ca^{2+} solution. Capacitance increases in WT and double-mutant fish in 2.8 Ca^{2+} external solution are the same as in (A).
 (E) Plot of current-voltage relationship of WT fish at 2.8 mM Ca^{2+} (black) and 10 mM Ca^{2+} (blue) external solution, and double-mutant fish at 2.8 mM Ca^{2+} external solution (red). At -20 mV, the calcium current of WT fish in 10 mM Ca^{2+} external solution is -9.39 ± 1.40 pA, compared to double-mutant fish in 2.8 mM Ca^{2+} external solution is 8.26 ± 0.58 pA.

22.7 ± 1.0 vesicles per micrometer perimeter in mutant ghost ribbons and 11.1 ± 0.9 vesicles per millimeter in images of ribbons of WT animals. Even after the removal of a subset of WT ribbons that had very few vesicles (five or less), the vesicle density on ribbons remained lower in the WT cells ($13.0 \pm 0.8 \mu m^{-1}$). Figure 3H plots a histogram of these values for both genotypes. To estimate the effect on overall vesicle number, we estimated the area of ribbon assayed in each 80-nm section relative to the total ribbon surface area using our spherical assumption. Based on this method, we calculated an estimate of 133 ± 17 vesicles per ribbon in WT animals and 129 ± 8 associated with ghost ribbons in *re[a(Δ10)/b(Δ7)]* double-mutant animals.

Lastly, we measured the size of the vesicles associated with ribbons and ghosts. We measured the size of vesicles associated with ribbons (n = 671) and ghost ribbons (n = 627). On average, ribbon-associated vesicles in WT animals had an average area of $1,631 \pm 15$ nm², whereas vesicles in *re[a(Δ10)/*

b(Δ7)] were $1,437 \pm 12$ nm². Since the vesicles are round in the images, we converted the areas into vesicle radii and plotted the results as a histogram in Figure 3I. While the difference in vesicle size is small (21.4 ± 0.09 in double homozygotes versus 22.4 ± 0.1 nm in WT), the differences are highly significant ($p < 0.003$ when comparing averages across ribbons).

***re[a(Δ10)/b(Δ7)]* Double Mutants Exhibit Enhanced Exocytosis and Calcium Current**

Next, we tested the release properties of the *re[a(Δ10)/b(Δ7)]* double-homozygous animals and WT animals. To do so, we performed whole-cell membrane capacitance recordings in response to long step depolarizations in both WT and *re[a(Δ10)/b(Δ7)]* double-homozygous fish 5–8 dpf, using a two-sine approach that allows for measuring exocytosis during a depolarization (Ricci et al., 2013; Schnee et al., 2011). Figure 4A, shows the average responses of 11 WT hair cells and 12 *re*

Table 1. Best-Fit Values of Hair Cell Capacitance Measurements from WT and Mutant Zebrafish

	Linear Phase, β (fF/s)	Amplitude, A (fF)	Time Constant, τ (ms)
Wild type/1 EGTA/2.8 Ca ²⁺	17.6	18.9	501

[a(Δ 10)/b(Δ 7)] fish in response to 3-s voltage steps to -10 mV. WT hair cells exhibited a steady rise in whole-cell capacitance, which could be well fit by the sum of an exponentially asymptoting fast phase and a linear continuous phase, similar to what has been observed in mouse (Moser and Beutner, 2000) and chick (Eisen et al., 2004) cochlear hair cells. To fit the data, the latter half of the capacitance response was fit to a straight line, and a line with that slope was subtracted from the raw data. The residual was then fit by an exponential. Using this approach, the WT response was best fit by a linear phase of 17.6 fF/s and an exponential with an amplitude of 18.9 fF and with a time constant of 501 ms (see Table 1).

Surprisingly, the capacitance response from *re[a(Δ 10)/b(Δ 7)]* double-homozygous animals showed a larger increase in capacitance in response to step depolarization (Figure 4A; Table 1). The linear phase (65% greater than WT) was specifically enhanced in mutant animals, whereas the exponential amplitude was only minimally larger (1.6% greater than WT). The enhanced exocytosis in double-homozygous mutant zebrafish was accompanied by an increase in the calcium current in the hair cells measured at -20 mV (Figure 4B). Figure 4C shows the average current as a function of membrane potential from WT ($n = 15$) and *re[a(Δ 10)/b(Δ 7)]* double-homozygous ($n = 17$) fish. While the shape of the current-voltage (I-V) relationship appeared similar, the calcium currents were found to be larger in the cells lacking Ribeye. Increasing extracellular calcium to 10 mM in WT animals resulted in an increase in calcium current (Figure 4D) and exocytosis (Figure 4E) to levels that mimicked that of *re[a(Δ 10)/b(Δ 7)]* double-homozygous animals, suggesting that the enhanced exocytosis can largely be explained by the enhanced calcium current.

Calcium Channels Are Poorly Coupled to Release in *re[a(Δ 10)/b(Δ 7)]* Double-Homozygous Hair Cells

Next, we performed co-immunofluorescence staining with an antibody for the calcium channel CaV1.3 (Sheets et al., 2011, 2012) and a post-synaptic marker pan-MAGUK (Meyer et al., 2005). In WT animals, CaV1.3 staining revealed spots (Figure 5A, red), which were found localized near pan-MAGUK spots (Figure 5A, green). By contrast, CaV1.3 and pan-MAGUK spots were spatially segregated in *re[a(Δ 10)/b(Δ 7)]* double homozygotes (Figure 5B), suggesting improper localization.

As a second test for the proximity between calcium channels and active zones, we determined the effect of the slow calcium buffer EGTA on exocytosis in WT and *re[a(Δ 10)/b(Δ 7)]* double-homozygous mutant animals. High concentrations of EGTA have little effect on calcium concentrations in small nano-domains near the mouth of open calcium channels but efficiently reduce bulk calcium concentrations and calcium at other distal locations away from the channels. Hence, if sites of exocytosis are very near calcium channels, EGTA is expected to have little effect on release. Electrophysiological studies from various synapses have used this method to demonstrate tight proximity of calcium channels to release sites (Mennerick and Matthews, 1996; Adler et al., 1991; Roberts, 1994; Moser and Beutner, 2000; Mehta et al., 2014; Coggins and Zenisek, 2009; Wong et al., 2014). Similarly, WT hair cells showed little change in the amount of exocytosis when 10 mM EGTA was introduced into the cell via patch pipette and stepped to -10 mV, suggesting tight coupling between calcium channels and release sites in these cells (Figure 5C). On average, the capacitance response to a 3-s step depolarization from -80 mV to -10 mV was 67.8 ± 5.0 fF for cells loaded with 1 mM EGTA ($n = 11$) and 62.8 ± 4.9 fF for cells loaded with 10 mM EGTA ($n = 7$) with similar kinetics. By contrast, 10 mM EGTA had a dramatic effect on ΔC_m in *re[a(Δ 10)/b(Δ 7)]* double-homozygous hair cells, reducing release by 66% relative to 1 mM EGTA and only 55% of WT hair cells loaded with 10 mM EGTA (Figure 5D; Table 1). The effect of EGTA was more pronounced in the continuous phase (72% reduced) than the exponential phase (33%). These results suggest that Ribeye is required for proper formation of calcium channel/vesicle nanodomains and that the enhanced release observed in *re[a(Δ 10)/b(Δ 7)]* double homozygotes may arise primarily from vesicles residing outside of calcium channel nanodomains.

Recordings from Afferent Neurons

The aforementioned results indicate that hair cells from *re[a(Δ 10)/b(Δ 7)]* double homozygotes continue to exhibit robust exocytosis in response to depolarization, despite lacking ribbon densities, but the release is inefficiently coupled to calcium channels, and ribbons are mislocalized. Next, we tested whether ghost-ribbon-containing hair cells could efficiently drive post-synaptic spiking in afferent neurons. To do so, we recorded action potentials from primary afferent neurons of the posterior lateral line system using loose-patch extracellular recordings in response to piezo-electrically driven stimuli directed to the kinocilia of neuromast hair cells (Levi et al., 2015). For these experiments, cells were selected for analysis only if a stimulus was found to generate action potentials in the recorded afferent. Hence, these recordings represent cells that receive synaptic input from hair cells. We could find no differences between WT and mutant animals in their afferent responses. Figure 6 summarizes our results from these recordings in WT and *re[a(Δ 10)/b(Δ 7)]* double-homozygous animals. Figure 6A shows representative recordings taken from neuromast L1 from a WT animal and a mutant animal stimulated at 60 Hz. As can be observed from the recordings, both the WT and mutant animals showed robust spiking throughout a 10-s stimulus train. We found no difference in the spontaneous spike rate before stimulation for WT and *re[a(Δ 10)/b(Δ 7)]* double-homozygous fish (Figure 6B). Figure 6C

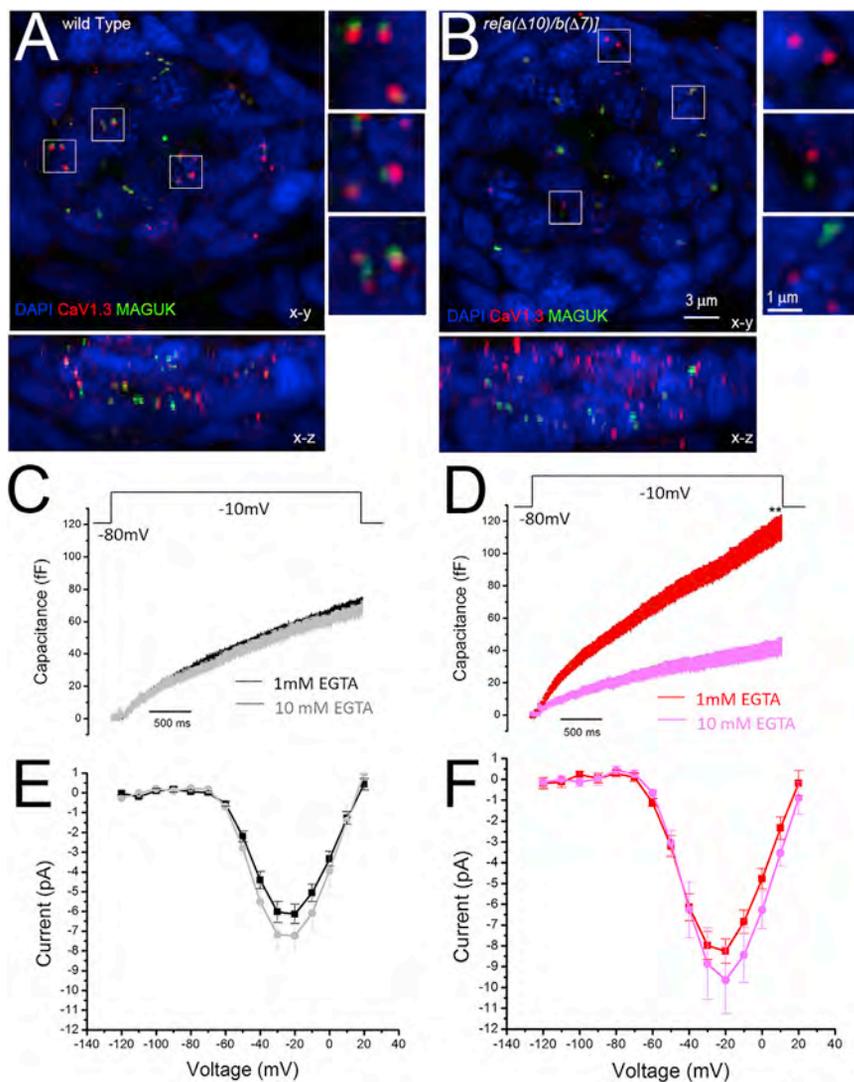

Figure 5. *re[a(Δ10)/b(Δ7)]* Homozygous Hair Cells Have Poorly Localized Calcium Channels and Exhibit Enhanced Sensitivity to 10 mM EGTA

(A and B) Immunolabel of CaV1.3a and MAGUK in 5-dpf WT (A) and *re[a(Δ10)/b(Δ7)]* (B). While Cav1.3 immunolabeled puncta generally localize to the presynapse adjacent to postsynaptic MAGUK immunolabel in WT (A; insets), CaV1.3a clusters fail to localize to the presynapse in *re[a(Δ10)/b(Δ7)]* mutants (B; inset).

(C and D) Capacitance increase of WT and double-mutant neuromast hair cells in response to a 3-s step depolarization with 1 mM EGTA or 10 mM EGTA (gray, n = 8) in the internal solution. The average capacitance increase at the end of the 3-s depolarization (averaged over 100 ms) of WT fish was 67.8 ± 5.0 fF at 1 mM EGTA (C; black, n = 11) and 62.8 ± 4.9 fF at 10 mM EGTA (C; gray, n = 7); p = 0.50. 10 mM EGTA blocks 7.4% of release, compared to 1 mM EGTA in WT fish. The average capacitance increase at the end of the 3-s depolarization (averaged over 100 ms) of double mutants was 106.1 ± 13.6 fF at 1 mM EGTA (D; red, n = 12), and 36.3 ± 8.7 fF at 10 mM EGTA (D; pink, n = 8), p = 0.01. 10 mM EGTA blocks 66.% of release compared to 1 mM EGTA.

(E and F), Plot of current-voltage relationship for WT fish NM hair cells (E) and *re[a(Δ10)/b(Δ7)]* homozygous mutant neuromast hair cells (F) at 1 mM EGTA and 10 mM EGTA internal solution. At -20 mV, the average current of WT cells was -6.1 ± 0.5 pA at 1 mM EGTA (E; red, n = 15) and 6.9 ± 0.9 pA (E; pink, n = 8). p = 0.46. The average current of mutant fish cells was -8.26 ± 0.58 pA at 1 mM EGTA solution (F; red, n = 17), and -9.9 ± 2.2 pA at 10 mM EGTA solution (F; pink, n = 6). p = 0.49. The fish recorded were between 5 and 8 days old, and the neuromasts recorded were P3 and P4.

plots the recorded spike frequency that has been time averaged over the 10-s stimulus train for three frequencies (2 Hz, 30 Hz, and 60 Hz). Figure 6F shows the spike rate over the entire 10 s of 60-Hz stimulation for all fish. As can be seen from the plots, *re[a(Δ10)/b(Δ7)]* double-homozygous fish exhibited spike rates similar to WT animals at all frequencies tested. We found no effect of genotype on the ability to phase lock to stimuli, as the vector strengths for both WT and mutant animals were similar across all stimulation frequencies (Figure 6D). Similarly, the measured preferred phase angles were indistinguishable among genotypes. Figure 6E shows that the latency to the first response was also unchanged in mutant animals.

DISCUSSION

Evidence for Ribeye Forming the Core of the Ribbon

In this study, we used genome editing techniques to introduce mutations into the coding regions of the synaptic ribbon-specific A-domain of both zebrafish *ribeye* genes. Mutant animals exhibit

greatly reduced levels of Ribeye, leading to striking morphological changes to the synaptic ribbons of hair cells. In particular, double-homozygous mutants have ribbons that lack the central electron density while maintaining a roughly spherical scaffold that harbors attached synaptic vesicles. Of note, the ghost ribbons were found to have lost 66% of their estimated volume, similar to the estimated contribution of Ribeye to ribbon volume in bipolar cells (Zenisek et al., 2004) but considerably more than the volume occupied by the density in micrographs. Previous studies have demonstrated that overexpressed Ribeye forms electron-dense aggregates in HEK and R28 cells (Schmitz et al., 2000; Magupalli et al., 2008) and leads to ectopic electron densities in neuromast hair cells (Sheets et al., 2011). In some systems, the A-domain alone is sufficient to form densities, whereas the B-domain alone forms a soluble protein (Schmitz et al., 2000). Summed together, it is reasonable to conclude that the core density observed in electron micrographs of synaptic ribbons is largely composed of the A-domain of Ribeye protein, whereas the surrounding halo of lighter material is made

Rim2, but each of these proteins is also found at conventional synapses, which lack the ribbon structure. Of note, a ribbon-specific isoform of Piccolo has been described in retina (Regus-Leidig et al., 2013, 2014b), suggesting that ribbon-specific splicing may underlie some of the diversity in ribbon shape and size.

It is noteworthy that some of the features we report here differ from those found in a recent report characterizing retinal ribbons in Ribeye knockout mice (Maxeiner et al., 2016). In that study, the authors found ribbons completely lacking from the retina and a general decrease in vesicles residing near active zones. Additionally, they found that synaptic transmission between rod bipolar cells and AII Amacrine cells was reduced by approximately 80%, whereas in our study, exocytosis, measured by capacitance, is slightly enhanced. As in our

study, the kinetics of the responses remained unchanged, suggesting that ribbons are not required to maintain continuous release from bipolar cells. Although the reasons for the differences in the two studies are unknown at this point, we hypothesize several possible explanations. (1) In our study, a small amount of Ribeye remains in hair cells, which may be sufficient to nucleate the ghost-ribbon structures and be sufficient to stabilize synaptic structures containing other ribbon proteins. (2) Occult ghost ribbons might account for 20% of release from mouse bipolar cells. Ghost ribbons lack the electron density and are smaller than WT ribbons and, thus, were initially difficult to find in electron micrographs in neuromast hair cells. Identifying such structures in mouse bipolar cells ribbons would be even more difficult, since bipolar cell ribbons are smaller and vesicles are found at high densities throughout the cytoplasm. Moreover, since release is reduced by 80%, ghost-ribbon

up of the B-domain of Ribeye along with other ribbon proteins that remain in place in our mutant animals. This idea is consistent with the original model put forth by Schmitz, Sudhof, and colleagues (Schmitz et al., 2000). We find that most “ghost ribbons,” while smaller, appear to take on a shape that is similar to that of normal ribbons (although see Figures 3C–3F) and still retain a scaffold capable of recruiting vesicles. Interestingly, we found two examples of ghost-ribbon-like structures in photoreceptors of mutant mice, which appeared more elongated than the hair cell ghost ribbons, mimicking the structure of photoreceptor ribbons. It remains possible that the sparse Ribeye remaining in these cells may maintain the structure but fail to form a density. Alternatively, numerous structural proteins have been shown to localize to the ribbon complex (Brandstätter et al., 1999), including Piccolo, Bassoon, Cast/ERC, Rim1, and

numbers may be similarly reduced. (3) The differences may reflect species- and/or tissue-specific roles for Ribeye.

Relationship between Ribeye and Vesicles

In this study, we find that ghost ribbons possess an estimated 50% of the surface area of WT ribbons, while maintaining near-normal vesicle numbers. Physical tethers linking the ribbon to synaptic vesicles are observable in some electron micrographs (e.g., Lenzi et al., 2002), but the molecular components of the tether remain obscure. Since vesicle numbers remain constant, despite dramatic reductions in Ribeye levels, we posit that a yet-to-be-identified protein may link vesicles to ribbons and that loss of ribbon volume results in an increase in concentration of this molecule on the ribbon. Our results here argue against Ribeye directly participating in the tethering of synaptic vesicles.

Synaptic vesicles associated with ghost ribbons were also found to be smaller than those associated with ribbons in WT animals. The reasons for this difference is currently unknown, but it is worth noting that Ribeye has been suggested to act as a lysophosphatidyl acyl transferase that adds an acyl group to lysolipids, thus converting lysophosphatidic acid (LPA) with one acyl chain to phosphatidic acid (PA) with two acyl chains (Schwarz et al., 2011). Since the LPA and PA have opposite effects on membrane curvature, the acyltransferase activity has the potential to influence membrane curvature and, by extension, vesicle size.

Ribeye, Synaptic Localization, and Calcium Channels

Prior to the present study, several lines of evidence have pointed toward a close relationship between Ribeye and calcium channels in ribbon synapses. Calcium channels have been shown to localize to clusters beneath the ribbon in ribbon synapses (Roberts et al., 1990; Zenisek et al., 2003; Frank et al., 2010). Moreover, the tight coupling of fast exocytosis to calcium channels appears to be a feature of many ribbon synapses (Singer and Diamond, 2003; Mennerick and Matthews, 1996; Moser and Beutner, 2000; Wong et al., 2014). A link between Ribeye and calcium channels has previously been inferred from overexpression and knockdown studies in zebrafish. MO-driven knockdown of ribeye leads to loss of calcium channel clusters in both retina (Lv et al., 2012) and neuromast hair cells (Sheets et al., 2012), whereas animals overexpressing Ribeye exhibit ectopic calcium channel clusters that colocalize with Ribeye protein aggregates (Sheets et al., 2012). More recently, knockout of Ribeye in mouse was found to cause a subtle change in the size of calcium channel clusters in photoreceptors (Maxeiner et al., 2016). Notably, in contrast to the previous MO results in retina (Lv et al., 2012), calcium channels remained clustered in discrete locations in the retina. Additionally, knockout mice were found to exhibit an increase in sensitivity of mEPSC frequency to high levels of the membrane-permeant analog of EGTA, EGTA-AM. Since mEPSC frequency is also reduced by calcium channel blockers (Mehta et al., 2013; Maxeiner et al., 2016), the results were suggestive of a loss of coupling between calcium channels and release sites.

Here, we show that genetic disruption of Ribeye expression leads to mislocalization and redistribution of calcium channels in neuromast hair cells, in line with the previous work using

MOs (Sheets et al., 2012). This redistribution of calcium channels is associated with a slight enhancement of calcium current. Although the reason for the increase in calcium current is unknown at present, we posit that homeostatic plasticity, in response to less neurotransmitter released on to afferent fibers, may trigger an upregulation of calcium current and exocytosis in these cells, similar to what has been described for other systems (Frank, 2014). Alternatively, Ribeye may act as a negative regulator of voltage-gated calcium channel expression or activity, with the latter being a distinct possibility, given that CtBP2 functions as a co-repressor. Further work will be necessary to determine the mechanisms behind the enhanced calcium current observed here. We also show here that the continuous phase of exocytosis in mutant animals exhibits an enhanced sensitivity to EGTA. Mutant hair cells retain an EGTA-insensitive component of release that retains similar exponential release kinetics, suggesting that some vesicles may still reside in nanodomains near calcium channels.

Of note, inner hair cells from mice harboring mutations to the synaptic ribbon protein Bassoon, which exhibit few ribbons that associate with the plasma-membrane exhibit a reduction in voltage-gated calcium current. Interestingly, a small subset of ribbons in Bsn mice associates with the plasma membrane at synapses, and these synapses exhibit more calcium channels than ribbon-less synapses (Frank et al., 2010). The opposite effect on calcium current in Bassoon mice, compared with *refa(Δ10)/b(Δ7)* double-homozygous fish, may indicate that the two proteins interact with and regulate calcium channels differently, with Bassoon influencing overall expression level or channel stability and Ribeye having an effect on channel localization.

Interestingly, several studies have demonstrated that mutations to calcium channel subunits have a reciprocal effect on synaptic ribbon morphology, although the magnitude and specific effects have varied between preparations. For example, a mutation in the zebrafish gene encoding for the alpha subunit of Cav 1.4 channels results in the disappearance of cone synaptic ribbons (Jia et al., 2014), whereas genetic or pharmacological removal of calcium conductance through Cav 1.3 channels increases the size of ribbons in lateral line hair cells (Sheets et al., 2012). In mouse, the genetic removal of Cav1.4 channels prevents the formation of mature synaptic ribbons (Liu et al., 2013; Regus-Leidig et al., 2014a), whereas Cav1.3 is not required for the generation or maturation of auditory hair cell ribbons but is required for proper maintenance of the synapses (Nemzou N et al., 2006).

Effects on Synaptic Transmission

Here, our results show an enhanced continuous phase of exocytosis in animals deficient in Ribeye. Given that there are fewer ghost ribbons than WT ribbons and that most ghost ribbons fail to localize to proper synaptic locations, we suggest that much of this continuous phase of release may arise from extra-ribbon locations. Our results are in line with several imaging and electrophysiological studies that have demonstrated that extra-ribbon release can occur in ribbon-bearing cells during prolonged stimulation (Mehta et al., 2014; Zenisek et al., 2000; Midorikawa et al., 2007; Pangršič et al., 2015; Chen et al.,

2013). We do not suggest, however, that synaptic transmission does not normally occur at ribbon locations in wild-type animals, since direct lines of evidence have firmly established exocytosis at ribbon sites (Vaithianathan et al., 2016; Zenisek, 2008; Chen et al., 2013; Midorikawa et al., 2007).

In contrast to our results here, acute inactivation of the synaptic ribbon using fluorophore-assisted light inactivation (FALI) of ribbon-targeted fluorescent peptides cause the loss of spontaneous and both fast and slow components of evoked release (Mehta et al., 2013; Snellman et al., 2011). Although the peptides used in those studies specifically target Ribeye, FALI generates a sphere of damage likely to also include local bystander proteins associated with the synaptic ribbon. The comparatively mild changes to release properties in cells missing Ribeye implicate these other nearby proteins in functions essential for maintaining focal neurotransmitter release in these cells. Indeed, ghost ribbons maintain a shape and vesicle clusters that resemble WT ribbons, suggesting that many ribbon-resident proteins inhabit these structures in mutant animals. Relatedly, inner hair cells from mice harboring mutations to Bassoon show decreases in both transient (Khimich et al., 2005) and sustained (Frank et al., 2010) components of exocytosis. This comparatively greater effect of Bassoon removal suggests that either Bassoon itself or proteins recruited by Bassoon to ribbons play a more fundamental role in determining release properties from ribbon synapses. Indeed, the genetic disruption of Bassoon causes a change in open probability, reduces channel number, and causes a redistribution of calcium channels in hair cells (Frank et al., 2010). The effect of Bassoon removal must overwhelm any homeostatic compensatory mechanisms that might normally return calcium current to normal levels. In addition to Bassoon, several other proteins already known to have critical functions in conventional synapses have been demonstrated to localize either to the ribbon or the plasma membrane beneath the ribbon (Regus-Leidig and Brandstatter, 2011; tom Dieck et al., 2005).

Surprisingly, despite the loss of efficient coupling between calcium channels and release sites in mutants and reduction in ribbon numbers, we could detect no differences in afferent responses. Spontaneous and evoked release rates at three different frequencies, the latency to first spike and the ability to phase lock were indistinguishable between genotypes. A key difference in capacitance measurements and afferent spike recordings is that afferent recordings are dependent upon exocytosis at specific locations, namely, on to receptors populating afferent fibers, whereas capacitance recordings have no such spatial requirements. As such capacitance measurements reflect both synaptic and extrasynaptic release. Similar to our results, hair cells in mice lacking endogenous calcium-binding proteins show enhanced continuous release, without an effect on afferent responses, consistent with extrasynaptic release contributing significantly to capacitance response (Pangršić et al., 2015). Given that, in the presence of 10 mM EGTA, some exocytosis persists with normal kinetics in mutant animals, we suggest that this EGTA-resistant component represents the subset of vesicles, which is properly localized near calcium channels, and could be sufficient to drive afferent neuron spiking to near normal levels for afferents that receive synaptic input. It

should be noted that, to perform afferent recordings, one first identifies and selects for synaptically connected neurons before performing experiments. Thus, recordings represent only those neurons, which generate spikes in response to mechanical stimuli to hair cells, and cannot account for cells that lack synaptic connections. These results suggest that when synapses with ghost ribbons are formed, they respond to stimuli normally under the conditions we tested. It should also be noted that while the stimulus frequencies we tested here are typical or slightly higher for neuromast hair cells, auditory hair cells of the inner ear respond to much higher frequencies and exhibit faster kinetics and greater demands on neurotransmitter release. Because of this, the faster hair cells of other systems may show greater defects in the absence of Ribeye.

EXPERIMENTAL PROCEDURES

Zebrafish Husbandry

Zebrafish were kept in accordance with the Yale University Animal Care and Use Committee guidelines.

Generation of *ribeye a* Mutant Fish

Ribeye a mutant fish were generated using zinc finger nucleases (ZFNs) targeting the A-domain of Ribeye a (ENSDARG00000044062) purchased from Sigma-Aldrich. mRNAs encoding the ZFNs were injected into one-cell-stage embryos, and progeny were screened for mutations. Mutants (Figure S1) were selected for breeding to generate homozygous mutants. Detailed experimental procedures are provided in the Supplemental Experimental Procedures.

Generation of *ribeye b* Mutant Fish

CRISPR/Cas9-induced mutagenesis procedures were adapted from previously published reports (Hruscha et al., 2013) and are detailed in the Supplemental Experimental Procedures. Single guide RNAs (sgRNAs) were designed to target to the Ribeye-specific A-domain of *ribeye b*. Several mutant lines were identified and selected for further study (Figure S2).

EM and Immunofluorescence

Procedures were adapted from standard previously published experimental protocols (Obholzer et al., 2008; Lv et al., 2012) and are detailed in the Supplemental Experimental Procedures.

Hair-Cell Voltage-Clamp Recordings

Whole-cell voltage-clamp recordings were carried out from neuromast hair cells in anesthetized live zebrafish (5–7 dpf), as previously described (Ricci et al., 2013). Details can be found in the Supplemental Experimental Procedures.

Afferent Neuron Recordings

Loose-patch recordings from soma of afferent neurons were made on anesthetized and paralyzed larval zebrafish as previously described and detailed in the Supplemental Experimental Procedures (Levi et al., 2015).

Statistical Analysis

Data are presented as mean \pm SEM. Statistical significance across datasets was determined using the unpaired two-tailed t test. Significance was considered $p < 0.05$; however, for most comparisons in the present study, $p < 0.01$.

SUPPLEMENTAL INFORMATION

Supplemental Information includes Supplemental Experimental Procedures and two figures and can be found with this article online at <http://dx.doi.org/10.1016/j.celrep.2016.05.045>.

Supplemental Experimental Procedures:

Zebrafish husbandry

Zebrafish were kept in accordance with the Yale University Animal Care and Use Committee guidelines.

Generation of *ribeye a* mutant fish

ZFN pairs recognizing the target sequence:

ATCGGCCGATCCCAGAGCTTGGGACACGCTGGGTGGGAATGAG (underline

indicates the cut site), in the coding region of the A-domain of *ribeye a*. were designed by and purchased from Sigma Aldrich. Plasmids containing the DNA sequences encoding the ZFN left and right arrays were linearized by digestion with XbaI and purified using the Qiaquick PCR purification kit (Qiagen). mRNA encoding the left and right arrays was synthesized using the mMessage mMachine T7 Ultra kit (Ambion), according to the manufacturer's protocol, and purified using the RNeasy kit (Qiagen)

mRNA encoding left and right ZFN arrays (50-200 pg) was injected into zebrafish embryos at the one-cell stage. To evaluate the efficiency of ZFN, the Genomic DNA was isolated from 10 ZFN-injected embryos lacking severe developmental defects at 24 hpf and the ZFN target region was amplified by PCR (upstream primer:

TTCCTTACACCACTTGACATCAGC, downstream primer:

CTATTGGTGGTCGGTCATAATGGC) and subcloned into the TOPO-TA vector

(Invitrogen). A total of 100 colonies were selected and colony PCR followed by high-resolution fragment analysis of groups of 3 colonies was used to detect insertion-deletion mutations.

ZFN-injected fish were raised to adulthood and in-crossed. Founders (F0) were identified as in (Cifuentes et al. 2010) with some modifications. Briefly, genomic DNA was isolated from ~30 embryos from each cross. PCR of the ZFN target region followed by high-resolution fragment analysis of groups of 2 embryos was used to identify indels. 6 adults were screened and 5 founders carrying frameshift indels were identified. Sequences were confirmed by amplifying the target region, cloning the PCR product into the TOPO-TA vector (Invitrogen), and Sanger sequencing of plasmids using M13F/R primers. High-resolution fragment analysis results were analyzed using GeneMarker software (SoftGenetics).

Generation of *ribeye b* mutant fish

CRISPR introduced knockout procedures were adapted from previously published papers (Hruscha et al. 2013; Huang and Tan 2013; Hwang et al. 2013; Jao et al. 2013). Briefly, chimeric guide RNA Oligos (TAGGCCGGCTGACAGGACTCCA, AAAGTGGAGTCCTGTCAGCCGG) targeting at zebrafish *ribeye b* (PubMed: 15673675) (GGCCGGCTGACAGGACTCCA) were designed by ZiFit Target Website (<http://zifit.partners.org>) (Sander et al. 2010; Sander et al. 2007). Two oligos were annealed and cloned into T7cas9sgRNA2 vector (Addgene) (Jao et al. 2013). Plasmids containing the guide RNA sequences were linearized by digestion with BamHI and purified using the Qiaquick PCR purification kit (Qiagen). Short mRNA was synthesized using the MEGAshortscript T7 kit (Ambion/Invitrogen), according to the manufacturer's protocol, and purified using the *mir*Vana miRNA Isolation Kit (Ambion/Invitrogen).

Zebrafish optimized vector pCS2-nls-zCas9-nls (Addgene) was used to generate the Cas9 mRNA as previously described (Jao et al. 2013).

About 1 nl of 0.05% phenol red, 120 mM KCl, and 20 mM HEPES, pH 7.0, 150 ng/μl of *nls-zCas9-nls* RNA, and 75 ng/μl of gRNA were injected into the embryos at 1-cell-stage. The T7E1 assay and NgoMIV enzyme digestion were used to evaluate the efficiency. Fish were screened as described for ZFN introduced *ribeye a* mutant. The primers used for fragment analysis are: 5'CTATCCCGGTCACTCCATTC3' (upstream), and 5'GCATCCTTTGAGTCACCACA3' (downstream).

Electron Microscopy

Electron microscopy protocols were adapted from previously published protocols (Obholzer et al. 2008). Briefly, 4-6 dpf zebrafish larvae were fixed overnight in 3% glutaraldehyde and 1.5% paraformaldehyde in 0.1M phosphate buffer on ice for 10 minutes and then overnight at room temperature. After rinsing in 0.1M PBS, samples were stained with 1% osmium, dehydrated in serial washes of 50%, 80%, 95% and then 100% ethanol. Fish were embedded in EMbed-812 (EMS). Hair cells from arterial neuromasts were imaged on Tecnai Biotwin electron microscope.

Measurement of vesicle size

To measure the size of vesicles, a blinded observer drew a region of interest (ROI) using ImageJ around each vesicle associated judged to be associated with every ribbon or ghost-ribbon. The area for each ROI encompassing a vesicle was calculated. Since

vesicle profiles were nearly circular, an effective radius was calculated assuming a circular area for each vesicle.

Immuno-fluorescence

For retina slides staining, similar as previously published (Lv et al. 2012), 5 dpf zebrafish larval were anaesthetized and fixed in 4% paraformaldehyde in PBS and embedded in optimal cutting temperature compound (Sakura, Tokyo, Japan). Cryosections (12 μ m thick) on polylysine-coated slides were permeabilized in blocking buffer (BB) consisting of 1% bovine serum albumin (v), 3% normal goat serum (v/v), and 0.1% Triton X-100 in PBS at room temperature for 30 min, followed by overnight incubation with primary antibodies diluted in blocking buffer at 4°C, then 2 hours secondary antibodies incubation at room temperature. The primary antibodies used for CtBP (CtBP (H-440, Santa Cruz, USA) and MAGUK (Neuromab) were diluted 1:500. Ribeye A and Ribeye B antibodies (both generously provided by Teresa Nicolson, Oregon Health Sciences Center) were diluted 1:2000 (Sheets et al. 2011). The secondary antibodies (Alexa Fluor 488/568 goat anti mouse/rabbit IgG(H+L), Molecular Probes, USA) were diluted 1:200.

The whole mount staining for neuromast hair cells was carried out in a manner similar to a previously reported protocol (Sheets et al. 2011). 5dpf zebrafish larvae were fixed in 4% paraformaldehyde in phosphate buffer for 6 hours at 4°C, permeabilized using acetone for 5 minutes at -20°C, and blocked with blocking buffer containing 2% goat serum, 1% bovine serum albumin (BSA), and 1% dimethyl sulfoxide (DMSO). Samples were incubated in a solution containing primary antibodies overnight at 4°C. Primary antibodies CtBP (CtBP (H-440, Santa Cruz, USA) and MAGUK (Neuromab) were

diluted 1:500 in blocking buffer. Ribeye A and Ribeye B and CaV1.3a antibody was diluted 1:1000 (all donated by Dr. Teresa Nicolson, Vollum Institute, Portland, OR). The secondary antibodies (Alexa Fluor 488/568 goat anti mouse/rabbit IgG(H+L), Molecular Probes, USA) were diluted 1:500.

Confocal images were acquired with a Zeiss (Germany) LSM 780 laser-scanning confocal using Plan-Apochromat 63x/1.40 Oil DIC M27 objective and 0.6x, 3x or 3.5x digital zoom. Alexa Fluor 488 samples were imaged using a 488 nm Argon laser for excitation. DAPI fluorescence was excited using a 405 nm diode laser. Alex-568 samples were images using a laser DPSS 561 nm. The filter sets for DAPI are 405nm excitation and 420-500nm emission, Alexa Fluor 488 are 488nm excitation and 495-555nm emission, and Alex-568 are 561nm excitation and 580-680nm emission using the “best signal scanning” software feature to optimize image acquisition parameters. Images of 512x512 pixels were acquired at a plane scanning mode with 4 line averages. Images were stored as 8-bit RGB tif files for further analysis and processing. Neuromast hair cell images are taken by z-stack, with 0.5-1 μm interval over 9-12 μm . Digital images were processed by Image J and Photoshop software.

Quantitative image analysis was performed on raw images using Amira 3D Analysis software. Prior to analysis, 7 μm^2 region containing the highest level of background was selected from a max-intensity projection of each stack, and the average-fluorescence intensity of that region was subtracted from each pixel in the stack. To quantitatively measure immunolabel intensity, a user-defined inclusive threshold was applied to isolate pixels occupied by Ribeye, CtBP, or MAGUK immunolabeled punctae. The inclusive threshold values for each label were determined using 3D isosurface renderings, with the

minimum threshold value defined as the value above which the user could resolve two closely adjacent spheres or patches. The Material Statistics function was then used to measure the cumulative intensity of fluorescent pixels (sum of the grayscale values) within each individual sphere or patch as well as define the x,y,z coordinates of the center of each puncta within the stack.

Hair Cell voltage clamp recordings

Hair cell recordings were performed as previously described (Ricci et al. 2013). Briefly, zebrafish of either sex ranging in age from 5 to 8 days post-fertilization (dpf) were anesthetized in Tricaine and paralyzed using Tubocurarine, mounted in a recording chamber and tied down using dental floss. An upright Olympus microscopy was used for viewing, and recordings were made with an Axon 200B amplifier with an Axon DD1322 digitizer. To access hair cells for whole-cell recordings, supporting cells surrounding the hair cells were first removed and cleaned using a large bore pipette (3-5M Ω). All recordings were made with jClamp software (Scisoft (www.scisoftco.com), Ridgefield, CT). Cells were held at a membrane potential of -80 mV. Extracellular solution was as follows (in mM): 125 NaCl, 1.0 KCl, 2.2 MgCl₂, 2.8 CaCl₂, 10 HEPES, 6 D-glucose, 285 mOsm, pH 7.6. Pipette solution was (in mM): 90 CsCl, 20 TEA, 5Na₂ATP, 3.5 MgCl₂, 10 HEPES, 1 or 10 EGTA, pH 7.2. The osmolarity was adjusted to 260 mOsm by diluting with water or addition of CsCl. Pipette resistance was typically 9-10M Ω with Cs pipette solutions. Capacitance measures were made using the dual sine admittance technique (Santos-Sacchi 2004). Recordings were made at room temperature. Capacitance data were smoothed by averaging 10 adjacent points in time before

averaging across cells. To measure the current-voltage relationship, hair cells were subjected to 50 ms voltage steps from a holding potential of -80 mV to membrane potentials ranging from -120 mV up to +20 mV in 10 mV increments.

Afferent neuron recordings

Electrophysiological recordings of afferent neurons were conducted on 4-6 dpf larvae. Prior to experiments, larvae were paralyzed by immersion in 1 mg/ml α -bungarotoxin (Sigma) in 10% Hank's solution. Larvae were then placed in a Sylgard-bottom dish containing extracellular solution (134 mM NaCl, 2.9 mM KCl, 1.2 mM MgCl₂, 2.1 mM CaCl₂, 10 mM glucose, 10 mM HEPES buffer, adjusted to a pH of 7.8 with NaOH) and positioned on their side by pinning them through the notochord with four etched tungsten pins.

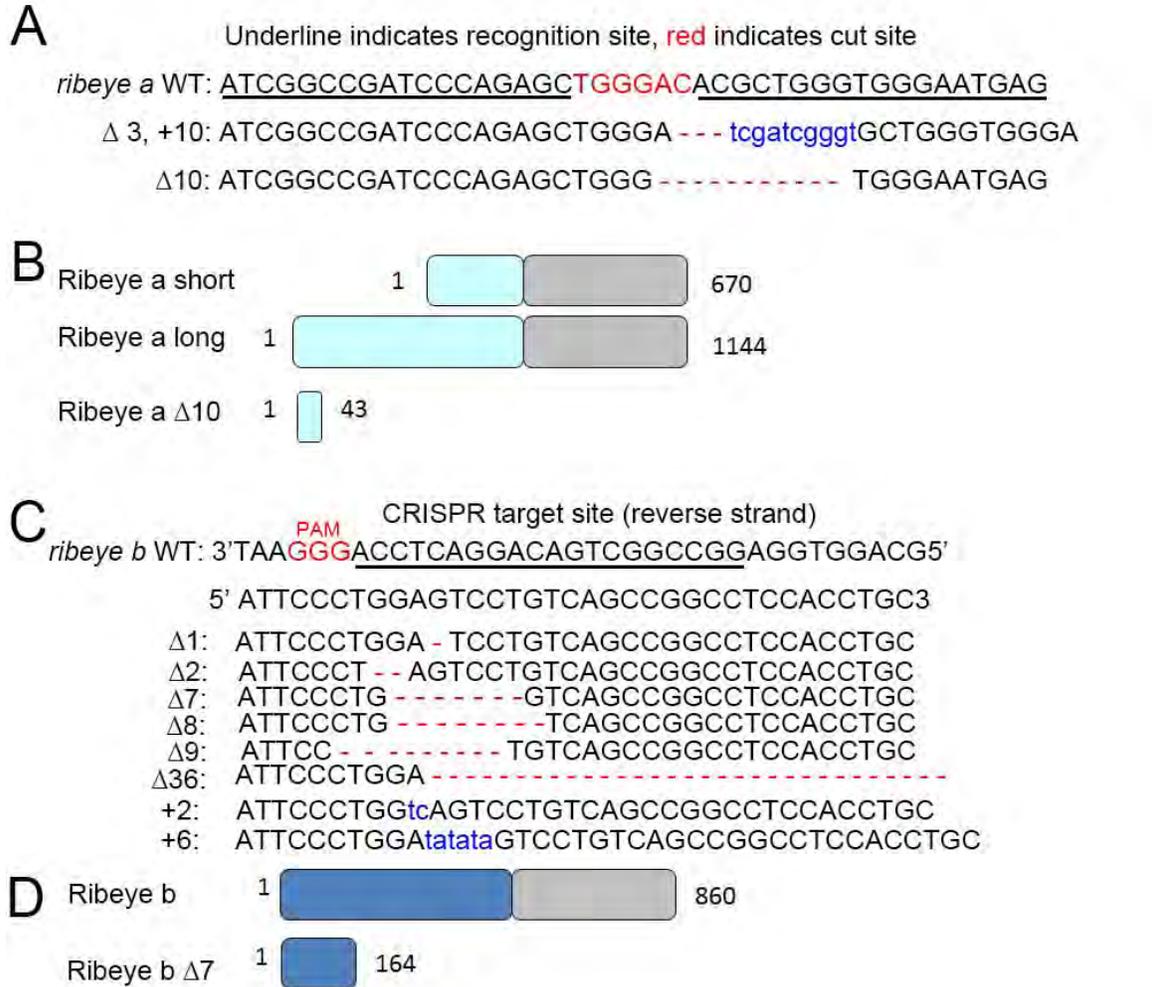

We deflected individual neuromasts of the posterior lateral line system in the zebrafish larvae. To stimulate a neuromast, the visible hair cell bundle (e.g., kinocilia) was deflected with a glass pipette attached to piezoelectric stimulator (30v300 model, Piezosystem, Jena, Germany; Figure 1A). The device was driven by an analog output from Digidata 1440A (Molecular Devices, Sunnyvale, CA). We deflected each neuromast for 10 seconds with sine wave stimuli at frequencies of 2, 30 and 60 Hz, which is within the frequency selectivity of superficial neuromasts (Levi et al., 2014). All stimulation protocols employed a constant amplitude of 50 μ m which was sufficient to evoke a reliable afferent response without visibly damaging the neuromast. The glass pipettes for stimulation were pulled from borosilicate glass (model G150-F-3; inner diameter, 0.86 mm; outer diameter, 1.5 mm; Warner Instruments) on a model P-97

Flaming/Brown micropipette puller (Sutter Instrument). The tip of the pipette was flame-polished to produce a spherical end that was approximately 75 μm in diameter.

Extracellular loose-patch recordings were made from the somata of single posterior lateral line afferent neurons. Patch electrodes were pulled from borosilicate glass (model G150-F-3; inner diameter, 0.86 mm; outer diameter, 1.5 mm; Warner Instruments) to 5–7 $\text{M}\Omega$ resistances on a model P-97 Flaming/Brown micropipette puller (Sutter Instrument). Neuronal activity was amplified with Axoclamp 770B (Molecular Devices, Sunnyvale, CA) at 10 kHz and gain of 1,000 in AC mode and then filtered between 300 Hz and 6 kHz. The signal was digitized with Digidata 1440A and saved with pClampv10 (Molecular Devices, Sunnyvale, CA). To find the neuromast that was connected to the recorded afferent neuron, we systematically stimulated neuromasts down the rostro-caudal axis of the body until we observed elicited spike responses. The afferent response to sine wave stimulation was quantified in terms of spike rate (number of spikes s^{-1}) and vector strength (phase locking between a periodic stimulus and a response) over the course of the 10 second stimulation, using the same procedure as in Levi et al, 2014. We calculated the latency of the afferent neuron's response as the delay in time between the onset of stimulation and the first spike. Recordings from 5 wt animals and 6 mutant animals were included for analysis.

Supplemental Figures:

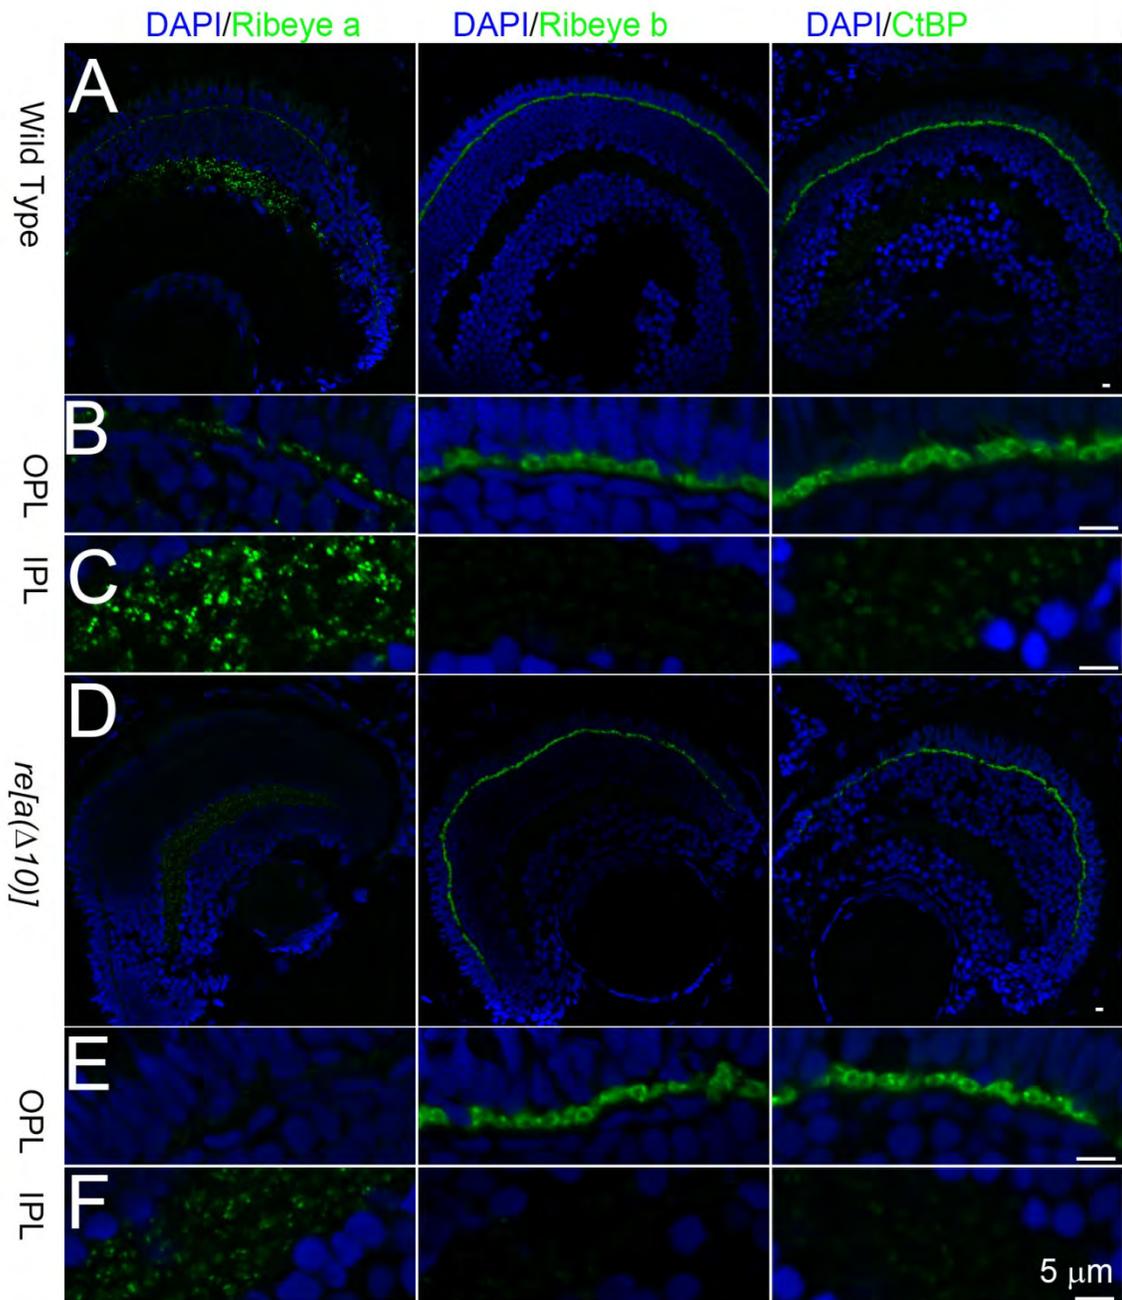

Supplemental Figure S1, related to Figure 1 and Experimental Procedures:

Supplemental Figure 1: Generation of Ribeye A and Ribeye B mutants. A, Alignment of wt and two mutant *ribeye a* genomic sequences showing the ZFN-induced mutations at the first exon. Underlines are ZFN recognition sites, and red letters are FokI enzyme cutting site. Red dashes are the nucleic tides missing, and blue letters are insertions. B, Schematic of Ribeye A and $\Delta 10$ mutation protein. Cyan indicates A domain, and grey indicates B domain. The deletion of 10 nucleic tides in $\Delta 10$ mutation cause a premature

stop codon, which make a very small protein with 43 amino acids. C, Alignment of wt and mutant *ribeye b* genomic sequences showing the CRISPR/Cas9-induced mutations at the first exon. Underlines are CRISPR guide RNA recognition site, and red letters show PAM. Red dashes are the nucleic tides missing, and blue letters are insertions. D, Schematic of Ribeye B and $\Delta 7$ mutation protein. Cyan indicates A domain, and grey indicates B domain. The deletion of 7 nucleic tides in $\Delta 7$ mutation cause a premature stop codon, which make a small protein with 164 amino acids.

Supplemental Figure 2, related to Figure 1 and Experimental Procedures

Supplemental Figure 2: Expression of Ribeye A, Ribeye B nor CtBP in 5dpf wt and ribeye a $\Delta 10$ retina. A, Confocal images of Ribeye A, Ribeye B, and CtBP staining (green) in 5dpf wt zebrafish retina. B, 3X magnification of outer plexiform layer staining

in wt 5dpf zebrafish retina. C, 3X magnification of inner plexiform layer staining in wt 5dpf zebrafish retina. D, Confocal images of Ribeye A, Ribeye B, and CtBP staining (green) in 5dpf *ribeye a* Δ 10 mutant fish retina. E, 3X amplification of outer plexiform layer staining in 5dpf *ribeye a* Δ 10 mutant fish retina. Notice the dramatic reduction of Ribeye A staining in *ribeye a* Δ 10 mutant fish. F, 3X magnification of inner plexiform layer staining in 5dpf *ribeye a* Δ 10 mutant fish retina. DAPI (blue) stains nucleus. WT and mutant fish were taken under the same settings for the same antibody. Scale bar is 5 μ m.

Received March 17, 1986; revision received May 28, 1986

Coronal sections through the eighth cranial nerve and medulla of the red-eared turtle were immunocytochemically stained for the astrocytic intermediate filament protein, glial fibrillary acidic protein. Reaction product appeared in the medial one-third of the eighth cranial nerve fibers as they penetrated the medulla. The remaining two-thirds of the nerve did not show any staining for glial fibrillary acidic protein. The lateral aspect of the nerve corresponds with the extracranial portion of the nerve. When the eighth cranial nerve of the turtle has been transected extracranially it still regenerates into the cochlear nuclei. Results of the present study indicate that the eighth cranial nerve was transected in earlier studies in a region devoid of astrocytes. © 1986 Academic Press, Inc.

INTRODUCTION

The glial dome (transition zone) (4, 9, 18, 23, 25) is found at the boundary between the central and the peripheral portions of a nerve. It is composed of subpial astrocytes, their processes, and basal laminae (4, 9, 25). Some investigators (18, 21, 23, 26) believe that elongating axons are unable to penetrate the transition zone and that this prevents successful regeneration. The ability of the eighth cranial nerve of the red-eared turtle to regenerate into the cochlear nuclei following transection was recently demonstrated (14-17). In those experiments, the nerve was transected extracranially between the audi-

Abbreviations: GFAP—glial fibrillary acidic protein; PBS—phosphate-buffered saline.

¹ This work was supported by a Research Career Development Award (J.S.S.) from the National Institute of Neurological and Communicative Disorders and Stroke and grants from the Deafness Research Foundation, the Foundation of the UMDNJ, and the National Institutes of Health (NS 21380-01).

tory ganglion cells and the medulla. However, it is not known where the eighth cranial nerve was transected in relation to the glial dome.

Understanding the phenomenon of eighth nerve regeneration requires identifying the glial dome; the interaction between elongating axons and their microenvironment at the site of injury is important (2, 11, 13, 29). The position of the lesion site relative to the transition area has different implications. If the nerve was axotomized in its central nervous system extent, regenerating axons would have elongated through a microenvironment of astrocytes, as occurs in amphibia (5, 22, 23). If the eighth nerve was transected in its peripheral nervous system portion, regenerating fibers would have been led initially by Schwann cells and their basal laminae, as in other systems (1, 6, 10, 11, 13) to the glial dome. Here, regenerating axons would have projected through the transition zone to enter the central nervous system.

In the rat (9, 19, 24), the auditory nerve is separated into a long central nervous system segment and a relatively short peripheral nervous system segment by a glial dome situated at the base of the modiulus. The location of the transition zone of the eighth nerve of the red-eared turtle has not yet been characterized. By using astrocytes as markers for the central nervous system portion, the location of the transection site relative to the glial dome may be determined. The present study labeled astrocytes of turtles' eighth cranial nerves immunocytochemically for the cytoplasmic intermediate filament protein, glial fibrillary acidic protein (GFAP).

MATERIALS AND METHODS

Six turtles, *Chrysemys scripta elegans*, weighing 250 to 450 g were overdosed with an intrathoracic injection of sodium pentobarbital (Sigma). When a suitable areflexic state was obtained, the plastron was drilled open and the heart exposed. Turtles were perfused transcardially with reptilian Ringer's (28) followed by a fixative solution (20) of 2% paraformaldehyde, 0.3% glutaraldehyde, 0.2% picric acid in 0.1 M phosphate-buffered saline (PBS), pH 7.6. Brains with eighth nerves intact were removed and placed overnight in a postperfusion fixative solution (20) of 2% paraformaldehyde and 0.2% picric acid in PBS. Specimens were then washed 3 h in a 15% sucrose PBS solution. Brains were frozen-sectioned at 20- μ m intervals on a freezing stage (Baileys) at -40°C , mounted on a microtome (A O Reichart). The sections were washed in a solution (20) of 0.3% Triton X-100 (Fluka) for 3 days.

Turtle brain sections were reacted for GFAP according to the peroxidase-antiperoxidase technique of Sternberger *et al.* (27) as modified by Oteniente *et al.* (20). Sections through the turtle medulla and the eighth cranial nerve

were preincubated 1 h in normal swine serum (Dako Corp., 1:200). After rinsing three times in 1 h in a solution of 0.01% Triton X-100 (Fluka) in PBS, the sections were incubated 4 days at 4°C in rabbit antiserum to bovine GFAP (Dako Corp., 1:2000). Control sections were simultaneously incubated 4 days with nonimmune serum (Dako Corp., 1:2000) at 4°C. Specimens were rinsed three times in 1 h in a solution of 0.01% Triton X-100 (Fluka) in PBS and incubated 2 h in swine antiserum to rabbit immunoglobulin (Dako Corp., 1:200). Following three rinses during 1 h in a solution of 0.01% Triton X-100 (Fluka) in PBS, the sections were incubated 30 min in soluble horseradish peroxidase-rabbit anti-horseradish peroxidase complex (Dako Corp., 1:800). Brain sections were washed three times in 0.01% Triton X-100 (Fluka) in PBS and then placed 15 min in a reaction solution of 0.025% 3,3-diaminobenzidine with 0.005% hydrogen peroxide in 0.05 *M* Tris buffer (pH 7.6). Reacted specimens were washed 20 min in PBS and mounted on slides subbed with gelatin-chrome alum. After air drying 1 h, mounted sections were dehydrated in a graded series of ethanol and coverslipped with permount (Fisher Scientific Corp.)

RESULTS

Coronal sections of the eighth cranial nerve and the medulla of turtles were immunocytochemically reacted for GFAP. Positively stained astrocytic processes were present in the eighth cranial nerve as it penetrated the medulla and continued extending laterally (Fig. 1). Many long, slender (<1.0 μm in diameter) fibers paralleled the eighth cranial nerve axons (Fig. 2). Branching was evident (Fig. 2) among the stained processes. No GFAP reaction product was demonstrated in control sections stained with nonimmune serum (Fig. 3).

On closer examination, reaction product appeared in cell bodies of astrocytes among the axonal fibers of the eighth cranial nerve (Fig. 2). Cell bodies were round to oval and between 6 and 14 μm in length. Multiple processes projected either bipolarly or in any plane (Fig. 2) from the astrocytic cell bodies.

Glial fibrillary acidic protein-stained structures were present only in the medial one-third of the eighth cranial nerve (Fig. 1). Immunocytochemical reaction product disappeared at the lateral two-thirds of the length of the eighth cranial nerve (Fig. 1), the extracranial extent of the nerve (Fig. 1).

Coronal sections of the medulla and the eighth cranial nerve of mice were also stained for GFAP immunoreactivity (unpublished data). Positively stained astrocytic intermediate filaments were present along the mouse eighth cranial nerve to the base of the modiolus. These findings complement the electron microscopic observations (9, 19, 24) of the eighth cranial nerve of the rat.

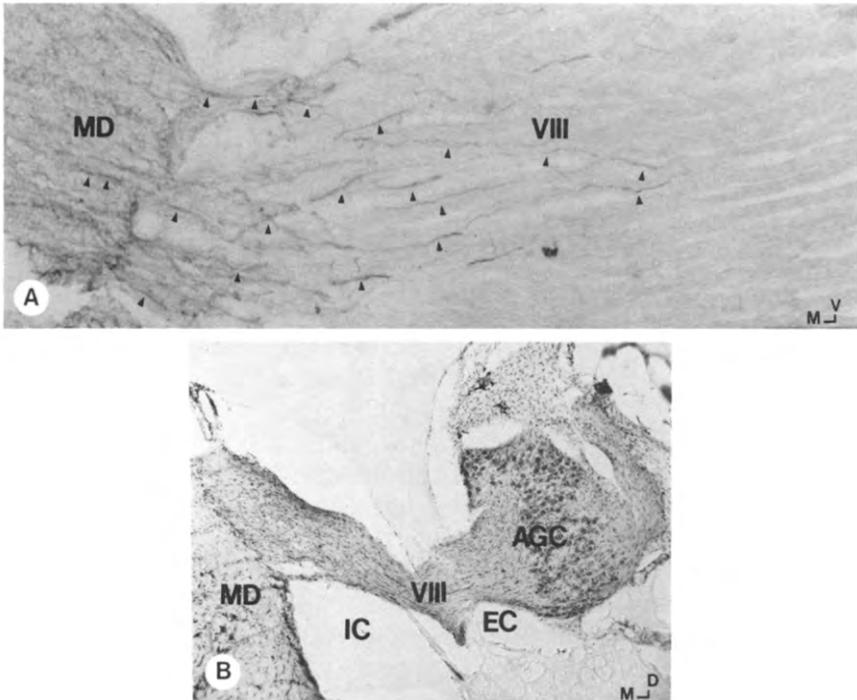

FIG. 1. A—glial fibrillary acidic protein (GFAP)-stained fibers (arrowheads) are evident in this coronal section through the eighth nerve (VIII) and the medulla (MD) of the red-eared turtle. Many positively stained processes parallel the VIII nerve axons. Immunocytochemical reaction product appears in the medial one-third of the nerve; this corresponds to a portion of the intracranial extent of the auditory nerve (VIII) (refer to B) $\times 195$; M, medial; V, ventral. B—the intra and extracranial (EC) portions of the VIII cranial nerve of the red-eared turtle are clearly delineated in this coronal section through the medulla (MD) and the nerve. Sections of turtle brain stained for GFAP (refer to A) contain reaction product in the medial one-third of the auditory nerve, i.e., intracranially (IC). Cresyl violet, $\times 60$; AGC, auditory ganglion cells; M, medial; D, dorsal.

DISCUSSION

Turtle astrocytes contain GFAP (7, 8, 20) similar in molecular weight and amino acid composition (7) to that of mammals. Although differences in peptide mapping (7) and immunological properties (7, 8) exist between turtle and mammalian GFAP, turtle astrocytic intermediate filament protein (7, 8) cross-reacts with antimammalian GFAP sera. Results of the present study confirm earlier reports (7, 20) of turtle astrocytic immunocytochemical staining with antimammalian GFAP sera. Biochemical (7) and many immu-

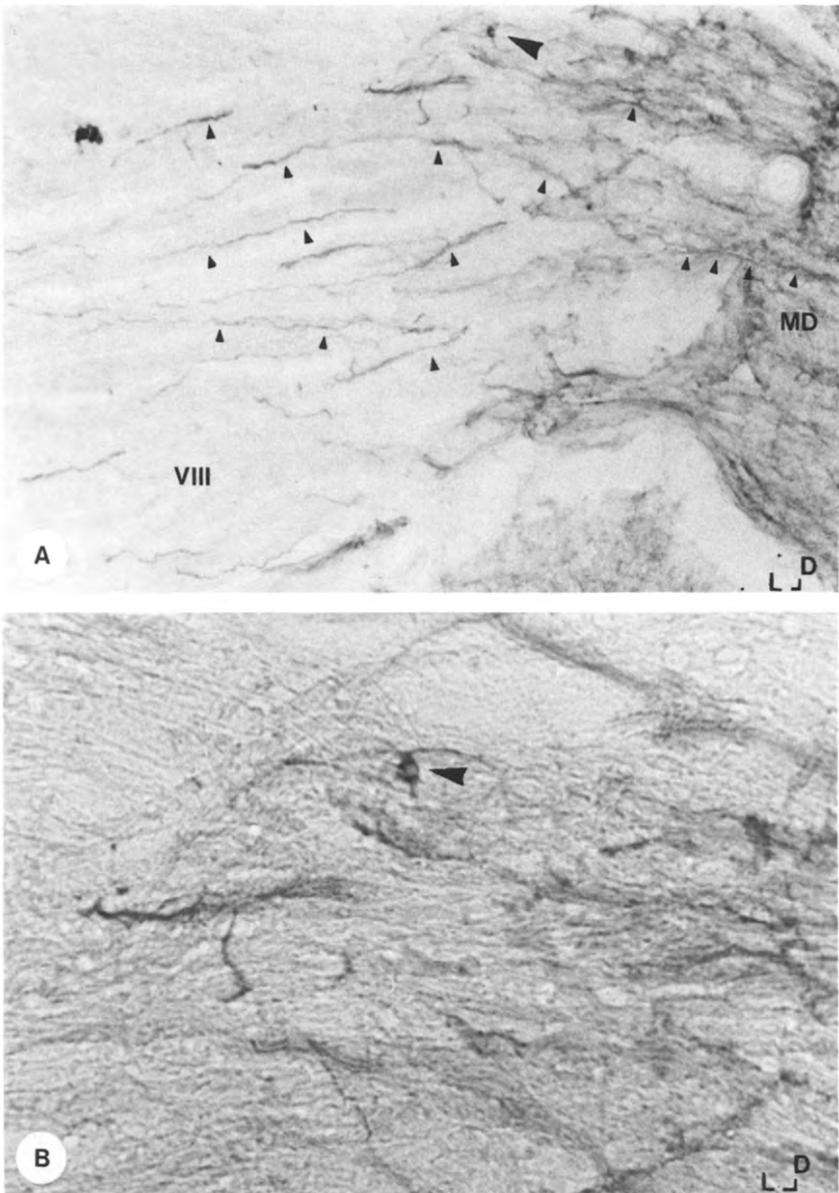

FIG. 2. A—GFAP stained processes are demonstrated in this coronal section through the VIII nerve and the medulla (MD) of the red-eared turtle. Branching is evident among the astrocytic fibers containing reaction product (small arrowheads). A stained astrocytic cell body (large arrowhead) lies among the axons of the VIII nerve $\times 160$; L, lateral; D, dorsal. B—at higher magnification ($\times 395$), the immunocytochemically stained astrocyte cell body (arrowhead) appeared round. Multiple processes appeared to be projecting from any plane of the glial cell. L, lateral; D, dorsal.

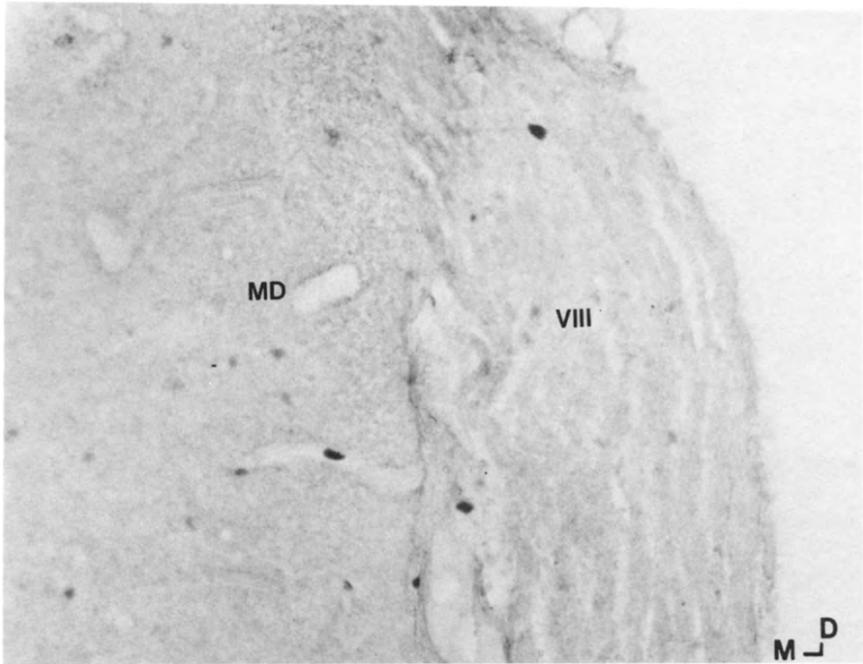

FIG. 3. No GFAP reaction product was demonstrated in this coronal section of turtle eighth nerve (VIII) and medulla (MD) incubated with nonimmune rabbit serum $\times 150$; M, medial; D, dorsal.

nological properties (7, 20) of GFAP have remained stable through the phylogenetic development from turtle to mammal.

Astrocytes are a major glial element of the reptilian central nervous system (12). The presence of astrocytes identifies a region of neural tissue as central. The extracranial portion of the turtle eighth cranial nerve lacks astrocytes and is therefore of peripheral nervous system origin. It is now clear that in earlier studies (14–17) the eighth cranial nerve was transected in its peripheral nervous system extent. It is significant that when the eighth cranial nerve of the turtle is axotomized extracranially (i.e., in its peripheral extent) it still regenerates into the cochlear nuclei in the medulla. Presumably regenerating eighth cranial nerve fibers were guided initially by Schwann cells and their basal laminae to the transition zone; regenerating axons then projected through the glial dome to enter the central nervous system.

The precise location of the glial dome in the eighth cranial nerve of the reared turtle was not identified in the present study; the intracranial astrocytic processes and scattered cell bodies indicate the general site of the transition

zone. Perhaps simultaneous immunocytochemical staining of the turtle eighth nerve with laminin and GFAP antisera (3) would demonstrate the glial dome more clearly, labeling peripheral and central nervous system elements. Electron microscopic examination of the intracranial extent of the turtle eighth cranial nerve also would determine the exact location of the glial dome and complement the data.

The A1555G mutation in the 12S rRNA gene of human mitochondrial DNA causes maternally inherited, nonsyndromic deafness, an extreme case of tissue-specific mitochondrial pathology. A transgenic mouse strain that robustly overexpresses the mitochondrial 12S ribosomal RNA methyltransferase TFB1M (Tg-mtTFB1 mice) exhibits progressive hearing loss that we proposed models aspects of A1555G-related pathology in humans. Although our previous studies of Tg-mtTFB1 mice implicated apoptosis in the spiral ganglion and stria vascularis because of mitochondrial reactive oxygen species-mediated activation of AMP kinase (AMPK) and the nuclear transcription factor E2F1, detailed auditory pathology was not delineated. Herein, we show that Tg-mtTFB1 mice have reduced endocochlear potential, indicative of significant stria vascularis dysfunction, but without obvious signs of stria atrophy. We also observed decreased auditory brainstem response peak 1 amplitude and prolonged wave I latency, consistent with apoptosis of spiral ganglion neurons. Although no major loss of hair cells was observed, there was a mild impairment of voltage-dependent electromotility of outer hair cells. On the basis of these results, we propose that these events conspire to produce the progressive hearing loss phenotype in Tg-mtTFB1 mice. Finally, genetically reducing AMPK $\alpha 1$ rescues hearing loss in Tg-mtTFB1 mice, confirming that aberrant up-regulation of AMPK signaling promotes the observed auditory pathology. The relevance of these findings to human A1555G patients and the potential therapeutic value of reducing AMPK activity are discussed. (*Am J Pathol* 2015, 185: 3132–3140; <http://dx.doi.org/10.1016/j.ajpath.2015.08.014>)

Mitochondria are essential organelles that produce ATP via the process of oxidative phosphorylation, but are multifunctional, playing additional key roles in metabolism, as well as other cellular processes like apoptosis, inflammation, and signal transduction.^{1–4} Human mitochondria possess a 16,565-bp circular genome that is maternally inherited and present at hundreds to thousands of copies per cell in most tissues.⁵ In mammals, mitochondrial DNA (mtDNA) encodes 13 oxidative phosphorylation complex subunits and the two rRNAs and 22 tRNAs needed for translation of these by dedicated mitochondrial ribosomes.⁶ All other components of the estimated 1200-member mitochondrial proteome, including the remaining 70 to 75 oxidative phosphorylation subunits and all of the factors needed for mtDNA replication and expression, are encoded by nuclear genes and imported into the organelle.⁷ Thus, signaling pathways between mitochondria and the nucleus are

required to coordinate the biogenesis, composition, and activity of mitochondria and to trigger homeostatic nuclear gene expression responses to mitochondrial dysfunction. These responses can be beneficial or harmful, depending on the precise cellular context and, to date, remain poorly understood.

Mitochondrial dysfunction causes human diseases, with an estimated occurrence of 1 in 5000 to 10,000 live births.^{8–10} These can be inherited maternally, because of mutations in mtDNA, or in a Mendelian manner, because of mutations in

Disclosures: None declared.

nuclear genes encoding mitochondrial components. Because mtDNA is present in multiple copies per cell, and different organs vary in their energy requirements, mitochondrial diseases are complicated and heterogeneous, characterized by cell- and tissue-specific responses and pathology.^{2,8–10} An extreme example of tissue specificity is the A1555G mtDNA mutation that causes maternally inherited deafness. This mutation causes a progressive, nonsyndromic hearing loss that can vary from mild to profound and has a variable age of onset.^{11,12} A1555G carriers can also be predisposed to aminoglycoside-induced deafness.¹³ Hearing loss induced by A1555G is incompletely penetrant, which has been attributed, at least in part, to multiple nuclear and mtDNA modifying loci.^{11,14,15} One such nuclear modifier is the *TFB1M* gene, which encodes an RNA methyltransferase that post-transcriptionally modifies the mtDNA-encoded 12S rRNA in mitochondrial ribosomes.¹⁶

The A1555G mutation is located near a highly conserved stem loop in the 12S rRNA that contains adjacent adenines that are dimethylated by TFB1M. We showed previously that patient-derived A1555G cybrid cell lines exhibit increased stem-loop dimethylation and/or increased amounts of 12S rRNA methylated at this site.^{17,18} These cells also exhibited enhanced apoptotic susceptibility in culture^{17,18} because of mitochondrial reactive oxygen species (ROS)–dependent activation of 5′-AMP–activated protein kinase (AMPK) that unmasks the pro-apoptotic function of the nuclear transcription factor E2F1. These phenotypes are recapitulated in cell lines that overexpress the TFB1M methyltransferase in the absence of the A1555G mutation. TFB1M binds to the mitochondrial RNA polymerase (POLRMT) in the context of mitochondrial ribosomes to promote proper 12S rRNA methylation and ribosome biogenesis.¹⁹ Thus, disruption of these interactions in the mature ribosome or during ribosome assembly may cause unique perturbations in mitochondrial homeostasis and increased ROS production that promote deafness. How this unique mitochondrial perturbation leads to tissue-specific pathology remains unknown.

Consistent with the above pathogenic mechanism, we showed that transgenic mice that globally overexpress TFB1M (Tg-mtTFB1) exhibit premature hearing loss in an E2F1-dependent manner.¹⁸ These mice have the increased 12S rRNA methylation signature and AMPK up-regulation in multiple tissues, as well as increased caspase 3 staining and E2F1 up-regulation in two tissues in the inner ear, the stria vascularis and spiral ganglion neurons. This suggested that deafness in Tg-mtTFB1 mice is induced by a pro-apoptotic, mROS-AMPK-E2F1 pathway similar to the one we delineated in the A1555G patient cybrids, making Tg-mtTFB1 mice an indirect, yet potentially useful, animal model for maternally inherited deafness caused by the A1555G mutation.¹⁸ Herein, we have characterized the mechanism of hearing loss in Tg-mtTFB1 mice and addressed directly the involvement of AMPK signaling in the pathogenic response *in vivo*.

Materials and Methods

Animals

The original mixed C57BL/6J × SJL/J transgenic Tg-mtTFB1 mice¹⁸ were extensively back-crossed to the C57BL/6J genetic background. F8 and F9 backcrossed animals were bred to generate the Tg-mtTFB1 and wild-type (WT) littermates used in electrophysiological and histological studies. F8 Tg-mtTFB1 mice were bred to C57BL/6J heterozygous knockouts of AMPK α 1^{+/-} (*Prkaa1*^{+/-}) obtained from Dr. Benoit Viollet (INSERM, Paris, France),^{20,21} and the resulting AMPK α 1^{+/-}/Tg-mtTFB1 mice were bred to AMPK α 1^{+/+} for studies of AMPK knockdown.

ABR Analysis

Animals were anesthetized with either 48 mg/kg pentobarbital or 480 mg/kg chloral hydrate (i.p.), and all recordings were conducted in a sound-attenuating chamber (Industrial Acoustics Corp., Bronx, NY). A customized TDT3 system (Tucker-Davis Technologies, Inc., Alachua, FL) was used for auditory brainstem response (ABR) recordings. Subdermal needle electrodes (Rochester Electro-Medical, Inc., Lutz, FL) were positioned at the vertex (active, noninverting), the infra-auricular mastoid region (reference, inverting), and the neck region (ground). Differentially recorded scalp potentials were bandpass filtered between 0.05 and 3 kHz over a 15-millisecond (ms) epoch. A total of 400 trials were averaged for each waveform for each stimulus condition.

Symmetrically shaped tone bursts were 3 ms long (1 ms raised cosine on/off ramps and 1 ms plateau). All acoustic stimuli were delivered free field via a speaker (Tucker Davis Technologies, Inc., Part FF1 2021) positioned 10 cm from the vertex. Stimulus levels were calibrated using a 0.5-in condenser microphone (model 4016; ACO Pacific, Belmont, CA) positioned at the approximate location of the animal's head during recording sessions and are reported in decibels sound pressure level (dB SPL; referenced to 20 μ Pa). Stimuli of alternating polarity were delivered at a rate of approximately 20 per second.

Tone burst responses were collected in half octave steps ranging from 32 to 2.0 kHz. The effects of level were determined by decreasing stimulus intensity in 5-dB steps. A maximum stimulus level of 90 dB SPL was used first to avoid overstimulation. If the thresholds exceed 90 dB SPL, gain was adjusted to 40 dB to deliver a maximum stimulus level of 110 dB SPL. ABR thresholds were determined visually by noting the response waveforms exceeding a 1:1 signal to noise ratio. A two-way analysis of variance was used to determine the overall effect of genotype on ABR thresholds at different frequencies. The uncorrected Fisher's least significant difference test was used to make post hoc comparisons for determining statistical significance at each frequency between WT and Tg-mtTFB1 mice.

Latencies of the initial four ABR peaks were measured from animals aged 3 to 6 months or 9 to 12 months by

setting time markers at maxima of the peaks and measuring the time from onset of stimulus to peaks. Measurements were made at 8 and 11 kHz on traces with visible peaks. Latencies of peak I and central conduction time (peak I to IV) were used in the analysis. Amplitudes of peak I were assessed by taking the mean of the ΔV of the upward and downward slopes of peak I.

EP Measurements

Tg-mtTFB1 and WT animals, aged 9 to 12 months, were anesthetized with sodium pentobarbital (48 mg/kg body weight as initial dose and supplement as needed at 24 mg/kg). Animals were then placed onto a stereotaxic mouse head holder (MA-6N; Narishige, Tokyo, Japan) mounted onto a ball-and-socket stage and a magnetic base (M-RN-56; Newport Corp.). The round window was exposed through a ventral approach by opening the bulla of the temporal bone. A sharp electrode (10 to 15 M Ω , 1B150F-4; World Precision Instruments, Sarasota, FL) with 3 mol/L KCl pipette solution was mounted onto a micromanipulator with a pulse motor driving unit (PF5-1; Narishige). Electrodes were first placed at the round window, with visualization under a surgical microscope. An Axon 200A patch clamp amplifier was used for current clamp recording with an Axon Digidata 1321A and jClamp software version 22.8.4 (Scisoft, Inc., Ridgefield, CT). When the electrode was inserted into the scala tympani, voltage was balanced to 0 mV and then the electrodes were advanced through the basilar membrane into the scala media to measure the endocochlear potential (EP). Pipettes were then withdrawn back to the scala tympani or advanced through the scala vestibuli for confirmation of EP. Data analyses were performed offline.

NLC Measurements

Whole cell patch clamp recordings were made from single isolated outer hair cells (OHCs) from the organ of Corti of Tg-mtTFB1 and WT mice. The temporal bones were excised, and the cochleae were dissected free. Enzyme treatment (1 mg/mL dispase I, 10 to 12 minutes) preceded gentle trituration, and isolated OHCs were placed in a glass-bottom recording chamber. An E600-FN microscope (Nikon, Tokyo, Japan) with a 40 \times water immersion objective was used to observe cells during voltage clamp. Experiments were performed at room temperature.

The base high chloride ionic blocking solution contained (in mmol/L) the following: NaCl, 100; TEA-Cl, 20; CsCl, 20; CoCl₂, 2; MgCl₂, 1; CaCl₂, 1; and HEPES, 10. Base intracellular solutions contained (in mmol/L) the following: CsCl, 140; MgCl₂, 2; HEPES, 10; and EGTA, 10. An Axon 200B amplifier was used for the whole-cell patch-clamping recording. Nonlinear capacitance (NLC) was measured using a continuous, high-resolution (2.56 ms sampling), two-sine stimulus protocol (10-mV peak at both 390.6 and 781.2 Hz) superimposed onto the voltage ramp range from

–200 to 200 mV.^{22,23} Capacitance data were fit to the first derivative of a two-state Boltzmann function.

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin} \quad (1)$$

$$\text{where } b = \exp\left(\frac{-ze(V_m - V_{pkCm})}{kT}\right). \quad (2)$$

Q_{\max} is the maximum nonlinear charge moved, V_h is voltage at peak capacitance or equivalently, at half maximum charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann constant, and T is absolute temperature.

Hair Cell Counts

The temporal bones of 9- to 12-month-old WT ($n = 5$) were dissected, and cochlea removed and immersion fixed for 24 to 48 hours in 4% paraformaldehyde in phosphate-buffered saline (PBS). Bony capsules were partially dissected to enable fluid penetration, and the entire structure was then transferred to a blocking solution containing 10% normal goat serum and 0.1% Tween 20 in PBS. Mouse monoclonal Myo7a antibody (Developmental Hybridoma Studies Bank, University of Iowa, Iowa City, IA) was applied in blocking buffer at a 1:500 dilution overnight at 4°C and detected using an Alexa 546 donkey anti-mouse secondary antibody (Jackson Immunological, West Grove, PA). The bony capsule was then carefully removed, and the organ of Corti was detached from the modiolus as a single strip. Spiral ligaments were then dissected away to allow good exposure of the organ of Corti. The organ of Corti was then dissected and mounted. The apical region ranged from 57% to 64% from the base. This region has been described by Müller et al²⁴ as corresponding to frequencies between 13.5 and 16 kHz, which encompasses the range of frequencies showing elevated ABR thresholds in the Tg-mtTFB1 mice. Myo7a-labeled inner hair cells (IHCs) and OHCs in this region were visualized with an IX-71 inverted fluorescence microscope (Olympus, Center Valley, PA), and images were collected and analyzed with a Spot camera (Diagnostic Instruments, Inc, Sterling Heights, MI). The number of cells was normalized and expressed as hair cells per 100 μm .

Stria Vascularis Measurements

Temporal bones were dissected and fixed in 4% paraformaldehyde in PBS at 4°C for 24 to 48 hours, followed by decalcification in 10% EDTA in PBS for 96 hours. The cochleae were bisected in the midmodiolar plane, and the two halves were embedded in paraffin, divided into sections, and stained with hematoxylin and eosin (Yale Pathology Developmental Histology Service, New Haven, CT). The width and thickness of intact, cross-sectioned striae were measured at multiple points at apical-basal locations^{25,26} in each animal using an Olympus microscope and Spot camera software version 5.1 for analysis. Strial width was measured as the

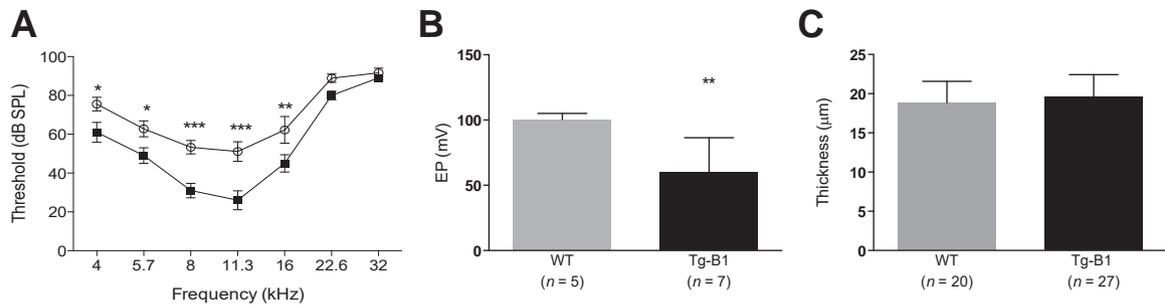

Figure 1 Hearing loss phenotype and stria vascularis dysfunction in a transgenic mouse strain that robustly overexpresses the mitochondrial 12S ribosomal RNA methyltransferase TFB1M (Tg-mtTFB1). **A:** Auditory brainstem response (ABR) results in wild-type (WT; closed squares) and Tg-mtTFB1 (Tg-B1; open circles) mice used in this study. Data were analyzed by two-way analysis of variance, and the main effect for genotype is $F_{(1,84)} = 38, P < 0.001$. Differences at each frequency were tested via post hoc Fisher’s least significant difference tests. **B:** Direct endocochlear potential (EP) measurements of the mice in **A**. No significant difference exists between WT and Tg-B1 mice [$t_{(45)} = 0.9$]. * $P < 0.05$, ** $P < 0.01$, and *** $P < 0.001$. dB SPL, decibels sound pressure level.

length of a curved line between the two end points of the stria in cross section, one near the insertion of Reissner’s membrane and the other near the spiral ligament. Thickness was measured by a straight line drawn through the midpoint of the section.

Results

Hearing Loss—Related Pathology in the Stria Vascularis

We previously characterized hearing loss in Tg-mtTFB1 mice as elevated ABR thresholds that progressed with age, accompanied by increased caspase 3 staining in the stria vascularis and spiral ganglia and reduced numbers of spiral ganglion neurons.¹⁸ Because defects in the stria vascularis, a three-layered epithelial organ lining the scala media and responsible for maintaining the requisite elevated extracellular potassium necessary for hair cell function, can also result in hearing loss characterized by increased ABR thresholds, we measured the EP to assess stria function directly. After confirming that ABR thresholds were prematurely elevated in a cohort of Tg-mtTFB1 mice now extensively backcrossed to the C57BL/6J background (Figure 1A), we recorded EP in a group of WT and Tg-mtTFB1 animals aged 9 to 12 months. We observed a 40% reduction in EP in Tg-mtTFB1 mice (mean_{Tg-mtTFB1} = 60 ± 10 mV) compared with WT controls, which was near 100 mV (mean_{WT} = 100.2 ± 2.1 mV) (Figure 1B). Hearing loss accompanied by stria dysfunction in aging humans is often accompanied by atrophy of the epithelium. To assess atrophy, the width and thickness of the stria were measured at multiple sites in cochlear cross sections of nine Tg-mtTFB1 and six WT animals. The widths, indicators of the cochlear spiral location of the stria, ranged from 131 to 387 µm in WT and from 98 to 358 µm in Tg-mtTFB1 animals. The thickness of the stria ranged from 13 to 22 µm in the WT and from 14 to 28 µm in the Tg-mtTFB1 animals. There was no significant correlation in either genotype between the width of the stria and the thickness (WT, $r^2 = -0.0049$; Tg-mtTFB1, $r^2 = 0.0077$). Because there was no difference in the

thickness as a function of apical-basal location, we combined all of the thickness measurements and compared the mean values by a *t*-test. There was no significant difference between WT and Tg-mtTFB1 mice (Figure 1C). These data suggest that the stria dysfunction in Tg-mtTFB1 mice is either distinct from presbycusis or we are sampling at a stage of progressive hearing loss that precedes gross stria atrophy.

To more precisely determine the source of auditory dysfunction, we analyzed details of the ABRs of WT and Tg-mtTFB1 mice with hearing loss. Mouse ABRs have five characteristic peaks, the first of which represents activity in nerve VIII. Changes in the latency or amplitude of peak I reflect dysfunctional cochlear and/or nerve VIII processing. By using two-way analysis of variance to assess the latency to peak I, we observed significant increases in 9- to 12-month-old Tg-mtTFB1 mice at both 8 kHz [$F_{(1,109)} = 34, P < 0.001$] (Figure 2A) and 11 kHz [$F_{(1,127)} = 28, P < 0.001$] (Figure 2B). When the same analysis was performed on 3- to 6-month-old animals, when only moderate ABR threshold shifts are observed in Tg-mtTFB1, the latencies were not significantly affected at 8 kHz [$F_{(1,128)} = 0.23$] (Figure 2C) or 11 kHz [$F_{(1,152)} = 0.04$] (Figure 2D). Thus, increased latency to peak I is only observed in older Tg-mtTFB1 animals with hearing loss. In contrast, central conduction time (elapsed time between peak I and peak IV), which reflects synaptic and nerve conduction timing after cochlear/nerve VIII processing, was unchanged in animals with severe hearing loss [$F_{(1,104)} = 1.2$ and $F_{(1,105)} = 1.0$] (Figure 2, E and F), respectively. These data suggest that hearing loss in Tg-mtTFB1 mice is induced by progressive pathological changes in the cochlea/nerve VIII, not central auditory system defects (ie, brainstem).

Hearing Loss—Related Pathology in OHCs

To determine whether hair cells are directly affected, we dissected the organ of Corti from cochleae of 9-month-old WT and Tg-mtTFB1 mice and labeled IHCs and OHCs with an antibody for Myo7a. Despite considerable ABR threshold

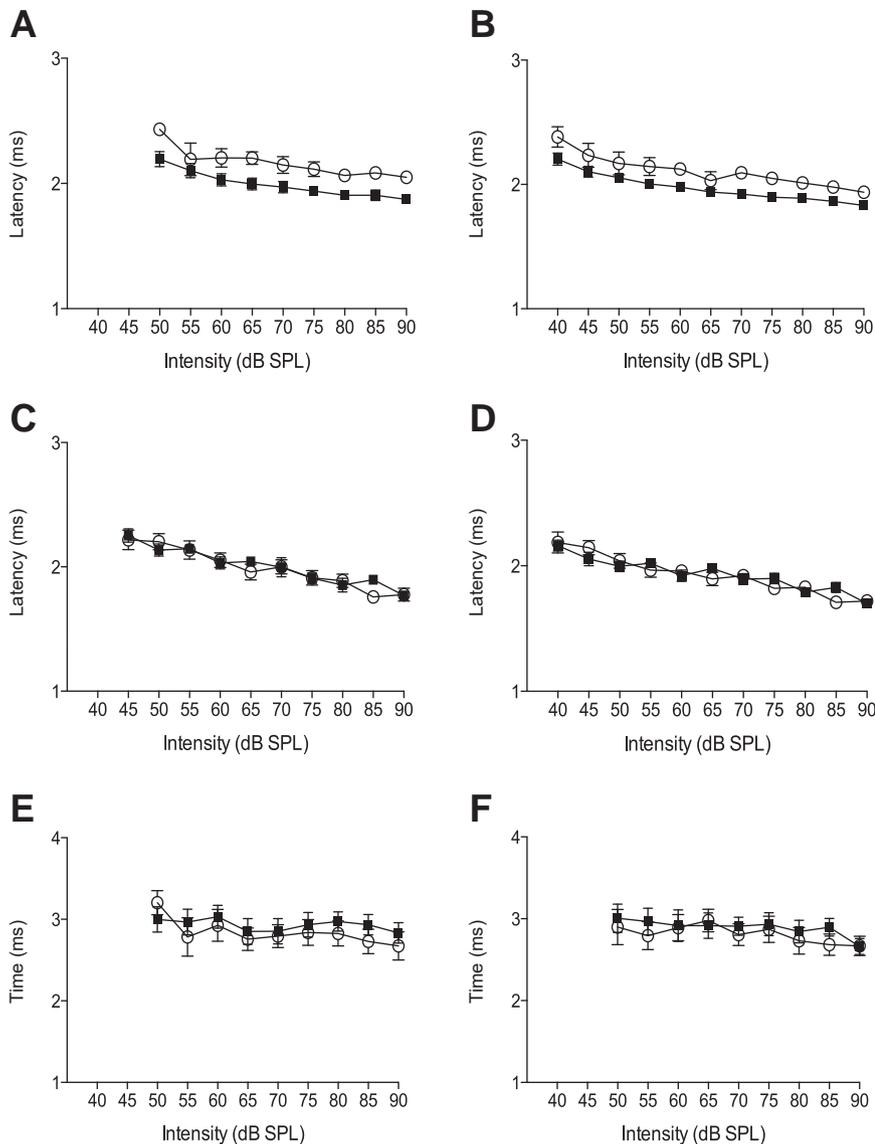

Figure 2 Changes in auditory brainstem response (ABR) latencies demonstrate progressive cochlear damage underlying deafness in a transgenic mouse strain that robustly overexpresses the mitochondrial 12S ribosomal RNA methyltransferase TFB1M (Tg-mtTFB1). The latency in milliseconds (ms) to ABR peak I is plotted as a function of the indicated suprathreshold decibels sound pressure level (dB SPL) for 9- to 12-month-old mice at 8 kHz (A), 9- to 12-month-old mice at 11 kHz (B), 3- to 6-month-old mice at 8 kHz (C), and 3- to 6-month-old mice at 11 kHz (D). The central conduction time was measured as the time from ABR peak I to peak IV and is shown for 9- to 12-month-old mice at 8 kHz (E) and 11 kHz (F). Closed squares indicate wild-type and open circles indicate Tg-mtTFB1 in all panels.

changes at frequencies from 4 to 16 kHz (Figure 1A), the hair cells in the apex of the cochlea, which detect frequencies in the range of hearing loss in Tg-mtTFB1 mice,²⁴ are largely intact, as evidenced by quantifying Myo7a-labeled IHCs and OHCs in the most apical 2.5 to 3.0 mm of the organ of Corti (Figure 3A). Although there might be a downward trend in the number of hair cells in Tg-mtTFB1 mice, a two-way analysis of variance shows that the counts do not differ significantly from WT [$F_{(1,10)} = 0.90$].

Next, to determine whether OHC function was altered, NLC, the electrical correlate of electromotility, was measured in OHCs isolated from WT and Tg-mtTFB1 mice between 9 and 12 months of age. NLC was measured by whole-cell patch clamp using symmetric chloride solutions (140 mmol/L Cl^- intracellular and extracellular). OHCs from Tg-mtTFB1 mice exhibited a positive shift of nearly 20 mV in the voltage at peak capacitance (V_h ; $\text{mean}_{\text{WT}} = -94 \pm 2.6$ mV; $\text{mean}_{\text{Tg-mtTFB1}} = -76 \pm 5$ mV) (Figure 3B), suggesting that

TFB1M overexpression in the cochlea induces a long-term change in OHC voltage responsiveness.

Functional Evidence for Spiral Ganglion Loss in Tg-mtTFB1 Mice

To determine whether the approximately 20% spiral ganglion neuronal loss we observe in Tg-mtTFB1 mice¹⁸ has an effect on hearing, we analyzed ABR peak I amplitude, which reflects the number of spiral ganglion neurons recruited for the generation of ABR and would be reduced in animals with neuronal death in the spiral ganglion. Consistent with spiral ganglion loss, peak I amplitudes were significantly reduced in 9- to 12-month-old Tg-mtTFB1 animals [$F_{(1,116)} = 57$, $P < 0.001$] (Figure 3C). In addition, as stimulus levels increase, the characteristics of the curves in Tg-mtTFB1 mice diverge from those of WT, which show a steeper upward slope (recruitment) >60 dB

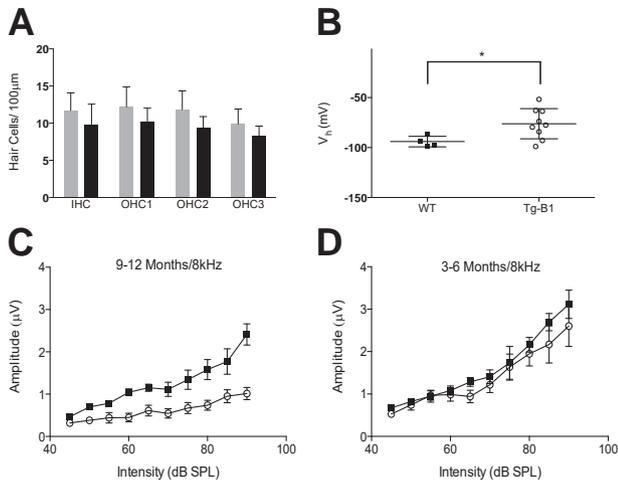

Figure 3 Outer hair cell dysfunction and reduced amplitude of auditory brainstem response (ABR) peak I in a transgenic mouse strain that robustly overexpresses the mitochondrial 12S ribosomal RNA methyltransferase TFB1M (Tg-mtTFB1). **A:** Hair cell counts in wild-type (WT; gray bars) and Tg-mtTFB1 (Tg-B1; black bars) mice. Cells counted are as indicated: inner hair cells (IHCs), outer hair cell rows 1 (OHC1), 2 (OHC2), and 3 (OHC3). **B:** Nonlinear capacitance (NLC) recordings from OHCs isolated from WT (closed squares) and Tg-B1 (open circles) mice. The voltage at peak capacitance (V_h) is plotted, and means were compared with a *t*-test. There is a statistically significant change in Tg-mtTFB1 [$t_{(11)} = 2.3$]. Other parameters of NLC were not different (means \pm SD): maximum nonlinear charge moved (pC), 0.54 ± 0.11 WT/ 0.42 ± 0.11 Tg-mtTFB1; *z*, 0.76 ± 0.05 WT/ 0.76 ± 0.07 Tg-mtTFB1; linear membrane capacitance (pF), 4.93 ± 0.47 WT/ 4.44 ± 0.72 Tg-mtTFB1. The amplitude of ABR peak I was measured at 8 kHz at the indicated intensities (decibels sound pressure level). Suprathreshold for 9- to 12-month-old mice (**C**) and 3- to 6-month-old mice (**D**). Suprathresholds at 9 to 12 months in Tg-mtTFB1 mice are significantly lower than WT controls by two-way analysis of variance. * $P < 0.05$.

(Figure 3C). This suggests that Tg-mtTFB1 animals have an impaired cochlear amplifier, consistent with the findings of EP decrease (Figure 1B) and OHC V_h shift (Figure 3B). Younger animals with only moderately elevated ABR thresholds (3 to 6 months) had no significant change in the peak I amplitude [$F_{(1,130)} = 3.1$, $P > 0.05$] (Figure 3D), consistent with a progressive nature to the hearing loss in Tg-mtTFB1 mice.

Rescue of Tg-mtTFB1 Hearing Loss by Genetically Reducing AMPK Signaling

We proposed previously that mitochondrial ribosomal disruptions in Tg-mtTFB1 mice resulted in increased mitochondrial ROS-mediated activation of AMPK that engages the pro-apoptotic function of E2F1.¹⁸ In Tg-mtTFB1 mice, there is also increased phosphorylation of AMPK in the spiral ligament, a tissue that supports the K-recirculation function of the stria vascularis.^{18,27} If up-regulation of AMPK in the stria (or other cochlear cells) activates E2F1 to initiate apoptosis or other deleterious signaling events, then reducing AMPK activity in Tg-mtTFB1 mice would be predicted to rescue hearing loss. We bred Tg-mtTFB1 mice with heterozygous AMPK $\alpha 1$ subunit knockout mice^{20,21} (AMPK $^{+/-}$) to

generate age-matched littermates of the following genotypes for ABR analysis: AMPK $^{+/+}$ WT (no transgene), AMPK $^{+/+}$ Tg-mtTFB1 (with mtTFB1 transgene), AMPK $^{+/-}$ WT (no transgene), and AMPK $^{+/-}$ Tg-mtTFB1 (with mtTFB1 transgene). At 9 to 12 months of age, we observed the typical increase in ABR threshold in Tg-mtTFB1 mice (Figure 4A). However, Tg-mtTFB1 mice with reduced AMPK signaling (AMPK $^{+/-}$) had an ABR threshold profile indistinguishable from WT littermate controls (Figure 4B). Thus, we conclude that reducing AMPK signaling has no effect on normal hearing at the ages tested, but rescues or delays premature hearing loss in Tg-mtTFB1 mitochondrial deafness model mice.

Discussion

In this study, we have characterized the pathological mechanisms of hearing loss in Tg-mtTFB1 mice that we speculate models, to some degree, the pathology underlying maternally inherited deafness in humans because of the common A1555G mtDNA mutation.¹⁸ Our results demonstrate that hearing loss in Tg-mtTFB1 mice is because of cochlear dysfunction rather than a central processing defect in the brainstem (Figure 2). In the cochlea, we observe multiple defects, including signs of reduced spiral ganglion output (Figure 3C) and direct evidence for dysfunction in the stria vascularis (Figure 1B). We did not observe significant atrophy in the stria (at the light microscopic level), suggesting the defects involve intrinsic functioning of the cells in the tissue (eg, an inability to maintain the proper ionic milieu of the endolymph and EP within the scala media). The mitochondrial dysfunction in these cells may affect the functioning of the many ion pumps and transporters that require high and sustained amounts of ATP to operate. Alternatively, or in addition, these cells may be

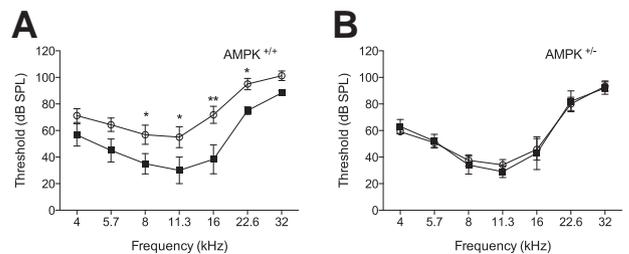

Figure 4 Reduced AMP kinase (AMPK) $\alpha 1$ signaling rescues hearing loss in a transgenic mouse strain that robustly overexpresses the mitochondrial 12S ribosomal RNA methyltransferase TFB1M (Tg-mtTFB1). Auditory brainstem response thresholds of littermates of the indicated genotypes were tested at 9 to 12 months of age. A two-way analysis of variance demonstrates that the overall effect for genotype was statistically significant [$F_{(3,126)} = 17$, $P < 0.001$]. **A:** All animals are AMPK $^{+/+}$ (wild-type for AMPK $\alpha 1$) and either wild-type (non-transgenic, closed squares) or transgenic for mtTFB1 (Tg-mtTFB1, open circles). **B:** All animals are AMPK $^{+/-}$ (heterozygous for AMPK $\alpha 1$) and either wild-type (non-transgenic) or transgenic for mtTFB1 (Tg-mtTFB1). Results of post hoc Fisher's least significant difference tests comparing the genotypes at individual frequencies. * $P < 0.05$, ** $P < 0.01$. db SPL, decibels sound pressure level.

more prone to oxidation reduction perturbations and oxidative stress driven by mitochondrial ROS. Also, Schmitz et al²⁶ observed reduced EP without morphological changes in the stria when hearing loss was induced with kanamycin and furosemide, which is similar to our results. We did not find evidence for major hair cell loss at ages when there is a clear ABR defect (Figure 3A), but there is some OHC dysfunction (Figure 3B). Interestingly, Niu et al²⁸ showed that mice with accumulated mtDNA mutations have hearing loss with pathological features in the spiral ganglion and stria vascularis, but do not display major effects on hair cells, suggesting this may be a common profile of mitochondrial dysfunction in the inner ear. The loss of spiral ganglion neurons we reported previously¹⁸ is consistent with the reduced ABR peak I amplitude (Figure 3C) caused by fewer nerve VIII fibers contributing to the compound action potential. We propose that this loss of spiral ganglion neurons is because of apoptosis on the basis of the heightened caspase 3 staining in this region we reported previously.¹⁸ Furthermore, we propose that the defects we observe in the stria, spiral ganglion neurons, and OHCs conspire to produce the observed progressive hearing loss profile in Tg-mtTFB1 mice. Whether different pathogenic mechanisms downstream of mitochondrial ribosome disruptions in Tg-mtTFB1 mice occur independently in the three cell types involved or defects in one tissue occur as the result of a primary dysfunction in another cannot be determined from our results.

One interesting issue raised by our findings is the functional changes in the OHCs. Tg-mtTFB1 OHCs show a shift in NLC *in vitro*, suggesting that some chronic change in their responsiveness had occurred *in vivo*. Shifts in NLC are expected to have detrimental effects on cochlear amplification.²⁹ It is possible that this shift is because of some intrinsic dysfunction. For example, the subsurface cisternae of the OHC that border the lateral membrane, which harbors the electromotile protein prestin,^{30,31} are lined by mitochondria,³² again suggesting that proper mitochondrial function may be necessary for normal OHC electromotility. Alternatively, stria dysfunction leading to altered composition of the endolymph (Figure 1B) may also produce some persistent cellular change in OHCs that we identified as a change in NLC. This could represent a new aspect of regulation of OHC activity.

Our previous study¹⁸ led to the formulation of a mitochondrial stress model that drives tissue-specific apoptotic signaling in the stria vascularis and spiral ganglion neurons. Specifically, altered mitochondrial ribosome activity and/or biogenesis because of premature or aberrant methylation of the 12S rRNA by TFB1M, or direct inhibition of ribosome assembly on the basis of our recent report of physical and functional interactions between TFB1M and POLRMT in the ribosome,¹⁹ is proposed to lead to ROS-dependent activation of AMPK kinase and unveiling of the pro-apoptotic function of the nuclear transcription factor E2F1.¹⁸ This model, based initially on *in vitro* results with

cultured human A1555G cybrids, was partially verified in our previous study¹⁸ by showing the following: i) hearing loss in Tg-mtTFB1 mice did not occur when E2F1 levels were reduced genetically, ii) there is increased E2F1 expression and caspase 3 activation in the strial epithelium, and iii) there is activation of AMPK in the associated spiral ligament. Herein, we provide additional direct evidence that the mitochondrial ROS-AMPK-E2F1 pathogenic signaling pathway is operational *in vivo* by showing that hearing loss in Tg-mtTFB1 is rescued by genetically reducing AMPK signaling. The AMPK α 1 form of the enzyme has been implicated in oxidative stress and ROS sensing,^{33–35} which is consistent with our results that hearing loss in Tg-mtTFB1 mice is rescued by inactivating one copy of the gene encoding AMPK α 1, which would presumably reduce signaling from mitochondrial ROS. Finally, thioredoxin regulates the oxidation reduction sensitivity of AMPK.³⁶ Thus, it will be interesting to determine whether this or other oxidation reduction-sensitive proteins are responsible for mediating mitochondrial ROS signals to AMPK in this pathogenic context and if antioxidants can also prove beneficial.

As a proposed animal model of the human deafness-associated A1555G mtDNA mutation, a comparison of our results in Tg-mtTFB1 mice to the human condition and how this might inform prophylactic or therapeutic strategies is warranted.^{37,38} In human A1555G patients, hearing loss is considered to be a progressive, sensorineural deafness. Two important audiological characteristics of A1555G patients compare favorably with Tg-mtTFB1. First, in A1555G carriers with normal hearing, there is a significant reduction in the distortion products of otoacoustic emissions³⁹ (DPOAEs). Reduced DPOAE is interpreted as OHC dysfunction, yet these patients have normal ABRs, indicating hair cells must be largely intact. In this case, the reduced DPOAE might suggest that it is the stria that is not functioning properly, leading to some dysfunction of the OHCs, but not enough to affect the ABR at the time of testing. Our observations of NLC may be relevant, and it is possible that the magnitude of OHC V_h shift in these patients is not sufficient to influence threshold. These asymptomatic carriers of the A1555G mutation may later lose their hearing either as part of the normal progression of the disease or in response to aminoglycosides or other cochlear stressors (eg, intense noise) that we predict might activate the mitochondrial ROS-AMPK-E2F1 pathway. The second relevant comparison between humans and the mouse model involves the peak I latency. In both cases, peak I takes significantly longer to reach maximum amplitude, suggesting that cochlear processing and activation of spiral ganglion neurons are impaired. Interestingly, central conduction time is not affected in this model or in A1555G carriers, thus eliminating any brainstem abnormalities from the pathogenic process.³⁹ One key difference between Tg-mtTFB1 mice and A1555G is the involvement of hair cells in humans with profound hearing loss who have no

measurable DPOAE, suggesting that they have no OHCs or they are seriously impaired. In contrast, Tg-mtTFB1 mice have intact OHCs and IHCs, as evidenced in this study both histologically and functionally. This may reflect a bona fide difference or a temporal difference in the progression of pathological events. Although future studies with older Tg-mtTFB1 mice might help clarify this, we acknowledge that studies of progressive hearing loss in the C57BL/6J background at older ages would become confounded by the age-related hearing loss locus in these mice that, on its own, causes premature deafness.^{40,41} Studies of Tg-mtTFB1 in other genetic backgrounds, that vary dramatically in their propensity for hearing loss,^{42,43} should help clarify the precise degree that our Tg-mtTFB1 mice model human deafness caused by the A1555G mutation.

Finally, it has recently been reported that lymphocytes and fibroblasts from A1555G patients do not exhibit increased 12S rRNA methylation like we observe in A1555G cybrid cells and Tg-mtTFB1 mice tissues.⁴⁴ Whether this reflects a difference in how methylation is assayed by our two groups or if increased methylation only occurs in the inner ear (or just during stress) in humans remains to be determined. It is also formally possible that increased 12S rRNA methylation of mature mitochondrial ribosomes is not the trigger of pathogenic responses in Tg-mtTFB1 mice or humans, as we proposed originally. For example, premature binding and/or methylation of 12S rRNA by TFB1M (eg, during transcription or before RNA processing is complete) might disrupt ribosome biogenesis. Alternatively, we have recently shown that TFB1M is in a complex with POLRMT in ribosomes¹⁹; thus, overexpression of TFB1M and/or the A1555G mutation may disrupt the function of this complex in ribosomes to initiate the mROS-AMPK-E2F1 pathway and hearing loss. These mechanistic details will be important to decipher to better understand deafness caused by the A1555G mutation in humans and the degree to which it can be modeled by our Tg-mtTFB1 mice.

Acknowledgments

We thank Drs. Benoit Viollet and Lawrence Young for providing the AMP kinase knockout mice for this study, Dr. Peter Santi for sharing data on stria morphology, and Dr. Reuben Shaw for helpful advice on AMP kinase.

Abstract

The transmembrane motor protein prestin is thought to underlie outer hair cell (OHC) motility. Prestin expressed in non-auditory cells confers OHC-like electrical characteristics to the cell membrane, including the generation of gating-like currents (or non-linear capacitance), whose voltage dependence is susceptible to membrane tension and initial voltage conditions. Here we report that prestin's voltage sensitivity is, like that of the native motor, markedly temperature dependent. Prestin-transfected HEK cells were whole-cell voltage clamped while temperature was varied from 10–35°C. V_{pkcm} , the voltage at peak capacitance, reversibly and linearly shifted to depolarized levels with increasing temperatures, while peak capacitance also increased, but with significant hysteresis upon recooling. Mathematical modeling suggests that this increase may be due to a charged voltage sensor having a wider range of movement through or larger unit charge within the plasma membrane at higher temperatures. © 2001 Elsevier Science Ireland Ltd. Keywords: Prestin; Temperature; Capacitance; Cochlea; Membranes; Outer hair cell

The ability of outer hair cells (OHC) to generate mechanical responses to electrical stimulation is critical for the precise tonotopic tuning of the mammalian cochlea [2]. For several years it has been known that the mechanism underlying this motor activity is localized to the basolateral membrane of the OHC [5], and more recently a novel protein, prestin, has been identified as the putative motor protein [16]. Evidence for voltage-dependent mechanical activity of OHCs is easily detectable in whole-cell patch recording as a non-linear capacitance, or gating current, indicating the presence of a charged voltage-sensor participating in a conformational change [1,10]. Transfection of prestin into human embryonic kidney (HEK) cells confers non-linear capacitance with similar characteristics to that of the OHC lateral membrane [8,13,16]. Notably, transfected cells can exhibit electromotile responses in microchamber experiments [16], and excised patches from such cells have been shown to generate mechanical force in response to electrical stimulation [8]. These are necessary characteristics of the molecular mechanism for outer hair cell motility,

and the finding that expression of prestin is necessary and sufficient to invoke them in non-auditory cells is convincing evidence that prestin is the motor protein of OHCs.

It remains in question, however, whether or not prestin alone is responsible for the mechanical properties of OHCs, or if an interaction with other molecular species in the OHC basolateral membrane is required. Evidence is accumulating that prestin alone can indeed account for all of the electromechanical properties of OHCs. One interesting aspect of OHC non-linear capacitance is that its voltage dependence is subject to modulation by such fundamental conditions as membrane tension [6], resting potential [10], and temperature [11]. Specifically, the voltage at which half maximal charge movement occurs, or, correspondingly, the voltage at peak capacitance (V_{pkcm}), can be shifted in the positive direction by increased intracellular pressure, negatively shifted holding potential, or increased temperature. The replication of these findings in prestin-transfected cells is crucial evidence that OHC electromotility relies on a monomolecular mechanism requiring only prestin. Effects of membrane tension [8,13] and holding potential [13] in prestin-transfected cells have been reported, and here we report on the effects of varying temperature. V_{pkcm} in prestin-transfected cells is markedly dependent on temperature, in a manner no different from that of the OHC. Increasing

temperature shifts V_{pkC_m} in a positive direction, and the effect appears to be linear in the temperature range under investigation. In addition, increasing temperature was seen to increase the magnitude of peak capacitance, but with significant hysteresis in the temperature dependence, suggesting that the relationship of peak capacitance to temperature is more complex than that of V_{pkC_m} . Fitting of capacitance data to the first derivative of a two-state Boltzmann function [10] indicates that the temperature-dependent increase in capacitance is accounted for by an increase in the voltage-sensitivity of the OHC motor protein (z), but not an increase in the maximum charge moved (Q_{max}). These results suggest that movement of a voltage-sensor in the membrane is maximized at physiological temperature.

Transient transfection of HEK 293 cells was conducted as follows: Cells were cultured in MEME with 10% fetal calf serum. Cells were trypsinized and replated in 35 mm culture dishes 24 h prior to transfection with Lipofectamine 2000 (Life Technologies, MD). The transfection mixture consisted of OPTI-MEM media, Lipofectamine, the gPrestin-containing plasmid pcDNA3.1(-), and the GFP-containing plasmid pGreenLantern, used as a marker for successfully transfected cells. Generally, cells that successfully express one plasmid in a dual transfection will express both, and indeed, in the course of our recordings only one cell was found that exhibited green fluorescence (GFP) but not non-linear capacitance (prestin).

Twenty-four to 72 h after transfection, whole-cell patch clamp recordings were performed while varying bath temperature. The 35 mm culture dishes containing the cells were placed in a Peltier device (Dagan HCC-100A Heating/Cooling Bath Temperature Controller with HE-204 stage, Dagan Corp., MN). A temperature probe was inserted into the bath within 2 mm of the recorded cells. Cells were either patched at 10°C or cooled from room temperature after patching, after which the temperature was raised gradually up to 35°C and lowered back down to 10°C, and the cycle repeated as long as good recordings could be obtained from the cells. At 5-degree temperature intervals, we obtained full capacitance-voltage ($C-V$) functions as described below.

Round, isolated (non-coupled) cells exhibiting GFP-fluorescence were selected for electrophysiological recordings. Cells were whole-cell voltage clamped with an Axopatch 200A amplifier (Axon, CA) at a holding potential of 0 mV. The patch pipette solution contained (in mM): 130 CsCl, 10 EGTA, 2 MgCl₂, 10 HEPES, pH 7.2. The external bath solution contained (in mM): 99.2 NaCl, 20 TEA-Cl, 20 CsCl, 2 CoCl₂, 1.47 MgCl₂, 10 HEPES, 2 CaCl₂, pH 7.2. Osmolarity was adjusted to 300 mOsm with glucose. Gigohm seals were obtained and electrode capacitance was compensated. Current responses were filtered at 10 kHz. Data collection and analyses were performed with a Windows-based whole-cell voltage clamp program, jClamp (SciSoft, CT, USA), using a National Instruments PCI-6052 interface.

The magnitude of non-linear membrane capacitance was

evaluated using a continuous high-resolution (2.56 ms sampling) two-sine voltage stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz), with subsequent FFT-based admittance analysis [12]. These high-frequency sinusoids were superimposed on a sinusoidal stimulus protocol sweeping from 0 to -175 mV, up to +175 mV, and back down to 0 mV. $C-V$ data were fit to the first derivative of a two-state Boltzmann function [10] where Q_{max} is the maximum non-linear charge moved, V_{pkC_m} is voltage at peak capacitance or half maximal non-linear charge transfer, V_m is membrane potential, C_{lin} is linear capacitance, z is valence, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. Gating currents were obtained with a standard P/5 protocol, at a subtraction potential of +50 mV, as previously described [10]. In addition, in some experiments V_{pkC_m} was continuously tracked with 2 mV resolution by monitoring the reversal of gating current polarity as fully described previously [6]. This real-time tracking of V_{pkC_m} allowed a direct observation of the temperature dependence of non-linear capacitance, as V_{pkC_m} was observed to continuously follow changes in temperature in a reversible fashion.

Our results were very similar to those obtained from OHCs [11]. Fig. 1 plots non-linear capacitance vs. voltage for a cell at two temperatures. Two main effects of temperature can be seen - at the higher temperature, the magnitude of the capacitance is slightly greater, and the voltage at which the peak capacitance occurs is shifted to the right, to a more positive voltage. In all transfected cells exhibiting non-linear capacitance, V_{pkC_m} was seen to shift linearly in a positive direction with increasing temperature, at a rate of about 16.1 ± 6.8 mV/10°C ($n = 5$). This result agrees well with findings in OHC cells, which exhibited an average shift of 19.7 mV/10°C. Fig. 2a illustrates that these effects are continuous and fully reversible, using the continuous tracking of V_{pkC_m} as described above.

In order to calculate the average rate of shift in V_{pkC_m} in response to temperature changes from the data of five cells, it was necessary to verify that the effect is linear in the temperature range studied. Fig. 2b, *top panel* illustrates that this is the case. Cells that were continuously held through a wide temperature range yielded data that consistently fit a linear regression function of V_{pkC_m} vs. temperature ($r^2 \sim 0.93$). Peak C_m was also seen to increase with temperature (Fig. 2b, *bottom panel*), but there is a considerable amount of hysteresis in the response, rather than the simple linear temperature dependence of V_{pkC_m} . With cooling, peak C_m in all cells was relatively stable until temperatures well below physiological (<25°C) were reached.

The reason for this non-linearity is not entirely clear. As Fig. 2 illustrates, there was often a lag in the temperature dependent change in peak capacitance, compared with the change in V_{pkC_m} , which precisely followed temperature changes. The lag ranged up to three minutes, as seen in Fig. 2a. Fig. 2b *bottom panel* shows that peak C_m continued to increase for a short while after heating, even when the cell was cooling back down. Note that this lag cannot be

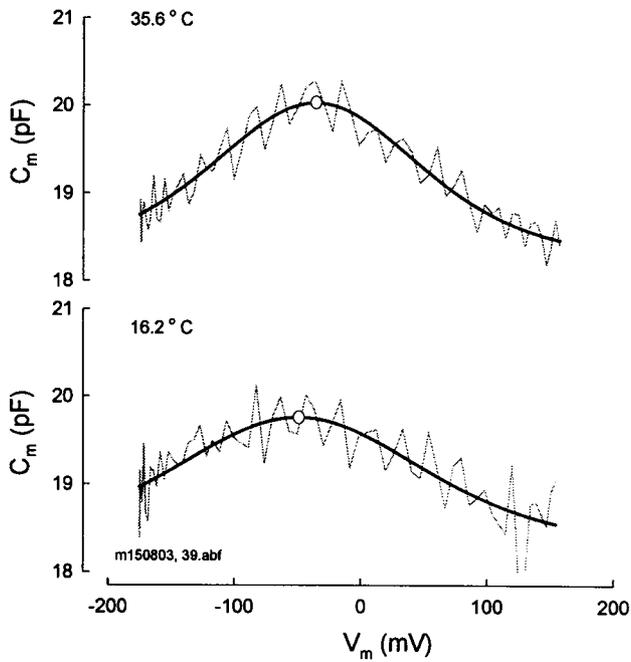

Fig. 1. Effect of temperature on non-linear capacitance of a prestin-transfected HEK cell. Capacitance was evaluated with a two-sine voltage stimulus protocol (see text) and the data were fit to the first derivative of a two-state Boltzmann function. Note two main effects of increasing temperature: a rightward (depolarizing) shift in the voltage at peak capacitance (V_{pkCm}), and an increase in peak capacitance. (35.6°C) V_{pkCm} : -32.2 mV, z : 0.49, Q_{max} : 0.37 pC, C_{lin} : 18.25 pF; (16.2°C) V_{pkCm} : -48.4 mV, z : 0.38, Q_{max} : 0.44 pC, C_{lin} : 18.17 pF.

explained by a discrepancy between the measured bath temperature and the actual temperature of the cell, since V_{pkCm} does not show any such delay. Such slow effects may be due to changes in metabolic processes, or state of motor protein phosphorylation [3,4]. It is significant that sensitivity to temperature change was minimal at physiological temperatures. Our results are comparable to those of Khvoles et al. [7], who found that the amplitude of otoacoustic emissions from rat cochleae is maximal and nearly temperature insensitive at temperatures approaching physiological, but is significantly and reversibly depressed at higher and lower temperatures. Otoacoustic emissions are a byproduct of the so-called ‘cochlear amplifier,’ which is thought to be dependent on the mechanical responses of OHCs. In related studies, Seifert et al. [14,15] found that the amplitude of otoacoustic emissions in humans and guinea pigs declines with decreasing temperature, and recovers with considerable hysteresis. Detectable emissions tended to return while rewarming at lower temperatures than those at which they disappeared during cooling. The authors hypothesize that hypothermia causes a hearing loss associated with a decline in function of the cochlear amplifier, due to a reduction in OHC motility subsequent to a depression of the endocochlear potential (EP). However, our results suggest that the effect is direct, a decrease in prestin’s non-linear capacitance being indicative of a decrease in its motor activity. Furthermore, the shift

in the voltage-dependence (indicated by V_{pkCm}) of the cochlear amplifier would affect its gain and influence emissions, even if EP were to remain constant.

To investigate further the nature of the temperature-dependent changes in prestin’s function, we fit voltage-dependent capacitance data to the first derivative of a two-state Boltzmann function, as described above and illustrated in Fig. 1. This fit allows for the derivation of the parameters Q_{max} , the total amount of non-linear charge moved, and z , the effective charge movement of a single voltage-sensor. An increase of either of these parameters would result in the increased capacitance seen at higher temperatures. Fig. 3 shows V_{pkCm} , Q_{max} , and z plotted at two temperatures for each of five cells. There was not a reliable trend in the variation of Q_{max} , which remains fairly stable, whereas z shows a consistent increase with increasing temperature. Similar findings were previously reported in OHCs [11]. z depends upon both the magnitude of charge and the distance it traverses within the membrane’s electric field. Thus, the increase in z may be caused by changes in either one of these factors. An increase in charge displacement may result from a decrease in plasma membrane viscosity at higher temperatures; the magnitude of charge may vary with phosphorylation and/or metabolism. Finally, it may be possible that some of the temperature-dependent effects that we observe could be due to a change in the availability of intracellular Cl^- , which is required for prestin activity [9]. These factors are expected to account for the non-linear effects of temperature on otoacoustic emissions [7,14,15], and their relative insensitivity to temperature changes in the physiological range. This insensitivity, reflecting properties of the motor protein prestin, would allow an animal to maintain

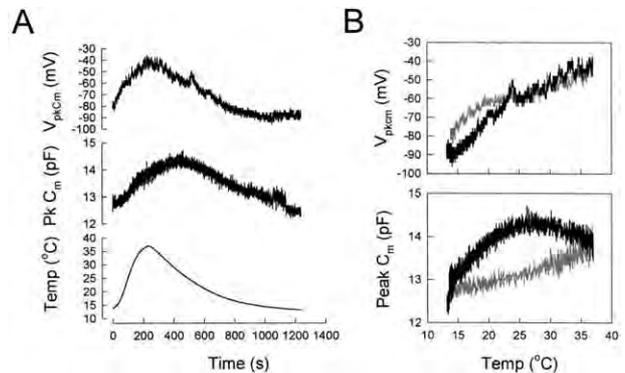

Fig. 2. (A) The voltage at peak capacitance (V_{pkCm}) and the peak capacitance (C_m) follow changes in temperature in a continuous and reversible manner. Here, a tracking procedure developed previously [6] was used to keep a cell voltage-clamped at V_{pkCm} during heating and cooling. (B) V_{pkCm} and peak C_m plotted as a function of temperature for the same cell. Data from the heating phase is shown in gray, while data obtained during subsequent cooling is plotted in black. V_{pkCm} increases nearly linearly with temperature (top panel), fitting a linear regression with $r^2 = 0.91$ (heating), $r^2 = 0.95$ (cooling). However, C_m shows considerable hysteresis in its response to changing temperature (bottom panel).

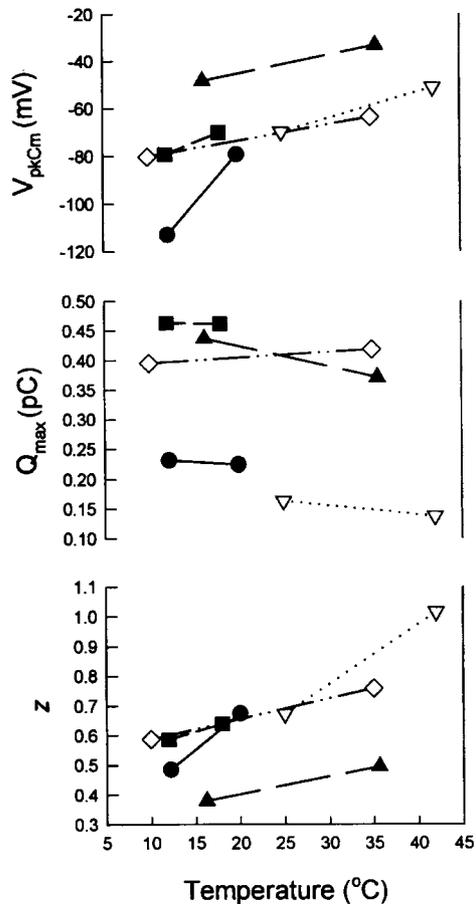

Fig. 3. The relationship between temperature and the parameters V_{pkCm} , Q_{max} , and z , derived from the fitting of capacitance data to a two-state Boltzmann function. Each of these quantities is plotted at two different temperatures for each of five cells. The increase in peak capacitance seen with increasing temperature cannot be due to an increased amount of total charge movement, because no clear increase is seen in Q_{max} . However, z shows a clear increasing trend.

optimal cochlear function across small fluctuations in environmental temperature.

ABSTRACT The outer hair cell lateral membrane motor, prestin, drives the cell's mechanical response that underpins mammalian cochlear amplification. Little is known about the protein's structure-function relations. Here we provide evidence that prestin is a 10-transmembrane domain protein whose membrane topology differs from that of previous models. We also present evidence that both intracellular termini of prestin are required for normal voltage sensing, with short truncations of either terminal resulting in absent or modified activity despite quantitative findings of normal membrane targeting. Finally, we show with fluorescence resonance energy transfer that prestin-prestin interactions are dependent on an intact N-terminus, suggesting that this terminus is important for homo-oligomerization of prestin. These domains, which we have perturbed, likely contribute to allosteric modulation of prestin via interactions among prestin molecules or possibly between prestin and other proteins, as well.

INTRODUCTION

A key evolutionary step in the development of high-frequency acoustic sensitivity in mammals appears to have been the recruitment of an anion transporter family member, prestin (SLC26A5) (1), to enable amplification of passive basilar membrane motion by outer hair cells (OHCs) (2). When transfected into nonauditory cells, this voltage-dependent, integral membrane protein presents all of the known biophysical attributes expressed by the native OHC lateral membrane motor, including voltage and tension sensitivity (1,3–6). These preserved attributes confirm the identity of prestin as the prime component of the lateral membrane motor. Nevertheless, we and others have noted some differences in the electromechanical activity of transfected prestin compared to that of the native OHC motor, and suggested that subunit interactions might be required for amplification of prestin's activity (6,7).

The molecular conformation or state of prestin, which underpins OHC electromotility and drives cochlear amplification, can be deduced from “gating charge” measures, or measures of the cell's voltage-dependent, nonlinear capacitance (NLC). Using these measures, the control of prestin's voltage-dependent activity has recently been linked to prestin's affinity for anions, in particular chloride ions (9,10). It has been suggested that these ions function either as extrinsic voltage sensors (9), or as allosteric modulators that influence the protein's steady-state energy profile (10,11). In this series of experiments, we extend our concept of allosteric modulation of prestin to include modulation via protein-protein interactions.

METHODS

Preparing mutants and transient transfection

Truncations of the N-terminus were achieved by introducing start codons before the indicated amino acid positions by polymerase chain reaction (PCR) amplification. Similarly, C-terminal truncations were obtained by introducing stop codons after the indicated positions. Yellow (YFP) or cyan (CFP) fluorescent protein fusion proteins were made by introducing the fluorescent proteins at the C-terminus of the prestin. In the case of the C-terminal truncations the truncated protein was fused directly to the N-terminus of YFP without an intervening stop codon. Amplification by PCR was done using Hi-Fidelity DNA polymerase (Roche, Indianapolis, IN). The parameters were 10 cycles of 94°C for 40 s, 55°C for 2 min, and 68°C for 6 min; and 30 cycles of 94°C for 40 s, 55°C for 2 min, and 68°C for 6 min, with 20 s extension for every cycle. A clone of gerbil prestin served as the template. Amplified products were purified, ligated into pCDNA 3.1 topo TA (Invitrogen, Carlsbad, CA) or into eYFPN1 (Clontech, Palo Alto, CA). Each of the clones generated were sequenced to exclude the possibility of PCR-generated errors. Transient cotransfection into Chinese hamster ovary (CHO) cells was achieved with Lipofectamine (Invitrogen) in accordance with the manufacturer's recommendations.

Fluorescence resonance energy transfer

Fluorescence resonance energy transfer (FRET) was determined using a Zeiss 510 with a meta-analyzer. CHO cells transiently transfected with prestin-YFP and prestin-CFP constructs (at a 2:3 ratio, to counter a lower CFP quantum yield and CFP's more diffuse emission spectrum) were analyzed 24–48 h after transfection. Emission from 10 defined regions of interest of each cell, detected by the meta-analyzer (in 10-nm increments) while excited at 458 nm were recorded before and after photobleaching at 514 nm. Photobleaching at 514 nm was done with the 40W argon laser set at maximum for a period of 1 min. FRET efficiency was defined as $(E_a - E_b) \times 100/E_a$, where E_a was the CFP emission (473–494 windows) after photobleaching and E_b the CFP emission before photobleaching, and calculated as previously described (12). In determining FRET efficiency in unbleached controls, CFP emission values obtained 1 min after determining the initial CFP emission were defined as E_a (a period of 1 min was the interval of photobleaching). To minimize CFP photobleaching while determining its emission, the laser intensity was set at 5% while measuring CFP emission. Although there was some minimal CFP bleaching during photobleaching of YFP, the effect was the same across all the sample combinations tested

where YFP photobleaching was performed. Thus, the increase in FRET efficiency observed in these bleaching experiments was found despite the slight decrease in CFP fluorescence after YFP bleaching. Thus, we cannot rule out that a relatively slight increase in FRET efficiency was masked in the observed decrease in efficiency found with start 21 prestin-YFP and prestin-CFP (see Fig. 5). Nevertheless, each group would be affected similarly.

Immunofluorescence staining

Affinity-purified rabbit polyclonal antibodies against two peptides corresponding to extracellular domains of prestin, GGKEFNERFKEKLPAPI (274–290) and KELANKHGYQVDGNQEL (359–375), respectively, were purchased from Genemed Synthesis (San Francisco, CA). Live OHCs or transfected CHO cells were incubated separately with these primary antibodies and then subsequently fixed. Primary antibody was detected using a fluorescent-labeled secondary antibody. Specificity of antibody labeling was established by preadsorption of the primary antibody with the corresponding peptide. Cells that were transfected with empty vector and stained in an identical fashion served as negative controls. Specific staining was not observed with either of these procedures.

Fluorescence-activated cell sorting analysis

CHO cells transfected with the different prestin-YFP constructs were labeled with affinity-purified anti-prestin antibodies. Live cells were dissociated and incubated with antibody in phosphate-buffered saline, 1% bovine serum albumin, and 0.5% fetal calf serum at 4°C. The primary antibody was detected using a biotinylated anti-rabbit antibody (Molecular Probes, Eugene, OR) followed by streptavidin conjugated to Alexa 647. The cells were fixed briefly in 1% paraformaldehyde before analysis. Fluorescence-activated cell sorting (FACS) analysis was carried out using FlowJo software. Stained cells were analyzed on a FACSCalibur TM (Becton Dickinson Immunocytometry Systems, Franklin Lakes, NJ). Forward and side scatter profiles were used to exclude dead cells. From 30,000 to 50,000 events were collected for analysis. Cells transfected with empty vector stained with the prestin antibodies and prestin-YFP stained with rabbit IgG served as negative controls for the primary and secondary antibodies, respectively.

Nonlinear capacitance

Cells were recorded by whole-cell patch-clamp configuration at room temperature using an Axon 200A amplifier (Axon Instruments, Foster City, CA), as described previously (13,14). The bath solution contained (in mM) TEA 20, CsCl 20, CoCl₂ 2, MgCl₂ 1.47, Hepes 10, NaCl 99.2, and CaCl₂·2H₂O 2, pH 7.2, and the pipette solution contained (in mM) CsCl 140, EGTA 10, MgCl₂ 2, and Hepes 10, pH 7.2. These conditions ensured that prestin-chloride interactions were maximal (9,10). Osmolarity was adjusted to 300 ± 2 mOsm with dextrose. Command delivery and data collections were carried out with a Windows-based whole-cell voltage-clamp program, jClamp (Scisoft, Ridgefield, CT), using an NI PCI 6052E interface (National Instruments, Austin, TX).

Capacitance was evaluated with a continuous high-resolution 2-sine wave technique fully described elsewhere (14,15). Capacitance data were fitted to the first derivative of a two-state Boltzmann function (13):

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}}, \quad (1)$$

where

$$b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right), \quad (2)$$

Q_{\max} is the maximum nonlinear charge transfer, V_h is the voltage at peak capacitance or half-maximal nonlinear charge transfer, V_m is membrane potential, C_{lin} is linear capacitance, z is valence, e is electron charge, k is

Boltzmann's constant, and T is absolute temperature. Gating charge currents were obtained with a standard $P/-5$ procedure (13).

RESULTS

CHO cells transfected with the gene for normal prestin show large gating currents and NLC, similar to that in OHCs (see Fig. 2 *B*). This signature of prestin's electromechanical activity was quantified through estimates of V_h (the voltage at half-maximal motor charge transfer), z (the charge valance), and Q_{\max} (total charge moved) that were derived from fits with two-state Boltzmann functions (13). With our intracellular and extracellular solutions, average normal values for V_h , z , and Q_{\max} (mean ± SE) were -102.4 ± 1.8 mV, 0.67 ± 0.02 , and 130 ± 20 fC, respectively ($n = 30$). Nonlinear charge density (coulombs per pF of linear capacitance) averaged 4.8 ± 0.6 fC/pF. Additionally, we were able to measure NLC in prestin that had been fused with YFP at its C-terminus ($n = 20$). This fusion construct of prestin provides electrical properties statistically indistinguishable from normal prestin; fusion constructs of mutant prestin that we made (see below) similarly remained unaffected by the tag. The assessment of this YFP fusion construct permitted not only quantitative electrical evaluations, but both qualitative and quantitative evaluations of membrane targeting via confocal microscopy and FACS, respectively.

To better understand structure-function relationships of prestin, we sought to refine our working knowledge of prestin topology (Fig. 1). The current membrane topology model of prestin posits 12 transmembrane (TM) domains (9,16). This model is, in part, based on placing two potential N glycosylation sites on the extracellular surface of the protein (17). In our modeling of prestin's TM regions, we abandoned this constraint based on several pieces of information. First, potential N glycosylation sites are common and often non-specific, being present even in frank intracellular proteins, including two potential N glycosylation sites that are within prestin's intracellular C-terminus (603 and 736). Second, in contradistinction to the results of Matsuda et al. (17), we find no significant effects of glycosylation site mutations (N163Q + N166Q) or glycosidase F treatment on the voltage dependence of NLC in transfected CHO cells (control ($n = 28$)/mutant ($n = 10$)/enzyme ($n = 13$): $V_h = -100.2 \pm 1.76/-95.9 \pm 3.92/-100.1 \pm 3.61$; t -tests, $p = 0.26/0.98$). Furthermore, the molecular mass of both prestin and doubly mutated prestin (N163Q and N166Q) were indistinguishable at 80 kD (Fig. 2 *J*), this also being in contradistinction to the results of Matsuda et al. (17). In the absence of that constraint, we are left with the observation, supported by epitope tagging and/or antibody staining of live and permeabilized cells, that the N- and C-termini are likely intracellular (9,16), results that we too have since replicated. Consequently, the molecule has an even number of TM domains, and based on an analysis of prestin's structure with a number of topology prediction programs (TMPred, DAS, TMAP, TMHMM, and

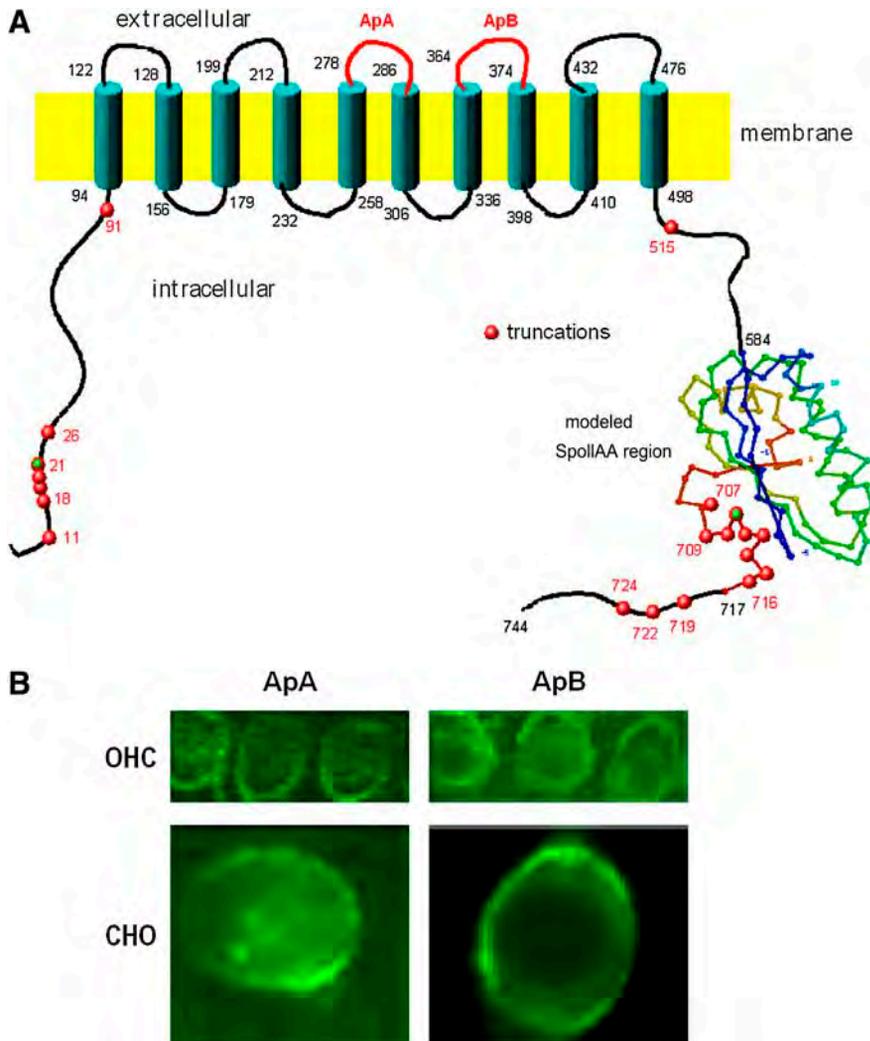

FIGURE 1 (A) Model of prestin's transmembrane topology that posits 10 transmembrane domains with intracellular amino and carboxy termini of the protein. Shown are the positions (red circles) of individual truncations of the protein that we tested. A cartoon of the crystal structure of the C-terminus of prestin modeled on the bacterial protein SpoIIAA, to which it shows strong homology, is shown. The positions of two peptides that would lie on the extracellular surface of the protein between transmembrane domains 4 and 5 (peptide A) and 6 and 7 (peptide B) are indicated. (B) Affinity-purified antibodies against these peptides (ApA and ApB) were used to stain both live guinea pig OHC (upper panel of confocal images) and live CHO cells transfected with prestin (lower panel). These results, together with other data (see text), confirm that these antigens lie on the extracellular surface, and support the 10-transmembrane model.

Predict Protein), we modeled prestin to contain 10 TM domains (Fig. 1 A). Our 10-TM model has a membrane topology the reverse of that previously proposed by Deak et al. (18); that is, segments on the intracellular surface in our model would lie on the extracellular surface of the cell in their model. We tested the model by immunostaining live outer hair cells and prestin-transfected CHO cells using antibodies raised to two peptides that are predicted, based on this model, to lie on the extracellular surface of the cell. The two peptides GGKEFNRFKEKLPAPI (274–290) and KE-LANKHGYQVDGNQEL (359–375) lie between TM domains 5 and 6, and 7 and 8 in our model (they would lie on the intracellular surface of the protein in the existing topology models (9,16,18)). We found live staining and fixed, nonpermeabilized staining of these cells with these two antibodies, confirming that the two peptides lie on the extracellular surface (Fig. 1 B). We also hemagglutinin (HA)-tagged prestin at residue 168, which proved functional, and were not able to find live staining by immunocytochemistry or FACS, but were able to immunocytochemically observe the tag after permeabilization (Fig. 2, A–F). HA tagging of residue 371

did not produce functional prestin (no NLC) and rarely showed membrane targeting; however, in those few rare cells live staining was observed (Fig. 2, G–I). We were unable to produce HA tagging of residue 281.

Our 10-TM model of prestin indicates that the amino and carboxy termini before residue 94 and after residue 498 reside intracellularly, that is, outside the lipid bilayer and beyond where a functional voltage sensor should reside. We used site-directed C-terminal and N-terminal truncations to evaluate the contribution of these intracellular moieties to prestin's voltage-dependent activity, as we did above with normal prestin. Successive truncations of the C- and N-terminus resulted in a graded decrease and eventual elimination of nonlinear charge movement (Fig. 2). In truncations that remained functional, voltage sensitivity (z) did not vary far from control values, indicating that the truncated protein's voltage sensor remained relatively unaltered. On the other hand, V_h varied among truncations, especially that of the N-terminal, and likely reflects structural influences on the steady-state energy profile that controls the voltage range over which the motors operate. Additionally, since the total

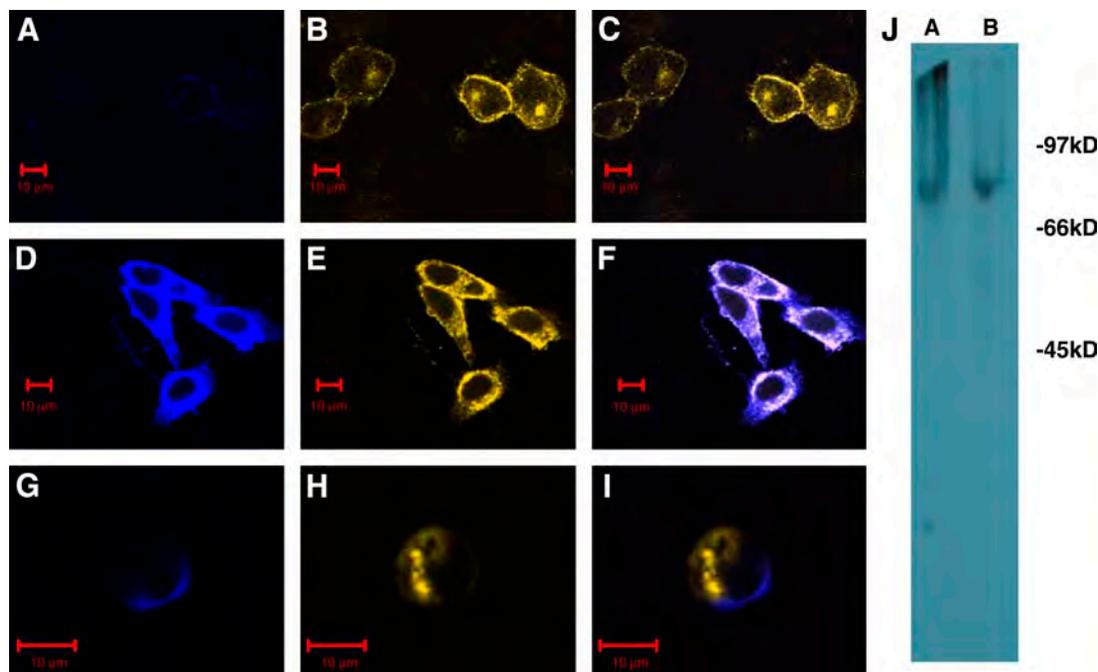

FIGURE 2 Confocal images show CHO cells transfected with prestin-YFP constructs into which the HA epitope was inserted into position 168 (A–F) and position 371 (G–I). The HA tags were detected with a mouse anti-HA epitope and Alexa 647-conjugated antimouse antibody (A, D, and G). (B, E, and H). YFP images. (C, F, and I) Merged images. Cells in A–C and G–I were stained live, and cells in D–F were fixed and permeabilized with detergent. As is evident, the detection of the HA epitope at position 168 required that the cells be permeabilized, whereas that at position 371 was detectable in live cells without permeabilization. These results suggest that position 168 of prestin in these constructs lies on the intracellular surface, whereas position 371 lies on the extracellular surface. (J) Substitution of the two potential N-glycosylation asparagine residues with glutamine residues does not result in a change in molecular weight, indicating that prestin is not glycosylated at these two residues. CHO cells were transfected with constructs of prestin fused to poly-His V5 epitope tag at its C-terminus (lane A) and prestin N163Q + N166Q double mutant fused to a poly-His V5 epitope tag at its C-terminus (lane B). Normal and mutated prestin were purified from lysed CHO cells on a Ni column and separated by PAGE (8%). The gel was blotted on to polyvinylidene difluoride and probed with an anti-V5 antibody/horseradish peroxidase-conjugated secondary antibody followed by enhanced chemiluminescence detection. As is evident, prestin migrates at its predicted molecular weight of 80 kD, as does the N163Q + N166Q double mutant.

charge movement Q_{\max} decreased, with z remaining normal, it appears that the number of functional proteins decreased. Stops N-terminal to residue 712 and starts C-terminal to residue 20 were functionally lethal, indicating catastrophic alterations in protein structure and/or absent or abnormal interactions with other potential intracellular subunits.

To rule out absent surface expression of these lethal truncations as a cause of a loss in NLC we confirmed proper targeting to the plasma membrane by live antibody staining of mutated prestin molecules in transfected cells. Similar patterns of antibody staining appear in both control and non-functional mutations. Additionally, several of the truncated mutations were evaluated with a YFP fusion construct. In each case, the results were the same as the ones we obtained with green fluorescent protein coexpression experiments, and each successfully targeted the plasma membrane (Fig. 3, E–G). The only exception was the full C-terminus truncation (stop 498), which was nonfunctional and confined intracellularly (Fig. 3 H). Full truncations of the C-terminus are not expected to properly target the membrane (D. Oliver, University of Freiburg, and J. Zheng, Northwestern University, personal communications, AOR meeting, 2004). Finally, to allay our concerns over the poor statistical power of confocal

microscopy, we used FACS in large populations of cells to confirm that membrane targeting was normal (Fig. 4). In these studies, the correspondence of fluorescence intensities in controls and mutants indicates that equal numbers of prestin molecules reach the plasma membrane in normal and mutant transfections. Thus, the proper targeting of functional and non-functional truncated mutations indicates that there is a decrease in the number of functional motors, not a decrease in the number of prestin molecules residing within the plasma membrane.

One possible mechanism for the reduction of functional motors is an interference with obligatory homomeric interactions among prestin molecules. To evaluate the possibility that prestin may function as multimers, we investigated whether individual prestin molecules could closely interact with each other using FRET. Fig. 5 shows that indeed close interactions (<100 Å) occur between fluorescently tagged neighboring C-terminals of prestin; additionally, controls with the fluorescently tagged Slo K channel do not show interactions with prestin. Restricting the area of interest to the plasma membrane produced the same FRET response, as larger cellular areas. Consistent with this data, chemical cross-linking of purified poly-his tagged prestin yielded a minimal molecular mass of 160 kD, suggesting that prestin formed dimers. To

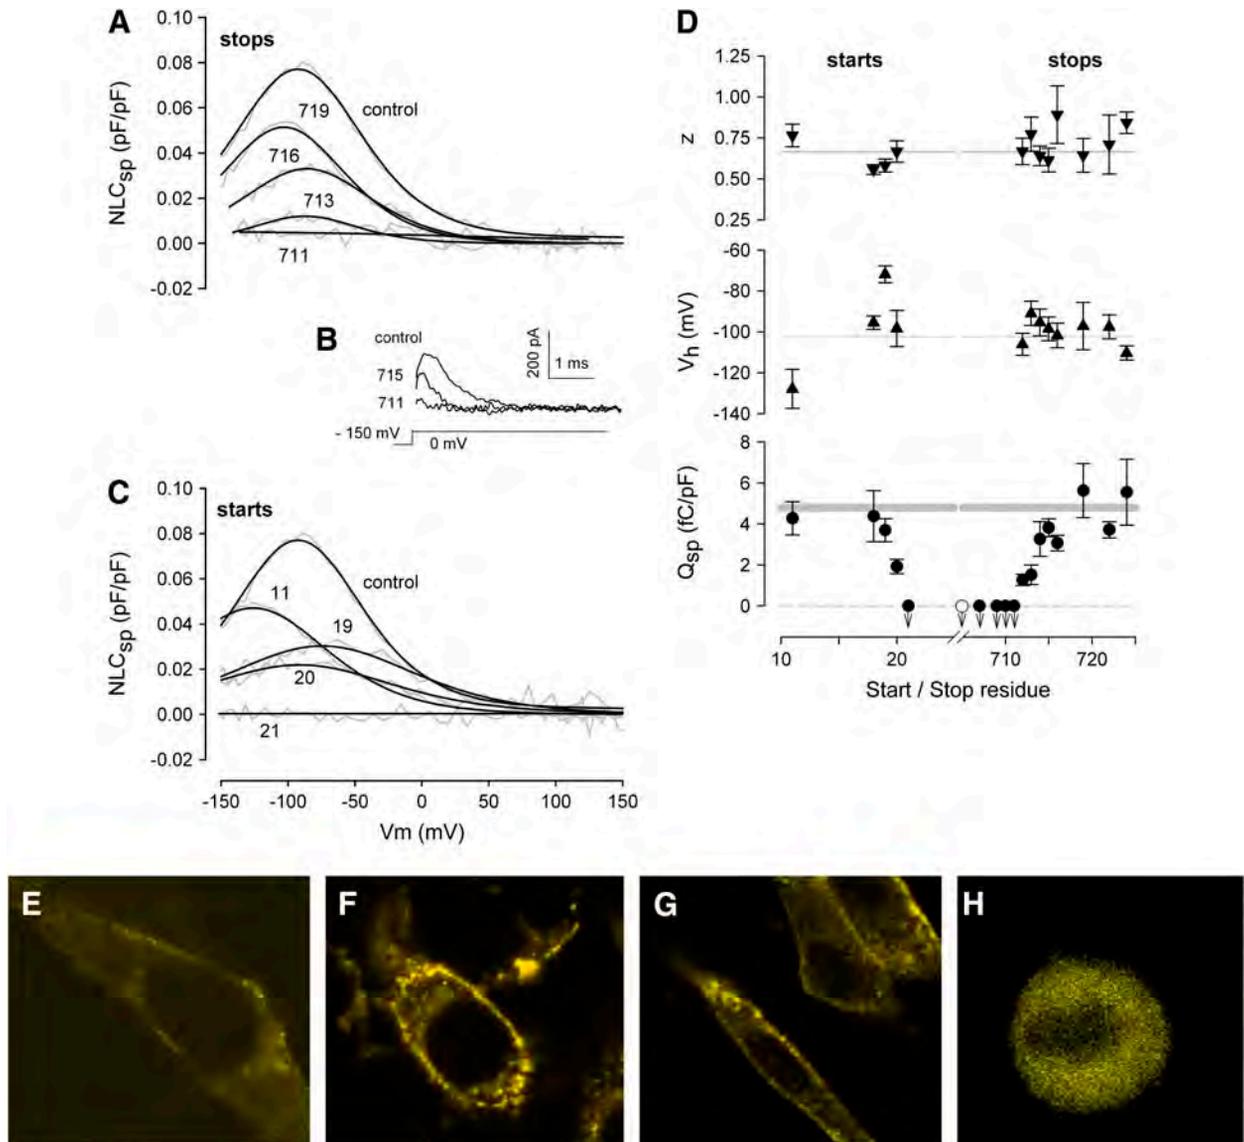

FIGURE 3 Serial truncations of the amino and carboxy termini of prestin result in a loss of NLC. (A) Nonlinear capacitance as a function of C-terminal truncations. A stop codon at 712 abolishes NLC. (B) Examples of gating currents induced by a voltage step showing a decrease in magnitude corresponding to reductions in NLC. (C) Nonlinear capacitance as a function of N-terminal truncations. A start codon at 21 abolishes NLC. (E–G) Confocal images of CHO cells transfected with prestin-YFP, start 21 prestin-YFP, and stop 709 prestin-YFP, respectively, showing plasma membrane targeting of these constructs. (H) A confocal image of a CHO cell transfected with stop 498 prestin-YFP that does not target the membrane (and corroborates work by other workers in the field; Jing Zheng, Northwestern University, and Dominik Oliver, University of Freiburg, personal communication, AOR meeting, 2004). These results confirm that the loss in NLC with these truncations is not due to absent targeting to the surface membrane.

determine whether the intracellular termini were required for these interactions, we used FRET to identify homomultimerization of two prestin truncations, start 21 prestin-YFP and stop 709 prestin-YFP, each of which was physiologically nonfunctional, but targeted the membrane successfully. In contrast to stop 709 prestin-YFP, which showed FRET when cotransfected with normal prestin-CFP, start 21 prestin-YFP did not show FRET when cotransfected with normal prestin-CFP. The differences in FRET efficiencies obtained before and after acceptor photobleaching were statistically significant (see Fig. 5), indicating that the N-terminus of prestin is

important for the formation of multimers, and the loss in NLC is possibly a result of an inability to form multimers. In contrast, since the C-terminal truncation that resulted in a loss of NLC was still able to form homomultimers, we speculate that the C-terminus interacts with other proteins that are important for generating NLC.

DISCUSSION

The discovery of prestin (19) identified a molecule that likely is the foundation of the mammalian auditory system’s

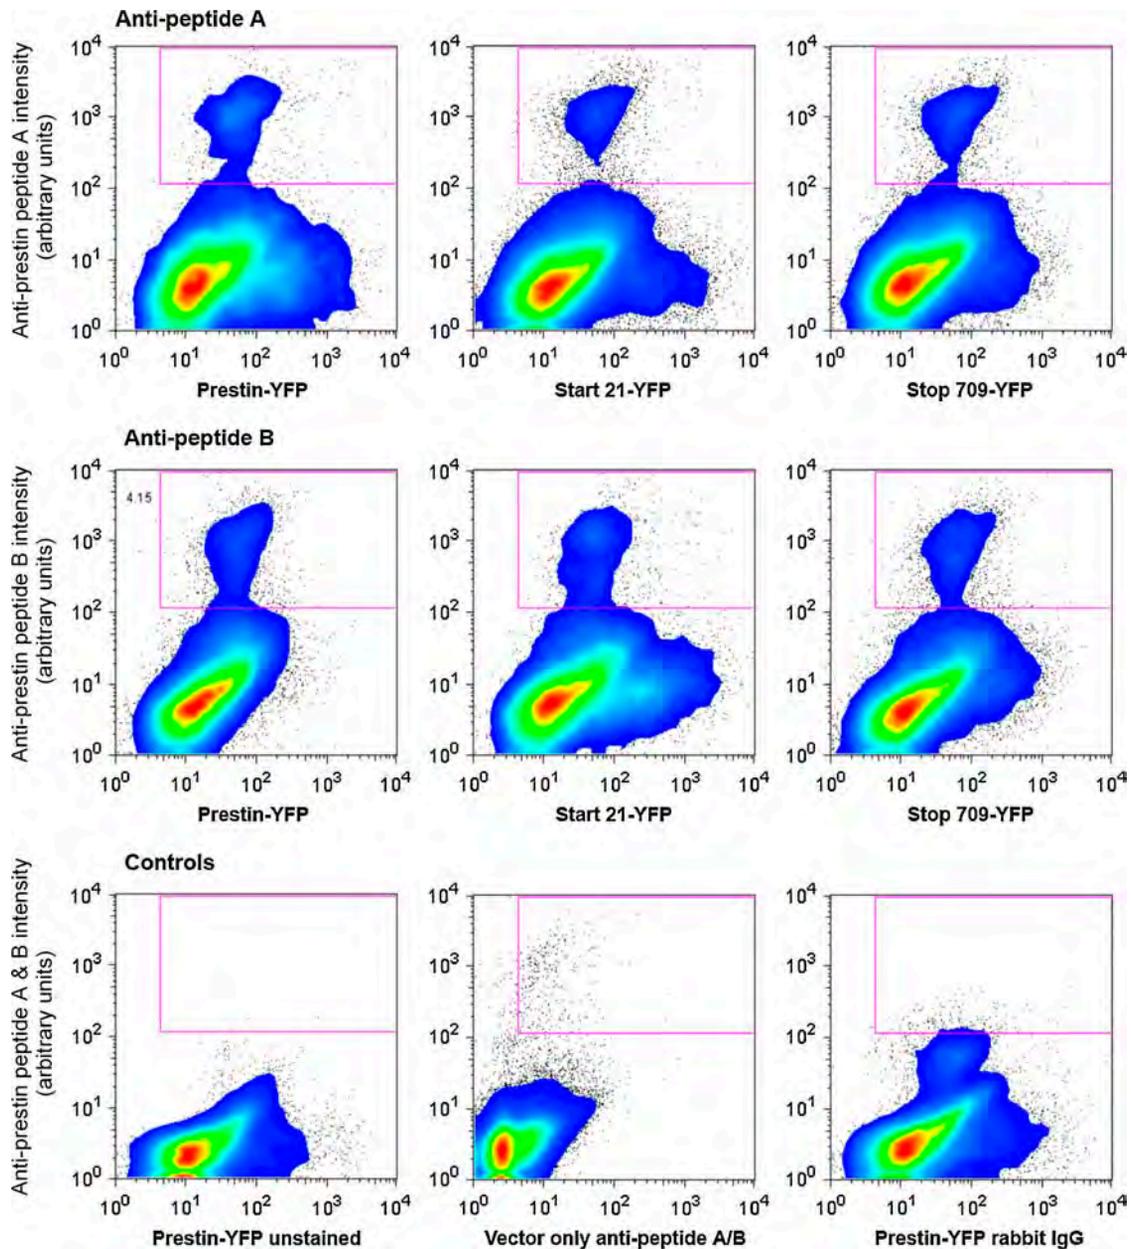

FIGURE 4 Quantification of prestin surface expression in transfected CHO cells by flow cytometry. CHO cells transfected with prestin-YFP fusion constructs (normal prestin, start 21, and stop 709) were dissociated and stained live with two affinity-purified rabbit polyclonal antibodies to two peptides expressed on the extracellular surface of the protein (*upper panels*: antibody to peptide A = GGKEFNRFKEKLPAPI (aa 274–290); *middle panels*: antibody to peptide B = KELANKHGYQVDGNQEL (aa 359–375)). The primary antibody was detected using a biotinylated anti-rabbit antibody (Molecular Probes) and streptavidin conjugated to Alexa 647. All antibody staining was done in phosphate-buffered saline and 0.5% bovine serum albumin at 4°C. The cells were then fixed in 4% paraformaldehyde before flow cytometric analysis. Shown are contour plots with outliers of YFP intensity (Phycocerythrin window) on the *x* axis and prestin intensity (Alexa 647) on the *y* axis of live stained cells (identified by forward and side scatter). As is evident, a subpopulation of YFP positive cells, recognized by both antibodies, is present in those cells transfected with the three prestin-YFP fusion constructs (normal prestin, start 21, and stop 709) and not in those cells transfected with empty vector alone stained with anti-prestin antibodies to peptides A and B, unstained prestin-YFP transfected cells, or prestin-YFP transfected cells stained with rabbit IgG (*lower panels*). Both the intensity of staining and the percentage of cells within the boxed area recognized by the antibodies are similar in cells transfected with full-length prestin (4.4% and 4.3% for anti-peptides A and B, respectively), start 21 (2.6% and 3.9%), and stop 709 (3.2% and 3.3%). The three control groups contained an insignificant number of cells labeled with the antibodies. Differences in number of cells indicate variability in expression efficiency among experiments hovering around 3–6%. These efficiencies are obtained by other workers in the field (Dominik Oliver, personal communication). These quantitative analyses are evidence that the absence in NLC in these two truncations is not due to aberrant surface expression.

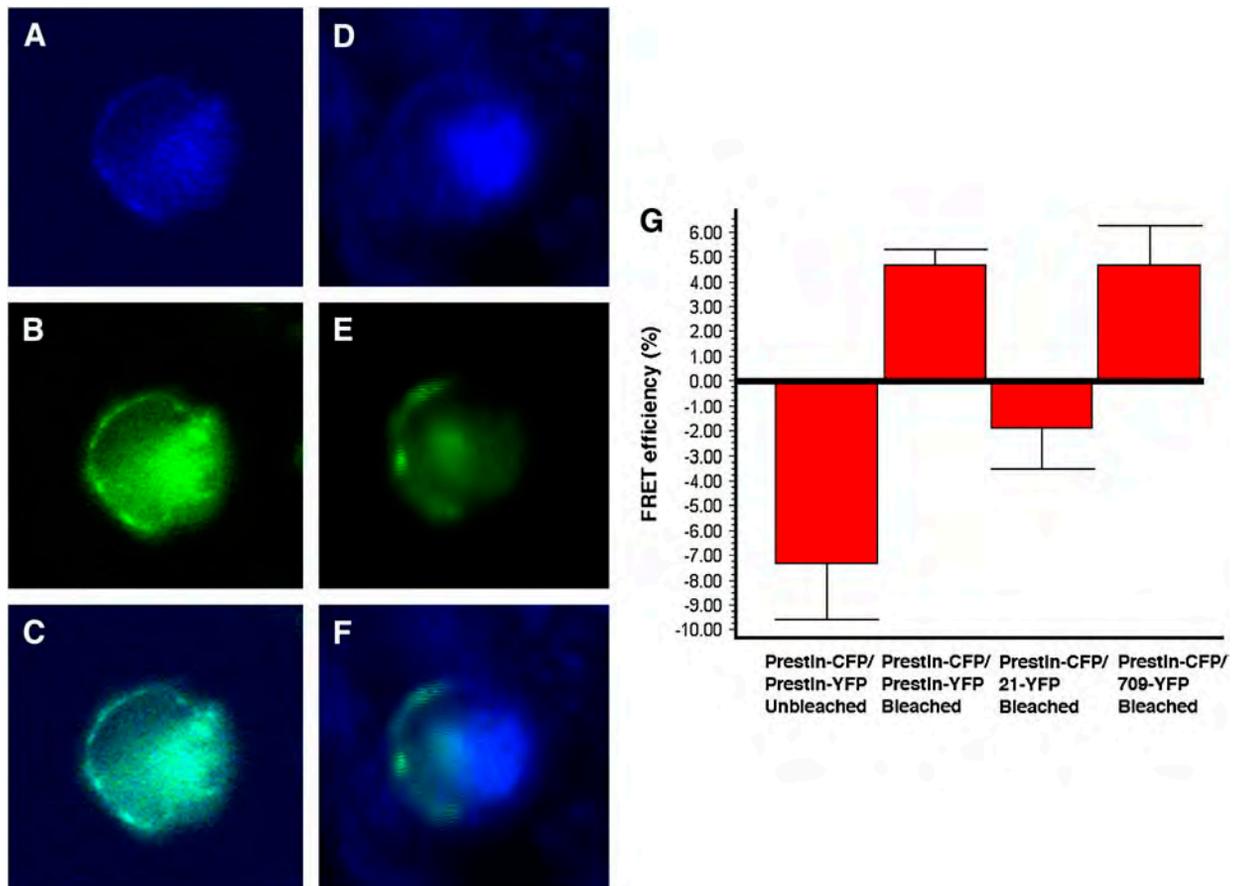

FIGURE 5 FRET demonstrated by acceptor (YFP) photobleaching confirms prestin-prestin interactions and suggests that the N-terminus is important in these interactions. The figure shows a CHO cell transfected with prestin-CFP (A and D) and prestin-YFP (B and E) before (A–C) and after (D–F) photobleaching YFP (514 line of the Argon laser) in the right half of the cell. (C and F) Merged images of A and B, and D and E, respectively. As is evident, there is an increase in CFP emission (D and F) concomitant with a decrease in YFP emission (E and F) in the right half of the cell. (G) The graph shows a quantitative estimate of FRET efficiencies after photobleaching (7). The efficiency of FRET is compared between CHO cells transfected with prestin-CFP together with prestin-YFP without (first bar) and with (second bar) acceptor photobleaching, prestin-CFP together with start 21 prestin-YFP (third bar), and prestin-CFP together with stop 709 prestin-YFP (fourth bar). A normal decrease in FRET efficiency in the absence of YFP photobleaching (-7.39 ± 2.189 (mean \pm SE), $n = 3$ cells) is converted to an increase in FRET efficiency with photobleaching in prestin-CFP and prestin-YFP (4.64 ± 0.63 , $n = 5$), and prestin-CFP and stop 709 prestin-YFP (4.67 ± 1.54 , $n = 4$), confirming interactions between normal prestin molecules, and C-terminally truncated prestin molecules and normal prestin. The absence of an increase in FRET efficiency with start 21 prestin-YFP and prestin-CFP (-1.94 ± 1.57 , $n = 4$ cells) confirms an absence of interaction between the N-terminally truncated prestin molecules and normal prestin. A one-way ANOVA between these groups demonstrated a significant difference between unbleached normal prestin and bleached normal prestin ($p < 0.002$) or stop 709 prestin ($p < 0.002$), but no difference between unbleached normal prestin and start 21 prestin. Similarly, there was a significant difference between FRET efficiencies in normal prestin and start 21 prestin ($p < 0.05$) transfected cells. Also noteworthy was that FRET efficiency at the membrane (6.5 ± 1.5 , $n = 3$) was not significantly different from elsewhere in the cell.

nonlinear amplificatory mechanism (20). How this protein works is key to understanding the remarkable ability of OHCs to respond mechanically to electrical stimuli, discovered some 20 years ago (21). Our observations on the functional consequences of short terminal truncations indicate that this protein does not work alone, but requires interacting partners to drive OHC motor activity. Though some molecular manipulations can interfere with proper membrane targeting (for example, full C-terminal truncations of prestin were not delivered to the plasma membrane), we combined techniques with low and high statistical power, namely confocal microscopy and FACS, respectively, to unambiguously confirm uncompromised membrane residence.

In previous work we demonstrated that intracellular chloride altered the operating voltage range of prestin, shifting V_h to more negative voltages (10). This observation was incongruent with a simple extrinsic voltage sensor scheme for anions previously proposed (9). Additionally, we showed that the valence of substituted anion did not, as expected, alter the valence of charge movement (11), further supporting our conclusion that anions serve as allosteric modulators rather than voltage sensors. However, although allosteric effects can be mediated by ion interactions with proteins, e.g., chloride with Cl channels (22) or Ca with K channels (23), conformational alterations can additionally arise from protein-protein/peptide/domain interactions (24).

Thus, our present data, which show a requirement for homomeric interactions among prestin's N-termini for normal charge movement, indicate that motor behavior is also allosterically controlled by these interactions. Indeed, we have previously interpreted the motors' sensitivity to prior voltage conditions as resulting from prestin-prestin interactions within the bilayer (6,14). Thus, we argued that prestin interactions may underlie the shift in the steady-state energy profile that results from prepulse perturbations, possibly through viscoelastic relaxations of prestin-induced membrane tension. Clearly, our new data open the possibility that these voltage-dependent viscoelastic effects could arise from interactions between homomeric components of prestin motor complexes, as well as among the complexes.

The topology of SLC26 transporter family members is not well delineated, with divergent models predicted possessing 10–14 TM domains (25). For prestin, a 12-TM domain model had been proposed, but our data do not support this model. Instead, we propose a 10-TM model, with the antibody-identified loops 5 (aa274–290) and 7 (aa359–375) residing extracellularly, as opposed to intracellularly as in previous models. Interestingly, Adler et al. (26), using antibody labeling, also placed region 274–290 on an extracellular loop. Additionally, the original 12-TM model of Zheng et al. (16,17) has recently been modified by that group with a reentrant loop to move a putative cGMP phosphorylation site at residue 238 onto the intracellular aspect of the protein (18)—a location already predicted by our model. Taken together, evidence for our 10-TM model is strong and dramatically changes our view of the landscape over which intracellular constituents can interact with prestin.

We thank Peter Dallos and colleagues for the gerbil prestin clone, and Margaret Mazzucco for technical help.

ABSTRACT The voltage-dependent activity of prestin, the outer hair cell (OHC) motor protein essential for its electromotility, enhances the mammalian inner ear's auditory sensitivity. We investigated the effect of prestin's activity on the plasma membrane's (PM) susceptibility to electroporation (EP) via cell-attached patch-clamping. Guinea pig OHCs, TSA201 cells, and prestin-transfected TSA cells were subjected to incremental 50 μ s and/or 50 ms voltage pulse trains, or ramps, at rates from 10 V/s to 1 kV/s, to a maximum transmembrane potential of ± 1000 mV. EP was determined by an increase in capacitance to whole-cell levels. OHCs were probed at the prestin-rich lateral PM or prestin-devoid basal portion; TSA cells were patched at random points. OHCs were consistently electroporated with 50 ms pulses, with significant resistance to depolarizing pulses. Although EP rarely occurred with 50 μ s pulses, prior stimulation with this protocol had a significant effect on the sensitivity to EP with 50 ms pulses, regardless of polarity or PM domain. Consistent with these results, resistance to EP with depolarizing 10-V/s ramps was also found. Our findings with TSA cells were comparable, showing resistance to EP with both depolarizing 50-ms pulses and 10 V/s ramps. We conclude prestin significantly affects susceptibility to EP, possibly via known biophysical influences on specific membrane capacitance and/or membrane stiffness.

INTRODUCTION

In the mammalian cochlea, outer hair cells (OHC) enhance hearing sensitivity and frequency selectivity (1). This enhancement, known as the "cochlear amplifier" (2), results from OHC mechanical activity, as this unique neuroepithelial cell can undergo electrically induced rapid length changes (3–6) at acoustic rates (7–9). Prestin, the OHC motor protein (10), is fundamental for OHC electromotility (11). Mechanical, electrical, and morphological data indicate that these motors are distributed preferentially within the cell's lateral plasma membrane (PM) (12–17).

A variety of models for electromotility have been proposed, based on electro-osmosis (4), electrophoresis (18), membrane bending (19), stiffness changes (20), and via surface area modulation, designated the "area-motor" model (21–26). The latter three remain serious candidates. We have proposed, based on modeling the voltage dependent capacitance of the OHC, that prestin's conformational change alters tension within the lateral membrane (27).

It is well known that cell membranes break down when subjected to mechanical or electrical stress, and that these stimuli can interact (28,29). The vulnerability to electroporation (EP) can provide insight into the interaction between PM and cortical cytoskeleton (29–31); for instance, negative pressure has been found to be more effective in producing membrane breakdown, presumably due to the greater interaction with the cytoskeleton with positive pressure (29). In addition, the integrity of the cytoskeleton

is critical for resealing (32). The composition of the membrane is also highly influential; an increase in cholesterol, protein content, or certain surfactants can alter the susceptibility of the lipid bilayer to applied electrical tension (28,33). A variety of models have been proposed to explain the molecular mechanism of EP. It is generally accepted that a progression of membrane defects occurs as the energy threshold for their production is surpassed and maintained, resulting in increased permeability.

We have studied EP via cell-attached patch-clamping in OHCs to determine whether the electromechanical activity of prestin alters the biophysical properties of the PM. We also tested prestin-transfected TSA201 cells to divorce prestin's activity from modulation by the OHC's specialized cytoskeletal lattice. We find significant differences in susceptibility to EP between the lateral and basal membranes of OHCs, as well as between prestin-transfected and untransfected TSA cells, which we attribute to the residence of prestin.

MATERIALS AND METHODS

Cell preparation

Guinea pigs were overdosed with halothane, according to Yale University's Animal Use and Care Committee guidelines. Their temporal bones were dissected, isolating the top two turns of the organ of Corti. OHCs were dissociated with dispase in calcium-free medium for 10–15 min, followed by gentle pipetting. The cell-enriched solution was transferred to a 700- μ L perfusion chamber and allowed to settle on the coverglass bottom for 10–15 min.

TSA201 cells, clones of human embryonic kidney (HEK) 293 cells that express the simian virus 40 large T-antigen in a stable manner, were cultured in Dulbecco's modified Eagle's medium (Sigma Chemical, St. Louis, MO) with 5% fetal bovine serum, 100 U/ml of penicillin and 100 μ g/ml of

streptomycin. Cells were plated for 24 h before transfection using effectene (Qiagen). The transfection reaction mixture consisted of 1 $\mu\text{g}/\text{ml}$ of Pres cDNA plasmid added to 0.1 $\mu\text{g}/\text{ml}$ of green fluorescent protein (GFP) plasmid, as a transfection marker in the 3 ml of Dulbecco's modified Eagle's medium the TSA cells were cultured in. Experiments were carried out 24–48 h posttransfection in the same culture dish without any dissociating procedures to avoid trauma to the cells.

Experimental setup

The guinea pig OHC and TSA cell PMs were probed via cell-attached patch-clamp recording. All experiments were performed at room temperature ($\sim 23^\circ\text{C}$). A Nikon Diaphot (Melville, NY) inverted microscope with Hoffman optics (Aurora, IL) and a Sony VCR Model EV-C200 (Tokyo, Japan), were used to observe and tape record the experiments with OHCs. A Leica DM-IRB inverted microscope (McHenry, IL) with differential interference contrast optics was used for experiments with TSA cells.

OHC patches were clamped with an Axon Instruments Axopatch 200B amplifier (Foster City, CA) at a holding potential of -20 mV, the resting potential of dissociated OHCs (6), to zero the transmembrane voltage drop. Gigohm seals were obtained at the OHC lateral PM, where there is a high concentration of prestin, and at the basal area, which is devoid of these motors. TSA cells were also patch-clamped on random points of their PM that appeared smooth with an Axon Instruments Axopatch 200 amplifier holding them at their estimated average resting potential of -10 mV (E. G. Navarrete, unpublished observations). An ionic blocking solution was used in the bath and pipette, consisting of (in mM) 20 TEA, 20 CsCl, 2 CoCl_2 , 1.47 MgCl_2 , 10 Hepes, 99 NaCl, and 2 CaCl_2 . CsOH and glucose were used to adjust pH to 7.2 and osmolarity to 300 mOsm. Ion channel blockers were used to avoid increases in membrane conductance due to channel activity and to measure prestin's voltage-dependent capacitance. Pipettes had an average aperture of 1.43 ± 0.03 μm (mean \pm SE; $n = 78$ measurements) and initial resistances ranged from 1.5 to 3 $\text{M}\Omega$.

Pulse and ramp protocols

In all cells, EP was investigated using square voltage pulses and ramps. We used stimulus protocols based on Akinlaja and Sachs (31) in the case of the pulse trains, and O'Neill and Tung (36) in the case of the ramp stimuli. Initially, in OHCs two different pulse protocols were used, varying the duration of the voltage stimulus. The first protocol consisted of a series of 50- μs voltage pulses with sequential increments of 50 mV and an interpulse delay of 5 s to a transmembrane potential (TMP) of at least ± 1000 mV (-1020 mV, $+1030$ mV). The second protocol consisted of 50 ms voltage pulses with sequential increments of 20 mV and an interpulse delay of 7 s, to a TMP of ± 1000 mV. The 50-ms protocol was administered after the 50- μs pulse train in all cells that did not undergo EP and additionally to a set of cells in isolation to check for prior stimulation effects. Because OHCs were rarely permeabilized with 50- μs protocols, and to avoid loss of seal resistance or sensitization, TSA cells were only subjected to a 50-ms pulse train starting at 400 mV. During the interpulse interval, membrane capacitance (C_m) was measured every 120 ms, with transient analysis (14). EP was determined by a step increase in capacitance to whole-cell levels (Fig. 1). Occasionally, transient EP occurred (Fig. 2), which we defined as an increase in C_m to whole-cell levels for a minimum of two data points.

Ramps at speeds from 10 V/s to 1 kV/s were additionally used to study both cell types, also to a maximum voltage of ± 1000 mV. Membrane breakdown (MB) was defined, as it was previously (32), as a step increase in the conductance of the membrane patch indicated by a sudden and sharp rise in current (I). As with the pulse protocol, C_m was measured with transient analysis after administering the stimulus, occasionally revealing an intact, resealed patch. Thus, we defined the permanent increase in C_m to whole-cell levels as patch breakdown (PB).

Although membrane conductance will increase with EP, only the increase in charging time/capacitance irrefutably demonstrates EP; however, it is

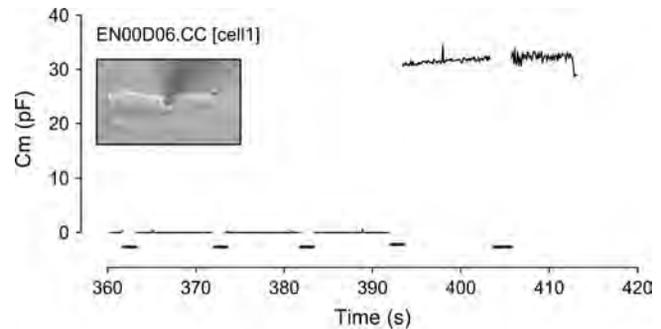

FIGURE 1 Increase in membrane capacitance (C_m) to whole-cell levels after a voltage pulse indicates electroporation (EP). Voltage pulses are indicated by the thick lines on the x axis.

possible that the plasma membrane was electroporated and quickly resealed. This would be unusual since cell membranes have relatively long sealing times, on the order of minutes; for example, in their study, O'Neill and Tung (34) found that conductance changes persisted when their cardiac myocytes were restimulated within a minute. Since the increase in capacitance may have been missed due to our sampling resolution, we proceeded to analyze the membrane instability (MI) and MB data.

Data analysis

Statistical analyses were performed with Excel (Microsoft) and Analyse-it (Analyse-it Software, Leeds, UK). To avoid obtaining a potentially misleading asymmetric polarity-dependent TMP at the onset of EP, the resting potential was subtracted/added to the applied voltage (35,36). For OHCs, absolute TMP at onset of EP was calculated taking into account the average resting potential of -20 mV (see above). With TSA we accounted for an average resting potential of -10 mV. Results were evaluated using parametric (t -tests, analysis of variance (ANOVA), and linear regression) and nonparametric (chi-square) statistical analyses when appropriate. After the electrical stimulation and establishment of whole-cell configuration, TSA cell capacitance was measured as fully described elsewhere (27,37) to confirm prestin's presence and functionality, and to measure the motor protein density. The density of prestin was assessed via charge density, a normalization metric measuring maximum charge moved per linear capacitance ($Q_{\text{max}}/C_{\text{lin}}$), since the linear capacitance will be proportional to cell surface area. To avoid sensitization, charge density in the cell-attached patch configuration was not measured before the EP protocols. It is assumed that the concentration of prestin would be very similar to the

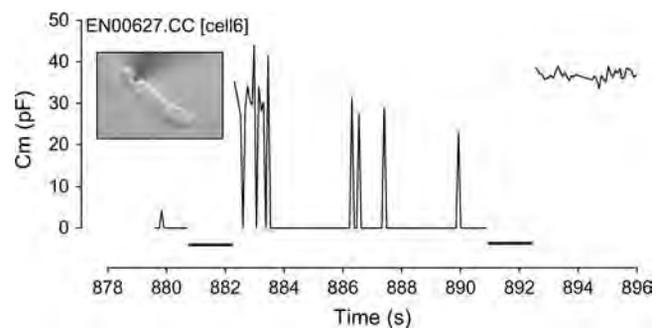

FIGURE 2 Episodes of transient membrane breakdown followed by fast resealing are indicated by the spikes in C_m on this data trace reaching whole-cell levels. Voltage pulses are indicated by the thick lines on the x axis. Electroporation is noted at the end of the trace by the sustained increase in C_m after a voltage pulse.

whole-cell value. We also assumed consistent patch geometry in TSA cells and OHCs based on images in the literature (13,31), although we did not control for this variable for each individual cell. A Windows-based software package, jClamp (SciSoft, Branford, CT), was used for acquisition and analysis. Igorpro (Wavemetrics; Lake Oswego, OR) was used to fit the capacitance data. All data are presented as mean ± SE.

RESULTS

Pulse protocols in outer hair cells

Susceptibility to EP with 50 μs pulse trains in our population of OHCs is very similar to that reported previously with HEK cells (29) and lipid bilayers (28). EP was rarely produced at voltages <1 V in the absence of extrinsic pressure (6.8%, *n* = 59). Nevertheless, the integrity of the membrane was undoubtedly compromised in the OHC by this prior stimulation. Sufficient current was injected through the patch to produce a change in the TMP and evoke the OHC's unique electromotile responses, as fast reversible movements in phase with the stimulus polarity were evident starting at an absolute average TMP of 765 mV. Furthermore, a consistent decrease in seal resistance was frequently revealed, which analyzed in isolation could have been mistaken for a loss of the seal were it not for our ability to monitor the electromotile responses and interpulse capacitance. Significant differences in the absolute average voltages at which mechanical responses occurred during 50 ms pulse trains were found depending on prior stimulation with the 50 μs protocol (71 ± 9 mV with prior stimulation versus 214 ± 12 mV with no prior stimulation, *p* < 0.001, *n* = 81, *t*-test). In addition, multiway analysis of variance demonstrated that prior stimulation with 50 μs pulses was a significant factor influencing the onset of EP in the OHC PM (*p* < 0.001, *n* = 85) during the subsequent 50 ms protocol.

EP occurred consistently between 240 and 580 mV, similar to the values reported previously for HEK cells (29). There was little difference in the average absolute TMP at onset of EP at the OHC basal area (see Table 1). At the lateral PM our results demonstrated a significant difference when polarity was varied (*p* < .05, *t*-test). Transient reversible EP with fast resealing (Fig. 2) on a timescale as short as 240 ms was observed in almost 20% (seven cells) of OHC patches subjected to depolarization (*n* = 40) at a TMP ranging be-

TABLE 1 Pulse protocols in OHCs: comparison of absolute TMP at onset of EP

Location	Stimulus polarity	Absolute TMP at onset of EP
Basal	Hyperpolarizing	388 ± 21 (<i>n</i> = 10)
	Depolarizing	382 ± 14 (<i>n</i> = 10)
Lateral	Hyperpolarizing	388 ± 13 (<i>n</i> = 10)
	Depolarizing	446 ± 20 (<i>n</i> = 10)

OHCs demonstrated a statistically significant difference in susceptibility to EP due to the effect of polarity at the lateral PM (*p* < .05, *t*-test). The incidence of EP was 100% in all categories. The charge density of the guinea pig OHCs lateral wall is estimated to be ~150–200 fC/pF.

tween 360 and 460 mV, regardless of location. Interestingly, this phenomenon was not observed with hyperpolarizing pulses, although its occurrence could have been possible at a timescale beyond the detection of our sampling frequency. Because of our 2-data-point minimum as criteria for determining transient reversible EP, it may also have been dismissed as noise.

Pulse protocols in prestin-transfected and nontransfected TSA cells

TSA cells transfected with gPres demonstrate significant resistance (*p* < .02, chi-square analysis) to EP with our depolarizing 50 ms pulse protocol, failing to be permeabilized in >50% of our sample (see Table 2). Untransfected TSA cells underwent EP in 90% of the cells tested at absolute TMPs between 400 and 580 mV, consistent with our OHC data. Regarding the average absolute TMP at onset of EP, no statistically significant trends were evident, although it is interesting that the average threshold TMPs required for EP were slightly higher in transfected cells, in addition to showing greater variance. Virtually every cell resealed within seconds of EP, regardless of transfection or stimulus polarity.

Ramp protocols in outer hair cells

Almost 100% of the OHCs displayed a period of MI before a rapid step increase in conductance attributed to MB (Fig. 3), as described in the literature (33), regardless of portion probed, polarity, or ramp speed. After the ramp stimulus, and despite evidence for MB during the ramp, *C_m* increase to whole-cell levels is not consistently observed at 1 kV/s (see Table 3). This resistance to EP was clearly a rate-dependent phenomenon as it occurred in almost 100% of the sample at 10 V/s (see Table 4). Significantly, the lateral PM was more resistant to PB with depolarizing 10 V/s ramps (*p* < .02, chi-square analysis). Although we find interesting polarity-dependent trends in both MI and MB, it is impossible to distinguish whether conductance increases were due to seal loss or EP without monitoring capacitance. Although it is plausible that the plasma membrane was electroporated and

TABLE 2 Pulse protocols in gPres transfected and nontransfected TSA cells: incidence of EP, absolute TMP at onset of EP

DNA	Stimulus polarity	EP incidence	Absolute TMP at onset of EP (mV)	Charge density
None	Hyperpolarizing	90% (<i>n</i> = 10)	464 ± 20	N/A
	Depolarizing	90% (<i>n</i> = 10)	495 ± 13	N/A
gPres	Hyperpolarizing	100% (<i>n</i> = 9)	549 ± 50	13.1 ± 3.1 fC/pF
	Depolarizing	44% (<i>n</i> = 9)	600 ± 122	14.5 ± 10.6 fC/pF

Transfected TSA cells demonstrate significantly reduced EP incidence with depolarizing 50 ms pulse trains (*p* < .02, chi-square analysis). No statistically significant differences are evident comparing absolute TMP at onset of EP.

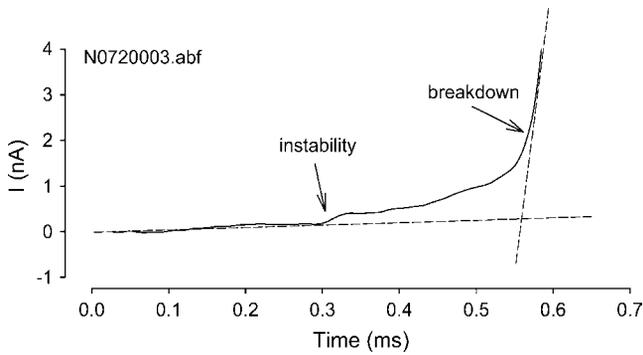

FIGURE 3 Response to a depolarizing voltage ramp at 1 kV/s in an OHC. Membrane instability is noted by the deviation from the preceding linear trace. Membrane breakdown is indicated by the rapid step increase in conductance.

quickly resealed, only the increase in capacitance indisputably demonstrates EP.

Since the increase in capacitance may have been missed due to our sampling resolution, we present our findings and analysis of the MI and MB data. Location did not have a significant effect on either MI or MB TMPs with the 1-kV/s ramps (see Table 3). The effect of polarity on the onset of MI is obvious at both ramp speeds, but more significant with 1 kV/s ramps ($p < .0001$, two-way ANOVA); there is more resistance to MI with depolarizing ramps. Interestingly, we find the opposite effect with 10 V/s ramps, an increased resistance to MI with hyperpolarizing ramps ($p < .05$, two-way ANOVA). We performed additional experiments using 100 mV/s ramps and found no polarity dependence in MI or MB at either region of the OHC (data not shown). Although there are no polarity-dependent differences with respect to MB at the lateral wall with 1 kV/s ramps, we find resistance to depolarizing ramps at the base. Regarding MB with 10 V/s ramps, we find significant effects due to polarity and resistance to depolarizing ramps ($p < .01$, two-way ANOVA), regardless of location.

Ramp protocols in prestin-transfected and nontransfected TSA cells

Both transfected and untransfected cells undergo MI somewhat consistently (100% at 1 kV/s, 77–93% at 10 V/s).

TABLE 3 Ramp protocols at 1 kV/s in OHCs: absolute TMP at onset of MI and MB and incidence of PB

Location	Polarity	MI (mV)	MB (mV)	PB
Basal	Hyperpolarizing	299 ± 4 ($n = 19$)	559 ± 9	16%
	Depolarizing	538 ± 12 ($n = 19$)	606 ± 11	37%
Lateral	Hyperpolarizing	290 ± 10 ($n = 18$)	590 ± 10	28%
	Depolarizing	527 ± 19 ($n = 13$)	582 ± 16	15%

PB did not occur consistently with this stimulus type. MI occurs at pronouncedly higher TMPs with depolarizing 1 kV/s ramps, demonstrating the significant effect of polarity ($p < .0001$, two-way ANOVA). MI and MB values are given as mean ± SE.

TABLE 4 Ramp protocols at 10 V/s in OHCs: absolute TMP at onset of MI and MB and incidence of PB

Location	Polarity	MI (mV)	MB (mV)	PB
Basal	Hyperpolarizing	314 ± 14 ($n = 12$)	445 ± 30	92%
	Depolarizing	273 ± 16 ($n = 13$)	374 ± 16	100%
Lateral	Hyperpolarizing	317 ± 12 ($n = 11$)	454 ± 31	91%
	Depolarizing	284 ± 10 ($n = 14$)	383 ± 15	57%

The incidence of PB is >90% at the basal area with 10 V/s ramps. Significantly, the lateral PM was more resistant to PB with depolarizing ramps ($p < .02$, chi-square analysis), although MI and MB are polarity-dependent regardless of region ($p < .05$ and $p < .01$, respectively, two-way ANOVA). In contrast to 1 kV/s responses, with 10 V/s ramps there is more resistance to MI with hyperpolarizing stimuli.

TMPs at onset of MI and MB were independent of transfection and polarity, although variance at 10 V/s in TSA cells was very large (see Tables 5 and 6).

After the ramp stimulus, PB was never observed after the 1 kV/s ramps. Interestingly, the incidence of PB at 10 V/s in the transfected TSA cell was virtually identical to that of the OHC lateral membrane, showing increased resistance to PB with depolarizing ramps ($p < .05$, chi-square analysis; see Table 6).

DISCUSSION

We have found that the OHC lateral membrane, as well as the prestin-transfected TSA cell membrane, exhibit polarity-dependent sensitivity to EP. Prestin's influence is to significantly increase resistance to EP and PB with depolarizing 50 ms pulse trains and with depolarizing 10 V/s ramps. These features appear to result from prestin's residence and/or activity within the PM. There are, however, clear differences in responses between OHCs and TSA cells that likely do not depend on prestin expression. First, in the TSA cell there was, in general, a greater resistance to EP, most notably with 50 ms pulse trains and 1 kV/s ramps. Also, unlike the OHC, MI in TSA cells was not affected by polarity when 1 kV/s ramps were used (see Tables 3 and 5) and we find higher TMPs at onset of MB with 10 V/s ramps (see Tables 4 and 6). Finally, in TSA cells, transient EP with fast resealing occurs much more frequently with pulse stimuli. It is conceivable that some of the divergence we find between responses of OHCs and transfected TSA cells may relate to peculiarities of each cell type. Probably most significant is the structural complexity of the OHC. In OHCs, prestin is uniformly concentrated within the lateral PM, which is closely associated with a well developed submembranous cortical cytoskeleton and subsurface cisternae. Additionally, the OHC has a cytoplasmic turgor pressure of up to 1–2 kPa (38), which contributes to cell shape and the tensile forces the OHC PM experiences. The TSA cell lacks these features, and prestin may be heterogeneously distributed throughout the entire PM, possibly providing patch densities that vary significantly. This disparity in prestin density is highlighted

TABLE 5 Ramp protocols at 1 kV/s in gPres transfected and nontransfected TSA cells: absolute TMP at onset of MI and MB

DNA	Polarity	MI (mV)	MB (mV)	Charge density
None	Hyperpolarizing	551 ± 27 (n = 9)	595 ± 35	N/A
	Depolarizing	526 ± 27 (n = 10)	601 ± 26	N/A
gPres	Hyperpolarizing	541 ± 36 (n = 10)	602 ± 36	30.3 ± 3.6 fC/pF
	Depolarizing	524 ± 20 (n = 10)	617 ± 23	20 ± 2 fC/pF

PB never occurred at this ramp speed.

by motor charge density estimates in OHCs (~150–200 fC/pF (14,25)) and our TSA cells (13–30 fC/pF). Despite these cell-specific contributing factors, our data clearly indicate that the presence of prestin within a membrane will alter the membrane's susceptibility to electrical breakdown.

Mechanistic considerations

Based on the mechanistic model of Needham and Hochmuth (28), derived from their investigation of lipid bilayers, membrane breakdown will occur when the average energy density, T , exceeds a critical value. T arises from mechanical and/or electrical loads applied to the membrane,

$$T = T_m + T_e, \quad (1)$$

where T_m is the mechanically induced tension and T_e is the electrically induced tension. The addition of mechanical tension to the PM will lower the voltage that is required for EP.

Though we did not subject the patches to extrinsic mechanical tension, mechanical forces must be taken into account due to the voltage-dependent conformational changes of prestin. As mentioned previously, we have evidence based on modeling of capacitance measures that depolarization, which drives the OHC into a compact state, produces tension in the lateral membrane (27). Consequently, depolarization might have been expected to be a more effective stimulus for EP in the lateral PM, but we found the opposite. It is possible that our data were influenced by the time dependence of interactions between electrical and mechanical tension, since we proposed that the tension generated by prestin dissipates in a multiexponential fashion (27). Time-dependent inter-

actions of electrical and mechanical tension have been observed previously. For example, though Akinlaja and Sachs (29) found that their results with HEK 293 cells probed with 50 μ s pulse trains were consistent with the simple Needham and Hochmuth model (see above), mechanical tension had no effect with longer 50 ms voltage pulses. There are probably other prestin-induced mechanical changes in the OHC PM that may influence EP. For example, lipid lateral diffusion in the OHC PM is a sigmoid function of voltage, depolarization reducing membrane fluidity by half (39). Voltage-dependent membrane folding could also explain the biophysical effects on the diffusion constant as well as on EP. In addition, a number of experiments suggest that the PM is a major contributor to the OHC's axial stiffness (40–43) and that this stiffness is also voltage-dependent secondary to the activity of prestin (44). These investigators have found that stiffness increases with hyperpolarized potentials and decreases with depolarization. Thus, prestin's effects on membrane fluidity and stiffness, as well as on electrically induced membrane bending, may significantly influence our results.

A role for prestin's voltage-dependent specific capacitance

We have previously noted polarity-dependent biophysical properties that prestin imparts to the PM in OHCs while studying capacitance changes at extreme voltages (25,45). In the OHC, we found that the linear capacitance is actually voltage-dependent and is greater in the hyperpolarized region. The capacitance increase, which averages 3.3 pF at voltages < -200 mV, is too great to be explained solely by the area motor model, and we concluded that the membrane dielectric and/or thickness is altered (see Fig. 4). The electrical tension is described by Needham and Hochmuth (28) as

$$T_e = \frac{1}{2} \epsilon \epsilon_0 (V/h_c)^2 h, \quad (2)$$

or, as simplified by Akinlaja and Sachs (31),

$$T_e = C_s V^2 / 2, \quad (3)$$

where ϵ_0 is the permittivity of free space, ϵ the dielectric constant of the membrane, V the transmembrane potential, h the membrane thickness, h_c the capacitive thickness of the membrane, and C_s the specific membrane capacitance.

TABLE 6 Ramp protocols at 10 V/s in gPres transfected and nontransfected TSA cells: absolute TMP at onset of MI and MB and incidence of PB

DNA	Polarity	MI (mV)	MB (mV)	PB	Charge density
None	Hyperpolarizing	321 ± 44 mV (n = 9)	514 ± 136 mV	100%	
	Depolarizing	331 ± 118 mV (n = 9)	579 ± 121 mV	88%	
gPres	Hyperpolarizing	338 ± 45 mV (n = 10)	592 ± 50 mV	90%	19.6 ± 4.2 fC/pF
	Depolarizing	364 ± 51 mV (n = 15)	564 ± 66 mV	53%	16.4 ± 3.2 fC/pF

Onset of MI and MB were independent of transfection and polarity. Increased resistance to PB with hyperpolarizing ramps ($p < .05$, chi-square analysis) in transfected TSA cells was consistent with the OHC lateral membrane results.

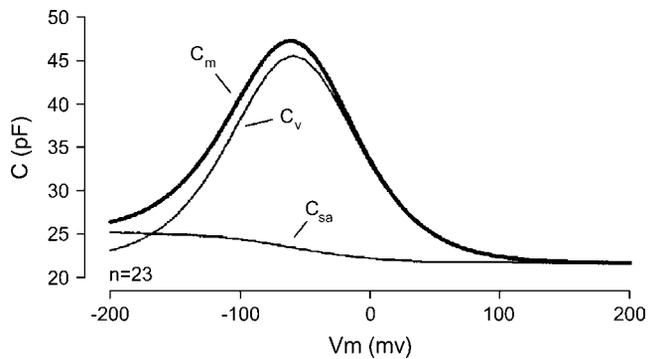

FIGURE 4 OHC capacitance derives from the sum of the parallel capacitance proportional to membrane surface area (C_{sa}) and the motor's voltage sensor-associated capacitance (C_v) to produce the total membrane capacitance (C_m).

It is clear that the effectiveness of a given voltage will depend directly on the specific capacitance of the membrane. If we assume that the specific capacitance of $0.5 \mu\text{F}/\text{cm}^2$ (48) characterizes the OHC PM at very positive voltage levels, then we estimate that the 3.3 pF increase at hyperpolarized extremes translates to an increased specific capacitance value of 0.61. Given this, we calculate for 50-ms pulse thresholds in the absence of prior stimulation:

$$T_{e\text{depol}} = 0.50 (0.446)^2 / 2 = 0.50 \text{ dynes/cm}$$

$$T_{e\text{hyperpol}} = 0.61 (0.388)^2 / 2 = 0.46 \text{ dynes/cm.}$$

To some extent, then, accounting for the voltage dependence of the OHC's specific membrane capacitance reconciles differences in breakdown voltage thresholds, since the membrane would require greater voltages in the depolarizing direction to reach breakdown threshold. Our values for pulse-induced breakdown are in line with those obtained by Akinlaja and Sachs (29), who found a T_e of 0.47 dynes/cm for hyperpolarizing pulses of 100 ms duration.

Time-dependent membrane breakdown and recovery

We find that the time integral of stimulation affects the membrane's susceptibility to EP; this is shown by the resistance to EP with 50 μs pulse trains compared to that with 50 ms pulse trains in the OHC. If the possibility of seal loss is eliminated, the short timescale of EP with 50 μs square voltage pulses would seem to have potential for gene transfer and drug delivery experiments in OHCs. Additionally, there is an increased susceptibility to PB with 10 V/s ramps, especially in TSA cells. After induced membrane instabilities, fast resealing was a common phenomenon in both cell types, although more frequent in TSA cells, probably due to prestin's reduced density, which likely results in faster lateral diffusion kinetics within the bilayer. Although fast resealing is commonly seen in pure lipid bilayers, such rapid resealing has never been documented in other biological

membranes (35,47,48) despite the vast amount of work done on HEK cell lines (34,49,50). Fast resealing may be impeded by the presence of proteins that limit the bilayer's lipid lateral diffusion (51). In the lateral OHC membrane, besides the high-density prestin known to be present, other protein species are present; these include AE2 (52), aquaporins (53,54), glut 5 (55,56), stretch-activated channels (57,58), and a nonselective stretch-sensitive conductance with significant chloride permeability (59). Although we can expect membrane composition to play an important role in fast resealing, we must also remain cognizant that within patches protein residence may be dramatically altered. In addition, the OHC's highly organized cytoskeleton, with its intimate relationship to the plasma membrane via the pillars, most likely plays a role in resealing, as it does in other cell types (31,32,47).

We should make one final point on resealing after apparent membrane breakdown during ramp stimuli in the prestin-containing membrane. The membrane breakdown (defined according to O'Neill and Tung (34)) during depolarizing ramp stimulation probably represents a lower energy state before PB, since subsequent C_m measures frequently do not show an increase to whole-cell levels. According to EP theory (60–63), progression from reversible unstable electropores to permanent stable electropores requires breaching a higher energy threshold. MB as defined by O'Neill and Tung (34) and the transient EP with fast resealing we encountered are likely a lower energy state with a predominance of unstable reversible electropores. Apparently the presence of prestin increases the energy requirement to achieve PB with depolarizing stimuli and fosters patch recovery after the electrical stimulus in the absence of a transmembrane potential. The fact that the thresholds for those patches that did undergo PB and those that did not were not significantly different in OHCs or TSA cells supports this conclusion. The differences between prestin's effects during ramp stimulation and during pulse stimulation, where breakdown thresholds were clearly altered during depolarization, again points to stimulus-type and rate influences on prestin's interaction with the lipid bilayer.

We thank Linda Bartoshuk and Adam Mendizabal for sharing their expertise in statistics in some of the analyses, Peter Dallos for his general support of this project, and the reviewers for their constructive and insightful comments.

IR Laser-Induced Perturbations of the Voltage-Dependent Solute Carrier Protein SLC26a5

Oluwarotimi Okunade[†] and Joseph Santos-Sacchi^{†‡§*}

[†]Department of Surgery (Otolaryngology), [‡]Department of Neurobiology, and [§]Department of Cellular and Molecular Physiology, Yale University School of Medicine, New Haven, Connecticut

ABSTRACT Alterations in membrane capacitance can arise from linear and nonlinear sources. For example, changes in membrane surface area or dielectric properties can modify capacitance linearly, whereas sensor residues of voltage-dependent proteins can modify capacitance nonlinearly. Here, we examined the effects of fast temperature jumps induced by an infrared (IR) laser in control and prestin (SLC26a5)-transfected human embryonic kidney (HEK) cells under whole-cell voltage clamp. Prestin's voltage sensor imparts a characteristic bell-shaped, voltage-dependent nonlinear capacitance (NLC). Temperature jumps in control HEK cells cause a monophasic increase in membrane capacitance (C_m) regardless of holding voltage due to double-layer effects. Prestin-transfected HEK cells, however, additionally show a biphasic increase/decrease in C_m with a reversal potential corresponding to the voltage at peak NLC of prestin (V_h), attributable to a rapid temperature-following shift in V_h , with shift rates up to 14 V/s over the course of a 5 ms IR pulse. Treatment with salicylate, a known inhibitor of NLC, reestablishes control cell behavior. A simple kinetic model recapitulates our biophysical observations. These results verify a voltage-dependent protein's ability to respond to fast temperature perturbations on a par with double-layer susceptibility. This likely arises from prestin's unique ability to move sensor charge at kilohertz rates, which is required for the outer hair cells' role as a cochlear amplifier.

INTRODUCTION

Outer hair cells (OHCs) are mechanically active components of the inner ear that underlie cochlear amplification (1). Cochlear amplification denotes a process whereby responses to low-level acoustic stimuli are enhanced, resulting in an increase in auditory sensitivity and frequency-resolving power. This is accomplished by OHCs feeding back mechanical energy into the vibrating sensory organ to boost stimulation to the inner hair cells, which are predominantly innervated by the auditory nerve. Prestin motor units (SLC26a5), proteins of the SLC26 anion transporter family (2), are localized to the OHC lateral membrane, drive rapid mechanical changes in OHCs, and are associated with nonlinear capacitance (NLC). NLC arises as the first derivative of a two-state Boltzmann function relating prestin voltage-sensor charge as a function of transmembrane voltage. It reflects the movement of charged residues within these motor units and peaks at a voltage (V_h) to which the OHCs' mechanical response is maximally sensitive. NLC is vulnerable to biophysical forces, including temperature and membrane tension (3–8).

Here, we examine the effects of fast temperature jumps induced by an infrared (IR) laser in control and prestin-transfected human embryonic kidney (HEK) cells under

whole-cell voltage clamp. We find effects on both linear and prestin-derived NLC. Whereas fast temperature jumps monotonically increase linear C_m in a voltage-independent manner, the Boltzmann distribution of motors along the voltage axis is rapidly and simultaneously altered in a reversible manner. Our observations clearly show that voltage-dependent proteins, given sufficiently fast kinetics (as with prestin), can contribute to rapid alterations of membrane capacitance.

MATERIALS AND METHODS

Cell culture and expression

We previously developed a tetracycline-inducible HEK293 cell line that highly expresses prestin (9). Here, we cultured HEK293 cells in Dulbecco's modified Eagle's high glucose base medium (DMEM) containing 50 U/ml each of penicillin, streptomycin, and L-glutamine, supplemented with 10% fetal bovine serum, 5 μ g/ml of blasticidin, and 130 μ g/ml of zeocin. The cells were maintained at 37°C in a humidified incubator gassed with 5% CO₂. The addition of 1 microgram/ml tetracycline to the growth medium induced prestin expression and trafficking to the cell membrane. Patch-clamp recordings of the cells were made 24–72 hr after induction at room temperature.

IR laser

Photonic stimulation with a Capella R-1850 laser was used to deliver rapid temperature jumps to cells in the recording chamber. The laser was coupled to a 600- μ m-diameter optical fiber that delivered an output wavelength of 1850 nm in pulses of variable duration. At a power setting of 100%, the optical pulse energy was 5 mJ/ms. Laser stimulation was computer-controlled via TTL and synchronized to voltage clamp commands using an Axon Instruments 1320 series A/D and D/A board. The laser fiber was mounted on a micromanipulator and the tip was placed within 0.5 mm of the recorded cell, ensuring that the whole cell was irradiated.

We assume that our observations arise from temperature changes within the membrane fostered by temperature changes in bath solution water, in accord with conclusions made in previous studies (10,11). We calibrated the temperature change indirectly by monitoring changes in patch electrode resistance (R_s , i.e., changes in I_{R_s} with fixed voltage stimulation) as in the previous studies. Thus, in preliminary experiments, we correlated R_s versus changes in whole bath temperature. In the physiological experiments, our admittance analysis of currents allowed us to quantify R_s changes independently of C_m and R_m changes (12). We found that a 33% change in R_s indicated a temperature change of 17°C. In our experiment, peak R_s change averaged $31.2 \pm 0.02\%$ ($n = 5$) at 40% laser power. Our previous observation that a 20 mV shift in NLC V_h occurs per 10°C change in bath temperature corroborates these estimates (3,4).

Patch-clamp electrophysiology

Ionic blocking solutions were used to remove voltage-dependent ionic conductances so that capacitive currents could be analyzed in isolation. Extracellular bath solutions for whole-cell recording in HEK293 cells consisted of (mM) 20 TEA, 20 CsCl, 2 CoCl₂, 1 MgCl₂, 10 Hepes, 1 CaCl₂, 100 NaCl adjusted to pH 7.22 with NaOH, and 301 mOsm using D-glucose. An extracellular perfusion solution containing 132 NaCl, 2 CaCl₂, 2 MgCl₂, 10 Hepes, 10 Na salicylate (pH 7.20, 300 mOsm) was also used for experiments to block NLC. Electrodes were filled with (mM) 140 CsCl, 2 MgCl₂, 10 Hepes, 10 EGTA (pH 7.27, 302 mOsm). All chemicals used were purchased from Sigma.

Borosilicate glass pipettes were pulled using a P-2000 laser-heating pipette puller (Sutter Instruments) to initial resistances ranging between 3.5 and 5 MΩ. Pipette stray capacitance was compensated for before recordings were obtained, and voltages were corrected for effects of series resistance offline. A Nikon Eclipse TE300 inverted microscope with Hoffmann optics was used to observe the cells during electrical recording. Round, isolated cells growing on a glass coverslip were patched 24–72 hr after tetracycline induction.

Cells were clamped to a holding potential of 0 mV using an Axon 200B patch-clamp amplifier. During the temperature jump protocol, cells were held under voltage clamp at 0 mV and stepped in 30 mV increments (from hyperpolarizing values of –150 mV to 150 mV) for 1024 ms during which a brief IR laser pulse was delivered to the cells for each voltage step. Solution exchange (e.g., with salicylate) was performed using gravity flow. All recordings were made at room temperature. Local temperature measurements of the cells were calculated by measuring changes in electrode resistance and extrapolating from a resistance-temperature calibration curve (11). A resistance-temperature calibration curve was obtained by observing changes in pipette resistance in a hot bath solution (~55°C) that was allowed to cool passively.

Cell capacitance was measured under a whole-cell configuration using jClamp software (SciSoft, CT; www.SciSoftCo.com). Voltage records sampled at 10 μs were filtered at 10 kHz with an eight-pole Bessel filter and saved to disk for offline analysis. NLC was measured using a continuous high-resolution (2.56 ms sampling), two-sine stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz) superimposed onto the voltage command (12,13). Capacitance data were fit to the first derivative of a two-state Boltzmann function (14):

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin}, \quad b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right) \quad (1)$$

where Q_{\max} is the maximum nonlinear charge moved; V_h is voltage at peak capacitance or, equivalently, at half-maximum charge transfer; V_m is membrane potential; z is valence; C_{lin} is linear membrane capacitance; e is electron charge; k is Boltzmann's constant; and T is absolute temperature. Our justification for using steady-state fits of prestin's charge movement at the

2.56 ms C_m measurement sampling rate is that the parameters are largely stable (z , Q_{\max}), except for V_h , across time samples. ΔC_m is defined as the difference between pre-IR and post-IR maximal capacitance. Results are reported as the mean \pm standard error (SE).

Model

To understand the biophysical data, we used a kinetic model of SLC26a5 that we previously developed (15). The model was developed to account for a chloride-dependent disparity between NLC and electromotility V_h , requiring intermediate transitions much slower than either chloride- or voltage-dependent transitions. A model cartoon is shown in Fig. 5 A of Song and Santos-Sacchi (15).

State X_o is SLC26a5 in the absence of bound anion; state X_c is with bound anion; state X is voltage-enabled after anion binding, with its residence being favored by hyperpolarization (expanded state); and state C results from depolarization (contracted state). The model has very fast anion (chloride) binding and unbinding transitions ($X_o \leftrightarrow X_c$) and very fast voltage-dependent conformational transitions ($X \leftrightarrow C$). The transition to state C carries a unit charge, q ; Q_{\max} , the total charge moved, will reflect the maximal accumulation of motors in that state. Nestled between the anion-binding and voltage-dependent transitions resides a nonvoltage-dependent transition ($X_c \leftrightarrow X$), which is very much slower than the other two transitions.

We assessed the kinetic model using MATLAB (The MathWorks, Natick, MA) Simulink via an automation link with jClamp (www.scisoftco.com). The kinetic model was interfaced to jClamp via a model of the patch-clamp amplifier and cell. The linear component of the patch-cell model possessed an R_s of 5 MΩ, R_m of 500 MΩ, and C_{lin} of 10 pF. The nonlinear component, NLC, derived from charge movement of the SLC26a5 model, with the following parameters: $k_1 = 10^7 * [Cl]_{in}$, $k_2 = 10^7 * k_d$, $\alpha_0 = 75 * \exp(t_m)$, $\beta_0 = 95$, $\alpha = 10^6 * \exp(zFV_m/2RT)$, $\beta = 583 * 10^9 * \exp(-zFV_m/2RT + t_m/2 - E_a/RT)$, $k_d c_1 = 0.001$, $T = 296$ kelvin, $E_a = 45$ kJ/mol, $F = 9.648 * 10^4$ C/mol, $R = 8.315$ J/Kmol, $k = 1.381 * 10^{-23}$ VC/K.

The rates α_0 and β are tension sensitive because tension is known to increase prestin residence in the expanded (X) state (5,6), t_m in units kT (eRT/F); the rate β is temperature sensitive, with Arrhenius activation energy, E_a . α and β are voltage dependent, with sensor valence $z = 0.7$. At $T = 296$ K, $V_m = 0$ mV, $T_m = 0$ kT, and $[Cl]_{in} = 0.14$ M, initial rates are $k_1 = 1.4e6$, $k_2 = 1e4$, $\alpha_0 = 75$, $\beta_0 = 95$, $\alpha = 1e6$, and $\beta = 1e5$. Chloride concentrations and K_d are in molar; rates are $1/t$, with time (t) being 1 s. Voltage is in volts.

RESULTS

Capacitance

The rapid temperature change associated with an IR laser pulse delivered directly to a cell via optical fiber alters membrane capacitance. Control HEK cells and cells of our uninduced SLC26a5 HEK cell line increase their linear membrane capacitance in a voltage-independent fashion. Fig. 1 A shows C_m measures of a voltage-clamped, uninduced SLC26a5 HEK cell for a wide range of holding potentials. The delivery of a 20 ms IR pulse (40% of maximal laser power) induces a linearly ramped increase in C_m coinciding with the duration of the pulse. To better visualize the overlapped traces and indicate holding voltage, we offset the

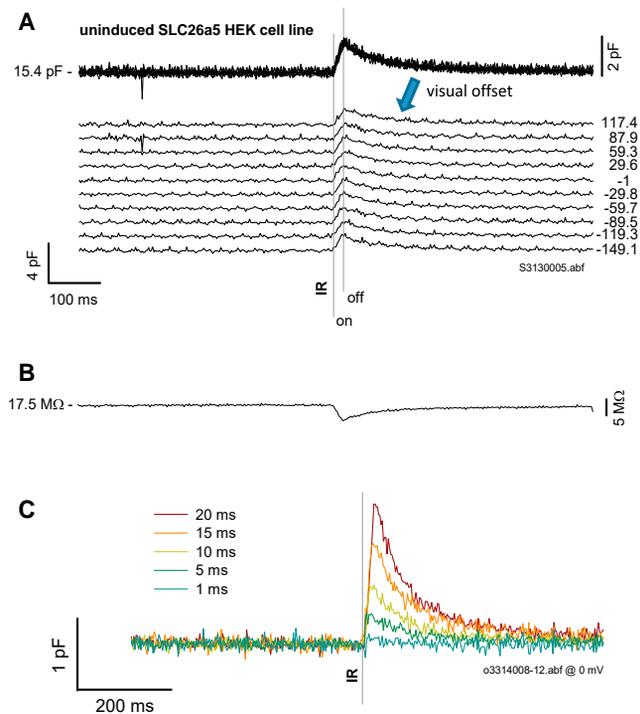

FIGURE 1 IR laser-induced temperature jump alters linear capacitance. (A) Under whole-cell voltage clamp, an uninduced SLC26a5 HEK cell was nominally stepped to the membrane potentials indicated. During the voltage step, an IR laser pulse of 20 ms duration (nominally 40% Capella laser power) was delivered via optical fiber. Regardless of the holding potential, the laser pulse induced a fixed maximal increase in C_m , $\sim 10\%$ of resting C_m . Averages are given in Results section. (B) Simultaneously measured series resistance indicates a linear increase in temperature during the pulse and an exponential cooling of bath media after the pulse. (C) An increase in duration of the pulse results in a greater C_m change. The holding potential is 0 mV.

traces by an arbitrary constant, allowing clearer observation of the voltage independence. The increase in C_m is $10.8\% \pm 2.5\%$ ($n = 5$) of whole-cell capacitance for a 20 ms pulse. In Fig. 1 A, at laser offset, a single exponential decrease in C_m occurs with a time constant of 70 ms at 0 holding potential (81.5 ± 3.2 ms; $n = 5$). These linear and exponential phases of C_m change correspond, respectively, to a linear increase in temperature during the pulse and an exponential cooling of the bath solution/cytoplasm after the pulse, both of which are reflected in simultaneous changes in the series resistance of the pipette electrode (Fig. 1 B). Our admittance analysis allows us to quantify R_s changes, which are known to correspond to temperature manipulations (11). Fig. 1 C shows that increases in pulse durations induce increasing temperature changes that evoke larger C_m responses. Within our exposure range, we do not see any threshold effect for cell damage that is not associated with loss of cell recording.

In our SLC26a5 HEK cell line after tetracycline induction, cells possess a voltage-dependent NLC atop their linear capacitance (16). This arises from the voltage sensor activity underlying the protein's role in OHC electromotility (3,4).

Fig. 2 illustrates the voltage-dependent nature of the induced HEK cell's C_m , and the influence of temperature jumps on NLC and linear C_m . Again, we offset the overlapped traces by an arbitrary constant, allowing clearer observation of the effects of IR pulse on C_m ; obvious differences are found in comparison with uninduced HEK cells (see Fig. 1). Indeed, a voltage-dependent effect is now observed. In Fig. 2 B, C_m - V_m functions are plotted at various time points relative to the start of the IR pulse. The laser pulse induced a shift of the C_m - V_m relation in the depolarizing direction. After correction of voltages for R_s effects, Boltzmann fits to the data (see Materials and Methods) allow a high-resolution (2.56 ms) inspection of dynamic changes in NLC and linear capacitance during and after the IR pulse (Fig. 2 C). In this example, NLC V_h shifted 40 mV in 20 ms at a linear rate of 2.03 V/s (average is 2.32 ± 0.21 V/s; $n = 6$) during the heating phase, and recovers (with temperature) exponentially with a time constant of 73 ms (average is 65.4 ± 10.8 ms; $n = 6$) during the cooling phase. The shift in V_h represents a redistribution of prestin motors into the

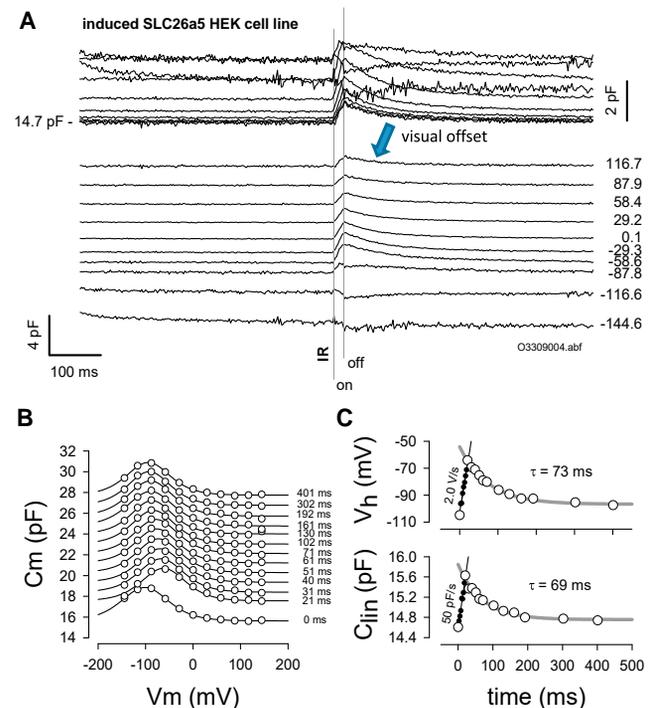

FIGURE 2 IR laser-induced temperature jump alters SLC26a5-generated NLC and linear capacitance. (A) Under whole-cell voltage clamp, an induced SLC26a5 HEK cell was nominally stepped to the membrane potentials indicated. During the voltage step, an IR laser pulse of 20 ms duration (nominally 40% Capella laser power) was delivered via optical fiber. The laser pulse induced a maximal change in C_m that depended on the holding potential. The change could be either an increase or decrease. (B) C_m - V_m plots of NLC as a function of time after pulse onset. Note the effect on the voltage dependence of NLC, namely, a shift to the right. (C) Changes in V_h and C_{lin} follow temperature. Rapid shifts and increases in C_{lin} occur during laser heating and return back to initial levels during bath cooling. Averages are given in the Results section. To see this figure in color, go online.

expanded conformation during heating. We previously observed this shift over the course of minutes using Peltier control of the bath solution temperature, with the shift averaging ~ 20 mV/10°C (3,4). In two additional cells, we were able to determine the V_h shift with 5 ms pulses at 90% laser power. The shift was 67 and 70 mV in 5 ms or 13.4 and 14 V/s, indicating that heating rates and corresponding V_h shift rates increase with greater laser power. The increase in rates with laser power indicates that we have yet to observe the fastest response and are limited by the laser power (for technical reasons, we avoid $>90\%$ power usage). Linear capacitance also changes simultaneously, with a time course similar to that of NLC V_h . In this case, there is a linear change of 50 pF/s during heating and a recovery due to cooling with a time constant of 69 ms (average is 78.9 ± 7.7 ms; $n = 6$). The changes due to cooling in linear capacitance are similar to those observed in control HEK cells. These rapid rates of change during heating and cooling mirror the changes in temperature as gauged from R_s inspection or predicted from previous observations on temperature-dependent shifts of V_h during slow bath changes in temperature (3,4), i.e., they correspond to a temperature-induced change of 20 mV/10°C.

The difference in susceptibility of NLC and linear C_m to temperature jump is readily illustrated by the behavior of ΔC_m , defined as the maximal difference between pre-IR and post-IR capacitance. Examples from two cells are shown in Fig. 3, A and B. Whereas IR pulse-induced linear C_m changes occur at the same magnitude and direction (increase) regardless of the holding potential (Fig. 1), NLC changes vary depending on the holding potential, and reverse in direction near voltages (average is -96.8 ± 6.4 mV; $n = 5$) around NLC V_h (average is $-94.7 \pm$

6.2 mV; $n = 5$), with an R^2 value of 0.9943 (Fig. 3, A and B). Thus, it is possible, depending on the magnitude of NLC and its V_h (relative to holding potential), to induce a decrease in C_m by IR laser pulse. Salicylate (10 mM) not only reduces NLC, as expected (18,19), but also eliminates the characteristic reversal of ΔC_m normally afforded by SLC26a5 expression, essentially returning the induced HEK cell back to its preinduced condition ($n = 2$). That is, only an increase in C_m is observed, regardless of the holding potential (Fig. 3 A).

To understand the data, we evaluated the temperature-dependent behavior of a recently developed kinetic model of SLC26a5 (15). In this model (see Materials and Methods), only the backward, voltage-dependent transition, β , is temperature sensitive, indicating that only movements into the hyperpolarized (expanded) state of SCL26a5 are affected by temperature. In the simulation, we simply modeled the temperature change as that revealed by our experimental measures of R_s (in this case, with a 23°C maximum change; Fig. 4 A). Similar to the biophysical data, a rapid temperature change followed by cooling induced characteristic changes in C_m , which derived from NLC magnitude and induced V_h shifts (Fig. 4, B and C). As we deduced from the biophysical data, NLC V_h shifts directly mirror temperature changes. To match the average biophysical data of 2.3V/s (~ 20 mV/10°C), an Arrhenius activation energy of 45 kJ/mol was required. The model also recapitulates the reversal of ΔC_m near V_h (Fig. 4 D). Also note that ΔC_m recovers with temperature back to zero at voltages away from V_h , in contrast to the biophysical data (Fig. 3), because the original model had no temperature-sensitive linear C_m (Fig. 4, solid circles). However, when a linearly temperature-dependent C_m is introduced, ΔC_m appears more similar to the biophysical data (Fig. 4 D, open circles). The original implementation of the kinetic model (15) had temperature dependence of both the backward intermediate rate, β_0 , and the backward voltage-dependent rate, β . Here, however, we obtained better correspondence to the biophysical data by setting temperature dependence only in β .

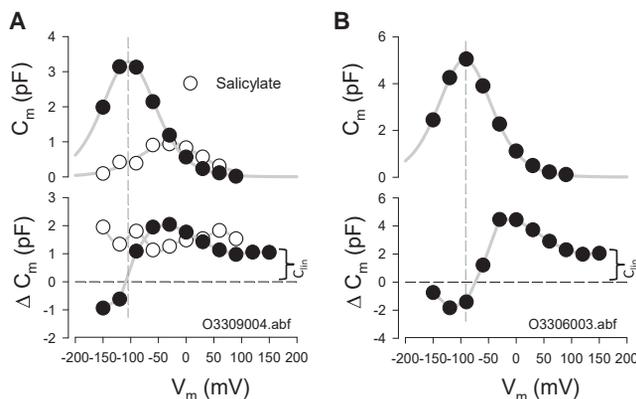

FIGURE 3 IR laser-induced temperature jump alters NLC showing increases and decreases that reverse near V_h of NLC. The NLC plotted is the one before the temperature jump. (A and B) Shown are data from two cells. ΔC_m at positive voltages remains offset from zero due to the temperature-dependent increase in linear C_m (curly brackets). In the first case (A), after data collection, salicylate (10 mM) was perfused onto the cell and collection was repeated. Salicylate removes the ΔC_m reversal as a result of NLC block, leaving intact a constant linear C_m increase across holding voltage. Averages are given in Results.

Currents

We found two components of currents associated with fast temperature jump (Fig. 5). The first component coincided with the IR heating phase and its magnitude was related to the rate of heating (or correspondingly to the rate of linear C_m change; Fig. 5, A and B). This current appeared to reverse at positive voltages, as found by Shapiro et al. (10) (Fig. 5 C). We agree with their discussion on the matter, especially their interpretation that this may arise from asymmetrical fixed charges on the membrane leaflets. The second, slower component, which reversed near 0 mV, peaked at maximal temperature and then decayed during the cooling phase (Fig. 5, C and D). We interpret this as

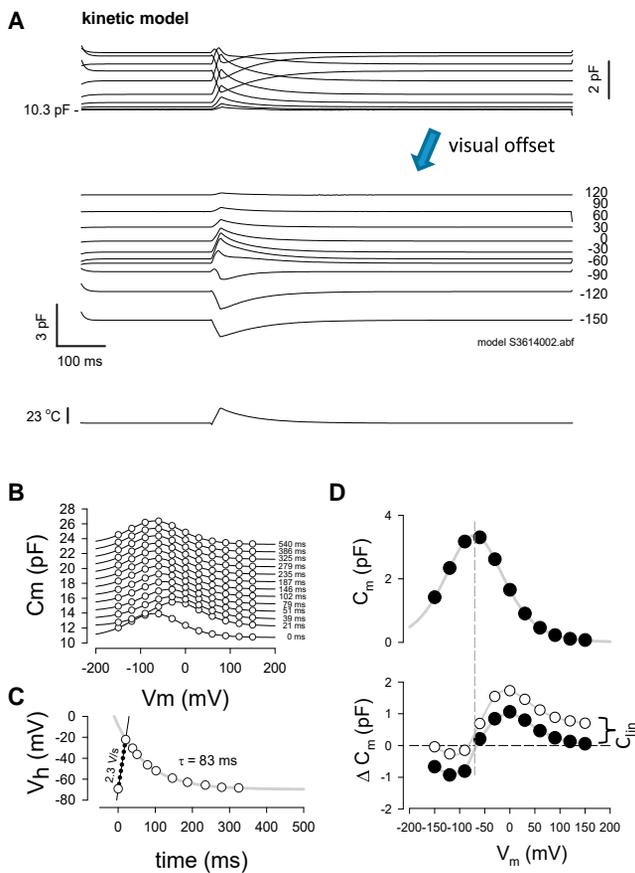

FIGURE 4 A kinetic model recapitulates biophysical data. (A) Stimulation with the experimentally observed temperature change induced by an IR laser pulse induces C_m behavior similar to the biophysical results. Here, the model transition rates are set to give a V_h of -71 mV. (B) Plots of NLC show rightward shifts along the voltage axis as a result of temperature increase. (C) Rates of V_h shift are comparable to biophysical data and directly follow temperature alterations. (D) Voltage at reversal of ΔC_m is related to V_h . Note that ΔC_m goes back to zero, in contrast to the biophysical data, when C_{in} is not temperature sensitive (closed circles). Including temperature dependence for C_{in} results in an offset similar to the biophysical data (open circles, curly brackets). To see this figure in color, go online.

an ionic current that is nonspecific with a reversal potential near zero. Sometimes we found that the second, slower component obscured the first component as described in Shapiro et al. (10). Nevertheless, the rapid component is clearly observable in the traces near zero potential (Fig. 5 C). The second, slow-decaying membrane current displays nonlinear features (Fig. 5 D) reminiscent of G_{metL} , a conductance found in OHCs with marked temperature dependence (20,21). The current increase due to IR stimulation is likewise nonlinear, and therefore is unlikely due to linear decreases in R_s with temperature.

DISCUSSION

Control HEK cells and HEK cells expressing the voltage-dependent protein SLC26a5 show very fast changes in membrane capacitance when rapid temperature jumps are

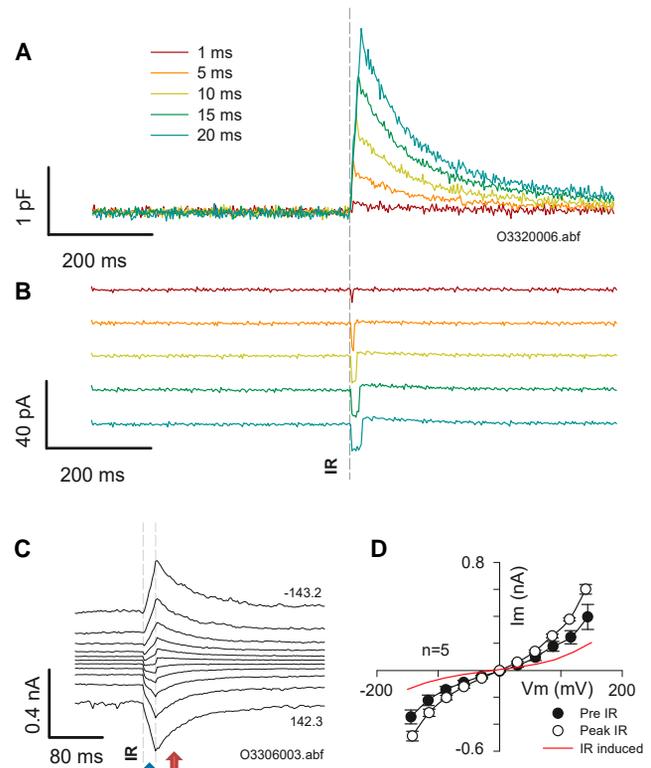

FIGURE 5 Two components of current induced during temperature jump. (A and B) Capacitance increases during temporally incremental IR laser pulses (A) and corresponding currents arise (B). Current magnitude depends on rate of C_m change and duration depends on pulse duration. For all traces, pulses were delivered at a holding potential of 0 mV. (C) Current responses for a 20 ms duration pulse within the holding potential extremes indicated, stepped nominally at 30 mV. Note the fast inward current response during the laser pulse, with a reversal potential predicted to be at positive potentials. Simultaneously, a slow-decaying current with reversal near 0 mV is observed. The red arrow shows the sum of the two components (note step behavior around zero potential that rides on the slower current ramp) and the blue arrow shows the slow component after the fast component ends after the laser pulse. (D) IV plot of average cell currents before and at termination of the IR pulse (mean \pm SE; $n = 5$). The red line is IR-induced current. Note that current voltage dependence is unaffected by temperature, unlike that of NLC.

delivered to the cells by IR laser. For control cells, rapid alterations in linear C_m directly follow changes in temperature, as observed by Shapiro et al. (10). With the pulse energies we used, the rates of change were up to 50 pF/s and magnitudes peaked near 10% of the cell's resting membrane capacitance. Effects were reversible upon heat dissipation through the bathing solution. HEK cells expressing prestin showed additional effects on the Boltzmann characteristics of voltage sensor-related NLC. With 20 ms IR pulse durations, V_h was shifted in the positive direction at an average rate of 2.3 V/s, corresponding to 20 mV/ $^{\circ}$ C, and subsequently returned to prior conditions as the heat dissipated. In two cells, delivery of near-maximum laser power produced V_h shift rates of 13–14 V/s. The rates of recovery of linear C_m and V_h with cooling were indistinguishable,

indicating that each is directly coupled to thermal energy. A simple kinetic model of prestin (15) that possesses temperature-sensitive, voltage-dependent transitions that move prestin into the expanded state can mimic our biophysical observations. Thus, we conclude that temperature-induced alteration of transition rates between voltage-dependent conformations of prestin can alter NLC as fast as thermal influences on the membrane double layer (10).

Capacitance

It is well established that capacitance is temperature sensitive; for example, Taylor (22) reported that squid axon capacitance increased 1% per degree centigrade. Others have reported that the kinetics of voltage-dependent channels is temperature sensitive, consequently influencing gating currents (23,24) and necessarily altering their equivalent voltage-dependent capacitance. It is therefore not surprising that prestin NLC is temperature dependent, as we previously showed with slow alterations in bath temperature (3,4). Prestin's NLC V_h shifts ~ 20 mV per 10°C . What may appear surprising is that prestin can redistribute between expanded and contracted states so rapidly upon IR stimulation, showing V_h shift rates up to 14 V/s. Of course, by nature, prestin is poised to transition between states at kilohertz rates, and apparently is capable of rapidly responding to a variety of energy forms, including mechanical, electrical, and thermal forms (7,8,25,26). Nevertheless, our observations are not simply related to the ability of prestin to rapidly transition between states; more importantly, they reflect the efficacy of realigning the protein's operating voltage range by external influences, namely, adjusting the gain of cochlear amplification.

Our modeling of temperature effects on prestin's voltage-dependent backward rate is similar to that employed to understand TRP channel heat sensitivity (27). In this regard, we recently found that prestin is sensitive to capsaicin (28), an agent that mimics heat activation of TRP channels. However, in prestin, the mechanism of action must be different from that of temperature since it causes negative shifts in V_h , pointing toward action on forward rates. Thus, it will be of interest to evaluate the simultaneous effects of capsaicin and temperature on prestin NLC. Of course, other proposed mechanisms in TRP channels that may also contribute to temperature sensing by prestin include allosteric mechanisms (29) and changes in specific heat capacity (30). Nevertheless, the simplest scheme is likely that of temperature-sensitive transition rates as modeled here, which show excellent agreement with the biophysical data. This is not to say that the sensitivities of the other transitions in the model, i.e., those displaying tension and chloride sensitivity, cannot influence the temperature-sensitive, voltage-dependent transition, as it is well known that a voltage-independent transition can affect the characteristics of a linked voltage-dependent one (31–33).

Currents

In this study, we used blockers to reduce ionic conductances so that we could effectively measure capacitance. We identified two components of residual current: one that is fast, coinciding with the duration of laser heating, and one that follows the temperature of the bath as it cooled. This observation is similar to that of Parker (24), who suggested that the fast component represents gating currents of oocyte ion channels. This was suggested because in the absence of the slow component (i.e., at its reversal potential), transient capacitive-like currents were revealed. Although we do expect that sensor charge movement (i.e., gating-like currents) should arise when prestin's V_h suddenly shifts, we find no evidence of transient-like currents near the reversal potential of our slow component, around 0 mV. We should note that when the cell is held at 0 mV, we are interrogating a linear region of C_m , since NLC V_h is very negative. Our laser-induced currents at 0 mV resemble those found by Shapiro et al. (10), and we conclude that they represent currents generated by rapid changes in linear C_m . The second component of current, which reverses near zero, has some nonlinear features of a conductance, G_{metL} , found in OHCs (20,21). Notably, increases in temperature augment the nonlinear current and are not simply leakage currents.

In summary, we find that SLC26a5 (prestin) is remarkably responsive to fast temperature jumps, rapidly moving its operating point along the voltage axis. This susceptibility to thermal perturbations likely arises from the protein's natural ability to follow voltage changes at acoustic frequencies, but it also has implications for manipulation of cochlear amplifier gain control. Thus, we predict that we may be able to drive auditory sensation by stimulating OHCs with a high-frequency gated IR laser, and manipulate cochlear amplification in vivo.

SUMMARY

Mitochondrial dysfunction causes poorly understood tissue-specific pathology stemming from primary defects in respiration, coupled with altered reactive oxygen species (ROS), metabolic signaling, and apoptosis. The A1555G mtDNA mutation that causes maternally inherited deafness disrupts mitochondrial ribosome function, in part, via increased methylation of the mitochondrial 12S rRNA by the methyltransferase mtTFB1. In patient-derived A1555G cells, we show that 12S rRNA hypermethylation causes ROS-dependent activation of AMP kinase and the proapoptotic nuclear transcription factor E2F1. This retrograde mitochondrial-stress relay is operative *in vivo*, as transgenic-mtTFB1 mice exhibit enhanced 12S rRNA methylation in multiple tissues, increased E2F1 and apoptosis in the stria vascularis and spiral ganglion neurons of the inner ear, and progressive E2F1-dependent hearing loss. This mouse mitochondrial disease model provides a robust platform for deciphering the complex tissue specificity of human mitochondrial-based disorders, as well as the precise pathogenic mechanism of maternally inherited deafness and its exacerbation by environmental factors.

INTRODUCTION

Mitochondria are multi-functional cellular organelles involved in oxidative metabolism, ion homeostasis, signal transduction, and apoptosis and hence contribute to human disease by a variety of mechanisms. Mitochondrial pathogenesis is complex and involves maternally inherited diseases due to mutations in mtDNA, as well as Mendelian-inherited disease due to mutations in nuclear genes required for mitochondrial function (DiMauro and Schon, 2003). Furthermore, mitochondrial dysfunction is implicated in more common disorders such as diabetes, heart

disease, cancer, neurodegeneration, and aging (Wallace, 2005; Shadel, 2008), making efforts to better understand how mitochondria cause and exacerbate human disease pathology imperative and of broad significance.

A major hurdle in understanding mitochondrial disease pathogenesis is the current lack of understanding of the often-extreme tissue specificity involved (DiMauro and Schon, 2003). Because defective oxidative phosphorylation (OXPHOS) *per se* can be pathogenic, this is often attributed to variable energetic thresholds in different cell types. However, defective OXPHOS is also frequently associated with increased mitochondrial reactive oxygen species (ROS) that are a major cause of pathology because they promote molecular damage, oxidative stress, and cell death. Finally, mitochondria and ROS are involved in signal transduction pathways (Hamanaka and Chandel, 2010) that are likely an underappreciated downstream cause of pathology due to mitochondrial dysfunction. For example, a major signaling node that reacts to mitochondrial dysfunction is the AMP-dependent protein kinase (AMPK) pathway, which responds to cellular energy decline that can occur when OXPHOS is disrupted (Hardie, 2007) and is regulated by ROS (Emerling et al., 2009; Quintero et al., 2006).

A hallmark case of tissue-specific mitochondrial disease pathology is maternally inherited deafness caused by the A1555G mutation in human mtDNA (Prezant et al., 1993). This relatively common mutation (Vandebona et al., 2009) causes nonsyndromic and/or aminoglycoside-induced deafness and occurs in the 12S rRNA gene, encoding the RNA component of the small (28S) mitochondrial ribosome subunit. It is also in close proximity to an evolutionarily conserved stem-loop that contains two tandem adenine residues that are methylated by the site-specific rRNA adenine N6-di-methyltransferase, h-mtTFB1/TFB1M (McCulloch et al., 2002; Seidel-Rogol et al., 2003). This methylation occurs during ribosome biogenesis in bacteria (Pulicherla et al., 2009) and is essential in mice, the lack of which disrupts mitochondrial 28S ribosome subunit assembly (Metodieva et al., 2009).

Hearing loss caused by the A1555G mutation is irreversible (Prezant et al., 1993), implying death of critical, irreplaceable cells in the inner ear by an unknown pathogenic cell-death pathway. The A1555G mutation alters mitochondrial ribosome

function and translation (Cotney et al., 2009; Guan et al., 1996, 2000; Hobbie et al., 2008), which in turn causes OXPHOS defects that are thought to contribute to deafness pathology. However, mitochondrial translation and OXPHOS defects observed in patient-derived primary and cytoplasmic hybrid (cybrid) cell lines are mild and highly dependent on the nuclear genetic background (Guan et al., 1996, 2000), suggesting that other aspects of mitochondrial dysfunction may also be operative. Finally, polymorphisms near the *TFB1M* gene encoding h-mtTFB1 are nuclear modifiers of the A1555G deafness phenotype (Bykhovskaya et al., 2004), suggesting a connection between 12S rRNA methylation and hearing loss (Shadel, 2004b).

We recently showed that patient-derived A1555G cybrids are hypermethylated at the 12S rRNA stem-loop methylated by h-mtTFB1 (Cotney et al., 2009). These A1555G cybrids exhibit defective mitochondrial biogenesis and membrane potential and heightened sensitivity to stress-induced apoptosis (Cotney et al., 2009), apparently due to disrupted coordination of overall mitochondrial biogenesis with the assembly of mitochondrial ribosomes (Cotney et al., 2007). Remarkably, these phenotypes are shared by HeLa cells with wild-type mtDNA that instead have hypermethylated 12S rRNA due to overexpression of h-mtTFB1, leading us to conclude that hypermethylation of mitochondrial ribosomes per se is a key molecular defect driving the apoptotic phenotype (Cotney et al., 2009).

In the current study, we tested the hypothesis that this hypermethylation of mitochondrial ribosomes instigates a unique form of mitochondrial stress signaling involved in the deafness pathology of the A1555G mutation. We show that increased mitochondrial ROS generated in A1555G cybrids activate the proapoptotic nuclear transcription factor E2F1 in an AMPK-dependent manner, and that overexpression of mtTFB1 in mice (to model pathogenesis due to increased mitochondrial 12S rRNA methylation) is sufficient to cause progressive hearing loss associated with tissue-specific upregulation of E2F1 and apoptosis of critical cells of the inner ear.

RESULTS

A Mitochondrial Stress-Response Pathway Activates Nuclear Transcription Factor E2F1

We hypothesized that mitochondrial defects due to 12S rRNA hypermethylation elicit a mitochondrial retrograde stress signal (Butow and Avadhani, 2004) that explains the apoptotic susceptibility we documented previously in A1555G and h-mtTFB1 methyltransferase overexpression cell lines (Cotney et al., 2009). Therefore, we performed microarray analysis on these cell lines, which exhibit 12S hypermethylation for different reasons (i.e., due to the A1555G point mutation or overexpression of the h-mtTFB1), reasoning that this would define a common transcriptional signature, which, in turn, would allow elements of this mitochondrial stress-response pathway to be deciphered.

Expression microarrays were performed on A1555G cybrids, using analogous 143B cybrids containing the corresponding wild-type mtDNA ("A" at position 1555) as the negative control, and on HeLa cells overexpressing h-mtTFB1 compared to

those expressing a methyltransferase-deficient G65A mutant of h-mtTFB1 as a negative control (Figure 1A). We identified genes that were significantly upregulated or downregulated in the hypermethylation cell lines (Table S1 available online), which we reasoned would include genes that were responding specifically to 12S hypermethylation. We then analyzed the promoters of this set of hypermethylation-responsive genes (Figure 1B) for transcription factor binding sites and found that E2F1 sites were the most frequently overrepresented in genes upregulated in 12S hypermethylation (Table 1). We next crossed our microarray dataset with a published dataset identifying E2F1-responsive genes and found significant overlap (Table S2), again supporting E2F1 induction in our experimental system. We also prepared a list of E2F1 targets by selecting human genes whose promoter is predicted to contain *cis*-elements for E2F1, and found that there is a significant enrichment of E2F1 targets in the transcripts induced by 12S rRNA hypermethylation (Table S2), again suggesting an increase in E2F1 transcriptional activity.

E2F1 Mediates Proapoptotic Signaling in Cells Containing the Human Deafness-Associated A1555G Mutation

E2F1 is one of a family of eight E2F transcription factors that are involved in cell cycle regulation through their cyclin-dependent interactions with pocket proteins, including the tumor suppressor Rb (DeGregori and Johnson, 2006). Of particular significance, E2F1 is involved in proapoptotic signaling (Field et al., 1996; Hou et al., 2000; Polager and Ginsberg, 2009). This connection to cell death, in conjunction with our microarray results, made E2F1 a likely candidate for a stress-responsive protein that is responding to mitochondrial dysfunction caused by the A1555G mutation and perhaps also the causative factor in the observed apoptosis susceptibility in the 12S hypermethylation cell lines (Cotney et al., 2009). Entirely consistent with this concept, we confirmed *E2F1* transcriptional induction in cells with 12S rRNA hypermethylation by q-PCR (Figure S1A), and found that the steady-state level of E2F1 protein was increased in A1555G cybrids and in HeLa cells that overexpress h-mtTFB1 compared to appropriate control lines (Figure 2A; Figure S1B). In addition, we observed a decrease in the steady-state amount of Rb (Figure 2A; Figure S1B) and/or its increased phosphorylation (Figure 2A; Figure S1B), either of which is consistent with increased E2F1 activity in the 12S hypermethylated cell lines.

Given the association of active E2F1 with apoptosis, we next tested whether the upregulation of E2F1 per se in A1555G cybrids is involved in their heightened sensitivity to apoptotic cell death. In strong support of this concept, we found that suppressing the hypermethylation of the 12S rRNA via knockdown of h-mtTFB1 abolished E2F1 induction (Figure 2B; Figure S1C) and reduced the susceptibility of A1555G cybrids to apoptosis (Figure 2C). Furthermore, reduction of E2F1 to near wild-type levels by shRNA in the A1555G cybrids abrogated the increase in apoptosis susceptibility, as measured by caspase 3/7 activity (Figure 2D) and accumulation of the cleaved form of PARP (Figure 2E; Figure S1D). Altogether, these results indicate that the Rb-E2F1 apoptotic pathway responds to

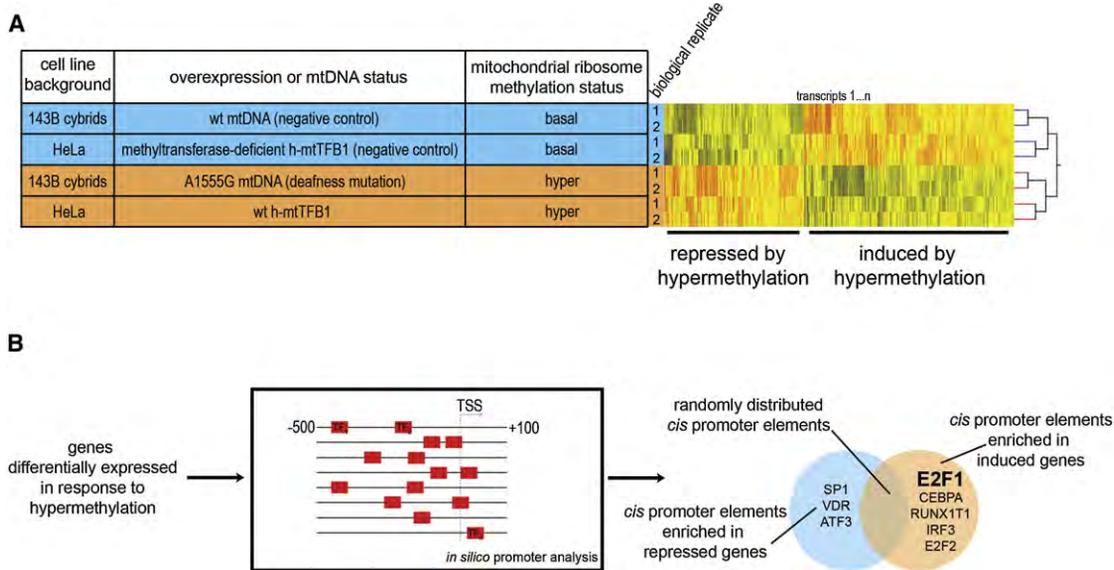

Figure 1. Integrative Genomic Analysis Reveals Upregulation of Nuclear Transcription Factor E2F1 in Response to Mitochondrial Stress Induced by Mitochondrial Ribosome Hypermethylation

(A) Table showing the four cell lines on which we performed microarray analysis to develop a signature of the gene expression response to mitochondrial 12S hypermethylation: two control lines with “basal” mitochondrial 12S hypermethylation (blue) and two experimental cell lines with 12S hypermethylation (orange), with the number of biological replicates indicated. To the right of the table is the representative heat map of all replicates of the cell lines analyzed, with transcripts that are induced or repressed depending on 12S hypermethylation status delineated. “wt” indicates wild-type with regard to either mtDNA or h-mtTFB1. Transcripts whose expression was significantly different (t test p value < 0.05) between the two groups (“basal” versus “hyper”-methylated) represented a 12S hypermethylation signature list that was analyzed further (total of 4,333 transcripts, 2,492 induced, and 1,841 repressed).

(B) The promoter regions (–500 to +100 bp of the predicted transcription start site, TSS) of the genes that were differentially expressed were analyzed for known transcription factor binding sites. The Venn diagram indicates the top transcription factors identified in the repressed (blue) and induced (orange) genes. Since E2F1 was the most overrepresented binding site in the genes induced by 12S rRNA hypermethylation, it became a focus of this study.

mitochondrial stress induced by hypermethylation of 12S rRNA in mitochondrial ribosomes.

ROS-Dependent AMPK Activation Underlies E2F1 Induction in A1555G Cells

To determine the proximal signal leading to E2F1 activation we examined respiratory function in A1555G and corresponding wild-type cybrids and found that the former have decreased basal and maximal mitochondrial O₂ consumption rates (Figure 3A). Furthermore, the respiratory chain in the A1555G cells

is reduced (Figure 3B), a condition conducive to increased ROS production (e.g., superoxide) (Jones et al., 2005). Accordingly, we found that A1555G cells have increased mitochondrial superoxide, as measured by MitoSox (Figure 3C). To determine if this increased superoxide was underlying proapoptotic signaling to E2F1 in A1555G cybrids, we overexpressed mitochondrial superoxide dismutase 2 (SOD2) and found that this eliminated E2F1 induction, increased the total amount of Rb, decreased Rb hyperphosphorylation and eliminated the apoptosis susceptibility in A1555G cells (Figures 3D and 3E).

We next sought to determine how mitochondrial superoxide is sensed and promotes E2F1 activation. AMPK is an established sensor of mitochondrial dysfunction. Furthermore, its activity is activated by superoxide (Quintero et al., 2006) and regulates E2F1 by phosphorylating Rb (Dasgupta and Milbrandt, 2009) making it a potential candidate in the stress pathway we have elucidated. Accordingly, we found that A1555G cybrids have increased active AMPK α (phospho-AMPK α) compared to wild-type controls, and that AMPK α activity was restored close to normal upon overexpression of SOD2 (Figure 3D). To determine if the increased AMPK activity was linked to E2F1 induction in A1555G cells, we treated A1555G cells with AMPK inhibitor compound C, which was confirmed by reduced phosphorylation of AMPK target acetyl-CoA carboxylase (ACC) (Figure 3F). Pharmacological inactivation of AMPK in A1555G cybrids reduced

Table 1. Transcription Factors Whose cis-Elements Are Detected in the Promoters of Transcripts Upregulated in Response to 12S rRNA Hypermethylation, but Not in the Promoters of the Downregulated Transcripts

Transcription Factor	Upregulated Target Genes	Downregulated Target Genes	p Value
E2F1	50	0	0.00010
CEBPA	43	0	0.00012
RUNX1T1	15	0	0.0010
IRF3	13	0	0.0018
E2F2	9	0	0.0128

The p value was calculated using Fisher’s exact test.

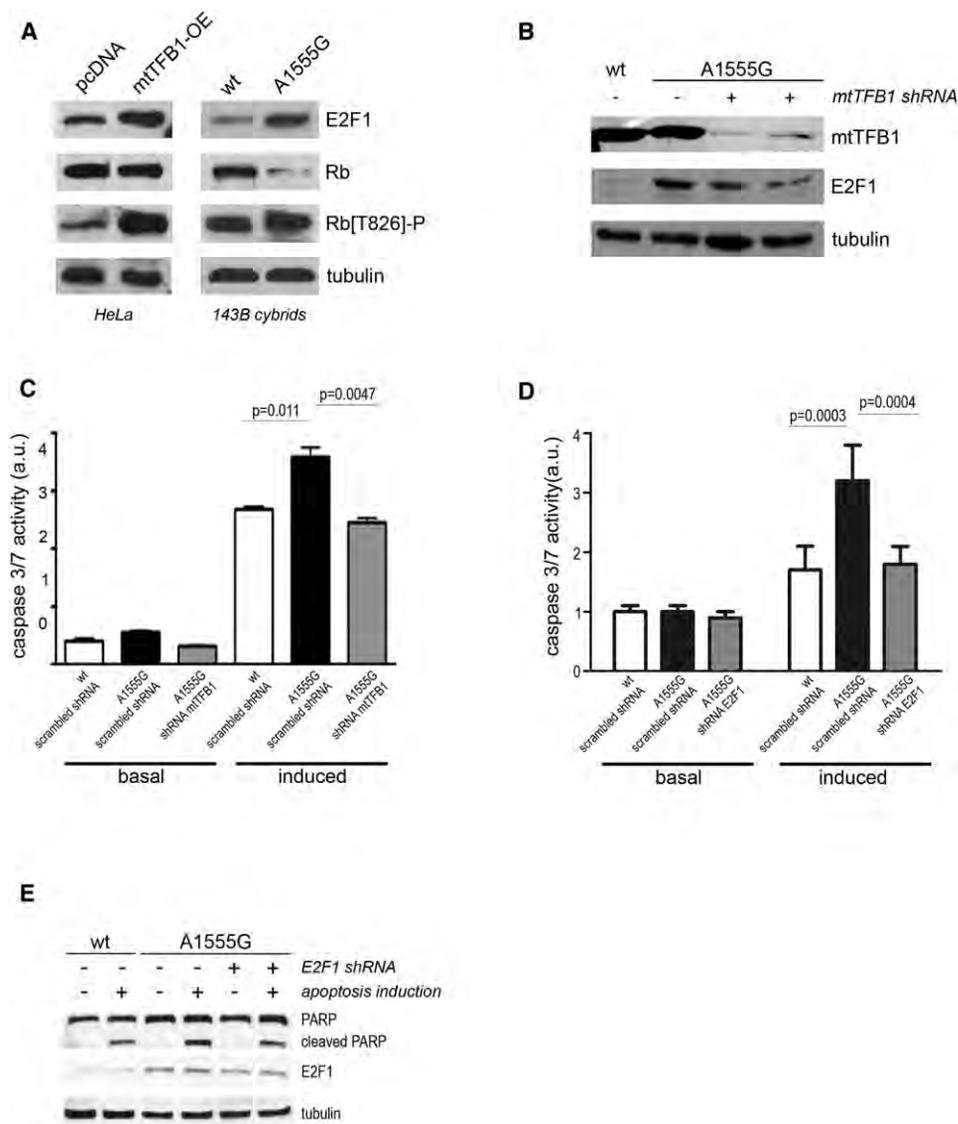

Figure 2. Hypermethylation of Mitochondrial 12S rRNA Leads to Activation of E2F1- and E2F1-Dependent Apoptosis

(A) Western blot analysis of whole-cell extracts for E2F1, Rb and phosphorylated-Rb, (Rb[T826]-P) in HeLa cells that overexpress h-mtTFB1 (mtTFB1-OE) compared to cell containing an empty-vector negative control (pcDNA), and in human 143B cybrids containing wild-type (wt) or A1555G mtDNA. Tubulin was probed as a loading control. Quantification is shown in Figure S1B.

(B) Effect of mtTFB1 knockdown (to reduce 12S hypermethylation) on E2F1 levels in A1555G cybrids by Western blot using tubulin as a loading control. Two independent knockdown constructs were used (+), and a scrambled shRNA was used as a negative control (-). 143B cybrids with wild-type (wt) mtDNA treated with the negative control shRNA are shown in lane 1. Quantification is shown in Figure S1C.

(C) Quantitation of apoptosis (caspase 3/7 activity) in 143B cybrids containing wild-type (wt) or A1555G mtDNA without (-) or with (+) mtTFB1 knocked down by shRNA. Basal and induced apoptosis refer to the presence and absence of staurosporine. The values plotted represent mean \pm standard deviation (n = 12), with t test p values indicated.

(D) Quantitation of apoptosis (caspase 3/7 activity) in 143B cybrids containing wild-type (wt) or A1555G mtDNA without (-) or with (+) E2F1 knocked down by shRNA. Basal and induced apoptosis refer to the presence and absence of staurosporine. The values plotted represent mean \pm standard deviation (n = 12), with t test p values indicated.

(E) Western blot analysis of full-length and cleaved PARP and of E2F1 in wild-type (wt) and A1555G treated with scrambled (-) or E2F1 (+) shRNA without (-) or with (+) induction of apoptosis by staurosporine. E2F1, full-length (PARP) and caspase-3-cleaved forms of PARP are shown, with tubulin probed as a loading control. Quantification is shown in Figure S1D.

Rb phosphorylation and E2F1 levels (Figure 3F), and lowered apoptosis susceptibility of the A1555G cells (Figure 3G). Taken together, these results strongly implicate AMPK as a ROS-sensi-

tive component of the mitochondrial stress-response pathway that leads to proapoptotic E2F1 signaling in cells containing the deafness-causing A1555G mutation.

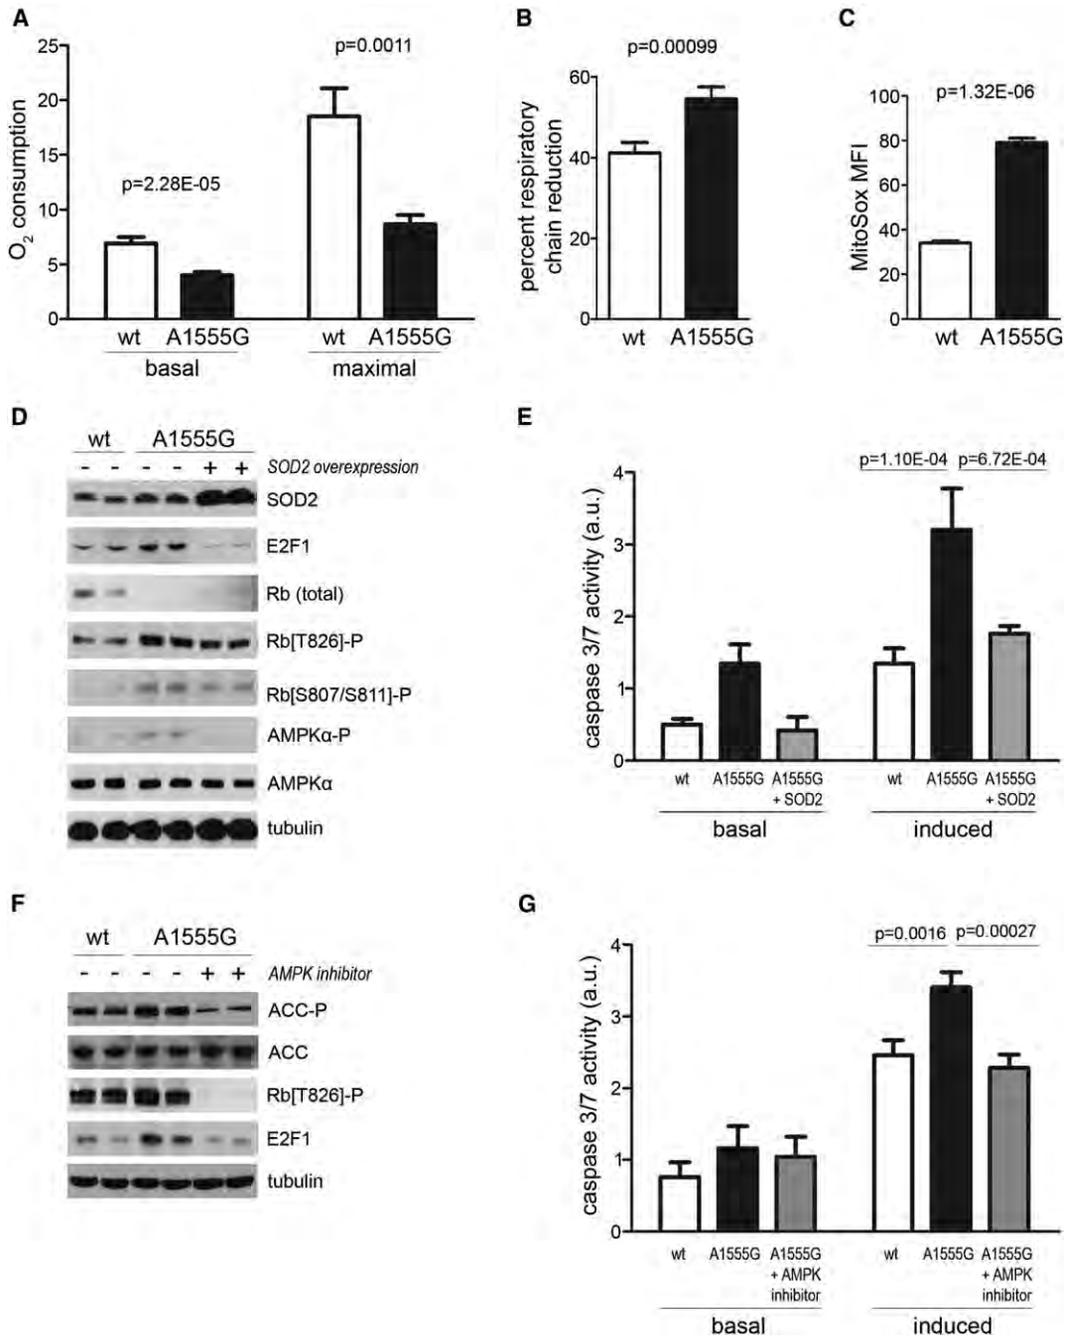

Figure 3. A Proapoptotic Mitochondrial Stress-Signaling Pathway that Involves Mitochondrial ROS-Dependent Activation of E2F1 by AMPK

(A) Basal and maximal (+ FCCP uncoupler) mitochondrial O₂ consumption rates in 143B cybrids containing wild-type (wt) or A1555G mtDNA are shown. The mean ± standard deviation (n = 24) is plotted, with t test p values indicated.

(B) Degree of respiratory chain reduction in the same cells as in (A). This is the ratio of basal to maximal respiration, the latter of which was considered 100% reduction (i.e., the chain handling the maximal amount of electrons). The mean ± standard deviation (n = 12) is plotted, with t test p values indicated.

(C) Mitochondrial ROS in 143B cybrids containing wild-type (wt) or A1555G mtDNA as measured by FACS analysis of MitoSox staining. The mean fluorescence intensity ± standard deviation is plotted (n = 3), with t test p values indicated.

(D) Western blot analysis of A1555G cybrids that overexpress SOD2. Immunoblotting of E2F1, Rb, phospho-Rb T826 and S807/811, AMPK α , and phospho-AMPK α T172 are shown in A1555G cybrids transfected with the SOD2 overexpression vector (lanes 5 and 6), and in control cybrids with wild-type mtDNA (“wt,” lanes 1 and 2) and A1555G mtDNA (lanes 3 and 4) transfected with empty vector. Lanes 1 and 2, 3 and 4, and 5 and 6 represent independent biological replicates. Tubulin was probed as a loading control.

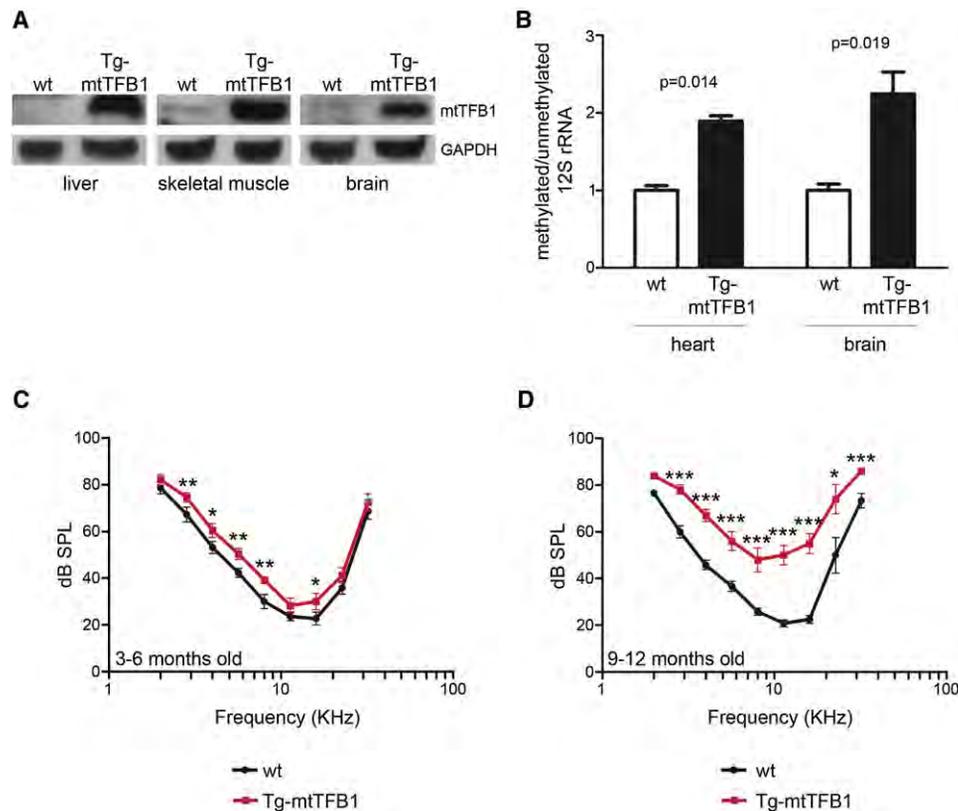

Figure 4. Transgenic Mice that Overexpress the mtTFB1 rRNA Methyltransferase Exhibit 12S Hypermethylation and Progressive Hearing Loss

(A) Western blot of mtTFB1 in wild-type (wt) and transgenic mtTFB1 (Tg-mtTFB1) mouse tissues using GAPDH as loading control.

(B) Quantification of the degree of 12S rRNA methylation in Tg-mtTFB1 mouse heart and brain tissues using a methylation-sensitive mitochondrial 12S rRNA primer-extension assay (Cotney et al., 2009). The values plotted represent mean of methylated/unmethylated \pm standard deviation ($n = 3$), with t test p values indicated.

(C) Hearing thresholds determined by ABR analysis of Tg-mtTFB1 (red points) and control wild-type (wt), nontransgenic littermate control mice (black points) are shown in the audiogram (frequency versus threshold curve). The threshold (in sound pressure level, dB SPL) was tested with 5 dB resolution and frequencies in half octave steps from 32 to 2 kHz. The values plotted represent mean \pm SEM, with t test p values indicated (* $p < 0.05$; ** $p < 0.01$; *** $p < 0.001$). Mice were tested at ages 3–6 months (9 wt mice and 12 Tg-mtTFB1 mice were used).

(D) Same as in (C) except mice were tested at ages 9–12 months (5 wild-type mice and 6 Tg-mtTFB1 mice were used).

Transgenic Mice that Overexpress the Mitochondrial rRNA Methyltransferase mtTFB1 Exhibit Increased Mitochondrial 12S rRNA Methylation in Multiple Tissues and Progressive Hearing Loss

The cell culture studies above strongly implicate an E2F1-dependent, proapoptotic mitochondrial stress signaling pathway downstream of mitochondrial 12S hypermethylation as a potential pathogenic component of deafness caused by the A1555G mtDNA mutation. To test this hypothesis directly, we generated

transgenic mice that globally overexpress the mouse mtTFB1 rRNA methyltransferase (Tg-mtTFB1) responsible for the specific mitochondrial 12S methylation event implicated (Seidel-Rogol et al., 2003). These animals are viable and fertile, and have increased mtTFB1 protein in multiple tissues (Figure 4A) that corresponds with increased 12S rRNA methylation (Figure 4B). When we measured hearing function in Tg-mtTFB1 mice by the auditory brainstem response (ABR) and compared them to age-matched, nontransgenic littermate controls, we found that

(E) Quantitation of apoptosis (caspase 3/7 activity) in 143B cybrids containing wild-type (wt) mtDNA (white bars) or A1555G mtDNA without (black bars) or with SOD2 overexpression (gray bars). Basal and induced apoptosis refer to the presence and absence of staurosporine. The values plotted represent mean \pm standard deviation ($n = 12$), with t test p values indicated.

(F) Effect of pharmacological AMPK inhibition on the levels of acetyl-CoA carboxylase (ACC), phospho-ACC S79 (ACC-P), phospho-Rb T826, and E2F1 in A1555G cybrids (lanes 5 and 6), determined by western blot of whole-cell extracts using tubulin as a loading control. Lanes 1 and 2 (wild-type cybrids) and 3 and 4 (A1555G cybrids) are the vehicle controls (–). Lanes 1 and 2, 3 and 4, and 5 and 6 represent independent biological replicates.

(G) Quantitation of apoptosis (caspase 3/7 activity) in 143B cybrids containing wild-type (wt) mtDNA (white bars), or A1555G mtDNA without (black bars) or with AMPK inhibition (gray bars). Basal and induced apoptosis refer to the presence and absence of staurosporine. The values plotted represent mean \pm standard deviation ($n = 12$), with t test p values indicated.

at 3–6 months of age Tg-mtTFB1 mice have higher ABR thresholds across the entire range of frequencies, indicating significant hearing loss (Figure 4C). Similar hearing-threshold defects are observed in patients with the A1555G mutation (Noguchi et al., 2004). This hearing loss in the Tg-mtTFB1 animals progresses dramatically with age, with a much greater difference in ABR thresholds in animals aged to 9–12 months (Figure 4D). It is important to note that, even though the C57BL/6 genetic background used here exhibits premature age-related hearing loss (Someya et al., 2009), significant decreases in ABR in these mice are not observed until 12–15 months of age, which is beyond the time frame we analyzed in this study.

E2F1 Induction and Apoptosis in Critical Inner Ear Cells of Tg-mtTFB1 Mice

The cochlea of the Tg-mtTFB1 mice display a largely normal structure, with no obvious loss of the hair cells in the organ of Corti (Figure 5A, upper panel) or obvious disruption of the spiral ganglion (Figure 5B, upper panel). Not observing significant hair cell dysfunction or apoptosis even in 1-year-old animals with severe hearing loss, we turned our attention to other critical inner ear cell types. We found that E2F1 protein was increased in the stria vascularis (Figure 5A, middle panel) and in the spiral ganglion neurons (Figure 5B, middle panel) of Tg-mtTFB1 mice, but not in the organ of Corti. This tissue-specific upregulation of E2F1 correlated with increased caspase 3/7 staining in the stria vascularis (Figure 5A, bottom panel) and spiral ganglion neurons (Figure 5B, bottom panel), consistent with E2F1 enacting a proapoptotic signal in critical cells involved in inner ear homeostasis and hearing. To confirm the caspase-3 activation in the spiral ganglion of Tg-mtTFB1 mice, we measured the number of spiral ganglion neurons and the number of caspase-3-positive neurons, and found that Tg-mtTFB1 mice have ~30% fewer spiral ganglion neurons and a 3-fold increase in the number of caspase-3-positive cells (Figure 5C). Consequently, the percentage of caspase-3-positive cells is 4-fold higher in Tg-mtTFB1 spiral ganglion (Figure 5D).

In support of the cell-type specificity of the mitochondrial-stress pathway to E2F1 *in vivo*, we found that E2F1 is not induced in other tissues of Tg-mtTFB1 mice (Figure S2A). Interestingly, activation of AMPK, measured by phosphorylation of both AMPK α and ACC, is detectable in some tissues (skeletal muscle and heart) but not in the liver (Figure S2A). To further confirm the tissue specificity of E2F1 activation, we measured the transcript levels of *E2F1*, and found an increase in the stria vascularis, but not in the organ of Corti or in the brain (Figure S2B). Furthermore, there is increased phospho-AMPK in the stria vascularis of Tg-mtTFB1 mice (Figure S2C). Finally, analysis of available microarray datasets from the mtDNA-mutator mouse (Trifunovic et al., 2004), which exhibits age-related pathology including deafness (Someya et al., 2008), revealed that E2F1 transcripts and its targets are upregulated in the cochlea, but not in skeletal muscle (Figure S2D; Table S3), further supporting the role of E2F1 in cell death in the inner ear.

E2F1 Mediates Hearing Loss in Tg-mtTFB1 Mice

In order to determine if E2F1 induction *per se* has a causal role in the observed hearing loss in this new mouse model of deafness,

we crossed the Tg-mtTFB1 mice with E2F1 knockout mice, to generate mice heterozygous for E2F1 that either overexpress Tg-mtTFB1 (E2F1^{+/-},Tg-mtTFB1) or not (E2F1^{+/-}). Evaluation of hearing function in these animals by ABR revealed that overexpression of mtTFB1 no longer promoted significant hearing loss in the E2F1^{+/-} genetic background (Figure 5E), which has reduced expression of E2F1. These results confirm a causal role for activation of E2F1 above a certain threshold level in the hearing loss observed in Tg-mtTFB1 mice.

DISCUSSION

In this study, we endeavored to gain new insight into the complexity and tissue specificity of mitochondrial-based diseases by studying the common human mtDNA mutation A1555G that has one primary outcome, deafness, and modeling its pathogenic mechanism in mice. Based on our results, we conclude that a major pathogenic driving force is cell death due to activation of the proapoptotic nuclear transcription factor E2F1 by a cell-type-specific mitochondrial stress pathway. Below we will discuss the results that led us to this conclusion and the potential broader implications of this study with regard to the documented environmental exacerbation of this form of deafness (Warchol, 2010), age-related hearing loss (presbycusis), and other diseases where mitochondria are implicated in pathogenesis.

We propose that mitochondrial stress due the hypermethylation of the mtDNA-encoded 12S rRNA is a critical component of the inner ear pathology associated with deafness caused by the human mtDNA A1555G mutation. This is perhaps best demonstrated by our results in the Tg-mtTFB1 transgenic mice, which exhibit 12S rRNA hypermethylation in multiple tissues and activation of the proapoptotic transcription factor E2F1 that causes progressive hearing loss similar to that observed in human A1555G patients. Deafness is the primary effect of the A1555G mutation even though most patients are homoplasmic (i.e., have 100% mutant mtDNA) in all cells and tissues (Fischel-Ghodsian, 1999; Prezant et al., 1993). This implies a cell-type specific response to mitochondrial dysfunction is at play. Our results showing that upregulation of E2F1 and increased cell death occur in the stria vascularis and in the spiral ganglion neurons, but not in the organ of Corti, are consistent with activation of E2F1 by mitochondrial stress occurring only in certain critical cells in the inner ear and their subsequent apoptosis via this pathway.

E2F1-dependent cell death in the stria vascularis and spiral ganglion neurons is consistent with the pattern of hearing loss across all frequencies that we observe in the Tg-mtTFB1 mice. With regard to the irreversible nature of the deafness, neurodegeneration in spiral ganglion itself could itself be responsible, as has been proposed for age-related hearing loss (Someya et al., 2009). Alternatively, or in addition, dysfunction of the stria vascularis and spiral ganglion neurons could ultimately result in a higher susceptibility of irreplaceable inner hair cells to undergo cell death (Fetoni et al., 2011). Furthermore, since activation of the cell cycle in post-mitotic neuronal cells is an established trigger for apoptosis (Chen et al., 2003; Hou et al., 2000; Shadel, 2004a) the mitochondrial stress pathway to E2F1 identified

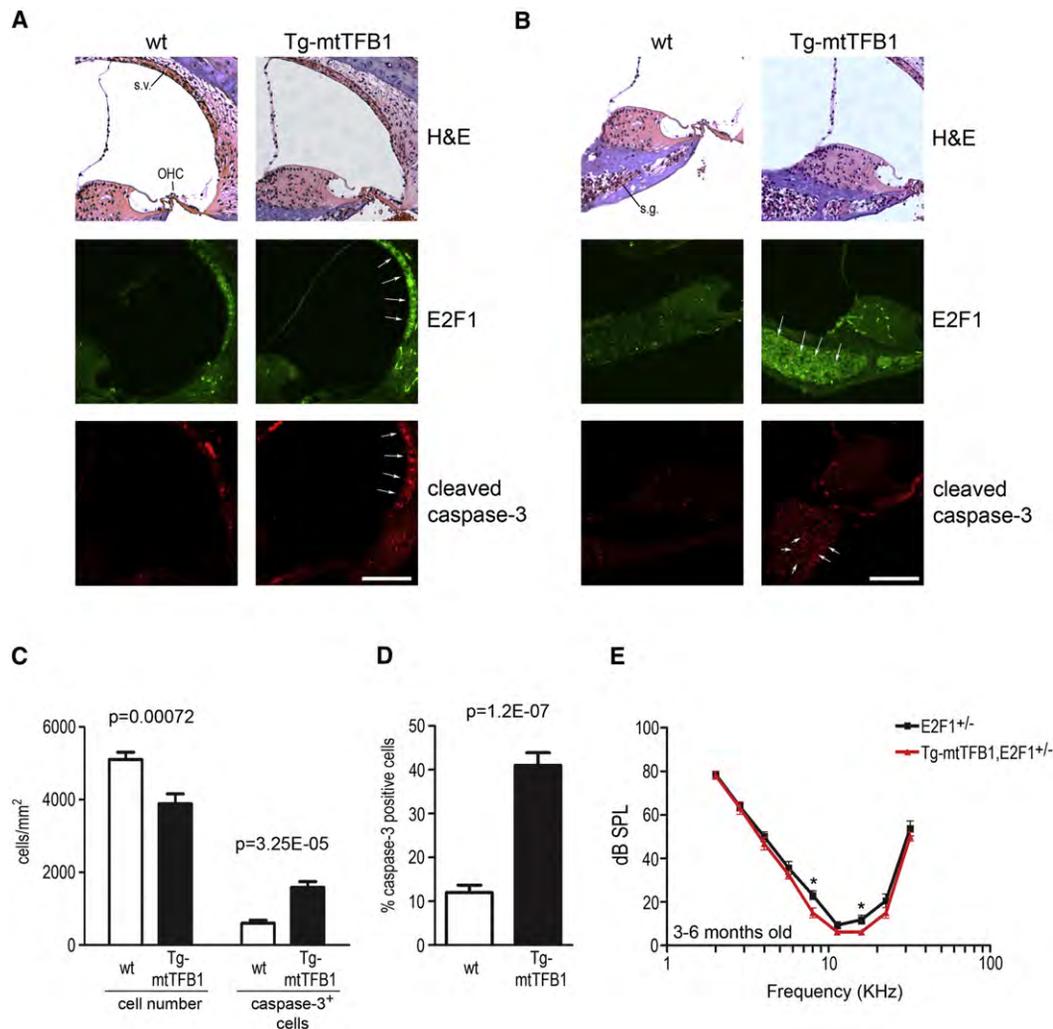

Figure 5. Deafness Pathology in Tg-mtTFB1 Mice Involves Upregulation of E2F1 and Apoptosis in the Stria Vascularis and Spiral Ganglion Neurons of the Inner Ear

(A) H&E staining of the organ of Corti and stria vascularis (top panels) from representative 1-year-old wild-type (wt, left column) and Tg-mtTFB1 mice (right column). The middle panels show immunohistochemistry staining for E2F1 and the lower panels show immunohistochemistry for cleaved caspase-3 in similar representative sections. White arrows indicate areas where significant changes in signal are observed. Stria vascularis (s.v.), outer hair cells (OHC), scale bar, 100 μ m. See also Figure S2.

(B) Same as in (A) but sections that highlight staining in the spiral ganglion neurons are shown. Spiral ganglion (s.g.), scale bar, 100 μ m.

(C) Quantification of cellular density in the spiral ganglion (the left side of the plot) and of caspase-3-positive spiral ganglion neurons (right side). The sections were obtained from three wild-type and three Tg-mtTFB1 mice at 1 year of age, and six independent sections were counted for each animal. The values plotted represent mean \pm standard deviation, with t test p values indicated.

(D) Same as in (C), but expressing the percentage of caspase-3-positive cells in the spiral ganglion. The values plotted represent mean \pm standard deviation, with t test p values indicated.

(E) ABR analysis of E2F1^{+/-} mice (black points) and E2F1^{+/-}/Tg-mtTFB1 mice (red points) performed as described in Figure 4C. Mice were tested at ages 3–6 months (eight E2F1^{+/-} mice and ten E2F1^{+/-}/Tg-mtTFB1 mice were used). The values plotted represent mean \pm SEM, with t test p values indicated (*p < 0.05).

herein may also make some cells of the inner ear inherently more susceptible to cell death due to being forced into the cell cycle, as opposed to activation the E2F1 apoptosis pathway per se. Based on these considerations, we propose that A155G patients would likewise be more prone to eventual loss of critical inner ear cells via this mitochondrial stress pathway to E2F1, explaining their irreversible hearing loss either spontaneously, as a function of age, or in response to environ-

mental stimuli such as noise or aminoglycosides. Even though our results strongly implicate 12S hypermethylation per se in the deafness phenotype in mice, it is likely that defects in mitochondrial translation caused by the A155G mutation, such as infidelity (Hobbie et al., 2008), conspire with hypermethylation to produce the precise deafness pathology in humans and/or mediate its exacerbation by aminoglycoside antibiotics. Therefore, it remains important to determine precisely which

mechanisms and cell types within the inner ear instigate deafness pathology in this new mouse model and in human A1555G patients. A full understanding of these events may be therapeutic in this regard and could help advance efforts to regenerate hearing function.

Our results in A1555G cybrids also provide key insight into the nature of the pathogenic mitochondrial stress-signaling pathway. Specifically, hypermethylation of mitochondrial ribosomes, which are needed for translational and assembly of the respiratory chain (Bonawitz et al., 2006), disrupts mitochondrial respiration in a manner that increases ROS production (Figure 3). We propose that increased mitochondrial superoxide is sensed by AMPK (Emerling et al., 2009; Quintero et al., 2006), activation of which relays the stress signal to E2F1. Since E2F1 activity is associated with proapoptotic signaling and is necessary for the enhanced cell death on A1555G cybrids (Figure 2D) and hearing loss in Tg-mtTFB1 mice (Figure 5E), we speculate ROS- and AMPK-dependent activation of E2F1 is the major mitochondrial stress-signaling pathway involved under these circumstances. Going forward, it will be important to determine precisely how E2F1 is regulated by ROS and AMPK.

The marked tissue specificity of E2F1 induction and, to a lesser degree, of AMPK activation (Figure S2A), provides insight into the complex mechanisms underlying tissue specificity of mitochondrial diseases. The requirement for multiple sequential steps to fully activate the mitochondrial ROS-AMPK-E2F1 apoptotic pathway provides a variety of opportunities for different tissues to suppress a pathogenic mechanism. For example, tissues with lower OXPHOS activity or better redox buffering could prevent initial activation of the pathogenic mechanism. Alternatively, in other tissues, AMPK may not respond to ROS, E2F1 may not be activated by AMPK, or E2F1 may not be a potent trigger of apoptosis, any of which would presumably prevent a pathogenic outcome. These observations may be generalizable, in that other pathogenic mitochondrial retrograde signaling pathways likely exist with their differential activation or readout in tissues contributing to the complex tissue specificity observed in mitochondrial diseases.

Finally, the induction of E2F1 in response to a mitochondrial malfunction may represent a paradigm in mitochondrial pathogenesis where the cause of the disease is not the immediate OXPHOS dysfunction, but instead the misinterpretation of resulting retrograde signals generated by mitochondria. The pivotal role of AMPK as a sensor of energy charge and now as a ROS-dependent regulator of E2F1 activity highlights the complexity of mitochondrial stress responses and the need for additional research to uncover other such pathways. Finally, it is tempting to speculate that aberrant mitochondrial stress signaling may also be of general significance in diseases and circumstances where mitochondrial dysfunction and apoptosis are implicated, such as heart disease, cancer, neurodegenerative diseases and aging.

EXPERIMENTAL PROCEDURES

Cell Culture, shRNA-Mediated Gene Knockdown, FACS Analysis, and 12S Methylation Assays

143B osteosarcoma cybrids containing either wild-type (A1555A) or mutant (A1555G) mtDNA (Guan et al., 2001) were grown in DMEM high glucose (Sigma

D5648) plus 10% fetal calf serum at 37°C and 5% CO₂. Prior to all experiments, cells were plated at 5,000 cells/cm² and grown for 96 hr to 70%–80% confluence. When puromycin was used for selection, it was removed at least 24 hr prior to harvesting cells. HeLa cells that overexpress h-mtTFB1 have been described (Cotney et al., 2007, 2009).

Retroviral-mediated shRNA knockdown of mtTFB1 and E2F1 by was carried as described (Cotney et al., 2009) with the following modifications. Wild-type or mutant 143B cybrids were transfected and plated at 5,000/cm² in DMEM with 10% fetal calf serum and 600 ng/ml puromycin and used for experiments at 70%–80% confluence. Puromycin was removed 48 hr prior to analysis. Target sequences ligated into the pSiren-RetroQ vector (Clontech) for mtTFB1 and E2F1 knockdown, as well the scrambled negative-control shRNA used were described previously (Cotney et al., 2009; Goto et al., 2006). To overexpress SOD2, cybrids were transfected with pCMV-SPORT6-SOD2 (Open Biosystems MMM4769-99609684) or pcDNA3.0 as a negative control as described (Cotney et al., 2009). To inhibit AMPK, cybrids were treated for 16 hr with 10 μM of compound C (Calbiochem) and then used immediately for experiments.

To analyze mitochondrial superoxide by FACS, wild-type and A1555G cybrids were treated with 50 nM MitoSOX (Invitrogen) for 20 min at 37°C, rinsed, and detached with trypsin. Fluorescence was measured using a FACScan (BD Biotechnology) and analyzed using FlowJo software. Primer-extension analysis of mitochondrial 12S rRNA adenine dimethylation was performed on 1–5 μg of total cellular or tissue RNA prepared using the RNEasy Kit (QIAGEN) as described (Cotney et al., 2007; Seidel-Rogol et al., 2003), except 2 μM each of dATP, dCTP, and dTTP and 0.5 μM ddGTP were used.

Western Blotting

Whole-cell extracts of cultured human cells were prepared in 1.5% n-dodecyl-maltoside in PBS as described (Raimundo et al., 2009). Gels were loaded with 50 μg of total protein per well, and the following antibodies were used for immunoblotting: E2F1 (Santa Cruz, sc193), mtTFB1/TFBM1 (McCulloch and Shadel, 2003) or that provided by Dr. Craig Cameron, tubulin (Thermo, DM1A), Rb (BD PharMingen, 554136), phospho-Rb (T826) (Abcam, ab4779-50), phospho-Rb (S807/811) (Cell Signaling, 9308S), AMPKα (Cell Signaling, 2603), phospho-AMPKα (T172) (Cell Signaling, 2535S), acetyl-CoA carboxylase (ACC) (Cell Signaling, 3676), phospho-ACC (S79) (Cell Signaling, 3661), SOD2 (Assay Designs, SOD-111), PARP (Cell Signaling, 9542), and GAPDH (Ambion, AM4300). Western blots were performed on three to four biological replicates and at least three technical replicates.

Apoptosis Assays

To induce E2F1-dependent apoptosis, cybrids were treated with 200 nM staurosporine for 3 hr in the presence of 10 mM wortmannin as described (Hallstrom et al., 2008). Cells were then rinsed and used for two different apoptosis assays. Caspase 3/7 activity was determined using a plate reader 1 hr after treatment with Caspase-Glo reagent (Promega) as described by the manufacturer, and full-length and cleaved PARP were assayed by western blot.

Oxygen Consumption Analysis

Cells were plated in XF96 plates (SeaHorse Biosciences) at 10,000 cells/well and the next day cellular O₂ consumption was determined in a SeaHorse Bioscience XF96 extracellular flux analyzer according to manufacturer instructions. Cells were maintained at 37°C in normal growth medium without serum. In some wells 8 μM of the mitochondrial uncoupler FCCP was added.

Microarrays and Data Analysis

Total cellular RNA from the cultured cells was prepared using an RNeasy mini RNA extraction kit (QIAGEN GmbH, Hilden, Germany) and used for the expression microarray procedure in conjunction with the Yale University W.M. Keck Foundation Biotechnology Resource Laboratory. RNA integrity was first verified by an Agilent Bioanalyzer and then amplified, labeled and hybridized onto GeneChip HG-U133 Plus 2.0 arrays (Affymetrix, Agilent, Santa Clara, CA) using standard protocols recommended by the manufacturer, starting from 5 μg of total RNA. Data were normalized by the RMA method (Irizarry et al., 2003), using commercial software (GeneSpring, Agilent, Santa Clara, California, CA). For each biological sample, two RNA samples were prepared

from two independently collected cell pellets. To analyze the expression data, samples were grouped according to their 12S rRNA methylation status (Figure 1A). The four samples in the hypermethylation group were compared to the four samples with basal methylation to control for nonspecific effects of overexpression of mtTFB1 independent of increased 12S rRNA methylation and in an attempt to subtract effects due to cell nuclear genetic background. Transcripts whose expression was significantly changed between the two groups formed the 12S rRNA hypermethylation list (4333 transcripts; Table S1). The student's t test was used to determine statistically significant changes in expression, with a cutoff p value of 0.05 (Raimundo et al., 2009). The false-positive rate was determined to be 3.8% as described (Hovatta et al., 2005). The correlation of the Q-PCR with the microarray results for six genes tested was $R^2 = 0.77$ (Raimundo et al., 2009).

To determine which *cis*-elements were present in the promoters of the genes up- or downregulated in 12S rRNA hypermethylated samples, we used the Biblosphere software (Genomatix Software GmbH, Munich, Germany). To minimize false positives, a cutoff of at least two *cis* element-gene cocitations was implemented. Enrichment in *cis*-elements of the genes up- or downregulated was determined by Fisher's exact test.

Generation and Analysis of Transgenic Mice that Overexpress mtTFB1

A mouse mtTFB1 cDNA was amplified with primers containing EcoR1 and EcoRV restriction sites and ligated into the vector pCAGGS that contains a CMV immediate early-enhancer/chicken β -actin/rabbit β -globin promoter (Niwa et al., 1991) and confirmed by sequencing. Purified pCAGGS/mtTFB1 plasmid was digested with Sall and PstI, to liberate a fragment containing the enhancer, promoter, *TFB1M* ORF, and poly-A tail. This linear DNA fragment was then used by the Yale Animal Genomic Services to microinject pronuclear, C57BL/6J X SJL/J embryos. Seventy-four animals were born from the six foster mothers. After genotyping, one female (F1) founder was identified that contained the transgene. This female was then mated with a wild-type C57BL/6J male to generate the second generation (F2) and then serially to create subsequent generations. Female F3 to F5 transgenics and control nontransgenic littermates were used for all of the experiments. All procedures were IACUC-approved as determined by the Yale University Animal Care and Use Committee.

For analysis of mouse samples, tissues from 9-month-old mice were harvested, immediately frozen in liquid nitrogen, and stored at -80°C . The tissues were ground using a mortar and pestle previously frozen at -80°C , kept on dry ice during the procedure. Whole-tissue homogenates were prepared as described (Cotney et al., 2009). Primer extension analysis and q-PCR were performed on RNA purified from these same mouse tissues using the RNeasy kit using the method already described for human cells, but with the following mouse 12S-specific primer: 5'-ATTATTCGAAGC-3'. To generate Tg-mtTFB1/E2F1^{+/-} mice, a C57BL/6J male E2F1^{-/-} was obtained from the Jackson Laboratory (Bar Harbor, ME) and mated with F4 Tg-mtTFB1 females, yielding E2F1^{+/-} progeny with and without the mtTFB1 transgene.

Auditory Brainstem Response and Cochlear Histology

Detailed methods for the ABR analysis can be found in the *Extended Experimental Procedures*. A total of 21 animals (9 Tg-mtTFB1 and 12 wild-type littermates) between the ages of 3 and 6 months, and 11 animals between 9 and 12 months (5 wild-type, 6 Tg-mtTFB1), were used for auditory brainstem response (ABR) testing. The E2F1^{+/-} animals were tested at 3–6 months of age (total of 20, 8 wild-type and 12 Tg-mtTFB1). In all experiments, age-matched littermates were compared directly on the same day and by the same experienced specialist blinded to the genotype of the mice. The mice were subsequently combined into 3–6 and 9–12 groups for data presentation and statistical analysis. Animals were anesthetized with chloral hydrate (480 mg/kg IP) and all recordings were conducted in a sound-attenuating chamber (Industrial Acoustics Corp) using a customized TDT3 system (Tucker-Davis Technologies, Inc.). A t test was used to determine the statistical significance of the threshold difference at each frequency.

The inner ear was prepared for histology by removing the temporal bone and exposing and rupturing the bulla. The cochlea was perfused with 4% paraformaldehyde (in PBS) using a syringe outfitted with small diameter tubing

through the oval and round windows. The tissue was incubated overnight, decalcified in 10% EDTA in PBS for 3 days, and then paraffin embedded, sectioned in 5 mm samples and mounted onto glass slides by the Yale Histology section. Following deparaffinization and rehydration, sections were used for immunohistochemistry and hematoxylin staining. Images were obtained using an Olympus IX71 microscope and Metamorph image analysis software. Nine independent cochlear sections were analyzed from three 1-year-old wild-type and three Tg-mtTFB1 mice. Spiral ganglion cells were counted using the DAPI counterstain in an area of 100 × 100 pixels and normalized to area (mm²). Cells displaying cytoplasmic foci of caspase-3 were considered caspase-3⁺.

ACCESSION NUMBERS

The raw data were deposited in the Gene Expression Omnibus repository (accession #GSE33780).

SUPPLEMENTAL INFORMATION

Supplemental Information includes Extended Experimental Procedures, three tables, and two figures and can be found with this article online at doi:10.1016/j.cell.2011.12.027.

Zebrafish are popular models for biological discovery. For investigators of the auditory and vestibular periphery, manipulations of hair cell and synaptic mechanisms have relied on inferences from extracellular recordings of physiological activity. We now provide data showing that hair cells and supporting cells of the lateral line can be directly patch-clamped, providing the first recordings of ionic channel activity, synaptic vesicle release, and gap junctional coupling in the neuromasts of living fish. Such capabilities will allow more detailed understanding of mechano-sensation of the zebrafish.

Introduction

Zebrafish hold promise for uncovering physiological mechanisms that are difficult to realize in other model species, because of the benefits of rapid reproductive rate and reduced organismal complexity (Rinkwitz et al., 2011). Indeed, progress has been enormous with this species, even in the auditory/vestibular arena, a field that usually prides itself on understanding human mechanisms with mammalian models. For example, great strides have been made in hair cell mechano-transduction and synaptic mechanisms (Nicolson, 2005). However, an obstacle to truly capitalizing on zebrafish for hair cell mechanism discovery is the heretofore inability to obtain patch-clamp recordings from neuromast sensory hair cells. We now report that this impediment has been overcome. We show preliminary data of whole-cell recordings from cells within lateral line neuromasts of living zebrafish, demonstrating ionic channel activity and synaptic vesicle release in hair cells. Additionally, we identify voltage-dependent gap junctional coupling in neuromast supporting cells. Our approach should help investigators obtain cellular data crucial to understanding the powerful genetic manipulations already available in zebrafish.

Materials and Methods

Zebrafish of either sex ranging in age from 3 to 14 days postfertilization (dpf) were anesthetized in Tricane and mounted in a recording chamber using dental floss tie downs (see Ricci and Fettiplace, 1997). Viability was monitored by visually monitoring heart rate and blood flow. An upright Nikon Eclipse was used for viewing, and recordings were made with an

Axon 200B amplifier with an Axon DD1322 digitizer. Images were enhanced with a Hamamatsu CCD camera. All recordings and image capture were made with jClamp software (Scisoft). Cells were held at -80 mV. Extracellular solution was as follows (in mM): 125 NaCl, 1.0 KCl, 2.2 MgCl₂, 2.8 CaCl₂, 10 HEPES, 6 D-glucose, 285 mOsm, pH 7.6. Pipette solution was (in mM): 90 CsCl, 20 TEA, 5 Na₂ATP, 3.5 MgCl₂, 10 HEPES, 1 EGTA, 260 mOsm, pH 7.2. Intracellular KCl (110 mM) solution lacked TEA. P/-5 protocols were made at a subtraction holding potential of -80 mV. Pipette resistance was typically 6.5 M Ω with Cs pipette solutions. Pipettes used to clean a pathway toward hair cells were ~ 1 –2 M Ω . For patch pipettes, 1.5-mm-thick-walled borosilicate glass was used without any coating. Capacitance measures were made with a dual sine admittance technique (Santos-Sacchi, 2004; Schnee et al., 2011a,b). Recordings were made at room temperature. Data are reported as mean \pm SE.

Results

Zebrafish lateral line neuromasts are peripherally located on each side of the zebrafish. Before scale formation, the organ is accessible via micropipette. Figure 1 shows a series of Hoffman optics images at different levels through the neuromast, starting apically where the hair cell kinocilia insert into the gelatinous cupola (A,B). Each kinocilium arises from one hair cell, and can be used to count the number of hair cells in the neuromast. In this example, 17 hair cells are present. Further medial, the outlines of the supporting cell boundaries (C,D; arrows) are visible. In the center of the neuromast, the tear drop-shaped hair cells are visible (E; arrows). To prepare for patch clamping, the supporting cells at the neuromast periphery must be breached by suction from a large-tipped pipette, whereupon entry into the neuromast is confirmed by positive pressure expanding the neuromast extracellular volume (F–H; arrows depict fluid-filled space). By maneuvering a patch pipette under positive pressure through the path previously made, a hair cell can be patched (I). This approach has been used to record from hair cells in a variety of hair cell organs (Ricci and Fettiplace, 1997; Ricci et al., 2005). We have recorded from >10 neuromasts on several fish. Gigohm seals were readily obtained. With Cs pipette solutions, average membrane capacitance (C_m) of hair cells determined from transient analysis at -80 mV at the

beginning of recording was 1.6 ± 0.09 pF ($n = 5$). Usually, 1–2 hair cells were recorded during a day's work.

Figure 2 shows K currents recorded from a patched hair cell with a K-based intracellular solution. Raw currents were evoked with voltage steps (C) following a prepulse to -120 mV from a holding potential of -80 mV. The outward currents were composed of at least two components, a fast decaying one and a slower noninactivating one (A). The fast-inactivating (A-type) current was removed with a prepulse to -40 mV (B), and by subtraction (traces A minus B), the transient current was isolated (D). Figure 2E shows an average $I-V$ curve of unsubtracted currents collected from a -80 mV holding potential, illustrating outward rectification averaging 0.25 ± 0.07 nA at $+10$ mV ($n = 3$). Slope resistance between -120 and -60 mV was ~ 2 G Ω . Using Cs solutions and P/N leakage subtraction, we also identified an inward Ca^{2+} current (Fig. 2F). The current was small and noninactivating during voltage steps. At -10 mV the Ca current averaged 0.018 ± 0.003 nA ($n = 5$). Ca influx is expected to release synaptic vesicles at the basal pole of hair cells. Figure 2G illustrates the release of vesicles, measured as a membrane capacitance increase. In this case, during the course of a 3 s depolarization to -10 mV, C_m increased ~ 40 fF. Open circles depict average responses. The average increase in C_m at 3 s under these conditions was 52 ± 23 fF ($n = 3$; initial C_m was 1.37 ± 0.15 pF). Assuming a vesicle capacitance of 38–50 aF (Schnee et al., 2005; Graydon et al., 2011), the C_m increase equates to a surface area equivalent to 1040–1370 vesicles. This release is greater than estimates of vesicles associated with synaptic ribbons (2–5 ribbons possessing ~ 120 vesicles each; Obholzer et al., 2008; Trapani and Nicolson, 2011), which predicts 12–30 fF for vesicles of 50 aF size. The larger measured values indicate recruitment of non-ribbon-associated vesicles, though not nearly at the rate observed in turtle or rat (Schnee et al., 2011a,b). We also tested for transduction currents during whole-cell voltage clamp by displacing the cupola sinusoidally with a fluid jet delivered by a puff pipette ($n = 4$) (Fig. 3). Currents of ~ 100 pA were evoked in this cell of ~ 1.3 G Ω input impedance. A decrease in amplitude during the extent of stimulation resembles adaptation. It should be noted that the Tricane anesthetic that we used is expected to reduce MET function (Farris et al., 2004).

Finally, we observed cells that had larger than the average 1.6 pF capacitance of hair cells, which we identify as supporting cells ($n = 4$). Auditory support cells are known to be joined into a

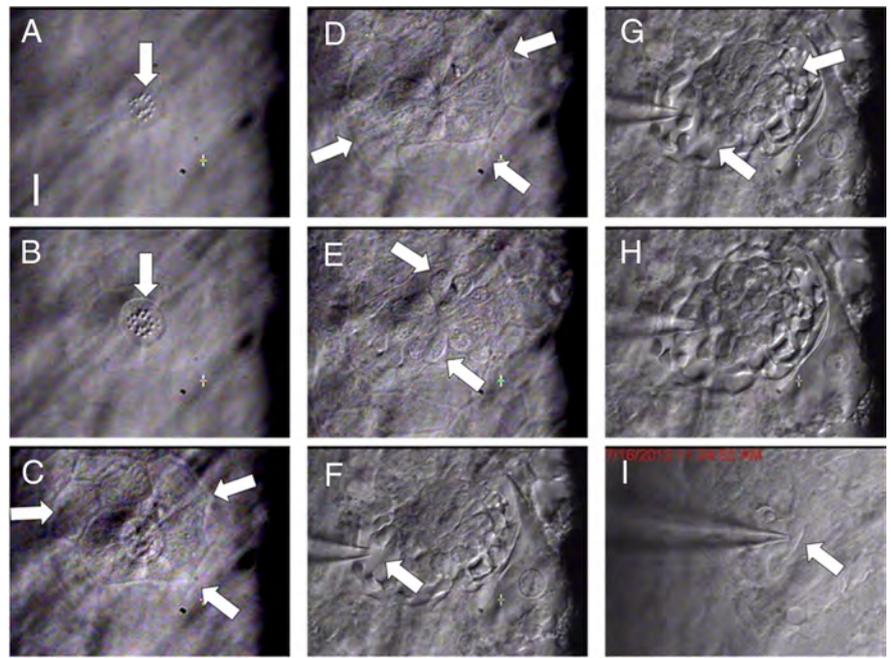

Figure 1. Electrode approach for patch clamping zebrafish hair cells. Zebrafish were anesthetized and fixed laterally onto a recording chamber. **A–E**, Images show neuromast structure from cupola/kinocilia top (**A**) to location of hair cell soma (**E**). See Results for details. **F–I**, Outer supporting cell ring is breached with large suction electrode, providing a path for patch electrode to seal on hair cell. See Results for details. Scale bar (**A**), 8 μm . Images from 7 dpf.

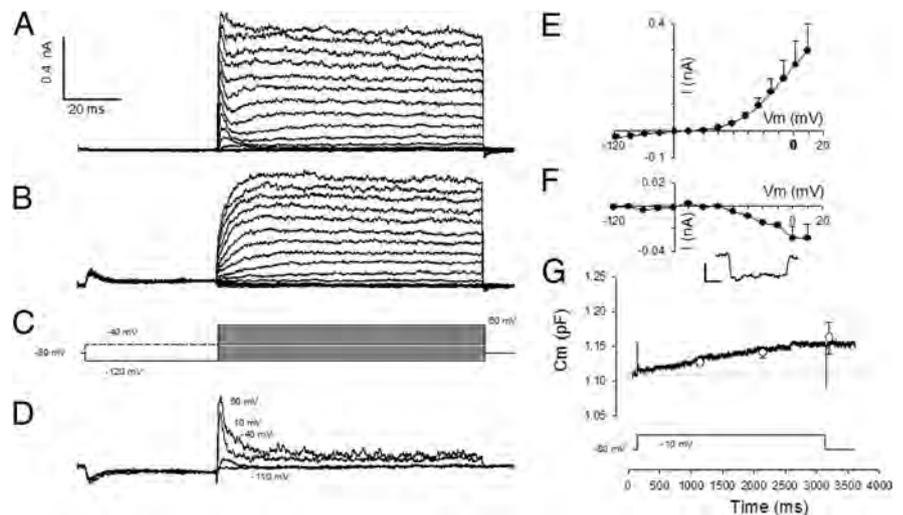

Figure 2. K, Ca currents and synaptic vesicle release from hair cells in living zebrafish. **A**, Outward K currents induced by voltage steps from prepulse level (-120 mV) to a range of voltages depicted in **C**. **B**, K currents generated following prepulse to -40 mV. **D**, Subtraction of traces (**A** minus **B**) reveals A-type inactivating current. **E**, Outward currents without leakage subtraction. Average $I-V$ ($+SE$; $n = 3$) of last 20 ms of 100 ms current traces. **F**, Inward Ca current is revealed by P/N leakage subtraction protocol collected with Cs pipette solution. Average $I-V$ ($+SE$; $n = 5$) of last 10 ms of 50 ms current traces. Inset, Noninactivating Ca current trace, generated in response to -30 mV step from -80 mV holding potential. Scale is 6 pA/10 ms. **G**, Hair cell synaptic vesicle release was determined with membrane capacitance measures. The cell was held at -80 mV and stepped to -10 mV for 3 s; vesicle release is evident from increase in C_m ; δC_m is ~ 40 fF (dark traces). Endocytosis was not observed in our experimental time frame. Dotted lines show initial capacitance level. Open circles indicate average ($\pm SE$) responses at 1 ($n = 5$), 2 ($n = 3$), and 3 ($n = 3$) s following the onset of depolarization. Data were obtained at 7–12 dpf.

syncytium and display large capacitances (Santos-Sacchi, 1991). Figure 4 illustrates supporting cell recordings where voltage was ramped to voltage extremes of $\sim \pm 90$ mV. Capacitance, in this case calculated from transient current response to step voltages, varied according to holding potential (Fig. 4A). In fact, there is the expected reciprocal relationship between input resistance and

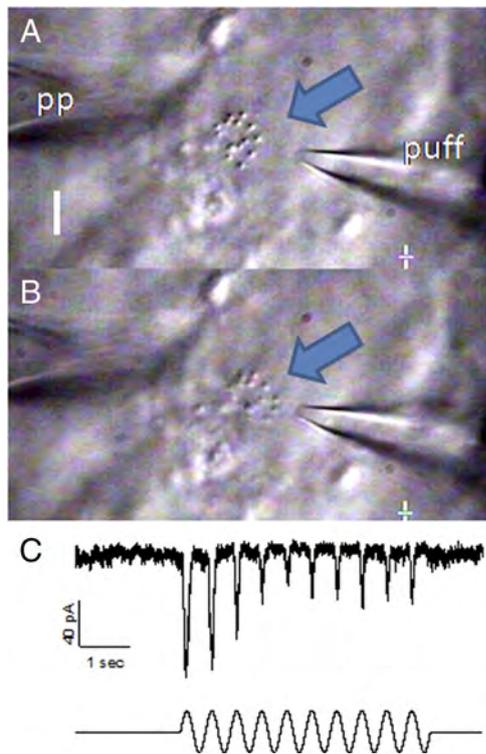

Figure 3. MET current activity during cupola deflection. *A*, A patch pipette (pp) voltage-clamped one hair cell in the neuromast, while a puff pipette (puff) was used to stimulate the kinocilia-embedded cupola. *B*, Suction phase of cupola stimulation showing kinocilia displaced closer to puff pipette. *C*, Receptor currents generated by sinusoidal fluid jet activity. Stimulus voltage driving the water jet is shown beneath currents. With the solutions we used, rectification of the response is expected (Farris et al., 2004). Scale bar, 6 μm . Data were obtained at dpf 7. Stimulus frequency was 2.0 Hz.

capacitance as gap junctions uncouple and recouple during depolarization and hyperpolarization, respectively (Fig. 4*B*). Auditory supporting cells possess voltage-dependent gap junctions (Zhao and Santos-Sacchi, 2000) and exhibit this type of behavior, as well.

Discussion

The zebrafish is a powerful model for auditory/vestibular research. Here we provide data demonstrating the feasibility of patch recording hair cells and supporting cells in lateral line neuromasts from the living zebrafish. The approach is similar to the one we have used to record from a variety of auditory/vestibular end organs (Ricci et al., 2005; Schnee et al., 2011a), and should allow direct assessment of hair cell function in the multitude of existing genetic manipulations available in the zebrafish.

Zebrafish hair cells possess outward K currents, and inward Ca currents similarly found in other auditory/vestibular-like organs. For example, the component K currents presented here are similar to those in the frog vestibular hair cell, where depolarizing prepulse was found to dissociate A-type and delayed rectifier-type contributions (Norris et al., 1992). Indeed, the basolateral electrical properties measured in the zebrafish hair cells are quite similar to those measured in bird (Lang and Correia, 1989; Ricci and Correia, 1999), frog (Norris et al., 1992; Masetto et al., 1994), turtle (Brichta et al., 2002), and mammal (Eatock and Hutzler, 1992). Though the zebrafish hair cell Ca current is small, its properties are similar to those of CaV(1.3) identified in zebrafish (Sidi et al., 2004) and its magnitude is similar to that of other vestibular hair cell types including those of frog (Prigioni et al., 1992;

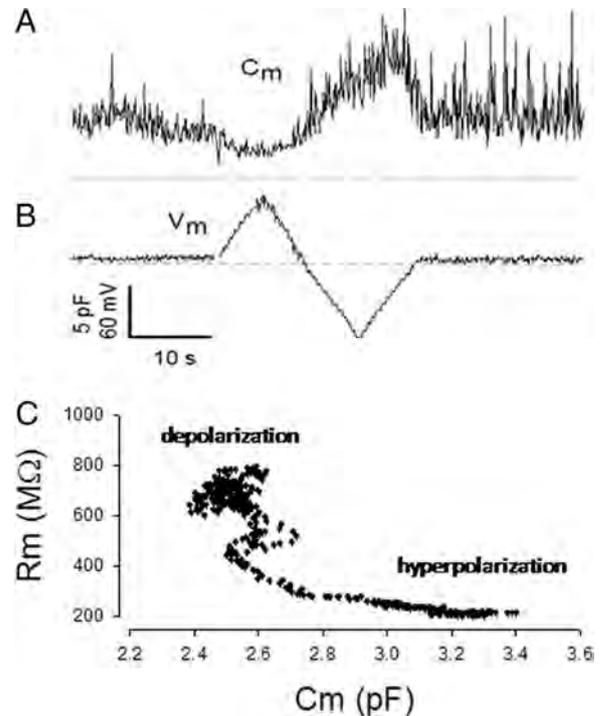

Figure 4. Input capacitance and resistance of supporting cell syncytium. *A*, *B*, An individual supporting cell was patch-clamped (*A*) and the membrane voltage modulated with a slow ramp to $\sim \pm 90$ mV (*B*). Note slow changes in input capacitance corresponding to membrane voltage, indicative of voltage-dependent gap junctional coupling found in the organ of Corti. Input capacitance indicates that several cells contribute to membrane surface area. Dotted lines indicate zero levels. Data were obtained at 12 dpf. *C*, In another cell, the reciprocal relationship between input resistance and capacitance as gap junctions uncouple and recouple during depolarization and hyperpolarization, respectively, is shown. Data were obtained at 3 dpf.

Martini et al., 2000), chick (Ohmori, 1984), and rat (Bao et al., 2003). Very recently, dissociated inner ear hair cells of the zebrafish were successfully recorded, and the reported K current was similar to that reported here (Einarsson et al., 2012).

The calcium current elicited was sufficient to evoke substantial transmitter release, indicative of vesicle replenishment from pools remote to the synaptic ribbon. The apparent absence of a superlinear vesicular release component that is found in auditory hair cells of turtle, mouse, and rat (Schnee et al., 2011a,b), and which may be associated with a release of intracellular stored Ca, might underscore differences in functional requirements for vesicle recruitment mechanisms in zebrafish hair cells. Perhaps this difference relates to auditory versus vestibular hair cell properties, although calcium-induced calcium release has been observed in frog vestibular hair cells (Lelli et al., 2003); alternatively, the very small volume of zebrafish hair cells may not require elaborate vesicle recruitment mechanisms, or the small volume may make a kinetic separation between release components more difficult to observe. Finally, in contrast to observations in some other species (Schnee et al., 2005; Graydon et al., 2011), the substantial vesicle release arising from such small Ca currents may indicate efficient synaptic mechanisms. Of course, the preliminary data we report here require further investigation. Nevertheless, one of the main benefits of recordings in the zebrafish hair cell will be to capitalize on the wealth of tools and genetic manipulations available for the ribbon synapse (Nicolson, 2005; Francis et al., 2011) in a preparation that we now show to be readily accessible.

Aside from direct investigations on sensory hair cell mechanisms, the neuromast provides an opportunity to understand supporting cell roles in sensory transduction. In the organ of

Corti, electrical coupling has been proposed to sink K away from active hair cells, thereby preserving indefatigable hair cell function (Santos-Sacchi, 1985, 2000). Our observation of similar voltage-dependent gap junctional coupling in zebrafish neuro-masts indicates a corresponding role in this simple organ, with the preparation offering model benefits similar to those for hair cell study.

Cl⁻ flux through a non-selective, stretch-sensitive conductance influences the outer hair cell motor of the guinea-pig

Volodymyr Rybalchenko and Joseph Santos-Sacchi

Departments of Surgery (Otolaryngology) and Neurobiology, Yale University School of Medicine, 333 Cedar Street, New Haven, CT 06510, USA

Outer hair cells underlie high frequency cochlear amplification in mammals. Fast somatic motility can be driven by voltage-dependent conformational changes in the motor protein, prestin, which resides exclusively within lateral plasma membrane of the cell. Yet, how a voltage-driven motor could contribute to high frequency amplification, despite the low-pass membrane filter of the cell, remains an enigma. The recent identification of prestin's Cl⁻ sensitivity revealed an alternative mechanism in which intracellular Cl⁻ fluctuations near prestin could influence the motor. We report the existence of a stretch-sensitive conductance within the lateral membrane that passes anions and cations and is gated at acoustic rates. The resultant intracellular Cl⁻ oscillations near prestin may drive motor protein transitions, as evidenced by pronounced shifts in prestin's state-probability function along the voltage axis. The sensitivity of prestin's state probability to intracellular Cl⁻ levels betokens a more complicated role for Cl⁻ than a simple extrinsic voltage sensor. Instead, we suggest an allosteric modulation of prestin by Cl⁻ and other anions. Finally, we hypothesize that prestin sensitivity to anion flux through the mechanically activated lateral membrane can provide a driving force that circumvents the membrane's low-pass filter, thus permitting amplification at high acoustic frequencies.

The mammalian outer hair cell (OHC) evolved from more primitive hair cells, such as its counterpart, the inner hair cell (IHC), to enhance detection and discrimination of high frequency sounds (Dallos, 1992). A key evolutionary step appears to have been the recruitment of an anion transporter family member, prestin (Zheng *et al.* 2000), to transform the cell into an effector as well as sensor, capable of boosting passive basilar membrane motion (Liberman *et al.* 2002). Electrical stimulation evokes rapid length changes in OHCs (Brownell *et al.* 1985; Kachar *et al.* 1986), which possibly result from membrane surface area changes caused by conformational transitions in the integral membrane motor protein (Kalinec *et al.* 1992; Santos-Sacchi, 1993; Iwasa, 1994; Santos-Sacchi & Navarrete, 2002). The mechanism displays a sigmoidal voltage dependence (Ashmore, 1987; Santos-Sacchi & Dilger, 1988), resides exclusively in the OHC lateral plasma membrane (Dallos *et al.* 1991; Huang & Santos-Sacchi, 1993; Takahashi & Santos-Sacchi, 2001) and shows reciprocal sensitivity to membrane voltage and tension (Iwasa, 1993; Gale & Ashmore, 1994; Kakehata & Santos-Sacchi, 1995; Ludwig *et al.* 2001; Santos-Sacchi *et al.* 2001). The electrical signature of the motor protein is its displacement current, or an

equivalent bell-shaped, voltage-dependent capacitance owing to its voltage sensor's charge movement within and normal to the plane of the lateral plasma membrane (Ashmore, 1990; Santos-Sacchi, 1991*b*). The probability of the motor being in a contracted or expanded state (referred to as state probability hereafter) can be determined from capacitance *vs.* voltage (*C-V*) functions.

Initial work on electromotility indicated that it was driven by transmembrane potassium current (Ashmore, 1986; Ashmore & Meech, 1986). Subsequently, evidence accumulated showing that the phenomenon was voltage dependent (Santos-Sacchi & Dilger, 1988; Ashmore, 1989; Iwasa & Kachar, 1989; Santos-Sacchi, 1992). This observation coupled to the finding that the gain of the mechanical response is less than maximal near the OHC's normal resting potential, led to the realization that the resistance-capacitance (RC) membrane filter would seriously limit the driving force for electromotility at high frequencies (Santos-Sacchi, 1989, 1992). But, in fact, the high frequency region is where the cochlear amplifier is most effective (Ruggero & Rich, 1991). Thus, although the prestin-based motor mechanism can be driven by experimentally

applied voltage sources at very high frequencies (> 70 kHz (Frank *et al.* 1999)), the problem remains that receptor potentials in the OHC are attenuated at 6 db octave⁻¹ above the cell's RC cut-off frequency (Dallos & Santos-Sacchi, 1983). The recent discovery of the intracellular Cl⁻ sensitivity of prestin (Oliver *et al.* 2001) revealed a possible alternative mechanism where a hypothetical transmembrane Cl⁻ current could affect prestin activity. We report here the existence of an OHC conductance that is Cl⁻ permeable, and mechanically gated at high frequencies. Spatially co-located with prestin to the lateral plasma membrane, this conductance results in changes in intracellular Cl⁻ concentration near prestin that drive motor protein transitions and, consequently, OHC mechanical activity. Thus, we hypothesize that a mechanically gated ionic current, which is intrinsically unaffected by the membrane time constant τ , could provide the driving force for the cochlear amplifier.

METHODS

General

Guinea-pigs were killed with halothane inhalation overdose in accordance with an approved protocol from Yale University's animal use and care committee. OHCs were freshly isolated from the adult guinea-pig organ of Corti by sequential enzymatic (dispase 0.5 mg ml⁻¹) and mechanical treatment in Ca²⁺-free medium. Currents from voltage-clamped cells were recorded at room temperature using an Axon 200B amplifier, Digidata 1231A board (Axon Instruments, CA, USA) and the software program jCLAMP (Scisoft, CT, USA). The major intracellular and extracellular solutions are listed in Tables 1 and 2. At the ion concentrations listed, pH was 7.25–7.30; the osmolality was ~ 325 mosmol kg⁻¹ for extracellular solutions, and ~ 5 mosmol kg⁻¹ lower for intracellular solutions to prevent swelling.

In some cases we added CdSO₄ (1 mM) to block Ca²⁺ currents. When evaluating K⁺ ions, 4-aminopyridine (4-AP; 1 mM) and linopirdine (200 μ M) were used to block K⁺ channels. Solutions were delivered to individual cells by Y tube, during continuous whole-bath perfusion with Tris-Hepes solution. Series resistance (before correction off-line) was ~ 7 –20 M Ω in Tris-Hepes solution. A combined Ag–AgCl–KCl–K₂SO₄-agar ground electrode maintained liquid junction potentials in the range ± 1 –2 mV during solution exchanges. Up to 1% DMSO used in extracellular solutions for dissolution of tested pharmacological agents had no influence on the membrane resistance, capacitance or ionic currents. All chemicals were from Sigma (MO, USA) or Fluka (Switzerland). Data are presented as means \pm S.E.M.

Measurement of non-linear capacitance

Non-linear membrane capacitance was evaluated using a continuous high resolution (2.56 ms sampling) two-sine voltage stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz), with subsequent fast Fourier transform-based admittance analysis as fully described by Santos-Sacchi *et al.* (1998b). These high frequency sinusoids were superimposed on voltage ramps. Peak non-linear capacitance was determined by subtracting linear capacitance. C–V data were fitted with the first derivative of a two-state

Boltzmann function and a constant representing the linear capacitance (Santos-Sacchi, 1991b):

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}}, \quad (1)$$

and

$$b = \exp\left(\frac{-ze(V_m - V_{\text{pkcm}})}{kT}\right),$$

where Q_{\max} is the maximum non-linear charge moved, V_{pkcm} is voltage at peak capacitance or half-maximal non-linear charge transfer, V_m is membrane potential, C_{lin} is linear capacitance, z is apparent valence, e is electron charge, k is Boltzmann's constant and T is absolute temperature.

Mechanical stimulation of the lateral membrane

Three methods were used to mechanically stimulate the lateral membrane while recording whole-cell currents. In order to induce steady-state changes in membrane tension, positive or negative pressure into the cells was applied through the patch pipette and was monitored with an electronic pressure monitor. For step and low frequency stimulation, a piezoelectrically driven stiff glass probe was used to deform the cell near the mid region of the lateral membrane. The device was the same as that used previously to calibrate a photodiode displacement measurement technique (see Santos-Sacchi, 1992). The long axis of the probe was positioned parallel to the perfusion chamber bottom and normal to the longitudinal axis of the cell (see Fig. 11). OHCs were compressed statically and vertical DC or AC displacements of the probe (± 2 μ m) were superimposed. For high frequency stimulation, a closely positioned (15–20 μ m) piezoelectric-driven fluid-jet pipette (5–10 μ m tip diameter) was used as previously described (Takahashi & Santos-Sacchi, 2001). The pipette contained bath solution and was pointed perpendicular to the surface of the lateral membrane. The latter system is similar to that used previously (Brundin & Russell, 1994), although we used it simply to stimulate the lateral membrane and measure whole-cell currents. That is, we did not replicate their study. Care was taken to drive the piezoelectric only within its linear range, and use filters to limit driver resonances. Following dissociation of OHCs in Ca²⁺-free medium, stereocilia were either fully absent or very badly damaged; thus there was no contribution from stereocilia to the mechanically generated currents we observed.

RESULTS

Intracellular dialysis of Cl⁻-free solution shifts prestin's voltage dependence with little effect on motor charge movement

In order to study the effects of Cl⁻ removal on the OHC motor, we used intracellular solutions that were either Tris-sulfate or Tris-Hepes based (Tables 1 and 2), as these solutes are expected to be neutral with respect to prestin activity (Oliver *et al.* 2001). The OHC presents a bell-shaped C–V function whose voltage at peak capacitance (V_{pkcm}) is highly susceptible to intracellular Cl⁻ washout following the establishment of whole-cell configuration, shifting in the depolarizing direction (Fig. 1). The degree of voltage shift and modulation of peak non-linear capacitance depends upon the species of control anion.

Figure 1A and B shows that, in the presence of 140 mM extracellular Cl⁻, and after washout of intracellular Cl⁻ during whole-cell dialysis with Cl⁻-free patch pipette solutions, peak non-linear capacitance remained stable when the major intracellular anion was sulfate (steady state: 96.5 ± 5 % of initial value of 20.63 ± 1.12 pF; mean ± S.E.M.; n = 5). However, V_{pkcm} showed a very large positive shift from an initial value of -4.9 ± 2.7 to +97.4 ± 7.6 mV, reflecting a change in motor-state probability. On the other hand, washout with Tris-Hepes based, Cl⁻-free intracellular solutions decreased peak C_m to 75.3 ± 3.7 % at steady state (initial value: 19.53 ± 2.64 pF; n = 4), with a smaller V_{pkcm} shift from -24.4 ± 0.6 to +8.2 ± 3.5 mV.

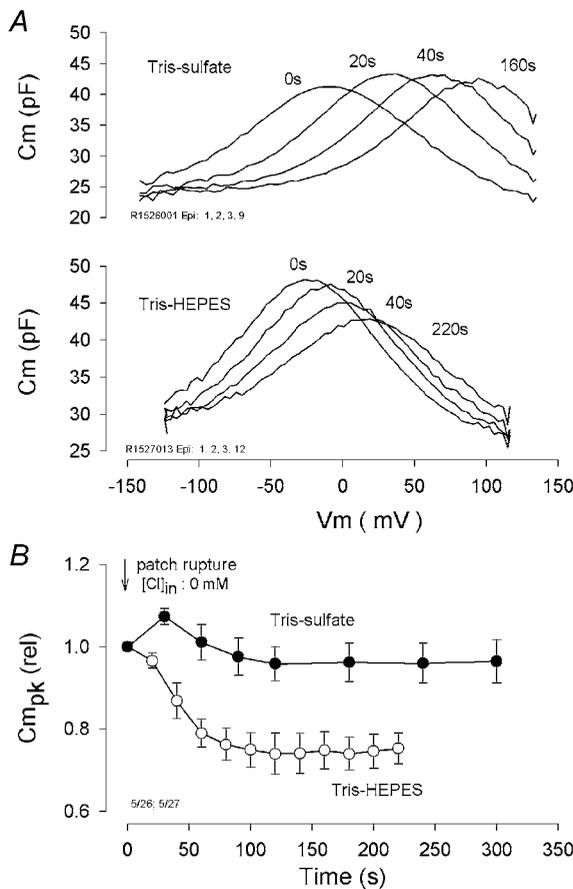

Figure 1. Effects of intracellular Cl⁻ on prestin-generated non-linear capacitance in outer hair cells (OHCs)

A, top, C-V functions of an OHC during washout of Cl⁻ with Tris-sulfate patch-pipette solution, in the presence of 140 mM Tris-Cl extracellular solution. Bottom, same as above except with Tris-Hepes pipette solution. B, relative peak non-linear capacitance (C_{mpk} (rel)) as a function of time after patch rupture with either Tris-sulfate (n = 4; mean ± S.E.M.) or Tris-Hepes (n = 5) Cl⁻-free intracellular solutions and Tris-Cl 140 mM (140 Cl) extracellular solution. Recordings began at the moment of patch rupture at a holding potential of 0 mV. Data were obtained from full C-V functions, and peak non-linear membrane capacitance C_m was obtained by subtracting linear capacitance determined by fits (see Methods) to the data. [Cl]_{in}, intracellular Cl⁻ concentration.

Since peak non-linear capacitance (C_{mpk} = Q_{max}ze/4kT) depends on slope (z) and Q_{max} of the charge-voltage (Q-V) relationship, the parameters describing the motor's charge movement were obtained by fitting (see Methods) OHC non-linear capacitance with the first derivative of a two-state Boltzmann function (Fig. 2). In addition to the large shifts in the operating voltage range, both the voltage sensitivity (z) and the maximum charge moved (Q_{max}) of the motor were affected by intracellular Cl⁻ removal; however, even in the steady state presence of Cl⁻-free intracellular solutions, Q_{max} remained greater than 80 % of initial values. Following the removal of extracellular Cl⁻, Q_{max} remained robust, but its magnitude, as well as that of z, depended on the species of intracellular anion (SO₄²⁻ vs. Hepes; see Fig. 2). In order to assure ourselves that sub-membranous, intracellular Cl⁻ and other active anions, e.g. bicarbonate (Oliver *et al.* 2001), were depleted, we pretreated cells in a continuous wash of Tris-Hepes Cl⁻-free extracellular solutions for over 4 h prior to recording with Cl⁻-free patch-pipette solutions, a procedure that has been shown to rapidly deplete intracellular stores of Cl⁻ (Aickin & Brading, 1984; Thoreson *et al.* 2000). Even under these conditions, non-linear charge movement remained considerable (Tris-sulfate intracellular: Q_{max}, 0.99 ± 0.27 pC; z, 0.62 ± 0.07; V_{pkcm}, 141 ± 9 mV; C_{lin}, 22.9 ± 1.7 pF; n = 5; Tris-Hepes intracellular: Q_{max}, 1.45 ± 0.19 pC; z, 0.66 ± 0.02; V_{pkcm}, 57 ± 4 mV; C_{lin}, 24.6 ± 2.0 pF; n = 5).

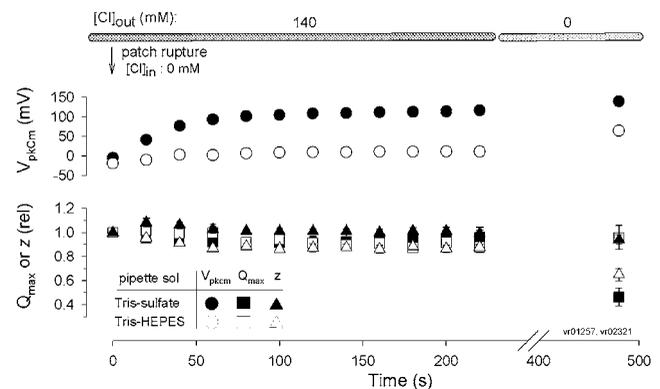

Figure 2. Boltzmann parameters of motor charge movement determined from capacitance functions during washout of intracellular Cl⁻

Horizontal bar at top represents extracellular Cl⁻ concentrations ([Cl]_{out}) during whole-cell recording. Pipette contained either Tris-sulfate or Tris-Hepes solutions (n = 5 for each condition; mean ± S.E.M.). The dominant effect of Cl⁻ washout is a shift in V_{pkcm}, with small changes in Q_{max} and z. Error bars are within symbol dimensions for most data points. After removal of extracellular Cl⁻, steady-state levels of parameters show changes that depend upon species of the intracellular substitute anion. Recordings began at the moment of patch rupture at a holding potential of 0 mV.

Our results differ from those of Oliver *et al.* (2001) since they found that non-linear capacitance was not affected by extracellular Cl^- manipulations and was abolished when intracellular Cl^- was removed. Figure 3A shows the relationship between extracellular Cl^- concentration and the magnitude of non-linear capacitance in OHCs. In this case, the extracellular Cl^- manipulations were made after the cells were allowed to equilibrate (> 5 min) with intracellular Tris-sulfate Cl^- -free solutions. For comparison, Fig. 3A also shows the relationship between intracellular Cl^- concentration and Q_{max} (derived from non-linear capacitance) determined by Oliver *et al.* (2001). At concentrations above 5 mM, manipulation of Cl^- concentration on the extracellular aspect of the OHC membrane mirrored the effects obtained by Oliver *et al.* (2001) that relate to manipulation of intracellular Cl^- ; however, we were unable to extinguish non-linear capacitance after total removal of extracellular (and intracellular) Cl^- . Another major difference between our results

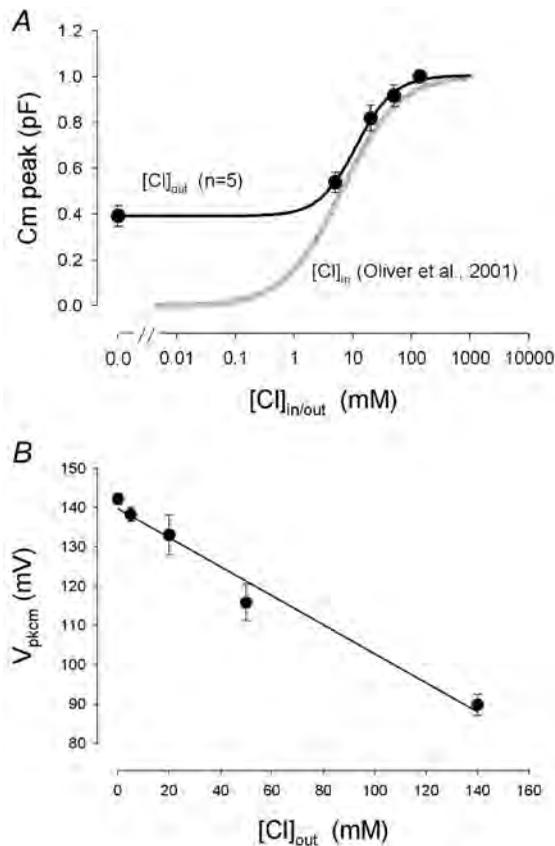

Figure 3. Dependence of peak C_m and V_{pkcm} on extracellular Cl^- concentration

A, continuous line is sigmoidal fit to data points (mean \pm S.E.M.; $n = 5$). Intracellular solution was Tris-sulfate (Table 1) and initial extracellular solution was 140 Cl (Table 2). Extracellular Cl^- ($[\text{Cl}]_{\text{out}}$) reductions were made by replacement with Hepes. For comparison, we show relative Q_{max} (determined from capacitance measures) vs. intracellular Cl^- ($[\text{Cl}]_{\text{in}}$) concentration published by Oliver *et al.* (2001). B, same procedures as above. Line is linear regression ($r^2 = 0.98$) with a slope of 0.37 mV mM^{-1} .

and theirs is our finding that very large shifts in V_{pkcm} occur not only as a function of intracellular- (see above) but also extracellular- Cl^- concentration (Fig. 3B). An increase in Cl^- concentration shifted V_{pkcm} to more negative potentials. The linear regression in Fig. 3B indicates a shift in V_{pkcm} of 0.37 mV mM^{-1} of extracellular Cl^- when Tris-sulfate Cl^- -free intracellular solutions were used. In the presence of Tris-Hepes intracellular solutions, the shift was about 0.1 mV mM^{-1} . Thus, the magnitude of the shift was dependent upon the identity of the intracellular anion.

In order to determine if differences in intracellular control solutions were responsible for some of the discrepancies between our results and those of Oliver *et al.* (2001), we tested their major control anion, pentane sulfonate, and found that intracellular dialysis of such Cl^- -free preparations (Table 1) had several atypical effects on OHC motor charge movement, compared with our other control anions. First, the initial peak C_m value ($11.5 \pm 1.1 \text{ pF}$; $n = 4$; collected within a few seconds after patch rupture) was about half that obtained with Tris-Hepes or Tris-sulfate solutions, indicating that the reduction following patch rupture was more rapid than the typical time course of ion washout (Pusch & Neher, 1988); the block is too fast to result from Cl^- removal during patch-pipette solution exchange. It is, however, typical of intracellular application of high affinity motor blockers, such as the charged form of salicylate, which blocks non-linear capacitance within seconds of patch rupture (Kakehata & Santos-Sacchi, 1996). As with salicylate, we still observed significant, though reduced, electromotility in all OHCs studied with

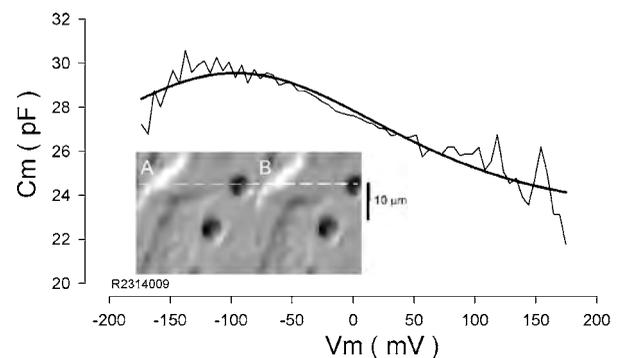

Figure 4. OHC non-linear capacitance and mechanical response with sodium pentane sulfonate patch-pipette solutions

In the presence of 140 Cl extracellular solution, and after steady-state intracellular perfusion of Cl^- -free pentane sulfonate solution, non-linear capacitance remains significant, and mechanical responses during voltage stimulation are prominent. Smooth line is fit to eqn (1) (V_{pkcm} , -96 mV ; z , 0.31; Q_{max} , 2.1 pC and C_{lin} , 23.2 pF, respectively). Inset: image of OHC at negative (A) and positive (B) extremes of voltage ramp. Note displacement of cuticular plate.

Table 1. Intracellular solutions

Solution name	Hepes (mM)	Tris ₂ SO ₄ (mM)	Sodium pentane sulfonate (mM)	MgSO ₄ (mM)	EGTA (mM)	Tris(OH) (mM), approx
Tris-Hepes	190	—	—	2	10	120
Tris-sulfate	10	110	—	2	10	35
Sodium pentane sulfonate	10	—	140	2	10	30

Cl⁻-free, pentane sulfonate solutions ($n = 5$; Fig. 4). At steady state (>3 min), intracellular pentane sulfonate solutions decreased peak C_m to $78.1 \pm 8.8\%$ of the initial value. Second, unlike the results with Hepes⁻ or SO₄²⁻ intracellular anions, the subsequent removal of extracellular Cl⁻ had no effect on the substantial remaining non-linear capacitance ($78.5 \pm 4.6\%$ of initial value). Last, shifts in V_{pkcm} were in the hyperpolarizing direction during washout, as opposed to the other control anion solutions we used. Boltzmann fits of these data showed that voltage sensitivity (z) was substantially reduced, while total charge moved was minimally affected (sodium pentane sulfonate intracellular; Cl⁻-free Tris-Hepes extracellular: Q_{max} , 1.71 ± 0.20 pC; z , 0.33 ± 0.02 ; V_{pkcm} , -99 ± 12 mV; C_{lin} , 21.9 ± 0.7 pF; $n = 5$). These data clearly show that the effect of pentane sulfonate is not due to manipulation of intracellular Cl⁻, but instead results from its direct action on the OHC motor.

Cl⁻ flux through a lateral membrane conductance influences prestin activity

Our data may indicate that in native, intact OHCs, extracellular Cl⁻ can influence the lateral membrane motor. Alternatively, Cl⁻ ions might be entering the OHC to work on the inner aspect of the lateral membrane. We evaluated this possibility by monitoring OHC currents and capacitance during whole-cell recording with Cl⁻-free intracellular solutions while manipulating extracellular Cl⁻ concentrations. Figure 5 shows results for a typical OHC held at 0 mV. As noted above, intracellular washout with Tris-Hepes solution causes an initial decrease in peak C_m , and a positive shift in V_{pkcm} , demonstrating the dependence of motor charge transfer on intracellular Cl⁻. Subsequently, in the face of continuous intracellular washout, the removal of extracellular Cl⁻ betrayed an outward current (Cl⁻ influx) that sustained a substantial component of non-linear capacitance; in the absence of current, owing to the removal of extracellular Cl⁻, capacitance again fell and V_{pkcm} shifted as intracellular Cl⁻ levels dropped. Steady-state levels were reached within minutes, which is typical for washout times under whole-cell voltage clamp (Pusch & Neher, 1988). Replenishment of extracellular Cl⁻ restored the Cl⁻ influx, thereby increasing the non-linear capacitance of the cell and shifting V_{pkcm} back to hyperpolarized levels. These effects were

repeatable. These experiments demonstrate that in the absence of Cl⁻ in the patch pipette, the source of intracellular Cl⁻ that modulates prestin derives from the extracellular solution.

In order to localize the Cl⁻ conductance, we directly mapped the increase in non-linear capacitance and Cl⁻ current as a restricted source of Cl⁻ roved along the length of OHCs whose intracellular Cl⁻ was depleted (Fig. 6). The largest responses were obtained along the lateral region of the OHC, in the same region where prestin is localised (Belyantseva *et al.* 2000a), and the reciprocal electro-mechanical sensitivity of the motor is found (Takahashi & Santos-Sacchi, 2001). Further confirmation of this conductance site is provided by reversal potential measurements during application of extracellular Cl⁻ solutions (see supporting data below). The site of this Cl⁻ conductance is ideally poised to affect the activity of prestin rapidly.

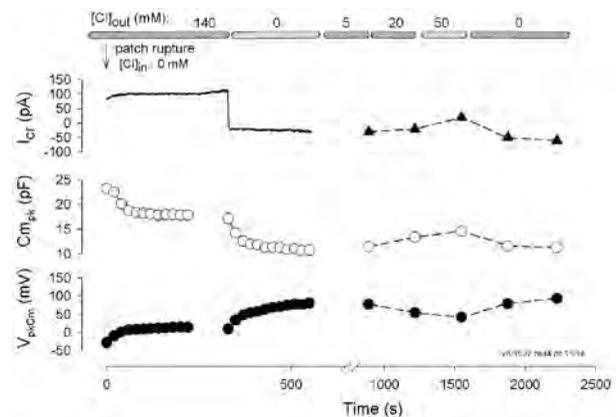

Figure 5. Correspondence among Cl⁻ current, peak non-linear C_m and V_{pkcm}

Horizontal bars at top represent extracellular Cl⁻ concentrations ($[Cl]_{out}$) during whole-cell recording. Recordings began at the moment of patch rupture with Tris-Hepes Cl⁻-free pipette solution at a holding potential of 0 mV. Despite a large sustained inward Cl⁻ flux (outward current; I_{Cl} , top), non-linear C_{mpk} decreases (middle), and V_{pkcm} shifts to depolarized levels (bottom) during Cl⁻ washout through the patch pipette. Subsequent removal of extracellular Cl⁻ shifts C_{mpk} and V_{pkcm} values further, showing their dependence on Cl⁻ influx into the cell. The treatments are reversible and responses are graded with magnitude of Cl⁻ current. ($[Cl]_{in}$, intracellular $[Cl^-]$).

Table 2. Extracellular solutions

Solution name	Hepes (mM)	HCl (mM)	NaOH (mM)	KOH (mM)	Tris(OH) (mM), approx	MgSO ₄ (mM)	CaSO ₄ (mM)
Tris-Hepes	210	—	—	—	110	5	0.2
140 Cl	10	140	—	—	155	5	0.2
80 Cl	108	80	—	—	30	5	0.2
80 Na	220	—	80	—	—	5	0.2
80 K	220	—	—	80	—	5	0.2

Cl⁻ channels do not underlie the lateral membrane conductance

Guinea-pig OHCs typically have a relatively low membrane resistance (< 300 MΩ) even in the presence of K⁺ and Ca²⁺ channel blockers (Santos-Sacchi, 1991b; Santos-Sacchi & Navarrete, 2002). However, when OHCs were perfused with solutions containing mainly large, poorly permeable ions (Tris-Hepes, see Tables 1 and 2), input resistances ranged from 1–3 GΩ. Under these conditions, with approximately equal amounts of Tris⁺ and Hepes⁻ as major charge carriers intra- and extracellularly, whole-cell steady-state currents revealed non-linear current-to-voltage characteristics (*I*-*V*s) reversing near 0 mV ($V_{rev,TH} = +1 \pm 1$ mV, range: -3 to +6 mV, $n = 20$); moderate inward and outward rectification was evident at hyperpolarizing and depolarizing potentials (Fig. 7Aa,b and B). The activation phase of currents at any voltage was faster than our clamp-time constant, typically less than 1 ms. These control currents were not influenced by the stereocilia transducer channel blocker streptomycin (500 μM) and were not due to an imperfect seal between patch pipette and OHC membrane, since their *I*-*V*s showed clearly reproducible non-linear, sigmoidal shapes. Preconditioning hyper-

polarizing steps did not influence the current at +60 mV (Fig. 7Aa and B). Additionally, a pre-depolarizing step to +60 mV did not influence the subsequently evoked currents at a variety of membrane potentials (Fig. 7 Ab and B), indicating that no slow-type inactivation of these currents (5 ms < τ < ~100 ms) exists at any physiological membrane potential.

To study the Cl⁻ permeability of the conductance responsible for the sigmoidal currents observed in Tris-Hepes solutions, we substituted the bulk of extracellular Hepes with 140 mM TrisCl. This substitution significantly and reversibly increased both inward and outward currents, whose kinetics, absence of slow gating and sigmoidal shape of *I*-*V*s were the same as for Tris-Hepes currents (Fig. 7Ac,d and B). The reversal potentials in 140 mM TrisCl extracellular solution ($V_{rev,140Cl}$) were smaller in magnitude than expected, but appropriate in polarity ($V_{rev,140Cl} = -12 \pm 2$ mV, range: -33 to -1 mV; $n = 20$). This deviation presumably derives from rapid equilibration of ions into the restricted space (~33 nm) between the lateral plasma membrane and subsurface cisternae (Pollice & Brownell, 1993). It is well known that such ion accumulation under whole-cell voltage clamp can affect reversal potentials and provide apparent changes in ion selectivity (Frazier *et al.* 2000). Accordingly, then, Cl⁻ applied extracellularly was the major carrier for outward currents (Cl⁻ influx), and its intracellular accumulation provided for the inward current component (Cl⁻ efflux).

In addition to Cl⁻, we tested whether the major monovalent cations, K⁺ and Na⁺, could carry measurable currents through this lateral membrane conductance. In the same cells, 80 mM K⁺, Na⁺ and Cl⁻ were sequentially substituted in the external solution for the equivalent amount of poorly permeable ions (K⁺ and Na⁺ for Tris⁺, Cl⁻ for Hepes⁻). In these experiments, 1 mM 4AP and 200 μM linopirdine were added to all solutions to block voltage-dependent potassium channels described earlier in OHCs (Santos-Sacchi & Dilger, 1988; Marcotti & Kros, 1999). All three substitutions increased both inward and outward components of the currents above controls (Fig. 7C). In fact, the resulting currents showed kinetics and rectification resembling those observed in reference Tris-Hepes solutions (Fig. 7C and E).

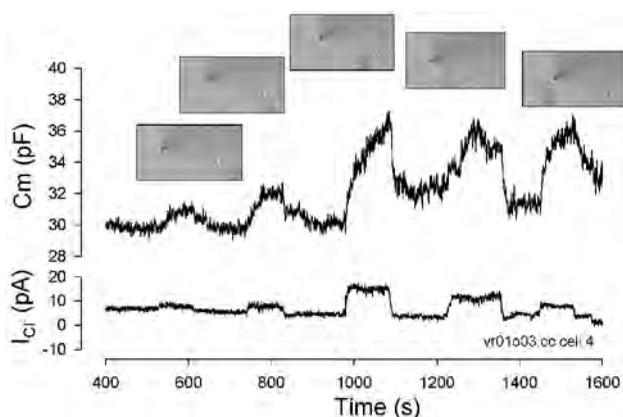

Figure 6. Localization of the Cl⁻ conductance to the lateral membrane

A 1 M Cl⁻ point-diffusion source (high impedance pipette), briefly positioned close to different OHC regions (image insets), revealed a maximum increase in *I*_{Cl} and *C*_m in the mid region of the cell. After each placement, the pipette was moved away from the cell and is indicated as a return of current and capacitance to near baseline.

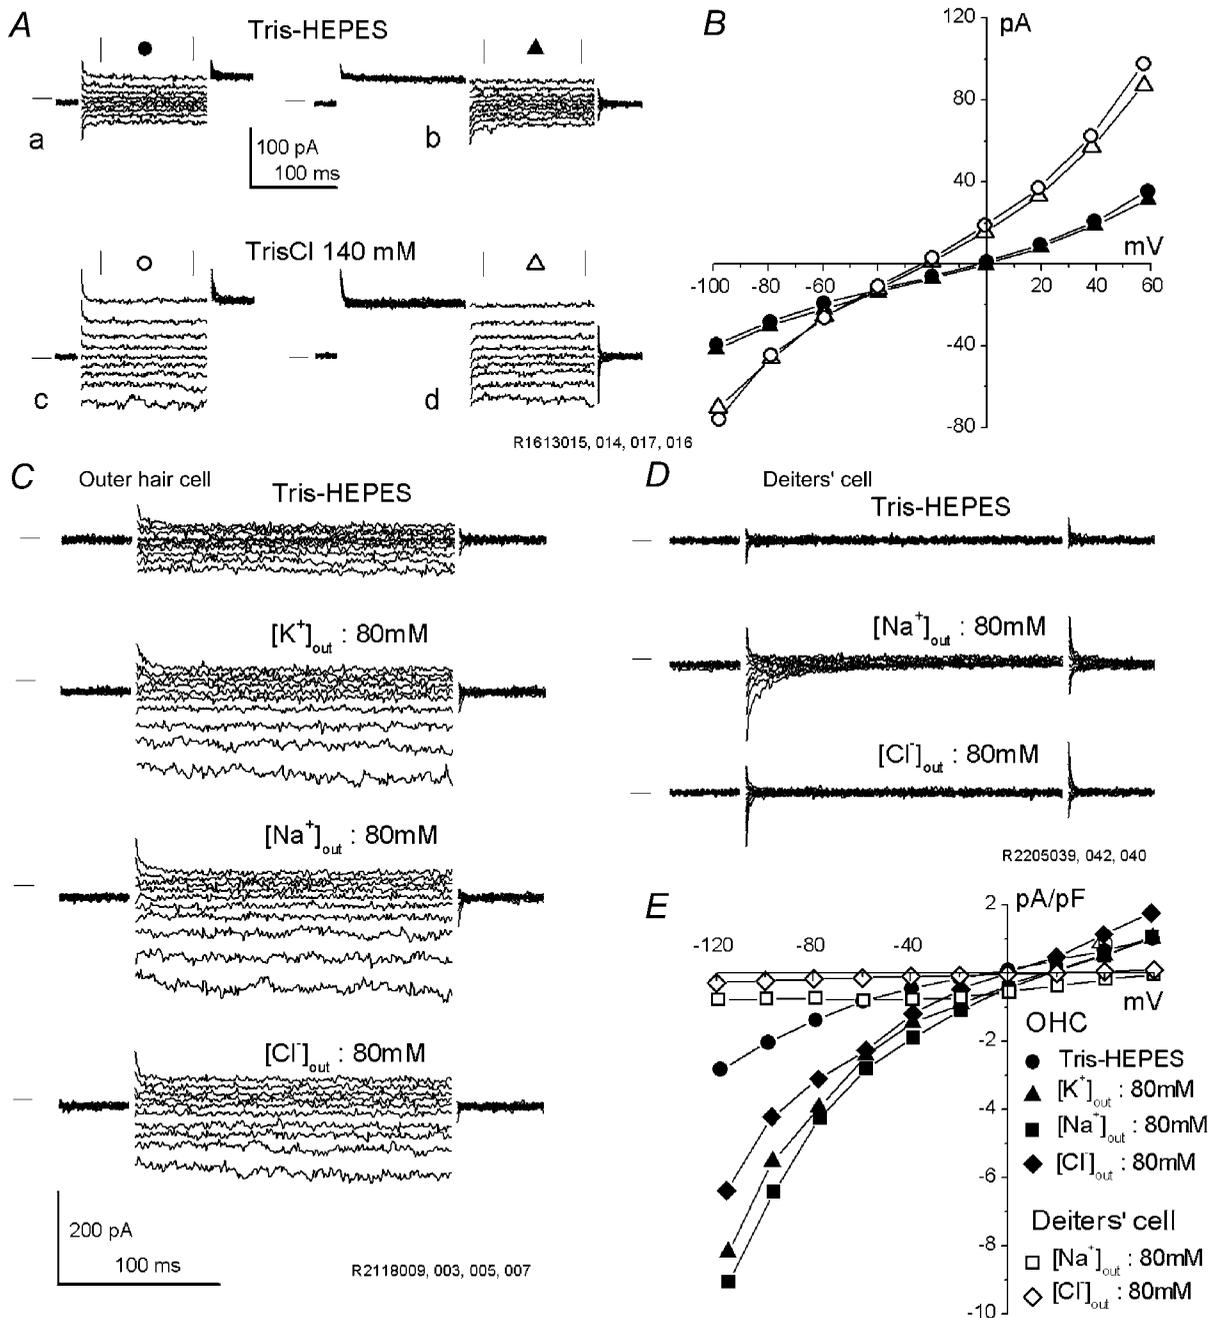

Figure 7. OHCs possess a voltage-dependent, cation-anion non-selective conductance

All recordings were made with Tris-Hepes intracellular solution (Table 1). *A*, currents recorded in the same OHC subjected to voltage pre-conditioning step protocol (*a,c*: holding potential, $V_{\text{hold}} = -20$ mV, 150 ms conditioning steps from -100 to $+60$ mV ($\Delta V = 20$ mV), 150 ms test step to $+60$ mV) and pre-depolarizing step protocol (*b,d*: $V_{\text{hold}} = -20$ mV, 150 ms conditioning step to $+60$ mV, 150 ms test steps from -100 to $+60$ mV ($\Delta V = 20$ mV)) in Tris-Hepes reference extracellular solution (*a,b*) or 140 mM TrisCl-based (140 Cl) extracellular solution (*c,d*). Horizontal lines at left of traces indicate zero-current level. *B*, series-resistance corrected I - V curves from currents in *A*, trace averaged between vertical marks. *C*, OHC currents recorded in (top to bottom) Tris-Hepes, 80 K, 80 Na and 80 Cl extracellular solutions (Table 2) in the presence of 1 mM 4AP + 200 μ M linopirdine, evoked by voltage steps from $+60$ to -120 mV ($\Delta V = -20$ mV) from $V_{\text{hold}} = -20$ mV. Records are from the same OHC. *D*, Deiters' cell currents recorded in (top to bottom) Tris-Hepes, 80 Na and 80 Cl extracellular solutions, evoked by the same voltage protocol as in *C*. Scale is same as in *C*. *E*, relative currents for OHC and Deiters' cell from *C* and *D* above, normalized by their membrane capacitance (24.7 pF linear capacitance for OHC and 21.8 pF linear capacitance for Deiters' cell).

In order to study further the accumulation of ions into the restricted sub-plasmalemmal space, we compared the reversal potentials of currents obtained in 80 mM $[\text{Na}^+]_{\text{out}}$ and 80 mM $[\text{Cl}^-]_{\text{out}}$ -containing extracellular solutions and found that although they were appropriate in polarity, they were smaller in magnitude than expected ($V_{\text{rev},80\text{Na}} = +29 \pm 2$ mV, range: 17 to 39 mV, $n = 12$; $V_{\text{rev},80\text{Cl}} = -16 \pm 3$ mV, range: -33 to $+3$ mV, $n = 14$). These results clearly indicate that both extracellular cations and anions can accumulate in the sub-plasmalemmal space of the OHC at our holding potential of 0 mV. For Cl^- , the Nernst equation shows that an intracellular concentration of ~ 40 mM was achieved at steady state with 80 mM Cl^- extracellularly. The same calculations for Na^+ show an intracellular concentration of ~ 30 mM. No indication of a similar

conductance was found under the same experimental conditions in isolated supporting Deiters' cells, which lack prestin but have approximately the same size and passive membrane capacitance as OHCs (Fig. 7D and E). Normalized conductance of Deiters' cells in Tris-Hepes and 80 mM $[\text{Cl}^-]_{\text{out}}$ (80 Cl) extracellular solutions was ($n = 5$) 1.0 ± 0.05 and 2.28 ± 0.73 pS pF^{-1} , respectively. For comparison, OHC conductance was 15.6 ± 5.5 and 56.6 ± 18.9 pS pF^{-1} , respectively.

We found that steady-state Cl^- current levels remain stable for several seconds at membrane potentials from -80 to $+40$ mV (Fig. 8A). However, during prolonged hyperpolarizations more negative to -100 mV, a slowly developing increase in current was often observed. Because such behaviour might be characteristic of ClC-2 chloride channels,

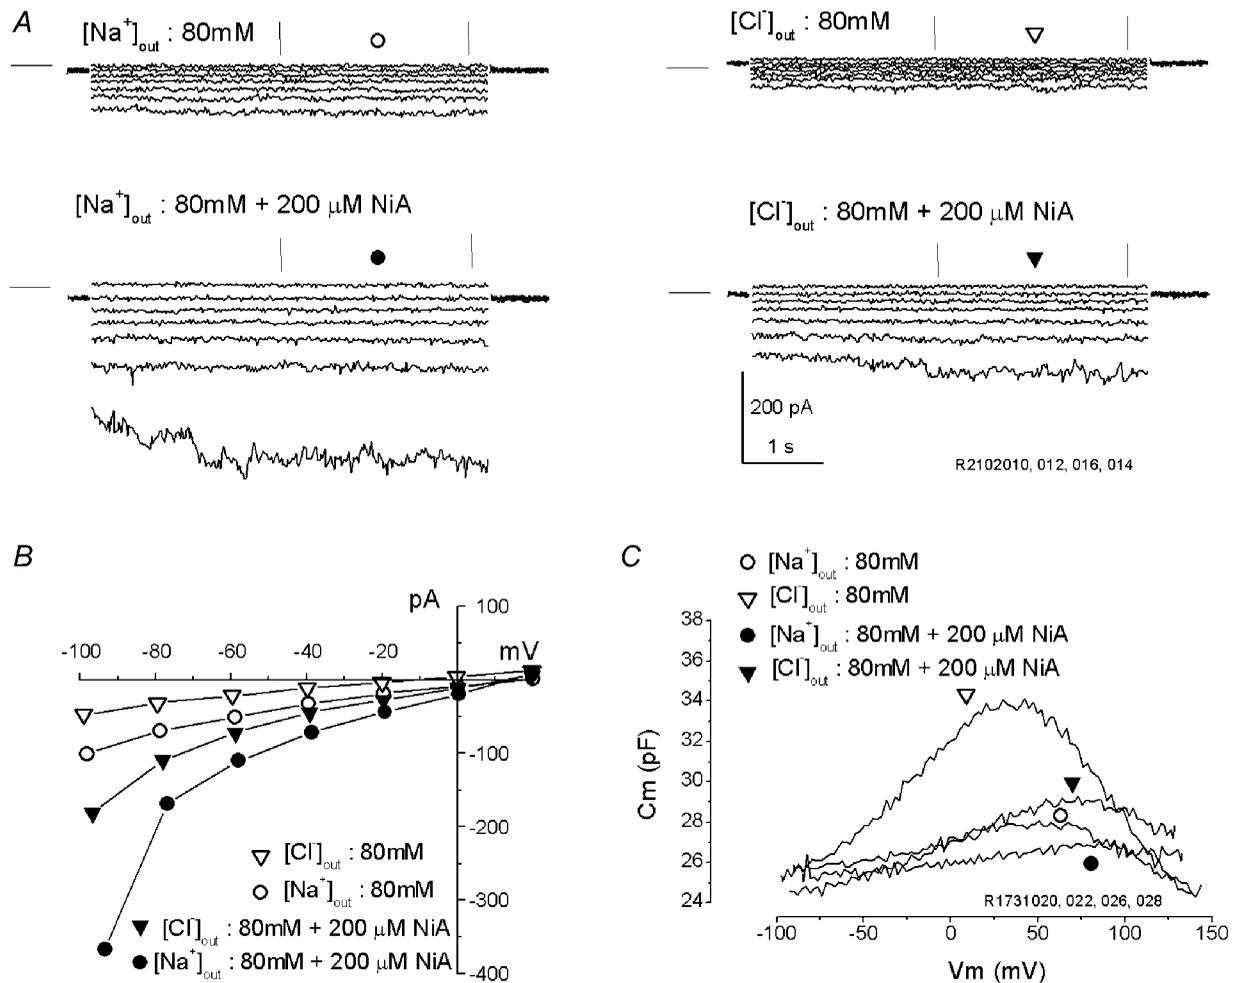

Figure 8. Cl^- channel blockers increase the lateral membrane conductance but block non-linear capacitance

A, currents were evoked by prolonged (5 s) pulses from $+20$ to -100 mV (step = -20 mV) from $V_{\text{hold}} = 0$ mV. Data were collected from the same OHC in 80 Na (left) or 80 Cl (right) extracellular solutions (Table 2), in the absence (top) or in the presence (bottom) of $200 \mu\text{M}$ niflumic acid (NiA). Horizontal lines at left of traces indicate zero-current level. Note the identical kinetics, voltage dependence and increase by NiA for Na^+ and Cl^- currents. B, $I-V$ plots obtained from trace averages (between vertical marks) in A above. C, C_m-V functions obtained from another OHC after treatments as in A above. Note potent block of niflumic acid of prestin-related non-linear capacitance, despite enhanced inward-outward Cl^- currents.

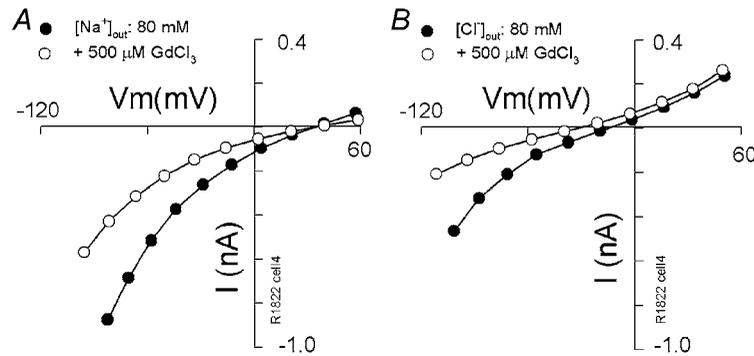

Figure 9. Partial block of the lateral membrane conductance by gadolinium

OHC I - V plots with extracellular solutions 80 Na (A) or 80 Cl (B) without (●) and with (○) the stretch-channel blocker gadolinium (500 μ M) obtained in the same cell.

we compared the currents at long hyperpolarizing potentials in 80 mM $[\text{Na}^+]_{\text{out}}$ and 80 mM $[\text{Cl}^-]_{\text{out}}$ extracellular solutions. Cl^- channels are not expected to pass cations. In either solution the slowly developing component was observed. Additionally, well-known Cl^- channel blockers (niflumic acid 200–400 μ M, DIDS 0.5–2.5 mM, furosemide 200 μ M, NPPB 10–500 μ M, 9-AC 1–2 mM; (Jentsch *et al.* 2002)) did not decrease the currents. Instead, Cl^- and Na^+ currents, including the slow component, were reversibly increased. For example, niflumic acid at 200 μ M increased the Cl^- current by a factor of 3.4 at -75 mV, while the Na^+ current was increased by a factor of 2.2 ($n = 3$). Figure 8B and C illustrates the effect of niflumic acid (200 μ M) on currents and capacitance. While currents were increased, non-

linear capacitance was reduced; in fact, niflumic acid was a potent blocker of non-linear capacitance, working in the micromolar range. Additionally, a slowly developing outward component, never observed in CIC-type channels, could also be observed at large depolarizing potentials (more positive to $+60$ mV), but could not be studied in detail because of irreversible damage to the OHC at prolonged depolarizations. Taken together, these observations clearly indicate that CIC channels, whose messenger RNA is found in OHCs (Kawasaki *et al.* 1999), or other clearly characterized types of Cl^- pathways (cystic fibrosis transmembrane conductance regulator (CFTR), transporters), do not underlie the non-selective conductance of the lateral membrane.

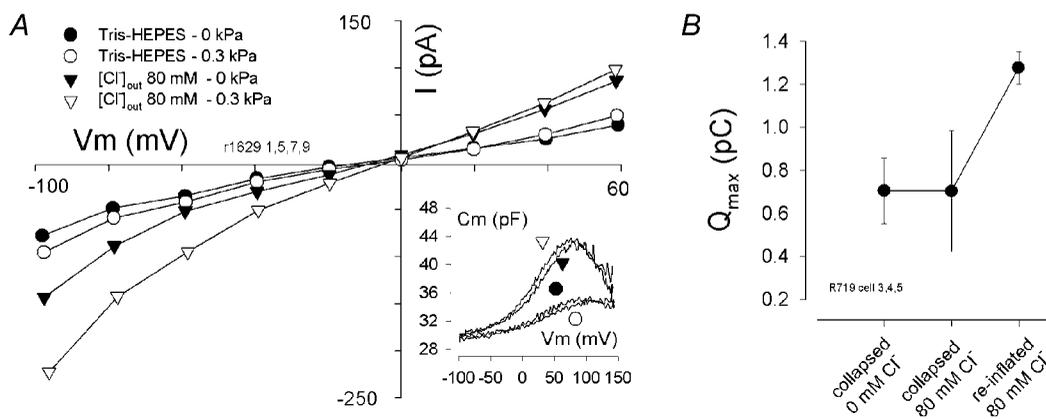

Figure 10. Membrane tension dependence of the Cl^- current

A, sigmoidal I - V curves were derived from trace-averaged currents recorded with Cl^- -free Tris-Hepes patch pipette in the presence of Tris-Hepes (circles) and 80 Cl (triangles) extracellular solutions before (filled symbols) and after (open symbols) turgor pressure increases in the initially cylindrical OHC ($V_{\text{hold}} = 0$ mV, step from $+60$ to -100 mV). Currents are substantially increased and pressure sensitive in Cl^- -containing solution. Inset: C - V functions, corresponding to the treatments in A, reflect a significant increase in membrane displacement charge and are shifted in the hyperpolarizing direction in Cl^- -containing solution. The additional charge increase and C_m shift in the pressurized state (∇) is due to increased Cl^- flux, because in Cl^- -free solutions (\circ), as well as in Cl^- -saturated solutions (Kakehata & Santos-Sacchi, 1995), the C_m functions are shifted to depolarizing potentials with positive pressure. B, non-linear charge (Q_{max}), determined from C - V function fits ($n = 3$) does not increase in initially collapsed cells in Cl^- -containing extracellular solution (140 Cl) until Cl^- flux is restored by cell re-inflation.

The lateral membrane current is partly reduced by blockers of stretch-activated conductances

Thus far we have ruled out the contribution of Cl^- and stereocilia transducer channels to the conductance we observe. In addition, we have evaluated other blockers of channels that conceivably could support components of the lateral membrane current. Blockers of aquaporin (HgCl_2 0.4–2 mM; (Belyantseva *et al.* 2000b)), gap junction hemichannels (carbenoxolone 200 μM , octanol 2 mM; (Santos-Sacchi, 1991a; Draguhn *et al.* 1998)) and cation-selective vanilloid receptor channels (Ruthenium Red; (Gunthorpe *et al.* 2002)) were without success. Additionally, the absence or presence of intra/extracellular Ca^{2+} , or the presence of intracellular ATP and GTP did not affect the currents.

Finally, we evaluated agents known to block swelling-activated conductances. Stretch-activated channels have been found in the lateral membrane of OHCs; however, they are selective for cations (Ding *et al.* 1991; Iwasa *et al.* 1991). Several blockers were partly effective. Gadolinium (Gd^{3+} ; 500 μM , $n = 5$; Fig. 9), tamoxifen (50 μM , $n = 4$ –7) and quinine (1 mM, $n = 4$) were from 10 to 40% effective at -60 mV in blocking Na^+ (relative I , Gd^{3+} : 0.59 ± 0.07 , quinine: 0.74 ± 0.05 , tamoxifen: 0.77 ± 0.04) and Cl^- currents (Gd^{3+} : 0.72 ± 0.2 , quinine: 0.76 ± 0.16 , tamoxifen:

0.91 ± 0.16). Whereas Gd^{3+} effectively blocked OHC capacitance and motility, even in the presence of high Cl^- levels (Santos-Sacchi, 1991b), tamoxifen and quinine did not. These blockers are non-specific, inasmuch as they have been shown to block a variety of anionic and cationic channels, some involved in cell swelling (Yang & Sachs, 1989; Allen *et al.* 1998; Welsh *et al.* 2000). Interestingly, tamoxifen and quinine are known to block swelling of OHCs in cochlear explants (Siegel *et al.* 2001), and Gd^{3+} interferes with volume regulation in isolated OHCs (Crist *et al.* 1993).

One other agent, poly-lysine (4 μM , molecular weight 70 000–150 000), which has been shown to block stretch-induced mechanical responses in OHCs (Brundin *et al.* 1989), had a small blocking effect on both Na^+ (relative I : 0.90 ± 0.2 ; $n = 3$) and Cl^- (relative I : 0.84 ± 0.13 ; $n = 3$) currents at -60 mV. Poly-lysine, which might be considered a potent charge-screening agent, had virtually no effect on the reversal potentials of the currents.

The Cl^- conductance is stretch sensitive and gated at acoustic rates

Since the lateral membrane ionic current was susceptible to stretch-activated channel blockers, we evaluated its response to membrane stress with a variety of means

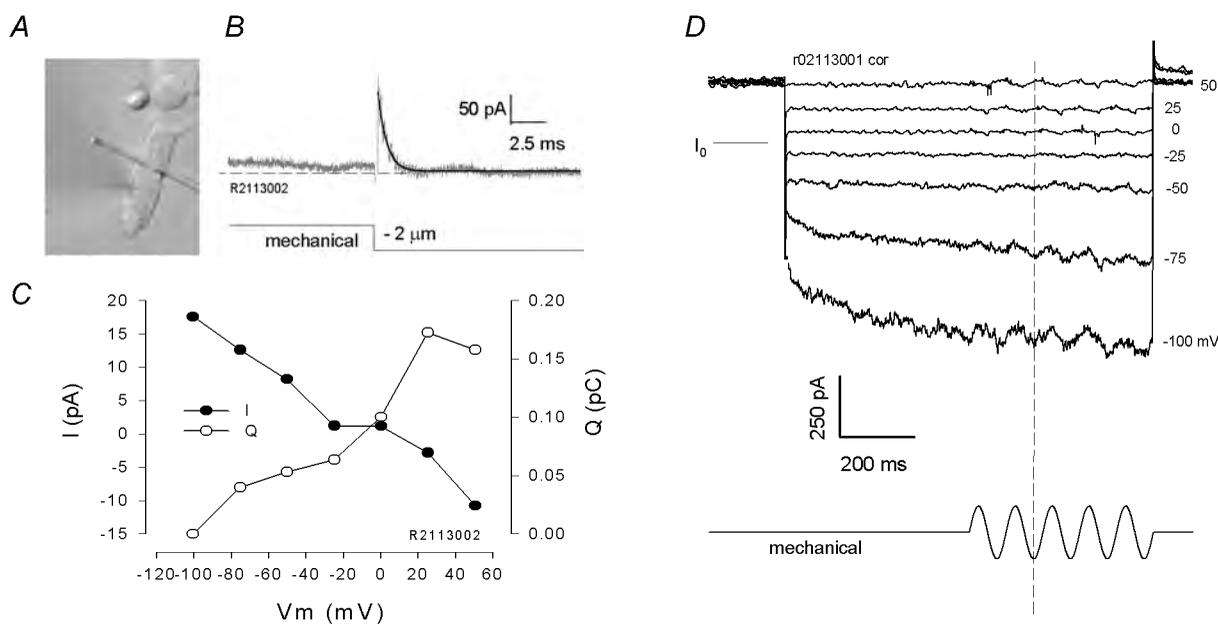

Figure 11. Whole-cell current responses evoked by stiff probe deformations of the lateral membrane

A, digitized image of OHC under whole-cell voltage clamp with stiff probe placed across the middle of the cell. B, step mechanical deformation of the lateral membrane evokes a transient gating current and a DC ionic current at the fixed potential of 50 mV. C, relationship of motor gating charge (integrated transient current, Q) and ionic current magnitude (I , difference between steady-state levels before and after membrane stress) with membrane voltage. Motor charge peaks at V_{pkcm} , whereas I reverses at the potential (-10.5 mV) where total current reverses. D, sinusoidal mechanical stimulation at various potentials produces a corresponding current whose phase reverses at the cell's steady ionic current reversal potential. Extracellular solution was 140 Cl and intracellular was Tris-Hepes + 1 mM Tris- Cl^- .

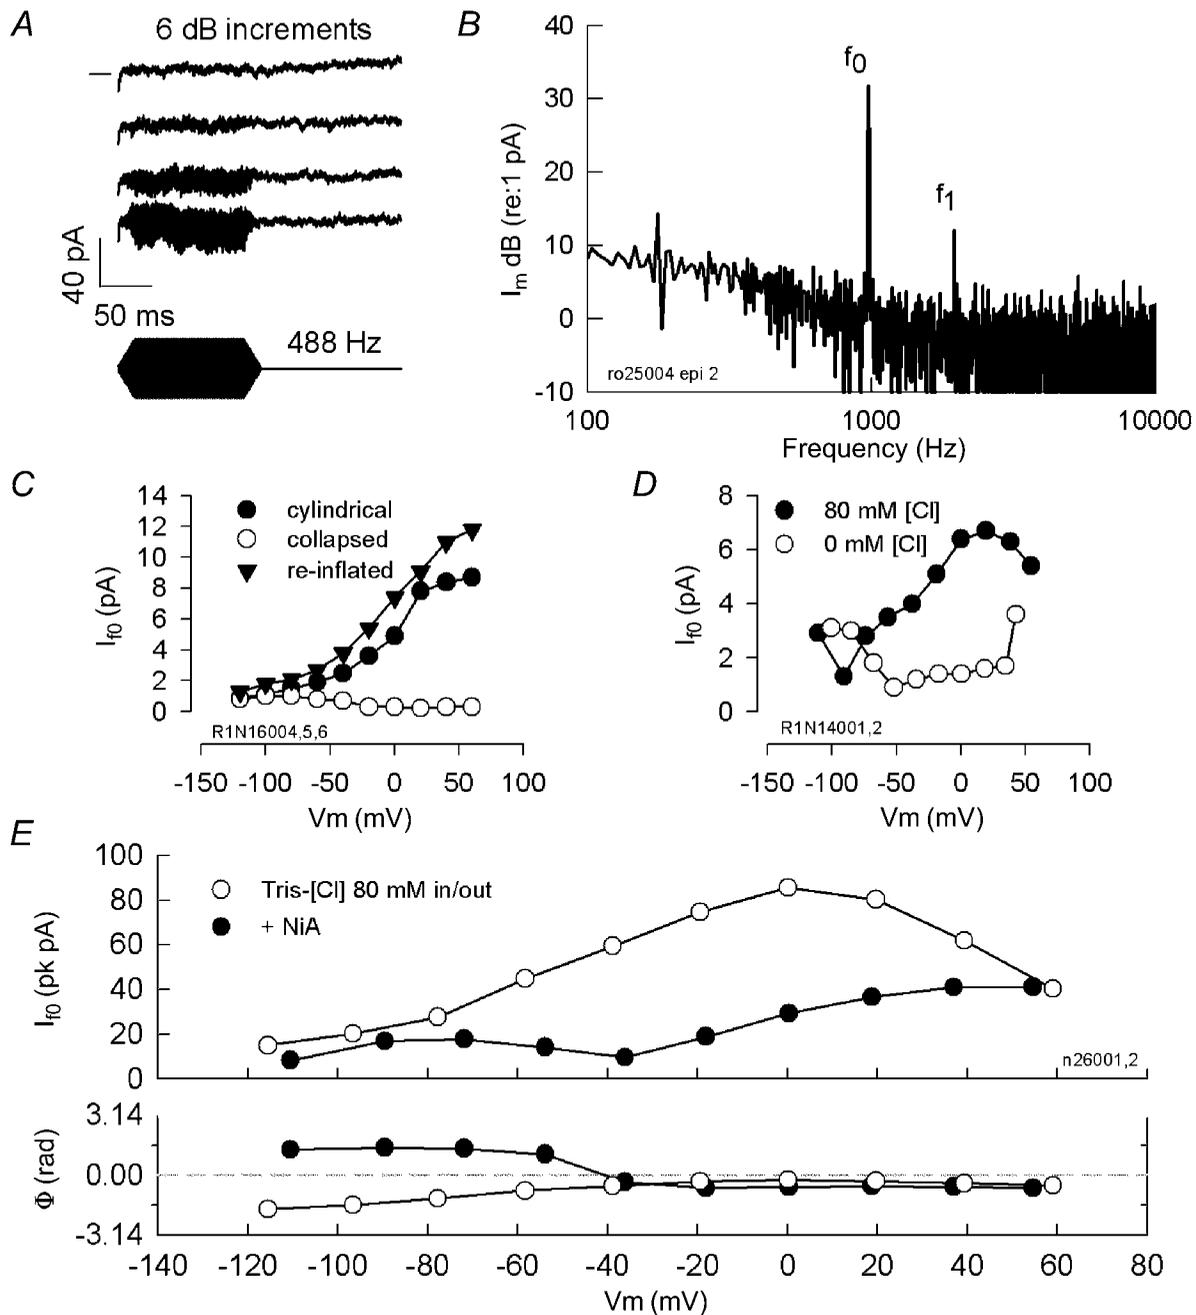

Figure 12. Whole-cell current responses evoked by fluid-jet stimulation of the lateral membrane

A, traces depict an intensity series (6 dB increments in the voltage that drives the piezoelectric fluid-jet) at 488 Hz. Note AC and DC components. DC components grow with stimulus level indicating that they do not arise from bottoming out of the piezoelectric driver. Zero current level is indicated by horizontal line on left of top trace. Traces are separated vertically for clarity. Tris-Hepes intracellular vs. 80 Cl extracellular. B, fundamental (f_0) and first harmonic (f_1) are present in FFT transform from whole-cell currents generated by OHC in response to 1 kHz fluid-jet mechanical stimulation against the lateral wall of the cell. I_m , membrane current plotted on a decibel scale. C, I_{f_0} is blocked by collapsing the OHC with negative pipette pressure; re-inflation restores the current. Niflumic acid (250 μ M)-treated OHC. D, removal of extracellular Cl⁻, in the absence of intracellular Cl⁻ reduces the fluid-jet evoked current. E, the reduction of non-linear peak capacitance after 250 μ M niflumic acid (NiA) treatment (16.6 pF (V_{pkcm} : -12.7 mV) vs. 8.63 pF (V_{pkcm} : 20.3 mV) derived from C-V functions) produced a reduction of the capacitive component and shift in the current's voltage dependence to the depolarized levels. Consequently, characteristics of the ionic component are revealed as I_{f_0} magnitude displays a minimum where an abrupt phase reversal occurs. Tris-Hepes-based intracellular solution (10 mM [Cl⁻]); extracellular solution 80 Cl.

including turgor pressure modulation, and localized membrane deformation with stiff probe and fluid jet. In the presence of only poorly permeable ions inside and outside the OHC, increasing intracellular pressure had only a slight effect on the resting conductance of the cell; subsequent to the addition of extracellular Cl^- the effect was much more pronounced (Fig. 10A). For example, at -60 mV the Cl^- current was nearly doubled. Simultaneous with the increase in Cl^- flux, the non-linear capacitance was augmented. In this example, the OHC was cylindrically shaped throughout the experiment, that is, there was tension on the membrane even when no positive pipette pressure was administered (0 kPa). The effect of the stretch sensitivity of the current on non-linear capacitance was more clearly appreciated when re-inflating initially collapsed OHCs, where the initial tension on the lateral membrane was minimal or absent (Fig. 10B). Indeed, the augmentation

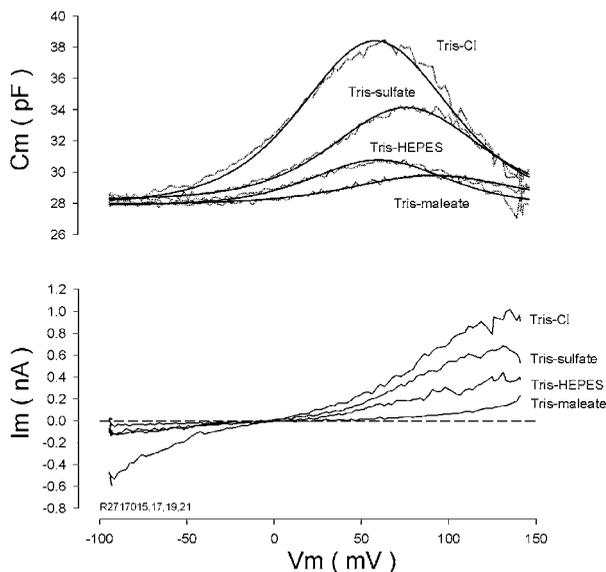

Figure 13. Effects of control anions on OHC non-linear capacitance and current

A, the OHC was perfused with solutions of minimal composition in order to evaluate the effects of control anions. The intracellular solution was maleate-based (mM: 120 maleate, 250 Tris, 2 EGTA). The initial extracellular maleate-based solution (mM: 120 maleate, 250 Tris) was sequentially substituted by Tris-Hepes (mM: 220 Hepes, 60 Tris), Tris-sulfate (mM: 120 SO_4^{2-} , 250 Tris) and Tris-Cl (mM: 155 Cl^- , 165 Tris) solutions. Capacitance measures and corresponding fits (smooth lines) to eqn (1) provide Boltzmann parameters for the tested anions: (maleate: V_{pkcm} , 91 mV; z , 0.82; Q_{max} , 0.23 pC; C_{lin} , 27.96 pF; Hepes: V_{pkcm} , 60 mV; z , 0.99; Q_{max} , 0.30 pC; C_{lin} , 27.89 pF; sulfate: V_{pkcm} , 75 mV; z , 0.92; Q_{max} , 0.65 pC; C_{lin} , 28.28 pF; Cl^- : V_{pkcm} , 58 mV; z , 0.91; Q_{max} , 1.16 pC; C_{lin} , 28.0 pF. B, corresponding ionic currents generated by downward voltage ramps (+150 to -100 mV, 125 ms; corrected for ramp-induced passive capacitive offset current component -52 pA for this cell). Note increasing outward (inward anionic) currents associated with the different anions, and the corresponding increases in non-linear capacitance.

of non-linear capacitance or charge movement by restoring extracellular Cl^- did not occur in OHCs that had been collapsed with negative pressure prior to the restoration, but ensued when the cells were returned to a cylindrical shape by positive intracellular pressure. The resulting increase in membrane tension caused an influx of Cl^- ions, and an augmentation of prestin-generated charge movement.

The stretch sensitivity of the Cl^- current was further tested by mechanically stimulating the lateral membrane with stiff glass probes (Fig. 11A). A step change in membrane deformation evoked an initial transient current due to motor charge movement, followed by a shift in steady-state current (Fig. 11B). As expected, the magnitude of the charge moved was dependent on holding potential and reached a maximum at positive potentials where V_{pkcm} resides under these ionic conditions (Gale & Ashmore, 1994; Zhao & Santos-Sacchi, 1999) (Fig. 11C). On the other hand, the polarity of the mechanically induced component of the ionic current reversed near the reversal potential (-10.5 mV) of the total ionic current. Low frequency AC stimulation with the probe generated corresponding AC currents whose phase reversed at the reversal potential of the current. The reversals in total current polarity are not exactly 180 deg since only a pure ionic current is expected to show this behaviour. These data are consistent with a dual-component current, one capacitive (motor-based) and one ionic.

Finally, in order to assess the physiological significance of the conductance better, we studied its gating by deformation of the lateral membrane at acoustic rates. We used stimulus frequencies that were physiologically appropriate for the OHCs that we isolated, namely for cells whose characteristic frequency ranged up to about 1 kHz (Dallos *et al.* 1982). Figure 12 illustrates that mechanical perturbation of the lateral membrane with micropipette-based, fluid-jet stimulation delivered at frequencies up to 1 kHz. The mechanical perturbation generated high frequency whole-cell currents that display distortion, including harmonic (I_{fl}) and DC components (Fig. 12A and B). This type of stimulation had been used previously to generate, poly-lysine-sensitive, tuned AC and DC mechanical responses from isolated OHCs (Brundin *et al.* 1989; Brundin & Russell, 1994); however, we did not measure the mechanical response of the cell under these conditions, which in any case would not be readily observable with our video sampling rate. We found strong evidence that the evoked current results from direct mechanical perturbation of the lateral cell membrane and is Cl^- dependent. First, it was generated only in OHCs possessing positive turgor pressure, and was reversibly abolished when the cells were collapsed (Fig. 12C). This dependence is similar to that of the mechanical sensitivity of prestin in the lateral membrane (Takahashi & Santos-Sacchi, 2001). Second, in the absence of intracellular Cl^- ,

removal of extracellular Cl⁻ abolished or reduced the current (Fig. 12D).

Since it is known that mechanical stimulation of the lateral membrane can generate non-linear capacitive currents (Gale & Ashmore, 1994; Zhao & Santos-Sacchi, 1999; Takahashi & Santos-Sacchi, 2001), we performed experiments to dissociate capacitive and ionic components of the high frequency current. As with our stiff probe experiments, several pieces of evidence indicate that it is composed of capacitive as well as ionic components. First, while DC current components (Fig. 12A) are not expected for mechanically driven capacitive currents, they can arise from the rectified ionic conductance we described above. Second, in cells that were treated with niflumic acid to decrease non-linear capacitance and increase ionic (Cl⁻) currents, I_{f0} showed two maxima: one near V_{pkcm} , where the non-linear capacitive component is largest (Gale & Ashmore, 1994; Zhao & Santos-Sacchi, 1999), and another at hyperpolarized potentials, where the ionic component is largest (Fig. 12E). Third, magnitude minima corresponded to abrupt phase changes, as expected for an ionic, but not for a mechanically driven capacitive current. The phase change in current polarity is not exactly 180 deg since only a purely ionic current is expected to show this behaviour. Based on results from all three methods of mechanical stimulation, we conclude that the mechanically evoked currents arise from two sources – the ionic conductance we described above, and the intrinsic displacement currents of the voltage sensor of prestin.

A role for sulfonic moieties in prestin activation

Since our observations and those of Oliver *et al.* (2001) suggest that variations in the cationic composition of solutions do not produce substantial effects on the non-linear capacitance of prestin, it is possible that our major control anions, Hepes⁻ and SO₄²⁻, could play a role as co-factors supporting the charge translocation of prestin. The common structural feature between these two anions is the presence of a negatively charged sulfonic group, SO₃. To explore the possible active role of sulfonate-containing molecules in prestin functioning further, we performed one last set of experiments using maleate (divalent, sulfonic-free) as control anion, in place of Hepes⁻ and SO₄²⁻ (Fig. 13). Under symmetrical maleate solutions intra- and extracellularly, a small non-linear capacitance still remained. However, the exchange of extracellular solutions with Tris-Hepes, Tris-sulfate, or Tris-Cl produced an increase in non-linear capacitance and a further shift in V_{pkcm} . Thus, each of these anions is able to permeate the lateral membrane through the non-selective conductance we describe above, and activate prestin. We conclude that in the intact OHC, maleate, which lacks a sulfonic group, is barely active, while Hepes⁻ and SO₄²⁻, which possess sulfonic groups, partially support prestin activity similar to Cl⁻.

DISCUSSION

We report several new observations. (1) Motor charge movement remains substantial in the absence of Cl⁻ and other known active anions inside and outside the intact OHC. (2) Cl⁻ ions significantly affect the state probability of prestin. (3) A Cl⁻ current through a non-selective lateral membrane conductance modulates prestin activity thereby making the OHC responsive to extracellular Cl⁻, and (4) the Cl⁻ current is stretch sensitive and gated at acoustic rates. Taken together, these observations have substantial impact on our understanding of OHC function.

How does Cl⁻ work on prestin?

The current state. Recently, Oliver *et al.* (2001) proposed that prestin possesses an extrinsic voltage sensor where charge movement arises due to the binding and subsequent translocation of Cl⁻ or other anions from the intracellular to the extracellular aspect of the plasma membrane of the cell; simultaneous with this translocation, prestin is driven to the expanded state producing cell elongation. Intracellular SO₄²⁻ ions were ineffective in promoting charge movement, as were extracellular Cl⁻ ions. This was observed in native OHC membrane patches and whole-cell recorded prestin-transfected CHO cells.

Evidence for a new state. One of the main differences that we have with the the data of Oliver *et al.* (2001) is our observation of large shifts in the operating voltage of the motor (V_{pkcm}) during intracellular Cl⁻ removal. Since we first presented evidence for this phenomenon (Rybalchenko & Santos-Sacchi, 2001), we realized that the simple voltage sensor scheme of Oliver *et al.* (2001) was incomplete. A shift in V_{pkcm} suggests significant changes in the energy profile for voltage-dependent motor transitions regardless of whether extrinsic or intrinsic voltage sensors control prestin. Supporting this contention, we previously showed that salicylate, working on the inner aspect of the lateral plasma membrane, not only reduces the voltage sensitivity of the motor (z), but shifts V_{pkcm} in the positive direction (Kakehata & Santos-Sacchi, 1996), indicating a more complex interaction than simple competition for an extrinsic sensor's binding site as suggested by Oliver *et al.* (2001).

Another major difference between our data and that of Oliver *et al.* (2001) is that we find that extracellular Cl⁻ can enter the cell through a lateral membrane stretch-activated conductance to influence prestin activity. Since they studied excised membrane patches, it is possible that in the absence of applied tension to the patch, the conductance was inactive. Additionally, in transfected cells the conductance may not have been expressed. In their motility studies on intact OHCs, the use of intracellular pentane sulfonate solutions confounded the evaluation of Cl⁻ effects.

Finally, the most controversial difference between our data and theirs is our observation that SO₄²⁻ and other

sulfonate-containing anions can support significant voltage sensitivity of prestin. The active role of SO_4^{2-} may not seem unreasonable since protein database comparisons indicate that prestin shows homology to sulfate transporters (Zheng *et al.* 2001). Nevertheless, we performed tests to rule out possible contamination of our solutions with other known active anions, namely the halides and nitrate. Independent laboratory (Galbraith Labs, TN, USA) tests indicate that these anions were less than 100–200 μM in our solutions. Additionally, we confirmed even lower Cl^- levels by measuring junction potentials at the Ag–AgCl pipette solution interface. Furthermore, bicarbonate, whose K_d for prestin effects is 44 mM (Oliver *et al.* 2001), is unlikely to be influential for several reasons. First, carbonic anhydrase is not located at the lateral wall but at the apical and basal ends of the OHC (Okamura *et al.* 1996); thus, under our conditions, the little bicarbonate that might be produced in the absence of energy substrates (i.e. in the absence of robust CO_2 generation) would be readily washed out from the cell's cytosol during pipette perfusion. Second, a control series of experiments in the presence of acetazolamide, a carbonic anhydrase inhibitor, performed in the absence of atmospheric CO_2 (using lithium hydroxide absorption), left our results unchanged (data not shown). Thus we are sure that contaminants are not responsible for our results, since, according to Oliver *et al.* (2001), at these levels of active anions non-linear capacitance should be miniscule.

Apart from differences in animal species, the membrane preparations used could be responsible for discrepancies between our data and those of Oliver *et al.* (2001) on the sulfate sensitivity of prestin. While it is certainly true that the isolated patch technique as used by Oliver *et al.* (2001) is a good method to control solutions delivered to the inner aspect of the membrane, potential problems may arise. For example, removal of a patch from a cell, or measurement of an attached patch in a transfected cell will drastically alter membrane structure, not to mention the intracellular environment that a transmembrane protein normally experiences (Milton & Caldwell, 1990). How this affects an integral membrane protein is difficult to assess. For example, both cell-attached and excised patches of oocyte-expressed Shaker-IR channels display anomalous mechanical sensitivity because normal cellular mechano-control mechanisms are absent (Gu *et al.* 2001). We have chosen to use the native, whole-cell approach because we are trying to understand how the intact cell functions. We conclude that we do have control over solutes delivered to the intracellular aspect of the lateral sub-plasmalemmal space (LSpS), at least at steady state. This, we are sure of because we find washout rates of Cl^- (based on prestin activity) typical for whole-cell washout (~ 1 – 3 min; (Pusch & Neher, 1988)); indeed, we have perfused for longer than 4 h and our results remain consistent. So, in the presence of the lateral membrane conductance that we find, the

continuous perfusion of Cl^- -free intracellular and extracellular solutions will eventually deplete Cl^- in the LSpS. Reversal potentials also indicate that we can effectively change LSpS Cl^- concentrations.

Allosteric effects on motor state. Oliver *et al.* (2001) suggested that extrinsic anions serve as the voltage sensor for prestin. Our data lead us to a differing view. The major effect of Cl^- is to shift the voltage operating range or state probability function of prestin along the voltage axis. The sensitivity of the operating range to Cl^- is remarkably similar to that of the CIC-0 channel (Pusch *et al.* 1995; Chen & Miller, 1996). State probability of that Cl^- channel is highly Cl^- dependent, showing a 40–50 mV change in the open probability function per 10-fold change in Cl^- concentration. We find a similar sensitivity to Cl^- concentration for prestin. In the case of CIC-0, this Cl^- sensitivity and the Cl^- ion requirement for gating have led to a consensus that the extrinsic ion serves as the voltage sensor of the channel; the channel maintains only slight residual voltage dependence under Cl^- -free conditions. Our data do not support a similar conclusion for prestin, since we find substantial voltage dependence under Cl^- -free conditions, with voltage sensitivity (z) and charge movement (Q_{max}) only partially affected, and dependent upon control anion species. Additionally, if prestin required an external anionic voltage sensor, the charge movement characteristics in the presence of SO_4^{2-} and absence of Cl^- should differ significantly, with z and Q_{max} doubling owing to the change in sensor valence from -1 to -2 . Thus, we conclude that the effect of Cl^- is probably due to an allosteric action on the motor protein, prestin. That is, as is typical of indirect allosteric interactions (Monod *et al.* 1963; Changeux & Edelstein, 1998), a modulator, in this case Cl^- , binds to a site (sites) that is distinct from the active site (sites) responsible for the main function of the protein, namely the intrinsically charged voltage-sensing moiety. The binding produces a reversible conformational change in prestin that changes the free energy minima of the steady-state energy profile. This we measure as a shift in the motor charge's Boltzmann function along the voltage axis. Allosteric modulation such as this is not unusual. For example, allosteric modulation of the HERG potassium channel by Ca^{2+} induces voltage shifts in the activation curve of the channel (Johnson *et al.* 2001).

Effect of Cl^- on area state of prestin. We showed that pentane sulfonate has direct effects on the OHC motor, depressing the motor's voltage sensitivity (z) much as salicylate does (Kakehata & Santos-Sacchi, 1996), while maintaining near normal Q_{max} . Indeed, as with salicylate, we still observe reduced electromotility, in contrast to the results of Oliver *et al.* (2001). Additionally, the shift of V_{pkcm} with pentane sulfonate solutions is opposite to that of our other control anions, sulfate or Hepes. We suspect that the lipophilic pentane side chain allows this organic

anion to work on normally inaccessible sites within the lipid environment of the motor, and its use does not allow an adequate evaluation of the effect of chloride on the charge or mechanical activity of prestin.

Oliver *et al.* (2001) concluded that removal of intracellular Cl⁻ causes the lateral membrane motor to reside in the contracted state, and consequently modelled prestin as expanding following the binding and translocation of intracellular Cl⁻ to the outer aspect of the membrane. However, this is unlikely because the state probability of the motor at a fixed holding voltage depends directly on the relative position of V_{pkcm} . Since we clearly show that the effects of pentane sulfate are unrelated to intracellular Cl⁻ concentration, their results probably reflect not the removal of Cl⁻, but the negative shift of V_{pkcm} produced by pentane sulfonate, which they exclusively used in their motility studies. We find that with sulfate- or HEPES-based solutions, where the effects we observe actually correspond to the removal of Cl⁻, the motors tend to reside in the expanded state with Cl⁻ removal, i.e. the OHC elongates at a fixed holding potential, as V_{pkcm} shifts in the positive direction. Thus, we conclude that the binding of Cl⁻ to prestin actually increases the probability that the protein resides in the contracted state and it is unlikely that binding and movement of the negatively charged Cl⁻ ion towards the outer membrane leaflet would increase prestin surface area as Oliver *et al.* (2001) modelled. We suggest that upon Cl⁻ binding, prestin activity is shifted into the physiological range of voltages where intrinsic charge may sense voltage perturbation. Contraction of prestin would be caused by a moiety of net positive charge moving outward, or one of net negative charge moving inward as the electrophysiological data suggests (Ashmore, 1990; Santos-Sacchi, 1991b).

How many prestin binding sites are there for anions? We find differential changes in V_{pkcm} , z and Q_{max} that depend on the control anions (sulfate or HEPES) that we use to replace Cl⁻. This observation indicates that multiple populations of anion-bound prestin may exist simultaneously, and we hypothesize that there are multiple binding sites that can bind not only Cl⁻ but other anions with different affinities, each having differential effects on the Boltzmann parameters. For the whole cell, and large patches, we must also be cognisant that still other restricted populations of motors (with different Boltzmann characteristics) may also exist as a result of local forces other than Cl⁻, e.g. tension, phosphorylation (Santos-Sacchi, 2002). Consequently, owing to distributed populations, the resulting single Boltzmann distributions that we observe do not demonstrate any apparent discontinuities.

Flux of Cl⁻ through the lateral membrane

Identity of the lateral membrane conductance. In this report we directly measured voltage- and stretch-activated anionic and cationic currents that arise from a lateral membrane conductance, and confirmed Cl⁻ movements

by monitoring non-linear capacitance. Several lines of evidence indicate that these non-selective currents, hereafter referred to as I_{metL} (mechano-electrical transducer, lateral membrane), pass through the same conductance: (1) the anionic and cationic currents co-vary in magnitude among OHCs, and never exist separately; each of the magnitudes proportionately fluctuates among and within cells; (2) all modulating agents (drugs, turgor pressure) affect each current in the same direction, and with approximately equal effects; (3) each shows identical rapid kinetics and sigmoidal voltage dependence; and (4) the currents localize to the lateral plasma membrane, being absent in plasma membrane lacking prestin, namely, at the OHC base and in supporting cells.

The number of ionic conductances that are known to exist in the OHC is growing. Some have been molecularly identified and physiologically characterized, e.g. the KCNQ channel subunits responsible for the $I_{k,n}$ current (Kubisch *et al.* 1999; Marcotti & Kros, 1999), or functionally linked to a particularly well characterized channel type, e.g. the L-type Ca²⁺ channel (Santos-Sacchi & Dilger, 1988; Nakagawa *et al.* 1991). Others have been identified through the detection of messenger RNA, e.g. ClC family members (Kawasaki *et al.* 1999), but lack corresponding physiological confirmation of expression. There are still others that have been highly characterized but whose molecular identity remains elusive after decades of study, e.g. the stereocilia transduction channel (Russell *et al.* 1989; Kros *et al.* 1992). Although the molecular identity of the conductance responsible for I_{metL} is unknown, its unusual characteristics are not unprecedented. Indeed, a poorly charge-selective, stretch-sensitive conductance that passes Na⁺, K⁺ and Cl⁻ has been characterized at the single channel level in opossum kidney cells (Uhl *et al.* 1988).

The major voltage-dependent ionic conductances of the OHC, including outward K⁺ and inward Ca²⁺, are restricted to the basal pole of the cell (Santos-Sacchi *et al.* 1997). Though it is generally accepted that the predominant constituent of the lateral membrane is the motor protein, prestin, ionic conductances other than the one we have characterized are localized to this region. Notably, stretch-activated channels have been found in the lateral membrane of OHCs, though they are selective for cations (Ding *et al.* 1991; Iwasa *et al.* 1991), and clearly could not account for the anionic currents that we observed. Brownell and colleagues have observed stretch-induced pore formation up to 4 nm in size in the OHC membrane, which is inhibited by chlorpromazine (Morimoto *et al.* 2002). They found that the pores passed mono and disaccharides, though the ionic permeability of these pores has not been elucidated. Interestingly, there are some reports that may have observed the effects of I_{metL} on OHC shape. Notably, tamoxifen and quinine have been shown to block swelling of OHCs in cochlear explants (Siegel *et al.* 2001), and Gd³⁺

was found to interfere with volume regulation in isolated OHCs (Crist *et al.* 1993). It was suggested that tamoxifen had its effect on ClC-3 channels in OHCs (Siegel *et al.* 2001). Our data do not support this.

Finally, we note that I_{metL} shares some properties of prestin, namely, its location, tension dependence, and modulation by Cl⁻ channel blockers. In this regard, it is well established that some transporters underlie ionic conductances, including CFTR (Hasegawa *et al.* 1992) and the sodium/bicarbonate co-transporter, NBCn1 (Choi *et al.* 2000). In fact, the Na⁺ current associated with NBCn1 expression shows an increase in response to DIDS (Choi *et al.* 2000), similar to the activity of this blocker on I_{metL} . It is conceivable that I_{metL} could result from the expression of prestin. Nevertheless, regardless of the conductance's molecular identity, it is clear that it has a major impact on the activity of prestin and the OHC.

Sub-membranous Cl⁻. I_{metL} is localized to the lateral plasma membrane of the OHC. The lateral membrane and subsurface cisternae form membranous barriers of a restricted compartment (LSpS) whose diffusional access to and from the cytosol is limited owing to its ~30 nm width (Pollice & Brownell, 1993). The LSpS may have distinctive properties (Halter *et al.* 1997; Ratnanather *et al.* 2000). As the cistern nearest the plasma membrane is continuous, ion diffusion must predominantly occur at the apical and basal extremes of the OHC, where the cisternae terminate. For the isolated cells we used in the present study, with lengths from 50 to 80 μm , the volume of the LSpS is about 47–66 fl. If washout from the bulk cytosol under whole-cell voltage clamp were completely absent, the magnitude of I_{metL} we observed, for example ~100 pA at -60 mV (see Fig. 10A), would change LSpS Cl⁻ levels at a rate of 20 mM s⁻¹. Actually, the concentration change just beneath the plasma membrane and at high frequencies (owing to diffusion-rate limitations), especially in the middle of the cell, could be substantially larger. This may explain to some extent our observation of non-uniform stretch-activated gating currents along the length of the OHCs, as non-linear capacitance magnitude will vary with Cl⁻ concentration (Takahashi & Santos-Sacchi, 2001). Since we find that intracellular dialysis with Cl⁻-free solutions affects prestin activity with a time course typical for whole-cell washout (Pusch & Neher, 1988), it is clear that LSpS is not absolutely isolated, and thus, Cl⁻ levels in that space are under our experimental control, at least at steady state (> 3 min). Nevertheless, reversal potential measures indicate substantial gradients in concentration between core cytosol and LSpS. Under whole-cell voltage clamp, the concentration of Cl⁻ in the LSpS is a balance between intracellular/LSpS diffusion and flux across the lateral plasma membrane. Clearly, then, in the absence of Cl⁻-containing solutions inside and outside the cell for more

than several minutes we are assured that Cl⁻ is depleted in the LSpS, and the conclusions that we reached based on this result, e.g. that Q_{max} is resistant to Cl⁻ depletion, are valid.

Under normal physiological conditions, other homeostatic mechanisms to control Cl⁻ levels may come into play, for example, pumps, transporters and sequestration mechanisms (see Frings *et al.* 2000), just as they do in calcium metabolism. Most cells maintain an intracellular Cl⁻ concentration that is substantially below the typical extracellular concentration of 140 mM, as in perilymph. Nevertheless, in many cell types Cl⁻ is maintained at levels higher than the predicted electrochemical equilibrium levels. This is usually achieved by Na⁺-K⁺-2Cl⁻ cotransport (Russell, 2000). However, there is an apparent absence of NKCC1 transporter in OHCs (Crouch *et al.* 1997; Goto *et al.* 1997); this may indicate that levels in the OHC are close to equilibrium levels, namely, for a resting potential < -70 mV (Dallos *et al.* 1982), Cl⁻ would be < 9 mM. Furthermore, efficient mechanisms for the control of Cl⁻ must exist within the very localized region of the LSpS, since an incessant flux of Cl⁻ across the lateral membrane is predicted to accompany acoustically induced (or basilar membrane vibration-induced) mechanical deformations of the cell. As noted above, changes in Cl⁻ levels in the LSpS will have a strong impact on OHC mechanical function. We speculate that the subsurface cisternae and associated mitochondria aid in controlling LSpS Cl⁻ levels. Indeed, it may be that interference with Cl⁻ homeostatic mechanisms underlies the susceptibility of the cochlear amplifier to trauma, or that modulation of these mechanisms accounts for normal phenomenon such as the shift in V_{pkcm} observed during OHC development (Oliver & Fakler, 1999).

Physiological implications of a fast stretch-activated lateral membrane Cl⁻ current – a hypothesis

The observation that OHC somatic motility is driven by voltage quickly led to the suggestion that the low-pass filter of the membrane would seriously limit high frequency electromotility (Santos-Sacchi, 1989). This problem only arises when one considers that owing to the non-linear nature of the mechanical response function, the mechanical gain of the OHC is about one tenth of its maximum (max: ~30 nm mV⁻¹) at the normal resting potential of -70 mV (Santos-Sacchi, 1989). Since that observation, a few solutions for the apparent RC filter problem have been suggested. Dallos & Evans (1995) suggested a mechanism that may work in the intact cochlea; during stimulation with high acoustic frequencies, extracellular voltages (which have a wider bandwidth than intracellular potentials) deriving from excited OHCs could induce a voltage drop across unexcited OHCs at basilar membrane regions basal to the excited cell region. Alternatively, we have suggested two cellular-based mechanisms whereby the problem could be alleviated. First, we found that the mechanical

gain of the cell at its resting potential could be increased via reductions in turgor pressure (Kakehata & Santos-Sacchi, 1995). Second, since we found that motor charge density is greater in higher frequency OHCs, we reasoned that the resultant electrical energy ($Q \times V$) delivered to the lateral membrane of high frequency OHCs could render the filter-induced drop in receptor potentials less detrimental (Santos-Sacchi *et al.* 1998a). All these arguments presuppose the existence of an RC filter problem due to voltage dependence of prestin. Our new data identify a potential mechanism for the operation of the cochlear amplifier without RC filter problems.

The identification of a stretch-activated conductance (G_{metL}) in the lateral membrane may indicate that the OHC motor can react to currents evoked by mechanical perturbations that accompany acoustic stimulation *in vivo*. This scenario had been envisioned following the discovery of stretch-activated cationic channels in the lateral membrane (Ding *et al.* 1991; Iwasa *et al.* 1991). Under that scheme, voltage perturbations accompanying the flux of cations were suggested to drive the OHC motor. However, in that case the RC filter problem remained. In our hypothetical view, however, Cl⁻ oscillations near prestin, driven by the stretch-activated AC and/or DC Cl⁻ current component of I_{metL} , would directly drive prestin transitions. This mechanism naturally follows from the substantial influence of Cl⁻ on the state probability of prestin. As the current or its integral, not the resultant voltage, would directly modulate prestin, the mechanism would be unencumbered by the RC membrane filter. Thus, we hypothesise that the OHC soma has adopted a mechanism similar to that which stereocilia may use to provide cochlear amplification in lower vertebrates (Choe *et al.* 1998; Ricci *et al.* 2000). In that case, Ca²⁺ ion entry through the mechanically gated transduction channels modulates the channels themselves and thus stereocilia bundle mechanics (Choe *et al.* 1998; Ricci *et al.* 2000). In an analogous manner, we view the lateral membrane as a forward and reverse transducer, where local changes in intracellular Cl⁻ levels lead to a cyclical binding of Cl⁻ to prestin, with resultant changes in OHC mechanical properties. Obviously, to be functional, the lateral membrane model must meet many of the requirements laid out for models of stereocilia amplification (Choe *et al.* 1998), including the need for rapid association and dissociation rate constants and mechanisms for Cl⁻ removal.

If this hypothesis has merit, then extracellular perilymphatic Cl⁻ levels should be important for normal auditory function. Manipulations of perilymphatic Cl⁻ levels have been made, but the results are not clear cut (Desmedt & Robertson, 1975). Regarding the interpretation of perilymphatic perfusion of any type, we must remain cognisant of the possibility that preparation for these kinds

of experiments can sometimes reduce response levels significantly such that threshold (active) effects can be missed. Indeed, Desmedt & Robertson (1975) described their preparations as 'fairly intact', and found variations of up to 20% in cochlear microphonic (CM) and eighth nerve compound action potential (N1) thresholds during control perfusions. Nevertheless, when low Cl⁻ perilymphatic-perfusion rates were increased so as to drop Cl⁻ levels down to 5 mM, N1 threshold levels did deteriorate, as we would predict.

ABSTRACT The outer hair cell from Corti's organ possesses voltage-dependent intramembranous molecular motors evolved from the SLC26 anion transporter family. The motor, identified as prestin (SLC26a5), is responsible for electromotility of outer hair cells and mammalian cochlear amplification, a process that heightens our auditory responsiveness. Here, we describe experiments designed to evaluate the effects of anions on the motor's voltage-sensor charge movement, focusing on prestin's voltage-dependent Boltzmann characteristics. We find that the nature of the anion, including species, valence, and structure, regulates characteristics of the charge movement, signifying that anions play a more complicated role than simple voltage sensing in cochlear amplification.

INTRODUCTION

The mammalian cochlea possesses unique cellular structures evolutionarily designed for active amplification, providing enhanced detection and discrimination of acoustic frequencies beyond 70 kHz (1,2). Despite much progress, our understanding of the molecular mechanisms responsible for this active amplification within the organ of Corti remains incomplete. Nevertheless, there is a growing consensus that it is the electrically evoked mechanical activity of the outer hair cells (OHCs) that boosts auditory performance (3–6). These OHCs possess a fast electromotility arising from the recently cloned voltage-sensitive protein prestin (SLC26a5) (7,8), which is densely expressed in the OHC lateral membrane (9,10). The electrical signature of conformational changes in prestin is a displacement current or nonlinear capacitance (NLC) (11–13). The estimated millions of motor molecules (14,15) that reside within each OHC power plasma membrane surface area fluctuations (16–18), thereby predominantly producing longitudinal movements of the cylindrically shaped cells on a submillisecond timescale.

The discovery of a fundamental role for intracellular anions (Cl⁻ in particular) in promoting prestin's voltage sensitivity (19) gave rise to a model in which anions serve as extrinsic voltage sensors whose intramembrane movement directly alters the conformational state of prestin. The model, which we refer to as the partial anion transporter (PAT) model, is encapsulated by an animated cartoon (www.sciencemag.org/content/vol292/issue5525/images/data/2340/DC1/Prestin_movie.mov). It purports that the voltage-driven movement of a bound anion from the intracellular aspect of prestin toward the extracellular

aspect (resulting from a truncated transport cycle) gates prestin from the contracted to the expanded state. Thus, apparent gating charge (z) would derive from the distance (d) that the anion/sensor charge ($q = \text{ion valence} \times e$) moves perpendicular to the membrane field; that is, two-state Boltzmann fits of gating charge or NLC would provide an apparent gating charge of $z = d \times q$. Thus, in this model, z is expected to scale with either d or anion valence. However, the model (19) posits only monovalent anion sensors.

This initial observation was complimented by our recent observations that certain intracellular anions, which were initially considered, according to the PAT model (19), to be unable to serve as prestin's voltage sensor (e.g., SO₄²⁻), can support NLC and shift prestin's voltage operational range (V_{op} , defined in Methods) (20). These observations led to a model for prestin voltage sensing in which anions allosterically modulate the voltage-sensing activity of intrinsic charged residues. In this model, apparent z is still obtained from fits to a two-state Boltzmann function, but it describes, instead, an equivalent charge, q , the sum of an unknown number of partial charges, through a trajectory perpendicular to the membrane field. In this model, z does not necessarily scale with anion valence. We also found that anions pass through a lateral membrane conductance, under the control of membrane stretch and voltage (20). These findings led to a hypothesis that prestin state transitions can occur at constant membrane potential (V_m), being driven by anion flux resulting from acoustically evoked OHC lateral membrane deformations (3,4,20,21). These conformational transitions would primarily result from binding and unbinding of anions, a process that could be unencumbered by the OHC's membrane RC filter (22,23). Here, we expand on our initial observation that intracellular anions significantly shift prestin's V_{op} , and we provide further data that the nature of the anion, including species, valence, and structure, regulates Boltzmann characteristics of the charge movement, indicating a more compli-

cated picture of anion interactions with prestin than a simple extrinsic voltage sensor model (19) can yield.

METHODS

Adult guinea pigs were euthanized with a halothane inhalation overdose protocol approved by the Yale University animal use and care committee. OHCs were freshly isolated from the organ of Corti after enzymatic (dispase 0.5 mg/ml) and mechanical treatment in Ca^{2+} -free medium. Cells of approximately the same size (50–70 μm) were used. Electrical recordings from voltage-clamped OHCs were done at room temperature, as described in our previous work (20). Combined leakage-free liquid bridges (Ag-ACI-TrisCl-TrisMalate-agar) were used in grounding and patch pipette circuits to minimize liquid junction potentials that were kept within ± 4 mV while Cl^- -free and Cl^- -containing solutions were exchanged during the experiment. These values were obtained in control test conditions with solution exchanges around an open pipette. The solution buildup within the bridge was not observed during the relatively short time of the exposure (~ 2 – 5 min) of one particular solution. The solutions were either low- Ca^{2+} or Ca^{2+} -free and K^+ -free (listed in Table 1) to prevent OHC K^+ and Ca^{2+} currents. At the ion concentrations listed, the osmolarity for extracellular solutions was ~ 325 mOsm, whereas solutions 5 mOsm lower were used intracellularly to prevent OHC swelling and effects of altered membrane tension on prestin's functional parameters (24–26). The pH of solutions was adjusted to ~ 7.25 – 7.30 with TrisOH. No difference in osmolarity for equimolar solutions of short- and long-tail sulfonic anions was noticed, indicating that no micelles were formed by any of the alkyl-sulfonates tested. All chemicals were from Sigma (St. Louis, MO) and Fluka (Buchs, Switzerland).

Extracellular solutions were locally applied to the individual cells by Y tube while a bath was continuously perfused with Tris-Hepes_(o) solution. When evaluating the effects of extracellularly applied anions on the intracellular aspect of prestin (see Figs. 3 and 4), at least a 2-min interval was allowed from

the moment of extracellular solution application to the time the membrane capacitance was recorded, to allow the extracellular anions to permeate the membrane and equilibrate with the intracellular solution. Where appropriate, as noted in the text, the patch pipette solutions were exchanged during continuous recording from the cell, using the intrapipette perfusion system 2PK+ (ALA Scientific Instruments, Westbury, NY). In most experiments, 200 μM streptomycin + 400 μM acetazolamide (OHC stereocilia channels and hemichannel blockers) were added to all extracellular solutions to rule out possible influence on the data from unaccounted currents.

OHC membrane capacitance measurements

The OHC voltage-dependent membrane capacitance (C_m), i.e., the capacitance-voltage (C-V) plot, was measured by applying a command voltage protocol (ramp + superimposed two-sine (10 mV peak at 390.6 and 781.2 Hz) from holding potential $V_{\text{hold}} = 0$ mV) that allowed us to sample at 2.56 ms resolution. Subsequently, off-line extraction of C-V plots was performed using a fast-Fourier-transform-based admittance analysis (27,28) incorporated into jClamp software (SciSoft, Branford, CT).

Prestin molecular parameters

Experimentally measured OHC C-V plots were fitted with the function $C_m = C_{\text{lin}} + C_v$, where C_{lin} is the voltage-independent (linear surface area component) capacitance of the lipid bilayer, and $C_v = dQ_{\text{nonl}}/dV$ is the voltage-dependent component of C_m originating from prestin's intramembrane voltage-sensor translocation evoked by external voltage, described with a two-state Boltzmann function, $Q = Q_{\text{max}}/(1 + \exp(-ze(V - V_{\text{pkCm}})/k_B T))$. The total nonlinear fitting function for C_m (13), $C_m = C_{\text{lin}} + \{Q_{\text{max}}ze/k_B T\} \times \exp(-ze(V - V_{\text{pkCm}})/k_B T)/(1 + \exp(-ze(V - V_{\text{pkCm}})/k_B T))^2$ represents a bell-shaped C-V plot (Fig. 1, middle) from which the parameters of Q_{max} , z , V_{pkCm} , and C_{lin} were obtained using a nonlinear curve-fitting procedure. Q_{max} is the total charge translocated if all active prestin molecules underwent conformational transition to the alternative state. $Q_{\text{max}} = q \times N$, where q is

Subscripts (i) and (o) are used to denote intracellular and extracellular solutions, respectively. All values are given in mM.

*The presence of 2 mM of SO_{4(i)}²⁻ in this solution did not influence the effect of the major anion.

prestin's voltage-sensor elementary charge and N is a number of prestin molecules. The measured "apparent valence" of prestin voltage sensor (z) is defined as $z = q \times d$, where d ($0 < d < 1$) is a normalized perpendicular projection of distance traveled by the voltage sensor within the plasma membrane field (Fig. 1). V_{pkCm} is the membrane potential (V_m) at which prestin molecules are equally distributed between expanded and contracted states. It corresponds to the peak of the C_v function. Another parameter, prestin's voltage operation range, was defined as $V_{op} = \{V_{10}, V_{90}\}$, within which the probability for prestin to switch from the expanded to the contracted state varies between 10% and 90%. Within the V_{op} , prestin molecules are sensitive to V_m variations, whereas at more negative potentials the prestin population is virtually locked in the expanded state, and at more positive potentials in the contracted state. As follows trivially from the above equation for Q , the $V_{op} = V_{pkCm} \pm 2.2k_B T/ze = V_{pkCm} \pm z^{-1} \times 56.2$ mV.

Experimental C-V curves were corrected off-line for the effects of series resistance, R_s , using a jClamp built-in algorithm. The nonlinear fitting of C-V curves was performed using the least-square algorithms incorporated in

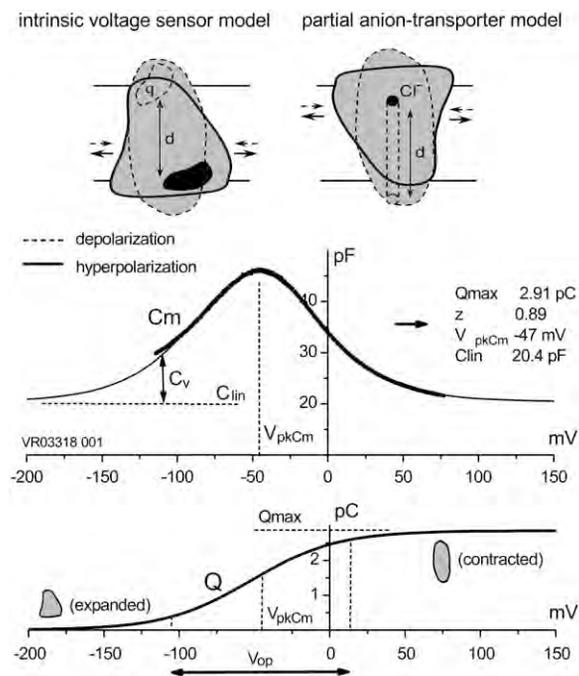

FIGURE 1 Schematic representation of the IVS and PAT models for prestin, and definitions of prestin molecular parameters. (Upper) Conformational transitions between prestin expanded (solid lines) and contracted (dashed lines) states after membrane hyper/depolarization cycles, result from intramembrane translocation of either 1), prestin's charged moiety q (IVS model, left); or 2), Cl^- /bicarbonate-binding moiety (PAT model, right). (Middle) Experimentally measured (in OHCs) bell-shaped C-V curve (heavy line) is composed of a passive capacitance of a membrane lipid bilayer (C_{lin}) and a bell-shaped voltage-dependent component of membrane capacitance (C_v) originating from intramembrane translocation of prestin's charged voltage sensor at membrane voltages within the prestin operation range (V_{op} , indicated in lower panel). The thin line is a two-state Boltzmann function first-derivative fit (see Methods) to a C-V component, from which the parameters characterizing prestin conformational transitions (Q_{max} , z , and V_{pkCm} (inset)) are obtained. Intracellular and extracellular solutions were Tris- $Cl_{(i)}$ and Tris- $Cl_{(o)}$, respectively. (Lower) Integration of the C_v component from the middle panel reproduces a Boltzmann function that characterizes prestin voltage-dependent transitions between expanded (hyperpolarization) and contracted (depolarization) states. The range of membrane potentials between 10% and 90% of prestin molecules residing in the contracted state is defined as prestin's voltage operation range (V_{op} ; see Methods).

jClamp and Origin (Microcal, Northampton, MA) software ($\Delta\chi^2 < 0.05$). Data are presented as mean \pm SD. The statistical significance of difference obtained for the parameters V_{pkCm} , Q_{max} , and z was calculated using one-way analysis of variance ($^o p < 0.1$, $*p < 0.05$, $**p < 0.01$, and $***p < 0.001$). For Figs. 3 and 5, statistics are relative to those characteristics for Cl^- . For Fig. 4, statistics are for the extracellular anions (2–6) relative to those characteristics for control conditions with basal extracellular solution Na-Mal(o)10Cl (1). The number of cells tested for each anion is presented in parentheses for V_{pkCm} , and at the bottom of columns for Q_{max} and z .

RESULTS

Recently, we reported that substitution of sulfate (SO_4^{2-}) for intracellular chloride ($Cl_{(i)}^-$) in guinea pig OHC cells supports NLC and shifts prestin's V_{op} to very positive membrane potentials without substantial change in electromechanical activity (20,29). We posited an intrinsic voltage sensor (IVS) model (20,29), wherein the existence of intracellular anion binding sites on prestin (binding both $Cl_{(i)}^-$ and SO_4^{2-}) influences the free energy profile for prestin's voltage-dependent transitions, thereby establishing V_{op} . According to the PAT model, however, the divalent sulfate is ineffective in supporting prestin charge movement, and the positive shift in V_{op} results from decreasing chloride levels (30). Clearly, if $Cl_{(i)}^-$ removal were the sole reason for the positive V_{op} shift during the $SO_4^{2-} \rightarrow Cl_{(i)}^-$ substitution, the shift should be in the same (positive) direction and of similar amplitude irrespective of the nature of the anion that substitutes for $Cl_{(i)}^-$. To address this issue, we monitored the changes in C-V functions during patch pipette solution washin using three different anion substitutes (SO_4^{2-} , HEPES $^{(-)}$, and 1-pentanesulfonate $^-$ ($PnSO_3^-$) (Fig. 2)). With SO_4^{2-} in the pipette, V_{pkCm} progressively shifted to high depolarizing potentials ($\sim +140$ mV) upon $Cl_{(i)}^-$ washout. The nonlinear C_v component of C-V function remained robust, in accordance with our earlier reports (20,29), but contrary to observations made on excised patches (30). With HEPES $^{(-)}$ anions in lieu of $Cl_{(i)}^-$, the rightward V_{pkCm} shift was less pronounced. Finally, with $PnSO_3^-$ in the pipette, the C-V curve shift was in the opposite (negative) direction, with V_{pkCm} stabilized at extremely hyperpolarized potentials (-150 to -180 mV). The experiments depicted in Fig. 2 clearly indicate that the direction and amplitude of the shift of prestin-generated C-V functions depend on the nature of the intracellular anion and not solely on $Cl_{(i)}^-$ washout.

From our data above, it is clear that the structurally different intracellular anions SO_4^{2-} , HEPES $^{(-)}$, and $PnSO_3^-$, which can be considered sulfonate (SO_3^-)-containing anions, shift prestin's C-V function over a wide range of membrane potentials. To better understand the structure-function aspects of prestin interaction with (SO_3^-)-containing anions, we examined C-V functions of prestin in the presence of alkylsulfonic anions with increasing hydrocarbon tail lengths. Because of technical difficulties with the intrapipette exchange of multiple solutions, the four sulfonic anions: methane SO_3^- ($MeSO_3^-$), ethane SO_3^- ($EtSO_3^-$), propane SO_3^- ($PrSO_3^-$), and $PnSO_3^-$, as well as SO_4^{2-} and Cl^- , were consecutively applied extracellularly to the same

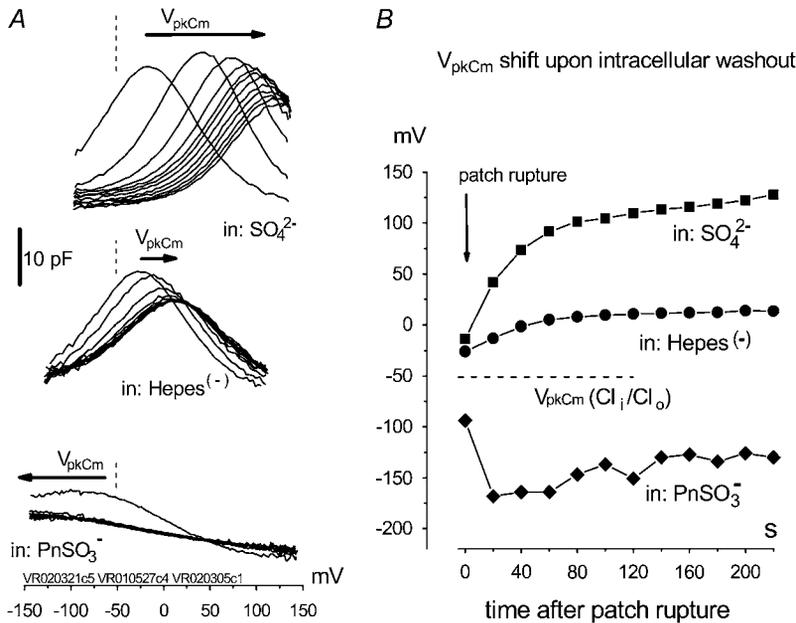

FIGURE 2 Removal of $\text{Cl}^-_{(i)}$ does not determine the direction of the shift of prestin's voltage operation range. (A) Three different OHCs were equilibrated with $\text{Cl}^-_{(i)}$ in Tris- $\text{Cl}_{(o)}$ extracellular solution and then were voltage-clamped using patch pipettes containing intracellular Tris- $\text{SO}_{4(i)}$ (upper), Tris-Hepes $_{(i)}$ (middle), and Na-Pn $\text{SO}_{3(i)}$ (lower) solutions. C-V curves were recorded at 20-s intervals starting at the moment of patch rupture. Upon $\text{Cl}^-_{(i)}$ substitution with intrapipette anions, the C-V characteristics exhibit a voltage shift of different amplitude and direction from $V_{\text{pkCm}}(\text{Cl}^-_{(i)}/\text{Cl}^-_{(o)}) = -51 \pm 11$ mV ($n = 9$, dashed line) recorded at the initial "all Cl^- conditions" (Tris- $\text{Cl}_{(i)}/\text{Tris-Cl}_{(o)}$). The shift depends on the nature of the substitute anion and is not a result of a reduction in $[\text{Cl}^-]_{(i)}$. The 10 pF scale is common for all panels. The horizontal axis is the scale for V_m . (B) V_{pkCm} values obtained from fits (not shown) to the experimental curves for three cells from A were plotted against time, starting from the moment of patch rupture. The irregular time course of the $V_{\text{pkCm}}(\text{PnSO}_{3(i)}/\text{Cl}^-_{(o)})$ curve is due to the difficulties in fitting C-V curves with V_{pkCm} values close to, or beyond, the limit of mechanical stability of the cell.

OHC during the experiment. In addition, we had to limit our voltage excursions to ± 100 mV to limit cell loss during the six perfusions and data collections. We have recently shown that extracellularly applied ions can pass through a nonselective OHC lateral membrane conductance (G_{metL}) to interact with prestin intracellularly (29). Intracellular malate²⁻ was used as a reference anion, since it supported the lowest Q_{max} in our previous experiments, allowing us to monitor increases in NLC due to supplemental anions. The C-V curves with fits from representative OHCs and statistics on V_{pkCm} values obtained from 10 cells ($n > 5$ for each particular anion) are presented in Fig. 3 A. In symmetric $\text{Mal}_{(i)}/\text{Mal}_{(o)}$ conditions, the reference values for $V_{\text{pkCm}}(\text{Mal}_{(i)}/\text{Mal}_{(o)}) = +99 \pm 22$ mV were at very positive membrane potentials, similar to the earlier measured $V_{\text{pkCm}}(\text{SO}_4^{2-})$. With extracellular MeSO_3^- and EtSO_3^- , V_{pkCm} was progressively shifted to more negative potentials: $V_{\text{pkCm}}(\text{Mal}_{(i)}/\text{MeSO}_3^-_{(o)}) = +79 \pm 28$ mV and $V_{\text{pkCm}}(\text{Mal}_{(i)}/\text{EtSO}_3^-_{(o)}) = +59 \pm 27$ mV. The appearance of the third alkyl-carbonate in the anion PrSO_3^- produced a dramatic shift of V_{pkCm} to negative membrane potentials: $V_{\text{pkCm}}(\text{Mal}_{(i)}/\text{PrSO}_3^-_{(o)}) = -68 \pm 54$ mV. Further elongation of the hydrocarbon chain for PnSO_3^- showed only moderate additional V_{pkCm} shift to more negative potentials: $V_{\text{pkCm}}(\text{Mal}_{(i)}/\text{PnSO}_3^-_{(o)}) = -97 \pm 21$ mV. The final control applications of Na- $\text{SO}_{4(o)}$ and Na- $\text{Cl}_{(o)}$ solutions produced $V_{\text{pkCm}}(\text{Mal}_{(i)}/\text{SO}_4^{2-}_{(o)}) = +96 \pm 23$ mV and $V_{\text{pkCm}}(\text{Mal}_{(i)}/\text{Cl}^-_{(o)}) = +36 \pm 13$ mV, in agreement with expected values. Statistics on Q_{max} and z values obtained in this series of experiments are presented in Fig. 3, B and C. $Q_{\text{max}}(\text{Mal}_{(i)}/\text{Mal}_{(o)}) = 0.63 \pm 0.15$ pC, $Q_{\text{max}}(\text{Mal}_{(i)}/\text{MeSO}_3^-_{(o)}) = 1.16 \pm 0.33$ pC, $Q_{\text{max}}(\text{Mal}_{(i)}/\text{EtSO}_3^-_{(o)}) = 1.42 \pm 0.47$ pC, $Q_{\text{max}}(\text{Mal}_{(i)}/\text{PrSO}_3^-_{(o)}) = 2.44 \pm 0.45$ pC, $Q_{\text{max}}(\text{Mal}_{(i)}/\text{PnSO}_3^-_{(o)}) = 2.70 \pm 0.68$ pC, $Q_{\text{max}}(\text{Mal}_{(i)}/\text{SO}_4^{2-}_{(o)}) =$

1.60 ± 0.35 pC, and $Q_{\text{max}}(\text{Mal}_{(i)}/\text{Cl}^-_{(o)}) = 2.59 \pm 0.73$ pC; and $z(\text{Mal}_{(i)}/\text{Mal}_{(o)}) = 0.71 \pm 0.10$, $z(\text{Mal}_{(i)}/\text{MeSO}_3^-_{(o)}) = 0.57 \pm 0.08$, $z(\text{Mal}_{(i)}/\text{EtSO}_3^-_{(o)}) = 0.51 \pm 0.08$, $z(\text{Mal}_{(i)}/\text{PrSO}_3^-_{(o)}) = 0.38 \pm 0.04$, $z(\text{Mal}_{(i)}/\text{PnSO}_3^-_{(o)}) = 0.30 \pm 0.05$, $z(\text{Mal}_{(i)}/\text{SO}_4^{2-}_{(o)}) = 0.58 \pm 0.07$, and $z(\text{Mal}_{(i)}/\text{Cl}^-_{(o)}) = 0.75 \pm 0.07$.

It should be noted that V_{pkCm} , Q_{max} , and z values obtained in these experiments simply serve to illustrate the general effects of these anions on NLC, since the accumulated intracellular concentration of tested anions is not known. Nevertheless, the relatively high Q_{max} values obtained for all tested anions, compared to the reference $Q_{\text{max}}(\text{Mal}_{(i)}/\text{Mal}_{(o)})$ value, indicated that accumulated concentrations of test anions were sufficient to substitute for malate²⁻ on prestin's intracellular anion-binding site(s) that modulates prestin's voltage sensor function. This issue is revisited in the experiments described in Fig. 4. It should also be noted that SO_4^{2-} and PnSO_3^- anions shift prestin C-V curves consistently in one direction (positive and negative, respectively) regardless of their intra- or extracellular application. This observation rules out the origin of V_{op} shifts from membrane charge screening effects and/or from liquid junction potential artifacts. The same observation ruled out electrogenic transport of those anions by prestin, since V_{pkCm} would be expected to shift in opposite directions upon switching the side of the membrane where the transported anions are applied.

Since different anion species can bind to prestin regulatory anion binding sites, it might be expected that various anions would compete for binding to these sites under normal conditions. At present, intracellular $\text{Cl}^-_{(i)}$ anions are strong candidates to be the major anions regulating prestin Q_{max} and V_{op} in OHCs. To verify whether the sulfonic anions can compete with $\text{Cl}^-_{(i)}$ for prestin regulatory binding sites, we repeated the previous experiment represented in Fig. 3 in the presence of 10 mM Cl^- in the intra- and extracellular solutions. The test

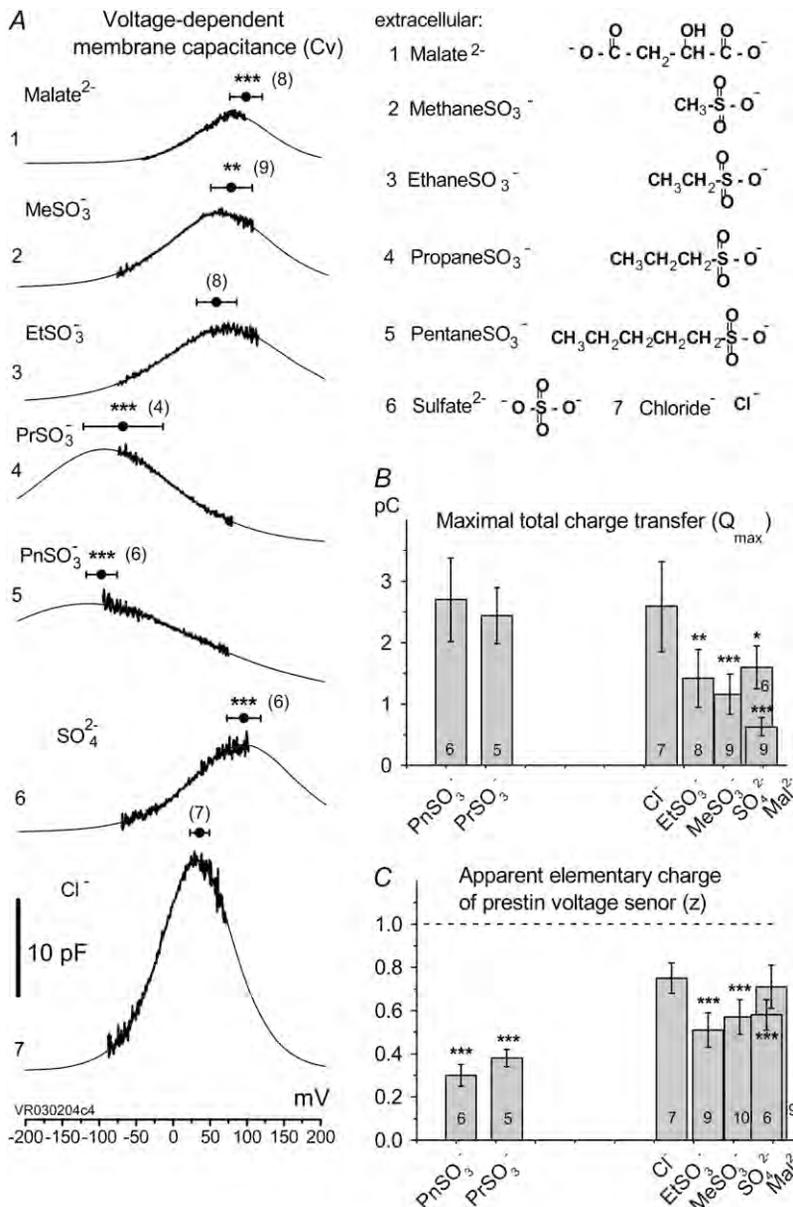

FIGURE 3 Alkylsulfonic anions shift prestin's V_{op} over a wide range (from depolarizing to hyperpolarizing) of membrane potentials as a function of hydrocarbon chain length. (A) C_v - V curves (thick line) and their fits (thin line) obtained from the same OHC perfused with Na-Mal_(i) intracellular solution while control anions and sulfonic anions with increasing hydrocarbon chain length were applied extracellularly in the order (of solutions) (1) Na-Mal_(o), (2) Na-MeSO_{3(o)}, (3) Na-EtSO_{3(o)}, (4) Na-PrSO_{3(o)}, (5) Na-PnSO_{3(o)}, (6) Na-SO_{4(o)}, and (7) Na-Cl_(o). Circles and horizontal error bars above traces represent mean \pm SD for prestin V_{pkCm} values obtained in 10 cells. (B and C) Columns and vertical error bars represent statistics (mean \pm SD) for Q_{max} (B) and z (C) values obtained from the same fits that were used to obtain V_{pkCm} parameters in A. Columns for the appropriate anions are placed in the order and relative position of their V_{pkCm} values on the scale of membrane potentials.

sulfonic anions were again applied extracellularly in order of their V_{pkCm} positive shift demonstrated in the previous experiment. The C-V curves and fits for representative OHCs and statistics on V_{pkCm} values obtained in five cells are presented in Fig. 4 A. In the present condition, where 10 mM $[Cl]_{(i)}$ is fixed, the reference value of $V_{pkCm}(Mal_{(i)}^{10Cl}/Mal_{(o)}^{10Cl}) = +2 \pm 7$ mV (Fig. 4 A I) was shifted to more negative potentials than the value of $V_{pkCm}(Mal_{(i)}/Cl_{(o)}) = +36$ mV obtained in the previous experiment for conditions with all Cl^- extracellular ($Mal_{(i)}/Cl_{(o)}$) (Figs. 3 A 7 and 4 A I (vertical dashed line)). The fact that the $V_{pkCm}(Mal_{(i)}/Cl_{(o)})$ value is more positive than the $V_{pkCm}(Mal_{(i)}^{10Cl}/Mal_{(o)}^{10Cl})$ value indicates that the averaged accumulated $[Cl^-]_{(i)}$ in the previous experiment (Fig. 3) for conditions of $Mal_{(i)}/Cl_{(o)}$ was <10 mM, since lower $[Cl^-]_{(i)}$ would shift the prestin V_{pkCm} to more positive potentials. Thus, we estimated that accumulated intracellular sub-

plasmalemmal concentrations of sulfonic anions applied extracellularly in this and the previous experiment did not reach (and were probably significantly lower than) 10 mM.

The following values of V_{pkCm} were obtained for conditions with fixed 10 mM $[Cl]_{(i)}$ and test anions applied extracellularly (Fig. 4 A): $V_{pkCm}(Mal_{(i)}^{10Cl}/SO_4^{2-(o)10Cl}) = +16 \pm 6$ mV, $V_{pkCm}(Mal_{(i)}^{10Cl}/MeSO_3^{-(o)10Cl}) = +38 \pm 7$ mV, $V_{pkCm}(Mal_{(i)}^{10Cl}/EtSO_3^{-(o)10Cl}) = +31 \pm 9$ mV, $V_{pkCm}(Mal_{(i)}^{10Cl}/PrSO_3^{-(o)10Cl}) = +8 \pm 37$ mV, $V_{pkCm}(Mal_{(i)}^{10Cl}/PnSO_3^{-(o)10Cl}) = -5 \pm 27$ mV. Using the relative shift of V_{pkCm} by SO_3^- -containing anions from reference $V_{pkCm}(Mal_{(i)}^{10Cl}/Mal_{(o)}^{10Cl}) = +2$ mV as a measure of their efficacy to alter V_{op} , the following rank was obtained: $MeSO_3^- > EtSO_3^- > SO_4^{2-}$. The displacement ability by $PrSO_3^-$ and $PnSO_3^-$ could not be ranked in these experiments

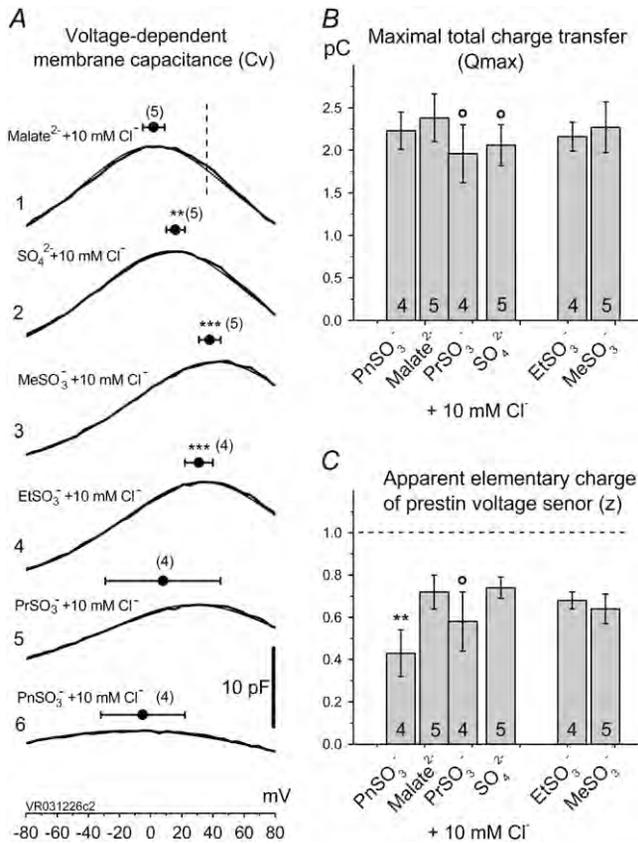

FIGURE 4 Sulfonic anions compete with Cl⁻ for prestin's regulatory anion-binding sites. (A) Select regions of C_v-V curves (thick lines) and their fits (thin lines, indistinguishable due to the close match) obtained from the same OHC examined at 10 mM intra- and extracellular [Cl⁻] "clamped" conditions with Na - Mal^{10Cl}_(i) intracellular and reference anion and SO₃⁻-containing extracellular solutions applied in the order (1), Na - Mal^{10Cl}_(o), (2), Na - SO₄^{10Cl}_(o), (3), Na - MeSO₃^{10Cl}_(o), (4), Na - EtSO₃^{10Cl}_(o), (5), Na - PrSO₃^{10Cl}_(o), and (6), Na - PnSO₃^{10Cl}_(o). Circles and horizontal error bars above traces represent mean ± SD for prestin V_{pkCm} values obtained in five cells. The vertical dashed line is drawn in the position of the V_{pkCm}(Mal_(i)/Cl_(o)) value from Fig. 3 A 7. (Note the different V_m scales in A of this figure and Fig. 3 A.) (B and C) Columns and vertical error bars represent statistics (mean ± SD) on Q_{max} (B) and z (C) values obtained from the same fits that were used to obtain V_{pkCm} parameters in A. Columns for the appropriate anions are placed in the order and relative position of their V_{pkCm} values on the scale of membrane potentials.

due to the high error margins. However, a visual inspection of C-V curves by those anions in most of the experiments (e.g., Fig. 4 A, 5 and 6) indicated their ability to modify the V_{pkCm} and z of prestin, regardless of the presence of Cl_(i)⁻. This is clear from the analysis of z values obtained through this series of experiments (Fig. 4 C): z(Mal_(i)^{10Cl}/Mal_(o)^{10Cl}) = 0.72 ± 0.08, z(Mal_(i)^{10Cl}/SO₄^{2-10Cl}) = 0.74 ± 0.05, z(Mal_(i)^{10Cl}/MeSO₃^{10Cl}) = 0.64 ± 0.07, z(Mal_(i)^{10Cl}/EtSO₃^{10Cl}) = 0.68 ± 0.04, z(Mal_(i)^{10Cl}/PrSO₃^{10Cl}) = 0.58 ± 0.14, and z(Mal_(i)^{10Cl}/PnSO₃^{10Cl}) = 0.43 ± 0.11. The ability of anions to decrease the parameter z (in the presence of 10 mM [Cl_(i)⁻]) seemed to be stronger for long-tail anions: PnSO₃⁻ > PrSO₃⁻ >

MeSO₃⁻ ≈ EtSO₃⁻ > SO₄²⁻. The Q_{max} values in these experiments (shown in Fig. 4 B) did not vary significantly from reference conditions: Q_{max}(Mal_(i)^{10Cl}/Mal_(o)^{10Cl}) = 2.38 ± 0.28 pC, Q_{max}(Mal_(i)^{10Cl}/SO₄^{2-10Cl}) = 2.06 ± 0.24 pC, Q_{max}(Mal_(i)^{10Cl}/MeSO₃^{10Cl}) = 2.27 ± 0.30 pC, Q_{max}(Mal_(i)^{10Cl}/EtSO₃^{10Cl}) = 2.16 ± 0.17 pC, Q_{max}(Mal_(i)^{10Cl}/PrSO₃^{10Cl}) = 1.96 ± 0.34 pC, Q_{max}(Mal_(i)^{10Cl}/PnSO₃^{10Cl}) = 2.23 ± 0.22 pC. For SO₄²⁻, MeSO₃⁻, and EtSO₃⁻ anions with relatively low intrinsic Q_{max} (Fig. 3 B), this result might indicate an overriding control of motor function by chloride. PrSO₃⁻ and PnSO₃⁻ anions appear to support high Q_{max} (comparable to that for Cl⁻) on their own (Fig. 3).

The series of experiments in Figs. 3 and 4 demonstrates that SO₃⁻-containing anions (including SO₄²⁻) control prestin's voltage sensitivity via shifts in V_{pkCm} and alteration of the V_{op} range, or, equivalently, z. Our data can be explained by reasoning that anions applied both intracellularly and extracellularly bind to putative intracellular regulatory binding sites on prestin, thereby producing an allosteric or electrostatic influence on prestin's intrinsic voltage sensor to alter its free energy profile. There is a host of evidence that anions work on prestin intracellularly (4,19,31,32). The possibility remains that some of the alkyl anion effects on V_{op} result from the hydrophobic nature of the anions, since we and others have found that membrane lipid reactive agents can alter NLC (33–38). However, we note that in our previous experiments (32), ethanol had minimal effects below concentrations of 1%, above which V_{op} shifted to the right, in a direction opposite to the effects of ethane sulfonate. Furthermore, the inability of these alkyl anions, in the presence of 10 mM [Cl_(i)⁻], to shift V_{op} to the extreme voltages observed in the absence of chloride indicates that they are not working via membrane perturbation alone, but somehow are competing with chloride to establish V_{op}. Perhaps alkyl anion lipid permeability enables access to anion interaction sites of prestin not normally accessible to lipid-insoluble anions.

In its current state, the PAT model does not explain the shift of prestin's V_{op} in both negative and positive directions upon intracellular Cl_(i)⁻ substitution by the various nonhalide anions (Figs. 2–4), even supposing that these anions are working as voltage-sensor substitutes.

Thus far, we have shown that anions other than Cl⁻ can support NLC. The capability of an alternative anion to serve as prestin's voltage sensor, as envisioned in the PAT model, can be tested knowing that the apparent valence, z, of the voltage sensor can be obtained from two-state Boltzmann function fits to C-V functions (see Methods). For di- and trivalent anions serving as voltage sensors, instead of Cl_(i)⁻, the experimentally measured z parameter should double or triple relative to the values obtained with monovalent Cl_(i)⁻, if the distance traveled by the replacement voltage sensor within the membrane (Fig. 1, d) remains approximately the same as for Cl_(i)⁻. In Fig. 5, we present experimental C-V curves and extracted values of z and Q_{max} obtained with patch pipettes filled

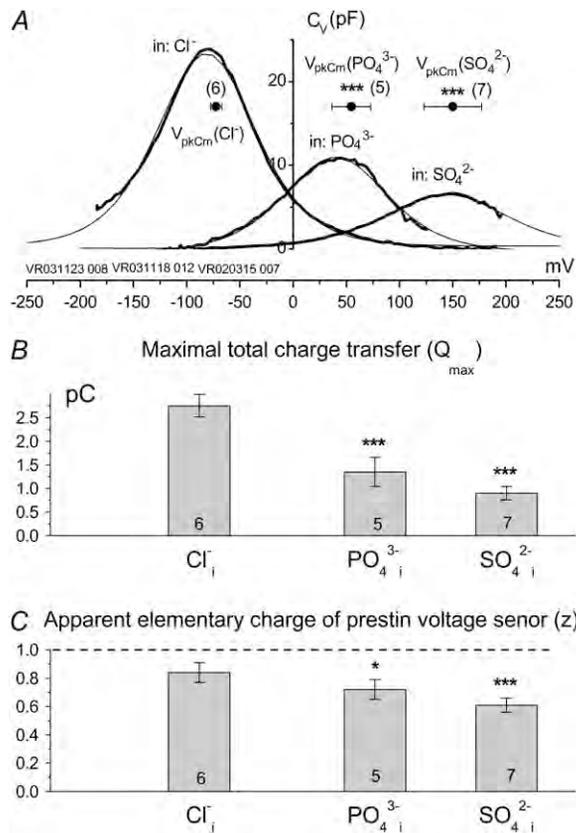

FIGURE 5 Experimentally measured apparent prestin voltage sensor elementary charge (z) is not proportional to the ionic valence of tested intracellular anions. (A) Voltage-dependent components (C_v) of C-V curves (thick line) and their theoretical fits (thin line) obtained from typical cells patch-clamped with pipettes filled with Tris-Cl_(i), Tris-SO_{4(i)}, and Tris-PO_{4(i)} solutions. The horizontal axis is the scale of membrane potentials. The solution was Tris-Hepes_(o). Solid circles with horizontal error bars represent statistics (mean ± SD) for V_{pkCm} values obtained from fits to the C_v-V curves (see Results). (B) and (C) Columns and vertical error bars represent statistics (mean ± SD) for Q_{max} (B) and z (C) values obtained from the same fits that were used to obtain V_{pkCm} parameters in A. Columns for the appropriate anions are placed at the relative position of their V_{pkCm} values on the scale of membrane potentials.

with intracellular solutions based on monovalent Cl⁻, and multivalent SO₄²⁻ and phosphate (HPO₄²⁻/PO₄³⁻) anions, whereas the extracellular solution contained Cl⁻-free Hepes⁻-based solution. C-V curves were recorded 8–10 min after the patch rupture and cell equilibration. With Tris-Cl_(i), the values of $Q_{max}(Cl^-) = 2.75 \pm 0.24$ pC and $z(Cl^-) = 0.84 \pm 0.07$ were obtained at $V_{pkCm}(Cl^-) = -72 \pm 5$ mV, resulting in prestin $V_{op}(Cl^-) = \{-139, -5\}$ mV ($n = 6$). With Tris-SO_{4(i)}, the values of $Q_{max}(SO_4^{2-}) = 0.90 \pm 0.14$ pC, $z(SO_4^{2-}) = 0.61 \pm 0.05$, and $V_{pkCm}(SO_4^{2-}) = +150 \pm 27$ mV resulted in $V_{op}(SO_4^{2-}) = \{+58, +242\}$ mV ($n = 7$). With Tris-PO_{4(i)}, the values of $Q_{max}(HPO_4^{2-}/PO_4^{3-}) = 1.35 \pm 0.31$ pC, $z(HPO_4^{2-}/PO_4^{3-}) = 0.72 \pm 0.07$, and $V_{pkCm}(HPO_4^{2-}/PO_4^{3-}) = +55 \pm 18$ mV resulted in $V_{op}\{HPO_4^{2-}/PO_4^{3-}\} = \{-23, +133\}$ mV ($n = 5$). Results obtained for z (Fig. 5 C) revealed that the values of z for multivalent anions decreased,

showing no correlation between the measured apparent elementary charge of prestin's voltage sensor and the ionic charge of the tested intracellular anions (Fig. 5 C). The observed motility of OHCs with SO₄²⁻ and HPO₄²⁻/PO₄³⁻ intracellular anions remained robust, confirming the proper function of prestin's voltage sensor/effector. Reduced Q_{max} values (Fig. 5 B) could indicate that either the number of active prestin molecules (N) or the elementary charge of prestin's voltage sensor (q) was reduced with SO₄²⁻ and HPO₄²⁻/PO₄³⁻ relative to conditions with Cl_(i)⁻. The latter suggestion is more likely, given the decreased values of z . Thus, the data in Fig. 5 appear to be incompatible with the PAT model.

DISCUSSION

The prevailing concept of OHC somatic electromotility is based on voltage-dependent conformational transitions between expanded and contracted states of millions of prestin molecules residing within the lateral OHC plasma membrane. Though the primary amino acid sequence of prestin was defined several years ago (7), controversy reigns in defining prestin membrane topology (5). To sustain significant size and shape rearrangements at high frequencies (up to 70 kHz), unique thermodynamic characteristics must have evolved to set prestin close to mechanical instability, having very shallow energy minima. Therefore, conventional protein structure analysis techniques that rely on energy minima resolution could easily fail or produce ambiguous results.

An analogous controversy exists over defining the structural part of the prestin molecule that grants it voltage sensitivity. Based on an apparent disappearance of prestin voltage sensitivity and OHC electromotility upon removal of halides and other monovalent anions from the cytoplasmic side of the membrane, the initial PAT model (19) postulated that intracellular monovalent anions are prestin's extrinsic voltage sensors. The other cornerstone of the PAT model was the absence in prestin's primary sequence (relative to other SLC26 family members that lack C_v) of a clearly identifiable cluster of charged residues that might serve as prestin's voltage sensor: selective point mutations of certain scattered charged amino acids could not alter prestin's apparent unitary charge, z . An additional attraction of the PAT model was provided by an analogy with the CIC-type chloride channel model, where mixed [Cl⁻]/voltage dependence of CIC-0 channel gating led to the suggestion that Cl⁻ anions serve as extrinsic voltage sensors (39).

Despite a logical background, the PAT model generated some immediate concerns (40): 1), single charged-residue mutations in prestin/pendrin (SLC26a5/SLC26a6) nonconsensus regions might be an insufficient test, since voltage sensitivity of prestin might be conferred by a number of small movements of distributed partial charges rather than movement of a single point charge; and 2), nonspecific anion binding might distort the local electrostatic field influencing prestin's properties. Recent findings on CIC channel structure also preclude a direct analogy between prestin PAT and CIC

channel models by reducing the voltage-sensing role of Cl^- anions in CIC channels to a mere competition with a Glu residue carboxyl group obstructing the CIC channel's ion pore. The conformational change associated with gating of the CIC channel was limited to a small and local swing of a single amino acid side chain (41,42). Quite a different role would be expected from the Cl^- anion in the prestin PAT model: to serve as prestin's voltage sensor, it must be trapped by a cytoplasmic mobile domain to drive this domain at hyperpolarizing potentials to the extracellular side of the membrane. The mobile domain must be large enough to account for significant changes in prestin's molecular shape during conformational transitions. Specifically, simple propulsion of the Cl^- anion inside prestin would not produce significant prestin resizing due to the small atomic size of the anion itself, $\sim 3 \text{ \AA}$. Structural rearrangements ranging up to 8 nm^2 are estimated to occur in prestin (17,24,25,43,44).

Soon after the development of the PAT model, we provided data that prompted rethinking of the PAT model, including observations that anion substitutes cause shifts in V_{pkcm} , and that the nonhalides SO_4^{2-} and PnSO_3^- are capable of supporting prestin's voltage sensitivity (20). In this work, we address in depth further issues of the PAT model. First, we emphasize that shifts of prestin's V_{op} are not a function of $[\text{Cl}^-]$ per se, but are determined by the nature of alternative intracellular anions (Figs. 2–4). Indeed, the wide variation in direction and amplitude of prestin's V_{op} shift by mono- and polyvalent organic and inorganic anions does not support the idea that monovalent Cl^- and HCO_3^- are the only natural chemical modulators of prestin's voltage sensitivity. In fact, all anions tested in our experiments are capable of interacting with prestin to modify its electromotive properties. Second, we obtained statistical data demonstrating that the experimentally measured apparent valence, z , of prestin's voltage sensor does not correspond to the molecular valence of intracellular polyvalent anions, as might be expected for the PAT model (Fig. 4).

Two mechanisms could serve to reconcile this latter observation with the PAT model: 1), protonation to achieve monovalency of polyvalent anions, and 2), an inversely proportional adjustment of distance (d) traveled within the membrane field based on the size of the anion or the magnitude of the anion charge. We believe it unlikely that the relatively small differences in anion size hinder a putative hemicycle movement within the prestin core, since the anions, according to the PAT model, must drive estimated conformational changes (see above) that are orders of magnitude larger. It is also difficult to conceive how the charge magnitude (valence of the anion) could be influential in reducing the ability of the anion to pass through the membrane field. Indeed, the electrical energy to work against the load on the OHC would be amplified by the increase in valence ($E = Q \times V$), so that higher-valence anions would likely move more efficiently through the membrane for a given voltage change. Finally, although protonation during the transport cycle is conceivable, the pH effects on the motor that would be expected in such a scenario are not found (45).

The most economical explanation of our data is that although polyvalent anions support charge movement by prestin, they work not as voltage sensors but as allosteric modulators.

A conventional model would consider prestin to be a voltage-dependent protein that possesses mobile charged residues forming an IVS. Due to prestin's unique functional properties (i.e., piezoelectric operability), its voltage-dependent transitions should be accompanied by significant rearrangement of the shape of the molecule, involving movements of multiple charged amino acid residues back and forth within the membrane. Indeed, as noted above, large surface area changes in the motor have been predicted. As a result, we have considered that even intracellular charged clusters at the C-terminus of prestin might be temporarily immersed in the membrane, participating in voltage-sensing events. However, our data do not support such a role for the C-terminus charges (46). At this time, it is difficult to predict which amino acids are more and which are less important in forming the voltage sensor, because the entire molecule might contain nonuniformly distributed elements of the voltage sensor.

The discovery of prestin's Cl^- sensitivity (19) was of fundamental importance, regardless of the mechanism whereby anions influence prestin's voltage sensitivity. Indeed, we have recently shown that manipulations of Cl^- within the living animal's cochlea can drastically alter cochlear amplification in a reversible manner (4). Nevertheless, we consider the mechanism of anionic control of prestin voltage sensitivity key to understanding how the motor molecule drives cochlear amplification. In this report, we highlight two observations that are not easily reconciled with the current embodiment of the PAT model, and we reason that anions may additionally, or only allosterically, modulate prestin by binding to intracellular target sites on the protein (5,20,29). Such allosteric effects of anions have been reported before, for example, for the yeast enzyme Fet3p (47). We expect that identification of anion binding sites and of residues that contribute to prestin's apparent charge will lead to a better understanding of how this remarkable protein boosts hearing.

Chapter 5

Prestin: Molecular Mechanisms Underlying Outer Hair Cell Electromotility

**Joseph Santos-Sacchi, Dhasakumar Navaratnam, Rob Raphael,
and Dominik Oliver**

Abstract Prestin is a member of the SLC26 family of anion transporters that has evolved to serve as a molecular motor in outer hair cells (OHCs) of the mammalian inner ear. The protein is piezoelectric-like, exhibiting voltage and tension sensitivity, with significant modulation by anions, chiefly intracellular chloride. Receptor potentials of OHCs drive molecular conformational changes in prestin, as evidenced by voltage sensor charge movements, that evoke robust length changes in OHCs, thereby contributing to a mechanical feedback mechanism and, therefore, to cochlear amplification, which enhances our auditory sensitivity. Current research has been focused on tertiary structural determinations, prestin interactions with other proteins and membrane lipids, trafficking, and the mechanism of anion effects. One of the key remaining questions is the determination of structural changes induced by membrane voltage perturbations and how those changes result in forces exerted by the OHCs. Indeed, much remains to be understood about this extraordinary molecule.

5.1 Introduction

Prestin is a remarkable protein that underlies our keen sense of hearing. It is a member of an anion transporter family (SLC26) that has role changed into a fast molecular motor that drives outer hair cell (OHC) somatic electromechanical activity, the transduction of the receptor potential of the cell (see Corey, Ó Maoiléidigh, and Ashmore, Chap. 4) into pronounced cell length changes at acoustic rates, thereby boosting perceptual thresholds by 40–60 dB. In this chapter, three broad areas focus on how this protein works. They include an overview of the protein's biophysical traits, the structural features of the protein that will lead to detailed structure–function relationships, and the role of accessory protein/lipid partners in helping this protein to carry out its important work. Much is to be learned. Pertinent reviews on the subjects of this chapter are available in the literature (He et al. 2006; Ashmore 2008; Ashmore et al. 2010).

5.2 Known Biophysical Properties of Prestin

5.2.1 *The OHC Sensor/Motor: Preprestin*

An intense investigation of this somatic motility began soon after its discovery by Bill Brownell and colleagues (Brownell et al. 1985; Kachar et al. 1986). Surprisingly, when OHCs are stimulated electrically by a current injection within or across the cell, their length changes as a function of stimulus intensity and waveform. It soon became clear that OHC somatic motility [also known as electromotility (eM)] was driven by voltage and not any particular ionic current (Ashmore 1987; Santos-Sacchi and Dilger 1988), evidencing movements of 15 nm/mV on average (Santos-Sacchi 1989). One of the most powerful pieces of evidence that eM was driven by voltage was the observation of displacement currents, capacitive-like currents, similar in some respects to the gating currents of ion channels (Bezanilla 2000), which are evoked by membrane voltage steps under whole cell voltage clamp (Ashmore 1989; Santos-Sacchi 1990). These displacement currents, or, equivalently, a voltage-dependent or nonlinear membrane capacitance (NLC), arise from the movements of a voltage sensor charge across the electric field of the membrane. The identification of such a charge movement immediately led to the notion of a sensorimotor unit residing in the OHC plasma membrane that obeyed

two-state Boltzmann statistics (Ashmore 1990; Santos-Sacchi 1991), where characterization of the charge-voltage (Q-V) or, equivalently, the capacitance-voltage (C-V) relationship provides estimates of the unitary sensor charge (z ; assuming full passage of the sensor charge through the field of the membrane), the maximum charge transferred (Q_{\max}), and, the voltage where charge is equally distributed across the membrane (V_h ; Fig. 5.1). The Boltzmann characterization of motor charge movement also provided the impetus for the development of “molecular” models of motor action that incorporated Boltzmann statistics, including area and conformational state models (Kalinec et al. 1992; Dallos et al. 1993; Iwasa 1994). Given the Q_{\max} and an elementary sensor charge estimate, the number of motors residing in the membrane can be estimated, giving a density in OHCs of about $10,000/\mu\text{m}^2$ (Huang and Santos-Sacchi 1993; Gale and Ashmore 1997a; Mahendrasingam et al. 2010), although this number may need to be reevaluated (Santos-Sacchi and Song 2016). V_h and z have been used to define the voltage operating range of the motor, with V_h localizing the eM-V function relative to the resting membrane potential of the cell and z defining the extent over which the motor is voltage sensitive. With z being less than unity, the motor has a quite shallow voltage dependence compared with ion channels. The two-state formalism also imposes strict correspondence between charge movement and eM, where according to a now widely accepted area-state model (Iwasa 1994; Santos-Sacchi and Song 2014a), motors will fluctuate between a compact and expanded surface area state, with unitary motor area change estimates varying between 0.37 and 8 nm^2 (Iwasa 1993; Santos-Sacchi 1993; Gale and Ashmore 1994; Adachi and

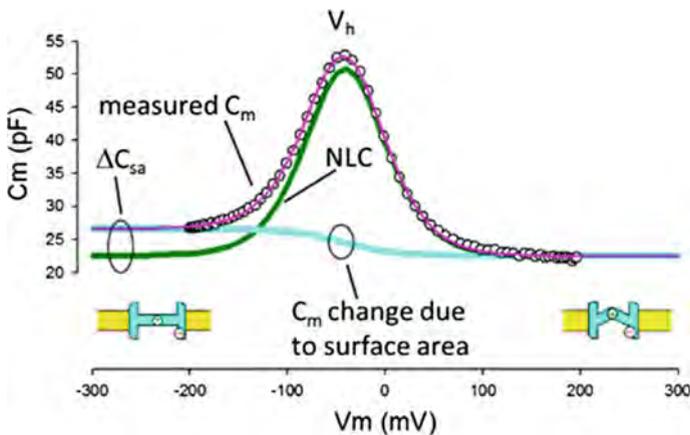

Fig. 5.1 Outer hair cell (OHC) nonlinear membrane capacitance (NLC). OHC voltage-dependent capacitance (*circles*) is composed of two components, both riding atop a linear capacitance corresponding to the cell’s surface area. One is associated with the voltage sensor charge of prestin (NLC; *green*), and the other is associated with motor state occupancy (*blue*). Cartoon depicts prestin in either state, expanded or contracted. V_h , voltage where charge is equally distributed across the membrane; C_m , membrane capacitance; ΔC_{sa} , state-dependent capacitance; V_m , membrane voltage. See text for further details. Modified from Santos-Sacchi and Navarrete (2002)

Iwasa 1999). As indicated in Fig. 5.1, voltage-dependent C_m possesses an additional component, state-dependent capacitance (ΔC_{sa}), that has been attributed to area/membrane thickness changes associated with motor state occupancy, each motor contributing an additional 17 aF when residing in the expanded state (Santos-Sacchi and Navarrete 2002). The high variance of area estimates highlights the need for structural observations at the molecular level.

During the ensuing years, a host of biophysical attributes of the OHC plasma membrane motor were characterized, and these traits, together with its NLC, would be crucial in identifying the molecular nature of the motor. One of the most important discoveries was the piezoelectric nature of the motor (Iwasa 1993). On introducing tension into the OHC membrane, NLC shifts along the voltage axis. The shift in V_h effects the charge movement in the membrane, and this phenomenon is intrinsic to the membrane (Gale and Ashmore 1994; Kakehata and Santos-Sacchi 1995). These data are fully consistent with a direct voltage-to-mechanical (and vice versa) transduction process that does not directly require any intermediate steps (e.g., second messengers) or biochemical energy sources (except, of course, those sources required to maintain the membrane voltage). Other early observations that defined the nature of the motor and set the stage for its molecular identification included the simultaneous block of the NLC and motor activity by intracellularly acting salicylate and extracellularly acting gadolinium (Santos-Sacchi 1991; Tunstall et al. 1995; Kakehata and Santos-Sacchi 1996), the influence of altered membrane potential (prepulse effect) on V_h (Santos-Sacchi et al. 1998), the tension and turgor pressure effects (piezoelectric-like) on the NLC (Iwasa 1993; Gale and Ashmore 1994; Kakehata and Santos-Sacchi 1995), and the temperature susceptibility of the NLC (Santos-Sacchi and Huang 1998; Meltzer and Santos-Sacchi 2001).

5.2.2 *Enter Prestin*

Zheng et al. (2000) identified the OHC motor protein as prestin (SLC26A5), a member of an anion transporter family. Key to this identification was the localization of the protein to the OHC lateral membrane where electromechanical activity is restricted (Dallos et al. 1991; Huang and Santos-Sacchi 1994) and biophysical demonstrations of OHC motor-like activity in heterologously transfected cells, including the NLC, the voltage-driven membrane movement, and a block by salicylate. Subsequently, prestin was shown to exhibit membrane tension (Ludwig et al. 2001; Santos-Sacchi et al. 2001), prepulse (Santos-Sacchi et al. 2001), and temperature sensitivities similar to those in the native OHCs (Meltzer and Santos-Sacchi 2001). It was clear at that point that all known biophysical traits of prestin matched those that had been identified before its discovery. Another fundamental observation that indisputably linked prestin to OHC eM was the absence of eM in the prestin-knockout mouse (Lieberman et al. 2002).

5.2.3 Importance of Prestin for Cochlear Amplification

Interestingly, while the knockout implicated the importance of prestin in cochlear amplification, issues were quickly identified that dampened such a conclusion, including the obvious mechanical impedance changes in the OHCs (and consequently the cochlear partition) that result from removal of the abundant protein content within the OHC lateral membrane, which substantially shortened OHCs. Subsequently, persuasive evidence that prestin predominantly underlies cochlear amplification was obtained from a knockin of mutated prestin (499 mutant) that has its voltage operating range (assessed by NLC V_h) shifted far out of the physiological range while maintaining other features of normal OHC function, structure, and mechanics (Dallos et al. 2008). That mutation also altered the kinetics of prestin (Homma et al. 2013). Another important observation linking prestin to cochlear amplification was that manipulations of chloride, previously shown to control the electromechanical activity of prestin (Oliver et al. 2001), reversibly altered the basilar membrane tuning in vivo (Santos-Sacchi et al. 2006). Salicylate, which competes with chloride for the anion binding site of prestin and reduces the NLC (Oliver et al. 2001), also adversely affects basilar membrane motion (Santos-Sacchi et al. 2006; Fisher et al. 2012). Finally, there is evidence for prestin mutations causing deafness (Mutai et al. 2013).

5.2.4 How Does Prestin Sense Voltage?

The voltage-dependent nature of eM naturally begs the question, What makes the protein sensitive to voltage? It is clear that prestin must possess a charged voltage sensor that is moved by voltage drops across the plasma membrane. In other well-studied voltage-dependent membrane proteins, charged amino acid residues serve this function. For example, the S4 segment in the voltage sensor domain of all classical voltage-gated ion channels comprises the voltage sensor domain (Bezanilla 2000). In a fundamental study investigating this issue, Oliver et al. (2001) found that neutralization of candidate electrically charged amino acid residues had little effect on voltage sensitivity of prestin, whereas removal of monovalent intracellular anions, namely intracellular chloride or bicarbonate, abolished charge movement and hence voltage sensitivity. Recently, careful examination of this phenomenon indicated that the OHC eM magnitude (Song and Santos-Sacchi 2013) and the total Q_{\max} (Santos-Sacchi and Song 2016) do not decrease with intracellular chloride level, but rather chloride levels influence the rate of prestin transitions (Santos-Sacchi and Song 2016), resulting in an apparent reduction of NLC when the membrane potential is changed at rates exceeding the Cl^- -dependent kinetics of prestin. Based on the observation of anion sensitivity, Oliver et al (2001) concluded that the voltage sensor of prestin is not made up from intrinsic residues in prestin, but instead, monovalent anions serve as extrinsic voltage sensors, i.e., that

charge movements (NLC) arise directly from the translocation of the anion across the electrical field along some hypothetical access channel in the protein. This anion translocation, in turn, would then drive simultaneous conformational changes between the expanded and contracted states, thus producing eM. In fact, the voltage dependence of prestin varied with the size of the monovalent anion present, as if bulkier anions can travel a smaller fraction of the electrical field (Oliver et al. 2001). However, other findings are difficult to reconcile with this simple external voltage sensor model. First, a shift of the voltage dependence (V_h) toward depolarized potentials observed when the anion concentration is lowered is contrary to the prediction of the model (Rybalchenko and Santos-Sacchi 2003a). Interestingly, a variety of anion substitutes can markedly shift V_h in either the depolarizing or hyperpolarizing direction to varying degrees (Oliver et al. 2001; Rybalchenko and Santos-Sacchi 2008). Second, if other than monovalent anions can maintain prestin function, the charge number z moved per prestin molecule should correspond to the valence of the anion serving as voltage sensor (assuming that the electrical distance traveled remains the same). However, an increase in z has not been observed when monovalent anions are substituted with di- or trivalent anions (Rybalchenko and Santos-Sacchi 2008). Third, hyperpolarization, which drives prestin into the expanded state, should move the anion toward a more extracellular position, but in the expanded state, the apparent affinity for the anions is reduced, suggesting the release toward the cytosol (Song and Santos-Sacchi 2010). Observations such as these have led to a counter theory that anions serve as allosteric-like modulators of prestin charge movement, anion binding conformationally transitioning the protein into a voltage-enabled state, with sensor charge contributed by a wide-ranging distribution of charged residues within the protein (Bai et al. 2009). A current structural view of anion interaction with prestin is provided in Sects. 5.3.4 and 5.3.5.

5.2.5 How Many States/Transitions Does Prestin Have?

Simply based on standard fits of the NLC, it was not possible to differentiate between two-state and multistate behavior in the motor protein prestin (Huang and Santos-Sacchi 1993; Scherer and Gummer 2005). For example, fits with two-state Boltzmann or infinite state Langevin equations each adequately fit the NLC because of measurement uncertainty at the extreme voltages needed to interrogate the very shallow voltage dependence of the protein. The NLC has been used routinely as a surrogate for eM under the assumption that sensor charge movement exhibits fast two-state behavior directly linked to eM. It was natural to assume such fast kinetics because eM had been measured in the acoustic frequency range (Ashmore 1987; Santos-Sacchi 1992; Dallos and Evans 1995), even out to about 80 kHz (Frank et al. 1999) at room temperature. Interestingly, the NLC cutoff frequency was near 10 kHz at room temperature (Gale and Ashmore 1997b). The recent observation that characteristics of the NLC and eM can diverge as a function of reduced anion

concentration revealed that prestin activity is not governed by a simple two-state process but is instead multistate (Song and Santos-Sacchi 2013). A basis for disparity between the two measures may be related to slow, chloride-controlled intermediate transitions between chloride-binding and voltage-enabled states (Song and Santos-Sacchi 2013; Santos-Sacchi and Song 2014a). Essentially, steady-state (or low-frequency) evaluations of eM do not correspond to sensor charge movement that is measured at higher frequencies because each will only be equal when measured at the same frequency. Although the simple model developed in that work (*meno presto* model) can recapitulate features of the behavior of prestin, thus revealing its multistate nature with attendant time/phase delays (Santos-Sacchi and Song 2014b), it is likely that models incorporating transporter characteristics expected from the SLC heritage of prestin will offer greater insight (Muallem and Ashmore 2006; Schaechinger et al. 2011), provided they can account for all known biophysical properties exhibited by prestin.

Clearly, a lack of consensus on the structure of prestin based on software prediction algorithms, as indicated by the wide range of secondary topologies attributed to the membrane protein such as the 12 transmembrane domain (TMD) model (Oliver et al. 2001; Deak et al. 2005; Rajagopalan et al. 2006), the 10 TMD model (Navaratnam et al. 2005), and the 8 TMD model (Lovas et al. 2015), has led to difficulties in understanding the biophysical basis of the NLC and eM. Additionally, the limited information on the interacting partners of prestin and the influence of its membrane environment has contributed to these difficulties. Fortunately, significant progress is currently being made on these fronts.

5.3 Structure and Function of Prestin

5.3.1 *Molecular and Functional Features of Prestin*

Prestin is the fifth member of the SLC26 family of anion exchangers (hence SLC26A5; Zheng et al. 2000), a group of 10 mammalian proteins (Mount and Romero 2004; Alper and Sharma 2013). SLC26 proteins belong to a large, ubiquitous, and evolutionarily ancient “sulfate permease” (SulP) family of anion transporters present in animals, plants, fungi, and bacteria. Although the SLC26 nomenclature was originally used for the mammalian SulP proteins (Mount and Romero 2004), the SulP and SLC26 nomenclature may be used interchangeably (Dorwart et al. 2008; Geertsma et al. 2015). These evolutionary and molecular relationships are of particular relevance because structural information on mammalian prestin has emerged only very recently and is entirely based on crystallographic data for close (i.e., within the SLC26/SulP family) or remotely homologous relatives of mammalian SLC26 proteins.

The mammalian SLC26 proteins are diverse in terms of both their transport substrates and the transport modes. Thus, SLC26 transport activities include

electrogenic or electroneutral exchange of monovalent (e.g., chloride, iodide) and divalent anions (e.g., sulfate, oxalate). Two members, SLC26A7 and SLC26A11, mediate uncoupled flux of chloride at high rates, which may indicate that these members function as anion channels. Detailed reviews on SLC26 transport function and roles in physiology and pathophysiology are available (Mount and Romero 2004; Dorwart et al. 2008; Alper and Sharma 2013).

The closest prestin relatives of mammalian prestin, nonmammalian orthologs of SLC26A5 (e.g., chicken and zebrafish prestin), are highly active anion transporters that mediate the stoichiometric exchange of monovalent anions such as chloride against divalent anions (either sulfate or oxalate; Schaechinger and Oliver 2007; Schaechinger et al. 2011). Because this transport mode is electrogenic, i.e., one electrical charge is transferred per transport cycle, nonmammalian prestins generate robust transport currents in the presence of divalent transport substrates (Schaechinger and Oliver 2007). In contrast, transport currents were not observed with mammalian prestin in the presence of divalents (Schaechinger and Oliver 2007; Schaechinger et al. 2011), indicating that prestin has no transport activity, that it acts in an electroneutral mode that does not generate electrical current, or that transport rates are much lower than in its nonmammalian orthologs. In fact, by using fluorescent pH sensors and electrophysiology, Mristik et al. (2012) showed that prestin may function as a $\text{Cl}^- / 2\text{HCO}_3^-$ exchanger, however with a low transport rate. Recently, prestin has been shown to allow ion currents through a pathway distinct from its transporter pathway (Bai et al. 2017). Moreover, based on a tracer-flux assay, one study suggested transport capability for formate and chloride (Bai et al. 2009), although another group could not reproduce this finding while confirming transport in nonmammalian orthologs (Tan et al. 2011). Interestingly, prestin, as well as other SLC26 proteins, mediates uncoupled permeation of thiocyanate (SCN^-) at appreciable rates (Schanzler and Fahlke 2012). Although the permeation of this anion has no obvious physiological relevance, this finding underscores the high degree of mechanistic and structural similarity between prestin and other SLC26 transporters and may turn out as helpful in deciphering potential common molecular mechanisms of transport and eM.

Mammalian prestin is a 744-amino acid protein with a high degree of sequence conservation across mammalian species (Zheng et al. 2000). As with other SLC26 proteins, prestin consists of a large TMD containing numerous hydrophobic stretches indicative of multiple transmembrane segments. This TMD is flanked by hydrophilic intracellular N- and C-termini (Ludwig et al. 2001; Zheng et al. 2001). The detailed topology of the TMD had long remained enigmatic, but it is now clear that it contains 14 membrane-spanning domains (Gorbunov et al. 2014; Geertsma et al. 2015). Within this TMD, two regions have been recognized for their particularly high sequence conservation across the SLC26/SulP family. One is located more N-terminally and is designated as the “SulP consensus signature” (Prosite PS01130); the other one located in the C-terminal half of the TMD is known as the Saier motif (Saier et al. 1999; Mount and Romero 2004). The high degree of conservation suggested that these protein regions are of particular importance for SLC26 function and may be critically involved in anion transport and possibly in eM. This is supported by the finding that transplantation of protein regions, including these motifs from mammalian prestin into

the prestin ortholog from zebrafish, is sufficient to confer mammalian-like function (i.e., fast charge transfer and eM) onto the nonmammalian prestin, which otherwise functions as a transporter (Schaechinger et al. 2011).

Another well-conserved domain of all mammalian and most bacterial SLC26/SuIP proteins is the sulfate transporter and anti-sigma factor antagonist (STAS) domain, which occupies most of the cytoplasmic C-terminus (Sharma et al. 2011). The name refers to sequence and structural similarity with bacterial anti-sigma factor antagonist (ASA) proteins. In prestin from rats, the STAS domain approximately comprises amino acids 505–714 (Pasqualetto et al. 2010). Although the TMD mediates and determines the eM and transport function of SLC26 members as shown by transplantation of domains between mammalian and transport-active nonmammalian prestin (Schaechinger et al. 2011), mutagenesis studies indicated that the STAS domain is indispensable both for proper membrane targeting (Navaratnam et al. 2005; Zheng et al. 2005) and for protein function (Bai et al. 2006) in prestin and in other SLC26 transporters (Sharma et al. 2011). How the cytosolic domain affects eM or transport function is yet unknown. Nevertheless, as also found with other SLC26 transporters (Ko et al. 2004), the STAS domain is implicated in the interaction of prestin with other proteins including MAP1S (Bai et al. 2010) and calmodulin (Keller et al. 2014; see Sect. 5.4.2).

Although the prestin sequence is generally highly conserved across mammalian species, parallel or convergent evolution of the prestin gene has been discovered in echolocating bats and whales (Li et al. 2010; Liu et al. 2010). Thus, the same amino acid substitutions are found specifically in these phylogenetically unrelated lineages of echolocating mammals. Most of these sites cluster in the cytoplasmic C-terminus including the STAS domain (Li et al. 2010; Liu et al. 2010). Some of these residue replacements were found to modulate the voltage dependence of prestin (Liu et al. 2014), but the physiological consequences of these specific molecular traits are unknown. Given the parallel occurrence in echolocating species that use particularly high frequencies, it has been speculated that these amino acid changes may support the function of prestin in ultrasonic hearing (Li et al. 2010; Liu et al. 2010).

5.3.2 *Molecular Structure of Prestin*

Two papers in 2014 and 2015 revealed the molecular structure of SLC26/SuIP transporters and of prestin in particular. Gorbunov et al. (2014) used a homology modeling approach based on the X-ray crystal structure of the bacterial uracil transporter UraA (Lu et al. 2011), which belongs to the NCS2 family of nucleobase/cation symporters, as the template. Although direct sequence conservation between UraA and prestin (or other mammalian SLC26 members) is low, advanced remote homology detection methods indicate that SLC26/SuIP and NCS transporters are directly related, arguing that they share a common molecular architecture (Hoglund et al. 2011; Wong et al. 2012; Vastermark and Saier 2014). Homology models of mammalian and chicken prestin were scrutinized and refined

by molecular dynamics (MD) simulations (Gorburnov et al. 2014), which supported the validity of this conclusion. Soon afterward, this homology model was confirmed by the first experimental atomic structure of a SLC26/SuIP transporter, the bacterial fumarate transporter SLC26Dg from *Deinococcus geothermalis* (Geertsma et al. 2015).

Modeling and X-ray crystallography consistently revealed a 7 + 7 inverted-repeat architecture for the TMD of SLC26 transporters and thus prestin (Gorburnov et al. 2014; Geertsma et al. 2015). As illustrated in Fig. 5.2, the central domain (TMD) of prestin is made up of 14 mostly helical transmembrane (TM) segments of variable length. The two halves (or repeats) of the TMD, each containing seven TM segments, are related to each other by a twofold pseudosymmetry such that they are inversely oriented with respect to the intracellular side. TMs from both repeats are interdigitated with their counterparts from the other repeat (Fig. 5.3a), forming the inverted-repeat organization that is characteristic of many different transporters (Forrest and Rudnick 2009). The topology of prestin was further probed by examining the intra- and extracellular accessibility of

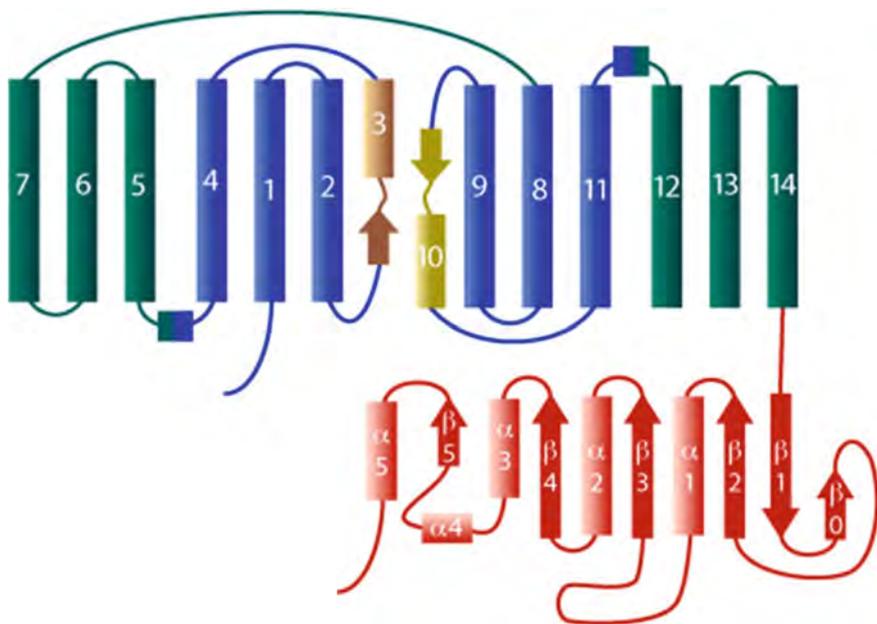

Fig. 5.2 Topology of prestin. The transmembrane domain (TMD) contains 14 largely helical membrane-spanning domains, forming two inverted repeats (TMs 1–7 and TMs 8–14). Colors indicate the three-dimensional structural organization into two main helix bundles, the “core” domain (blue) and the “gate” domain (green). Two central, partially helical and antiparallel TMs within the core domain are highlighted in brown (TM3) and yellow (TM10). Arrows: short β -strand segments. The cytoplasmic C-terminus (red) is mostly folded into a sulfate transporter and anti-sigma factor antagonist (STAS) domain consisting of several α -helical and β -strand segments

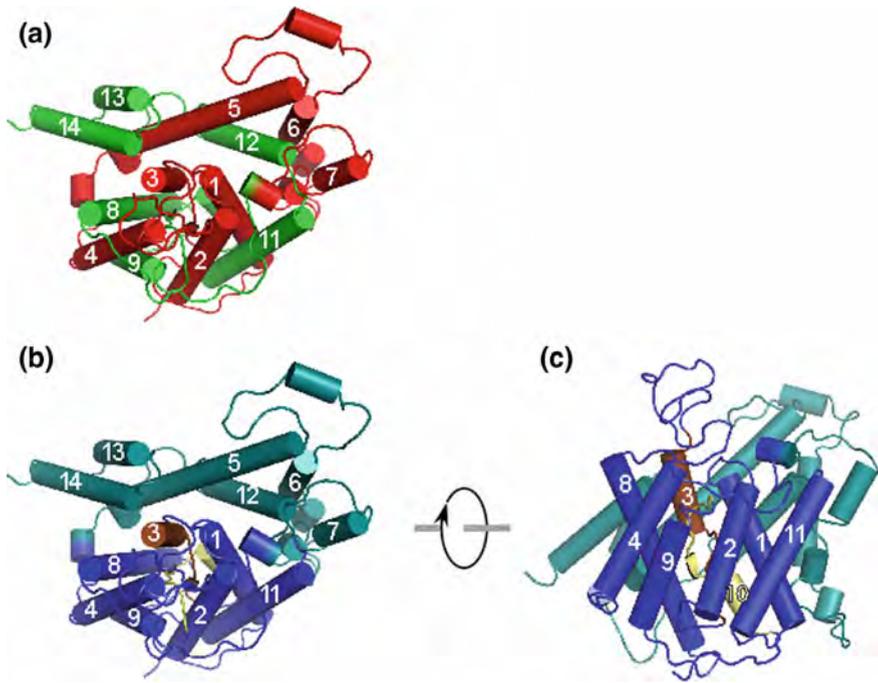

Fig. 5.3 Three-dimensional structure of prestin. **a** Extracellular surface view of overall TMD structure of prestin as derived from homology modeling with the experimental structure of SLC26Dg (Geertsma et al. 2015) as the template. *Red*: inverted repeat I; *green*: inverted repeat II. Transmembrane segments are labeled as in Fig. 5.2; helical part of TM10 is largely hidden by TM1. **b** Same structure colored according to structural organization in core and gate domain. Color code as in Fig. 5.2. **c** Side view

mutationally inserted cysteine residues to cysteine-reactive, membrane-impermeant reagents (Gorbunov et al. 2014). These experiments unequivocally showed that the topology of mammalian prestin is fully consistent with the architecture of the bacterial homolog and the homology model based on UraA.

The TMD is organized into two structural units, each consisting of a bundle of TM helices containing segments from both inverted repeats (Figs. 5.2, 5.3b, c). TMs 1–4 and the pseudosymmetry-related counterpart TMs 8–11 form a compact bundle that has been designated the core domain. TMs 5–7 and 12–14 fold into a more planar (extended) bundle of helices termed the gate domain, which aligns with one side of the core domain, forming an extensive interface between both domains (Fig. 5.3b).

Attempts were also made to address the molecular structure of SLC26A6 and prestin by homology modeling based on the crystal structures of a bacterial chloride transporter, CLC-ec1 (Ohana et al. 2011), or the bacterial amino acid transporter Glt_{PH} (Lovas et al. 2015) as the templates, respectively. However, these approaches produced structures that can now be excluded given the lack of similarity with the

SLC26 crystal structure (Geertsma et al. 2015), disagreement with the experimentally determined topology (Gorbunov et al. 2014), and the lack of a sufficiently close evolutionary relationship between the respective transporter families and the SLC26/SulP family (Hoglund et al. 2011; Vastermark and Saier 2014).

The structure of the cytosolic STAS domain of prestin was solved at atomic resolution both for mammalian prestin (from the rat; Pasqualetto et al. 2010) and nonmammalian prestin (from the chicken; Lolli et al. 2015), revealing an ovoid domain assembled from a central β -sheet surrounded by five α -helices (Fig. 5.2). The core of the domain is structurally similar to STAS domains of bacterial SulP/LC26 proteins and to bacterial ASA proteins, but there are significant differences at the N- and C-termini, most notably an N-terminal extension including some rigid turns and an extra β -strand. Interestingly, the mammalian, but not the chicken, STAS domain harbors an anion binding site, the function of which is yet unknown (Lolli et al. 2015). Given its impact on prestin function, a close structural interaction with the TMD would seem likely. Although Pasqualetto et al. (2010) identified a molecular surface that may interact with either the lipid bilayer or the intracellular face of the TMD, the STAS orientation relative to the TMD remains unknown in the vertebrate SLC26 proteins. In the bacterial SLC26Dg full-length structure, the domain is facing away from the TMD and occupies a position corresponding to the inner lipid bilayer, which is apparently an artifact from cocrystallization with a nanobody (Geertsma et al. 2015). Low-resolution structural data from additional prokaryotic SLC26 homologs suggested that the STAS domain may project away from the TMD (Compton et al. 2014).

5.3.3 *Oligomerization*

Biochemical and low-resolution structural findings indicated that eukaryotic and bacterial SLC26 transporters share a conserved dimeric architecture (Detro-Dassen et al. 2008; Compton et al. 2011, 2014). However, some studies suggest that prestin forms tetramers (Zheng et al. 2006; Hallworth and Nichols 2012). Tetramers might be expected because particles in the lateral membrane of OHCs that are observed by freeze-fracture electron microscopy (EM) and believed to represent native prestin molecules, showed estimated diameters somewhat above 10 nm (Forge 1991; Kalinec et al. 1992). Given the dimensions of an SLC26 monomer of about 4.5×6 nm in the membrane plane (Gorbunov et al. 2014; Geertsma et al. 2015), these EM-resolved particles may correspond to tetrameric prestin assemblies. Also, a low-resolution structure of recombinant prestin, as obtained by a three-dimensional reconstruction based on single-particle EM images, exhibited four-fold symmetry consistent with tetrameric stoichiometry (Mio et al. 2008). It remains to be shown if these observations are due to the formation of higher order oligomers (i.e., dimers of dimers) and, if so, whether tetrameric assembly is important for functional or cell biological behavior.

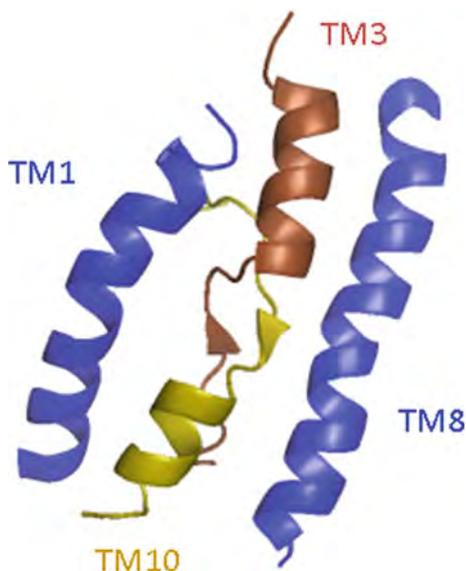

The recent crystal structure of the bacterial SLC26Dg as well as the prestin homology structure provided no direct clues to the structural nature of dimerization. However, Geertsma et al. (2015) noted that the surface of the gate domain (opposite to the interface with the core domain) stood out due to high sequence conservation, which suggested that it may mediate dimerization. Interestingly, a recent crystal structure of the human anion exchanger AE1 (SLC4A1; also known as erythrocyte band 3 protein) showed that SLC4 transporters also share the 7 + 7 inverted-repeat architecture with SLC26 transporters, including an essentially superimposable arrangement of core and gate domains (Arakawa et al. 2015). This is consistent with the fact that together with the NCS2 family, the SLC4 family of bicarbonate transporters is one of the closest SulP/SLC26 relatives as indicated, e.g., by the Pfam database of protein families (Finn et al. 2014). This AE1 structure revealed a dimeric structure mediated by dimerization of the gate domains, lending support to a similar dimeric assembly of SLC26 proteins through the gate domains as proposed for SLC26 by Geertsma et al. (2015).

Although the mechanistic role of oligomerization in the transport or motor function of SLC26 proteins is unknown, for prestin it has been shown that subunits interact functionally, likely by an allosteric mechanism (Detro-Dassen et al. 2008). However, the atomic structure revealed the complete anion binding site and putative translocation pathway within the monomeric subunit (see Sect. 5.3.4), indicating that each subunit is basically functioning as an independent unit rather than forming an oligomeric common transport or motor domain with the other subunit.

5.3.4 Anion Binding Site

The SLC26/prestin structures provided a fresh mechanistic view into the anion dependence of the electromotile activity of prestin and the relationship to the transport function of related SLC26 proteins. Thus, the SLC26 structures feature a central cavity in the TMD, located halfway through the membrane and close to the interface between the core and gate domains. In both computational and X-ray structures, this cavity is accessible to solutes from the cytoplasm but is occluded from the extracellular space. Structural considerations and experimental evidence indicate that this central cavity is the principal binding site for the transport substrate in SLC26 transporters and specifically for the anion that enables eM in mammalian prestin. The pocket is formed largely by the two complementary pseudosymmetry-related, partially helical TMs 3 and 10 and by two complementary TM helices 1 and 8 (Fig. 5.4). Notably, these regions overlap with the Saier motif comprising TMs 9 and 10 (Saier et al. 1999; Mount and Romero 2004; Gorbunov et al. 2014), consistent with the high functional importance of this protein region as suggested by sequence conservation. Moreover, two protein regions previously recognized as molecular determinants of electromotile capability in prestin (Schaechinger et al. 2011) largely coincide with the domains forming the central pocket, further emphasizing the functional importance of these domains.

Fig. 5.4 Anion binding site. Main structural elements that contribute to the proposed central anion binding site. Anions are thought to bind at a central binding site with contributions from the nonhelical segments and the inward-pointing (N-terminal) ends of the partial helices of TMDs 3 and 10

In the crystal structure of the (non-SLC26) transporter UraA, a substrate molecule, uracil, occupies the structurally equivalent central site (Lu et al. 2011). Although the SLC26Dg crystal structure lacked bound substrate, the high similarity to UraA and structural details support the identity of the binding site. The dimensions of the cavity in computational and experimental SLC26 structures are compatible with the range of the substrate anions accepted by SLC26Dg and prestin, respectively (Gorbunov et al. 2014; Geertsma et al. 2015). Furthermore, the N-terminal ends of the partial helices from TM segments 3 and 10 point toward the binding site from opposite directions, providing likely hydrogen-bond partners for the substrate (Geertsma et al. 2015; Fig. 5.4). In UraA, a similar arrangement has been observed, with additional coordination of the substrate by side-chain interactions (Lu et al. 2011). For prestin, Gorbunov et al. (2014) directly tested the role of the structurally corresponding positions by introducing point mutations. Such mutations either altered the anion selectivity of prestin, affected the efficacy of the competitive inhibitory anion salicylate, or abolished function. Similarly, mutations at the homologous positions in transport-competent prestin orthologs from non-mammals (chicken; cPres) altered anion selectivity or abolished transport function (Gorbunov et al. 2014). Altogether, as expected for a transporter, a substrate binding site is located centrally in SLC26 proteins, including prestin. Importantly, the mutational analysis suggested that this same binding site not only mediates transport in SLC26 transporters (including nonmammalian prestin) but also is responsible for the anion-dependence of eM and NLC mediated by mammalian prestin.

How can these structural findings be reconciled with the functional knowledge on prestin? Kinetic analysis of the charge movement and motility of prestin indicated that rapid initial binding of a monovalent anion (chloride) is followed by a

slower transition and, subsequently, by the fast voltage-dependent rearrangement that generates both molecular motion and charge movement (Song and Santos-Sacchi 2013). Given that mutating the binding site disrupts prestin function, a plausible conclusion is that the first fast binding step corresponds to the binding of chloride into the SLC26 substrate binding site.

5.3.5 Electromotile Molecular Transitions

Here we consider the prestin structure in the context of the prevailing area-motor model that postulates (at least) two major states with different cross-sectional dimensions. Although this issue awaits its elucidation, some considerations can be made on the basis of the current knowledge.

Functionally, binding of an anion and a subsequent slower conformational transition appear to precede the mechanically productive fast structural rearrangement in mammalian prestin (Oliver et al. 2001; Song and Santos-Sacchi 2013). The concept of molecular rearrangements following binding of an anion into the central substrate binding site shared with other SLC26 homologs (Gorbunov et al. 2014) has been taken to indicate that the mechanical activity of prestin is mechanistically related to the anion transport cycle (Schaechinger et al. 2011; Gorbunov et al. 2014; Geertsma et al. 2015).

In many secondary transporters, substrate translocation occurs via an alternate access mechanism. Thus, a central binding site is alternately exposed to the extra- and intracellular environment, thereby allowing binding of a substrate on one site and dissociation/release at the opposite site of the membrane (Rudnick 2013). Such a mechanism involves at least one major conformational rearrangement and may additionally involve an intermediate occluded state (Fig. 5.5). For some

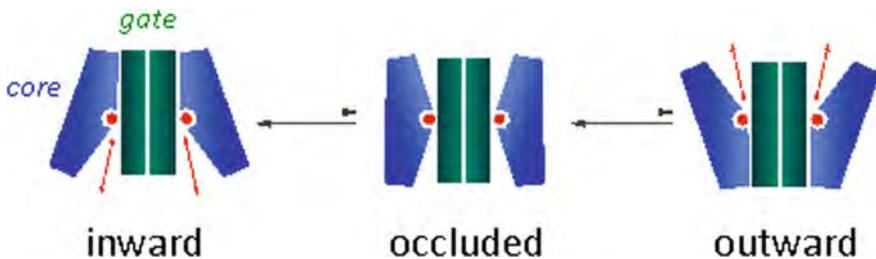

Fig. 5.5 Structural model for anion transport by SLC26. Alternating access of the central anion binding site may result from rotational movement of the core domains against the dimerized gate domains acting as a central scaffold. Experimental crystal structure of SLC26Dg and computational structures of prestin have an inward-facing conformation, but the experimental structure of the structurally homologous exchanger, AE1, revealed an outward-facing conformation (Arakawa et al. 2015). The conformational repertoire of mammalian prestin may be restricted to inward-open and hypothetical occluded states. Modified from Geertsma et al. (2015)

transporters, the conformational change mediating alternate access transport has been structurally resolved. Notably, these transporters also conform to the principle of inverted-repeat architecture, although they are not directly related to SLC26 transporters (Vastermark and Saier 2014). It was shown that there, the conformational switch between inward and outward orientation occurs by a tilting motion between rigid TM bundles (Forrest and Rudnick 2009; Rudnick 2013). For SLC26 transporters, the available structure of SLC26Dg and the UraA-based homology model (as well as the UraA structure itself) describe essentially the same inward-open conformation; therefore, the nature of the molecular rearrangements could not be inferred directly from the structural data (Lu et al. 2011; Gorbunov et al. 2014; Geertsma et al. 2015). However, it has been suggested that a relative motion between core and gate domains mediates transport in SLC26 transporters and UraA (Lu et al. 2011; Gorbunov et al. 2014; Geertsma et al. 2015). Indeed, this idea is strongly supported by the AE1 structure, which revealed an (inhibitor-bound) outside-out state. This structure superposes closely with the UraA and SLC26 structures, with the exception of altered relative positions of core and gate domains (Arakawa et al. 2015). The AE1 structure thus supports the idea of rotation between core and gate domain as the conformational mechanism mediating substrate transport as previously suggested by Gorbunov et al. (2014) and Geertsma et al. (2015; Fig. 5.5). Additional experimental support comes from the finding that a cysteine residue introduced into the central binding site of the transport-active prestin ortholog from chicken is accessible to nonpermeable cysteine-modifying reagents both from the intra- and extracellular sites, consistent with the alternate exposure of this site to both faces of the membrane (Gorbunov et al. 2014).

Given that anion binding into the central binding site in prestin enables eM, it is tempting to speculate that (voltage-dependent) motor activity arises from subsequent conformational transitions equivalent to those mediating anion translocation in other SLC26 transporters (Schaechinger et al. 2011; Gorbunov et al. 2014; Geertsma et al. 2015). In fact, a chimeric SLC26A5 construct based on the zebrafish prestin ortholog (“synthetic prestin”) has both electromechanical and transport activity, consistent with the idea that the transport cycle may accommodate transitions that produce eM (Schaechinger et al. 2011). Also, observations on native chicken hair cells suggested that even nonmammalian, i.e., transport-competent, prestin orthologs may be able to generate forces sufficient for motions at the cellular scale (Beurg et al. 2013). However, in contrast to the transport-active prestin orthologs, the central binding of mammalian prestin is exclusively exposed to the intracellular side (Gorbunov et al. 2014), which is consistent with its interaction with anions selectively at the intracellular, cytoplasmic side (Oliver et al. 2001; Rybalchenko and Santos-Sacchi 2003b, 2008). In structural terms, this indicated that mammalian prestin is unable to reach a state where the binding site is fully exposed to the extracellular medium (Schaechinger et al. 2011; Gorbunov et al. 2014). Therefore, if eM arises from structural rearrangements similar to those that mediate anion transport, these states should be equivalent to a segment of the transport cycle from the fully inward-open conformation to a state preceding full exposure to the extracellular face (Schaechinger et al. 2011; Gorbunov et al. 2014).

Another open issue is the molecular nature of the voltage sensitivity of prestin. The steepness of the voltage-induced motility or charge movement suggests that roughly one elementary electrical charge is moved across the electrical field of the membrane to drive electromechanical activity (Santos-Sacchi 1991). Either exchanging the prevalent intracellular monovalent anion (Oliver et al. 2001) or neutralizing the charged amino acids by mutation (Bai et al. 2009) affects the steepness of the voltage dependence of prestin. Accordingly, anions or polar protein domains have been postulated as extrinsic or intrinsic voltage sensors, respectively. Structural identification of the mechanically effective conformational rearrangements should help to identify the molecular nature of the voltage sensor. Understanding the dynamic electromechanical behavior on this structural level will be one of the most fascinating challenges for future work on prestin.

5.4 Interaction of Prestin with Its Cellular Environment

5.4.1 *Localization of Prestin Along the Basolateral Wall*

After the identification of prestin (Zheng et al. 2000), immunolocalization studies showed the protein along the basolateral surface of OHCs (Belyantseva et al. 2000; Yu et al. 2006). These observations were presaged by electrophysiological localization of motor activity along the lateral membrane (Kalinec et al. 1992; Dallos et al. 1993; Huang and Santos-Sacchi 1993). This localization pattern has important physiological significance because the electromotile force generated by prestin is directed along the longitudinal axis of these elongated cells (Holley and Ashmore 1990; Holley et al. 1992; Matsumoto et al. 2010). It is believed that the unusual structure of the lateral wall of the OHCs, encompassing a prestin-containing plasma membrane, the underlying cortical cytoskeleton, and subsurface cisternae, plays a critical role in eM. The plasma membrane is connected to the underlying cytoskeleton by “pillars,” ultrastructurally identified electron-dense entities (Holley and Ashmore 1990; Forge 1991). Nonetheless, the molecular links of prestin to the underlying cytoskeleton are unknown.

The delivery of prestin to the basolateral wall of OHCs has several potential confounding mechanisms. Protein sorting has been best studied in polarized epithelial cells, where work has established a dichotomy of targeting to the apical or basolateral surface. Although hair cells are polarized epithelial cells, they also show properties of neurons, with an apical-receptive area housing the mechanosensitive channels corresponding to a dendritic end and a basal pole housing the synaptic machinery that corresponds to a neuronal axonal end. A long-standing hypothesis first proposed by Dotti and Simons (1990) posited the dendritic end of a neuron to be equivalent to the basolateral surface and the axonal end to correspond to the apical end of polarized epithelial cells. Hair cells, however, confound this neat

division. Thus, hair cells have to be categorized in terms of protein sorting as either epithelial cell-like or neuronal-like.

It has long been established that classic basolateral markers such as β -catenin and Na^+/K^+ -ATPase are localized along the basolateral surface of hair cells (Schneider et al. 1987; Leonova and Raphael 1997; Zhang et al. 2015). Zheng et al. (2010) demonstrated that stereociliary proteins, including harmonin and cadherin 23, are targeted to the apical surface of the CL4 cell, a model polarized epithelial cell. The authors also established that prestin was targeted to the basolateral surface of CL4 cells. These data confirm that, at least for these proteins, hair cell protein-sorting mechanisms are akin to those of polarized epithelial cells. Interestingly, using the apically targeted pendrin as a vehicle, Zheng et al. (2010) showed that basolateral targeting of prestin is determined by the C-terminus of prestin. Using site-directed mutagenesis, Zhang et al. (2015) established that two tyrosine residues, Y520 and Y667, are important for targeting prestin to the basolateral surface of polarized MDCK cells. Moreover, these authors demonstrated that this targeting is also dependent on AP μ 1-B, which is present in hair cells (and epithelial cells) but absent in neuronal cells (Zhang et al. 2015).

5.4.2 *Prestin's Interactome*

As alluded to in Sect. 5.2, the identity of prestin as the protein responsible for OHC eM has been well established. Recent efforts have also focused on identifying the role of ancillary proteins in the function of prestin. Because prestin has all the molecular features of the motor responsible for eM, this raises the question, Why look for other associated proteins? The response to this lies in three parts. First, in parallel with other systems, in particular ion channels, ancillary proteins modify the biophysical properties of the protein while establishing its localization and transport between different vesicular compartments as well as modifying its rates of turnover. Thus, protein partners may play a similar role with prestin. Second, although many of the biophysical attributes of prestin in OHCs are comparable to those of prestin expressed in heterologous cells, important discrepancies exist (for instance, the V_h of prestin in OHCs lies between -40 and -80 mV, whereas prestin in heterologous cells consistently shows more negative V_h values). Third, although prestin is clearly responsible for eM, there is evidence that links to the underlying cytoskeleton are important for harnessing forces generated by prestin along the longitudinal axis of the cell (Holley and Ashmore 1990; Holley et al. 1992; Matsumoto et al. 2010). How this is brought about is still unknown.

5.4.2.1 **Vesicle-Associated Membrane Protein**

To date, many proteins that interact with prestin have been identified, although definitive interactions and a clear physiological role have yet to be defined for the

vast majority of these proteins. An initial membrane yeast two-hybrid screen identified several proteins as potential prestin interactors (Zheng et al. 2009). Chief among these interacting proteins were those known for transport between different vesicular compartments. These include vesicle-associated membrane protein, vesicle-associated protein A (VAPA), and Yip1 domain family member 6 (Yipf6; Zheng et al. 2009). Association with VAPA, important for integrity of the endoplasmic reticulum (ER), was found to increase the surface expression of prestin. Interestingly, the effect seemed reciprocal, with decreased amounts of VAPA in prestin-knockout OHCs (Zheng et al. 2009). Although a role for Yipf6 in prestin transport has not been demonstrated, its closest yeast homolog, Yip1p, has been demonstrated to be important for Rab-mediated transport from the ER to the Golgi apparatus (Matern et al. 2000; Barrowman et al. 2003; Spang 2004). Yipf6 mutants have intestinal inflammatory disease, although a clear mechanism has yet to be identified and a hearing phenotype has not yet been defined (Brandl et al. 2012). A second group of proteins (38%) identified by the membrane yeast two-hybrid screen included several mitochondrial membrane proteins (cytochrome *b*, subunits of NADH-ubiquinone oxidoreductase, and ATP synthase 6; Zheng et al. 2009). Mitochondrial proteins are known to be nonspecific interactors in yeast two-hybrid screens. In their screens, mitochondrial proteins were a dominant fraction, and they saw no interactions between mitochondrial proteins and the tip-link protein cadherin 23, arguing against a nonspecific interaction. OHCs from prestin knockouts and knock-in mice with altered voltage sensitivity showed early cell death. Actual measures of mitochondrial dysfunction in prestin knockouts have, however, yet to be demonstrated.

5.4.2.2 Cystic Fibrosis Transmembrane Conductance Regulator

The cystic fibrosis transmembrane conductance regulator (CFTR) was identified by Homma et al. (2010) as interacting with prestin. Interest in the CFTR was piqued because a lateral wall conductance that carries Cl^- has been identified in OHCs (Rybalchenko and Santos-Sacchi 2003b) and because Cl^- is a critical modulator of prestin activity (see Sect. 5.2.5). Like the lateral wall Cl^- conductance, the CFTR also shows mechanosensitivity (Zhang et al. 2010). The CFTR has been shown to interact with a number of other SLC26 family members through their STAS domain (Ko et al. 2004). Although many of these interactions are dependent on PKA phosphorylation of the CFTR R domain, the interactions also result in a mutual activation of CFTR and SLC26 transporter activity (Ko et al. 2004). Homma et al. (2010) convincingly showed interactions between prestin and the CFTR (although the interaction is not dependent on PKA phosphorylation). They also showed that the presence of prestin results in the localization of CFTR from its exclusively apical location to a partial basolateral location in OHCs. Unexpectedly, however, there was little reciprocal functional effect on prestin or the CFTR in OHCs; no effects on NLC or CFTR conductance were observed. In contrast, the interaction in heterologous cells results in enhanced prestin charge movement in response to PKA

activation; a reciprocal enhanced effect on CFTR conductance was not demonstrable in the presence of prestin. Although the findings of the CFTR in the lateral membrane of OHCs in the presence of prestin is intriguing, a physiological role for the CFTR in OHCs has yet to be established. Blockers of CFTR had no effect on OHC lateral wall Cl^- conductance (Rybalchenko and Santos-Sacchi 2003b). Furthermore, mutations of CFTR that causes cystic fibrosis are not associated with hearing defects. Hearing phenotypes in these patients have been well studied, and sensorineural hearing loss was described only in the context of toxic levels of gentamicin that is used for treating repeated pulmonary infections in these patients (Homma et al. 2010).

5.4.2.3 Calmodulin

A recent paper by Keller et al. (2014) identified calmodulin as an interactor of prestin. The identity of calmodulin as an interactor was determined after initial assessments showed intrinsically disordered regions in the C-terminus of prestin in proximity to its STAS domain (Keller et al. 2014). Intrinsically disordered regions have been shown to interact with calmodulin, and Keller et al. (2014) go on to show that prestin binds to calmodulin using these regions in a Ca^{2+} -dependent manner. Importantly, they show a 35-mV shift in V_h with increasing Ca^{2+} , an effect that was reversed by the calmodulin inhibitor trifluoperazine (Keller et al. 2014). The authors then speculate that the Ca^{2+} -induced changes in V_h could have physiological importance, with efferent modulation from the olivocochlear bundle effecting changes in OHC stiffness through increases in Ca^{2+} . These interpretations may not be complete, with changes in V_h induced by Ca^{2+} perfusion being secondary to the effects on turgor pressure and not entirely due to the effects on V_h by a direct effect from calmodulin binding to prestin. Thus, the changes in V_h were not evident when the cells were collapsed before Ca^{2+} perfusion (Song and Santos-Sacchi 2015).

5.4.2.4 Microtubule-Associated Proteins

Microtubule-associated protein 1S (MAP1S) is a protein that was identified as interacting with prestin using a conventional Gal4-based yeast two-hybrid assay (Surguchev et al. 2012). In this assay, the C-terminus of prestin was used as bait. MAP1S is a member of the microtubule-associated protein family. MAP1S coexpression enhanced the surface expression of prestin as established by both biochemical and electrophysiological measures (Surguchev et al. 2012). These findings are paralleled by a gradient of MAP1S mRNA expression along the tonotopic axis, suggesting that MAP1S may bring about the higher amounts of prestin in the plasma membrane of high-frequency hair cells. Interestingly, MAP1S has also been shown to interact with actin, and its concentration in proximity to the lateral wall of OHCs raises the possibility that it serves as the link between prestin and the underlying cytoskeleton. As previously referred to, the lateral wall of OHCs

includes a cortical cytoskeleton sandwiched between subsurface cisternae and the lateral plasma membrane. The cortical cytoskeleton consists of circumferentially arranged actin filaments linked to longitudinally arranged spectrin ($\alpha 2$, $\beta 5$) filaments (Forge 1991; Kalinec et al. 1992; Legendre et al. 2008). Previous work identified pillars that are electron-dense entities linking OHC lateral membranes to circumferentially arranged actin filaments (Holley and Ashmore 1990; Forge 1991; Kalinec et al. 1992). The molecular composition of pillars is unknown. Because MAP1S also forms a complex with a host of other actin-binding proteins (Liu et al. 2002; Liu and McKeehan 2002), these data raise the possibility that MAP1S is one component of a complex of proteins that form pillar structures.

5.4.2.5 Spectrin and Spectrin-Interacting Proteins

Although prior reports have shown a concentration of two spectrin-interacting proteins (ankyrin or protein 4.1) along the periphery of OHCs (Knipper et al. 1995; Zine and Schweitzer 1997), the wide gap (50 nm) between the cytoskeleton and the lateral membrane makes it unclear whether these proteins have a physiological role or not (Legendre et al. 2008). Moreover, there are no data showing a direct interaction between prestin and ankyrin or protein 4.1. Interestingly, a paper identifying $\beta 5$ spectrin as a component of the OHC cytoskeleton showed no interaction between prestin and this spectrin isoform (Legendre et al. 2008). However, these authors found an unknown component in OHC lysates that enabled such an interaction. A key area of research in the future will be exploring the interactions between prestin and other components of the lateral wall.

5.4.2.6 Calcium/Calmodulin-Dependent Serine Protein Kinase

A subsequent study using yeast two-hybrid screens identified calcium/calmodulin-dependent serine protein kinase (CASK) as an interacting partner of prestin (Cimerman et al. 2013). CASK is a membrane-associated guanylate kinase (MAGUK). Members of this family have been shown in other systems to bind membrane proteins linking them to actin through protein 4.1 (Zhu et al. 2016). The subcellular distribution of CASK showed a developmental change that correlated with prestin and was affected by thyroid hormone levels. Normally, by postnatal day (P) 18, both NLC and eM reach mature levels. In hypothyroid animals, there is a delay in the expression of prestin, with NLC levels taking until P28 to reach normal levels. Prestin is normally expressed along the entire basolateral surface early in development and is then localized predominantly along the lateral wall while being largely excluded from the basal pole. In contrast, CASK is found predominantly at the basal pole where OHCs contact Deiters cells. In hypothyroid animals, CASK is expressed at low levels, with prestin expressed over the entire basolateral surface at P28. Coincidentally, although NLC levels were normal, eM responses were markedly reduced. Zhu et al. (2016) reasoned that the interactions

with CASK may be involved in the redistribution of prestin to the lateral wall and in generating force, possibly through the cytoskeleton or OHC interactions with Deiter's cells.

5.4.3 Prestin in the Membrane Environment

It is becoming increasingly appreciated that an interplay of membrane structure, organization, and mechanics regulates the function of membrane proteins. It is thus important to understand how the membrane environment affects the function of prestin. From a thermodynamic point of view, the lipid environment is the “solvent” in which prestin operates, just as water is the solvent for biochemical reactions. Thus, changes in the composition, fluidity, and mechanical properties of the membrane can all affect the molecular function of prestin. At the same time, prestin has a large C-terminus that contains a STAS domain possessing a number of potential protein-protein interaction motifs. It is reasonable to postulate that the STAS domain connects prestin to the cytoskeleton of the cell and places constraints on its mobility. Understanding these supramolecular interactions of prestin is necessary to ultimately understand how the molecular nanoscale events that occur in the prestin protein proper result in the mesoscale rearrangements that must ultimately be responsible for OHC eM.

5.4.3.1 Prestin as a Mechanosensitive Protein

After the original discovery that the membrane capacitance of the OHC was sensitive to membrane stress (Iwasa 1993), the tension sensitivity of prestin was further characterized in both OHCs and HEK cells expressing prestin (Kakehata and Santos-Sacchi 1995; Ludwig et al. 2001; Santos-Sacchi et al. 2001). These studies implied that the application of mechanical force results in a geometric rearrangement in prestin that, in turn, affects its ability to move charge in response to voltage changes, establishing prestin as similar to mechanosensitive channels such as MscL, Piezo1, and TREK1 (Sukharev et al. 1996; Coste et al. 2010; Brohawn et al. 2014). Given that the OHC is under turgor pressure, this mechanical sensitivity is likely to be physiologically important.

The question may be raised as to how prestin senses membrane mechanical forces. Membranes are thin structures that have a large resistance to changes in surface area but a very small resistance to changes in curvature. Curvature stress can be induced by differential partitioning of molecules into the two leaflets of the membrane, corresponding to the classic “bilayer couple” explanation of red blood cell shape changes (Singer and Oster 1992). It has become increasingly appreciated that many mechanosensitive membrane proteins sense mechanical force through the lipid bilayer in accordance with the “force from lipid” principle (Anishkin et al. 2014). Forces may be applied to the lipid bilayer by stretching the area or through

the direct or indirect application of membrane curvature stress. Indeed, many reagents that affect prestin function are also known to change membrane curvature (Oghalai et al. 2000; Brownell et al. 2001). It has been postulated that in the intact OHC, turgor pressure would supply a force leading to nanoscale bending of the membrane between the pillar proteins (Raphael et al. 2000; Spector et al. 2006). Although this is difficult to directly measure in living cells with current technology, measurements using fluorescence polarization microscopy (Greeson and Raphael 2009) are consistent with both the existence of nanoscale curvature and pharmacological-induced changes in this curvature. Specifically, reagents that changed the curvature in opposite directions were found to be consistent with the corresponding changes in the function of prestin as measured by the Boltzmann parameter (V_h) of the NLC (Fang et al. 2007; Greeson and Raphael 2009). Other studies have obtained evidence that prestin is also sensitive to the thickness of the membrane (Fang et al. 2010).

One of the challenges in prestin research has been the lack of pharmacological compounds that inhibit its function. This is an also issue for other mechanosensitive proteins such as MscL (Hamill 2006). The most utilized inhibitor of prestin function is salicylate, an active metabolite of aspirin related to nonsteroidal anti-inflammatory drugs (NSAIDs). NSAIDs and analgesics are associated with ototoxicity, hearing loss, and tinnitus (ringing in the ears). In other membrane proteins, NSAID effects have been attributed to both indirect effects on membrane properties and direct binding to functional regions of proteins (Lichtenberger et al. 2006; Manrique-Moreno et al. 2009). Additional research is needed to identify specific inhibitors of prestin function.

5.4.3.2 Prestin as a Confined Protein

The original fluid-mosaic membrane model proposed that proteins diffuse freely in a sea of lipids (Singer and Nicolson 1972). This picture has been refined by the discovery that different proteins have varying degrees of confinement in the membrane. In the membrane biophysics community, many concepts such as “membrane microdomains” and “lipid rafts” have been espoused to characterize the restricted mobility of membrane proteins. Here, the important questions are, Can prestin diffuse freely or is it constrained? If it is constrained, does this occur through interactions with the cytoskeleton?

The lateral diffusion of prestin was first directly measured using fluorescence recovery after photobleaching (FRAP) in HEK cells expressing prestin (Organ and Raphael 2007). These studies revealed that the diffusion of prestin is relatively slow when compared with proteins of similar molecular weight. In addition, using a dual-bleach protocol, these studies suggested that prestin was transiently confined. To confirm transient confinement and better understand the membrane dynamics of prestin, single-molecule imaging studies were performed (Kamar et al. 2012). Individual molecules of prestin labeled with a highly stable fluorophore were expressed in HEK cells and tracked using total internal fluorescence microscopy.

These studies confirmed that prestin is indeed confined in the membrane and undergoes anomalous diffusion (Kamar et al. 2012). The results could be fit to a “hop-diffusion” model in which prestin molecules diffuse within a limited area, then “hop” to a different area of the membrane. In this model, there is a timescale associated with confinement that corresponds to the strength of the intermolecular interactions restricting free diffusion of the protein. These studies raised the question of how prestin diffuses in the native OHCs. Later studies in knock-in mice expressing prestin fused to yellow fluorescent protein (YFP) obtained results consistent with the minimal diffusion of prestin in OHCs as measured with traditional FRAP (Yamashita et al. 2015). When compared with the HEK cell single-molecule results, it appears that OHCs contain additional mechanisms that further confine prestin (Yamashita et al. 2015). This raises the question whether robust electromechanical activity seen in OHCs as opposed to HEK cells could be related to the presence of additional interactions that limit the membrane lateral mobility of prestin, i.e., whether membrane confinement has implications for prestin function. One of the key ways to alter the confinement of membrane proteins is to manipulate membrane cholesterol, which changes the structure of membrane microdomains. Depletion of membrane cholesterol with MBCD was shown to have a dramatic impact on prestin confinement (Kamar et al. 2012). Taking into account an earlier study that indicated that cholesterol affects the Boltzmann parameter (V_h) of the NLC in OHCs (Rajagopalan et al. 2007), it suggests that alterations in prestin confinement affect at least the operating voltage range of prestin. Similar cholesterol depletion experiments were also carried out in the knock-in mouse model (Yamashita et al. 2015), but here the addition of salicylate was also required to enable prestin to undergo free membrane diffusion. Identifying the molecular mechanisms responsible for prestin confinement and understanding whether they affect prestin function is an important priority for future research.

5.5 Conclusions and Open Questions

Gaining a molecular and cellular understanding of eM function has been the major driving force for the research summarized above. Considering the major advances achieved over the last decade, a mechanistic framework for prestin function is finally emerging.

Only recently have experimental and computational data on the structure of prestin and its relatives been obtained. Yet, these findings already provide unprecedented insights and show remarkable agreement between structure and the wealth of biophysical data assembled since the discovery of eM. This initial structural picture of prestin should now provide a productive ground for well-directed structural and functional approaches toward understanding how molecular conformational dynamics generate eM. Given this goal, it should be kept in mind that the present structural data provide only a snapshot of one particular state, that many structural details are still missing, and, importantly, that the structure of prestin itself

has not been determined experimentally. Thus, much remains to be explored. Additionally, such work may also provide important insights into the inner workings of other SLC26 transporters, including pendrin, another SLC26 member with high relevance for cochlear homeostasis and pathophysiology.

Structure-function results are consistent with the idea that prestin works as a conformationally constrained alternate access transporter (see Fig. 5.5). In such a model, eM would arise from the transition between distinct states within an anion transport cycle that differ mechanically and electrostatically, in turn rendering prestin mechanosensitive. The conformational transition may result in a change of cross-sectional area as proposed by the prevailing area motor model (Iwasa 1994); alternatively, the tilting motion between helical bundles suggested by the available structural data may also indicate the generation of differential stresses between the two leaflets of the membrane bilayer, consistent with a previously proposed membrane bending model of eM based on flexoelectricity (Raphael et al. 2000).

Beyond these molecular mechanisms, many observations suggest that integration of prestin into a complex cellular structure, i.e., the highly specialized trilaminar lateral wall of OHCs, is important for effectively channeling the molecular movements into the generation of macroscopic cellular eM. Yet, components of this cortical structure as well as how it is assembled and whether prestin is part of it remain unknown. Despite identification of various potential interaction partners of prestin described in this chapter, their involvement in the OHC lateral wall and thus their relevance for eM remain unknown. Other important interaction partners likely await identification. Future work on the function of prestin-associated proteins will not only require elucidation of their ultrastructural localization and molecular interactions within the supramolecular OHC cortex but should also include selective manipulation of these proteins and disruption of their interactions in living OHCs.

It can be anticipated that the molecular and supramolecular characterization of prestin will lead to new approaches for selective alteration of eM that can, in turn, increase our overall understanding of the role of eM in cochlear mechanics (i.e., amplification). Ultimately, research along these avenues will increase our understanding of this unique protein that is so important for our sense of hearing.

An electronmicroscopic study of microtubules in the development of marginal cells of the mouse stria vascularis *

J. Santos-Sacchi

*Auditory Physiology Laboratory, Frances Searle Bldg., Northwestern University, 2299 Sheridan Rd.,
Evanston, IL 60201, U.S.A.*

(Received 22 January 1981; accepted 26 June 1981)

This study provides an ultrastructural evaluation of cytoplasmic microtubules during the maturation of marginal cells of the mouse stria vascularis. Postnatal marginal cells are cuboidal in structure and over a period of days develop the numerous cellular processes typical of transporting epithelia. Immediately after birth, marginal cells contain numerous microtubules randomly oriented throughout the cytoplasm. Golgi bodies and vesicles are also abundant. The initiation of cellular extension is characterized by the presence of sheet-like extensions of plasma membrane about areas of the cell periphery. Subsequently, large organelle-containing processes form, whose plasmalemma appear pleated due to the presence of the above mentioned sheet-like extensions. Typically, these processes contain microtubules oriented parallel to the direction of their extension. Within these processes, microtubules are closely associated with organelles, such as mitochondria, and may function to displace and stratify these organelles within the processes. The number and length of microtubules increase as the processes grow larger. In the adult mouse, the stria marginal cell processes are attenuated and contain almost exclusively microtubules and mitochondria. The membrane pleats unfold, apparently to provide plasma membrane for cellular extension. The data strongly implicate microtubules in stria development. Furthermore, it is suggested that the depolymerization of microtubules in the adult may underlie stria atrophy.

Key words: stria marginal cells; microtubules; development.

Introduction

Cell surface folding is the single common anatomic feature of transporting epithelia [1]. Such folding greatly expands the cell membrane surface area, thereby providing an enhanced ability for membrane transport. The stria vascularis displays numerous interdigitations among its cell components [7,15]. The establishment of this adult stria architecture is prerequisite for the development of the endolymph's ionic composition and electrical potential and, in turn, for normal cochlear function [2,5,8]. Kikuchi and Hilding [9] have shown that the adult stria evolves from a single

* Portions of this work were completed at Mt. Sinai School of Medicine, Department of Anatomy and Otolaryngology, and School for Biomedical Education, City College, City University of New York.

layer of cuboidal marginal cells separated from underlying fibroblasts by a basement membrane. After varying periods of time, depending upon the position along the length of the cochlear duct, the numerous interdigitations characteristic of the adult stria are formed. However, the basement membrane is absent from beneath the marginal cells. The fully differentiated form of the stria vascularis is dependent upon a process of cellular extension.

Recently, Santos-Sacchi [13] noted the abundance of microtubules within the cytoplasm of adult mouse marginal cells and suggested a possible role for microtubules in strial maturation. Microtubules have been shown to be involved in cell shape development. For example, Heywood et al. [6] provided morphologic evidence that microtubules influence cell shape during *in vitro* development of vestibular hair cells. The present study offers a morphologic evaluation of marginal cell cytoplasmic microtubules during the development of strial architecture.

Methods

The preservation of microtubules necessitates the use of aldehyde fixatives; unfortunately, glutaraldehyde fixation of strial tissue induces artifacts such as mitochondrial vacuolation [10,14].

Mice (Balb/cJ) at varying stages from newborn (0, 2, 4, 6, 8, 10 days postnatal) to adult were decapitated, the cochleae dissected out, fractured open and immersed in either 2% or 6% glutaraldehyde buffered with cacodylate (0.1 M), pH 7.4, at room temperature. After 2 h primary fixation, strial tissue from various cochlear turns was microdissected free and post-fixed in cacodylate-buffered 1% osmium tetroxide, pH 7.4, at 0–4°C for 2 h. Samples were rinsed with buffer, rapidly dehydrated in a graded series of acetone, and embedded in Epon at 60°C overnight. Thick sections were cut and stained with toluidine blue for orientation purposes. Gray-silver sections (50–80 nm) were cut with a diamond knife on an LKB Ultratome, stained with lead citrate, and examined with a Zeiss 9S-2 or Philips 300 electron microscope.

Results

Although the onset of marginal cell development proceeds from base to apex over an extended period of time [9], the cellular mechanisms involved are the same regardless of location along the cochlear duct. Areas of transition between developing and immature marginal cells along the duct were chosen for study. As such, marginal cells are characterized by the degree of maturation and not by their location along the duct or by the age of the particular animal.

Prior to the evolution of adult strial structure, marginal cells can be distinguished within the cochlear duct by virtue of their dark cytoplasm. Whereas future intermediate and basal cells generally contain few organelles at this time, marginal cells possess numerous structural elements. Particularly prominent are the Golgi bodies (Fig 1). Microtubules are present in immature cuboidal marginal cells at birth. They

are randomly distributed within the cytoplasm (Fig. 1). This random orientation is preserved in the apical cytoplasm through adulthood, although occasionally microtubules are found perpendicular to the apical plasma membrane in the adult [13].

The initiation of marginal cell development is characterized by the production of small cellular extensions, about 60 nm in width, within which microfilaments may sometimes be distinguished. These extensions occur laterally as well as basally (Figs. 2, 3). Serial sectioning demonstrates that they are sheet-like. Subsequently, large organelle-containing cell processes extend basally (Figs. 2, 3). The plasmalemma of these large processes often appears pleated due to the presence of the smaller sheet-like extensions which decorate the perimeter of the large processes (Fig. 3). Within the processes microtubules are invariably found, frequently oriented parallel to the longitudinal axes of the processes. As the processes increase in size, the number and length of microtubules increase. In fact, microtubules can often be observed coursing for several micrometers within developing cell elongations.

The basement membrane which is present between the cuboidal marginal cells

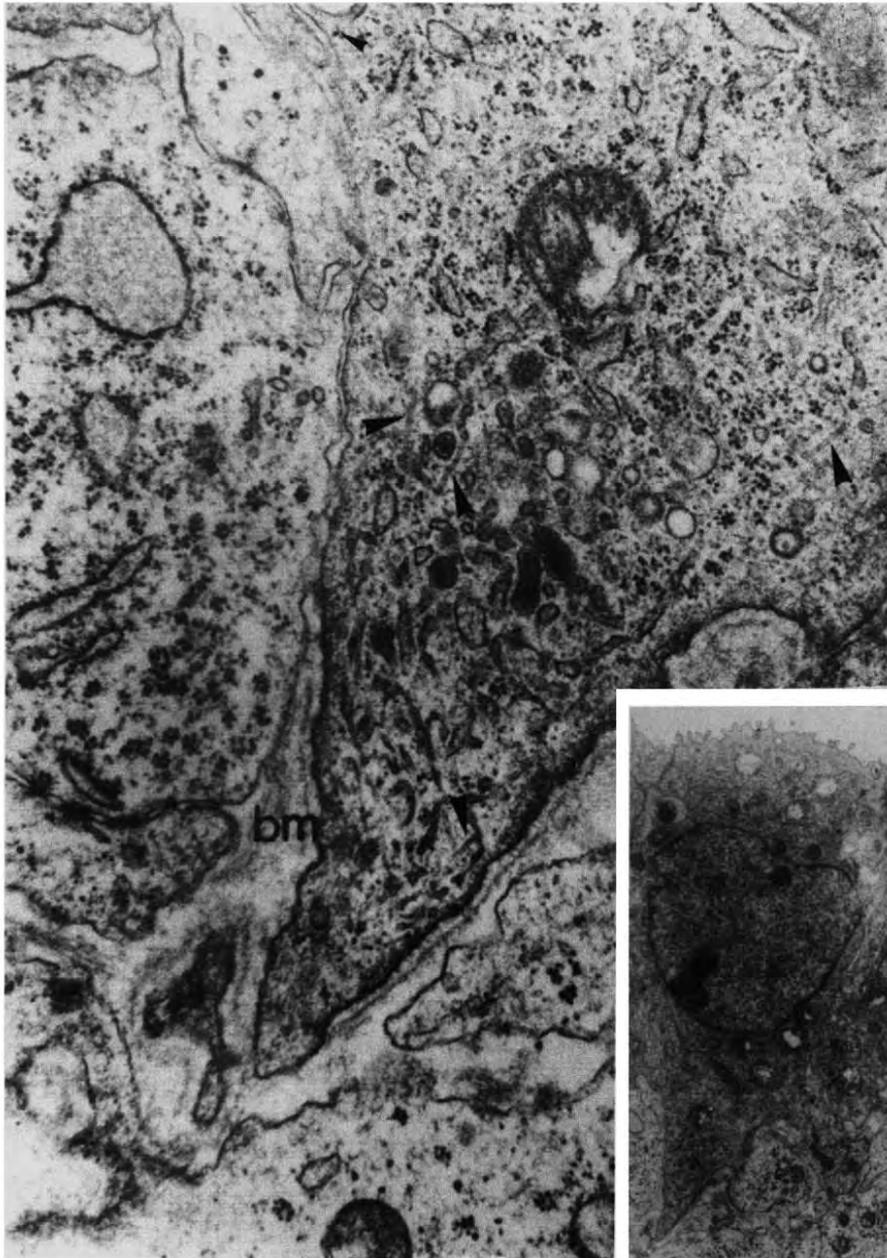

Fig. 2. Early developing cell process of marginal cell. Large arrows indicate microtubules. Small arrow indicates lateral sheet-like extension. bm, basement membrane. $\times 32,000$. Insert: Low-power electron-micrograph of same marginal cell. $\times 4,200$.

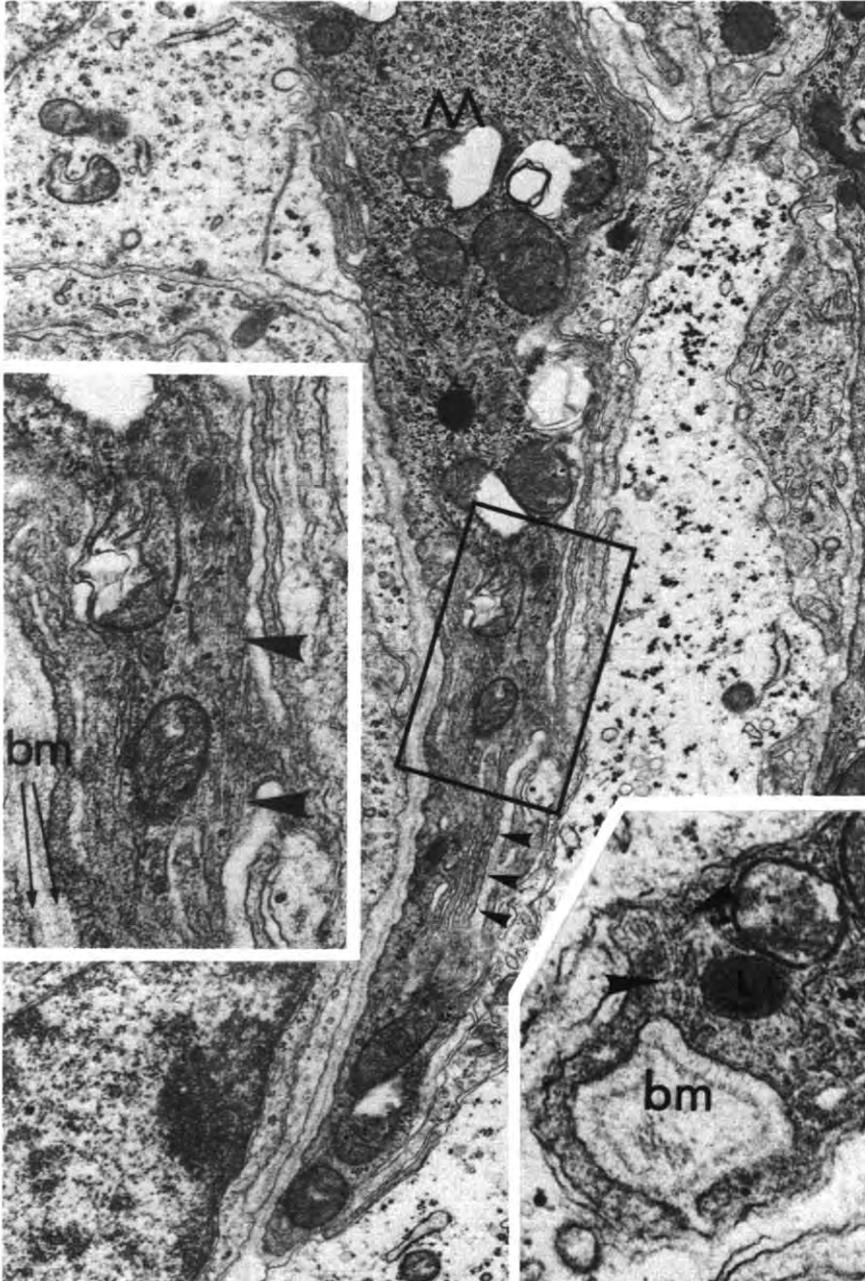

Fig. 3. Cell process (M) of maturing marginal cell abutting strial capillary. Small arrows indicate plicating of plasmalemma of large process by small sheet-like extensions. Insert at left: enlargement of boxed-in area. Note longitudinally oriented microtubules (arrows) and double basement membrane (bm) adjacent to capillary. Insert at lower right shows tip of a different maturing marginal cell process engulfing basement membrane. Note microtubules and lysosome (L). $\times 17000$. Left insert: $\times 34000$. Right insert: $\times 40000$.

and deeper cell layers of the immature stria disappears during maturation. Initially, the basement membrane extends with the developing marginal cell processes (Figs. 2, 3), and occasionally it can be observed within marginal cell invaginations, as if being phagocytized (Fig. 3, insert lower right). Despite this, the absence of a basement membrane in the adult is probably largely due to dispersion and thinning of this structure as a result of the expansive increase of plasma membrane surface area.

Discussion

Numerous researchers have presented evidence that microtubules are important for cellular elongation [3,12]. In addition, microtubules have been implicated in the process of organelle displacement. For example, Raine et al. [11] reported close lateral associations between mitochondria and microtubules within mammalian axons and suggested that microtubules may provide a mechanism for mitochondrial displacement. The close proximity of microtubules to organelles, especially mitochondria, in marginal cell processes may be indicative of such a function. Indeed, such associations apparently promote the stratification of mitochondria within the cell processes, thereby providing the spatial arrangement of energy production sites requisite for fluid transport.

The dramatic increase in cell surface area which accompanies cellular extension necessitates the manufacture and incorporation of new plasma membrane. Accordingly, immature cuboidal marginal cells often contain large amounts of smooth endoplasmic reticulum, Golgi bodies, and vesicles. It is interesting to note that in the adult mouse the typical marginal cell process is extremely attenuated, contains almost exclusively mitochondria and microtubules, and the membrane pleats characteristic of immature cell processes are largely absent [13]. Apparently, as processes extend, membrane pleats unfold. In addition, the number of apical microvilli is drastically reduced in the adult marginal cell, and this process may provide another source of plasma membrane for the rapidly expanding cell surface.

The data presented here indicate an important role for microtubules in strial development. Microtubular integrity may also be required for the morphologic stability of the adult stria. It is known that disruption of microtubules by anti-tubulins can induce the retraction of cell processes [16]. The strial atrophy induced by a number of experimental manipulations, including intermixing of endolymph and perilymph [4] may be related to microtubule effects. Although microtubules have not been studied under such circumstances, electron micrographs of atrophied striae show extensive loss of cellular processes. The study of microtubular integrity under conditions of advancing strial atrophy is certainly warranted.

Short Communication

A re-evaluation of cell coupling in the organ of Corti

J. Santos-Sacchi *

Laboratory of Neurobiology and Department of Anatomy, University of Puerto Rico Medical School, Rio Piedras, PR 00931, U.S.A.

(Received 17 January 1984; accepted 8 March 1984)

Intercellular electrical coupling was assessed in an in vitro organ of Corti preparation using separate electrodes to inject current and record voltage drops in Hensen's cells. The results demonstrate much better coupling among these supporting cells than previously thought. Coupling ratios between adjacent Hensen's cells are greater than 0.6.

electrical coupling, organ of Corti, gap junction

All the supporting cells of the organ of Corti are structurally joined to each other by communicating or gap junctions [2,3,4]. Recently, Santos-Sacchi and Dallos [5], demonstrated that these junctions permit the passage of electrical currents between Hensen's cells. In that study, the degree of electrical coupling between cells was difficult to assess accurately since a single electrode-bridge balance system was used to inject current and record voltage simultaneously. The coupling ratio is defined as the voltage drop in one cell (V_2) divided by the voltage drop due to current injections in a neighboring cell (V_1). Thus, if an inaccurate measure of the voltage drop, V_1 , is obtained due to bridge unbalancing as a result of electrode resistance change, the degree of coupling between cells is misjudged. A decrease of the electrode resistance occurring upon entry into a cell will produce overestimates of coupling ratios; an increase in resistance will produce underestimates. There is evidence that electrode resistance increases intracellularly [6]. This possibility led us to speculate from indirect measures (spatial spread of current studies) that the coupling between supporting cells was greater than that suggested by the

data (see footnote in [5]). This report corroborates that initial speculation.

Cochleas were removed after decapitation of anesthetized guinea pigs. The apical and third turns of the cochlea, lateral wall removed, were placed in one piece into a microscope perfusion chamber. The organ was perfused at a rate of 0.8 ml/min with artificial perilymph, bubbled with O_2 (tissue culture medium M199 with Hank's salts (1.26 mM $CaCl_2$, 1.7 μM $Fe(NO_3)_3$, 5.36 mM KCl, 0.44 mM KH_2PO_4 , 0.81 mM $MgSO_4$, 137 mM NaCl, 4.16 mM $NaHCO_3$, 0.33 mM Na_2HPO_4), pH 7.2, Gibco, Grand Island, N.Y.) and the temperature was maintained near 37°C. Membrane potentials and coupling responses were measured with high-input impedance devices using KCl (3 M) electrodes. Coupling measures were performed by injecting current pulses into one cell through one barrel of a double-barreled electrode, while measuring voltage drops in that same cell with the other barrel and in a neighboring cell with a single electrode.

Immediately after dissection, membrane potentials of the Hensen's cells are low (ca. -20 mV); however, over the next 2–3 h the potentials gradually recover and reach levels which are recorded in vivo (-60 to -80 mV [1,5]). Cell-to-cell coupling occurs throughout this recovery period. Fig. 1 demonstrates electrical coupling between two adjacent Hensen's cells, both with good membrane

* Present address: Dept. of Surgery, Section of Otolaryngology, New Jersey Medical School, Medical Sciences Building H586, 100 Bergen St., Newark, NJ 07103, U.S.A.

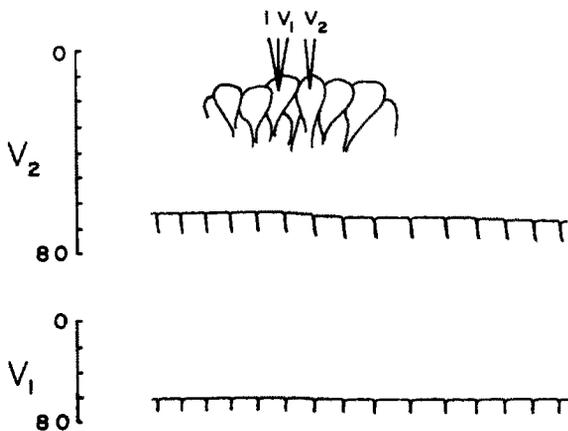

Fig. 1. Under visual control, adjacent Hensen's cells were impaled with 3 M KCl glass microelectrodes. Constant current pulses (-11 nA, 0.5 s) were delivered every 5 s through one barrel of the double-barreled microelectrode. Voltage drops in that same cell and the adjacent cell were measured with voltage recording electrodes. The coupling ratio (V_2/V_1) for this preparation was 0.77 . The organ had been in culture for 2 h when the measure was taken.

potentials. The coupling ratio in this case is 0.77 . Although coupling can be variable, it is usually greater than 0.6 for adjacent cells (5 animals) and is much greater than the estimates previously obtained with the single electrode technique [5]. Input resistance of Hensen's cells in this in vitro preparation is $1-3$ M Ω , one order of magnitude less than previous measures using the single electrode technique.

These results clearly show that electrical coupling among the supporting cells of the organ of Corti is much better than previously thought. It is not clear, however, whether these results are indicative of the in vivo situation. Considering the harsh treatment to the organ necessitated by the in vitro setup, if a difference in coupling did exist, one might expect coupling to be poorer in vitro than in vivo (M.V.L. Bennett, pers. commun.). The fact that membrane potentials are similar in both preparations lends credence to the notion that coupling is also similar. Nevertheless, other factors (e.g. EP, endolymph-perilymph compartmentalization) may be influential in affecting in vivo coupling. In vivo re-evaluations are planned.

The fact that coupling (and space constant) is now known to be substantial provides impetus to

re-evaluate the absence of dye coupling previously reported [5]. It had been suggested then that dye coupling might exist, but that because of slow transfer between cells and dilution within the cytoplasm the dye was impossible to visualize with the experimental setup available. Image enhancement techniques may be necessary to fully evaluate this issue.

The role that such electrical communication may play in an organ whose electrical activity is of paramount functional importance remains unclear. There can be no doubt, however, that supporting cells play a crucial role in inner ear function – perhaps even in sensory transduction. That is, it is inconceivable that the supporting cells do not influence cochlear micromechanics. Supporting cells, as do hair cells, contain contractile and structural proteins [7], which may be modified by ionic conditions. Substantial electrical/ionic communication might provide a means to effectively influence organ of Corti structure and function.

The effects of cytoplasmic acidification upon electrical coupling in the organ of Corti

J. Santos-Sacchi

Department of Surgery, Section of Otolaryngology, MSB 11518, UMDNJ – New Jersey Medical School, Newark, NJ 07103, U.S.A.

(Received 18 February 1985; accepted 8 July 1985)

The supporting cells of the organ of Corti are joined to one another by gap junctions, and electrical coupling among them is known to be good. It is demonstrated here, using an in vitro preparation, that electrical communication between Hensen's cells can be modified by treatments which are known to cause cytoplasmic acidification. Treatment of the preparation with 100% CO₂-saturated medium causes a drop in membrane potential, increase in input resistance, and decrease in steady-state coupling ratio. These measures return to pretreatment levels upon washout of the CO₂ medium. Also, direct injection of H⁺ into a Hensen's cell uncouples that cell from the supporting cell network. An increase in coupling ratio is sometimes observed immediately before and after uncoupling due to CO₂ treatment. In fact, in some cases it is possible to solely increase coupling ratios with limited CO₂ treatments, although prolonged treatment with CO₂ invariably produces uncoupling. This phenomenon may be due to an increase in cell resistance without a change in junctional conductance. A few possible roles for gap junctions in the inner ear are suggested, and the significance of the present results discussed.

carbon dioxide, organ of Corti, cell coupling, gap junction, pH

Introduction

In the latter part of the last decade various groups demonstrated by electronmicroscopy the presence of gap junctions between all the supporting cells of the mammalian organ of Corti [13,17,18]. These results suggested that the supporting cells form a functional syncytium interconnected via low-resistance pathways. This concept was recently confirmed by studies which demonstrated electrical coupling in the supporting cells both in vivo and in vitro [24,25,26]. The supporting cells of the organ of Corti supply physical support for the receptor cells (inner and outer hair cells); and although current concepts of cochlear function rest heavily upon micromechanical interactions between receptor cells [20,35], it is difficult to ignore a possible influence of supporting cells on cochlear micromechanics. In addition, because of the avascular nature of the organ proper, metabolic cooperation between supporting cells may be important in meeting the metabolic de-

mands of the organ of Corti.

Cell-to-cell communication can be modulated experimentally by treatments (e.g. CO₂ treatment) which alter intracellular hydrogen ion activity [31,33]. For example, Turin and Warner [37,38] have shown that cytoplasmic acidification of coupled *Xenopus* blastomeres produces a reversible electrical uncoupling. Subsequently, uncoupling (electrical or dye) due to cytoplasmic acidification has been demonstrated in many cell types [6,7,12,19,22,27].

The pH of the cochlear fluids is near 7.2–7.4 [34], and may be influenced by the very high carbonic anhydrase activity of the inner ear [10]. The pH of the endolymph can be markedly reduced within minutes after the onset of anoxia [4]. Because of the possible importance of hydrogen ion control in the normal and pathologic functioning of the inner ear, the present studies were designed to evaluate the effects of cytoplasmic acidification upon electrical coupling in an in vitro preparation of the organ of Corti.

Methods

Guinea pigs were anesthetized with pentobarbital and killed by decapitation. The cochleas were quickly removed, and the apical and third turn in one piece was microdissected free after removing the spiral ligament and stria vascularis. The preparation was transferred to a perfusion chamber on a Nikon Diaphot inverted microscope. Alternately, the whole temporal bone was placed in a perfusion chamber on a Zeiss ACM microscope, and the bony capsule around the two most apical turns chipped away. The stria vascularis and spiral ligament were removed. In some instances membrane potentials of the Hensen's cells were measured before and after the removal of the stria vascularis and spiral ligament. Both chambers were maintained near 37°C with Peltier devices (Bailey Instruments, NJ). Medium 199 (with Hanks' salts (1.26 mM CaCl₂, 1.7 μM Fe(NO₃)₃, 5.36 mM KCl, 0.44 mM KH₂PO₄, 0.81 mM MgSO₄, 137 mM NaCl, 4.16 mM NaHCO₃, 0.33 mM Na₂HPO₄; for HEPES-buffered media (25 mM) and high K⁺ media, NaCl was adjusted to maintain tonicity), pH 7.2–7.4, Gibco, NY; in some experiments gassed with 100% oxygen) was perfused at a rate of 0.8–1.5 ml/min. Electrodes were pulled on a Narishige puller.

Coupling measurements were made with high input impedance devices (WPI KS-700, Dagan 8100-1) capable of constant current injection. Coupling was assessed by injecting negative current pulses of varying magnitudes into one cell and noting the voltage drop in the same and an adjacent cell. Under visual control, Hensen's cells were impaled with electrodes; four electrode techniques were used to record from Hensen's cells. (1) Single-barreled electrodes were inserted into adjacent or neighboring cells. Using bridge balance techniques, the voltage drops in the two cells (V_1 , V_2) were measured in response to current injection in one (I_1). Alternately, a sampling technique using the switched current clamp mode of the Dagan 8100-1 was used to obtain the voltage drop in the current injected cell (V_1). Using this sampling technique, measurement of V_1 was obtained without contamination from electrode voltage drop. (2) Double-barreled electrodes or theta glass electrodes were used to separately inject current

(I_1) and record voltage drops (V_1) in one cell, while a neighboring cell was impaled with a single-barreled voltage recording electrode (V_2). (3) Patch-type electrodes (140 mM KCl, 2 mM MgCl₂, 5 mM EGTA, 10 mM HEPES, pH 7.2) were used to suck into adjacent Hensen's cells. These electrodes permit the rapid exchange of electrode fluids within the cell interior. The switched current clamp was used in these cases. (4) Three separate electrodes were used: one for current injection (I) in one cell, one for voltage recording (V_1) in a cell nearby, and another for voltage recording in a cell more distal (V_2).

Coupling responses, membrane potentials, and current magnitude were recorded on a Gould four channel recorder. In some experiments extracellular pH was measured and recorded as well. Current pulses were generated by an A/D converter controlled by an IBM PC/XT. Coupling ratios were either determined offline, by visual inspection of the records, or online using a Data 6000 waveform analyzer (Data Precision, MA) in conjunction with the IBM. Individual coupling responses were digitally stored within the Data 6000 and saved to disk.

Coupling ratio is defined as the voltage drop in cell 2 divided by the voltage drop in cell 1 in response to current injection in cell 1 (V_2/V_1) [2]*. CO₂ effects were evaluated by measuring the changes in steady state coupling after introducing various amounts of 100% CO₂-saturated medium into the perfusion system, followed by a return to normal medium. Control perfusions of media buffered to low pH levels were performed to evaluate the effects of extracellular acidification. HCl- (0.1M) filled electrodes were used to evaluate the effects of intracellular ionophoretic injection of hydrogen ions. High K⁺ solutions (70 mM) were perfused through the cell chamber in order to evaluate the effects of depolarization on coupling.

* In a two cell system, coupling ratio is determined by $R_{m2}/(R_j + R_{m2})$, where R_{m2} is the membrane resistance of cell 2 and R_j is the junctional resistance between cells 1 and 2. Thus, changes in coupling ratio may occur due to changes in membrane and/or junctional resistance. Whereas it is possible to calculate membrane resistance and junctional conductance in a two cell system, from experimentally determined input and transfer resistances, it is not possible to do the same for a cellular syncytium (see [2]).

Results

Electrical coupling in the supporting cells of the organ of Corti, utilizing Hensen's cells as a model, is very good. Frequently, coupling ratios greater than 0.8 are found between adjacent Hensen's cells (Fig. 1). It was previously reported that the membrane potentials of Hensen's cells in vitro (-63 ± 10 mV; $n = 111$; [26]) are very close to those obtained in vivo when in vitro recordings are made by passing electrodes through Reissner's membrane in the intact cochlear duct. After removal of the stria vascularis and spiral ligament, however, membrane potentials are dramatically reduced, but subsequently recover during the next few hours of incubation. For example, in a series of 9 preparations the membrane potential was -32 ± 10.9 mV ($n = 27$) at the beginning of the experiment, and within a few hours the membrane potential recovered to -58.96 ± 8.99 mV. Despite low membrane potentials at the outset, coupling is present.

Treatment with CO₂-saturated medium disrupts electrical communication between Hensen's cells. Fig. 2a demonstrates the effects of a 45 s bolus of

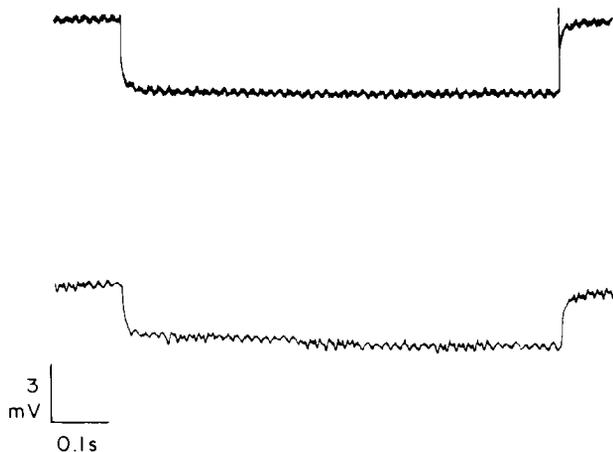

Fig. 1. Neighboring Hensen's cells, separated by one intervening cell, were impaled with electrodes. The traces were digitally stored and plotted. The top trace is of a cell with a membrane potential of -62 mV into which a 0.8 s current pulse of -10 nA was injected through one barrel of a theta glass electrode. The resulting voltage drop measured through the other barrel indicates an input resistance of 0.7 M Ω . The membrane potential of the neighboring cell depicted in the bottom trace is -60 mV and the coupling response measured indicates a coupling ratio of about 0.8.

CO₂-saturated medium injected into the perfusion system. Coupling ratio in this example is initially greater than 0.6. When the CO₂ medium enters the cell chamber, indicated by the drop in extracellular pH, several changes in steady-state conditions are noted. Initially, cell membrane potentials depolarize, in this case 25–30 mV, relative to resting potentials. The voltage drop due to -5 nA current pulses in cell 1 indicates that cell input resistance increases, and concurrently, electrical communication between the two cells decreases, as indicated by the coupling ratio. As the extracellular CO₂ is washed away, and presumably intracellular pH returns to normal, membrane potentials, input resistance and coupling ratio return to pretreatment levels. This uncoupling procedure is repeatable upon further exposures to CO₂-saturated medium. Fig. 2b presents individual coupling responses during a similar uncoupling event. The top two traces show the voltage drops in cell 1 and 2 in response to a -10 nA pulse in cell 1. The coupling ratio is 0.66. The bottom measures were taken at the maximum point of uncoupling after a 40 s bolus of CO₂ medium. The coupling ratio at this point is 0.22. Equivalent perfusions of the organ with low pH-buffered media produced neither depolarizations nor uncoupling, although in one case of prolonged exposure a slight increase in coupling ratio occurred.

Direct acidification of Hensen's cell cytoplasm can be accomplished by intracellular ionophoretic injection of H⁺ ions. Injection into one cell of a neighboring pair uncouples only the injected cell; other neighboring cells in the tissue network remain coupled. Fig. 3 demonstrates the uncoupling effect of H⁺ injection. It can be seen that in response to injection of H⁺ the coupling response in the adjacent cell decreases, followed by recovery. Associated with the increase in intracellular hydrogen ion activity is a drop in membrane potential. On many occasions injection of H⁺ caused complete irreversible uncoupling, associated with lasting depolarization of the injected cell. Suction into Hensen's cells with patch pipets containing acidic solutions also demonstrated a drop in coupling associated with depolarization.

Fig. 4 again shows uncoupling, accompanied by membrane depolarization and increased input resistance following treatment with CO₂-saturated

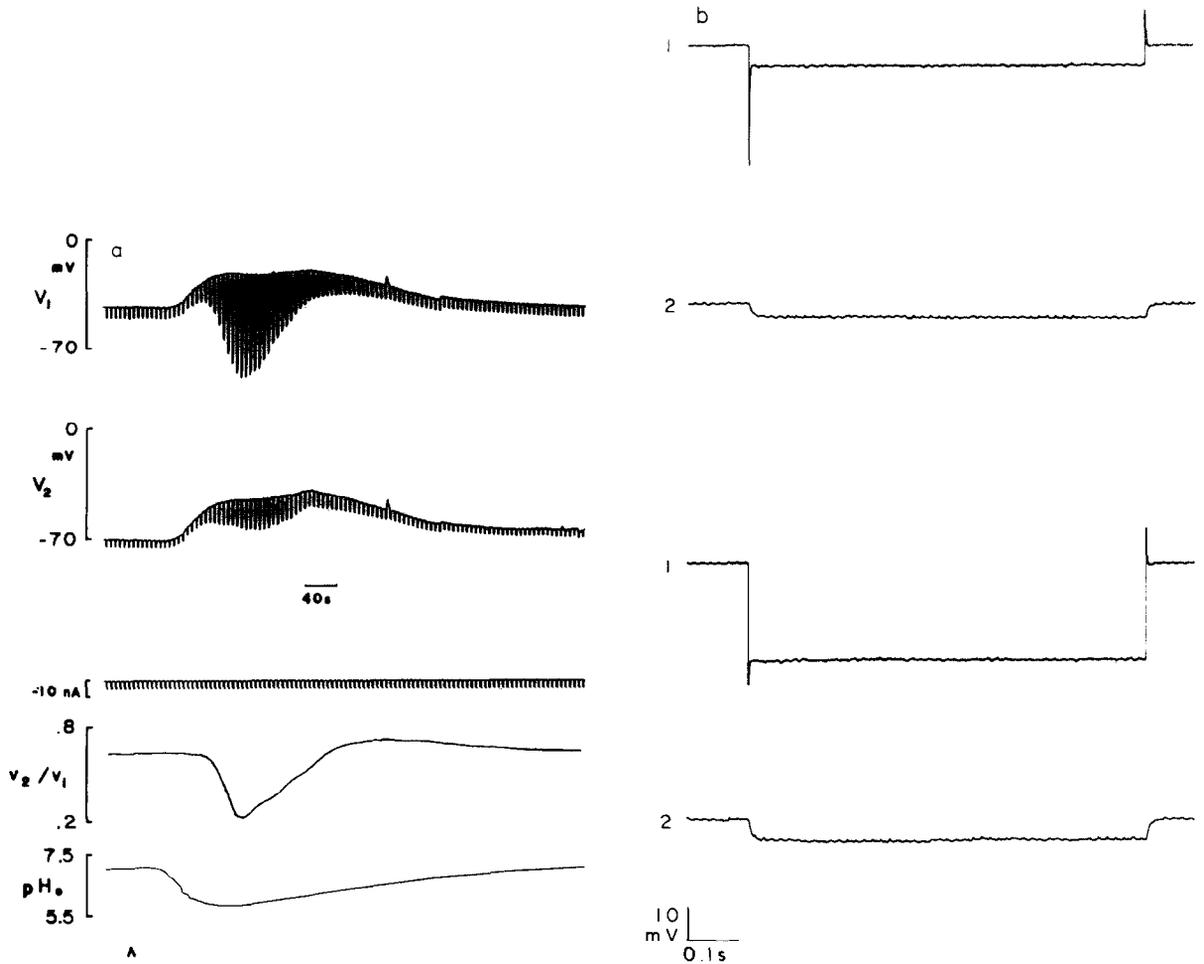

Fig. 2. (a) Impaled Hensen's cells are separated by two intervening cells in this case. A double-barreled electrode was used in cell 1. Steady-state coupling ratio is about 0.64. The arrow indicates the end of a 45 s injection of CO_2 -saturated medium into the perfusion system, whereupon perfusion of normal medium is reinstated. The CO_2 medium reaches the chamber at the time indicated by the drop in extracellular pH (bottom trace). Associated with the CO_2 treatment is a drop in the membrane potentials, an increase in input resistance, and a decrease in coupling ratio. Upon washout of the CO_2 medium, these measures return to pretreatment levels. (b) Conditions were the same in (a); however, individual coupling responses were digitally stored during steady-state coupling (top two traces, cell 1 and cell 2; coupling ratio 0.66) and during maximum uncoupling (bottom two traces; coupling ratio 0.22) in response to a 40 s treatment with CO_2 medium. Capacitive coupling of the double-barreled glass is apparent.

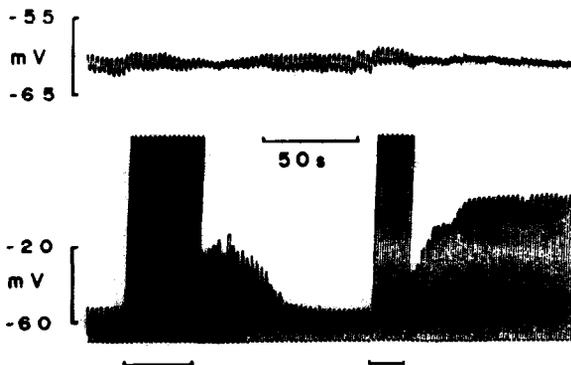

Fig. 3. Neighboring Hensen's cells were impaled with single-barreled electrodes, one containing 0.1 M HCl and the other 3 M KCl. Constant current pulses of -10 nA were injected into one cell through the HCl electrode (bottom trace) and the coupling response in the other cell was recorded (top trace). It was impossible to balance out the voltage drop in the high resistance HCl electrode. At the first bar indicator, a positive steady current of 3.1 nA was superimposed on the pulsed negative current in order to eject H^+ from the electrode into the cell. Consequently, the coupling response decreased (top trace) along with the membrane potential of the injected cell (bottom trace). Both measures recovered, whereupon another positive current injection produced irreversible uncoupling and depolarization in the injected cell.

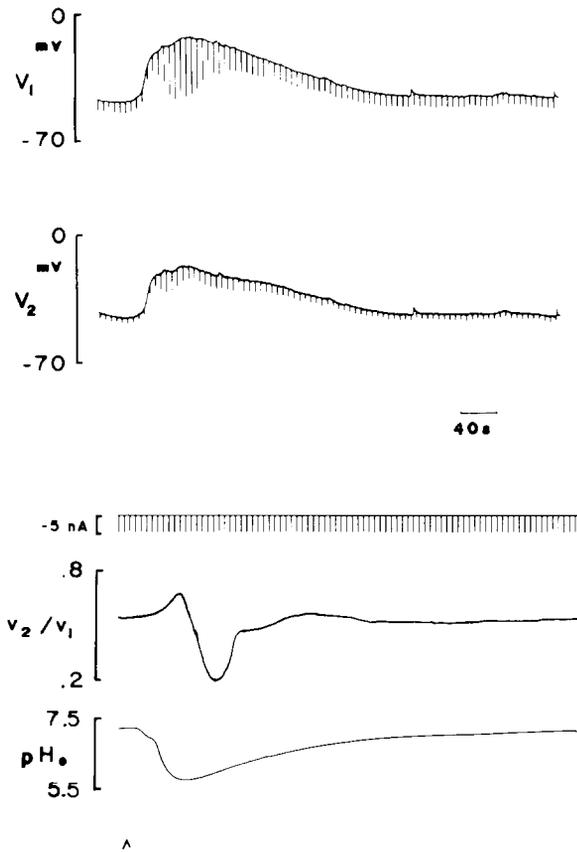

Fig. 4. Adjacent Hensen's cells were impaled with single-barreled electrodes. Current was injected into the cell depicted in the top trace by means of the switched current clamp mode of the Dagan 8100-1. The first arrow indicates the end of a 30 s injection of CO_2 -saturated medium into the perfusion system. An increase in coupling ratio can be observed prior to the uncoupling effects of intracellular acidification. After washout of the CO_2 medium, measures return to steady state.

medium. In this instance, however, there is a transient increase in coupling ratio preceding the drop in coupling ratio. After return to normal medium there is recovery of the cells. Preliminary experiments indicate that high potassium medium causes the membrane potentials to depolarize, and the input resistance to decrease slightly. There is no dramatic uncoupling as occurs with CO_2 treatment.

The increase in coupling ratio noted in Fig. 4 is often seen prior to and sometimes following uncoupling due to CO_2 treatment. It is possible, however, to observe instances where only an in-

crease in coupling ratio occurs in response to CO_2 treatments. Fig. 5 demonstrates this phenomenon. In response to CO_2 treatment, the membrane potentials depolarize, and input resistance increases; however, there is a dramatic increase in coupling ratio from a steady state level of just over 0.6 to nearly 1. The electrical measures return to pretreatment levels following washout of the CO_2 medium. This phenomenon is further demonstrated in Fig. 6 where three separate electrodes are used to gauge current spread through the organ's supporting cells. The ratio of voltage drops between these two Hensen's cells, one more distal than the other to the current injected cell, increases in response to CO_2 treatment. However, it is always possible to inevitably produce uncoupling with prolonged CO_2 treatments.

Discussion

The drop in membrane potentials of the Hensen's cells in response to removal of the lateral wall of the cochlear duct may be accounted for by the presence of gap junctions between the Claudius' cells and the Hensen's cells. The removal of the lateral wall is accomplished by tearing at the interface of these two cell types and consequently the intracellular space of the torn cells is exposed to the extracellular medium. Damage to coupled cardiac muscle fibers also results in a drop in membrane potential of coupled cells [8], and in damaged lens fibers there is a leakage of K^+ ions into the extracellular medium [3]. Over time, as the cytoplasmic faces of the gap junctions in the injured cells close off, the membrane potentials of the undamaged cells recover, and the K^+ leakage subsides. This process is known as healing over.

The supporting cells of the organ of Corti can be reversibly uncoupled by treatments which acidify their cell cytoplasm. H^+ injection directly acidifies the cell interior. CO_2 treatment is known to acidify cytoplasm by crossing the cell membrane and becoming hydrated by the action of carbonic anhydrase. It then dissociates to H^+ and HCO_3^- intracellularly. The process is reversible upon washout of extracellular CO_2 . The extent of cytoplasmic acidification is determined by the amount of H^+ released or injected intracellularly and the cell's buffering capacity. In the present

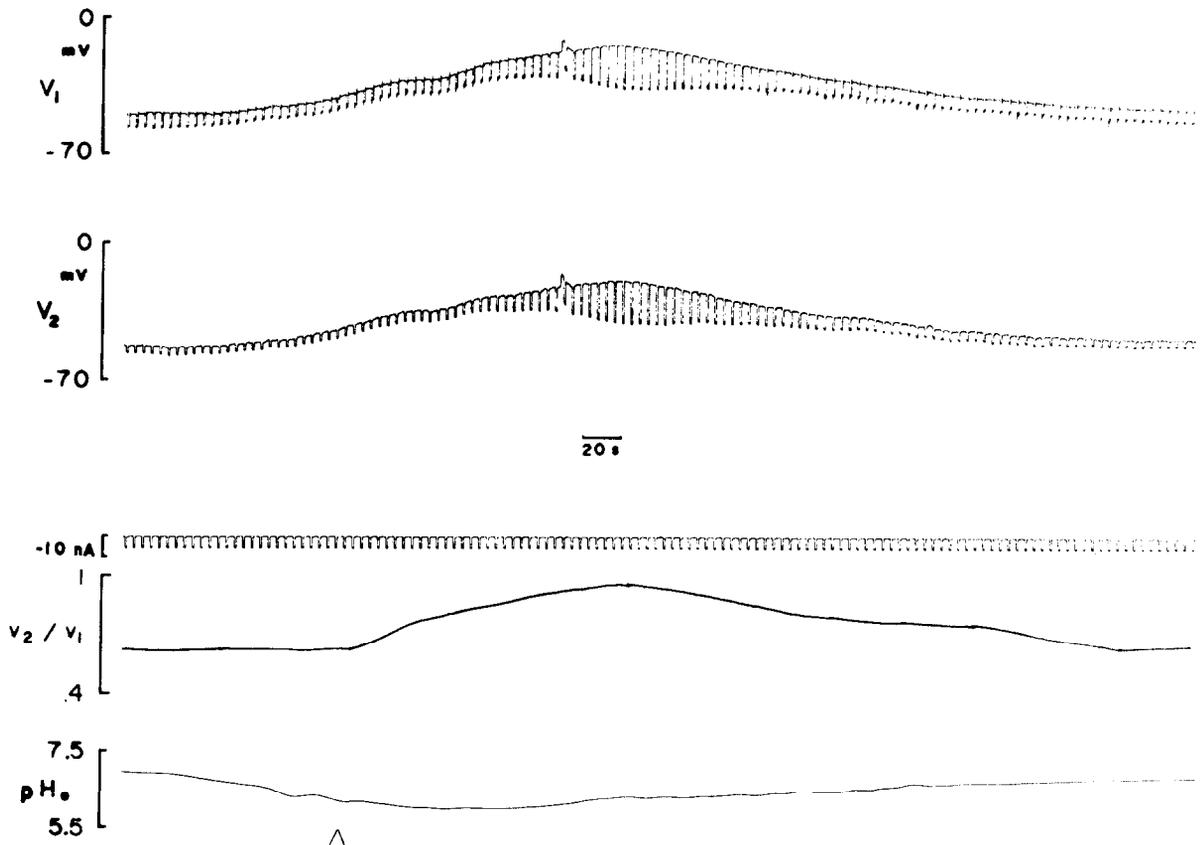

Fig. 5. Adjacent Hensen's cells were impaled, the one depicted in the top trace with a theta glass electrode and the other with a single-barreled electrode. In this case the organ was perfused with HEPES-buffered medium. The arrow indicates the end of a 3 min injection of CO_2 -saturated medium into the perfusion system. Membrane potentials drop but there is a dramatic increase in coupling ratio from about 0.62 to about 0.96. Measures return to pretreatment levels after washout of CO_2 medium.

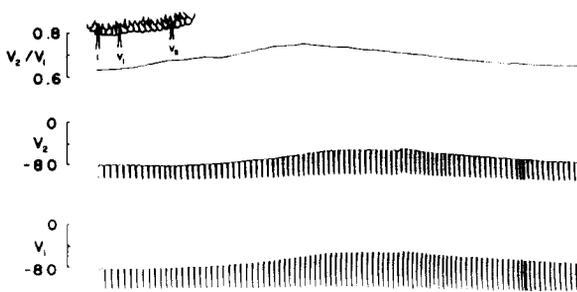

Fig. 6. Three separate Hensen's cells were impaled, one with a current injecting electrode, another with a voltage recording electrode and a more distal one with another voltage recording electrode. The beginning of the traces marks the end of a 25 s injection of CO_2 medium into the perfusion system. Current pulses of -40 nA were delivered about every 2.5 s. The ratio of voltage drops between the two distal cells increases concurrently with membrane depolarization, indicating an increase in the space constant. Measures return to pretreatment levels as the CO_2 medium is washed out.

experiments it is not known to what extent the intracellular pH declined. It is known that the slope of junctional conductance vs. intracellular pH varies among cell types [22,29]. The susceptibility to uncoupling depends upon the steepness of this slope, and the position of the normal resting intracellular pH relative to the pK_H ; thus a similar acidification in two different cell types may have different effects. Intracellular pH measurements are required to determine the precise relationship between coupling and pH in the supporting cells.

Uncoupling of the supporting cells can also be accomplished by intracellular Ca^{2+} injection [23]. There are known to be intracellular interactions between H^+ and Ca^{2+} , such that increases in one ion's activity can increase the activity of the other. However, Spray et al. [33,30], at least in their

model system, have demonstrated a far greater effect of H^+ than Ca^{2+} upon junctional communication. This is still a controversial issue and indeed membrane potential (inside–outside and trans-junctional) may play an important role in the control of junctional conductance [21,32]. Although preliminary studies indicate that membrane potential appears not to play a critical role in cell coupling in the supporting cells *in vitro*, further studies, perhaps using isolated supporting cells and voltage clamp techniques, may be required to fully evaluate the issue. Such studies performed in other cell systems have demonstrated uncoupling due to cytoplasmic acidification under voltage clamp conditions; still there appears to be interactions between membrane potential, H^+ , and Ca^{2+} in the control of junctional conductance [21,32].

The increase in coupling ratio that is occasionally observed upon treatment with CO_2 medium was an unexpected result. It is, however, important because it demonstrates that the intracellular spread of current between supporting cells can be increased under certain conditions. This may have important consequences as discussed below. Three explanations of this phenomenon can be presented. First, it may be possible that the effect is actually due to an increase in junctional conductance caused by an *increase* in intracellular pH. Reber and Weingart [22] have found a decrease in the longitudinal resistance of Purkinje fibers in response to an increase in intracellular pH above resting levels. Perhaps the effect of sub-uncoupling levels of CO_2 primes the supporting cells to enhance their H^+ pumping and buffering capabilities, thus raising intracellular pH. It should be stated, however, that in one preliminary attempt to raise Hensen's cell pH by NH_4Cl treatment, no effects were noted upon supporting cell coupling. This must be investigated further, however. Second, there may be a decrease in the intracellular Ca^{2+} activity due to cell acidification. This has been shown to occur in sheep cardiac Purkinje fibers [15]. A decrease in Ca^{2+} activity might increase junctional conductance. Third, and probably the simplest explanation may be that the membrane resistance of the supporting cells increases without a concomitant decrease in junctional conductance. Such an effect would produce

a greater flow of ions through gap junctions relative to the flow to ground (extracellular medium). Thus the space constant would increase. These possibilities are being evaluated.

Previous studies have suggested that all the supporting cells of the organ of Corti are coupled via gap junctions [13,17,18]. However, it is difficult to quantify the exact distribution of gap junctions by electron microscopy. Light microscopic visualization by the fluorescent antibody (against gap junction protein [14]) technique may provide a more comprehensive demonstration of gap junction distribution in the organ of Corti. Still, the demonstration of gap junctions cannot provide information as to the extent of electrical coupling; nor can the demonstration of electrical communication necessarily indicate that larger molecules (dyes, metabolites) are able to pass through gap junctions. The previously reported lack of dye spread between Hensen's cells illustrates this problem [26]. Others have found this to be the case in other electrically coupled cells [1,36]. Recent efforts to reinvestigate this issue, have revealed that injection of Lucifer Yellow into Hensen's cells causes depolarization, which raises the possibility that the dye is toxic to these cells and may uncouple them. In any case, the existence of electrical communication and the possibility of metabolic communication in the supporting cells may indicate roles in the inner ear similar to those proposed in other tissues. They are discussed below.

(1) The supporting cells may provide a K^+ buffering system whereby increases in local extracellular K^+ in response to hair cell and neuronal activity are reduced by active uptake of K^+ by supporting cells, as is thought to occur in the CNS by astrocytes [28,11]. The syncytial nature of the supporting cells might then allow shunting of K^+ from the tunnel and spaces of Nuel through the supporting cells to areas of lower K^+ concentration (nonactive regions of the duct) or perhaps through metabolic means into the scala media. Supporting cells are known to have microvilli on the endolymphatic surface which are ATPase positive [16]. Thus high K^+ concentrations would be reduced in regions where the ion might interfere with hair cell and neural activity.

(2) Metabolically, the supporting cells may provide for the rapid dissemination of energy sub-

strates in areas of the cochlea duct requiring these molecules. Perhaps the external sulcus cells whose projections are intertwined with spiral ligament capillaries [9] initiate a transfer of metabolites through the Claudius cells to the Hensen's cells and then on to the other supporting cells. The fact that there is a drop in supporting cell membrane potentials, with a subsequent healing over, when the spiral ligament and stria vascularis are removed by means of a tear in the Claudius cell-Hensen's cell interface, indicates that electrical communication occurs between this interface. Thus the possibility of a metabolic route also exists.

(3) Finally, the syncytial nature of the supporting cells may permit pervasive modifications of supporting cell tonus which could affect organ of Corti micromechanics. If ionic conditions arose in a localized area due to local receptor-neuronal activity, and these in some manner effected alterations in local supporting cell structural-contraction proteins, gap junctional communication might permit the spread of these ionically mediated alterations to areas beyond the area of local activity. It is interesting to note that Brownell et al. [5] detected structural changes in response to current only in outer hair cells and not in inner hair cells or supporting cells. However, they noted that changes in supporting cell shape may have been below their limit of resolution. It is difficult to imagine that even slight changes in supporting cell tonus would not affect organ of Corti function, based on numbers of supporting cells and their structural role.

If indeed any of these above mentioned roles exist, the results presented here demonstrate that they could be modified by certain changes in the organ of Corti's microenvironment. Thus in cases where the supporting cell length constant may increase, a possible increase in K^+ buffering and shunting capacity may occur. On the other hand, uncoupling of supporting cell gap junctions might compromise K^+ shunting and metabolic cooperation which could detrimentally affect the organ.

The temperature dependence of electrical coupling in the organ of Corti

J. Santos-Sacchi

Laboratory of Otolaryngology, Dept. of Surgery, Sect. of Otolaryngology, MSB H518, UMDNJ-New Jersey Medical School, Newark, NJ 07103, U.S.A.

(Received 27 August 1985; accepted 8 December 1985)

Electrical coupling in an in vitro preparation of the organ of Corti was evaluated during changes in temperature of the bathing media. The effect of cooling the organ from $35 \pm 2^\circ\text{C}$ to $17 \pm 3^\circ\text{C}$ is to reduce membrane potentials, increase input resistance and decrease coupling ratios. Decreases in coupling ratios ranging from 15 to 75% have been observed. The effects are reversible upon warming. Membrane potentials are very susceptible to depolarization caused by cooling. The reduction in coupling is not due to depolarization nor is it dependent upon extracellular Ca^{2+} . It is conceivable, however, that intracellular stores of Ca^{2+} are released or that intracellular pH is altered.

electrical coupling, gap junctions, organ of Corti, temperature effects, DNP, membrane potentials

Introduction

Gap junctions are thought to mediate intercellular communication between a variety of cell types (Bennett and Goodenough, 1978). These channels permit the direct cellular exchange of materials (ions, dyes and metabolites) up to molecular masses of approximately 1000 daltons in mammalian cell types (Flagg-Newton et al., 1979). Over the past 20 years a variety of treatments has been shown to influence the conductance of these junctions (Spray and Bennett, 1985). In the supporting cells of the organ of Corti, electrical coupling via gap junctions is present (Santos-Sacchi and Dallos, 1982, 1983; Santos-Sacchi, 1984a) and can be modified by treatments which alter the intracellular activities of Ca^{2+} and H^+ (Santos-Sacchi, 1984b, 1985). Gap junctional communication in the organ of Corti may be important for normal cochlear function (Santos-Sacchi, 1985), and may (1) underlie metabolic cooperation among the supporting cells, (2) provide a means to buffer K^+ in the extracellular spaces of the organ of Corti, as occurs in the CNS by ionically coupled astrocytes, and (3) influence cochlear micromechanics by permitting the spread of ionically mediated tonus alterations throughout the supporting cells.

Many studies have shown that cochlear electrophysiology is quite sensitive to cochlear temperature (Butler et al., 1960; Coats, 1965; Manley and Johnstone, 1974; Brown et al., 1983). Temperature is also known to influence gap junctional communication (Politoff et al., 1967; Payton et al., 1969). The present study evaluates the effects of cooling upon electrical coupling between supporting cells in vitro.

Methods

Guinea pigs were anesthetized with pentobarbitol and killed by decapitation. The whole temporal bone was placed in a perfusion chamber on a Zeiss ACM microscope, and the bony capsule around the two most apical turns was chipped away. The stria vascularis and spiral ligament were removed. Medium 199 (with Hanks salts [1.26 mM CaCl_2 , 1.7 μM $\text{Fe}(\text{NO}_3)_3$, 5.36 mM KCl , 0.44 mM KH_2PO_4 , 0.81 mM MgSO_4 , 137 mM NaCl , 4.16 mM NaHCO_3 , 0.33 mM Na_2HPO_4 ; for high K^+ media, NaCl was adjusted to maintain tonicity, pH 7.2–7.4, Gibco, NY) was perfused at a rate of 0.8–1.5 ml/min under an air atmosphere. High K^+ solutions (140 mM) were perfused through the cell chamber in order to evaluate the effects of depolarization on coupling.

2,4-Dinitrophenol (2,4-DNP) (1 mM) was used to evaluate the effect of this metabolic inhibitor on membrane potential. Ca^{2+} -free medium was used to evaluate the effects of extracellular Ca^{2+} upon changes which occur with temperature manipulations. The temperature of the preparation was controlled by Peltier devices utilizing a Bailey Instruments (NJ) controller unit. Electrodes were pulled on a Narishige puller.

Coupling measurements were made with high input impedance devices (WPI KS-700, Dagan 8100-1) capable of constant current injection. Coupling was assessed by injecting negative current pulses of varying magnitudes into one cell and noting the voltage drop in the same and an adjacent cell. Under visual control, Hensen's cells were impaled with electrodes; double-barreled theta glass electrodes were used to inject separately current (I_1) and record voltage drops (V_1) in one cell, while a neighboring cell was impaled with a single-barreled voltage recording electrode (V_2).

Coupling ratio is defined as the voltage drop in cell 2 divided by the voltage drop in cell 1 in response to current injection in cell 1 (V_2/V_1) (Bennett, 1966). Current pulses were generated by a D/A converter controlled by an IBM PC/XT.

Coupling ratios were determined online using a Data 6000 waveform analyzer (Data Precision, MA) in conjunction with the IBM. Coupling responses, membrane potentials, coupling ratios and temperature were recorded on a Gould four-channel recorder. Individual coupling responses were digitally stored within the Data 6000 and saved to disk.

Results

The supporting cells of the organ of Corti are very susceptible to cold-induced depolarization. Fig. 1 illustrates the effects of a reduction in temperature from 35 to 15°C upon membrane potential. The Hensen's cell depolarizes coincident with the temperature drop, and repolarizes as the temperature rises. A lack of precise temporal correspondence between the measured temperature change and membrane potential change is possibly due to the inability to place the temperature probe directly on the specimen. In 7 preparations (35 cells), a 10°C drop in temperature caused an average drop in membrane potential of 13.98 ± 4.44 mV, with the original membrane potentials being 40 ± 10 mV. The magnitude of the depolarization associated with the temperature decrease

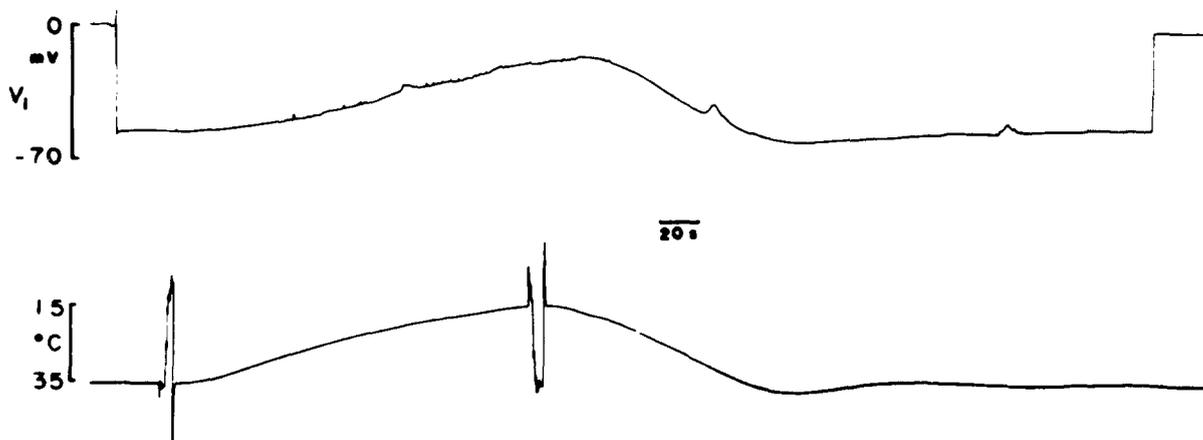

Fig. 1. The effect of cooling upon supporting cell membrane potential. The top trace is a strip chart recording of the membrane potential of a Hensen's cell. The bottom trace indicates the temperature of the perfused media which bathes the cell. As the temperature is reduced from about 36 to 15°C there is a corresponding drop in the membrane potential of the Hensen's cells. Return of the temperature to pretreatment levels causes a repolarization of the membrane potential. Note that the temperature overshoots the initial level during rewarming, and the membrane potential follows this overshoot.

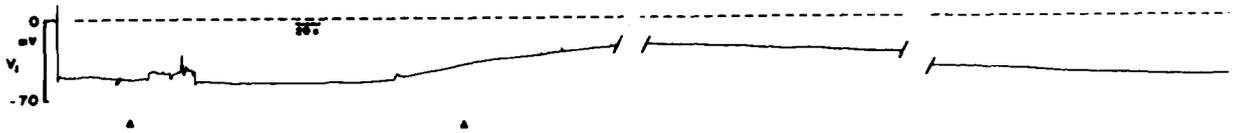

Fig. 2. The effect of 2,4-DNP on membrane potential. A Hensen's cell was recorded from during perfusion of the bath with 1 mM DNP. The first arrow indicates the start of the DNP perfusion and the second arrow indicates the return to normal medium. Membrane potential undergoes a gradual depolarization which is reversible upon washout of the poison. Portions of the trace were removed and accounted for 150 and 340 s, respectively.

was positively correlated with the initial membrane potential of cell ($r = +0.573$, $p < 0.01$, two-tailed). Since a reduction in temperature is known to affect metabolic rate, it was of interest to determine if a metabolic poison would also produce depolarization of Hensen's cells. This might help differentiate between a direct effect upon the cell membrane and an intermediate ef-

fect upon metabolism. As is demonstrated in Fig. 2, the metabolic inhibitor 2,4-DNP also depolarizes cells in a reversible manner although the time course is longer because of the time required to wash out the poison.

Electrical coupling between Hensen's cells is dependent upon temperature as well. However, the uncoupling due to cold is variable in extent

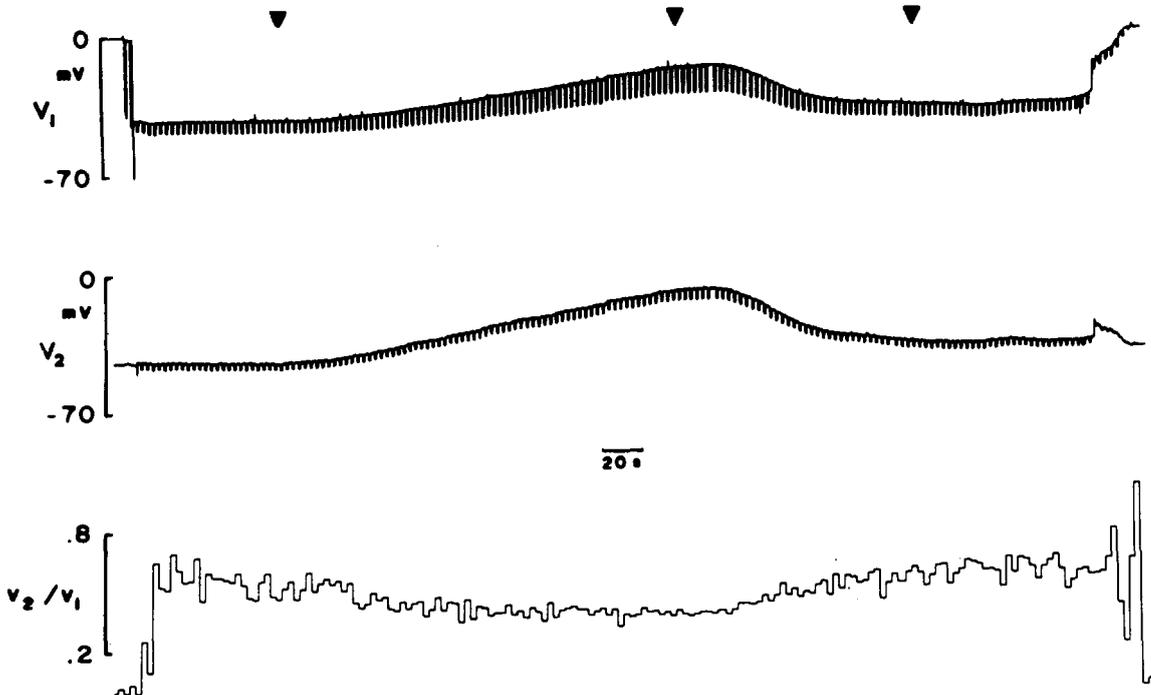

Fig. 3. The effect of cooling upon electrical coupling between supporting cells. Two neighboring Hensen's cells were penetrated with 3 M KCl electrodes. Cell 1 received current pulses of -15 nA through one barrel of a theta glass electrode and the resulting voltage drop was recorded with the other barrel. The coupling response in the other cell was measured with a single barreled electrode. Coupling ratio (bottom trace) was computed on-line and plotted out simultaneously. Temperature of the bath was 37°C initially, and cooling began at the first arrow. A temperature of 15°C was reached at the second arrow, whereupon rewarming began. 37°C was reached at the third arrow. The result of cooling is to reduce membrane potentials, increase input resistance, and decrease coupling ratio. These measures return to pretreatment levels upon rewarming.

despite the fact that depolarization is always substantial. Fig. 3 depicts the effects of lowering the temperature from 37 to 15°C upon electrically coupled supporting cells. In response to cooling, membrane potentials drop, input resistance increases and coupling ratios decrease; upon warming, the measures recover. Reductions in initial coupling ratios ranged from 15 to 75% for temperature changes from 37 ± 2 to $17 \pm 3^\circ\text{C}$. Mean coupling ratios for these temperature extremes are 0.58 ± 0.17 and 0.34 ± 0.11 , respectively ($n = 17$, 9 preparations).

Note in Fig. 3 that near the end of the trace there is a sudden drop in the membrane potentials of the cells. This apparently indicates some sort of injury to cell 1, since its membrane potential continues to decline while cell 2's membrane potential recovers. That is, because the cells are electrically

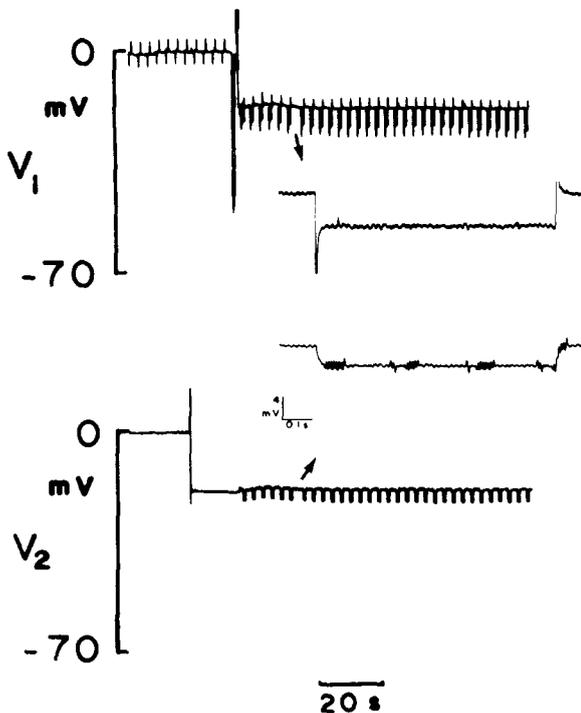

Fig. 4. Good coupling is demonstrable despite low membrane potentials of Hensen's cells. Immediately after removal of the lateral wall of the cochlear duct, membrane potentials drop, but recover over time. This example illustrates that coupling between supporting cells is substantial during periods of reduced membrane potential. Current pulses of -10 nA into cell 1 produces voltage drops in both cells which calculate to a coupling ratio of about 0.7. Inserts are plots of the digitally saved voltage drops in each cell.

coupled, the membrane potential of cell 2 initially follows that of cell 1. The subsequent recovery of cell 2 indicates that uncoupling of the cells is occurring. It is interesting to note that the ratio of initial membrane potential drop in cells 1 and 2 in response to cell 1 injury is, in fact, equivalent to the coupling ratio.

Since uncoupling due to reduced temperature and other treatments (e.g., lowered pH (Santos-Sacchi, 1985)) is accompanied by depolarization, it is of interest to determine if depolarization, per se, is causal. It is known that supporting cells initially have low membrane potentials following removal of the stria vascularis and spiral ligament which recover over time (Santos-Sacchi, 1984a, 1985). Yet, even prior to the recovery of the supporting cell membrane potentials, good coupling is demonstrable (Fig. 4). Furthermore, treatment of Hensen's cells with high potassium solutions, while causing depolarization, neither results in an increase in input resistance nor a concomitant reduction of coupling ratio (Fig. 5). Fig 6 presents a scatter plot of the magnitude of decrease in coupling ratio versus the magnitude (cell

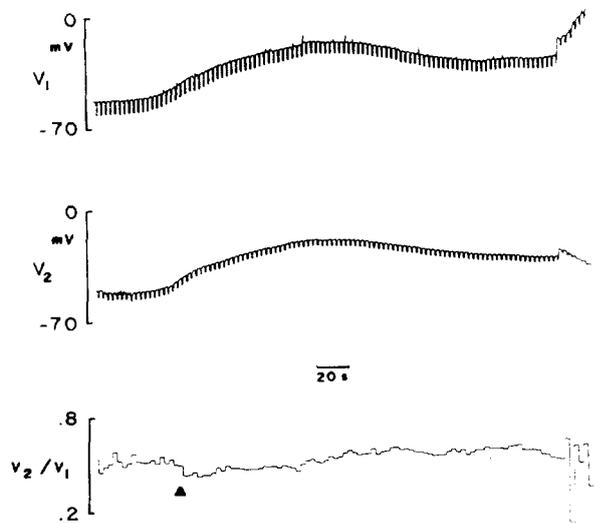

Fig. 5. Effect of depolarization upon coupling in supporting cells. High K^+ media (140 mM) was perfused into the organ chamber for 130 s, and normal medium perfusion was reinstated at the arrow. In response to the high extracellular K^+ , a rapid fall in membrane potential is seen. Input resistance decreases slightly, and no uncoupling trend is correlated with the pronounced depolarization. Upon washout of the K^+ , membrane potentials repolarize.

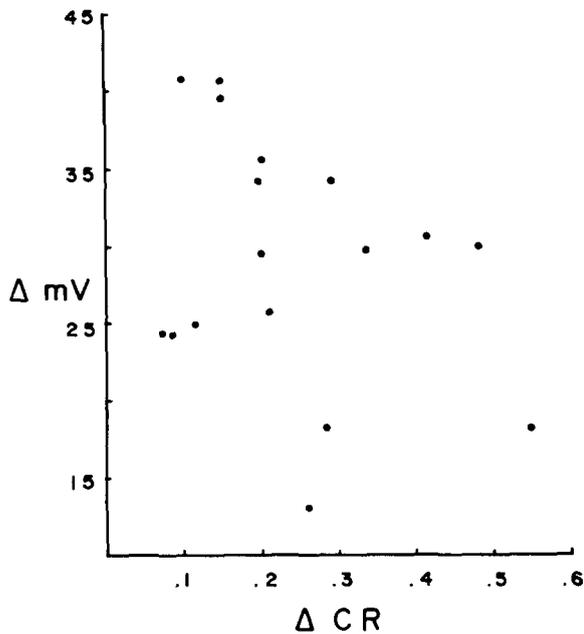

Fig. 6. Scatter plot of the magnitude of depolarization (Δ mV) vs. magnitude of coupling ratio change (Δ CR) in response to cooling the preparation from $37 \pm 2^\circ\text{C}$ to $17 \pm 3^\circ\text{C}$. Correlation coefficient is -0.29 , but is not significant at the 0.1 level.

pair average) of concomitant membrane depolarization in response to cooling. Correlation between the two is not significant ($r = -0.29$, $p > 0.1$, two-tailed). Thus, depolarization of the cell membrane is probably not related to the uncoupling action of reduced temperature.

The recovery of supporting cell membrane potentials following removal of the lateral well is probably similar to the 'healing over' process observed following injury to cardiac purkinje fibers (DeMello, 1983). Extracellular Ca^{2+} is known to be required for this 'healing over'. This is also the case for the supporting cells, since incubation of the organ of Corti in calcium-free media prevents the recovery of membrane potentials. Fig. 7 demonstrates that coupling during this type of incubation is good, and that reduced temperature still promotes uncoupling. Influx of extracellular calcium is therefore not required for the uncoupling effect.

Discussion

The present results indicate that temperature is an important factor which influences both membrane potentials and coupling ratios of supporting cells of the organ of Corti.

Temperature and metabolic inhibitors have been shown to influence membrane potentials of some cells in other systems, but not of others. For example, Creed and McDonald (1975) found no temperature effect (20 – 40°C) upon resting potentials of submandibular acinar cells but did find a 50% drop in membrane potentials with prolonged exposure to DNP, *in vivo*. Similarly, Payton et al. (1969) found only small depolarizations in crayfish giant axons upon cooling to 5°C , which they attributed to alteration of the electrode tip potential. In the present study, only very small (< 5 mV) changes in electrode tip potential were associated with temperature reductions capable of near total depolarization of the supporting cells. Al-

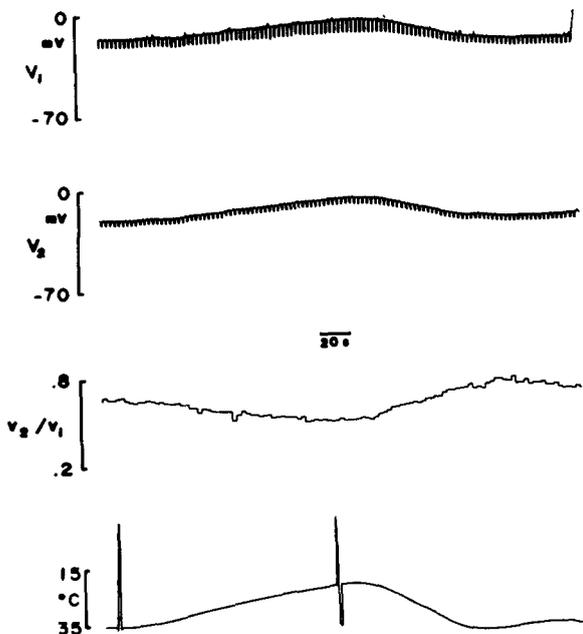

Fig. 7. Effect of cooling on coupling in Ca^{2+} -free media. In this example, it is demonstrated that coupling ratios are decreased upon cooling despite the absence of Ca^{2+} in the external medium, thus indicating that Ca^{2+} influx is not required for uncoupling. Current pulses into cell 1 are -20 nA. Note the close correspondence between coupling ratio and temperature.

though no alterations in membrane potential were noted by Payton et al. (1969), cooling had a profound effect upon junctional communication between crayfish axons. Junctional conductance was found to follow rapidly alterations in temperature, similar to the effects reported here on supporting cell coupling ratios. It is interesting that slow cooling of the crayfish axon apparently does not alter junctional conductance (Ramon and Zampighi, 1980).

Politoff et al. (1967) did find a reduction of membrane potential associated with cooling of salivary glands of *Chironomus thummi* larvae from 20 to 5°C. However, uncoupling of cells from this tissue, which was observed, initially required prolonged cooling. These authors speculated that some change in a metabolically dependent concentration of a cellular constituent (e.g., Ca^{2+}) occurs which is responsible for the uncoupling. Subsequently, they showed that depolarization of these cells by outward currents caused uncoupling, and again they speculated that it was possibly due to an increase in intracellular Ca^{2+} . It is currently known that Ca^{2+} can uncouple cells although H^+ is apparently a more potent uncoupler (Spray et al., 1982). Supporting cells of the organ of Corti can be uncoupled by treatments which increase the intracellular concentrations of either ion (Santos-Sacchi, 1984b, 1985). Whereas membrane potential (both inside-out and transjunctional) may be important factors in junctional conductance of non-mammalian cells, it appears not to be for mammalian cells (Spray and Bennett, 1985). It is demonstrated here that depolarization, per se, of Hensen's cells does not interfere with cellular communication. In addition, an influx of extracellular Ca^{2+} is not responsible for the uncoupling observed; however, the release of an intracellular store of Ca^{2+} or a decrease in intracellular pH is a possibility. Intracellular pH and Ca^{2+} measurements are required to evaluate this issue. Finally, a direct effect of cooling upon membrane structure cannot be ruled out (Payton et al., 1969).

The fact that 2,4-DNP produces a drop in membrane potential may indicate that temperature reductions produce depolarizations via metabolic interference. Nuttall and Lawrence (1978) found minimal changes in the in vivo recorded membrane potentials of supporting cells

during anoxia. In fact, membrane potentials remain stable for some time after death of the animal (J.S.S., unpublished observations). These apparent differences between in vivo and in vitro susceptibility to metabolic insult warrants investigation, especially since there is currently widespread use of in vitro preparations to study organ of Corti function.

As indicated in the introduction, cell coupling in the organ of Corti may be very important for the normal functioning of the inner ear. Interference with cell coupling by temperature reductions or metabolic insults may possibly contribute to the altered functioning of the ear which occurs during such manipulations. For example, if the supporting cells act as a buffer to maintain low potassium levels in the spaces of Nuel, uncoupling these cells might compromise this function and ultimately interfere with hair cell and neuronal electrical activity. Experiments which measure extracellular potassium in the organ of Corti during temperature manipulations may shed light on this issue.

Electrical coupling differs in the in vitro and in vivo organ of Corti

J. Santos-Sacchi

Laboratory of Otolaryngology, Dept. of Surgery, Sect. of Otolaryngology, MSB H518, UMDNJ-New Jersey Medical School, Newark, NJ 07103, U.S.A.

(Received 16 March 1986; accepted 17 August 1986)

Electrical communication between the supporting cells of the guinea pig organ of Corti was studied. For in vitro experiments, the inner ear was rapidly removed and placed in a heated perfusion chamber. Medium 199 was used. The bony cochlea and the lateral wall (spiral ligament and stria vascularis) were removed to expose the top two coils of the organ of Corti. In vivo experiments were performed upon anesthetized animals whose cochleas were exposed surgically. A tiny fenestra was made in the bony cochlea which permitted the passage of electrodes through the lateral wall and into the organ of Corti of the third turn. Coupling was assessed by impaling neighboring cells with 3 M KCl electrodes, and noting the spread of intracellularly injected current. Coupling ratios in the in vitro preparation were consistently greater than those obtained in vivo (0.58 ± 0.17 vs. 0.104 ± 0.064). Differences exist between the in vitro and in vivo preparations which might account for these results. In vivo the supporting cells are bathed in two different media, endolymph apically, and perilymph basally. Consequently, on their apical side the supporting cells are exposed to fluid high in K^+ , low in Ca^{2+} and at a potential of 80 mV, the endolymphatic potential. In vitro the cells are bathed on all sides in fluid similar to perilymph. Intermixing the fluids in an in vivo preparation, by tearing away the stria vascularis and Reissner's membrane, increases the magnitude of the coupling ratio (0.455 ± 0.209). Thus the unique microenvironment of the inner ear maintains lower coupling ratios, and smaller space constants for the supporting cells.

organ of Corti, supporting cell, electrical coupling, in vivo, in vitro, gap junction

Introduction

The organ of Corti, the sensory epithelium of the mammalian inner ear, is composed of hair cells and supporting cells. The extracellular fluid environments facing the epithelium's apical and basal surfaces are markedly different in composition. For example, the apical environment, the endolymphatic space, has concentrations of K^+ , Na^+ , and Ca^{2+} of about 140 mM, 1 mM and 25 μ M, respectively (Bosher and Warren, 1968, 1978); all are maintained by metabolic processes. In addition, the electrical potential of this apical compartment is about 80 mV relative to the basal compartment, a perilymphatic space, whose ionic composition is more typical of extracellular fluid. This unique compartmentalization is required for normal auditory function.

Adjacent supporting cells in vitro (wholly incubated in perilymph-like culture media) can have coupling ratios greater than 0.8 (Santos-Sacchi,

1984, 1985). This implies that supporting cells directly interact over a wide area of the organ, potentially permitting ionically mediated changes in supporting cell tonus to spread along the organ. If coupling in vivo is comparable, then such interactions may influence cochlear micromechanics. It is important, therefore, to determine if electrical coupling among supporting cells is as good under in vivo conditions as is indicated by the in vitro studies.

Methods

In vitro

Guinea pigs were anesthetized with pentobarbital and killed by decapitation. The whole temporal bone was placed in a perfusion chamber on a Zeiss ACM microscope, and the bony capsule around the two most apical turns was chipped away. The stria vascularis and spiral ligament were removed. Medium 199 (with Hanks salts

[1.26 mM CaCl_2 , 1.7 μM $\text{Fe}(\text{NO}_3)_3$, 5.36 mM KCl , 0.44 mM KH_2PO_4 , 0.81 mM MgSO_4 , 137 mM NaCl , 4.16 mM NaHCO_3 , 0.33 mM Na_2HPO_4], pH 7.2–7.4, Gibco, NY) was perfused at a rate of 0.8 to 1.5 ml/min under an air atmosphere. The temperature of the preparation was controlled by Peltier devices utilizing a Bailey Instruments (NJ) controller unit.

In vivo

A ventrolateral approach was used to expose the right cochlea of anesthetized guinea pigs. The animals were artificially respirated during surgery and experimentation. A small fenestra (0.3×0.5 mm) was made in the bony cochlea overlying the lateral wall (stria vascularis and spiral ligament) of the third turn. Through this fenestra electrode penetrations were made into the organ of Corti with the aid of fiber optic backlight transillumination. In order to intermix cochlear fluids the lateral wall was torn away.

Coupling measurements were made with high input impedance devices (WPI KS-700, Dagan 8100-1) capable of constant current injection. Coupling was assessed by injecting negative current pulses of varying magnitudes into one cell and noting the voltage drop in the same and an adjacent cell. Electrodes (10–15 $\text{M}\Omega$) were pulled on a Narashige puller; double-barreled theta glass electrodes were used to separately inject current (I_1) and record voltage drops (V_1) in one cell, while a neighboring cell was impaled with a single-barreled voltage recording electrode (V_2). For *in vitro* experiments, electrodes were separately impaled into neighboring cells under visual observation. For *in vivo* experiments, a single barreled electrode was bent according to the method of Hudspeth and Corey (1979) so that it and a theta electrode could be epoxied together with the shanks parallel and tips separated by 25–40 μm . Because the Hensen's cells are 15–25 μm in diameter, this design permits the penetration of adjacent Hensen's cells despite the inability to view the organ of Corti beyond the lateral wall.

Coupling ratio is defined as the voltage drop in cell 2 divided by the voltage drop in cell 1 in response to current injection in cell 1 (V_2/V_1) (Bennett, 1966). Current pulses were generated by

a D/A convertor controlled by an IBM PC/XT. Coupling ratios were determined online using a Data 6000 waveform analyzer (Data Precision, MA) in conjunction with the IBM. Membrane potentials, coupling responses, and coupling ratios were recorded on a Gould four channel recorder. Individual coupling responses were digitally stored within the Data 6000 and saved to disk.

Results

Adjacent Hensen's cells *in vitro* are very well coupled electrically. Fig. 1c illustrates electrical coupling in a pair of cells. Current injection of a -5 nA 0.8 s pulse into one cell produces a voltage drop in that same cell and in an adjacent one. The coupling ratio in this case is 0.6. Coupling ratios averaged 0.58 ± 0.17 ($n = 17$ cell pairs, 9 preparations). The input resistance of these cells *in vitro* is 0.47 ± 0.15 $\text{M}\Omega$ ($n = 47$, 5 preparations).

Unlike the *in vitro* preparation, the *in vivo* preparation consistently demonstrates poor coupling. Fig. 2c illustrates this point. Current pulses of -25 nA were injected into one Hensen's cell and the voltage drops in that cell and an adjacent cell indicate a coupling ratio of 0.12. After pulling out of the cells the endolymphatic potential is encountered; a potential of zero is obtained upon further withdrawal of the electrodes outside the scala media. Coupling ratios obtained *in vivo* averaged 0.104 ± 0.064 ($n = 40$ cell pairs, 9 preparations). The input resistance under these circumstances is 0.43 ± 0.23 $\text{M}\Omega$ ($n = 47$, 7 preparations).

One obvious difference between these two experimental conditions is the lack of physiologic compartmentalization *in vitro*. That is, the cells of the organ of Corti are bathed on both sides by perilymph-like media, unlike *in vivo* where the fluids bathing the apical and basal compartments differ drastically in ionic composition and electrical potential. In order to evaluate whether this may be the cause for the difference in coupling ratios, the normal compartmentalization of the *in vivo* preparation was disrupted by tearing away the lateral wall of the cochlear duct as illustrated in Fig. 3. By doing so the fluids of the three scalae are intermixed and the endolymphatic potential is abolished. Since there is a greater volume of per-

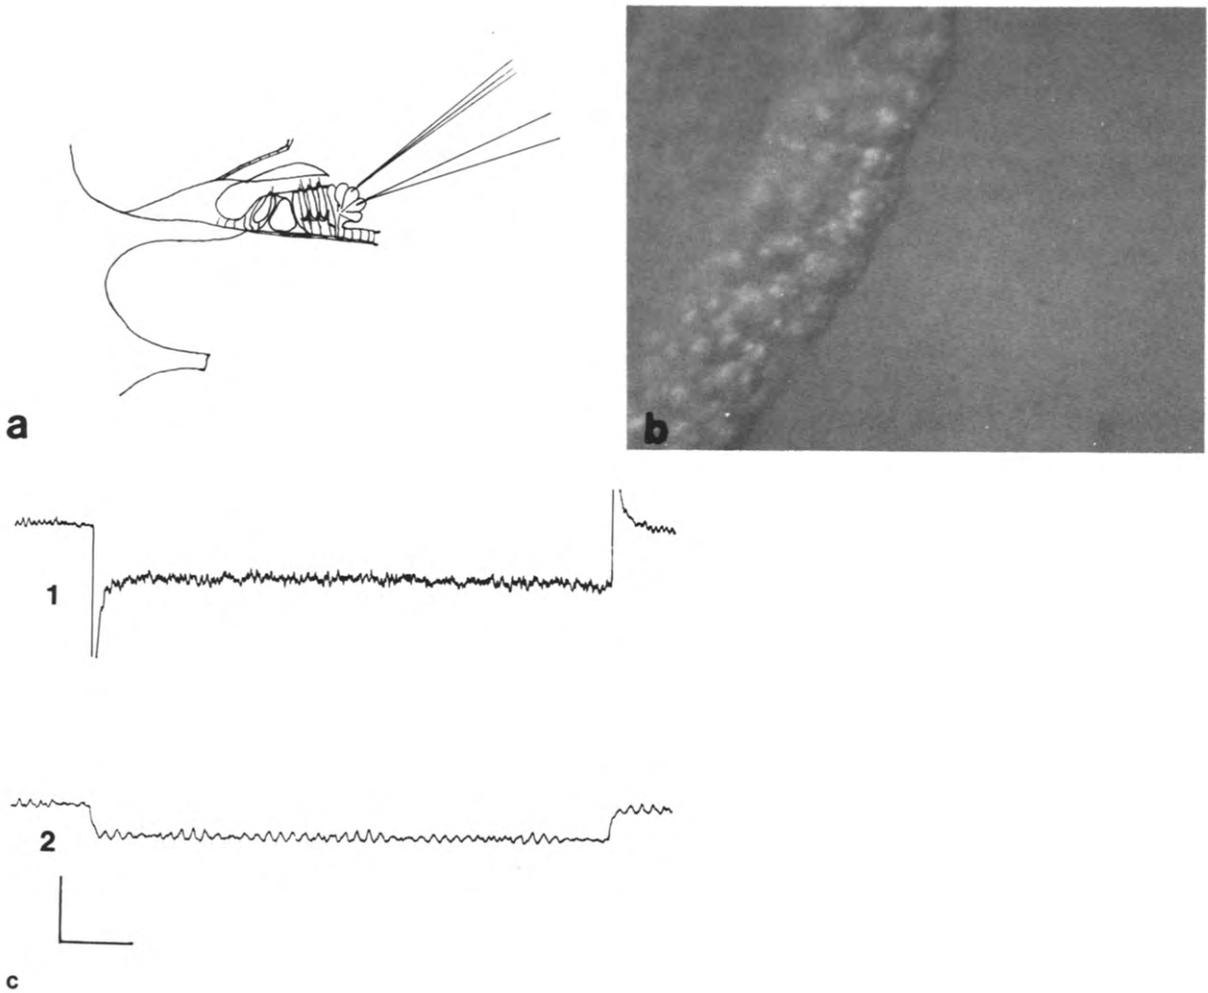

Fig. 1. (a) A schematic drawing showing the in vitro experimental setup. (b) A photomicrograph of the Hensen's cells within the perfusion chamber. (c) A trace of the voltage drop in cell 1 and the coupling response in cell 2, in response to a current pulse (0.8 s) of -5 nA in cell 1. The coupling ratio in this example is 0.6. Horizontal scale, 0.1 s; vertical scale, 6 mV.

ilymph, this fluid, albeit diluted somewhat with endolymph, will surround the organ of Corti. Under such conditions it is demonstrated that coupling ratios between Hensen's cell are increased in magnitude. Fig. 3 illustrates a case where -20 nA current pulses were delivered intracellularly into one Hensen's cell. The voltage drops in that cell and an adjacent one indicate a coupling ratio of 0.69. Upon pulling out of the cells, the potential drops to zero because the stria had been torn away. Coupling ratios under these conditions averaged 0.455 ± 0.209 ($n = 42$ cell pairs, 7 pre-

parations). The input resistance was 0.50 ± 0.21 M Ω ($n = 29$, 5 preparations).

It is interesting to note that the membrane potentials of the Hensen's cells in vitro are reduced initially after stripping away the lateral wall, but that these potentials recover over time close to those recorded under normal in vivo conditions (Santos-Sacchi, 1985). This is also the case for the membrane potentials recorded in the in vivo condition after removal of the lateral wall. For example, the membrane potentials of the preparation illustrated in Fig. 3 initially measured

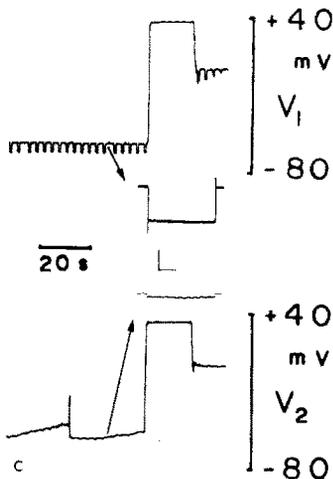

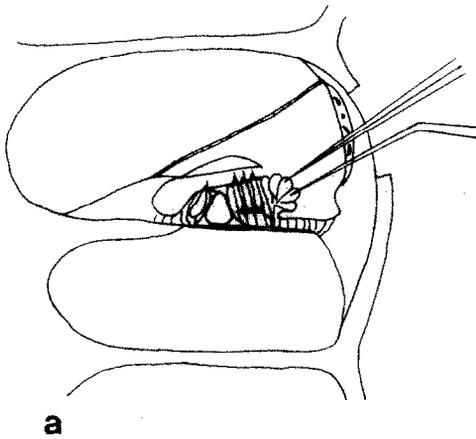

Fig. 2. (a) A schematic drawing showing the in vivo experimental setup. (b) A photo through the operating microscope showing the cochlea backlit with a fiber optic light source. The electrodes can be seen penetrating through a fenestra made in the bone overlying the third turn of the cochlear duct. (c) Traces depicting electrical coupling in vivo. Cell 1 received current pulses of -25 nA. After recording coupling ratios, the electrodes were withdrawn into the scala media where the resting potential is positive. Upon withdrawal from the cochlea the potential drops to zero. The arrows indicate that region of the traces from which the expanded insets are taken. The coupling ratio in this case is 0.12. Inset horizontal scale, 0.2 s; vertical scale, 6 mV.

around -20 mV following removal of the lateral wall; after a few hours they had returned to normal levels. This possibly signifies a process similar to the "healing over" which occurs in cardiac muscle and lens following injury to these tissues (De Mello, 1983; Bernardini et al., 1981). As with the in vitro inner ear preparation, coupling ratios in vivo are good throughout the recovery of membrane potentials.

Discussion

The results demonstrate that coupling ratios in the in vitro and in vivo preparation of the organ of Corti differ in magnitude. In vivo electrical coupling is substantially poorer than in vitro. Fur-

thermore, this poor coupling appears to be due to the physiologic compartmentalization which characterizes the intact cochlea, since disruption of the organ's normal architecture (with concomitant intermixing of cochlear fluids) increases electrical coupling in vivo.

Recently, it has become clear that micromechanical interactions between outer and inner hair cells may underlie the inner ear's exquisite frequency resolving power (see Dallos, 1985). These interactions are thought to be mediated by hair cell cytoskeletal characteristics. It is also known, however, that supporting cells possess cytoskeletal elements (Slepecky and Chamberlain, 1983), which conceivably could influence organ of Corti micromechanics. Since the frequency resolv-

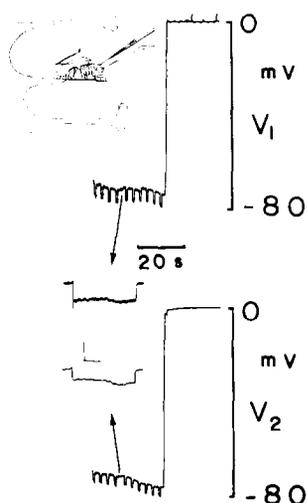

Fig. 3. After recording from the intact cochlea, the lateral wall of the cochlear duct was torn away. In the upper left portion of the figure is a schematic drawing showing the experimental setup. The traces depict electrical coupling *in vivo* after intermixing the cochlear fluids. Cell 1 received -20 nA current pulses. After recording coupling ratios, the electrodes were withdrawn into the scala media. The positive resting potential of the scala media is abolished by the experimental treatment. The arrows indicate that region of the traces from which the expanded insets are taken. The coupling ratio in this case is 0.69. Inset horizontal scale, 0.2 s; vertical scale, 6 mV.

ing power of the inner ear is dependent upon the ability to physically perturb small, discrete portions of the basilar membrane, upon which the organ of Corti lies, it would appear non-advantageous that supporting cells ionically and electrically communicate over long distances. Thus it may be requisite for normal function that the inner ear's unique compartmentalization maintains low coupling ratios and space constants for the supporting cells.

Electrical coupling can be modified by alterations of cellular ionic environment. For example, acidification of cell cytoplasm can decrease coupling (Spray et al., 1981). This is also true for *in vitro* preparations of the organ of Corti (Santos-Sacchi, 1985). Although it is demonstrated here that the unique compartmentalization of the inner ear maintains low coupling ratios and space constants *in vivo*, it is not known what particular aspect of the physiological compartmentalization is responsible for this observation. We have preliminary evidence (Santos-Sacchi and Marbey, un-

publ.), however, that the endolymphatic potential is not a contributing factor. In addition, it is known that high K^+ solutions do not decrease the coupling ratio *in vitro* (Santos-Sacchi, 1986b). Experimental modifications of the endolymph composition *in vivo* may provide a means to determine possible contributions.

Interestingly, Chuang et al. (1985) have found differences between electrical coupling in explanted vs. intact newt embryo epithelium. They suggested that the extraepithelial environment in the intact system promoted coupling as compared to the explant system. It is known that hormones and second messengers can influence the production and the conduction of gap junctions in sensitive tissues, such as the myometrium and sympathetic neurons (MacKenzie and Garfield, 1985; Wolinsky et al., 1985). It is conceivable that in the present experiments something similar is occurring. That is, perhaps the lateral wall produces some factor which acts via the endolymph to inhibit coupling, or the *in vitro* and *in vivo* stria removed condition provides some factor to enhance coupling. In the myometrium (MacKenzie and Garfield, 1985), estradiol treatment can actually increase the frequency of gap junctions between smooth muscle cells. It would be worthwhile evaluating, ultrastructurally, the frequency of occurrence and structure of gap junctions in the inner ear under high and low coupling conditions.

In contrast to our initial concepts (Santos-Sacchi and Dallos, 1983), it is now established that dye coupling is present in the *in vitro* preparation of the organ of Corti (Santos-Sacchi, 1986a). This suggests that metabolic cooperation may occur between the supporting cells of the organ. However, the present finding that electrical coupling in the normal *in vivo* preparation is poor could indicate that dye coupling *in vivo* is likewise poor. This may not be the case, however, depending on the reason for the poor electrical coupling *in vivo*. Coupling ratios are dependent not only upon the junctional resistance between cells but also upon the non-junctional membrane resistance. Thus coupling ratios may increase or decrease due to an increase or decrease in the non-junctional membrane resistance, without a concomitant alteration of junctional conductance. If the poor coupling *in vivo* is simply due to a lower membrane resistance

than is present *in vitro*, dye coupling may not be compromised. Yet, if the difference in coupling ratios is due to junctional conductance differences, then the degree of dye coupling may correspond with the degree of electrical coupling. Since the organ is an electrical syncytium, only input resistance can be measured directly and this measure is a function of both membrane and junctional resistances. Dye coupling studies performed *in vivo* will help determine whether junctional conductance is similar to that measured *in vitro*.

Asymmetry in Voltage-Dependent Movements of Isolated Outer Hair Cells from the Organ of Corti

J. Santos-Sacchi

Laboratory of Otolaryngology, UMDNJ–New Jersey Medical School, Newark, New Jersey 07103

The electrically induced movements of outer hair cells (OHC) were studied using the whole-cell voltage-clamp technique and video analysis. Cell shortening occurs during depolarization and elongation occurs during hyperpolarization from holding potentials near -70 mV. However, a marked asymmetry in response magnitude exists such that depolarization produces larger cell length changes than do comparable levels of hyperpolarization. The response is such that at normal resting potentials *in vivo*, displacements are about 2 nm/mV, but increase to about 15 nm/mV as the cell is depolarized. This mechanical rectification in the depolarizing direction manifests itself during symmetrical sinusoidal voltage stimulation as a “DC” reduction in cell length superimposed upon “AC” length changes. The observed OHC mechanical rectification may be involved in the reported production of “DC” basilar membrane displacements during suprathreshold acoustic stimulation (LePage, 1987). Estimates of the magnitude of OHC movements at acoustic threshold levels induced by receptor potentials in the high-frequency region of the cochlea indicate a disparity between basilar membrane and OHC movements on the order of 21 dB. Thus, it appears questionable whether OHC mechanical movements solely underlie the “active process” thought to be responsible for the high degree of neural tuning at sound pressures near 0 dB.

The organ of Corti is composed of a variety of cell types, including supporting and receptor cells. Two populations of receptor cells exist in the organ, inner (IHC) and outer hair cells (OHC). Each type of hair cell produces receptor potentials in response to acoustic stimulation (Dallos et al., 1982; Russell and Sellick, 1983). However, IHCs receive the majority of afferent innervation from the eighth nerve (Spoendlin, 1969), indicating the IHC's predominant role in information transfer to the CNS. It is becoming increasingly clear that OHCs influence, possibly through mechanical means, the electrical activity of IHCs (Mountain, 1980; Siegal and Kim, 1982; Brown et al., 1983; Nuttall, 1985). The net result of this interaction is the exquisite tuning characteristics and sensitivity of eighth nerve fibers.

Direct electrical stimulation of isolated OHCs induces reversible cell length changes on the order of micrometers which

are not based upon an actin–myosin system (Brownell et al., 1985; Ashmore, 1986; Brownell, 1986; Kachar et al., 1986). These fast mechanical responses, measured up to 8 kHz (Ashmore and Brownell, 1986; Ashmore, 1987), conceivably underlie the mechanical interactions alluded to above and appear to depend upon transmembrane potential since blocking the known ionic conductances of these cells during voltage clamp does not interfere with the mechanical response due to depolarization (Santos-Sacchi and Dilger, 1988a, b). Thus, the OHC may function as both receptor and effector, generating receptor potentials that modify cell length and, in turn, influence organ of Corti micromechanics.

Brownell (1983, 1984) first demonstrated the polarity dependence of electrically induced OHC movements—hyperpolarizing currents elongate and depolarizing currents shorten the OHC. Studies on the displacement magnitude due to electrical stimulation in the hyperpolarizing and depolarizing directions have provided conflicting results. Ashmore (1987) determined that the responses are largely symmetrical, whereas Evans (1988) found them to be asymmetrical. The asymmetry noted by Evans indicates that for a given stimulus magnitude, elongation of the OHC is as much as 50% greater than shortening. Considering the recent finding of LePage (1987) that basilar membrane “DC” displacements occur in response to tone bursts and that OHC movements may be implicated, it is important to determine the existence and extent of mechanical rectification in the OHC.

Preliminary reports of some of the results have been presented (Santos-Sacchi, 1988a, b).

Materials and Methods

Sensory and supporting cells were isolated from guinea pig cochleas by gentle pipetting of the isolated top 2 turns of the organ of Corti. No enzymatic digestion was employed for hair cell isolation. The cell-enriched supernatant was then transferred to a 700 μ l perfusion chamber, and cells were permitted to settle onto the coverglass bottom. A Nikon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical recording. A modified Leibovitz medium (NaCl, 142.2 mM; KCl, 5.37 mM; CaCl_2 , 1.25 mM; MgCl_2 , 1.48 mM; HEPES, 5.0 mM; dextrose, 5.0 mM; pH 7.0–7.2) was used as the perfusate. Patch electrodes (flint glass) had initial resistances of 3–5 M Ω . The series resistance, i.e., the actual electrode resistance obtained upon establishment of whole-cell configuration, typically ranged from 8 to 15 M Ω . These values were estimated from current transients initiated at the onset of voltage pulses and were corrected during analysis (Marty and Neher, 1983). Pipette solutions were composed of 140 mM KCl, 1, 5, or 10 mM EGTA, 2 mM MgCl_2 , and 5 mM HEPES buffered to pH 7.0–7.2. Giga-ohm seals were obtained at the nuclear level of the OHC membrane prior to whole-cell recording.

Single cells were clamped to holding potentials near -70 mV using a Dagan patch-clamp amplifier. Under computer control, hyperpolarizing and depolarizing voltage steps, 200 msec long, nominally ranging from -170 to $+30$ or $+50$ mV, in 10 or 20 mV steps, were used to elicit membrane currents and mechanical movements. Current records, filtered at 2 kHz with an 8-pole Bessel filter, were digitized and stored

on a Data 6000 waveform analyzer and saved to disk for off-line analysis. All OHC movements were taped with a Panasonic AG6300 video recorder. Movements of the cuticular plate region were analyzed off the video monitor during playback using differential optoresistors (output filtered at 30 Hz) placed across the image of the cuticular plate at a monitor magnification of $2800\times$. The linearity of the optoresistor method was confirmed by measuring the video taped movement of the tip of a microelectrode driven by a piezoelectric bimorph element (Fig. 2C). Absolute values were determined by measuring off the video monitor the cell movement in response to the largest depolarizing voltage step. The error in absolute measures was estimated to be less than 20%. Apical and basal ends of the OHC move towards and away from the electrode insertion point during depolarization and hyperpolarization, respectively (Santos-Sacchi and Dilger, 1988a, b). Because the movement of the cuticular plate is relative to the stationary insertion point of the electrode, which was typically near the nuclear region, total cell length change was determined by multiplying the measured movements of the cuticular region by the ratio of total cell length to electrode-cuticular plate distance.

OHC capacitance measures were determined by 2 methods. Electrode shanks were coated with M-coat D (M-Line Accessories, Raleigh, NC) in order to reduce electrode capacitance, and during gigaseal establishment and prior to cell entry, electrode capacitance was compensated fully. For these procedures the current records were filtered at 7 or 10 kHz. The first method involved a determination of the time constant of the initial current transient of the whole-cell voltage-clamp circuit in response to a voltage step of 10 mV from the holding potential. The time constant was estimated by a computerized exponential fitting procedure. The electrode series resistance was estimated from the fitted onset current, and the cell resistance, corrected for the series resistance, was measured from the steady-state current. The capacitance and time constant of the cell were determined as follows (Lecar and Smith, 1985; Ogden and Stanfield, 1987):

Clamp - cell model

$$\tau_{\text{clamp}} = C_m R_{\parallel}, \text{ where } R_{\parallel} = \left[\frac{R_m R_s}{R_m + R_s} \right] \quad (1)$$

$$C_m = \frac{\tau_{\text{clamp}}}{R_{\parallel}} \quad (2)$$

$$\tau_{\text{cell}} = R_m C_m \quad (3)$$

where τ_{clamp} is the voltage-clamp time constant, C_m is the capacitance of the cell, R_m is the resistance of the cell, R_s is the series resistance of the electrode, R_{\parallel} is the parallel resistance of R_m and R_s , and τ_{cell} is the time constant of the cell.

The other method involved an AC analysis of the whole-cell voltage-clamp circuit, using a DSP-16 digital signal-processing unit with associated software (sys16; Ariel Corp., NY). After establishing whole-cell configuration, periodic swept frequency bursts (0.005–8 kHz) of a constant voltage (5–20 mV peak) were delivered through the electrode at a holding potential near -70 mV. The frequency response of the clamp amplifier was 10 kHz. Current responses were time-averaged a minimum of 20 times. The resultant average was fast-Fourier-transformed and stored for subsequent analysis. An analysis of the current magnitude responses provides the necessary information for cell-capacitance determination.

The input impedance of the whole-cell voltage-clamp model is given as follows (Lakshminarayanaiah, 1984), where $s = j\omega$, $\omega = 2\pi f$, and $j = \sqrt{-1}$:

$$Z_{\text{in}} = (R_s + R_m) \left[\frac{1 + R_m C_m s}{1 + R_m C_m s} \right] \quad (4)$$

Substituting the time constant terms τ_{\parallel} for $R_m C_m$ and τ_m for $R_m C_m$

$$Z_{\text{in}} = (R_s + R_m) \left[\frac{1 + \tau_{\parallel} s}{1 + \tau_m s} \right] \quad (5)$$

The resulting magnitude function for $I = V/Z_{\text{in}}$ is a high-pass response (see Fig. 6B) with a high-frequency asymptote whose magnitude is dependent upon R_s and whose 3 dB break frequency (f_{high}) is related to τ_{\parallel} . The low-frequency asymptote is dependent upon $R_s + R_m$, and its break frequency is related to τ_m . Thus, the capacitance can be calculated by

$$C_m = \frac{1}{2\pi R_{\parallel} f_{\text{high}}} \quad (6)$$

Results

A variety of cell types can be viably isolated from the mammalian organ of Corti. These include outer and inner hair cells, Deiter cells, and Hensen cells. Although OHCs and Deiter cells are easily isolated mechanically without the use of enzymatic treatment, Hensen cells require additional trypsinization to obtain single cells. IHCs are seen in short rows of cells.

Figure 1 illustrates $I-V$ plots of these cell types with their associated current traces. All cells demonstrate an outward rectification upon depolarization from a holding potential near -70 mV. In Hensen cells and OHCs these outward currents have been shown to be K^+ currents (Santos-Sacchi and Dilger, 1986, 1988a, b; Santos-Sacchi, 1988a, b). The magnitude and voltage dependence of outward rectification varies among cell type, with the IHC demonstrating the largest currents. The time dependence of outward currents also differs, although OHCs and Deiter cells are similar. Despite some electrical similarities among these cells, only OHCs respond to voltage steps from the holding potential by altering their cell length (Fig. 2). The length changes are not dependent upon specific or total transmembrane current but appear to be voltage dependent (Santos-Sacchi and Dilger, 1988a, b).

The direction of the OHC length changes depends upon the polarity of the step; however, the magnitude of length change is not equal for symmetrical voltage displacements of opposite polarity. Depolarizations elicit larger mechanical responses than do hyperpolarizations. Figure 2, A, B illustrates whole-cell currents and mechanical responses for an isolated OHC in response to voltage steps above and below the holding potential of -67 mV. Time- and voltage-dependent outward currents are generated in response to depolarization; inward currents generated upon hyperpolarization probably represent currents of the anomalous inward rectifier, as described by Ohmori (1984) in vestibular hair cells. The voltage-dependent displacements of the OHC are linear with voltage steps in the depolarizing direction (up to $+20$ mV, above which the response begins to saturate; Santos-Sacchi and Dilger, 1988a, b). However, mechanical responses saturate rapidly at step levels more negative than the holding potential. This phenomenon is demonstrated for 9 cells in Figure 3. In each case, the mechanical response is rectified in the depolarizing direction. The average response in the depolarizing direction is about 15 nm/mV; in the hyper-

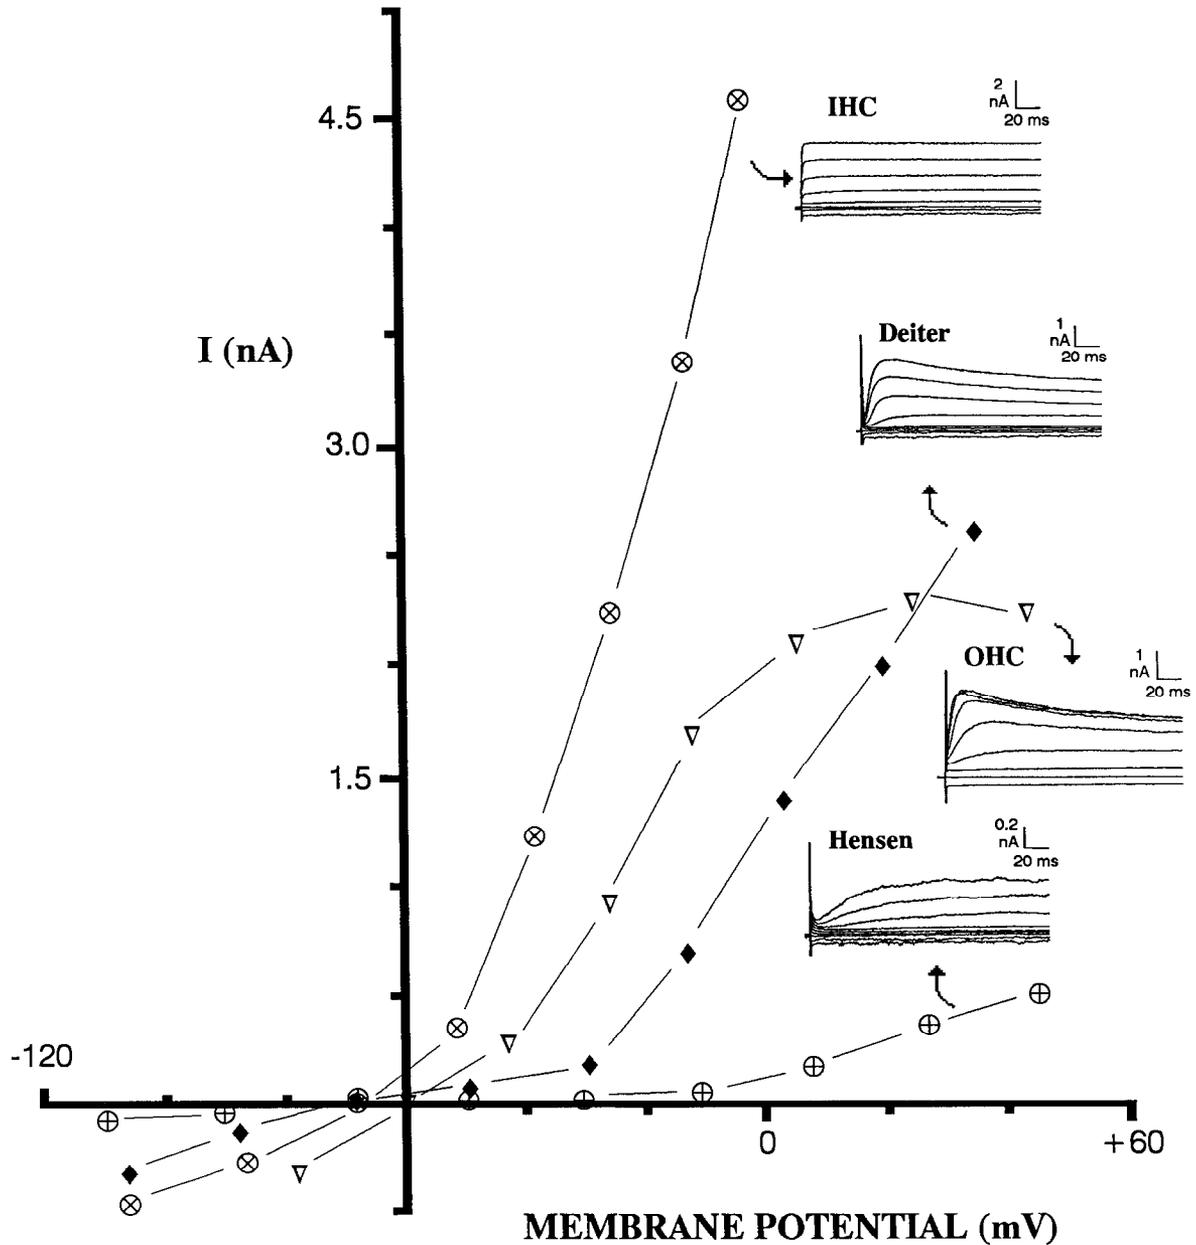

Figure 1. Examples of current recordings from isolated cells from the organ of Corti under whole-cell voltage clamp. Electrode solution contained 140 mM K⁺, 2 mM MgCl₂, 1 mM EGTA, 5 mM HEPES, pH 7.0. Traces and plots are not leakage-subtracted. Note differences in current-magnitude scales beside each trace. Holding potentials and input resistances corrected for series resistance: Hensen cell, -69.6 mV, 687 M Ω ; Deiter cell, -68.3 mV, 127 M Ω ; OHC, -59.7 mV, 69 M Ω ; IHC, -67.4 mV, 92 M Ω .

polarizing direction, it is about 2 nm/mV. It was of interest to determine whether the rectified mechanical response is dependent upon rectified currents generated during voltage steps (Santos-Sacchi and Dilger, 1988a, b). Treatments that block the various ionic conductances of OHCs (e.g., intracellular Cs⁺, extracellular Cd²⁺, Ba²⁺, TEA) also do not affect the mechanical rectification. Figure 4 demonstrates the Ca²⁺ independence of the mechanical rectification. In this case, the electrode solution contained 5 mM EGTA and no added calcium, and the extracellular medium contained 1 mM EGTA with no added calcium.

This mechanical rectification indicates that sinusoidal voltage stimulation should produce a sustained shortening of the OHC during an AC voltage stimulus. This, in fact, occurs. Figure 5A

demonstrates the mechanical rectification of an OHC in response to 400 msec bursts of a 10 Hz command voltage of about 90 mV peak to peak, at a holding potential near -70 mV. The "AC" mechanical response is superimposed upon a "DC" shift (reduction) in the length of the cell. The trace in Figure 5B is the response of a glass probe driven at 10 Hz by a piezoelectric bimorph, which displays symmetrical movements, indicating that rectification under these conditions is not due to the measuring technique. Higher frequency stimulation of OHCs also produced a "DC" shift, but the "AC" response appeared as a blurring of the image on the video monitor. Because the linear portion of the OHC mechanical response function lies roughly between -60 and $+20$ mV, the value of the holding potential

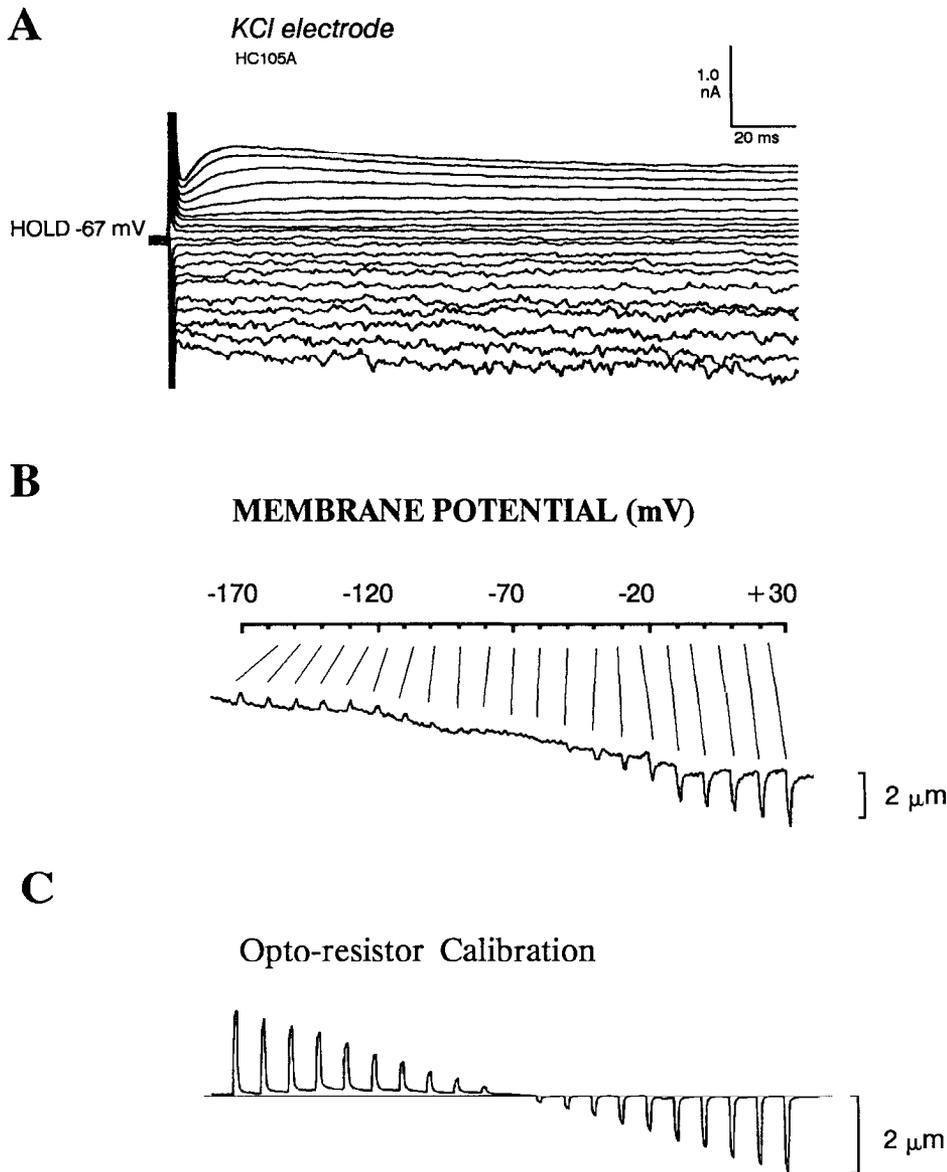

Figure 2. *A*, An isolated OHC was whole-cell voltage-clamped at a holding potential of -67 mV and stepped to various membrane potentials for periods of 200 msec. The traces depict currents generated during depolarizations (upward) and during hyperpolarizations (downward). The membrane potentials during each step are illustrated in *B*. *B*, Record of the output from the differential optoresistor indicating the magnitude of the cell's displacement (downward deflections represent cell shortening). The lines point to the membrane potential of the cell, corrected for series resistance, during each displacement. Note that cell elongations associated with hyperpolarizing voltage steps saturate rapidly above the holding potential, whereas cell contractions associated with depolarizations do not saturate in the range of voltages studied here. *C*, A glass probe driven by a piezoelectric bimorph was displaced for 200 msec and then returned to baseline. Twenty displacements, in linearly graded steps, were produced such that an absolute maximum displacement of about ± 2 μm about the resting baseline was video recorded. The displacements were measured during playback with differential optoresistors placed on the video screen over the image of probe, perpendicular to the displacement axis. The linearity of the measuring device is evident in the recorded output.

should influence the direction of mechanical rectification due to sinusoidal stimulation. Figure 5C illustrates this effect. When the holding potential is changed from -70 to 0 mV, the direction of the "DC" length shift appears to reverse. This occurs because the hyperpolarizing phase of the stimulus now resides in the linear portion of the mechanical response function, whereas at a holding potential of -70 mV the depolarizing phase of the stimulus resided in the linear portion of the function.

Capacitance of the OHC was estimated for a total of 15 cells using 2 methods described in Materials and Methods. Figure 6 illustrates examples for each method. The current transient method ($n = 8$) yielded an average (\pm SD) capacitance of 38.6 ± 4.7 pF, with an average clamp time constant (τ_{clamp}) equal to 0.34 ± 0.072 msec and an average cell resistance equal to 96 ± 91 M Ω . The AC analysis method ($n = 7$) yielded a capacitance of 39.5 ± 5.7 pF, with an average τ_{clamp} equal to 0.38 ± 0.15 msec and an average cell resistance equal to 80 ± 34 M Ω . These measurements indicate an average OHC membrane time constant of about 3.5 msec.

The average cell surface area of these cells, using a cylindrical cell body model and not including stereocilia, was $2.32 \pm 0.45 \times 10^{-5}$ cm 2 for the transient analysis group and $2.50 \pm 0.38 \times 10^{-5}$ cm 2 for the AC analysis group. Stereocilia measures were not included because most cells lose their stereocilia during the isolation procedure. If actual basolateral surface area is 133% of that estimated from light microscopy (due to lateral membrane ruffling; Dallos, 1983), then the specific capacitance of the OHC membrane is roughly 1.2 $\mu\text{F}/\text{cm}^2$.

Discussion

Of all the cells studied that rest upon the basilar membrane, only the OHCs appear to respond to voltage alterations by modifying their cell length. These cells are truly unique in that they may function as both receptor and effector. The mechanical responses of OHCs are large in the depolarizing direction, attaining length reductions up to a few micrometers; however, the responses are rectified such that at typical *in vivo* resting potentials of -70 to -90 mV, responses are much smaller. Thus, at

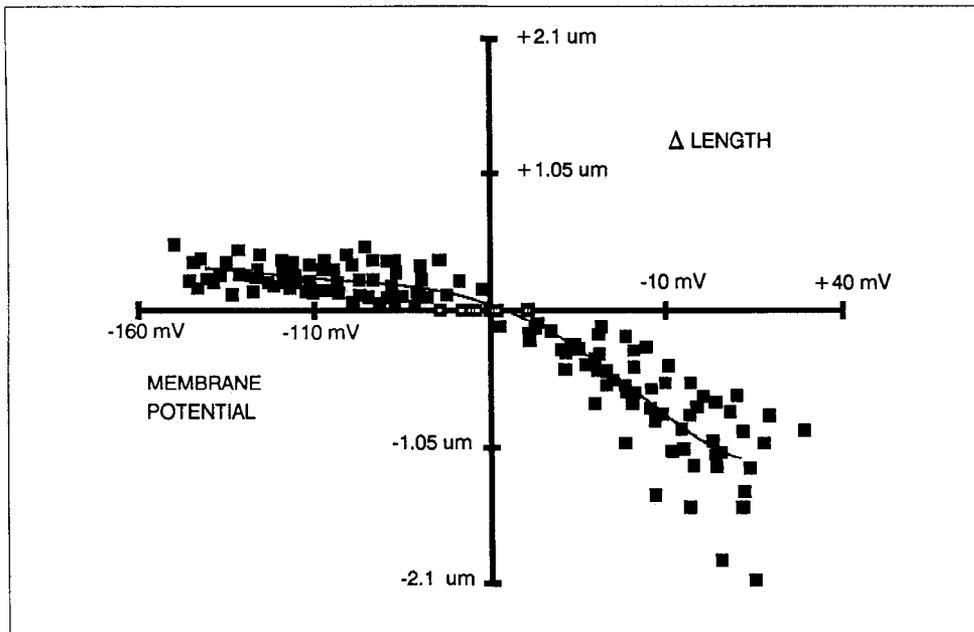

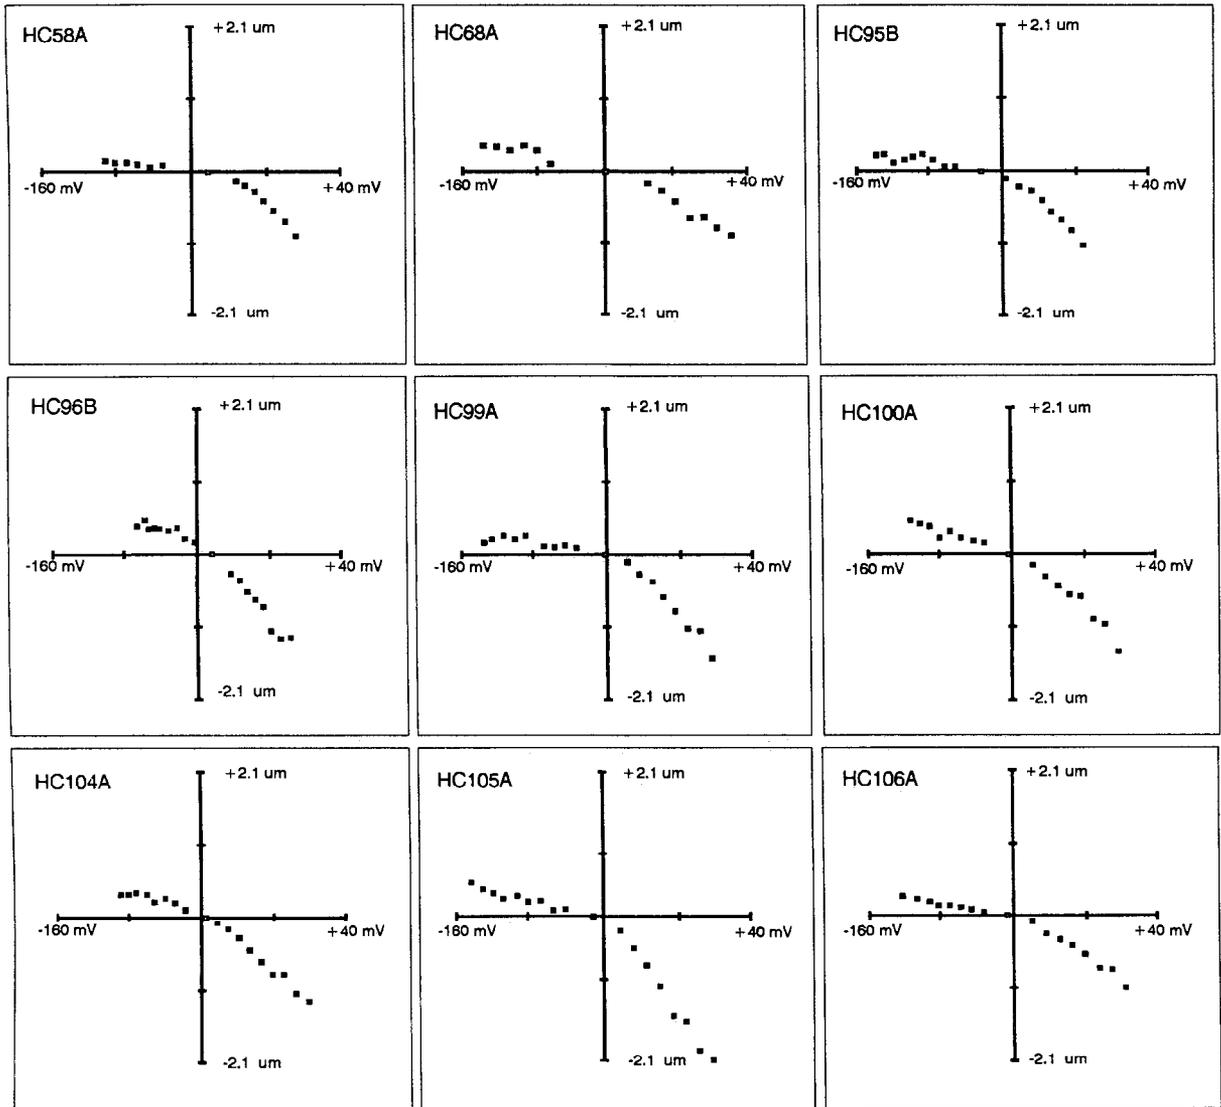

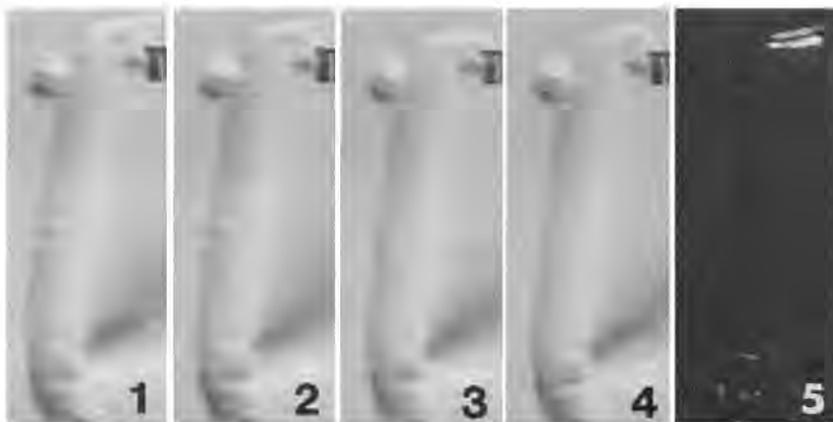

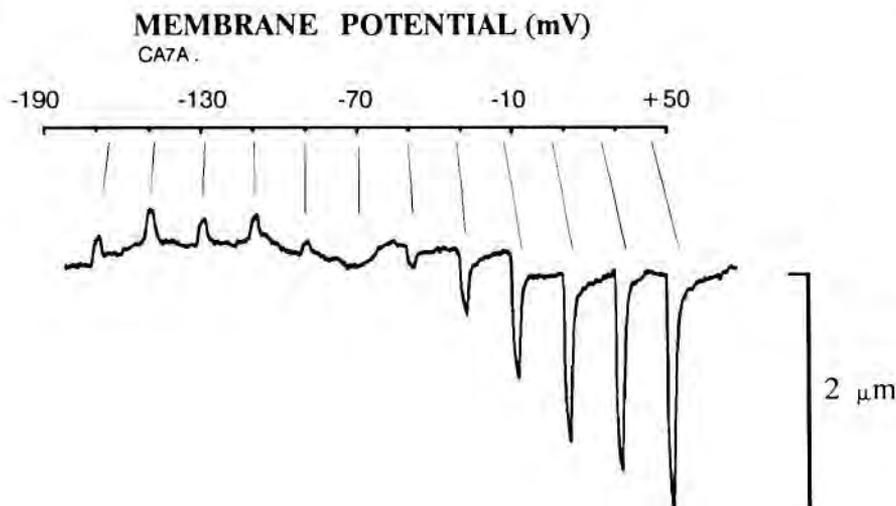

Figure 3. Voltage-displacement functions for 9 OHCs. Open boxes on the abscissa indicate the holding potential. Each function was measured as in Figure 2. In each case, mechanical responses to depolarizations are larger than equivalent amplitude hyperpolarizations. Pooled data in the bottom plot clearly indicate the mechanical rectification in the depolarizing direction. The average slope in the depolarizing direction is about 15 nm/mV, and in the hyperpolarizing direction < 2 nm/mV.

A**B**

the cell's normal resting potential it is capable of shortening to a greater extent than lengthening. Evans (1988) reported that mechanical responses are asymmetrical but that elongation is greater than shortening for a given stimulus strength. In that study, cells were stimulated with transmembrane current via an extracellular electrode, and membrane potential was not measured. Because isolated OHCs can have depolarized membrane potentials, and cell movement is not dependent upon absolute transmembrane current (Santos-Sacchi and Dilger, 1988a, b), it is difficult to interpret these data. It is possible, however, that the results represent responses under depolarized conditions, where hyperpolarization would be a more effective stimulus because of the mechanical response saturation in the depolarizing direction.¹

Ashmore (1987) reported on mechanical responses of OHCs under whole-cell voltage clamp. Near the holding potentials

¹ Recently, Evans et al. (1989) have demonstrated that asymmetry in the OHC mechanical response due to extracellular AC current stimulation is biphasic. At low current magnitudes, the "DC" component of the response is toward contraction. However, as the current magnitude is increased, the "DC" component eventually changes towards elongation.

used in that study, the mechanical responses were fairly symmetrical but saturated at reported voltage levels far removed from the holding potential (see figure 7, Ashmore, 1987). The rate of saturation in the hyperpolarizing direction was much less than reported here. However, in his study, the estimation of absolute voltage levels was confounded by the very high series resistance of the patch electrodes. The average value of the series resistance can be determined from the data presented in that report and calculates to about 83 M Ω .² The voltage divider effect

² Ashmore (1987) reported that the average time constant of his clamp (τ_{clamp}) was 1.29 msec, which, incidentally, was erroneously reported to be the OHC's membrane time constant. Cell capacitance (C_m) was reported to be 27.3 pF, and from his data on 7 cells that the OHC mechanical movements were 2.11 nm/pA, or correspondingly, 19.8 nm/mV (p. 331), an average input resistance (R_{in}) of 106 M Ω can be deduced. Although this value of input resistance is very similar to our results (Santos-Sacchi and Dilger, 1988a, b), the actual value in his report may be less since series resistance compensation, when performed, was not complete (as indicated in his figure legends). Using this value, however, the average series resistance can be calculated as

$$R_s = \frac{R_{\text{in}} \tau_{\text{clamp}}}{(R_{\text{in}} C_m) - \tau_{\text{clamp}}} = 83.4 \text{ M}\Omega$$

Figure 4. Rectification of OHC mechanical response in Ca^{2+} -free, 1 mM EGTA extracellular media. Electrode solution contained 140 mM KCl, 2 mM MgCl_2 , 5 mM EGTA, 5 mM HEPES, pH 7.0. **A:** 1, Video print of digitally captured image of the OHC induced to elongate by stepping cell membrane potential from -69 to -165 mV. 2, After return to holding potential of -69 mV. 3, During voltage step to $+43$ mV. 4, After return to holding potential of -69 mV. 5, Digital subtraction of 3 and 4 indicating distance moved of cuticular plate. Note the obvious shortening of cell during depolarization but the difficulty in observing elongation due to hyperpolarization. Height of black mark in upper-right corner is 6 μm . **B,** Mechanical response measured with optoresistors indicating mechanical rectification as cell is stepped for 200 msec to various potentials from the holding potential of -69 mV.

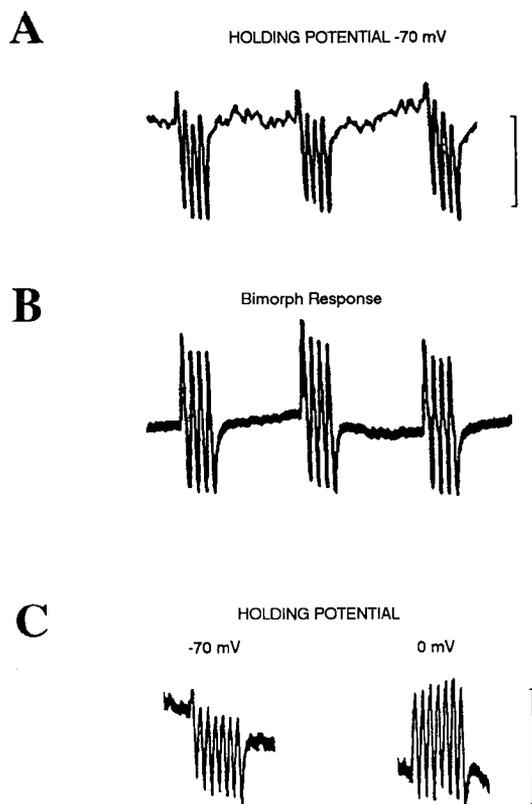

Figure 5. *A*, This trace depicts the movement of an OHC in response to 400 msec bursts of a 10 Hz voltage sinusoid at a level of 90 mV peak to peak. Downward deflections represent cell contractions. Note, in addition to an “AC” displacement at the stimulus frequency, a “DC” shift, indicating a sustained reduction in length during the stimulus. The frequency response of the optoresistor is considerably low-pass, such that the scale for the “AC” component whose magnitude was measured off the video monitor is $0.7 \mu\text{m}$ and that estimated for the “DC” component is about $0.23 \mu\text{m}$. *B*, This trace illustrates the symmetrical response from a bimorph probe at 10 Hz, indicating that the “DC” offset is not due to the measuring procedure. *C*, Both traces illustrate movements of a different cell in response to stimuli as in *A*, except at bursts of 700 msec, and at the holding potentials indicated. Note that at the holding potential of -70 mV the “DC” displacement is in the downward direction (contraction), but at the holding potential of 0 mV the “DC” displacement is in the upward direction (elongation). Scale values are as in *A*.

of such a high series resistance will drastically compromise the amplifier’s ability to clamp the potential of OHCs whose membrane resistances are of the same magnitude. Even if series resistance is compensated somewhat, large overestimates of the membrane voltage will exist unless voltages are subsequently corrected for residual series resistance effects, which was not performed in that study. In the present study, patch electrode resistance was initially low and series resistance was corrected for during analysis. A correction for series resistance in Ashmore’s data would tend to reconcile some of the differences between our data.

We have previously studied the mechanical responses of OHCs in response to depolarizing voltage steps and determined that responses as large as 29 nm/mV occur (Santos-Sacchi and Dilger, 1988a, b). In the present study, the average response in the depolarizing direction was about 15 nm/mV . Ashmore (1987) obtained similar response magnitudes (19.8 nm/mV) in the lin-

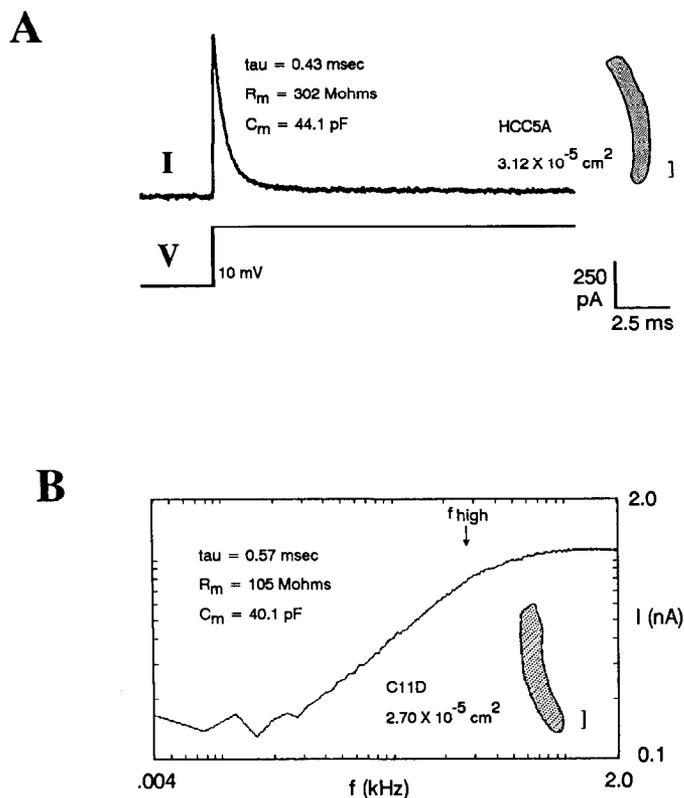

Figure 6. Examples of capacitance determination utilizing transient and AC analyses. *A*, OHC was voltage-clamped at a holding potential near -70 mV and a voltage step of 10 mV elicited a current response that was analyzed to determine the values indicated. See Materials and Methods for details. Cell outline is shown as drawn from the video monitor. Surface area was estimated as in Materials and Methods. Small scale bar, $10 \mu\text{m}$. *B*, OHC was voltage-clamped at a holding potential near -70 mV and the response to a periodic swept frequency burst (20 mV peak) was time-averaged 20 times. The FFT of this average is shown and was used to determine the values indicated. The high-frequency cutoff (f_{high}) is 286 Hz . See Materials and Methods for details. Cell outline is shown as drawn from the video monitor. Surface area was estimated as in Materials and Methods. Small scale bar, $10 \mu\text{m}$.

ear portion of OHC mechanical responses. The findings of the present study, however, indicate that at the normal resting potential of OHCs *in vivo* (-70 to -90 mV ; Dallos et al., 1982), mechanical responses are about an order of magnitude smaller, near 2 nm/mV . Thus, at low sound pressures, where receptor potentials are small and symmetrical, mechanical responses will be small and symmetrical.

Receptor potentials from OHCs in the apical and basal regions of the cochlea have been recorded *in vivo*, and the tuning of these cells is as fine as basilar membrane or neural tuning (Dallos et al., 1982; Khanna and Leonard, 1982; Patuzzi and Sellick, 1983; Robles et al., 1986; Russell et al., 1986). Clearly, if basilar membrane tuning is dependent upon an “active” mechanism (Neely and Kim, 1986) and the active mechanism is indeed the mechanical response of OHCs, then the effect should be present at threshold, near sound pressure levels of 0 dB , where the sharpest tuning occurs. At present, the data, especially for the high-frequency region of the organ, are not persuasive. The problem stems from the observation that the mechanical responses of the OHCs are voltage dependent. This dependency places constraints upon the physiological relevance of the phe-

nomenon at frequencies where hair cell receptor potentials, the presumed stimuli for OHC mechanical responses, are attenuated by the membrane time constant, τ_{cell} . The scenario is somewhat more complex; since the mechanical response is dependent upon transmembrane potential, the effects of extracellular potentials, the cochlear microphonic and summing potential, must be accounted for in determining actual transmembrane potential.

The specific capacitance of the OHC membrane was calculated in the present study to be about $1.2 \mu\text{F}/\text{cm}^2$. For the large low-frequency OHCs (60–80 μm in length) utilized in this study, the calculated membrane time constant, τ_{cell} , was about 3.5 msec. Calculations using data in Ashmore (1987) give a time constant of about 3 msec. These figures indicate a cutoff frequency for OHCs in the low-frequency area of the cochlea of about 46 Hz. This is markedly different from the time constants obtained *in vivo* from receptor potential measures, where corner frequencies near 1200 Hz are obtained from OHCs (Dallos and Santos-Sacchi, 1983). These measures indicate a time constant of 0.13 msec. Of course, input resistance measures of OHCs *in vivo* are low, averaging 30 M Ω or less. This may be due to the poor sealing properties of the high-resistance microelectrodes used and may account for the small time constants observed. Alternatively, the input resistance of hair cells under *in vivo* conditions may be less than measured *in vitro*. Ohmori (1985) obtained time constants for vestibular hair cells *in vitro* that ranged from 4.5 to 50 msec. He speculated that activation of membrane conductances at physiologically depolarized membrane potentials may reduce the cell's time constant. For OHCs in the high-frequency region of the cochlea where cell length is about one-third, the time constant should not be too different from that of the low-frequency OHC, considering that, as capacitance of the cell decreases due to less membrane surface area, input resistance will likely increase.

Response magnitudes near auditory threshold for OHCs in the apical and basal regions are quite small. Electrical measurements made in the low-frequency area of the cochlea are not hampered by the roll-off associated with high-impedance electrode filter characteristics, but in the high-frequency region corrections are required. After such corrections (Russell et al., 1986), threshold measures from OHCs in the 14 kHz region indicate AC responses near $15 \mu\text{V}$. In the 0.8 kHz region, AC responses in OHCs at 0 dB SPL have been measured, and magnitudes up to $100 \mu\text{V}$ occur (Dallos and Santos-Sacchi, 1983; Dallos, personal communication). Using this information from low-frequency OHCs, a corroboration of the OHC response at 14 kHz can be made, considering a 6 dB/octave roll-off above 1200 Hz for *in vivo* OHCs (Dallos and Santos-Sacchi, 1983; Russell et al., 1986). The calculated value of about $9 \mu\text{V}$ is in agreement with that calculated from Russell et al. (1986). Thus, estimates of OHC mechanical responses (assuming a 2 nm/mV movement at resting potentials near -70 mV) generated by

receptor potentials near threshold are probably less than 0.03 nm in magnitude. Corresponding basilar membrane displacement at the high-frequency region is 0.35 nm (Sellick et al., 1982), which indicates a disparity of about 21 dB between basilar membrane displacement and OHC movements.

These calculations indicate that a possible influence of OHC mechanical responses at threshold is questionable, especially at high frequencies where active mechanisms are most expected. At higher suprathreshold levels, however, 2 mechanisms will affect the mechanical movements of the OHCs—first, the inherent nonlinear mechanical response magnitude function described here (i.e., a shift from 2 nm/nV towards 15 nm/mV at increasing depolarization levels) and, second, the inherent rectification present in the receptor potential generator mechanism (Dallos et al., 1982; Russell et al., 1986). Theoretically, these 2 mechanisms should jointly promote an increased OHC shortening at progressively higher sound pressure levels, thereby raising the likelihood of OHC-basilar membrane interactions. In fact, at suprathreshold levels, rectified mechanical responses of OHCs may underlie some of the rapid “DC” basilar membrane displacements noted by LePage (1987) in response to tone bursts of 55–75 dB SPL. On the other hand, the cumulative displacements he also noted are not likely to reflect the fast mechanical motion of the OHCs but conceivably may be due to osmotic- or K^+ -induced OHC morphologic alterations (Zenner et al., 1985), which have a longer time course than the electrically induced movements. *In vivo* the time course of these slower movements may further reflect an ability of electrically communicating supporting cells to buffer K^+ released into the spaces of Nuel during hair and nerve cell excitation (Santos-Sacchi, 1986).

The demonstration by Kemp (1978) of otoacoustic emissions initiated the growing consensus that passive basilar membrane tuning is fine-tuned by an “active process” that somehow involves the OHC. A body of data confirms the OHC's role (Mountain, 1980; Siegal and Kim, 1982; Brown et al., 1983; Nuttall, 1985); and with the discovery of Brownell (1983), the source of this “active process” was assumed to be the ability of the OHC to alter its length (Geisler, 1986). The voltage dependence of these OHC mechanical responses (Santos-Sacchi and Dilger, 1988a, b) and the results presented here place constraints upon this assumption and suggest that other mechanisms may be involved. Indeed, it may be that a variety of factors supplementary to OHC mechanical responses, such as stereociliar and tectorial membrane micromechanics (Allen, 1980, 1988; Zwislocki and Kletsky, 1980; Crawford and Fettiplace, 1985; Zwislocki, 1986; Howard and Hudspeth, 1987) mutually effect sharp tuning at auditory threshold.

³ The symmetrical AC receptor potentials noted in high-frequency OHCs (Russell et al., 1986) may lead some to infer that these OHCs function in the linear region of their $I-V$ function and hence to infer that these cells normally function in the linear (15–29 nm/mV) range of the voltage-cell displacement function described here. The $I-V$ functions described for OHCs by various investigators are essentially DC evaluations and therefore cannot be used to predict high-frequency response characteristics. The current traces depicted here (Figs. 1, 2) and in previous reports (Santos-Sacchi and Dilger, 1988a, b) clearly show that the outward rectification is time dependent, with a time constant of several milliseconds. At increasingly smaller time intervals following voltage stimulation, the traces clearly show that the $I-V$ response becomes more and more linear, and more accurately reflects basolateral conductance effects upon high-frequency receptor potentials. Clearly, the OHC can produce symmetrical AC receptor poten-

tials at resting potentials ranging from -70 to -100 mV , if rectifying basolateral conductances are not activated by these potentials either because of their speed or small amplitude. Thus, symmetrical AC receptor potentials do not require that the cell function in the linear portion of the $I-V$ curve, and likewise do not indicate that the OHC is functioning in the 15–29 nm/mV range of the voltage-cell displacement function. The important factor determining whether the cell functions in the 2 or the 15–29 nm/mV range is the resting potential. OHCs whose normal resting potential is from -70 to -100 mV should function in the 2 nm/mV range, unless the cell is sufficiently depolarized.
