Whole cell voltage clamp studies were performed upon isolated and small groups of supporting cells from the guinea pig organ of Corti in order to evaluate junctional and non-junctional membrane characteristics. Single Hensen cells have an average input resistance and capacitance of 1.03 G Ω and 24.9 pF, respectively. I-V functions indicate an outward K⁺ rectification, which is blocked by external TEA, intracellular Cs, or photo-irradiation of intracellularly injected fluorescent dye. Voltage clamping of pairs or small groups of cells indicates that supporting cells 'share' K⁺ channels within the syncytium. The input impedance of coupled cells was studied during uncoupling with CO₂ or octanol media. As expected, coupled cells showed an increase in input capacitance and a decrease in input resistance over single cell values. Input capacitance is a more sensitive indicator of cell coupling than dc input resistance. During uncoupling, input capacitance values drop to single cell levels prior to an increase of dc input resistance to single cell levels. Modeling the results indicates that Hensen cells are well-coupled under normal conditions and may have junctional resistances with values less than 0.1% of the non-junctional resistance. The sensitivity of the supporting cell syncytium's input impedance to small changes in junctional resistance markedly influences the syncytium's RC filter characteristics, and thus may control the frequency response of sound evoked electrical activity measurable in supporting cells *in vivo*.

Voltage clamp; Organ of Corti; Supporting cells; Gap junctions; Cell coupling

Introduction

The mammalian organ of Corti is comprised of sensory (inner and outer hair cells) and supporting cells (e.g., Hensen, Deiter, Pillar cells). Ultrastructural studies established that the various supporting cells are joined to one another by gap junctions (Iurato et al., 1976; Jahnke, 1975; Gulley and Reese, 1976; Hama and Saito, 1977). Subsequently, it was demonstrated that these supporting cells are dye and electrically coupled, presumably via gap junctions (Santos-Sacchi and Dallos, 1983; Santos-Sacchi, 1984b; 1986a). Electrical coupling among these cells can be modulated by a variety of treatments, including alteration of intracellular pH, Ca²⁺ and temperature

(Santos-Sacchi, 1984a; 1985; 1986a). A possible physiological role for such coupling may involve K⁺ uptake and buffering in areas of the organ where hair cell and neuronal activity is high. Although electrical coupling between sensory and supporting cells may occur in the lower vertebrate inner ear (Weiss et al., 1975), ultrastructural studies (cited above) as well as indirect electrophysiological evidence (Oesterle and Dallos, 1988; 1989) indicate an absence of electrical communication between supporting and sensory cells in the mammal.

Previous measures of electrical coupling in the supporting cells have relied upon coupling ratio measurements (the ratio of voltage drops in adjacent cells due to current injection in one cell; Bennett, 1966) in the intact organ of Corti, both *in vitro* and *in vivo* (Santos-Sacchi, 1987). Because these measures were made in a coupled syncytium, no estimates of junctional conductance could be made. The present report relies upon the analysis

of input impedance measures from isolated and small groups of supporting cells using whole cell voltage clamp to provide estimates of junctional and non-junctional conductances. Preliminary accounts of this work have been reported (Santos-Sacchi, 1988a, b).

Methods

Isolated Hensen cells or cell aggregates were obtained from the excised guinea pig organ of Corti by agitation for 15 min in Ca^{2+} -free Leibovitz medium containing 1 mg/ml of trypsin. The cell enriched supernatant was then transferred to a 700 μl perfusion chamber, and cells were allowed to settle and attach to the untreated glass bottom of the chamber at room temperature. A modified Leibovitz medium (NaCl 136.9 mM, KCl 5.37 mM, CaCl_2 1.25 mM, MgSO_4 0.81 mM, MgCl_2 , 0.98 mM, KH_2PO_4 0.44 mM, NaHPO_4 1.54, Dextrose 5.00 mM, pH 7.0) was used as the normal perfusate. In some experiments, 10 mM TEA was added to the culture media (NaCl adjusted) to block K^+ currents. The cells were washed with medium to remove the enzyme and cell debris (≈ 15 min) prior to recording, and were continuously perfused for the duration of each experiment. Pipette solutions were composed of 140 mM KCl or CsCl, 1 mM EGTA, 2 mM MgCl_2 , and 5 mM HEPES, pH 7.0. Patch electrodes (flint glass) had initial resistances of 3–5 $\text{M}\Omega$. Subsequent to the formation of gigohm seals, cells were whole cell voltage clamped at a holding potential near -70 mV and pulsed to various potentials for 200 ms at 1 s intervals, under computer control. Current traces sampled at 25–30 μs and filtered at 3 kHz with an eight pole bessel filter were observed on a D6000 waveform analyzer (Analogic, MA) and stored to disk for subsequent analysis. Actual voltages were obtained by correcting for the electrode series resistance (10–15 $\text{M}\Omega$) which was estimated from the capacitative current transient at the onset of the voltage pulse (Marty and Neher, 1983). Current values for I-V plots were obtained by averaging the final 20 ms of each current trace. Chord conductance [$g_{\kappa} = I/(V_m - V_{\text{eq}})$] for outwardly rectifying K^+ currents between -30 and 50 mV was calculated using a K equilibrium potential (V_{eq}) of -81 mV. Linear

leakage current was subtracted for these calculations.

Specific membrane capacity of biologic membrane is a fairly robust quality, which according to Cole (1971) is 'largely independent of cell physiology, pathology and pharmacology, and probably life itself.' Measurements of membrane capacitance have been used extensively during this cen-

Fig. 1. Video prints of isolated Hensen cells viewed with Hoffman optics. (a) single cell; (b) cell pair; (c) three cell group. Note lipid inclusions. Scale bar: 10 μm .

tury to estimate the amount of electrically contiguous membrane surface area of cells, a technique which has its origins in the classical experiments of Fricke (1925). In the present report, membrane capacitance measures are used in conjunction with input resistance measures to estimate changes in electrical coupling between and among supporting cells, since by definition, membranes of coupled cells are electrically contiguous.

In order to evaluate the changes of input capacitance and resistance during Hensen cell uncoupling, the cells were treated with the known uncoupling agents, CO_2 and octanol (Turin and Warner, 1977; Johnston et al., 1980). CO_2 saturated media was perfused through the chamber. Saturated octanol media was perfused directly on the cells via a separate small tipped pipette. At the holding potential, input capacitance and resistance were determined using 10 mV pulses of 25–30 ms duration, by integration of the capacitative current transient and measuring steady state current, respectively (Marty and Neher, 1983; Ogden and Stanfield, 1987). These measures were performed online every 3.5–4.5 s, and the results saved to disk. Data were smoothed using a three point running average, and for presentation purposes, sigmoidal fits were made.

Fluorescein was delivered through patch pipettes which contained 1–5% dye. Epi-illumination was provided by a Nikon Diaphot filter system with a 50 watt high pressure mercury lamp. All experiments were video taped with a Panasonic AG6300 recorder, and photographs were made with an Hitachi video printer.

Results

Hensen cells isolated from the apical turns of the guinea pig cochlea are readily identified by light microscopy due to their lipid inclusions (Fig. 1). Groups of any number of cells can be obtained, although with larger groups it is difficult to determine exact numbers. The size of the cells is quite variable as is indicated by input resistance and capacitance measures. Isolated cells have input resistances much higher than those determined from the intact organ of Corti ($1.03 \pm 0.585 \text{ G}\Omega$ [$N = 9$] vs. $0.5 \text{ M}\Omega$ [Santos-Sacchi, 1987a]), indicating the high degree of electrical coupling pre-

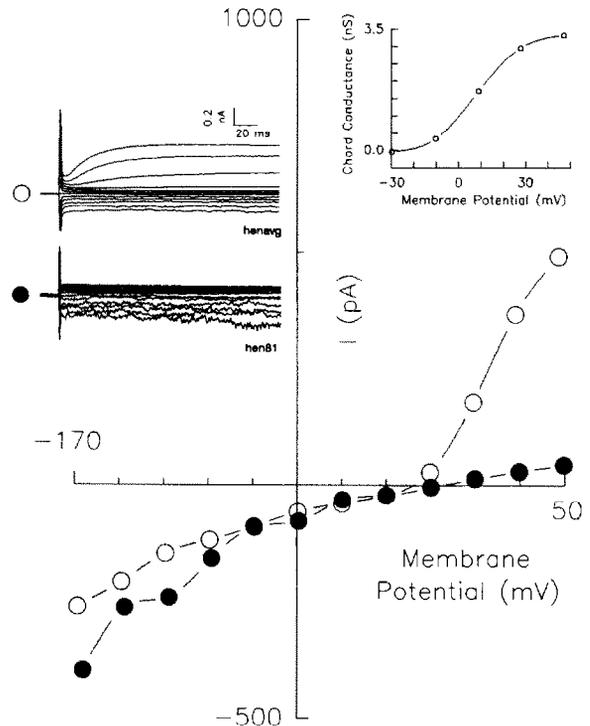

Fig. 2. Seven single isolated Hensen cells were individually whole cell voltage clamped at a holding potential of -70 mV , with normal perfusion media and KCl electrode solutions. The averaged traces (open circles) depict currents generated by pulsing the membrane potential to potentials nominally ranging from -170 to 50 mV , in steps of 20 mV . Outward current is upward. Linear leakage currents have not been subtracted in any of the figures. The I-V plot represents the averaged currents obtained during the last 20 ms of the traces, corrected for residual series resistance. Note the delayed outward rectification at potentials greater than -30 mV . Average resting potential estimated from zero current is -20 mV . Traces and I-V plot labeled with closed circles represent responses from a single isolated Hensen cell as above, except that CsCl replaced KCl in the patch pipette. Note the absence of outward rectification, indicating that K^+ ions are the charge carriers. Resting potential estimated from zero current is $+2 \text{ mV}$. Insert: Average K chord conductance after subtraction of linear leakage currents for the seven Hensen cells exhibiting outward rectification above (see Methods). Probability of K channel activation is very low at potentials more hyperpolarized than -30 mV and reaches a maximum value near $+50 \text{ mV}$.

sent in the intact in vitro syncytium. The average capacitance of these isolated cells was $24.9 \pm 9.19 \text{ pF}$. Fig. 2 shows averaged current traces and an I-V plot (open circles) obtained from 7 isolated Hensen cells in response to a series of voltage steps. Delayed outward currents were measured

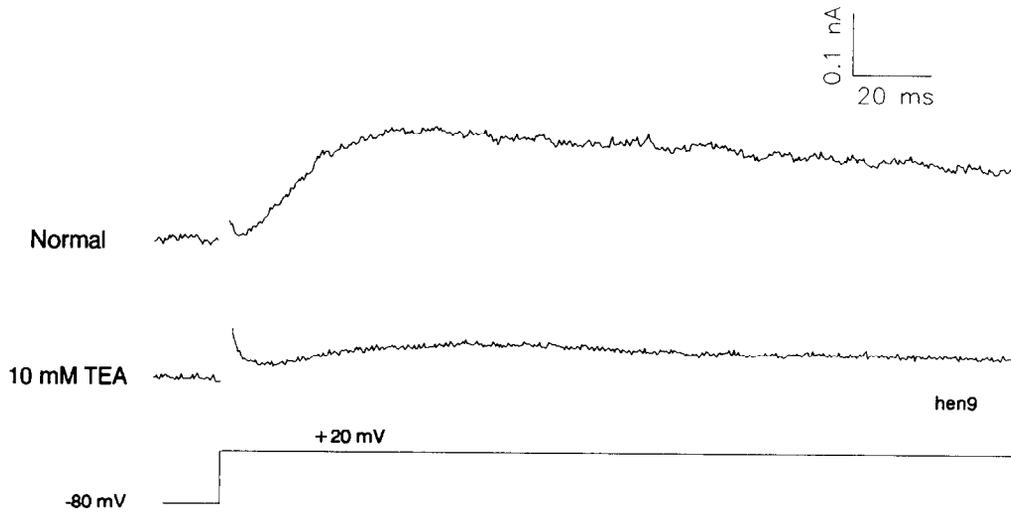

Fig. 3. Outward K^+ current trace obtained from a single Hensen cell before and after perfusion of the cell with 10 mM TEA solution. Note marked reduction of outward current in response to treatment with the K^+ channel blocker. Outward currents returned following washout of TEA. Zero current potentials before, during and after TEA treatment were -24 , -8 , -17 mV, respectively.

upon depolarizations greater than -30 mV, and were blocked by intracellular CsCl (closed circles), indicating that they are K^+ currents. Reversible block of these outward currents by 10 mM TEA provides further evidence that these currents are carried by K^+ (Fig. 3). Zero current levels for isolated cells recorded with the KCl intracellular solution indicate a resting potential of -20 mV. After subtraction of linear leakage currents, the average chord conductance for the outwardly rectifying K^+ currents increased sigmoidally from very low levels at -30 mV to a near maximum value of 3.3 nS at a potential of -47.3 mV (Fig. 2, insert). The inward currents noted upon hyperpolarization probably represent K^+ currents through the inward rectifier as has been demonstrated in the vestibular hair cell (Ohmori, 1985).

Interestingly, the outward K^+ currents were also blocked by photo-irradiating cells which had been perfused intracellularly with fluorescein (Fig. 4), a procedure which is known to electrically uncouple Hensen cells (Santos-Sacchi, 1986b). TEA, intracellular cesium, and photo-irradiation also produced a depolarization of isolated Hensen cells, as estimated from zero current levels (Figs. 2, 3 and 4); in the case of TEA blockade, repolarization follows washout.

Cell coupling in isolated cell aggregates was studied by noting cell input resistance and capacitance changes during uncoupling with CO_2 saturated media. Fig. 5 demonstrates uncoupling-induced changes in the I-V characteristics of a large group (≈ 10) of Hensen cells, one of which was whole cell recorded. The tremendous outward current depicted in Fig. 5 prior to uncoupling (note scales) indicates the summation of outward K^+ currents from the electrically coupled cells. Also note the summation of hyperpolarization-induced inward currents, and the large capacitive transients, indicating a large membrane surface area. Due to the large cytoplasmic volume resulting from coupling, and the attenuating effects of the junctional resistances, it is unlikely that all cells were voltage clamped equally; despite this, however, elicited currents indicate substantial voltage alterations in adjacent cells. After perfusion of the cells with CO_2 saturated medium, the cells uncouple from each other and the current traces approach those of a single cell. Fig. 6 depicts similar results obtained with a group of four Hensen cells. As expected, the currents and capacitive transients are smaller in magnitude than the 10 cell group; after CO_2 treatment, values approach that of a single Hensen cell. These data

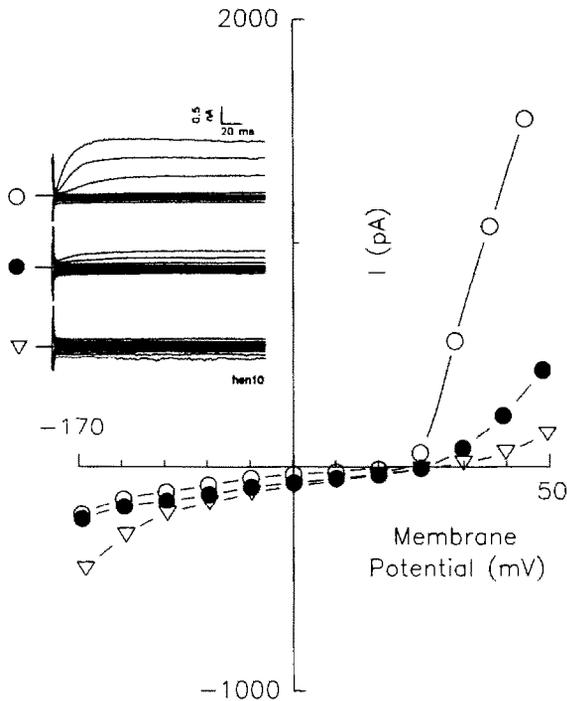

Fig. 4. Single isolated Hensen cell with KCl pipette solution, except that 5% fluorescein was added. I-V plot of steady state current vs. membrane potential corrected for series resistance. Open circles represent currents obtained after fluorescein had entered the cell, but prior to epi-illumination. Note outward rectification similar to cells not containing fluorescein. After 12 s of epi-illumination, the outward K^+ current is partially reduced (closed circles). After a total of 28s exposure, the K^+ current is markedly reduced, probably due to release of free radicals during fluorescence of the dye (open triangles). Membrane potential of the cell, estimated from zero current levels, decreased during the channel inactivation [0 s, -27 mV; 12 s, -8 mV; 28 s, -2 mV], indicating that K^+ permeability is involved in the maintenance of membrane potential in isolated cells.

suggest that coupled supporting cells 'share' K^+ channels via functional gap junctions. To provide clearer proof of this phenomenon, Fig. 7a shows the results of a similar treatment on a group of three Hensen cells; however, in this case, the K^+ channels of the recorded cell were blocked by the use of a CsCl electrode solution. Note that prior to uncoupling, outward K^+ currents are present, and represent only the currents generated in the adjacent coupled cells, since upon uncoupling by CO_2 treatment, the current response is solely from

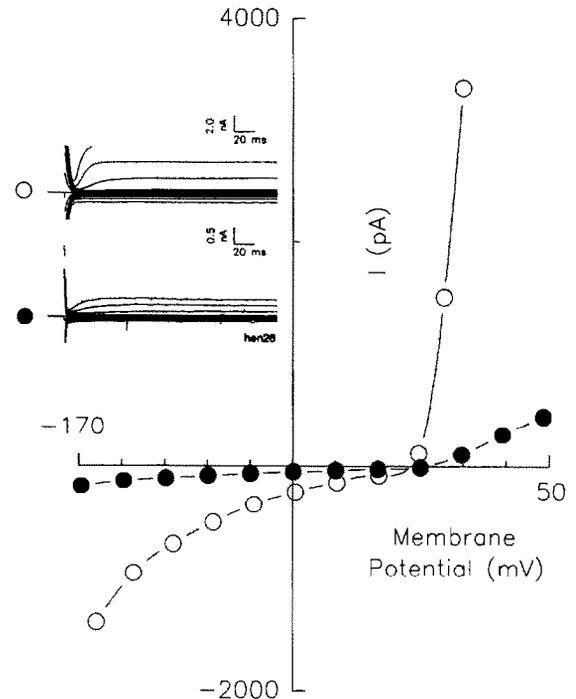

Fig. 5. Voltage clamp of single Hensen cell within a large group (≈ 10) of cells. I-V plot of steady state current vs. membrane potential corrected for series resistance. The tremendous outward current indicates the summation of outward currents from electrically coupled cells (open circles). Due to the large cytoplasmic volume resulting from coupling, it is unlikely that all cells were voltage clamped equally. After perfusion of the cells with CO_2 saturated medium, the cells uncouple from each other and the I-V response approaches that of a single cell (closed circles).

the recorded cell, and lacks outward currents due to the cesium block. Apparently, sufficient amounts of Cs^+ did not diffuse into the adjacent cells through gap junctions during the 5 min period required to collect the data. Fig. 7b shows the time course of input resistance and capacitance changes which accompany uncoupling. During CO_2 perfusion, input capacitance decreases and input resistance increases, until single cell values are attained.

Fig. 8a demonstrates the effect of octanol perfusion on a coupled Hensen cell pair. Octanol rapidly abolishes cell communication. During the process of uncoupling, it is typically found that input capacitance decreases to single cell values

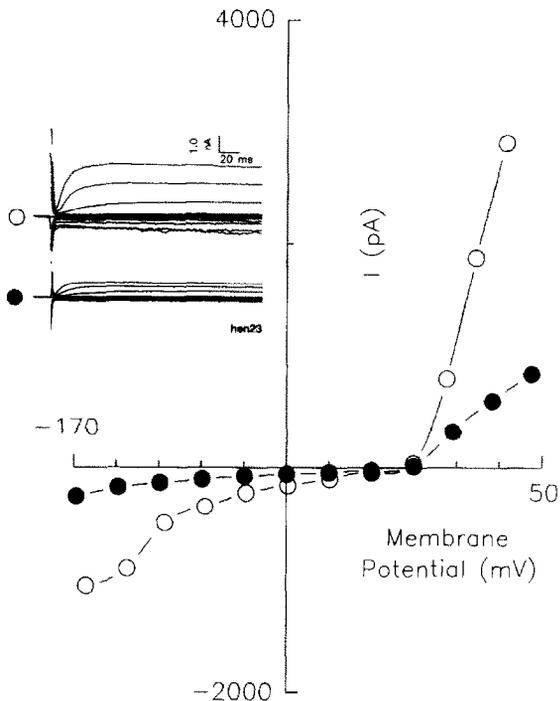

Fig. 6. Single Hensen cell within a group of four cells voltage clamped as in Fig. 5. Currents are smaller than that of the 10 cell group in Fig. 5, but larger than that of single cells, indicating that these cells are electrically coupled (open circles). After perfusion of CO_2 saturated medium, the I-V response is reduced to that of a single cell, confirming that the cells were coupled and that channel 'sharing' among the cells occurs (closed circles).

before dc input resistance reaches single cell values. The reversibility of octanol uncoupling is readily demonstrated by monitoring input capacitance during treatment and washout (Fig. 8b).

Discussion

Hensen cells display an outward rectification upon depolarization, which is mediated by K^+ channels. For individual Hensen cells, this current is small and is activated at potentials far removed from the normal *in vivo* resting potential. Deiter cells, supporting cells which are closely apposed to outer hair cells and are also coupled to Hensen cells (Santos-Sacchi, 1986b), exhibit larger outward currents (Santos-Sacchi, 1989). Supporting cells within the organ of Corti typically have resting potentials ranging from -60 to -100 mV, and are dependent upon extracellular K^+ con-

centration, since high extracellular potassium solutions produce reversible depolarizations in the *in vitro* organ (Santos-Sacchi, 1986a). The membrane potential of isolated supporting cells as determined from zero current levels is depolarized compared to normal resting levels, being on average about -20 mV. It has been demonstrated that the potential of Hensen cells in the intact (stria removed) *in vitro* organ of Corti is about -32 mV immediately upon removal from the animal, but increases to *in vivo* levels (-59 mV) over the course of a few hours only when the temperature is maintained at 37°C (Santos-Sacchi, 1985a). In that study, it was also shown that metabolic inhibitors can induce depolarization. Interestingly, whole cell recordings from isolated OHCs indicate that their membrane potentials are depolarized compared to *in vivo* values (Santos-Sacchi and Dilger, 1988; Dallos et al., 1982); but in many OHCs the potential approaches *in vivo* levels as the KCl patch pipette solution enters the cell over the course of a few minutes. This has not been observed with isolated Hensen cells. A variety of factors may be responsible for the depolarized state of isolated Hensen cells in this study, including temperature, use of simple salt solutions as opposed to culture media, and isolation procedure. Nevertheless, it has been shown that uncoupling agents will produce a depolarization in the Hensen cell syncytium (Santos-Sacchi, 1985; 1986a, b), and obviously, isolated cells and small groups of cells are uncoupled from the very large number of supporting cells normally forming the intact syncytium. It is demonstrated here that membrane potentials of isolated supporting cells are decreased by treatments (TEA, intracellular cesium, photoirradiation of intracellularly inject dye) which block K^+ conductance, indicating the dependence of membrane potential in these isolated cells upon a susceptible K^+ conductance. Conceivably, photoirradiation may produce free radicals which destroy K^+ channel function; Hensen cells have been shown to be uncoupled by the same treatment (Santos-Sacchi, 1986b). Clearly, the present results indicate that the supporting cells can 'share' ionic channels with neighboring cells, and for a cell type whose membrane potential is to some degree K^+ dependent, this may play an important role in maintaining the stable

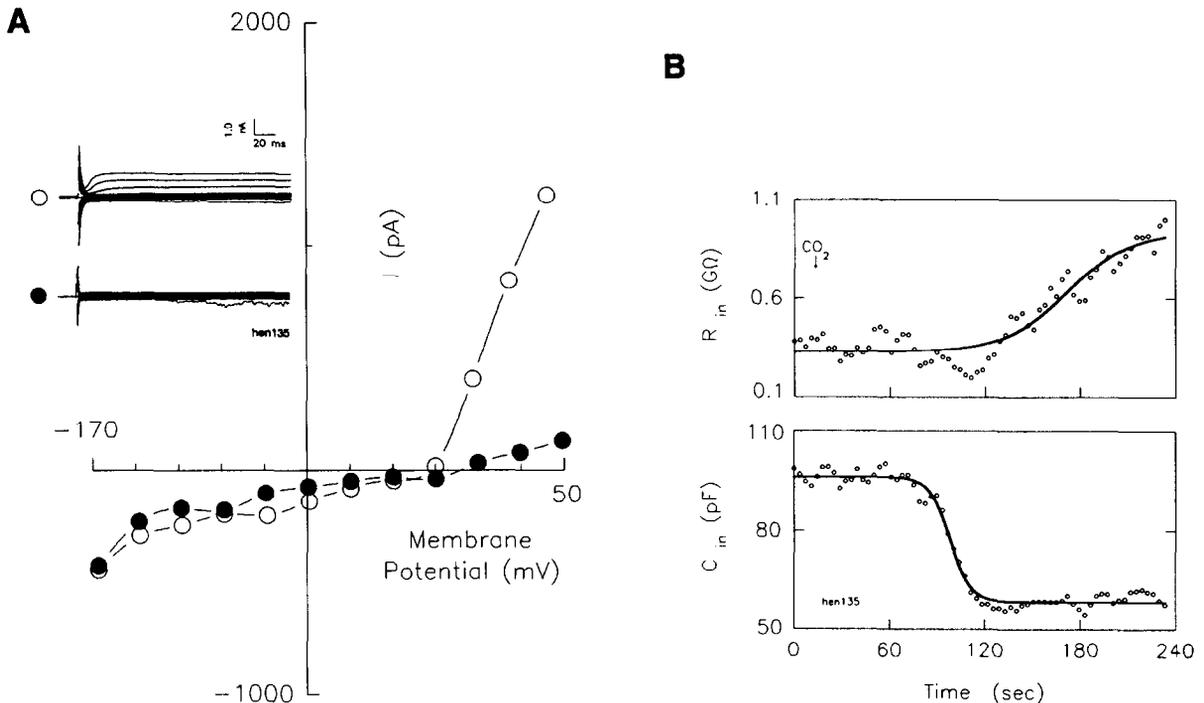

Fig. 7. (A) Single Hensen cell in a group of 3 Hensen cells was voltage clamped with a patch electrode containing the K^+ channel blocker CsCl. Normally, the CsCl patch solution will replace intracellular fluid and block the K^+ channels, thus eliminating outward rectification as in Fig. 2. In this case, however, outward rectification is present (open circles), because the pipette solution has not replaced the intracellular fluid of the other two coupled cells. Thus, the cell which is recorded from is utilizing the K^+ channels of its neighbors. After perfusion of CO_2 saturated medium, the cells uncouple and the cell recorded from appears as a single cell whose K^+ channels are blocked by Cs^+ (closed circles). (B) Time course of CO_2 uncoupling as indicated by changes in input resistance and capacitance. At onset of recording, R_{in} is low relative to isolated single cells and C_{in} is high relative to isolated single cells (see Results). During CO_2 medium perfusion, there is a dramatic change in these values, such that they approach the values of single cells, as would be expected in the uncoupled state. Note that capacitance values reach a minimum before resistance values reach a maximum.

resting potentials found *in vivo*. Maruyama et al. (1983) have estimated that isolated salivary acinar cells have few potassium channels per cell, numbering about 50. Open channel probability is very low at normal resting potentials, and since the possibility exists that no K^+ channels will be open at a given point in time, it was speculated that the stability of the K^+ -dependent resting potentials noted in the intact acinar syncytium is due to the sharing of these channels among coupled cells. The input conductance of isolated Hensen cells is less than 1 nS at the holding potential of -70 mV, and it appears that a major component of this may be due to linear leakage current. Conceivably, a non-specific leakage current may dominate any potential generating effects of a small K^+ conductance at normal resting potentials. Thus, it is

possible that the highly coupled nature of the supporting cells of the organ of Corti, with the attendant 'sharing' of K^+ channels, contributes to the stable, highly negative, K^+ -dependent resting potentials encountered in the intact syncytium. This would indicate that the drop in membrane potential noted upon uncoupling of Hensen cells (Santos-Sacchi, 1985; 1986a) may have been due to the reduction of utilizable neighboring cell K^+ channels.

The change in input resistance and capacitance which occurs upon uncoupling of cell groups or pairs is interesting in that the increase in input resistance is preceded by a reduction of input capacitance values to single cell levels. This type of behavior may not appear intuitive since one might expect both input capacitance and input

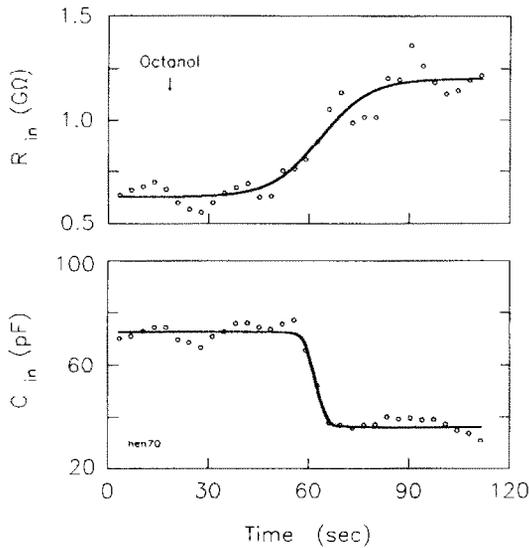

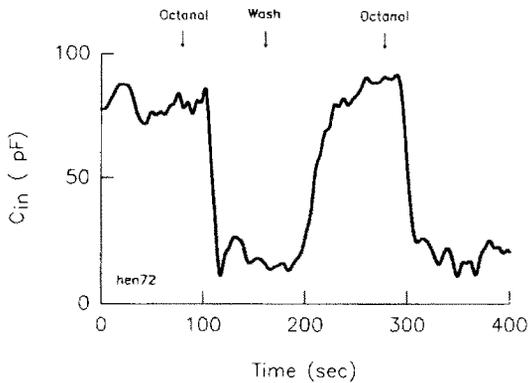

A**B**

Fig. 8. (a) Demonstration that octanol is capable of uncoupling a pair of Hensen cells. Note similarities with CO_2 uncoupling, i.e., the capacitance decreases to single cell values before resistance change is complete. Fig. 9 presents an electrical model based on these data. (b) Reversibility of uncoupling by octanol in a group of 4 Hensen cells. C_{in} decreases to single cell levels during perfusion with octanol, and returns to coupled state levels during washout. Further treatment with octanol uncouples the cells again.

resistance to change reciprocally. The results, however, are not aberrant, as is demonstrated by an analysis of cell models comprised solely of resistive and capacitive elements. In fact, these alterations of input impedance provide information which allows the estimation of gap junctional conductance between the Hensen cells. Fig. 9 de-

picts a circuit model and a voltage step analysis of a cell pair, with single cell component values of $1.1 \text{ G}\Omega$ and 35 pF , and a series resistance of $10 \text{ M}\Omega$, similar to the values obtained from the cell pair of Fig. 8a, after uncoupling.

Fig. 9 indicates the results of a computer simulation where the junctional resistance, R_j , is varied over ten orders of magnitude, and the input capacitance and dc resistance are plotted. It can be seen that the resultant changes in impedance are similar to those of the actual cells, and corroborates the observation that input capacitance is a more sensitive indicator of the state of coupling at low R_j values than dc input resistance. Analyses such as these indicate that junctional conductance in the supporting cells of the organ of Corti can be 3 orders of magnitude larger than non-junctional resting conductance, in this case about $1 \mu\text{S}$ vs. 900pS , respectively. Freeze fracture studies have indicated expansive areas of gap junctional mem-

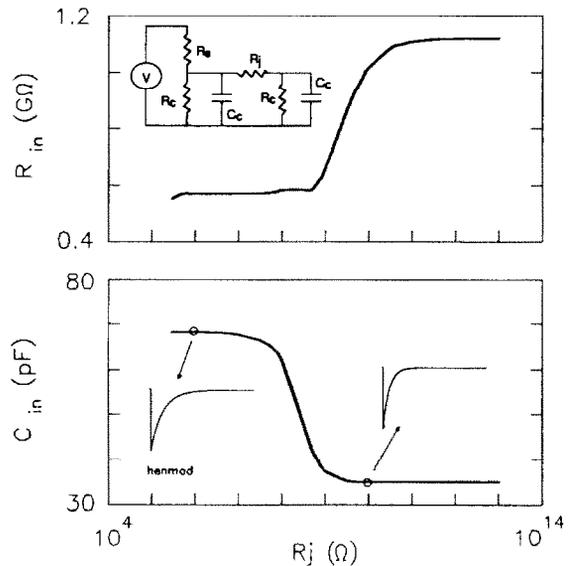

Fig. 9. Two cell model of uncoupling based on data from Fig. 8a. Values for individual cell resistance (R_c) and capacitance (C_c) are $1.1 \text{ G}\Omega$ and 35 pF , respectively. Electrode series resistance (R_s) is $10 \text{ M}\Omega$. Uncoupling was simulated by varying the junctional resistance (R_j) and a voltage step analysis of the network R_{in} and C_{in} was performed. The resulting plots are similar to actual data in that values approach single cell levels as junctional conductance is decreased. For these cells, R_j in the normal coupled state appears to be less than $1 \times 10^6 \Omega$. Capacitive current traces are shown for R_j values of $1 \times 10^6 \Omega$ and $1 \times 10^{10} \Omega$.

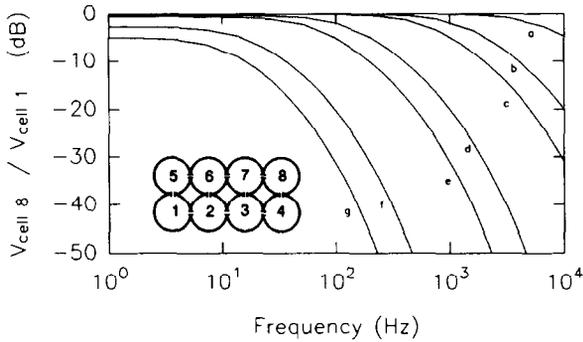

Fig. 10. Simulated ac response in cell 8 in response to a constant voltage injection into cell 1, in a coupled eight cell model (insert). Individual cell capacitances and resistances were 35 pF and 1 G Ω , respectively. Junctional resistances were varied: a, 0.1 M Ω ; b, 0.5 M Ω ; c, 1.0 M Ω ; d, 5.0 M Ω ; e, 10 M Ω ; f, 50 M Ω ; g, 100 M Ω . Note the dramatic drop in cutoff frequency as the junctional conductance is reduced, whereas very low frequency coupling is little affected.

brane which may account for such high junctional conductance (Jahnke, 1975; Gulley and Reese, 1976; Iurato et al., 1976).

Various investigators have recorded sound evoked electrical activity from mammalian supporting cells (Dallos et al., 1982; Goodman et al., 1982; Russell and Sellick, 1978; Oesterle and Dallos, 1986; 1989). In the mammal, this activity is thought to be passively picked up from hair cells (Russell and Sellick, 1978; Oesterle and Dallos, 1988, 1989). Regardless of the mechanism whereby acoustically evoked potentials are established in the supporting cells, it is important to understand the effects of junctional conduction upon such measures. The presently reported sensitivity of supporting cell input impedance to small changes in junctional conductance may indicate that the spectral content of evoked ac activity in supporting cells is sensitive to modifications of gap junctional communication. That is, small fluctuations in gap junctional conductance may alter the low pass RC filter effect of the coupled syncytium. This is examined in Fig. 10 where the ac frequency response is simulated in a model of eight coupled supporting cells. The ratio of the response measured in cell 8 to a constant voltage input into the system via cell 1 is plotted against frequency. The family of curves (a–g) represents the result of a decreasing junctional conductance (non-junctional

membrane conductance and capacitance kept constant, see figure legend for values), and indicates that the frequency response of a coupled cell in the syncytium falls dramatically with relatively small changes in junctional conductance. For example, a change in junctional conductance from 10 μ S (response a) to 0.1 μ S (response e) results in a two octave shift (reduction) in the high frequency cut-off, but only results in about a one dB drop in the dc (0.001 kHz) response. Clearly, good dc coupling can remain during dramatic changes in ac coupling. Since supporting cell coupling can be perturbed by a variety of micro-environmental influences (Santos-Sacchi, 1984a; 1985; 1986a) it is conceivable that fluctuations in organ of Corti homeostasis are more readily expressed as changes in ac coupling rather than dc coupling. This observation may prove useful in future evaluations of coupling in the organ of Corti. For example, in vivo studies of electrical coupling using a dc paradigm to measure cell-to-cell communication alterations during manipulation of the endolymphatic potential have demonstrated little effect upon coupling (Santos-Sacchi and Marbey, 1987). Perhaps an ac analysis would provide the required sensitivity to detect changes in junctional communication during such manipulations.

Finally, the sharing of K⁺ channels of the inwardly rectifying type may help buffer K⁺ levels in the extracellular spaces of the organ of Corti, where K⁺ levels may increase over perilymphatic levels due to sensory and neural activity. Increased K⁺ in the spaces of Nuel may induce slow length changes of outer hair cells (Goldstein and Mizukoshi, 1967; Zenner et al., 1985) and affect the rapid motility characteristics of these cells by its depolarizing effects (Santos-Sacchi, 1989). Obviously, extracellular K⁺ levels must be controlled. It is conceivable that the high resting membrane potentials of the supporting cells (up to –100 mV) may induce a steady state activation of the inward rectifier, thereby promoting K⁺ uptake; gap junctions may contribute to the overall buffering as is speculated in the CNS (Smojen, 1979).

Reversible Inhibition of Voltage-dependent Outer Hair Cell Motility and Capacitance

J. Santos-Sacchi^a

Laboratory of Otolaryngology, UMDNJ–New Jersey Medical School, Newark, New Jersey 07103

Outer hair cells (OHC) from the organ of Corti are capable of fast voltage-induced length changes (Santos-Sacchi and Dilger, 1988), suggesting that an associated voltage sensor should reside in the OHC plasma membrane. Voltage-dependent mechanical responses and nonlinear charge movement of isolated OHCs from the guinea pig were analyzed using the whole-cell voltage-clamp technique. Ionic currents in the cells were blocked. Nonlinear voltage-dependent charge movement or, correspondingly, voltage-dependent capacitance was measured with step or AC analysis. OHC movements were measured either from video or using a differential photodiode technique. Maximum charge movements up to 2.5 pC were measured in OHCs from the low-frequency region of the cochlea. Both AC and step analyses indicated a peak nonlinear capacitance of 16–17 pF. The voltage dependence was fit to a Boltzmann relation with the step analysis indicating a maximum nonlinear capacitance at –23 mV step potential from a holding potential of about –120 mV, and AC analysis indicating a maximum at a holding potential near –40 mV. AC analysis probably provides a more accurate evaluation of voltage dependence. Measures of OHC motility magnitude versus voltage follow the nonlinear capacitance–voltage function obtained from AC measures. Treatment of the cells with gadolinium ions (0.5–1 mM) blocked OHC motility. This treatment also produced a shift of the nonlinear capacitance function along the voltage axis in the depolarizing direction, which can be explained by membrane surface charge screening. However, maximum capacitance was reduced as well and may correspond to the reduction or abolition of OHC motility in response to gadolinium treatment. Gadolinium effects were reversible. Nonlinear capacitance is not a function of membrane deformation due to length changes, since removal of OHC cytosol via the patch pipette abolished longitudinal movement but did not reduce nonlinear charge movement. It is interesting to note that the nonlinear capacitance will dynamically influence the time constant of the OHC during acoustically evoked receptor potential generation.

Both types of hair cells within the organ of Corti, inner (IHC) and outer (OHC), transduce mechanical movements of the basilar membrane into electrical responses. However, even though OHCs are capable of generating receptor potentials (Dallos et al., 1982) and have recently been shown to possess depolarization induced inward calcium currents (a requisite for vesicular transmitter release; Katz and Miledi, 1967; Santos-Sacchi and Dilger, 1988; Santos-Sacchi, 1989b; Lin et al., 1990), it is not certain whether OHCs participate in the direct transfer of neurally coded information to the CNS. It is certainly clear, however, that OHCs participate in the shaping of acoustical information that reaches the CNS. A variety of experiments have established this, including OHC lesion experiments (Dallos and Harris, 1978; Harrison and Evans, 1979) and crossed olivocochlear bundle (COCB) stimulation experiments (Brown and Nuttall, 1984). The participation appears to be at the level of OHC–IHC interaction. However, neither morphologic data (Iurato et al., 1976) nor indirect physiologic data (Oesterle and Dallos, 1988) indicate the existence of direct electrical interactions. The early work of Kemp (1978) on otoacoustic emissions indicated that some sort of active process occurs within the cochlea. This concept was strengthened by studies demonstrating electrically evoked acoustic emissions (Hubbard and Mountain, 1983). With the discovery of Brownell et al. (1985) that isolated OHCs are capable of electrically induced rapid length changes, an exciting new concept arose regarding OHC function—one that envisions a mechanical feedback of OHCs upon basilar membrane motion, which in turn determines the input to the inner hair cell stereocilia (Mountain et al., 1983; Patuzzi et al., 1989). Indeed, evidence suggesting a role of OHCs in controlling basilar membrane motion has been recently obtained (Ruggero and Rich, 1991).

Several lines of evidence indicate that the fast mechanical response of the OHC is voltage dependent (Santos-Sacchi and Dilger, 1988; Iwasa and Kachar, 1989). At the systems level, this voltage dependency is important for understanding the role of OHC motility in frequency selectivity and sensitivity in the mammalian inner ear, since the AC receptor potential generated in these cells *in vivo*, that is, the presumed driving force for OHC motility, will be attenuated above the cells' RC cutoff frequency; thus, the magnitude of mechanical response will necessarily depend upon the frequency of acoustic stimulation (see Santos-Sacchi, 1989c). At the cellular level, a voltage dependence of OHC motility suggests that a charged voltage-sensing particle should reside in the OHC membrane. This concept was first postulated for voltage-dependent ionic channels (Hodgkin and Huxley, 1952), and indeed, nonlinear charge movement, which implies the existence of channel-gating particle movement, is

now known to occur during activation of a variety of ionic channels (Armstrong and Bezanilla, 1973; Bezanilla et al., 1982a; Adams et al., 1990). Recently, nonlinear charge movement (which presents itself as a voltage-dependent capacitance) has been detected in the OHC (Ashmore, 1989).

The voltage-dependent movement of the OHC cannot be blocked by a variety of treatments, including ionic channel blockers, metabolic inhibitors, Ca^{2+} -free media, and anti-cytoskeletal agents (Kachar et al., 1986; Holley and Ashmore, 1988; Santos-Sacchi and Dilger, 1988). While these data indicate that the rapid movements are not based upon a muscle-like system, they have created a sense that fast voltage-dependent OHC movement is unstoppable, except by irreversible means. The ability to reversibly inhibit a phenomenon is an important step in understanding its underlying mechanism. I report here two methods that rapidly and reversibly diminish or abolish longitudinal OHC mechanical responses induced under voltage clamp. The first is treatment of OHCs with gadolinium (Gd^{3+}) ions, and the second is the removal of OHC cytosol via a patch pipette. These two treatments appear to interfere with the mechanical response at distinct cellular levels, since only Gd^{3+} treatment reversibly reduces the voltage-dependent capacitance of the OHC membrane.

Preliminary accounts of this work have been reported (Santos-Sacchi, 1989a, 1990a,b).

Materials and Methods

General. Guinea pigs were anesthetized with pentobarbital and decapitated. The temporal bones were removed, and the sensory and supporting cells were isolated from the cochleas by gentle pipetting of the isolated top two turns of the organ of Corti. No enzymatic digestion was employed for isolation of OHCs or Deiters cells; however, Hensen cells were isolated using trypsin (Santos-Sacchi, 1991). The cell-enriched supernatant was then transferred to a 700 μl perfusion chamber, and cells were permitted to settle onto the coverglass bottom. All experiments were performed at room temperature ($\sim 23^\circ\text{C}$). A Nikon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical recording. All experiments were taped with a Panasonic AG6300 video recorder. A modified Leibovitz medium (NaCl , 142.2 mM; KCl , 5.37 mM; CaCl_2 , 1.25 mM; MgCl_2 , 1.48 mM; HEPES, 5.0 mM; dextrose, 5.0 mM; pH 7.2) was used as the normal perfusate. Modifications to the extracellular medium are noted in figure captions, with NaCl adjusted to maintain osmolarity (300 mOsm). Extracellular solutions were changed via two methods. The chamber perfusion system permits the fluid in the whole chamber to be constantly exchanged with fresh medium (0.1–1 ml/min) and can be used to change to solutions of different ionic makeup. A more rapid and direct perfusion system was used to perfuse single cells selectively under voltage clamp, during continuous exchange of bulk medium via chamber perfusion. The device is a two- or four-barreled glass pipette tapered to about 100 μm and fitted with a polyethylene sleeve at the tip to permit fluid flow from a single port with a small dead volume. Solutions are fed to the pipette under gravity control and are rapidly switched with solenoid valves. The tip of the pipette is brought to within 50 μm of the cell being studied, and the flow of solution is adjusted so as not to perturb the cell physically.

Voltage step studies were performed with an Axolab 1100 A/D and D/A board (Axon Instruments, Foster City, CA) with associated software (pCLAMP). AC studies were performed using a digital signal processing board with custom-written software (DSP-16; Ariel Corp., Highland Park, NJ) capable of delivering and analyzing pure tone or swept frequency stimuli. Filtered current records were saved to disk for offline analysis.

Patch electrodes (flint or borosilicate glass) had initial resistances of 3–6 M Ω . The series resistance, that is, the actual electrode resistance obtained upon establishment of whole-cell configuration, typically ranged from 6 to 14 M Ω ; for the collection of gating currents and short-duration mechanical events, care was taken to maintain low series resistance values during recording by delivering transient positive or negative pressure into the electrode to maintain an unobstructed orifice. The resistance values were estimated from current transients initiated at the

onset of voltage pulses and were corrected for during analysis, so that actual voltages imposed upon the cell are known (Marty and Neher, 1983). The program CLAMPX (Axon Instruments) was modified to provide a continuous display of clamp time constant, cell capacitance (C_m) and resistance (R_m), and series resistance (R_s) between data collections. Pipette solutions were composed of 140 mM KCl or CsCl , 5 or 10 mM EGTA, 2 mM MgCl_2 , and 5 mM HEPES buffered to pH 7.2. In some cases, EGTA was not used. Gigohm seals were obtained at the nuclear level of the cell membrane, and electrode capacitance was compensated prior to whole-cell recording. Generally, single cells were clamped to holding potentials near -70 to -80 mV using a Dagan patch-clamp amplifier. Hyperpolarizing and depolarizing voltage steps, 5–500 msec in length, were used to elicit membrane currents (filtered at 10 kHz) and, in the case of OHCs, mechanical movements.

Measurement of OHC voltage-dependent capacitance. In response to membrane potential perturbations induced by voltage-clamp stimuli, ionic and capacitive membrane currents are normally generated. In order to permit the study of capacitive currents in isolation, OHC ionic currents were blocked. Typically, patch electrodes contained 140 mM CsCl , and extracellular solutions contained 20 mM tetraethylammonium (TEA), 20 mM CsCl , and 2 mM CoCl_2 (see figure captions for modifications). These ionic substitutions were used to block outward and inward K^+ currents and Ca^{2+} currents. Although hair cells possess no fast inward sodium currents (however, see Evans and Fuchs, 1987), in some experiments TTX was used in an attempt to reduce residual leakage currents. No apparent effects were noted in those cases.

Step analysis. The aim of the following voltage step protocols was to extract nonlinear charge movement from total charge movement by subtracting out that component due to the linear dielectric properties of the membrane. OHC gating currents (nonlinear capacitive currents) were measured by averaging current responses elicited by voltage pulses (5 msec) of alternating polarity (40 mV magnitude) about the holding potential of -80 mV ($\pm P$ technique; Armstrong and Bezanilla, 1973). Under certain conditions, this technique may not adequately measure nonlinear charge movement. That is, the amount of charge movement produced for opposite-polarity pulses depends upon where the holding potential lies along the actual nonlinear Q - V function. Thus, at holding potentials well within this function, the capacitive current induced by a hyperpolarizing pulse is not solely linear, and this technique will result in measurement inaccuracies (see Bezanilla and Armstrong, 1977). In the present study, this technique was only used to evaluate relative changes in nonlinear charge movement at a fixed holding potential. In order to evaluate the voltage dependency of nonlinear charge movement, the following protocols were used to overcome the problems inherent in the $\pm P$ technique.

Detailed measures of voltage versus charge movement were obtained by using a $P/-4$ protocol (Bezanilla and Armstrong, 1977) at a holding and subtraction potential of -120 mV. This technique derives nonlinear charge movement from total charge movement by subtracting estimates of linear charge movement obtained at a membrane potential where nonlinear components are small or absent. The procedure entails the presentation of four subpulses of a magnitude equal to $P/-4$; the generated capacitive currents of these subpulses are summed and added to those generated by the depolarizing pulse, P . The highly negative holding potential should provide subtraction currents that will more accurately permit measures of nonlinear charge movement for a range of step potentials. Alternatively, linear charge movement was estimated with 5 mV hyperpolarizing pulses at a holding potential of -120 mV, scaled, and subtracted from total charge movement measured in response to a range of depolarizing voltage steps. Voltage-dependent nonlinear charge [$Q_{(v)}$] was fit to a Boltzmann function (see Fig. 6A and top of Fig. 10A,B):

$$Q_{(v)} = \left(\frac{Q_{\text{max}}}{1 + \exp[-ze(V - V_h)/kT]} \right) + Q_{\text{min}} \quad (1)$$

where V is the potential of the step corrected for series resistance using non-leakage-subtracted steady state current levels at the end of the step, V_h is voltage at half-maximal charge movement, e is electron charge, k

¹ For a nonlinear voltage-dependent charge movement that occurs only upon depolarization from a given holding potential, the summation of capacitive currents induced by opposite polarity steps about the holding potential will result in the extraction of nonlinear capacitive currents. That is, the linear capacitive current produced by the hyperpolarizing step is used to subtract out the linear component induced by the depolarizing step, and only the nonlinear charge movement remains.

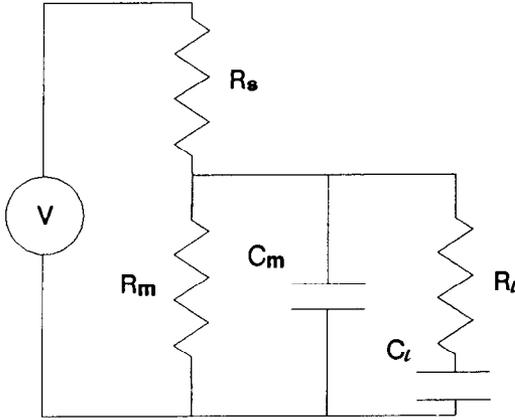

Figure 1. Cell-electrode model. See Materials and Methods for description.

is Boltzmann's constant, T is absolute temperature, z is the valence, Q_{\max} is maximum charge transfer, and Q_{\min} is minimum charge transfer (an offset included to account for possible nonlinear charge movement at levels more hyperpolarized than the subtraction holding potential). Since capacitance, in this case voltage-dependent [$C_{(v)}$], is defined as the first derivative of charge with respect to voltage,

$$C_{(v)} = \frac{dQ_{(v)}}{dv} \quad (2)$$

estimates of voltage-dependent capacitance were obtained by differentiation of the Boltzmann fits of nonlinear charge movement (see Fig. 6B).

AC analysis. AC analyses of the voltage-dependent capacitance were also made using the Ariel DSP board, with sampling at 12 kHz. OHCs were ramped to hyperpolarized and depolarized potentials from a holding potential of -80 mV, and after 0.2 sec, continuous swept frequency stimuli of constant voltage (3.53 mV RMS) were delivered; filtered current responses and input voltage (6 kHz, eight pole Bessel; averaged $20\times$) were saved to disk. The first two collections were discarded prior to averaging. Cell capacitance was evaluated using impedance data similar to techniques used by others (Fishman et al., 1977; Takashima, 1978; Fernández et al., 1982); however, estimates were made using measures of capacitive reactance (X_c) obtained from the impedance calculations. The real and imaginary components of the impedance were obtained by Fast Fourier transform (FFT) using the software package MATLAB (Mathworks, Natick, MA).

A model often used to analyze whole-cell voltage-clamp data is composed of an electrode resistance (series resistance, R_s) in series with a parallel combination of a membrane resistance (R_m) and a membrane capacitance (C_m) (Ogden and Stanfield, 1987; see model schematic in Santos-Sacchi, 1989c). The capacitive reactance (X_c) of such an RC-dominated system can be described as a bell-shaped function of frequency (using a linear-log plot), whose characteristic frequency is dependent upon the cell membrane's RC time constant (see Schanne and Ruiz P.-Ceretti, 1978, their Appendix 2). It is a function in which the effects of R_s are absent:

$$X_c = \frac{\omega C_m R_m^2}{1 + \omega^2 C_m^2 R_m^2}, \quad \omega = 2\pi f. \quad (3)$$

It is useful to avoid the effects of series resistance during the fitting of the experimental data to the model, because series resistance is difficult to measure precisely and can influence the analysis of impedance data (Fernández et al., 1982; Salzberg and Bezanilla, 1983). Unfortunately, the simple model of Equation 3 cannot account for the frequency-dependent nature of membrane capacitance observed in cells possessing nonlinear charge movement. For example, in the squid axon, Fernández et al. (1982) required an additional single or double time constant factor, modeled as lossy capacitors in parallel with the membrane capacitance.²

² The physical correlates of this model are not easily made. However, the lossy capacitance (series combination of resistance and capacitance) may be viewed as

In the present study, fits of experimentally measured X_c to that of clamp-cell models were made using the Nelder-Mead simplex algorithm for frequencies between 0.1 and 3 kHz, across a range of holding potentials. The characteristic frequency of the OHC's X_c is well below 100 Hz because the cell's time constant under the experimental conditions is quite large; for example, Santos-Sacchi (1989c) determined the OHC time constant at -70 mV to be about 3.5 msec (45 Hz). Actually, the characteristic frequency will change as a function of holding potential and ultimately depends upon changes of input capacitance (due to voltage-dependent capacitance) and input resistance (due to unblocked nonlinear leakage currents). Fits of the measured X_c at various holding potentials were made to determine the model's component values. Goodness of fit was estimated from the square root of the sum of squared residuals: the smaller the value, the better the fit. Fits of OHC X_c with the simple RC model of Equation 3 (illustrated in Santos-Sacchi, 1989c) did demonstrate voltage-dependent capacitance, but the goodness of fit was poorer than that obtained with the model of Figure 1, which incorporates an additional lossy capacitance (described below). For an example, see the caption of Figure 7 where the results of fitting the data to both models are presented. While at very negative potentials (e.g., -136 mV) both models yield similarly good fits, at depolarized potentials, where voltage-dependent capacitance is substantial, the model of Figure 1 fits the data points more accurately. Therefore, for the analysis of the AC data, the input impedance of the OHC in series with the electrode resistance (R_s) was modeled as a membrane resistance (R_m) and capacitance (C_m) in parallel with a lossy dielectric consisting of a series combination of another capacitance (C_l) and resistance (R_l):

$$Z_{in} = (R_s + R_{ren}) - jX_c \quad (4)$$

$$= R_s + \frac{R_m(R_l + 1/sC_l)}{(1 + sC_m R_m)(R_l + 1/sC_l + R_m/(1 + sC_m R_m))}, \quad (5)$$

where $s = j\omega$ and $j = \sqrt{-1}$. The model's capacitive reactance (X_c) is given as

$$X_c = -\text{imag}(Z_{in}) \quad (6)$$

$$= \frac{R_m \omega (\tau_m + \tau_{im} + \tau_m \tau_l^2 \omega^2)}{1 + \omega^2 (\tau_m^2 + \tau_l^2 + 2\tau_m \tau_{im} + 2\tau_l \tau_{im} + \tau_{im}^2) + \tau_m^2 \tau_l^2 \omega^4}, \quad (7)$$

where $\tau_l = R_l C_l$, $\tau_{im} = R_m C_l$, and $\tau_m = R_m C_m$.

Although the capacitive reactance is independent of R_s , all other components (R_m , C_m , R_l , and C_l) contribute. Thus, by fitting OHC X_c with the parameters of the model, an estimate of the cell's total capacitance can be obtained ($C_{tot} = C_m || C_l$, the parallel combination of the component capacitances; Chandler et al., 1976).

The total capacitance of the OHC ($C_{(v)}$) at any given holding potential is the sum of the linear, non-voltage-dependent, capacitance (C_{lin}) and voltage-dependent capacitance ($C_{(v)}$):

$$C_{tot} = C_{(v)} + C_{lin} \quad (8)$$

Estimates of linear and voltage-dependent capacitance were made by fitting C_{tot} to Equation 8, with $C_{(v)}$ defined as the first derivative of a Boltzmann function relating charge movement and voltage (see Fig. 8 and bottom of Fig. 10A,B):

$$C_{(v)} = \left\{ \frac{(Q_{\max} z e / k T)}{\exp[(z e / k T)\{V - V_h\}][1 + \exp[-(z e / k T)\{V - V_h\}]]^2} \right\}. \quad (9)$$

Measurement of OHC movement. Movements of the OHCs were analyzed by three methods. For steady state movements (voltage steps > 100 msec), length changes were analyzed off the video monitor during playback either by direct measurement off the video monitor using single still frames (Santos-Sacchi and Dilger, 1988) or by placing differential optoresistors or a position-sensitive detector (PSD; Hamamatsu Corp., Bridgewater, NJ) (output filtered at 30 Hz) across the image of the cuticular plate at a monitor magnification of $2800\times$. The linearity of

the voltage-dependent capacitive component, and the frequency dependence it imparts to the model may correspond to the time-dependent nature of nonlinear charge movement within the membrane (see Fernández et al., 1982).

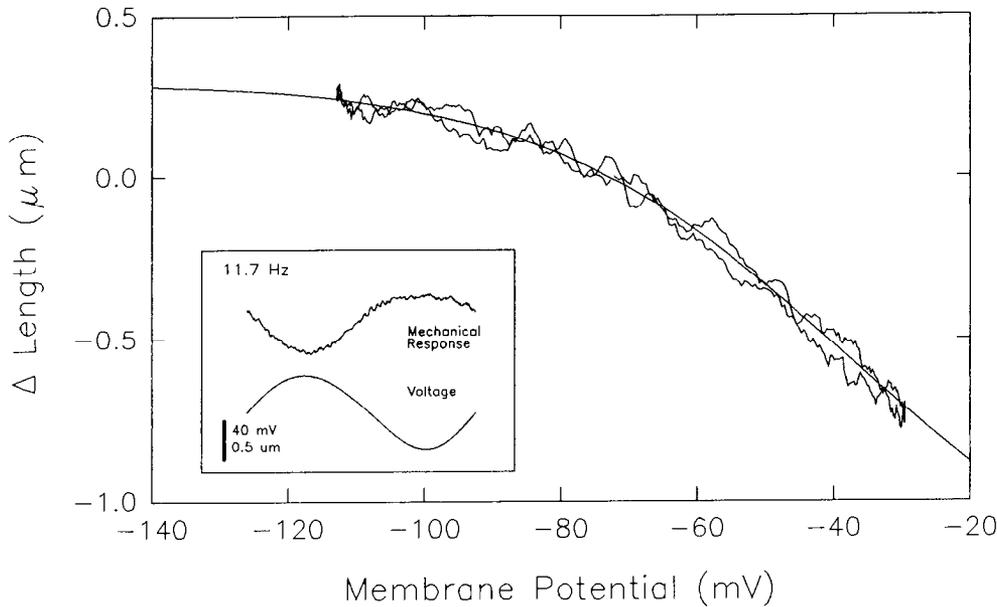

Figure 2. The voltage–displacement response of an OHC to an 11.7 Hz sinusoidal voltage stimulus superimposed upon a holding potential of about -74 mV, as measured with the differential photodiode technique. *Solid smooth line* is fit to a Boltzmann function with V_h at -38 mV and $z = 1.14$. *Inset*, Movement and voltage waveforms. Series resistance–corrected voltage trace was derived from the simultaneously recorded whole-cell current record by modeling the cell-clamp setup as a simple $R_m C_m$ cell circuit in series with the electrode's series resistance (Santos-Sacchi, 1989c), the values of which were estimated from responses to voltage steps. Current was transformed into the frequency domain by FFT and the voltage was calculated using the component values and converted into the time domain by reverse Fourier transform. Extracellular medium contained 20 mM TEA, 300 nM TTX, and no added Ca^{2+} . CsCl pipette solution.

the optoresistor method was confirmed by measuring the videotaped movement of the tip of a microelectrode driven by a piezoelectric bimorph element (Santos-Sacchi, 1989c). Fast OHC movements elicited by voltage clamp with short-duration stimuli (below video detection) were measured with a differential photodiode onto which the image of the cuticular plate from the microscope was projected. The placement and manipulation of the photodiode was accomplished by a computer controlled micromanipulator. The photodiode was backlit by two fiber optic beams projected through the microscope's camera port onto a 30% mirrored glass coverslip base of the perfusion chamber, and reflected back to a charge coupled device (CCD) video camera via a 90° prism to allow photodiode placement during simultaneous cell visualization on a mixed video–computer monitor (Matrox Corp., Canada). Backlighting was not required after calibration of the photodiode's position on the monitor. The frequency response of the differential photodiode was flat out to 2 kHz (measured with a light-emitting diode or piezoelectric bimorph). Measures of OHC movements by the photodiode method were performed by averaging the simultaneously recorded current and photodiode output 200 times, in response to step or pure tone voltage stimuli. Absolute calibration of cell movements was determined by measuring off the video monitor the cell movement in response to a large steady state depolarizing voltage stimulus. The error in absolute measures was estimated to be less than 20%.

Results

Under voltage clamp, OHCs respond to voltage alterations by changing their length. Figure 2 illustrates the voltage dependence of the magnitude of OHC cell length changes. At a holding potential near -75 mV, an 11.7 Hz sinusoidal voltage stimulation of the OHC induces contraction during the depolarizing phase and elongation during the hyperpolarizing phase. The response is greater in the depolarization direction and corroborates the voltage–mechanical response function obtained by voltage step analysis (Santos-Sacchi, 1989c). The maximum excursion for these mechanical responses, at voltage step extremes, can be up to about 3–4 μm , with slopes in the midregion as great as 30 nm/mV. The voltage–mechanical response function indicates that at potentials near the resting potential measured *in vivo*, -70 mV (Dallos et al., 1982), sinusoidal stimulation will produce asymmetrical mechanical responses, that is, DC mechanical responses in addition to sinusoidal responses (Santos-Sacchi, 1989c). These DC responses are in the depolar-

ization–contraction direction and have been observed up to frequencies as high as 3.2 kHz (J. Santos-Sacchi, unpublished observations).

Depolarization of the OHC elicits outward K^+ currents, which are blocked to varying degrees by a host of treatments, including intracellular Cs, or extracellular TEA, Cd^{2+} , Ba^{2+} , charybdotoxin (ChTX), 4-aminopyridine (4-AP), octanol, and Gd^{3+} . Figure 3A illustrates an I – V function and associated current traces for a cell voltage clamped with a pipette containing KCl solution, before and after treatment with 500 μM Gd^{3+} . Outward K^+ currents are blocked by Gd^{3+} ; however, unlike other ionic blockers, Gd^{3+} treatment reduces or abolishes the OHC mechanical responses elicited by depolarizations. This can be seen in the simultaneously measured mechanical responses of this cell; mechanical responses were undetectable after Gd^{3+} treatment (Fig. 3A).

OHC mechanical responses are rapid in onset following a voltage stimulus, with the onset time constant principally determined by the speed of the voltage clamp (Santos-Sacchi, 1990a). Figure 3B depicts the response of an OHC to voltage steps of 5 msec duration. Treatment of this cell with 1 mM Gd^{3+} caused a developing block of motility (traces a–d). In this case, about 5 min after the start of Gd^{3+} perfusion, the cell contractions stopped. Recovery followed washout. Traces labeled f represent steps from -80 mV to -30 , 0, and $+30$ mV and illustrate the saturating nonlinearity in the magnitude of response occurring at highly depolarized levels (Santos-Sacchi and Dilger, 1988). The time constant of mechanical response onset changed during the development of Gd^{3+} block. Since this time constant is critically dependent upon the time constant of the clamp amplifier (Santos-Sacchi, 1990a), it is necessary to determine whether the clamp time constant was altered during the data collections. Simultaneously recorded currents revealed that the clamp time constant actually shortened (from 0.21 to 0.18 msec) during the collections and thus could not account for the increases of the time constant for mechanical responses (0.26, 0.44, and 0.57 msec for traces a–c, respectively).

The reversibility of the Gd^{3+} effects upon the OHC mechan-

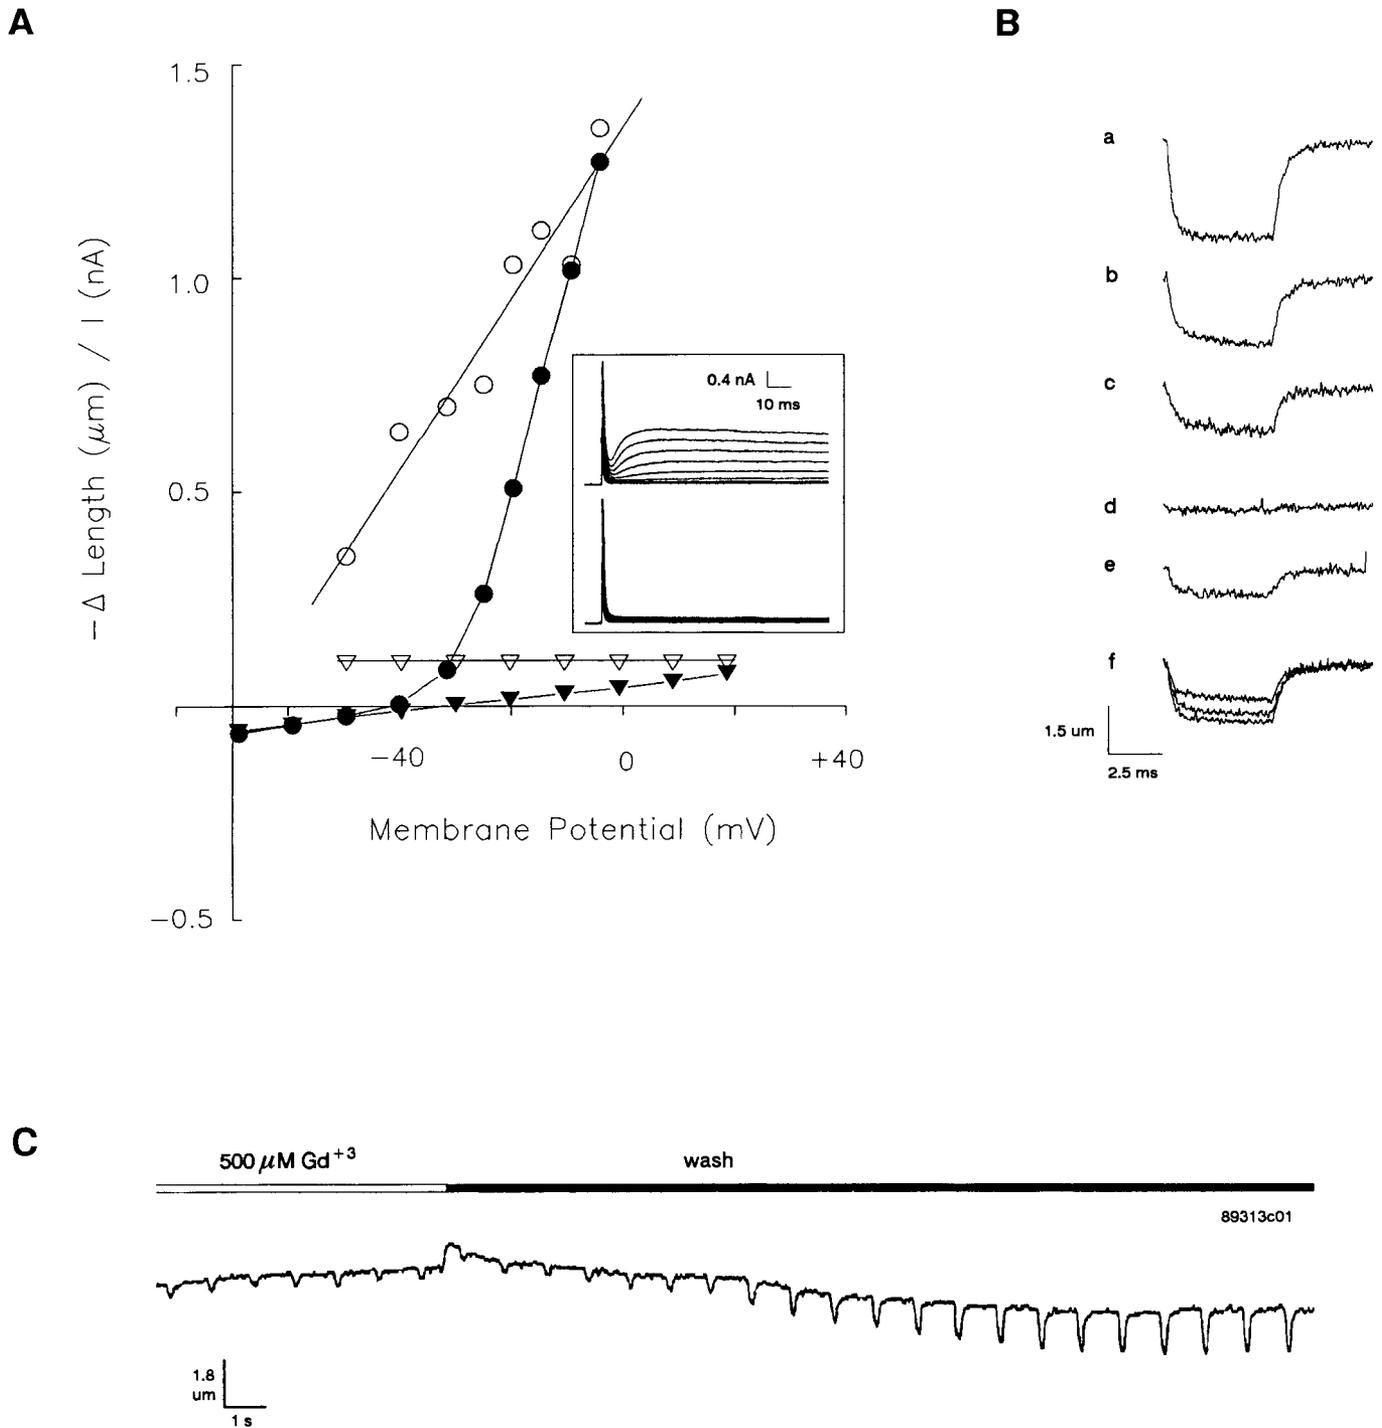

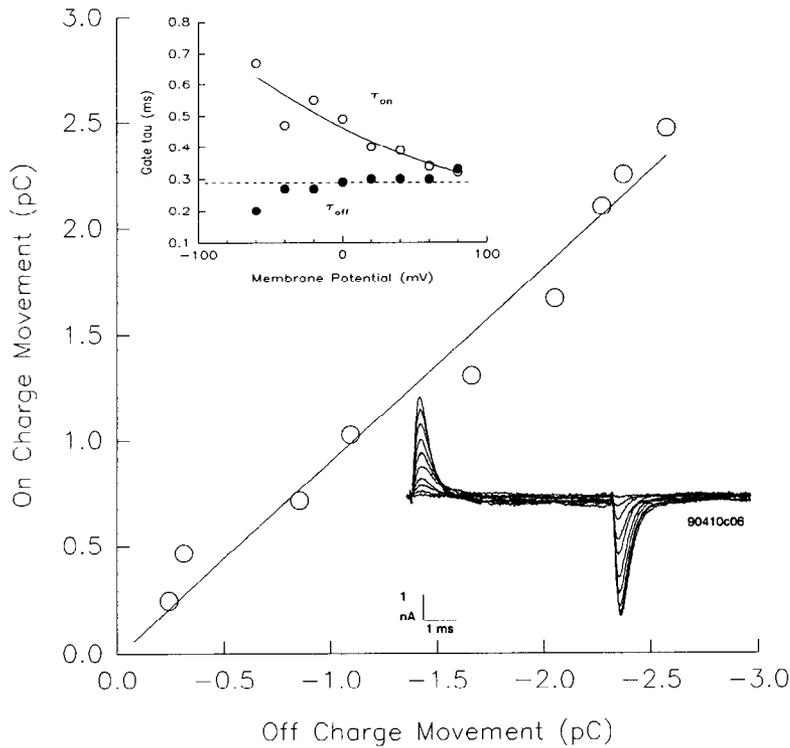

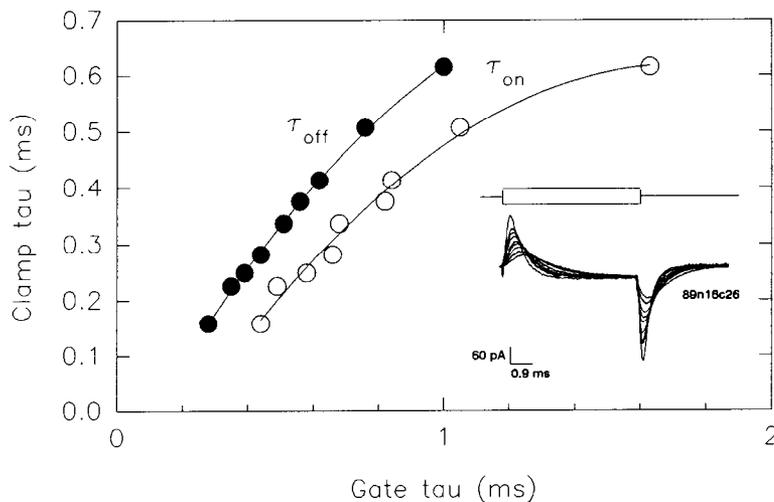

Figure 3. *A*, Simultaneously recorded whole-cell currents and mechanical responses of an OHC before and after treatment with 500 μM Gd^{3+} . Medium was Leibovitz without added Ca^{2+} . Electrode contained KCl solution. *Solid circles*, Currents before Gd^{3+} treatment; *open circles*, movements before Gd^{3+} treatment measured with differential optoresistor from video monitor. *Solid triangles*, Currents after addition of Gd^{3+} ; *open triangles*, movements undetectable after Gd^{3+} . Vertical scale corresponds to nA or μm of contraction. Series resistance corrected, no leakage current subtraction. *Inset*, Current traces before and after Gd^{3+} treatment. *B*, Mechanical responses of an OHC to short duration voltage steps from a holding potential of -80 to 40 mV (nominal; *a–e*) before (*a*), during [*b* (1 min), *c* (2 min), *d* (5 min)], and after [*e* (2 min wash)] perfusion with 1 mM Gd^{3+} . Traces labeled *f* (7 min wash) depict mechanical responses to voltages of -30 , 0 , and $+30$ mV. Extracellular medium contained 20 mM TEA, 20 mM CsCl, and no added Ca^{2+} . CsCl pipette solution. *C*, Reversibility of Gd^{3+} effects upon mechanical response. OHC was directly perfused with 500 μM Gd^{3+} in Ca-free Leibovitz, as indicated. Upon washout of the trivalent cation, the mechanical response increases over time. Contraction of the cell is indicated by the downward deflections of the trace measured with differential optoresistor from video monitor.

A

B

ical response is more clearly demonstrated in Figure 3C. This cell was continuously stepped to a voltage of 0 mV from a holding potential near -80 mV. While the cell was in the presence of $500 \mu\text{M}$ Gd^{3+} , mechanical responses were barely detectable; however, changeover to wash medium quickly initiated a recovery from the trivalent cation's effects. The block of ionic conductances is also rapidly reversible. Interestingly, washout with medium containing $500 \mu\text{M}$ Cd^{2+} did not restore motility. It is important to note that the block of OHC longitudinal motility by gadolinium ions was not due to or associated with a loss of cell turgor (see below). However, gadolinium produced a lengthening of the OHC, sometimes up to several micrometers.

The shapes of supporting cells were not affected by similar treatments. Typically, concentrations of about $500 \mu\text{M}$ were required to interfere with the magnitude of mechanical response. On the other hand, OHC outward currents were readily blocked, and under current clamp, membrane potentials were reversibly depolarized at concentrations as low as $50 \mu\text{M}$. Low concentrations of Gd^{3+} similarly affected ionic currents of supporting Deiters cells.

OHCs exhibit a nonlinear capacitive (gating) current that is directed outward at the onset of a voltage depolarization and inward during the repolarization. Such gating currents are readily observed after blocking ionic currents (Fig. 4A, trace inset).

Figure 4. *A*, OHC on-charge versus off-charge measured by integrating on- and off-gating currents over time as a function of voltage step size. *Trace inset* depicts nonlinear capacitive currents obtained by $P/4$ procedure at a holding and subtracting potential of -120 mV. Step depolarizations were in 20 mV increments up to 80 mV. *Line* is least-squares linear fit, indicating roughly equal nonlinear charge movements at onset and offset of voltage pulses. *Inset*, Single exponential time constant of current decay for on and off currents as a function of step potential. *Broken line* indicates clamp time constant. *Open circles*, τ_{on} ; *solid circles*, τ_{off} . Cell perfused with Leibovitz containing 20 mM TEA, 20 mM CsCl, and 2 mM CoCl_2 . CsCl electrode. *B*, Dependence of OHC gating current time constants upon clamp time constant. Procedure was $\pm P$ (40 mV) at a holding potential of -80 mV. *Traces* depict nine individual collections (averaged $200\times$) with different clamp time constants. The time constant of the clamp is dependent upon the series resistance of the patch electrode (Ogden and Stanfield, 1987) and was modified by electronically compensating the series resistance through feedback controls on the amplifier. *Open circles*, τ_{on} ; *solid circles*, τ_{off} . Cell perfused with 20 mM TEA Leibovitz. CsCl electrode.

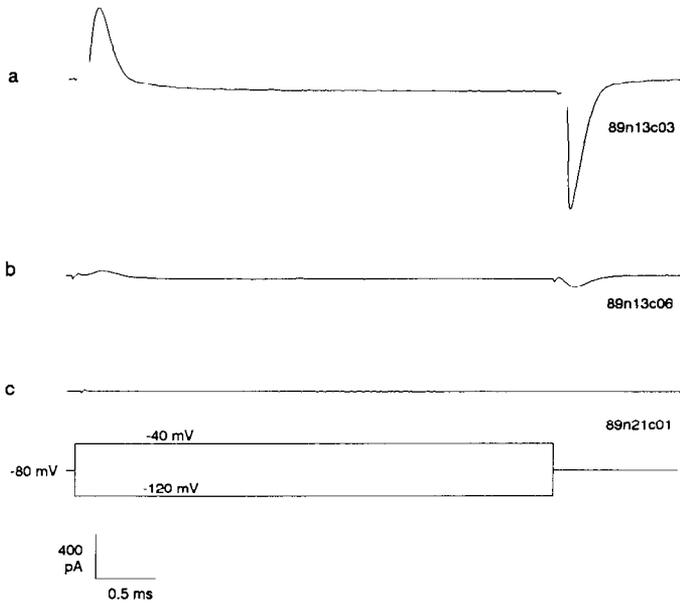

Figure 5. Block of OHC nonlinear charge movement by gadolinium ions. *Bottom trace* indicates voltage protocol of the $\pm P$ technique used to obtain the current traces (see Materials and Methods). *a*, Gating currents of OHC measured with the $\pm P$ technique; 10 mM TEA, 300 nM TTX Leibovitz. CsCl electrode. *b*, Same cell after treatment with same medium containing 500 μM Gd^{3+} . Gating current returned after washout. *c*, Absence of gating currents in Deiters cell; 20 mM TEA Leibovitz. CsCl electrode.

Charge transfer at voltage step onset and offset is essentially equal (Fig. 4). In cells where nonlinear leakage currents were small it was possible to look at the time constant of decay of the on-gate current. Whereas the time constant for the off-gate current was not voltage dependent, that of the on-gate was voltage dependent, decreasing with increasing depolarization step size until it approached both off-gate and clamp time constant values (Fig. 4*A*, inset); however, it was impossible to study this relationship validly because both gate time constants were dependent upon the time constant of the voltage clamp. Figure 4*B* clearly demonstrates this dependence and indicates that charge movement across the membrane is redistributed in time as a function of clamp time constant.

Figure 5 illustrates the effect of Gd^{3+} treatment on OHC gating current measured at -80 mV with the $\pm P$ technique. In this case, 500 μM Gd^{3+} nearly abolishes the current (Fig. 5*b*); the current can recover during washout of Gd^{3+} . Supporting cells do not demonstrate a nonlinear capacitive current under the same conditions (Fig. 5*c*). A more detailed analysis of the effects of Gd^{3+} on OHC nonlinear charge movement follows.

OHC nonlinear charge movement displays a saturating magnitude–voltage relation (Fig. 6*A*, solid circles). A Boltzmann fit to the data (solid line) indicates that the voltage (V_h) for half-maximal charge movement is -23.8 mV, with a valence (z) of 0.87. Maximum charge transfer up to about 2.5 pC has been observed in OHCs from the apical portion of the cochlea using the $P/-4$ technique at a holding and subtraction potential of -120 mV. Differentiating the Boltzmann fit (Fig. 6*B*, solid line marked with solid circle) indicates a peak nonlinear voltage-dependent capacitance of about 17 pF. Gadolinium ions shift

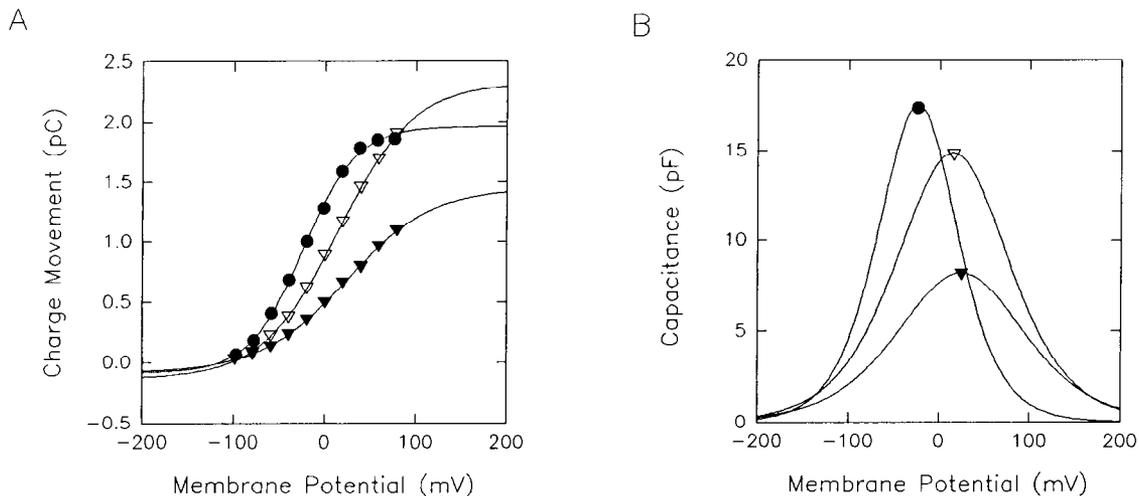

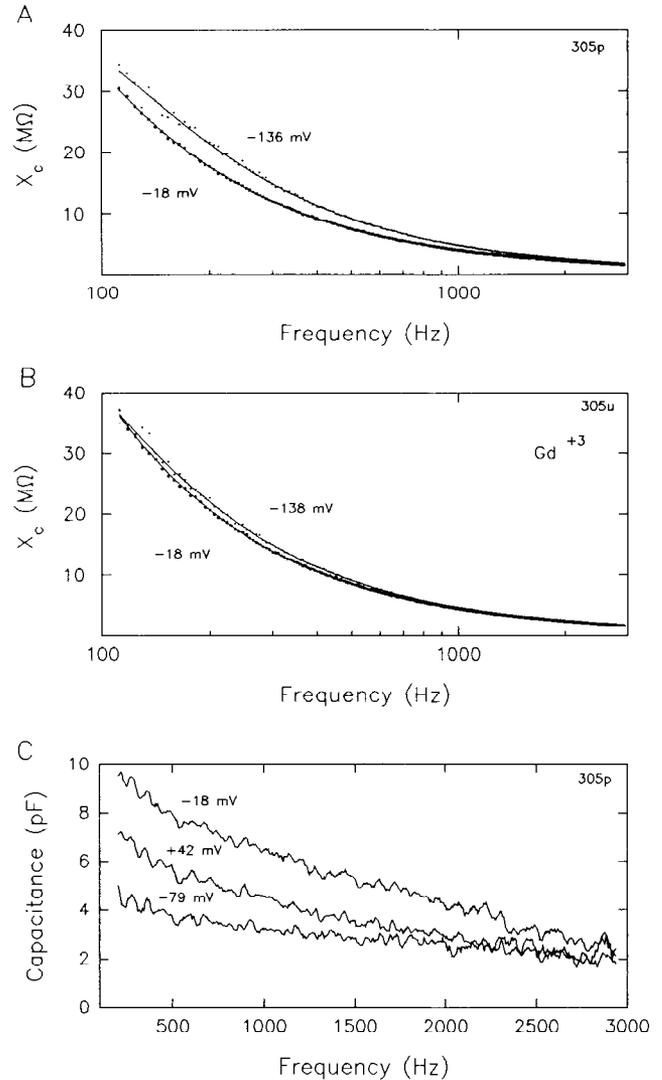

Figure 6. Average nonlinear charge movement and capacitance versus step potential corrected for series resistance determined using the $P/-4$ technique. On-charge and off-charge were averaged. Cells were held at -120 mV and stepped in 20 mV increments to a maximum of 80 mV (nominal voltages; see Materials and Methods). *A*, *Solid circles*, Average of four cells. *Solid line* is the fit to Equation 1. V_h and z : -23.8 mV and 0.87, respectively. Bath perfusion contained 20 mM TEA, 20 mM CsCl, 2 mM CoCl_2 , and no added Ca^{2+} . No direct cell perfusion. CsCl electrode, no EGTA. *Open triangles*, Average of four different cells. *Solid line* is the fit to Equation 1. V_h and z : 14.8 mV and 0.62, respectively. Cells were individually perfused with 20 mM TEA, 20 mM CsCl, 2 mM CoCl_2 , and no added Ca^{2+} medium from one barrel of a double-barreled pipette whose other barrel contained an additional 1 mM GdCl_3 . Bath perfusion as above. CsCl electrode, no EGTA. *Solid triangles*, Average of same four cells as depicted by *open triangles*. *Solid line* is the fit to Equation 1. V_h and z : 24.1 mV and 0.55, respectively. Cells were individually perfused from barrel containing 20 mM TEA, 20 mM CsCl, 2 mM CoCl_2 , 1 mM GdCl_3 , and no added Ca^{2+} medium. Bath perfusion as above. CsCl electrode, no EGTA. *B*, Voltage-dependent capacitance of cells in *A* as determined from first derivative of fitted charge movement with respect to voltage. *Symbol-marked curves* correspond to fits in *A*. Note, in addition to apparent charge screening by gadolinium, the reduction of voltage-dependent capacitance.

the voltage dependence and reduce the amount of OHC nonlinear charge movement. Charge movements represented by the open triangles in Figure 6A were obtained while perfusing an ionic blocking solution (see figure caption) via a double-barreled pipette, the other barrel containing an additional 1 mM Gd^{3+} . The voltage shift relative to the data represented by the solid circles suggests that charge screening³ had occurred due to diffusion of Gd^{3+} from the gadolinium-containing barrel. A Boltzmann fit to these data (solid line) indicates a V_h of 14.8 mV and z of 0.62. Figure 6B indicates that the peak capacitance is about 14 pF (solid line marked with open triangle). Upon perfusion with the 1 mM Gd^{3+} -containing solution, an additional voltage shift is noted and a marked decrease in the charge displacement is observed (solid triangles). The Boltzmann fit (solid line) gives a V_h of 24.2 mV and z of 0.55. Corresponding peak capacitance is about 7.5 pF (Fig. 6B, solid line marked with solid triangle).

Analysis of the nonlinear charge movement in the frequency domain for the same cells corroborates the time domain analysis. The capacitive reactance of the cells was determined at various holding potentials for frequencies up to 3 kHz. These measures were fit with the model of Figure 1 to obtain estimates of linear and nonlinear membrane capacitance. Figure 7A demonstrates that the capacitive reactance (X_c) of the OHC changes when the holding potential of the cell is changed from -136 to -18 mV. In this case, fitting the data (solid lines; see Materials and Methods) reveals an increase of about 10 pF upon depolarization of the cell to -18 mV. Perfusion of the cell with 1 mM Gd^{3+} reduces the nonlinear voltage-dependent capacitance (Fig. 7B). Since measures of X_c reflect the contribution of resistive as well as capacitive elements, frequency-dependent changes in cell capacitance cannot be obtained simply by taking the difference between X_c measures obtained at different holding levels. In order to evaluate the frequency dependence of the membrane capacitance, it is necessary to process the impedance data according to the techniques of Fernández et al. (1982).⁴ Figure 7C illustrates the results of such an analysis. The traces depict the voltage-dependent capacitance at selected holding potentials (-79 , -18 , and $+42$ mV; corrected for series resis-

³ Membrane surface potentials can arise from fixed surface charges. Charge screening refers to the alteration of this surface potential by the application of counterions. Since the voltage that a membrane-bound voltage sensor detects will be influenced by the membrane surface potential, the alteration of surface potential by charge screening can shift voltage-dependent membrane processes along the voltage axis (for review, see Hille, 1984).

⁴ The technique involves manipulation of the impedance data, after removal of series resistance effects. Briefly, after subtracting estimates of the series resistance from the input impedance measures and calculating the susceptance (B_m) from the admittance transform ($1/Z_{in}$), a measure of cell capacitance as a function of frequency (B_m/ω) can be obtained (for more detailed information, see Fernández et al., 1982).

Figure 7. Capacitive reactance of OHC as determined with AC analysis (see Materials and Methods). *A*, Capacitive reactance (points) prior to gadolinium treatment determined at a holding potential of -136 and -18 mV as indicated in figure. Fitted curves were obtained with Equation 7. Fitted parameters for -136 mV collection were R_m , 87.2 $M\Omega$; C_m , 29 pF; R_s , 13.4 $M\Omega$; C_s , 5.5 pF. C_{tot} ($C_m \parallel C_s$), 34.5 pF. Goodness of fit (see Materials and Methods), 4.5 $M\Omega$. Fitted parameters for -18 mV collection were R_m , 132 $M\Omega$; C_m , 32.4 pF; R_s , 11.4 $M\Omega$; C_s , 11.6 pF. C_{tot} ($C_m \parallel C_s$), 44 pF. Goodness of fit, 1.1 $M\Omega$. Voltage-dependent change in capacitance, 9.5 pF. Data were also fitted (not shown) to the simple RC model (Eq. 3) described in Materials and Methods. Fitted parameters for -136 mV collection were R_m , 82.5 $M\Omega$; C_m , 34.2 pF. Goodness of fit, 5.2 $M\Omega$. Fitted parameters for -18 mV collection were R_m , 86.6

$M\Omega$; C_m , 42.1 pF. Goodness of fit, 5.9 $M\Omega$. Voltage-dependent change in capacitance, 7.9 pF. Cell was individually perfused with 20 mM TEA, 20 mM CsCl, 2 mM $CoCl_2$, and no added Ca^{2+} medium from one barrel of a double-barreled pipette whose other barrel contained an additional 1 mM $GdCl_3$. Bath perfusion as in Figure 6. CsCl electrode, no EGTA. *B*, Capacitive reactance (points) of same cell after gadolinium treatment determined at a holding potential of -138 and -18 mV as indicated in figure. Fitted curves were obtained with Equation 7. Fitted parameters for -138 mV collection were R_m , 120 $M\Omega$; C_m , 29 pF; R_s , 12.1 $M\Omega$; C_s , 5.95 pF. C_{tot} ($C_m \parallel C_s$), 34.95 pF. Goodness of fit, 3.9 $M\Omega$. Fitted parameters for -18 mV collection were R_m , 236 $M\Omega$; C_m , 31.7 pF; R_s , 21.5 $M\Omega$; C_s , 6.6 pF. C_{tot} ($C_m \parallel C_s$), 38.3 pF. Goodness of fit, 1.8 $M\Omega$. Voltage-dependent change in capacitance, 3.3 pF. Data were also fitted (not shown) to the simple RC model (Eq. 3) described in Materials and Methods. Fitted parameters for -136 mV collection were R_m , 109 $M\Omega$; C_m , 34.5 pF. Goodness of fit, 5.2 $M\Omega$. Fitted parameters for -18 mV collection were R_m , 130 $M\Omega$; C_m , 37 pF. Goodness of fit, 5.9 $M\Omega$. Voltage-dependent change in capacitance, 2.5 pF. Cell was individually perfused from barrel containing 20 mM TEA, 20 mM CsCl, 2 mM $CoCl_2$, 1 mM $GdCl_3$, and no added Ca^{2+} medium. Bath perfusion as in Figure 6. CsCl electrode, no EGTA. *C*, Membrane capacitance of the OHC in *A*. The frequency dependence of OHC membrane capacitance was estimated using the technique of Fernández et al. (1982) (see footnote 4) and plotted using linear axes. Data are plotted after subtraction of the response obtained at -136 mV, and were smoothed using a five-point running average. These plots are a true measure of the real part of the membrane's voltage-dependent complex capacitance, provided that the value used for series resistance subtraction is correct and that minimal voltage-dependent capacitance is present at the subtraction holding potential of -136 mV.

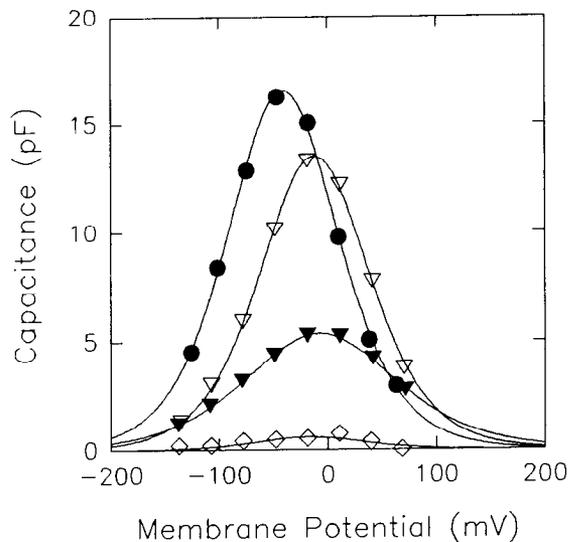

Figure 8. Average voltage-dependent capacitance determined from AC analysis for same cells as in Figure 6. Total capacitance was determined as a function of holding potential as in Figure 7 (see Materials and Methods). Symbols correspond to those of Figure 6. In addition, *open diamonds* represent average of data obtained from two Deiters cells and two Hensen cells, treated the same as those cells depicted by *solid circles* (see Fig. 6). Data were fit to Equation 8 to obtain voltage-dependent ($C_{(v)}$) and non-voltage-dependent ($C_{(in)}$) capacitance and were plotted after subtracting $C_{(in)}$. $C_{(in)}$, V_{h_2} , and z : *solid circles*, 23.2 pF, -40.7 mV, 0.76; *open triangles*, 29.9 pF, -11.8 mV, 0.76; *solid triangles*, 30.3 pF, -7 mV, 0.55; *open diamonds*, 30 pF, -16.3 mV, 0.76.

tance effects) as a function of frequency. The data demonstrate the voltage- and frequency-dependent nature of OHC membrane capacitance and are similar to the results obtained by Fernández et al. (1982) in the squid giant axon. Unfortunately, the usefulness of this type of analysis depends upon precise measurement of series resistance, since small inaccuracies in the measurement will provide incorrect estimates of the capacitance's frequency dependence. It should be reemphasized that estimating model parameters from reactance measures avoids problems imposed by series resistance effects, since these measures are not influenced by series resistance (see Materials and Methods).

Figure 8 shows the average input capacitance obtained, using AC analysis, from the same cells as in Figure 6, as a function of holding potential, before and after gadolinium treatment (symbols correspond to those in Fig. 6). A significant nonlinear capacitance is present at potentials near the normal resting potential *in vivo*, -70 mV. As was evident in the time domain analysis (Fig. 6B), AC measures indicate that treatment with gadolinium ions reduces the magnitude of the voltage-dependent capacitance and does not merely shift its voltage dependence. Supporting cells (Deiters and Hensen) demonstrate no or very little nonlinear capacitance when analyzed in the frequency domain (Fig. 8, open diamonds). OHC peak nonlinear capacitance occurs at potentials that are shifted about 17 mV in the hyperpolarizing direction compared to step analyses. Since holding potentials were different for the AC and time domain analyses, it is conceivable that initial conditions may be responsible for the shift. Such effects have been found for Na

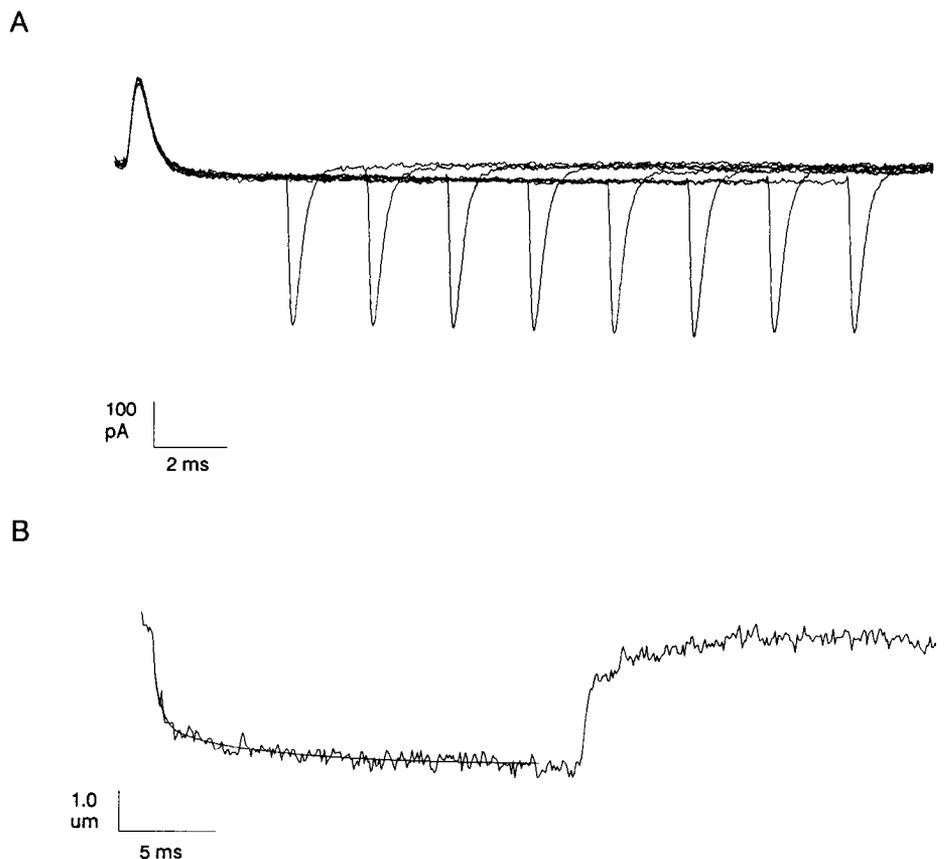

Figure 9. Demonstration of absence of gating charge immobilization or mechanical response decay. *A*, An OHC was held at -80 mV, and gating currents were obtained with the $\pm P$ method for a range of voltage step durations. Traces are overlaid, and the occurrence of equivalent off-charge movement at differing pulse widths indicates absence of charge immobilization in this time frame. Charge immobilization would have been indicated by a decreasing off-charge movement as a function of increasing pulse duration. *B*, An OHC was stepped to $+40$ mV from a holding potential of -80 mV for about 20 msec, and the mechanical response was measured with the differential photodiode technique. Downward deflection is contraction. Note absence of decay in the mechanical response during depolarization.

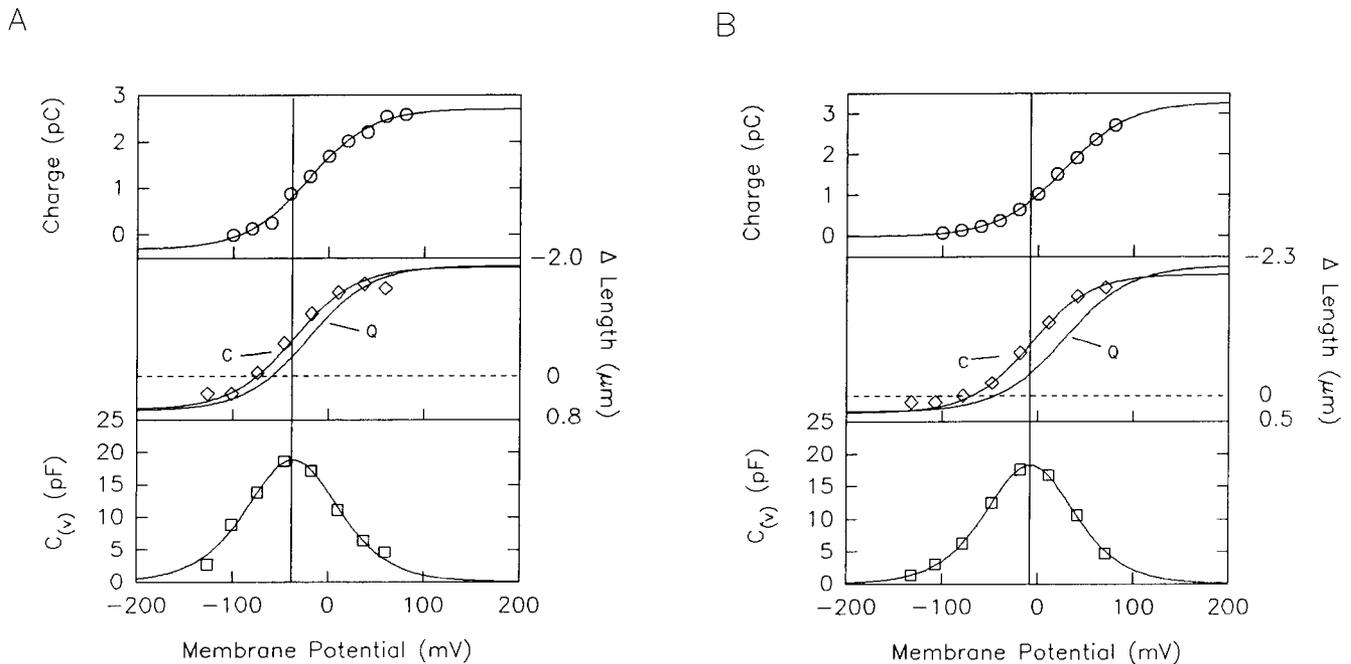

Figure 10. Comparison of AC-determined capacitance (*open squares*), step-determined charge movement (*open circles*), and mechanical response (*open diamonds*) for two OHCs demonstrating differing V_h . Comparison indicates that voltage dependence of mechanical response more closely corresponds to voltage dependence of capacitance derived from AC analysis (V_h of AC measures indicated by vertical lines through plots) than to voltage dependence derived from step analysis. OHC mechanical responses were measured off the video monitor with the differential optoresistor. *A*, Parameters determined from charge movement measures (*open circles*): V_h , -21 mV; z , 0.78 . Parameters determined from AC capacitance measures (*open squares*): V_h , -37 mV; z , 0.79 . Mechanical response (*open diamonds*) is plotted along with scaled Boltzmann functions using V_h and z values obtained from charge data (Q) or capacitance data (C). Note the closer correspondence of the mechanical data points with the function obtained from the capacitance fit (C). No direct cell perfusion. CsCl electrode, no EGTA. Bath perfusion contained 20 mM TEA, 20 mM CsCl, 2 mM CoCl₂, and no added Ca²⁺. *B*, Parameters determined from charge movement measures (*open circles*): V_h , 26.7 mV; z , 0.75 . Parameters determined from AC capacitance measures (*open squares*): V_h , -8 mV; z , 0.82 . Mechanical response (*open diamonds*) is plotted along with scaled Boltzmann functions using V_h and z values obtained from charge data (Q) or capacitance data (C). Note the closer correspondence of the mechanical data points with the function obtained from the capacitance fit (C). Cell individually perfused with 20 mM TEA, 20 mM CsCl, 2 mM CoCl₂, and no added Ca²⁺ medium from one barrel of a double-barreled pipette whose other barrel contained an additional 1 mM GdCl₃. Bath perfusion as above. CsCl electrode, no EGTA.

channel nonlinear charge movement (Bezanilla et al., 1982b; Fernández et al., 1982). In that case, charge immobilization⁵ as well as long-term inactivation may contribute to apparent voltage shifts. However, in the OHC charge immobilization is absent, since off-gating charge magnitude is not time dependent (Fig. 9A). In addition, unlike Na currents, OHC mechanical responses demonstrate no decay during prolonged depolarizations (Fig. 9B, see Fig. 11).

The differing voltage dependencies of OHC nonlinear capacitance obtained with the two measurement techniques used here may be due to problems that are associated with the step analysis technique (see Discussion). It is suggested that the AC analysis result more accurately reflects the voltage dependency of nonlinear capacitance. It is of interest, therefore, to make comparisons between the voltage dependence of OHC motility and the voltage dependence of nonlinear capacitance obtained by AC or step analysis. Figure 10 demonstrates for two OHCs that the voltage dependence of OHC motility corresponds more closely to the voltage dependence of nonlinear capacitance obtained by

the AC method, rather than that obtained by step analysis. This result may be due to an inaccurate estimate of the voltage dependency of OHC nonlinear capacitance by step analysis.

It is conceivable that voltage-induced length changes may cause deformation of the OHC membrane (stretching and contracting), leading to changes in the specific membrane capacitance. Therefore, it is necessary to determine the possible contribution of such a phenomenon to the measured nonlinear capacitance. This issue was directly evaluated by taking advantage of the observations of Brownell et al. (1989a,b) that cell turgor governs the robustness of electrically induced OHC motility. That is, experiments were performed to determine whether gating currents are abolished when OHC longitudinal motility is inhibited due to loss of cell turgor. Utilizing fairly large-tipped patch pipettes (~ 2 μ m), it is possible to induce reversible cytosolic volume changes rapidly by applying slight suction or pressure to the pipette. Such was the case for the cell depicted in Figure 11. Length changes induced by depolarizing the cell from -80 to $+40$ mV were absent when the cell's cytosol was removed. Immediately upon refilling the cell, the length changes were robust. The effect can be reversibly repeated as long as the whole-cell configuration is maintained. Gating currents (Fig. 11E) were not blocked by the cytosolic volume reduction. These results indicate that nonlinear capacitance is not a function of membrane deformations induced by longitudinal length changes.

⁵ Charge immobilization refers to magnitude inequalities of on- and off-gating charge generated by a voltage step. These measures are thought to reflect processes involved in fast inactivation and long-term depolarization-induced slow inactivation of Na currents. That is, there is a decrease in off-gating charge relative to on charge that is time dependent; the time course is correlated with the time course of Na current inactivation (for review, see Hille, 1984).

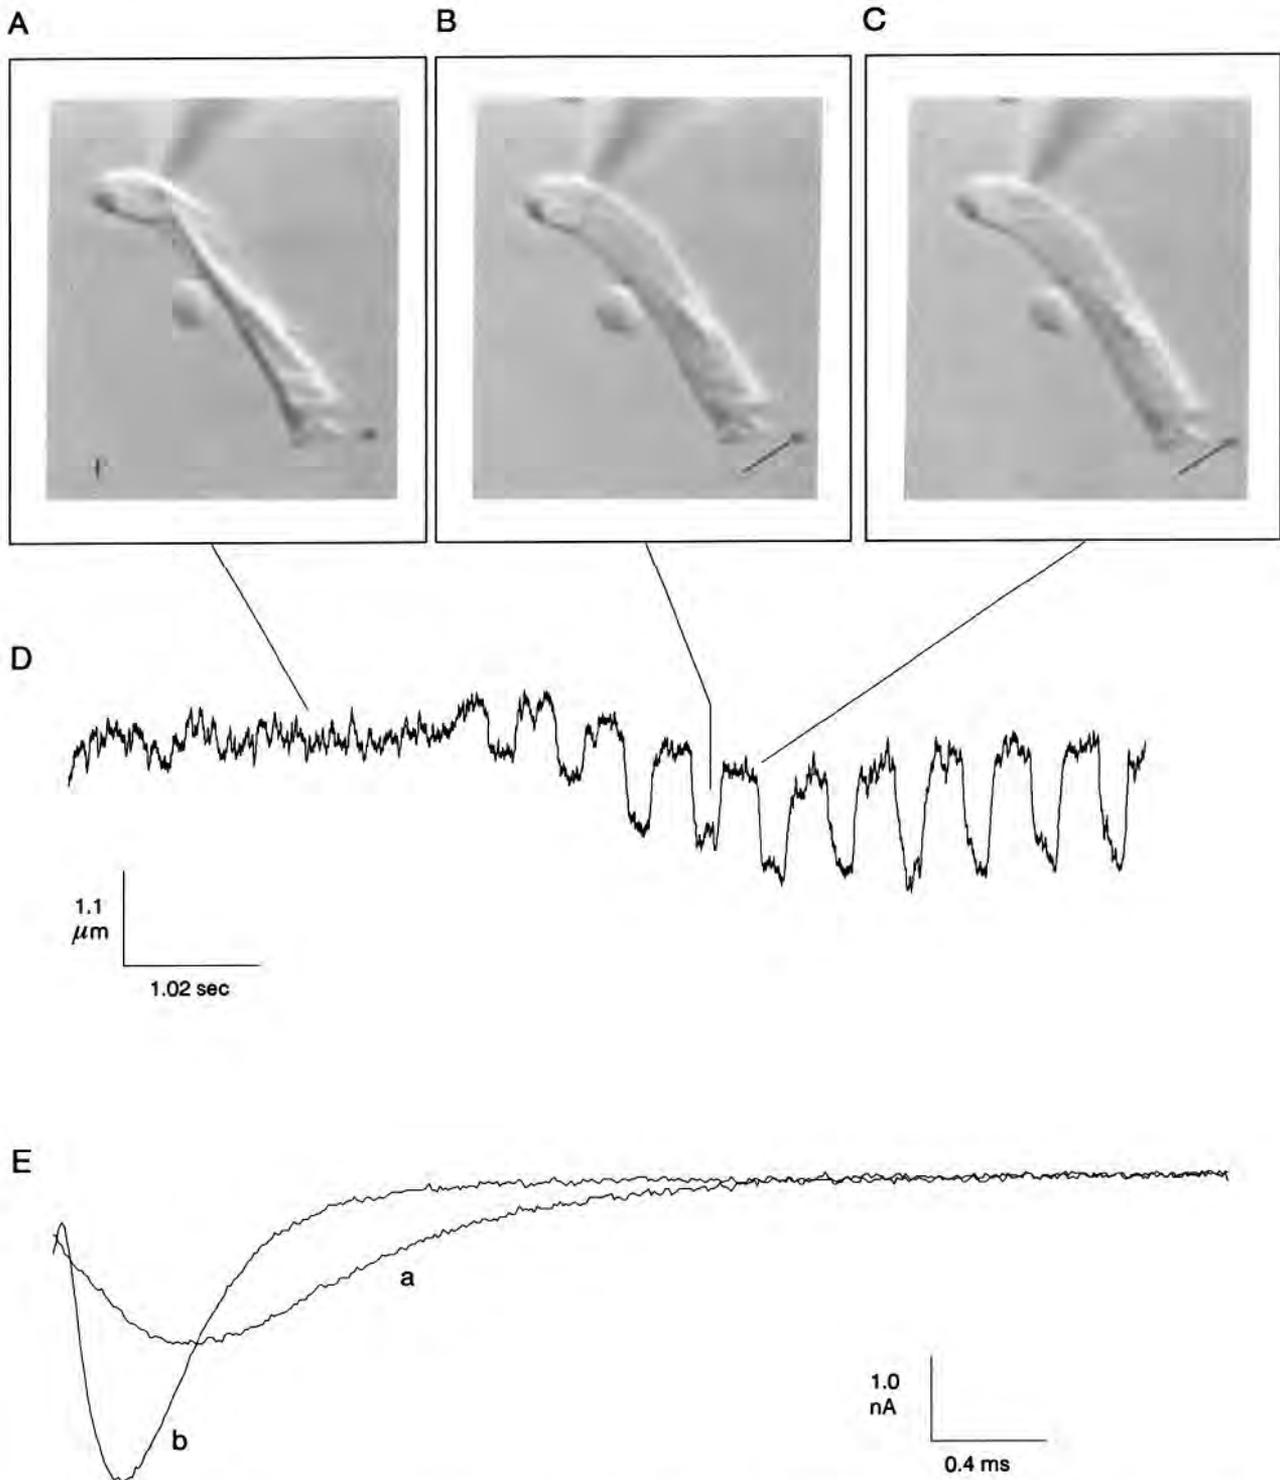

Figure 11. Effect of cytosolic volume alterations on voltage-induced OHC movements: video prints of an OHC that was induced to collapse by gentle suction on the patch electrode located at the nuclear pole of the cell (*A*) and after restoring normal cell volume by gentle pressure into the pipette (*B*, during depolarization of the cell to 40 mV; and *C*, at the holding potential of -80 mV). Scale bar in *A*, $3\ \mu\text{m}$. Simultaneously collected trace of cuticular plate movements (*D*) indicates that movement was abolished during volume reduction but returned immediately upon volume replacement. Downward deflections indicate contraction. Traces in *E* were obtained from a different cell and depict off-gate currents obtained with the $P/-4$ technique at a step potential of $+80$ mV from a holding potential of -120 mV (nominal). Trace *a* was collected when the cell was flattened due to loss of turgor, and trace *b* was obtained immediately after reinflating the cell. Integration indicates that the nonlinear charge movements were roughly equivalent, differing by about 10%, with the deflated condition being larger. This difference may be due to the change in the series resistance before ($11.4\ \text{M}\Omega$) and after ($6.4\ \text{M}\Omega$) reinflation. Series resistance consistently decreases when cells are reinflated by applying pressure to the patch electrode, and this is reflected in the redistribution of charge in time (difference between trace time constants) for conditions *a* and *b*.

Under the deflated conditions, slight dimpling of the OHC's lateral membrane coincident with voltage steps was noted. Gadolinium ions can reduce or abolish this voltage-dependent dimpling.

Discussion

Nonlinear capacitance of the OHC membrane

AC and step analyses presented here demonstrate that OHC membranes possess a capacitance that is voltage dependent. Previous measures of OHC membrane capacitance (Santos-Sacchi, 1988, 1989c) demonstrated that these cells possess input capacitance values, at holding potentials near *in vivo* levels, exceeding the typical $1 \mu\text{F}/\text{cm}^2$ found in biological membranes. In that study, input capacitance of OHCs from the apical turns of the cochlea averaged near 38 pF (at a holding potential of -70 mV), with a specific capacitance of about $1.2 \mu\text{F}/\text{cm}^2$. Clearly, the present findings indicate that such large values were due to the significant nonlinear capacitance present at typical *in vivo* potentials. Ashmore (1987) had also measured OHC membrane capacitance from cells dissociated from the apical turns, reporting an average value of 27 pF, which corresponded to estimates based upon a specific capacity of $1 \mu\text{F}/\text{cm}^2$. This is surprising since measures were made at holding potentials where the nonlinear capacitance should have been substantial. Subsequently, Ashmore (1989, 1990) demonstrated the existence of nonlinear charge movement in OHCs and estimated maximum charge movements of 350 fC for OHCs from the low-frequency region of the cochlea; it was stated that 5% of the cell's capacitance is membrane potential sensitive. In the present study, average maximum nonlinear charge transfer was shown to be about 2 pC, and step or AC analysis provided roughly equivalent estimates of peak nonlinear capacitance of about 17 pF; that is, about 40% of the cell's maximum capacitance is membrane potential sensitive. It is not clear why such large differences exist between the present results and those of Ashmore (1989, 1990), although the $\pm P$ technique was exclusively used in that study.

The magnitude of nonlinear capacitance relative to membrane potential follows a bell-shaped function, whereby it increases upon depolarization from highly negative membrane potentials, reaches a maximum, and then declines upon further depolarization. However, the step and AC analyses utilized in this study give differing voltage dependencies, with the AC voltage technique indicating a peak capacitance at about -40 mV and the step technique indicating a peak at about -23 mV . Bezanilla et al. (1982b) have demonstrated that the voltage dependence of nonlinear charge movement due to Na channel gating is dependent upon holding potential, that is, the initial conditions prior to charge movement measurement. This dependence is thought to be related to processes underlying the inactivation of sodium currents. Although the holding potentials were different for the two measuring techniques used in this study, it is unlikely that a voltage shift due to initial conditions as occurs for the Na channel is responsible for the present results. That is, it was shown that charge immobilization is absent in the OHC, at least during the time window reported here. Correspondingly, the OHC mechanical response does not inactivate, even for durations up to 500 msec (Fig. 11). Furthermore, prolonged depolarization (up to 2 min at 0 mV , followed by return to -80 mV) also has no apparent effect on gating currents or mechanical responses. Still, initial condition effects should be evaluated more systematically.

There are several problems with the step analysis technique that are not encountered with the AC technique. First, because of series resistance, a true voltage step is not delivered to the cell because of the large capacitive currents generated, and consequently the voltage applied across the cell membrane is significantly less depolarized during step depolarizations than is commanded, even at steady state. In addition, due to the voltage-dependent capacitance, the clamp time constant, and consequently the time course of membrane potential change, will vary at different levels of step depolarizations, as it depends upon cell capacitance and series resistance. Nevertheless, the total charge movement should be independent of the time it takes to reach steady state, and correcting voltages for series resistance effects using steady state, non-leak-subtracted current levels should prove sufficient. Unfortunately, the on-line subtraction protocol to extract nonlinear charge movement ($P/-4$) is based on the assumption that series resistance effects are absent. That is, the protocol simply measures linear charge movement at a selected potential and scales that charge movement prior to subtraction based on nominal voltages, without taking into account nonlinear leakage current, which can often be a confounding factor in time domain analysis (Fernández et al., 1982). Thus, scaling inaccuracies may arise and may depend upon the value of the series resistance. Furthermore, in the present experiments the subtraction potential (-120 mV) used for removal of linear charge displacement still falls within the region where some nonlinear charge contributes, as is evident in the AC data. Thus, subtraction values include linear as well as nonlinear components, and this may further contribute to an apparent voltage shift between step and AC data. Other problems associated with comparisons between time and frequency domain measures of nonlinear capacitance have been discussed by Fernández et al. (1982). While holding the OHC at very hyperpolarized subtraction levels would permit a more accurate step analysis, such potentials are difficult to use because the cell-electrode setup becomes unstable. Despite these problems and the differing voltage dependencies⁶ derived from the AC and step techniques, both methods indicate similar estimates of peak nonlinear capacitance in the OHC.

Measures of the gating currents associated with ionic channel activation have been useful in estimating the number of channels within a membrane (see Hille, 1984). Estimates are achieved by comparing the voltage-dependent characteristics of charge movement to those characteristics of the processes that are controlled by such charge movements (e.g., ion conductance). For example, Nonner et al. (1975) determined that two particles with an effective charge of $-1.65e^-$ move within the membrane to activate the sodium channel in frog node of Ranvier. This was determined by computing the ratio of effective valence (z) of the sodium conductance-voltage ($g_{\text{Na}}-V$) function to that of the $Q-V$ function associated with channel activation. Since total nonlinear charge was $17,200 e^-/\mu\text{m}^2$ in their preparation, the number of channels was estimated to be $5212/\mu\text{m}^2$ [i.e., $17,200/(2 \times 1.65)$]. In a similar manner, the number of voltage sensors within the OHC membrane can be estimated. The average total nonlinear charge (Q_{max}) of about 2 pC per OHC observed in the

⁶ It should be reemphasized that voltage-dependent processes are susceptible to the ionic makeup (charge screening ability) of the medium that bathes the plasmalemma. Thus, the *in vitro* voltage dependence of nonlinear capacitance and motility shown here may not reflect *in vivo* conditions.

present study translates to about $3850 e^-/\mu\text{m}^2$. Assuming that this charge movement is associated with the motility of the cell, the similarity of the valences of OHC length changes and charge movement indicates the existence of a single voltage-sensing particle with an absolute charge magnitude close to $1 e^-$. Thus, the number of voltage-sensing particles within the OHC membrane approaches $4000/\mu\text{m}^2$. These particles presumably represent the voltage sensors of independent, membrane-bound motor elements. In fact, Dallos et al. (1991) have elegantly shown that, indeed, OHC motility is driven by independent motor elements distributed in the basolateral region of the cell. They extend from nuclear to cuticular regions, that is, roughly paralleling the extent of the subsurface cisternae. Interestingly, the number of motor elements inferred from charge movement data reported here is of the same order of magnitude as the number of tightly packed 10 nm intramembranous particles recently observed by Kalinec et al. (1991). These investigators have speculated that the intramembranous particles represent the OHC motor units.

Initial observations that OHC motility and gating currents were blocked by gadolinium ions (Santos-Sacchi, 1989a) raised the possibility that voltage-dependent stretch-activated channels may underlie the observed gating and mechanical events through some sort of reverse process, since it had been shown that gadolinium is a potent blocker of stretch-activated channels (Yang and Sachs, 1989). In fact, voltage-dependent stretch-activated channels have been found in the lateral membrane of the OHC (Ding et al., 1989, 1991), but the channel number is probably too low to account for the observed charge displacement.

Interestingly, Ashmore (1987) ruled out any interaction between plasma membrane and the extensive intracellular subsurface cisternal membrane system of the OHC because his calculations indicated that OHC capacitance can be accounted for by linear dielectric plasmalemmal properties. Since it is now clear that OHC capacitance is not simply due to linear membrane properties, possible voltage-dependent electrical interactions between these two membranous systems should be considered. However, similar considerations concerning a possible voltage-dependent recruitment of a hypothetically unavailable portion of transverse tubular membrane capacitance in striated muscle have proved untenable (Chandler et al., 1976). Indeed, there is rather good evidence now that the bulk of nonlinear charge displacement in striated muscle is afforded by dihydropyridine-sensitive calcium channels (Adams et al., 1990). It may be that most of the nonlinear charge movement in OHCs is associated with intramembranous voltage sensors responsible for OHC motility, but certainly the issue of a subsurface cisternal contribution is not yet resolved. However, it is unlikely that the nonlinear capacitance is a function of membrane deformations caused by length changes since charge movement is still measured during loss of cell turgor, which abolishes longitudinal movement. Also, changes in membrane dielectric properties due to electrostriction can be ruled out based on the arguments of Chandler et al. (1976). It should also be pointed out that a possible contribution may come from gating currents associated with ionic channels within the OHC membrane. Regardless of the underlying mechanisms that contribute to the voltage-dependent capacitance, its existence will alter the RC time constant of the OHC in a voltage-dependent manner, thereby dynamically modifying the receptor potential waveform generated *in vivo*. This leads to the conclusion that sensing of the stimulus

for OHC motility effectively modifies the stimulus for OHC motility.

Relation between nonlinear capacitance and cell motility

As discussed above, the voltage dependence of OHC fast motility suggests the existence of a corresponding gating current. In other systems, correlation between gating current characteristics and the processes they presumably control provides evidence linking the two. In squid axon, for example, treatments that modify gating current characteristics typically are reflected in measures of Na currents (Bezanilla and Armstrong, 1974; Armstrong, 1981; although see Tanguy and Yeh, 1988). It is shown here that gadolinium ions are capable of simultaneously reducing or abolishing OHC motility and gating currents (or nonlinear capacitance). This blockade and the reversibility of gadolinium's effects upon washout may indicate that the two phenomena are dependent. Further evidence linking the two includes their similar voltage dependencies and their similar susceptibility to charge screening. Based on these results, a more detailed study of the concentration-dependent effects of gadolinium is warranted and may lead to quantitative estimates of OHC membrane surface charge.

It is interesting to note that the time course of gating current is a function of clamp time constant, indicating that charge movement is redistributed in time depending upon the speed of transmembrane voltage change. The speed limitations imposed by electrode series resistance prevent an accurate measure of the actual gating time constant, which is probably much faster than can be measured. However, the dependence of gating time constant upon clamp time constant can be used to characterize further the relationship between charge movement and OHC motility. Thus, it has been shown that the speed or frequency response of OHC motility increases in parallel with clamp time constant or correspondingly with gate time constant (Santos-Sacchi, 1990a).

Cell turgor requirement for fast motility

Brownell et al. (1989a,b) have demonstrated that prolonged depolarization of the OHC under voltage clamp or treatments with salicylates causes a decrease in OHC cytoplasmic turgor. The process is slow and reversible (on the order of tens of minutes) and is accompanied by a reduction or abolition of longitudinal OHC motility, which also recovers upon restoration of cell turgor. The results presented here demonstrate directly that the reduction of cytosolic volume is one factor responsible for the reduction in OHC motility, since holding potential was held constant and no exogenous treatments were involved. This clearly confirms the hypothesis of Brownell and colleagues that cell turgor is directly involved in the robustness of electrically evoked OHC motility. Cell turgor may underlie the translation of voltage-dependent membrane phenomena to longitudinal force generation. Indeed, gating currents remain intact during cell turgor alterations. The observation of depolarization-induced membrane dimpling, which was susceptible to gadolinium treatment, during loss of cell turgor further suggests that the membrane-associated portion of the OHC motility mechanism remained intact and was simply uncoupled from a longitudinal translation process. It is conceivable that loss of cell volume disrupts elements linking a motility voltage sensor and subsurface structures; however, clearly, such a disruption must be reversible on a time scale of tens of minutes, at least (Brownell et al., 1989a,b). The study of the intricate subplas-

mammalian cytoskeleton and cisterns of the OHC may provide clues needed to understand the translational process (Bannister et al., 1988; Slepecky, 1989; Evans, 1990; Holley and Ashmore, 1990; Dieler et al., 1991).

For some time, anecdotal observations of isolated OHCs have led to the idea that the intracellular pressure of the OHC is greater than extracellular pressure. For example, OHCs often burst when impaled with microelectrodes, ejecting cytoplasm and intracellular organelles (Brownell, 1983). Kaufman and Brownell (1991) have recently provided indirect evidence confirming this notion. Considering the dependence of longitudinal motility upon cell turgor, it is now clear that estimates of the magnitude of OHC motility may require reinspection. That is, measures of the voltage versus length function of OHCs have been made with the use of the whole-cell voltage-clamp configuration, where inherently the cells' internal turgor pressure is compromised by establishing contiguity between cell and pipette interiors (Ashmore, 1987; Santos-Sacchi and Dilger, 1988; Santos-Sacchi, 1989c). For example, Santos-Sacchi (1989c) estimated that near the normal *in vivo* resting potential, -70 mV, the response of the OHC is about 2 nm/mV; at that holding potential the cells reside near the hyperpolarizing saturation area of the response function. Based on these observations and on evidence indicating the voltage dependence of OHC motility (Santos-Sacchi and Dilger, 1988), a calculated disparity of 21 dB exists between threshold basilar membrane motion and OHC motion at high frequencies (see Santos-Sacchi, 1989c). Obviously, this leads to difficulties in assigning the role of "cochlear amplifier" solely to OHCs. It is now clear that these measures of OHC movement may be underestimates, though certainly not approaching an order of magnitude. Nevertheless, nonintracellular techniques, such as that used by Evans et al. (1989), may provide more accurate estimates of movement magnitude since cell turgor is not directly compromised. Still, these techniques pose other problems; notably, membrane potential must be estimated and cannot be directly measured or controlled with the precision of the whole-cell voltage-clamp technique.

The evidence linking basilar membrane mechanics to OHC function is growing (Ruggero and Rich, 1991). Currently, the most likely candidate responsible for this interaction is the motility of the OHC, which has recently been shown to have a much wider frequency response than previously thought, the 3 dB break frequency of which approaches 1 kHz (Santos-Sacchi, 1990a). Although many basic properties of the OHC and its motility have been detailed, the molecular basis of this motility remains to be determined and no doubt promises to be a novel cellular adaptation designed to meet the mammals' high frequency communicative requirements.

Note added in proof. Ashmore presented data on the nonlinear capacitance of OHCs in the published proceedings of the Taniguchi International Symposium on Visual Science [Neurosci Res, Suppl 12 (1990) S39-S50], which indicate larger values of nonlinear capacitance than his other reports. Experimental methods were not detailed, but estimates of capacitance were obtained at different holding potentials by integration of the charging transient presumably induced by a small voltage step. His data appear to be in general agreement with the capacitance data reported here.

On the Frequency Limit and Phase of Outer Hair Cell Motility: Effects of the Membrane Filter

J. Santos-Sacchi

Sections of Otolaryngology and Neurobiology, Yale University School of Medicine, New Haven, Connecticut 06510

Whole-cell voltage clamp and displacement-measuring photodiode techniques were used to study electrophysiological and mechanical properties of the guinea pig outer hair cell (OHC). OHCs demonstrate a voltage–mechanical response (V-M) function that can be fit by a two state Boltzmann relation, where the cell normally rests near the hyperpolarizing saturation region (–70 to –90 mV). The voltage at half-maximal length change (V_h) is depolarized relative to the resting potential, and this ensures that for symmetrical sinusoidal voltage stimulation about the resting potential, AC and DC mechanical responses will be generated. Analysis of OHC motility using pure tone voltage bursts from 11 to 3200 Hz demonstrates both AC and DC mechanical responses. By exploiting the frequency-dependent current–voltage phase separation that is characteristic of an RC-dominated system under voltage clamp, it is demonstrated that OHC motility follows the phase of AC transmembrane voltage and not that of current. For voltage stimulation across frequencies in the acoustic range, the motility cutoff frequency corresponds to the cutoff frequency of the imposed transmembrane voltage. Frequency cutoffs approaching 1 kHz have been measured but are clamp time constant limited. These observations are congruent with the voltage dependency hypothesis of OHC motility. In addition, the DC component of the mechanical response is shown to be frequency independent, but to decrease in magnitude disproportionately compared to the AC component as the magnitude of the driving voltage decreases. This is predicted from the form of the V-M function, whose level dependent DC nonlinearity is a consequence of the resting potential being displaced from V_h . The net effect is that the mechanical DC:AC ratio approaches zero for small AC voltages. Taken together, these findings question the ability of the OHC mechanical response to influence organ of Corti micromechanics at high acoustic frequencies where a tuned amplification of basilar membrane motion is hypothesized.

Hair cells transduce mechanical stimuli into electrical signals by modulating a standing transduction current in response to stereocilia displacement; this current induces a receptor poten-

tial across the basolateral membrane of the cell, the depolarizing phase of which may promote the release of neurotransmitter (Hudspeth, 1989). Although evidence had accumulated that some type of interaction between outer (OHCs) and inner hair cells (IHCs) of the organ of Corti promoted the highly selective and sensitive responses of the mammalian auditory system to high-frequency acoustic stimulation (Dallos and Harris, 1978; Harrison and Evans, 1979; Brown and Nuttall, 1984), a potential mechanism for such an interaction remained obscure until recently. Following the discovery that the OHC is capable of electrically evoked mechanical responses (Brownell et al., 1985), a reevaluation of the classical concepts of mammalian hearing has been underway. Current theories concerning the basis of a cochlear amplifier envision an acoustically evoked cycle by cycle feedback process between OHC and basilar membrane (Geisler and Shan, 1990; Robles et al., 1991; Ruggero and Rich, 1991). That is, *in vivo*, the acoustically evoked electrical responses of the OHC should effect rapid length changes of these cells that modify the mechanical input to the IHC—the receptor cell that receives up to 95% of the afferent innervation (Spoendlin, 1988).

We have previously shown that under whole-cell voltage clamp, blocking the known ionic conductances of the OHC does not interfere with the cell's mechanical response, and we proposed that transmembrane potential was the driving force responsible for OHC motility (Santos-Sacchi and Dilger, 1988). Although the molecular basis of OHC motility remains to be determined, the physiological consequences of its voltage dependence are readily discernible. For example, the voltage dependence suggests that AC motility magnitude and phase characteristics should be governed by the attenuation effects of the OHC membrane (RC) filter. Any feedback contribution of the OHC to basilar membrane mechanics will be dependent upon these magnitude and phase characteristics. I report here that an analysis of OHC motility in response to step and AC voltage stimuli confirms the voltage dependency hypothesis, since the frequency extent and phase of motility are dependent upon the extent and phase of the imposed transmembrane voltage. Furthermore, while the effects of the membrane filter influence the AC mechanical component directly, the DC component is indirectly susceptible. Indeed, the DC component is far more susceptible than the AC component. These results are important for understanding the possible contribution of OHC motility in peripheral auditory processing.

Preliminary reports of this work have been presented previously (Santos-Sacchi, 1990, 1991a).

Materials and Methods

General. Guinea pigs were overdosed with pentobarbital. The temporal bones were removed, and OHCs were isolated nonenzymatically from

the cochleas by gentle pipetting of the isolated top two turns of the organ of Corti. The cell enriched supernatant was then transferred to a 700 μ l perfusion chamber, and cells were permitted to settle onto the cover glass bottom. All experiments were performed at room temperature ($\sim 23^\circ\text{C}$). A Nikon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical recording. All experiments were taped with a Panasonic AG6300 video recorder. A modified Leibovitz medium (NaCl, 142.2 mM; KCl, 5.37 mM; CaCl_2 , 1.25 mM; MgCl_2 , 1.48 mM; HEPES, 5.0 mM; dextrose, 5.0 mM; pH 7.2) was used as the normal perfusate. Modifications to the extracellular medium are noted in figure captions, with NaCl adjusted to maintain osmolarity (300 mOsm). Extracellular solutions were changed via two methods. A chamber perfusion system permitted the fluid in the whole chamber to be constantly exchanged with fresh medium (0.1–1 ml/min). A more rapid and direct perfusion system was used to perfuse single cells selectively under voltage clamp, during continuous exchange of bulk medium via chamber perfusion. The device is a four-barreled glass pipette tapered to about 100 μ m and fitted with a polyethylene sleeve at the tip to permit fluid flow from a single port with a small dead volume. Solutions were fed to the pipette under gravity control and rapidly switched with solenoid valves. The tip of the pipette was brought to within 50 μ m of the cell being studied, and the flow of solution was adjusted so as not to perturb the cell physically.

Electrical recording. OHCs were whole-cell voltage clamped with a Dagan patch-clamp amplifier at holding potentials between -70 and -80 mV, similar to potentials recorded *in vivo* (Dallos et al., 1982). Pipette solutions were composed of 140 mM KCl or CsCl, 5 or 10 mM EGTA, 2 mM MgCl_2 , and 5 mM HEPES buffered to pH 7.2. Gigohm seals were obtained at the nuclear level of the cell membrane, and electrode capacitance was compensated prior to whole-cell recording. Voltage step studies were performed with an Axolab 1100 A/D and D/A board (Axon Instruments, Foster City, CA) with associated software (PCLAMP). AC studies were performed using a digital signal processing board with custom-written software (DSP-16; Ariel Corp., Highland Park, NJ) capable of delivering and analyzing pure tone or swept frequency stimuli. Data were saved to disk for off-line analysis.

For most experiments, ionic conductances were blocked. Under these conditions, the cell clamp can be modeled most simply as an electrode resistance (R_e) in series with a parallel combination of the membrane resistance (R_m) and capacitance (C_m). These component values were estimated at the holding potential from current records in response to -10 mV voltage steps, and were accounted for during analysis, so that actual voltages imposed upon the cell are known (Marty and Neher, 1983). Care was taken to maintain low series resistance values during recording by delivering transient positive or negative pressure into the electrode to maintain an unobstructed orifice; electronic series resistance compensation was employed as well. The program CLAMPX (Axon Instruments, Foster City, CA) was modified to provide a continuous display of clamp time constant, cell capacitance and resistance, and series resistance between data collections. The magnitude and phase of the transmembrane voltage (V_m), predicted from the command voltage (V_c), were obtained using the estimated component values by modeling the impedance (Z_{in}) of the cell clamp with the software package MATLAB (Mathworks, Natick, MA):

$$Z_{in} = R_s + Z_m, \quad (1)$$

where

$$Z_m = \frac{R_m}{1 + sC_m R_m}, \quad s = j\omega, \quad j = \sqrt{-1}, \quad \omega = 2\pi f; \quad (2)$$

$$I = V_c / Z_{in}; \quad (2)$$

$$V_m = I Z_m. \quad (3)$$

In some cases, an absolute delay ($I = I \cdot e^{-st}$, where t is the delay in seconds) was included in the model so that the predicted phase plots coincided (as determined by eye) with those of the measured current and mechanical response plots. Typically, this was required when series resistance compensation was used, and may be the result of delays introduced as a result of the compensation feedback.

OHC motility measures. OHC mechanical responses and currents were simultaneously measured in response to step or sinusoidal voltage stimuli. For steady state movements (voltage steps > 100 msec), length changes were analyzed off the video monitor during playback by placing differential optoresistors or a position-sensitive detector (Hamamatsu

Corp., NJ; output filtered at 30 Hz) across the image of the cuticular plate (apical end of the cell) at a monitor magnification of $2800\times$ (Santos-Sacchi, 1989). Fast OHC movements elicited by voltage clamp with short-duration stimuli (below video detection) were measured with a differential photodiode (PD) onto which the image of the cuticular plate from the microscope was projected. Placement of the PD was accomplished remotely by a computer-controlled micromanipulator, so as not to perturb whole-cell recording. The PD was backlit by two fiber optic beams projected through the microscope's camera port onto a 30% mirrored glass coverslip base of the perfusion chamber, and reflected back to a CCD video camera via a 90° prism to allow PD placement during simultaneous cell visualization on a mixed video-computer monitor (Matrox Corp., Dorval, Quebec, Canada). Backlighting was not required after calibration of the PD's position on the monitor. The frequency response of the PD system was measured by driving an on-biased light-emitting diode (LED) and had a 3 dB rolloff at 6 kHz (Fig. 1). The validity of the PD system was verified by measuring the movements of a glass probe driven by a piezoelectric bimorph (Fig. 1, insets). Sinusoidal voltage bursts (onset and offset linearly ramped) of frequencies ranging from 11.7 to 3201 Hz were delivered to OHCs under voltage clamp. PD output and whole-cell currents were filtered at 10 kHz (12 dB/octave) and collected simultaneously using a sampling rate of 20 kHz for AC analysis or up to 50 kHz for step analysis. Responses were averaged 200 times. Fundamental magnitude and phase of the mechanical responses were measured by fast Fourier transformation (FFT) of the central portion of the digitized waveforms using the software package MATLAB. Mechanical responses were corrected for the phase and magnitude characteristics of the PD system. Absolute calibration of cell movements was determined by measuring off the video monitor the cell movement in response to a large steady state depolarizing voltage stimulus (Santos-Sacchi, 1989).

Motility estimates using a photodiode technique rely upon intensity measures of the projected image of the OHC's cuticular plate. The problems with such a technique have been addressed by Clark et al. (1990). In the present study, care was taken to maintain the position of the cells within the bounds of the differential photodiode; in order to check this, cells were visualized on a video monitor during data collection. While magnitude measures may be affected by changes in image intensity, phase measures should not. Similar cutoff frequencies of the mechanical responses were obtained from phase and magnitude data, indicating that the image intensity did not change during the data collection period, typically about 5 min.

The mechanical response $\Delta L(v)$ was fit with a Boltzmann function:

$$\Delta L(v) = \left[\frac{\Delta L_{\max}}{1 + e^{(V_m - V_h)/b}} \right] + \Delta L_{\min}, \quad (4)$$

where ΔL_{\max} and ΔL_{\min} are the fitted maximum and minimum length changes from the resting state, b is the voltage slope factor, and V_h is the voltage at half-maximal length change.

Results

The OHC changes length when its transmembrane potential is altered. Figure 2A demonstrates the V-M function for an isolated OHC using step voltage commands from a holding potential of -68.4 mV. The function follows a saturating Boltzmann relation, such that the mechanical response is larger in the depolarizing (shortening) direction near the cell's normal resting potential. This is a consequence of the holding potential being displaced from V_h . For this cell, a maximum slope of about 21 nm/mV at -26 mV is calculated (Fig. 2B). Responses as large as 30 nm/mV have been observed (Santos-Sacchi and Dilger, 1988).

The OHC membrane possesses a nonlinear charge movement that is correlated in time and voltage dependence with induced length changes (Ashmore, 1989; Santos-Sacchi, 1990, 1991b); this nonlinear charge probably represents the movement of membrane-bound voltage sensors responsible for the cell's voltage-dependent mechanical response. Figure 3 demonstrates that the kinetics of the charge movement are such that the time

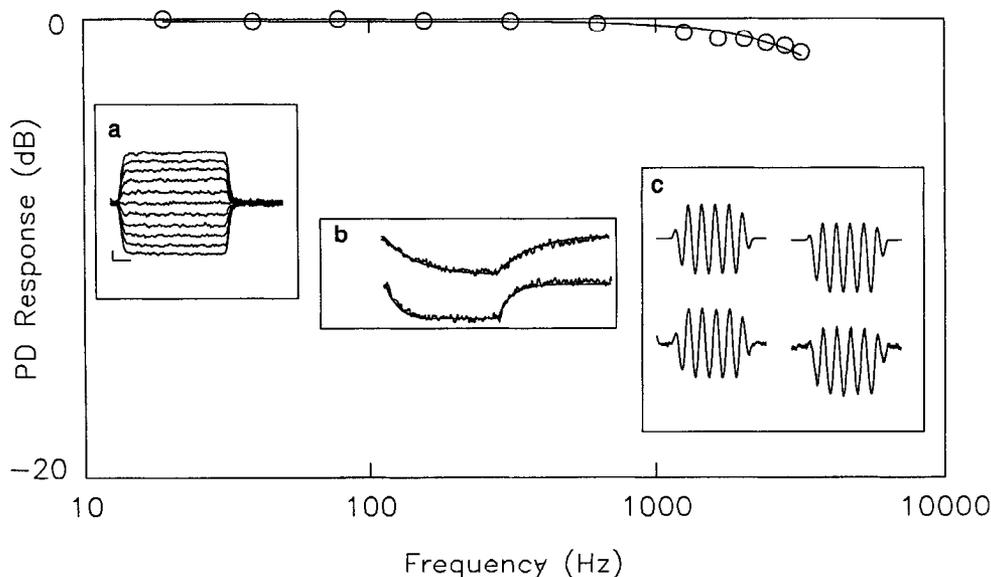

Figure 1. Characteristics of the movement measurement system. Frequency response of differential PD output (*open circles*, averaged 200 \times) in response to off-centered LED emission elicited by sine wave bursts. Cutoff frequency was 6 kHz. *Insets*, Outputs from PD in response to simulated cell movement. The tip of a glass microelectrode shank was melted to a sphere of about 15 μm ; transmitted light produced a bright area in the sphere's center, which was used to mimic the bright OHC cuticular plate observed under Hoffmann optics. The artificial cell was attached to a piezoelectric bimorph and moved using various voltage waveform inputs to test the linearity and frequency following capability of the PD measurement system. *a*, PD output measured in response to bimorph movements produced by fixed incremental voltage steps (filtered to avoid bimorph resonance at 2 kHz). Linearity is good. Response filtered at 800 Hz. Calibration *vertical*, 0.1 μm ; *horizontal*, 2 msec. *b*, PD output (*noisy traces*) in response to bimorph voltage stepped through a filter of 100 Hz (*top trace*) and 300 Hz (*bottom trace*). Simultaneously recorded voltage (*solid traces*) corresponds faithfully to the PD output. Maximum excursion is about 1 μm . Pulse width is 5 msec. *c*, Bimorph was stimulated with sinusoidal voltage bursts (156 Hz). *Two traces on top* are measured voltage; corresponding *two traces on bottom* are PD output (filtered at 800 Hz). Excellent frequency following is apparent. Stimulus and response traces on *right* demonstrate that the measurement system is capable of detecting DC offsets.

constant of the voltage-clamp amplifier limits their study under whole-cell configuration. That is, the time constant of nonlinear capacitive current decay follows changes in the time constant of the clamp amplifier, indicating that the kinetics are faster than the fastest clamp speed presently attainable. Measures of OHC mechanical response induced by voltage steps indicate a similar trend (Fig. 4A). In this case, an OHC was stepped from a holding potential near -70 mV to about 40 mV, while the clamp time constant was modified between 0.8 and 0.52 msec with series resistance feedback compensation. Both movement onset and offset are directly correlated with clamp time constant. Note that fitted single exponentials of the movement onset appear faster than the clamp time constant. This is due to the fact that the voltage steps are saturating, and is consistent with model simulations based on the OHC's V-M function (see Discussion). It was noted by Ashmore (1987) that delays in mechanical response onset occurred following voltage step onset. The insets in Figure 4A illustrate that clamp time constant modifications do not appear to influence the mechanical response onset, which occurred within 40 μsec of stimulus onset in this case. In other cells, however, delays were observed up to about 100 μsec (Fig. 4B). It is conceivable that alterations of cell turgor that occur during whole-cell voltage clamp may underlie this delay phenomenon (Santos-Sacchi, 1991b). Figure 4C illustrates the mechanical response of an OHC driven by a voltage step depolarization of about 5 msec in duration, with one of the fastest clamp time constants attained, 0.14 msec. The onset of the mechanical response is rapid (onset τ of a double exponential fit, 0.240 msec); a maximum velocity of 6.5 mm/sec is calcu-

lated, which is about 3.5 times faster than previous estimates of OHC velocity (Ashmore, 1987).

The form of the V-M function (Fig. 2A) indicates that the mechanical response will include both AC and DC components when a sinusoidal voltage command is delivered about the holding potential. Such mechanical rectification has been demonstrated with low-frequency sinusoidal stimuli (Evans et al., 1989; Santos-Sacchi, 1989). Figure 5 illustrates this phenomenon as a function of stimulus frequency. Sinusoidal voltage command stimuli of frequencies ranging from 11.7 to 3201 Hz elicit AC and DC mechanical responses. Figure 5A documents the rectified nature of the V-M function of this cell based on the response from an 11.7 Hz transmembrane voltage stimulus. Mechanical rectification is also apparent at higher stimulus frequencies, as reflected in the DC mechanical components present in the raw data (Fig. 5B). The measured reduction in magnitude of the mechanical response as frequency increases is *not* inherent in the OHC, but is due to limitations of the voltage-clamp amplifier. That is, command voltage magnitude decreases with increasing frequency because of the voltage clamp's limited frequency response;¹ therefore, voltage dependent AC mechanical responses roll off as well (see below).

As command voltage magnitude decreases (due to the clamp time constant), there is a disproportionate decrease in the mag-

¹ The effectiveness of the whole-cell voltage clamp technique is limited by the patch electrode's series resistance and the cell's impedance. The speed at which a voltage can be imposed across the membrane of a cell depends upon the clamp time constant ($\tau = R_s \parallel R_m C_m$). This time constant corresponds to the effective bandwidth of AC stimulation ($f_{\text{cutoff}} = 1/2\pi\tau$).

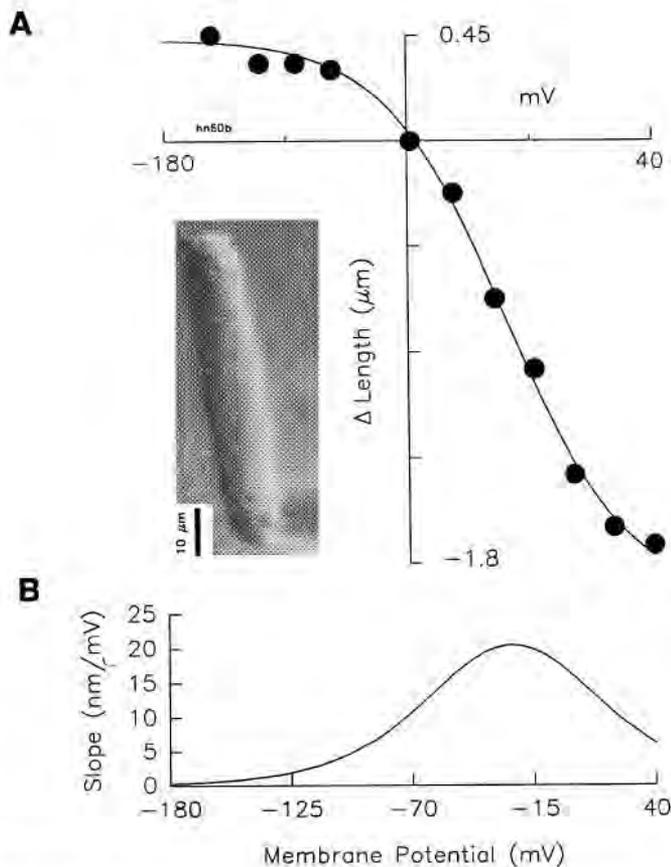

Figure 2. *A*, Change in length of an isolated OHC in response to voltage steps delivered from a holding potential of -68.4 mV. The residual series resistance has been corrected. Hyperpolarizing steps from the holding potential induce elongations whose magnitudes saturate more rapidly with step potential than do contractions due to depolarizing steps. The mechanical response $\Delta L(v)$ was fit with a Boltzmann function (Eq. 1; solid line). The least squares fit gives $V_h = -25.7$ mV and $b = 27$ mV. Normal extracellular solution, and KCl-containing patch pipette. Cell length measures were made off the video monitor. *Inset*, Digitally captured video image of the whole-cell voltage-clamped OHC. *B*, Slope of the Boltzmann fit above, indicating the voltage sensitivity of the mechanical response across voltage. The sensitivity at the holding potential of -68.4 mV is smaller than the maximum.

nitude of the DC mechanical component relative to the decrease of the AC mechanical component. This phenomenon is an inherent property of the V-M function of the OHC; as the AC voltage excursion about the holding potential is reduced, the input-output function within the limited stimulus region approaches linearity. Although Evans et al. (1990) obtain similar V-M functions (see Fig. 5*A*, solid triangles), they report a linear correspondence between AC and DC mechanical responses as voltage magnitude is altered. However, Figure 5*C* exemplifies the nonlinear correspondence inherent in the V-M function by plotting the ratio of DC to AC mechanical response as a function of AC voltage magnitude. The measured ratio (open circles) decreases as the stimulating voltage magnitude decreases, and is well predicted (solid line) from the V-M function of this cell (Fig. 5*A*). This observation indicates that the form of the V-M function measured at 11.7 Hz is preserved at higher frequencies; that is, the nature of the function is *frequency independent*.

The top panels of Figure 6, *A* and *B*, examine the magnitude of the mechanical response fundamental (obtained by FFT) and

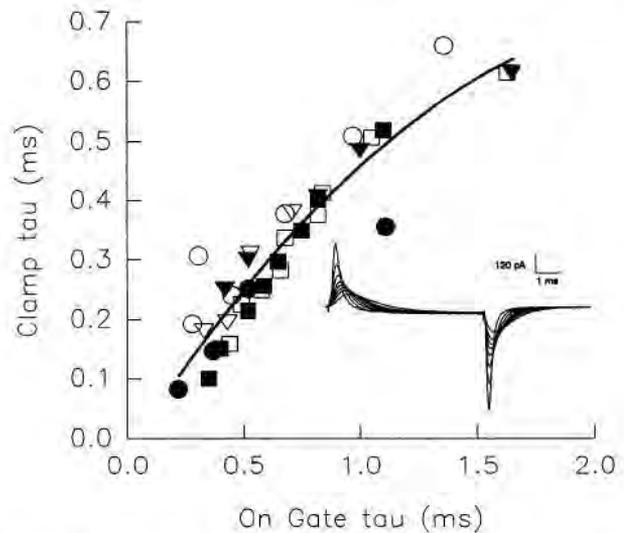

Figure 3. Dependence of on-gate current time constant upon time constant of clamp amplifier. Six cells (different symbols) were held at a potential of -80 mV and alternately pulsed to 40 mV above and below the holding potential. Nonlinear capacitive currents were unmasked by averaging the resultant currents 200 times ($\pm P$ technique; Armstrong and Bezanilla, 1973). Clamp time constants were determined by fitting single exponentials to the decaying current transient in response to a -10 mV step. Time constants of on-gate currents were also single exponential fits of current decay. Clamp time constant was modified by adjusting the electronic compensation for the series resistance. Reduction of clamp time constant caused reduction of gate time constant. *Inset*, A series of nonlinear capacitive current traces from a single OHC under different clamp time constant conditions. Note the shift in the speed of current response. Both on-gate and off-gate time constants are directly influenced by clamp time constant. CsCl electrode solution. Extracellular solution was Leibovitz with 10 mM tetraethylammonium (TEA) and 300 nM TTX.

compare it to the voltage delivered to the cell as predicted from the clamp time constant, before (top panel, Fig. 6*A*) and after (top panel, Fig. 6*B*) series resistance compensation. The cutoff frequency of the cell's mechanical response increased following compensation of the series resistance. The mechanical response rolloff roughly follows the rolloff of the transmembrane voltage, demonstrating that the mechanical response can follow rapid voltage fluctuations quite faithfully ($f_{\text{cutoff}} \sim 1$ kHz). This is in marked contrast to the limited frequency response ($f_{\text{cutoff}} \sim 60$ Hz) reported by Ashmore (1987; see thick line in top panels of Fig. 6*A,B*). The analysis of phase data presents a more robust test of the voltage dependence hypothesis. In an RC-dominated system, such as the OHC under voltage clamp, as voltage command frequency is increased, an asymptotic phase separation of 1.57 radians (90°) will develop between injected current and voltage. Voltage phase will lag that of current. The clamp time constant, $R_s \parallel R_m C_m$, dictates the resultant frequency dependence of the separation. The bottom panels in Figure 6, indeed, demonstrate that the mechanical response follows the phase of the induced transmembrane voltage and not that of the transmembrane current. Similar data on the magnitude and phase of current, voltage, and motility obtained from four additional cells, each with a different clamp time constant, are presented in Figure 7. In all, an asymptotic phase separation between motility and injected transmembrane current is reached [1.66 ± 0.18 radians at 625 Hz (mean \pm SD; $n = 6$ cells)], as would be

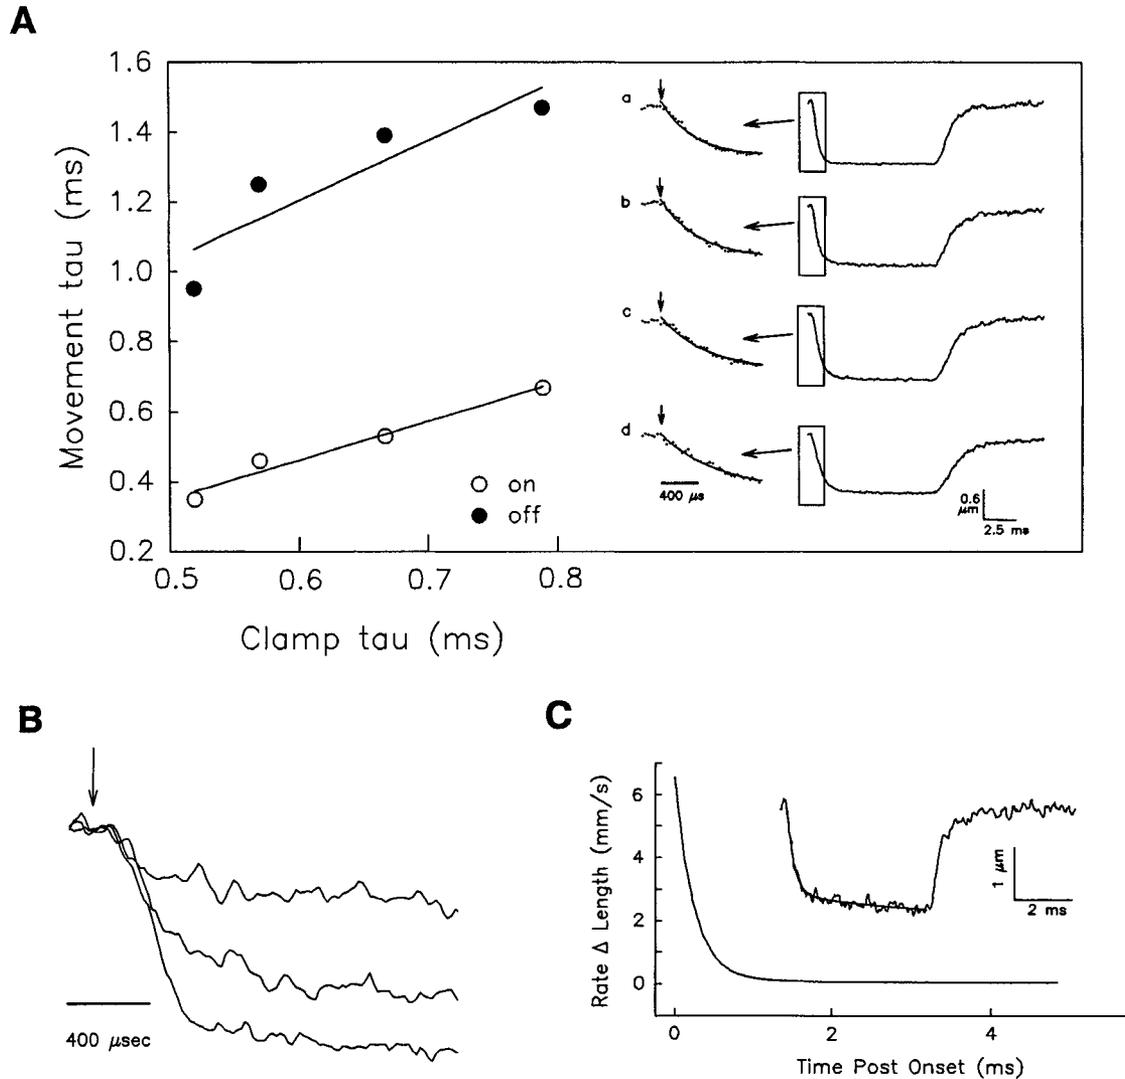

Figure 4. *A*, Effect of clamp time constant upon speed of OHC movement induced by voltage steps. An OHC was nominally held at -80 mV and stepped to $+40$ mV for 10 msec. *Traces a–d* represent the contraction of the OHC (photodiode output) as the clamp time constant is modified. Responses were averaged $200\times$. Single exponentials were fit to the onset (expanded fits shown) and offset of cell movement. It is clear that movement time constants are dependent upon clamp time constants. *Downward arrows* of expanded onset traces indicate voltage step onset. Holding potential and steady state potential (corrected for series resistance) were *a*, -73.5 mV, 36.8 mV; *b*, -72.8 mV, 36.6 mV; *c*, -71.1 mV, 35.8 mV; *d*, -69.2 mV, 35 mV. *B*, *Traces* represent mechanical responses of an OHC stepped nominally to -30 , 0 , and $+30$ mV from a holding potential of -80 mV. *Downward arrow* indicates voltage step onset. Note the delay in onset of the mechanical responses. Also note the saturation of the response at the most depolarized potential, and the resultant apparent decrease in the onset time constant compared to the other responses. *C*, Rate of length change of an OHC to a depolarizing step from -78 mV to $+29$ mV (residual series resistance corrected). Rate was obtained from the first derivative of the fitted mechanical response to *inset*. *Inset*, Mechanical response filtered at 3.184 kHz and fit with a double exponential (*smooth line*). The time constants were 0.24 msec and 5 msec, with an amplitude ratio of $4:1$. Clamp time constant was 0.14 msec.

expected for a voltage driven process. This is strong evidence favoring the voltage dependence hypothesis of OHC motility.²

The relationship of the mechanical response time constant (i.e., cutoff frequency) to that of the voltage clamp is summarized for five cells in Figure 8. The frequency response of OHC motility is positively correlated with the speed of the voltage clamp.

² It should be noted that the measured current phase consists of both a resistive and capacitive component, and that at high frequencies the capacitive component dominates. However, the current through membrane-resistive elements is always in phase with transmembrane voltage. Nevertheless, alterations of the resistive currents by means of various ionic blocking agents do not interfere with voltage-induced mechanical responses (Santos-Sacchi and Dilger, 1988; Santos-Sacchi, 1989, 1991b).

For two OHCs (circles and diamonds), mechanical responses were obtained before and after series resistance compensation; mechanical response cutoff frequency paralleled the resulting changes in clamp speed. There is, however, a trend for the mechanical response fundamental to roll off at lower frequencies than the applied transmembrane voltage. This phenomenon may be a consequence of the nonlinear V-M function, as a similar trend is also found with model simulations (solid line, Fig. 8).

Discussion

The data presented here provide insight into the mechanism and potential significance of OHC motility. The observation

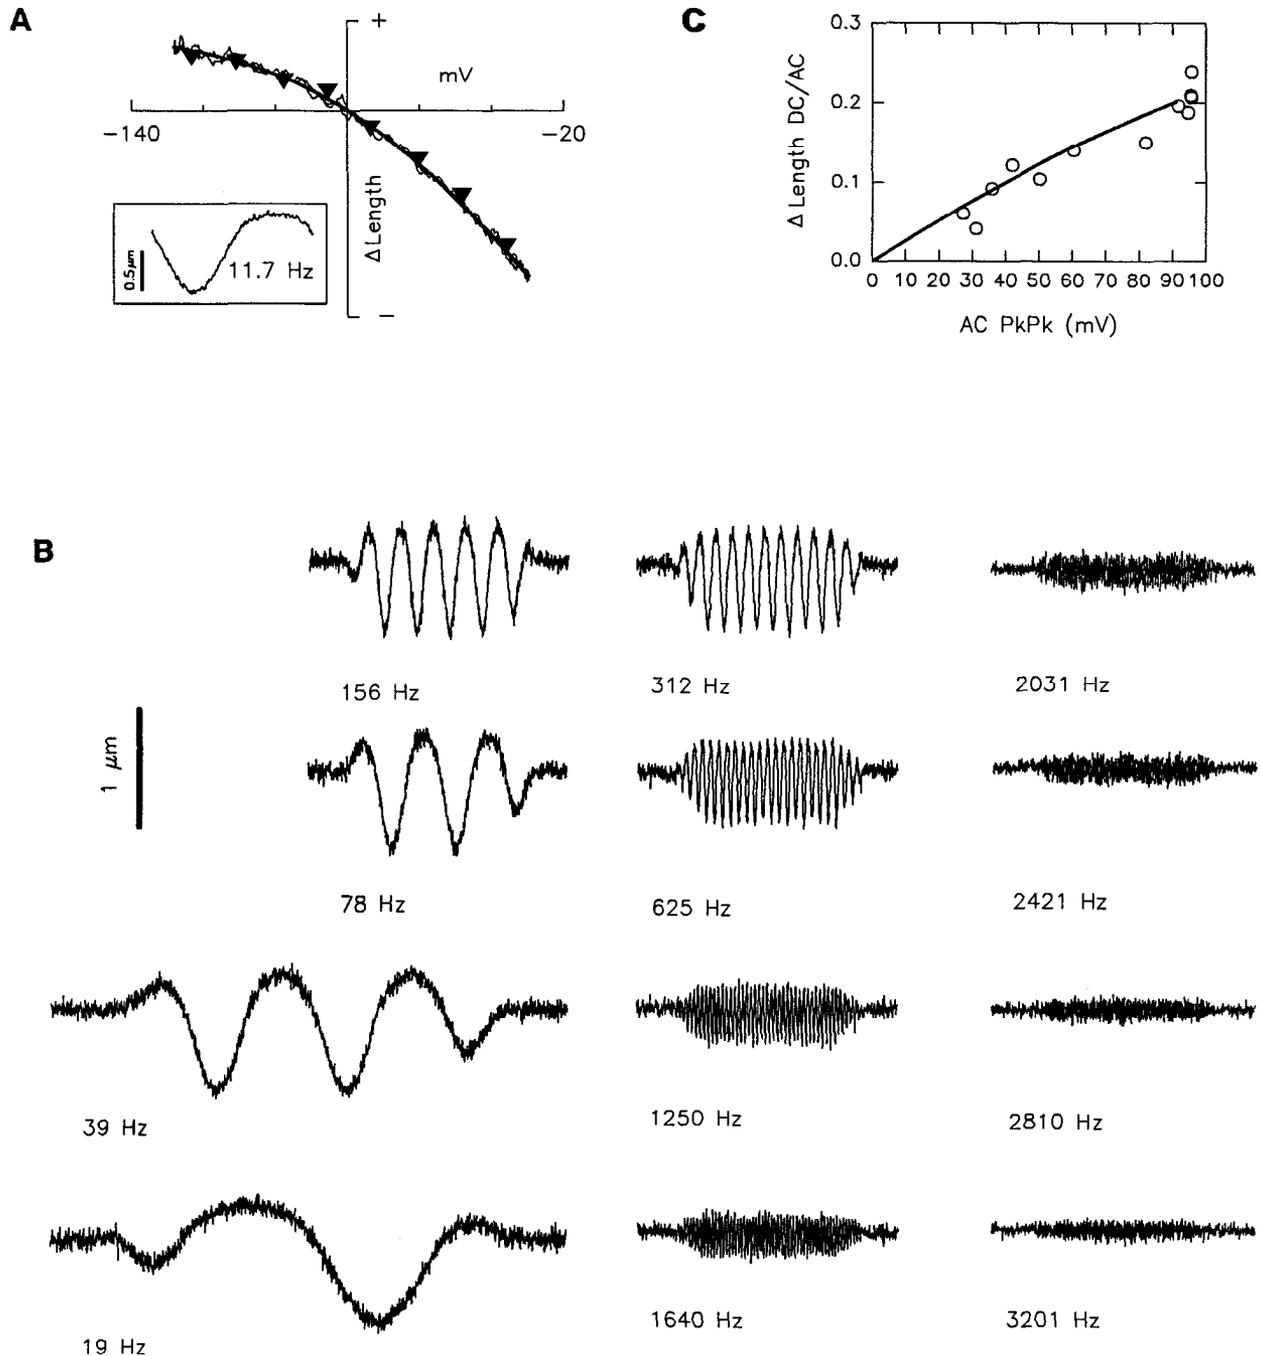

Figure 5. OHC AC and DC mechanical responses elicited by AC voltage stimulation. *A*, Voltage versus movement for an 11.7 Hz voltage stimulus. Voltage is the estimated intracellular potential obtained from the command potential corrected for series resistance and phase shifted to minimize phase differences between it and movement response. The *solid line* is a fit to a portion of a Boltzmann function with $V_h = -30.5$ mV and $b = 31$ mV. For comparison, the data (*solid triangles*) of Evans et al. (1990) based on step commands about the authors' estimated resting potential of -60 mV were scaled and superimposed (see Results and Discussion). *Inset*, Movement response waveform smoothed with five point running average. Peak-to-peak (PkPk) response is about $1 \mu\text{m}$. *B*, Photodiode output indicating the movement of the OHC in response to voltage sine wave bursts of varying frequency. The movement consists of an AC and DC response, both of which decrease as a function of frequency; this results from the decrease of the magnitude of voltage stimulation due to the voltage-clamp time constant. DC responses can be observed above 3 kHz but decrease in magnitude disproportionately compared to AC response magnitude. *C*, Ratio of DC movement to AC PkPk movement versus PkPk voltage stimulus corrected for the frequency-dependent attenuating effects of series resistance. Measures are from the raw data shown in *B*. Data were obtained by visually determining PkPk movement response and DC movement response (difference between baseline and half-PkPk response). The *solid line* is the predicted ratio based upon the movement versus voltage response for 11.7 Hz as in *A*. Note the greater susceptibility of the DC response to reduction of driving voltage magnitude. That is, the DC:AC ratio is *not* constant as a function of driving voltage magnitude.

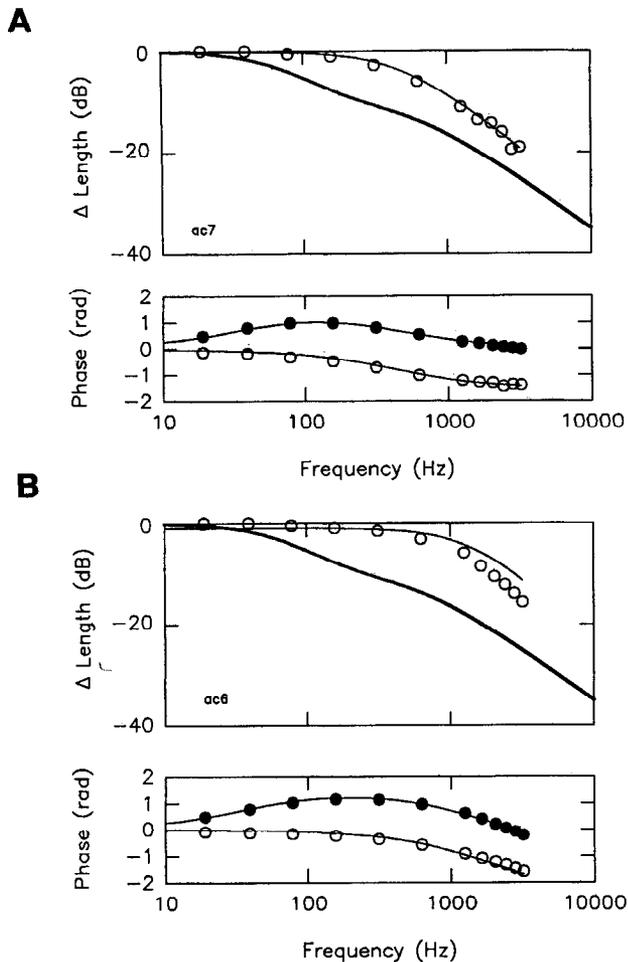

Figure 6. Frequency response (magnitude and phase) of OHC motility for the cell of Figure 5 with a clamp time constant of 0.38 msec (*A*; no series resistance compensation) or 0.125 msec (*B*; series resistance maximally compensated). Nominal peak voltage was 50 mV. CsCl electrode. Extracellular medium was Ca-free Leibovitz with 20 mM TEA and 20 mM CsCl. *A*: Top, Magnitude. Open circles represent the fundamental magnitude of length change obtained by FFT (see Materials and Methods). The line through the data points is the predicted cell voltage using a voltage clamp-cell model (see Materials and Methods), with the electrical characteristics of the clamp-cell setup determined from the current response to a 5 mV step ($R_m = 139.5$ M Ω ; $C_m = 33.3$ pF; clamp $\tau = 0.38$ msec). For comparison, the thick line is Ashmore's fit to his data (1987, Fig. 7). Bottom, Phase. The solid circles represent the phase of the fundamental component of the simultaneously recorded current, after equipment phase correction. The open circles represent the phase of the length change fundamental. The solid lines are the predicted phase for the current and voltage using the voltage clamp-cell model component values. No absolute phase delay is included in the phase predictions. *B*, As in *A*, except clamp-cell electrical characteristics at this time were $R_m = 125.5$ M Ω , $C_m = 35.4$ pF, and clamp $\tau = 0.125$ msec. An absolute phase delay of 25 μ sec is included in current and voltage predictions.

that OHC motility does indeed follow the time course and phase of transmembrane voltage stimuli provides the strongest evidence thus far that the motility mechanism is voltage dependent.³ The presence of voltage-dependent nonlinear charge

³ While the results of Dallos et al. (1991a) clearly demonstrate the elemental nature of the OHC motor, their data do not unequivocally support the voltage dependency hypothesis. Neither transmembrane current nor transmembrane voltage could be measured with the microchamber technique, and either would have been in phase opposition at the opposite poles of the cell, just as the mechanical responses were.

movement within the membrane of the OHC (indicative of membrane-bound voltage sensors) corroborates this concept (Ashmore, 1989; Santos-Sacchi, 1990, 1991b). Similarities between characteristics of the nonlinear charge movement and motility, including voltage dependence (V_h , b), susceptibility to charge screening, and reversible block by gadolinium ions, indicate that the estimated 4000 voltage sensors/ μm^2 control OHC length through an equal number of associated elemental motors (Santos-Sacchi, 1991b). Assuming that the motors are equally distributed within the membrane along the extent of the sub-surface cisternae, it is calculated that each elemental motor would contribute an effective unit displacement of about 1 nm in the longitudinal direction. The actual displacement vector may not be purely longitudinal (Dallos et al., 1991b). Ultimately, the dependence of OHC motility on transmembrane voltage and the form of the V-M function will determine the physiological significance of OHC motility.

Velocity and frequency response of OHC motility

An important indicator for evaluating the significance of OHC motility in inner ear function is its frequency response. Certainly, there will be a point at which the OHC will be unable physically to follow an imposed transmembrane AC voltage, and a determination of this cutoff frequency will permit a more realistic assessment of the OHC's mechanical influence in the high-frequency region of the cochlea. Unfortunately, the maximum velocity and the frequency extent of OHC motility are as yet undetermined, due to the speed limitations imposed by the voltage-clamp amplifier. Thus, the current maximum OHC velocity measured during a step response (6.5 mm/sec; Fig. 4C), or estimated from the AC data [Fig. 6B; ($\Delta L/\omega$) 4 mm/sec at 1250 Hz] is likely to be an underestimate. Indeed, the OHC mechanical response probably extends beyond the widest frequency response measured, which approached a 1 kHz cutoff.

It is interesting to note that although the speed of the mechanical response follows changes in the speed of the imposed voltage, the time constants of each are not necessarily equal. In fact, in Figure 4 it was illustrated that the mechanical on-response can have an apparent time constant faster than that of the imposed voltage; contrarily, the off-response can be slower than the imposed voltage. This is not unusual for a nonlinear system, and the same effects are simulated for a model V-M function in Figure 9. It is clear that despite a constant membrane potential time course, level-dependent changes in the apparent time constant of the mechanical response arise. Mechanical response saturation at the extremes of the V-M function accounts for much of these effects. The tendency for the mechanical frequency response to roll off sooner than the imposed voltage frequency response (Fig. 8) may also reflect the effects of the nonlinear V-M function. If the resting potential (holding potential) were equal to V_h and the stimulus amplitude were very small, the time course of the mechanical response would more closely mirror that of the driving voltage.

Despite their limitations, the measurements of velocity and frequency response reported here more closely reflect OHC mechanical response capabilities than previous measures (Ashmore, 1987), and are useful in evaluating some timely issues. For example, electrically evoked otoacoustic emissions recorded from the ear canal, presumably due to the activity of OHCs, have been measured in pass bands up to several kHz (Hubbard and Mountain, 1990). These investigators have suggested, based on Ashmore's (1987) mechanical frequency response data, that

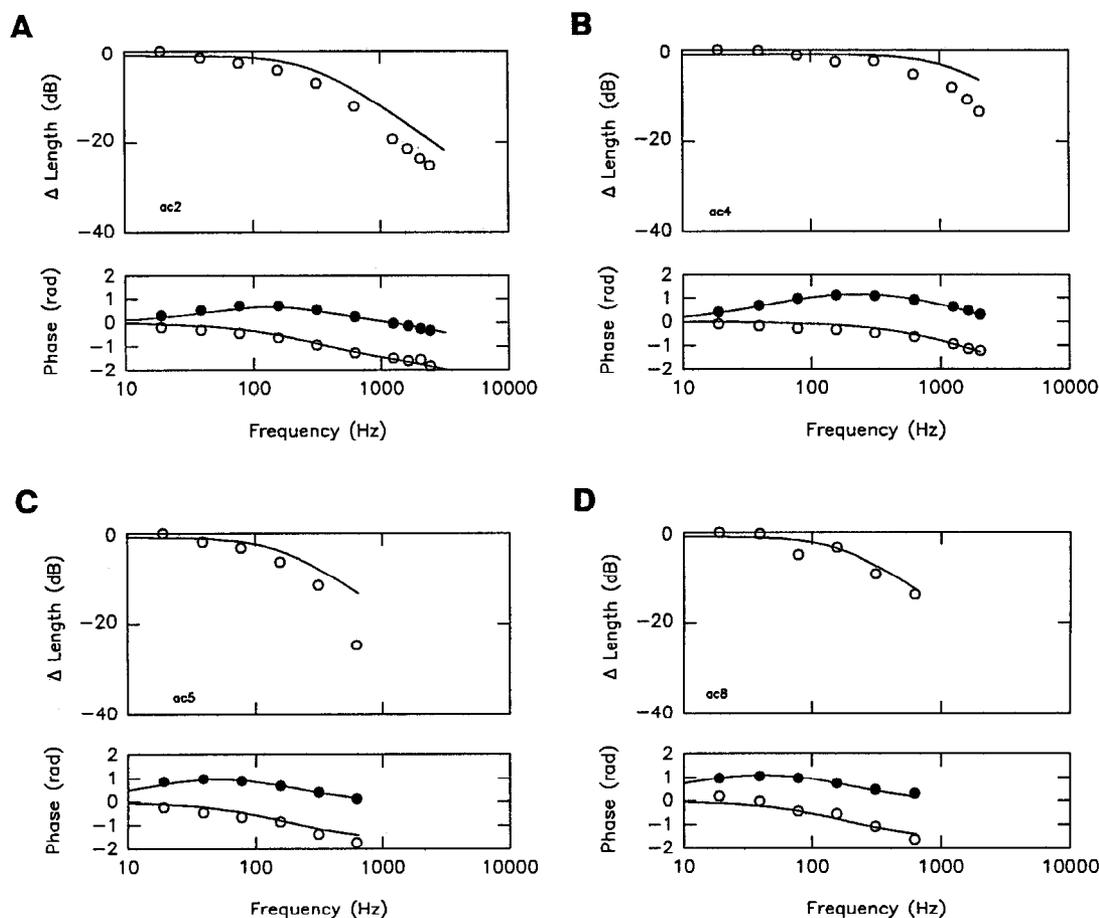

Figure 7. Frequency response for four additional cells (magnitude and phase) with varying clamp time constants. See Figure 6 for details. Clamp-cell electrical characteristics are as follows: *A*, $R_m = 96 \text{ M}\Omega$, $C_m = 24.73 \text{ pF}$, clamp $\tau = 0.553 \text{ msec}$. Absolute phase delay, $25 \text{ }\mu\text{sec}$. Nominal peak voltage was 60 mV . CsCl electrode. Extracellular medium was Leibovitz with 20 mM TEA . *B*, $R_m = 79 \text{ M}\Omega$, $C_m = 41.89 \text{ pF}$, clamp $\tau = 0.128 \text{ msec}$. Absolute delay, $20 \text{ }\mu\text{sec}$. Nominal peak voltage was 40 mV . CsCl electrode. Extracellular medium was Leibovitz with 20 mM TEA , 300 nM TTX , and 1 mM CdCl_2 . *C*, $R_m = 346 \text{ M}\Omega$, $C_m = 27.35 \text{ pF}$, clamp $\tau = 1.00 \text{ msec}$. Absolute delay, $20 \text{ }\mu\text{sec}$. Nominal peak voltage was 40 mV . CsCl electrode. Extracellular medium was Leibovitz with 20 mM TEA and 300 nM TTX . *D*, $R_m = 490 \text{ M}\Omega$, $C_m = 33.0 \text{ pF}$, clamp $\tau = 0.934 \text{ msec}$. Absolute delay, $20 \text{ }\mu\text{sec}$. Nominal peak voltage was 100 mV . CsCl electrode. Extracellular medium was Leibovitz with 10 mM TEA and 300 nM TTX .

the OHC length changes are too low pass to account for such high-frequency phenomena. Clearly, the data presented here suggest that OHC length changes may be significant at those acoustic frequencies where electrically evoked otoacoustic emissions occur. Ashmore's (1987) observation that OHC motility was extremely low pass was probably due to the very slow clamp time constants achieved in that study (see footnote 3 of Santos-Sacchi, 1989).

Since the *in vivo* receptor potential will provide the OHC motility driving force, the effectiveness of evoked AC mechanical events in influencing organ of Corti micromechanics at high frequencies can be evaluated to a first approximation by an assessment of OHC receptor potential characteristics. Thus, it is known that OHC AC receptor potentials for cells with high characteristic frequencies ($> 15 \text{ kHz}$) are quite small due to the cell's RC time constant ($f_{\text{cutoff}} \sim 1.2 \text{ kHz}$); AC potentials of about $15 \text{ }\mu\text{V}$ have been recorded in these cells near auditory threshold (Russell et al., 1986). Consequently, it has been argued that evoked AC movements of an OHC with a resting potential of 70 mV are much smaller ($\sim 20 \text{ dB}$) than basilar membrane movements near auditory threshold (Santos-Sacchi, 1989; but see Santos-Sacchi, 1991b).

The present velocity estimates, though clamp limited, appear incompatible with the electro-osmotic theory of OHC motility proposed by Brownell and Kachar (1986). The rate of movement is far greater than that attributable to an electro-osmotic mechanism; experiments on a variety of preparations indicate the maximum velocity achievable is $1 \text{ }\mu\text{m/sec}$ per V/cm (McLaughlin and Mathias, 1985). The steady state voltage drop across the membrane of the OHC in Figure 4C was 107 mV . The maximum field strength along a cell of $70 \text{ }\mu\text{m}$, assuming that the total imposed voltage drops across the length of the cell (which is unlikely, since space-clamp estimates indicate little longitudinal decay) would be 15.3 V/cm . Thus, an electro-osmotic based velocity of $15.3 \text{ }\mu\text{m/sec}$ is predicted, over 2 orders of magnitude smaller than the observed maximum velocity. Iwasa and Kachar (1989) employed the same argument against an electro-osmotic mechanism, although the disparity between their velocity measures and electro-osmotic estimates were not as great as those reported here. Furthermore, an electro-osmotic mechanism would predict that the velocity, not the displacement, of OHC motility would be in phase with voltage. This is in conflict with the phase data reported here. It should be noted that velocities associated with electro-osmosis are derived for

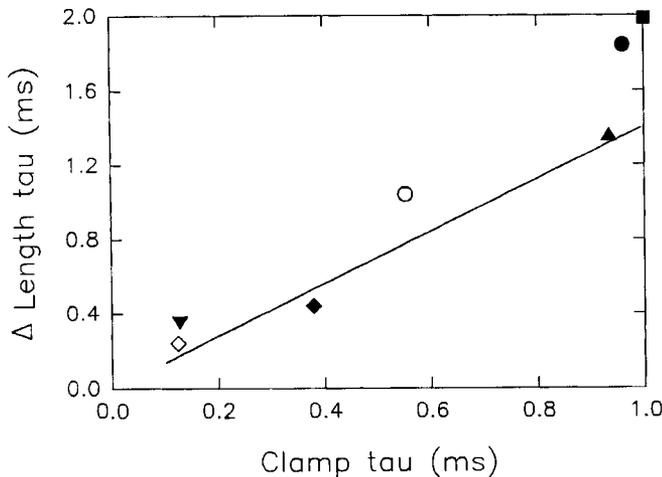

Figure 8. Clamp time constant versus measured time constant of movement. Time constants of movement were from linear interpolation of 3 dB breakpoint of measured magnitude response as in Figure 2. Data from a total of five cells (different symbols) are presented, with two cells (circles and diamonds) being measured at two different clamp time constants (open and solid symbols). Clamp time constant dictates frequency response of OHC motility. However, the mechanical response has a slower time constant (lower cutoff frequency) than the voltage command. This may be a function of the nonlinear V-M function since model simulations predict this type of behavior. For example, the solid line was obtained by performing the same type of analysis on a model V-M function with Boltzmann parameters of $b = 26$ mV and $V_h = -30$ mV, at a holding potential of -70 mV, with a peak AC voltage stimulation of 50 mV.

steady state conditions, and the preceding arguments may not be absolutely appropriate. Nevertheless, in the absence of a more complete electro-osmotic model of OHC motility, it remains questionable whether electro-osmosis can account for the maximum velocity and phase of OHC motility presently found. Dallos et al. (1991a) also dismissed an electro-osmotic mechanism based on other arguments.

DC mechanical response

Voltage-dependent OHC motility, analyzed under whole-cell voltage clamp, is well characterized by a two-state Boltzmann function, whose V_h is offset in the depolarizing direction relative to the normal resting potential of the cell. A mechanical DC nonlinearity is not inherent in the V-M function but is expressed only due to this voltage offset. This concept differs from the contention of Dallos et al. (1991b), who suggest, based on DC responses measured at very small stimulus levels, that the DC component is the result of an essential nonlinearity of the OHC's stochastic motor. Clearly, however, should the cell's resting potential and V_h superimpose, then no DC mechanical component would arise.

The normal resting potential *in vivo* is near -70 mV (Dallos et al., 1982; Russell and Sellick, 1983). V_h of the V-M function ranged from about -40 mV to -20 mV, which to a large extent is dependent upon membrane surface charge and agents that affect the resultant surface potential (Santos-Sacchi, 1991b). Thus, a DC mechanical response appears ensured under normal *in vivo* conditions⁴ and is dependent on the many factors governing

OHC resting membrane potential and membrane surface potential. The effects of resting potential on the sum of elemental motor contributions, that is, on the observable OHC mechanical response, can be complex. For example, whereas shifts of the normal resting potential toward V_h will reduce the DC component, the peak-to-peak component can grow. It is interesting to note that noise-induced threshold shift, which produces a depolarization of the OHC (Cody and Russell, 1985), should affect both AC and DC mechanical response production.

It is demonstrated here that the OHC DC mechanical response is a frequency-independent consequence of the V-M function. The persistence of the DC mechanical response above 3 kHz is the first demonstration that the mechanical rectification extends to physiologically important frequencies. Previous studies have reported DC responses at frequencies between 10 and 200 Hz (Evans et al., 1989; Santos-Sacchi, 1989). It is conceivable that DC mechanical responses of OHCs could provide a bias that may change mechanical characteristics (e.g., stiffness) of the organ of Corti–basilar membrane complex, leading in some manner to enhanced tuning. At first thought, this may appear to alleviate some of the problems associated with the membrane filtering effects on the high-frequency AC mechanical response. However, the DC nonlinearity is highly stimulus level dependent, greatly diminishing with level. Consequently, as the AC voltage stimulus is reduced (e.g., due to the membrane filter), the DC mechanical response magnitude declines much more precipitously than the AC mechanical response. Figure 10 demonstrates this inherent outcome of such a V-M function in a model AC simulation. DC mechanical components are vanishingly small at low stimulus levels.

Evans et al. (1990, 1991) have reported significant DC mechanical responses at low AC stimulation levels. The superposition of their data (from Evans et al., 1990, their Fig. 2) onto the AC data in Figure 2A indicates that the form of their V-M function in the voltage range shown is remarkably similar to the form obtained in the present study under voltage clamp. This is of interest since their stimulus delivery technique (a partitioning microchamber) differs from the whole-cell technique used here. However, while they may have control over the voltage imposed across the membrane of the OHC, their technique permits neither the control of the resting membrane potential nor the control of the intracellular environment (e.g., pH). Calculation of the DC:AC ratio predicted by their V-M function presents essentially the same result as that calculated for the voltage-clamp data reported here. It is surprising, therefore, that they detect a linear modification in both the AC and DC mechanical components as stimulus magnitude is changed. The inability to control resting potential and/or intracellular environment with the microchamber technique may underlie their observation; for example, the resting potential along the V-M function or V_h may be changing as a function of stimulus level. DC responses necessarily change when resting voltage shifts relative to V_h . Relatedly, Evans et al. (1991) presented data that they interpreted to indicate that the DC component was vulnerable to repeated voltage stimulations. These data may

⁴ Actually, V_h is not known for the *in vivo* situation. Unfortunately, the traditional *in vitro* whole-cell technique modifies both intra- and extracellular environments, so that biochemical conditions (e.g., membrane surface charge screening, phosphorylations, etc.) existing *in vitro* may not represent those *in vivo*. Thus, it is very difficult extrapolating to *in vivo* conditions. It should be noted, however, that DC mechanical responses of the basilar membrane *in vivo*, presumably due to the effects of OHCs, have been measured at high sound pressure levels (LePage, 1987). Obviously, it is important to obtain V_h estimates *in vivo*. Since the voltage dependence of nonlinear capacitance in the OHC is similar to that of the cell's mechanical response (Santos-Sacchi, 1991b), inferences concerning the mechanical response V_h may be made from *in vivo* estimates of voltage-dependent capacitance.

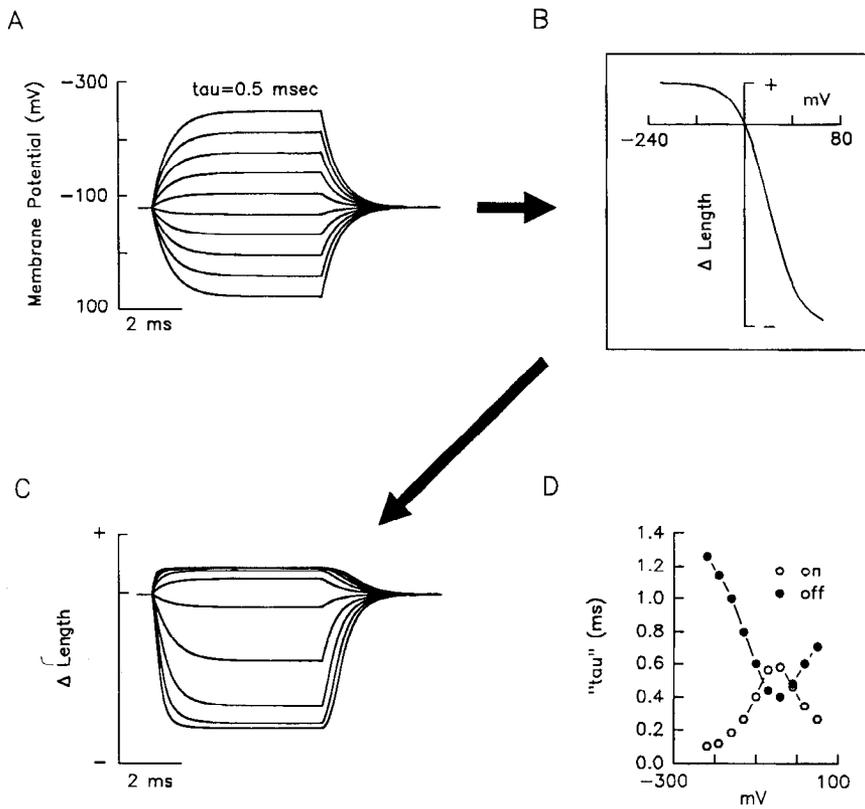

Figure 9. Simulation of voltage step induction of mechanical response in an OHC based on a model input-output V-M function. Filtered voltage steps ($\tau = 0.5$ msec) of various magnitudes (A) about the holding potential of -80 mV were passed through the model OHC V-M function (B) of $V_h = -40$ and $b = 25$ mV. The resultant motility responses (C) are governed by the form of the V-M function, and the value of the holding potential. The saturating nonlinearity of the V-M function produces apparent level-dependent (step potential) changes in the "time constant" of the mechanical response (D). Time constants (" τ ") for on and off responses were determined by noting the time to rise to 63% or fall to 37% of the steady state values, respectively.

also reflect the effects of a drift of the resting potential or V_h of the OHC, and not an induced linearization of the V-M function. No induced linearization of a given V-M function is observed under whole-cell voltage clamp, where the holding potential is readily maintained and the intracellular environment is highly buffered, even with prolonged saturating voltage stimuli.

The physiological consequence of a level-dependent DC mechanical component is clear. *In vivo*, for a $15 \mu\text{V}$ AC receptor potential near auditory threshold, it is calculated that the mechanical DC:AC ratio will be less than 0.0004. Even if the OHC mechanical response were as great as the largest response we have observed in the midregion of the V-M function (~ 30 nm/

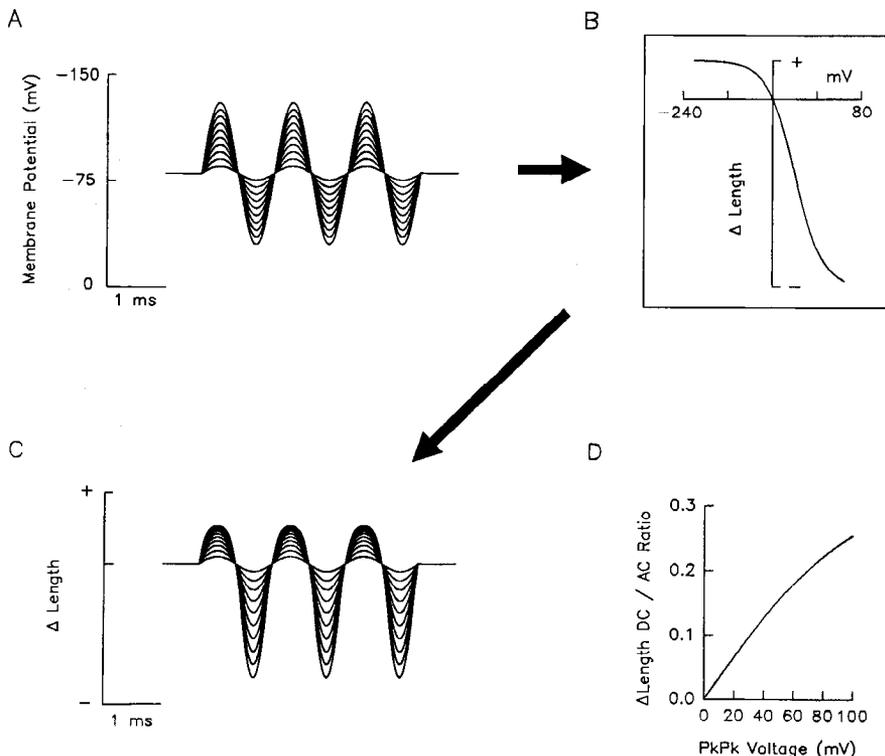

Figure 10. Simulation of voltage sine wave burst induction of AC and DC mechanical responses in an OHC based on a model input-output V-M function. Voltage sine wave bursts of various magnitudes (A) about the holding potential of -80 mV were passed through the model OHC V-M function (B) of $V_h = -40$ and $b = 25$ mV. The resultant motility responses (C) are governed by the form of the V-M function, and the value of the holding potential. The offset of V_h from the holding potential ensures the production of DC responses (difference between baseline and half-PkPk response). A decrease in the amplitude of the driving voltage affects the magnitudes of the AC and DC responses differently. The DC:AC ratio (D) clearly indicates that the DC response is more susceptible to voltage magnitude alterations.

mV),⁵ the DC mechanical response would be 18 fm. Clearly, it is difficult to imagine the significance of such DC displacements when basilar membrane motions at threshold are estimated to be near 350 pm in the guinea pig (Sellick et al., 1982) and 2000 pm in the chinchilla (Robles et al., 1986).⁶ It is important to note, however, that hair cells are capable of generating DC receptor potentials that are not susceptible to the attenuation effects of the cell's RC time constant (Dallos et al., 1982; Russell and Sellick, 1983). Such DC potentials generated at high acoustic frequencies should induce movements of the OHC. However, whereas IHCs produce significant DC potentials at the characteristic frequency threshold in the high-frequency region of the cochlea, OHCs do not (Russell et al., 1986). Thus, the occurrence of rapid, stimulus related DC mechanical responses that are physiologically significant at auditory threshold is not readily envisioned.

In summary, this report demonstrates the widest mechanical frequency response of the OHC measured to date, and shows that the mechanical rectification due to the V-M function extends well into the kilohertz range. These results attest to the unique nature of the OHC's motility mechanism among known cellular mechanisms of movement. Nevertheless, the results confirm the voltage dependency hypothesis of OHC motility, and the limitations that this dependency imposes *in vivo* remain to be reconciled with current concepts of OHC performance in the high-frequency region of the mammalian inner ear.

⁵ The use of the ~30 nm/mV figure (from Santos-Sacchi and Dilger, 1988) is unrealistic since the OHC normally rests at a potential of about -70 mV and the mechanical response slope at this region of the V-M function is far smaller than the maximum slope (see Fig. 2B).

⁶ The inherent linearization of the OHC mechanical response at low stimulation levels was alluded to previously (Santos-Sacchi, 1989) but was deemed incorrect by Evans et al. (1991) based on their measures of large DC mechanical components at low stimulus levels. They suggested, based on their measures, that the nonlinearity of OHC motility may be an important source of cochlear nonlinearity. However, considering the present findings, it remains questionable whether their suggestion is valid at threshold in the high-frequency regions of the cochlea.

Harmonics of Outer Hair Cell Motility

J. Santos-Sacchi

Sections of Otolaryngology and Neurobiology, Yale University School of Medicine, New Haven, Connecticut 06510 USA

ABSTRACT The voltage-dependent mechanical activity of outer hair cells (OHC) from the organ of Corti is considered responsible for the peripheral auditory system's enhanced ability to detect and analyze sound. Nonlinear processes within the inner ear are presumed to be characteristic of this enhancement process. Harmonic distortion in the OHC mechanical response was analyzed under whole-cell voltage clamp. It is shown that the OHC produces DC, fundamental and second harmonic length changes in response to sinusoidal transmembrane voltage stimulation. Mechanical second harmonic distortion decreases with frequency, whereas the predicted transmembrane second harmonic voltage increases with frequency. Furthermore, the phase of the second harmonic distortion does not correspond to the phase of the predicted transmembrane voltage. In contradistinction, it has been previously shown (Santos-Sacchi, J. 1992. *Neuroscience*. 12:1906–1916) that fundamental voltage and evoked mechanical responses share magnitude and phase characteristics. OHC length changes are modeled as resulting from voltage-dependent cell surface area changes. The model suggests that the observed harmonic responses in the mechanical response are consistent with the nonlinearity of the voltage-to-length change ($V\text{-}\delta L$) function. While these conclusions hold for the data obtained with the present voltage clamp protocol and help to understand the mechanism of OHC motility, modeling the electromechanical system of the OHC in the *in vivo* state indicates that the mechanical nonlinearity of the OHC contributes minimally to mechanical distortion. That is, *in vivo*, at moderate sound pressure levels and below, the dominant factor which contributes to nonlinearities of the OHC mechanical response resides within the nonlinear, voltage-generating, stereociliar transduction process.

INTRODUCTION

The organ of Corti, the mammalian auditory sensory epithelium, possesses two types of sensory cells, the inner (IHC) and outer (OHC) hair cells. The OHC has received a tremendous amount of attention in the last decade, primarily because it appears to function as both receptor and effector (Brownell, 1992; Dallos, 1992). The OHC produces receptor potentials in response to acoustic stimulation (Dallos et al., 1982; Russell et al., 1986), and rapidly alters its length as a function of transmembrane voltage (Ashmore, 1987; Santos-Sacchi and Dilger, 1988; Santos-Sacchi, 1992). Currently, the OHC is presumed to modify basilar membrane motion through a mechanical feedback mechanism (Ruggero, 1992). This feedback is ultimately considered to enhance the tuning and sensitivity characteristics of the inner hair cell, the cell type which is innervated by the majority of eighth nerve fibers.

Factors which influence the voltages generated in the OHC are therefore crucial in understanding the impact of the postulated OHC mechanical feedback within the organ of Corti. There are a variety of intrinsic nonlinear processes which may shape the voltages controlling OHC mechanical activity. Included are asymmetrical transduction processes (Russell et al., 1986; Dallos, 1986), and voltage-dependent basolateral membrane conductances (Santos-Sacchi and Dilger, 1988; Ashmore and Meech, 1986; Nakagawa et al., 1991; Housley and Ashmore, 1992) and capacitance (Ashmore, 1989; Santos-Sacchi, 1990, 1991). These nonlinearities

will be expected to generate distortions (DC and harmonic components) in AC membrane voltages, which should be reflected in the voltage-dependent mechanical activity of the OHC. In this report, I evaluate the OHC mechanical response with the whole cell voltage clamp, under conditions where the nonlinear basolateral and transducer conductances contribute minimally. It is demonstrated that fundamental and harmonic mechanical responses are generated upon sinusoidal transmembrane voltage stimulation. Furthermore, it is shown that the phase of the second mechanical harmonic does not correspond to the phase of the second voltage harmonic. Thus, while the phase and magnitude of the fundamental mechanical component mirror that of the fundamental membrane voltage (Santos-Sacchi, 1992), the nonlinearity of the voltage-to-length change ($V\text{-}\delta L$) function dominates the production of higher mechanical harmonics under voltage clamp at the voltage magnitudes studied. Nevertheless, through modeling, it is shown that mechanical nonlinearities in the *in vivo* situation will be a dominant function of voltage nonlinearities effected by the stereociliar transducer mechanism.

MATERIALS AND METHODS

General

Guinea pigs were overdosed with pentobarbital. The temporal bones were removed, and OHCs were isolated nonenzymatically from the cochleas by gentle pipetting of the isolated top two turns of the organ of Corti in Ca^{2+} -free medium. OHC stereocilia are damaged or lost during this treatment. The cell-enriched supernatant was then transferred to a 700-ml perfusion chamber, and the cells permitted to settle onto the cover glass bottom. All experiments were performed at room temperature ($\sim 23^\circ\text{C}$). A Nikon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical and mechanical recording. All experiments were taped with

a Panasonic AG6300 video recorder. A modified Leibovitz medium (142.2 mM NaCl, 5.37 mM KCl, 1.25 mM CaCl₂, 1.48 mM MgCl₂, 5.0 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid, 5.0 mM dextrose, pH 7.2) was used as the normal perfusate. Modifications made to the extracellular medium in order to block ionic conductances are noted in figure legends. NaCl was adjusted to maintain osmolarity (300 mOsm).

Electrical recording

OHCs were whole cell voltage-clamped with a Dagan patch clamp amplifier at holding potentials between -70 and -80 mV, similar to potentials recorded *in vivo* (Dallos et al., 1982). Pipette solutions were composed of 140 mM CsCl, 5 or 10 mM EGTA, 2 mM MgCl₂, and 5 mM 4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid buffered to pH 7.2. Gigohm seals were obtained at the nuclear level of the cell membrane and electrode capacitance was compensated prior to whole cell recording. AC studies were performed using a digital signal-processing board with custom written software (DSP-16; Ariel Corp., Highland Park, NJ), capable of delivering and analyzing pure tone or swept frequency stimuli. Data were saved to disk for off-line analysis.

Electrode resistance (R_s), membrane resistance (R_m), and capacitance (C_m) were estimated from current transients evoked by small voltage steps (Santos-Sacchi, 1992). Care was taken to maintain low series resistance values during recording by delivering transient positive or negative pressure into the electrode to maintain an unobstructed orifice; electronic series resistance compensation was employed as well. Measurements were made on a physical R-C cell model to rule out potential artifacts generated within the voltage clamp system.

OHC Motility Measures

OHC mechanical responses and currents were simultaneously measured in response to sinusoidal voltage stimuli. Fast OHC movements were measured

with a differential photodiode (PD) onto which the image of the cuticular plate (apical end of cell) from the microscope was projected (Santos-Sacchi, 1992). Placement of the PD was accomplished remotely by a computer-controlled micromanipulator, so as not to perturb whole cell recording. The frequency response of the PD system, measured with an LED, had a 3-dB rolloff at 6 kHz. Sinusoidal voltage bursts (onset and offset linearly ramped) were delivered to OHCs under voltage clamp. PD output and whole cell currents were filtered at 10 kHz (12 dB/octave) and collected simultaneously using a sampling rate of 20 kHz. Responses were averaged 200 times. Magnitude and phase of the current and mechanical responses were measured by fast Fourier transform of the central portion of the digitized waveforms using the software package Matlab (Mathworks, Natick, MA). Numerical solutions to model equations were also performed with this package. Mechanical responses were corrected for the phase and magnitude characteristics of the PD system. The pertinent response characteristics of the system were evaluated by measuring the movements of a glass probe driven by a piezoelectric bimorph (Fig. 1). Since the measured quantities in these experiments are the change in cell length (δL) and the current through the resistance of the patch electrode (I_R), all phase relations (data and model) are conveniently referenced to that of current (I_R). That is, fundamental movement phase [$\phi(\delta L_{f_0})$] is referenced to fundamental current phase [$\phi(I_{Rf_0})$], and harmonic movement phase [$\phi(\delta L_{fn})$] is referenced to harmonic current phase [$\phi(I_{Rfn})$]. Absolute calibration of cell movements was determined by measuring off the video monitor the cell movement in response to a large steady state depolarizing voltage stimulus (Santos-Sacchi, 1989).

RESULTS

Sinusoidal voltage stimulation of the OHC produces sinusoidal alterations in the cell's length. Fig. 2 illustrates, for three cells, the waveforms, magnitudes, and phases of the

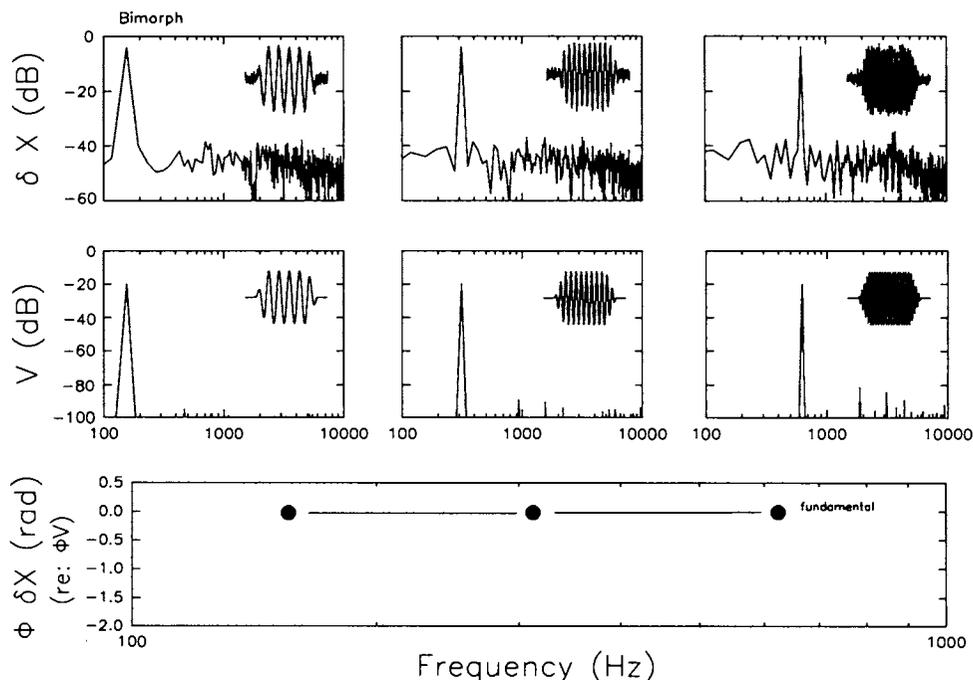

FIGURE 1 Characteristics of the mechanical measurement system. Outputs from PD in response to simulated cell movement. The tip of a glass microelectrode shank was melted to a sphere of about $15 \mu\text{m}$; transmitted light produced a bright area in the sphere's center which was used to mimic the bright OHC cuticular plate observed under Hoffmann optics. The artificial cell was attached to a piezoelectric bimorph and moved using the same voltage waveforms that were used to collect OHC movement data. Upper panel depicts the movement waveforms and magnitude responses obtained by FFT for the stimulus frequencies of 156, 313, and 625 Hz. Peak to peak movements were about $1 \mu\text{m}$. Middle panel depicts the voltage stimulus waveforms and magnitude responses. Note that only fundamental components are observed, indicating the linearity of the measurement system. Lower panel shows the phase of the mechanical response fundamental relative to the driving voltage. As expected for the voltage-dependent piezoelectric response, the phase difference is zero.

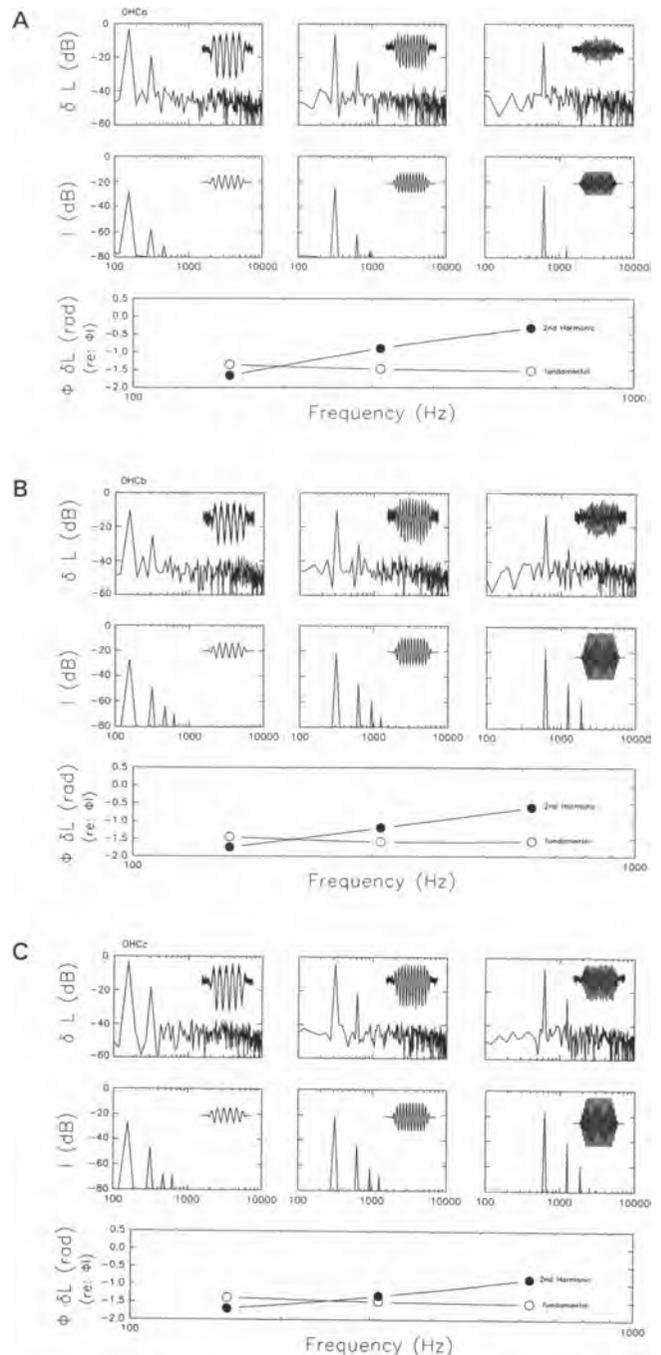

FIGURE 2 OHC mechanical responses induced by sinusoidal voltage clamp stimulation. Results from three different cells are presented in *A*, *B*, and *C*. Upper panels depict the movement waveforms and magnitude responses obtained by FFT for the stimulus frequencies of 156, 313, and 625 Hz. Middle panels depict the measured current waveforms and magnitude responses. Peak-to-peak movements at low frequency were about 1 μm . Lower panel shows the phase of the mechanical response fundamental and second harmonic relative to the measured current phase. Phase is plotted versus fundamental frequency. Note in each case that the mechanical response consists of a DC, fundamental, and second harmonic response. The phase of the fundamental component asymptotes near -1.57 rad, while that of the second harmonic presents an initial phase lag of greater than -1.57 rad which decreases as frequency increases. Clamp-cell electrical characteristics: (*A*) $R_m = 96 \text{ M}\Omega$; $C_m = 24.73 \text{ pF}$; clamp tau = 0.553 ms. Nominal peak voltage was 60 mV. CsCl electrode. Extracellular medium was Leibovitz with 20 mM TEA. (*B*) $R_m = 79 \text{ M}\Omega$; $C_m = 41.89 \text{ pF}$; clamp tau = 0.128 ms. Nominal peak voltage was 40 mV. CsCl electrode. Extracellular medium was Leibovitz with 20 mM TEA, 300 nM TTX, and 1 mM CdCl₂. (*C*) Nominal peak voltage: 50 mV. CsCl electrode. Extracellular medium was Ca²⁺-free Leibovitz with 20 mM TEA and 20 mM CsCl. $R_m = 125 \text{ M}\Omega$; $C_m = 35.4 \text{ pF}$; and clamp tau = 0.125 ms.

measured mechanical and current responses at three frequencies, 156, 313, and 625 Hz. In addition to the fundamental component, the mechanical responses exhibit nonlinear characteristics, including a DC component and a second harmonic (higher harmonics may lie below the noise floor). In all cells successfully recorded from ($n = 9$), harmonics were observed. The DC component is clearly due to the nonlinear form of the V - δL function, and the position of the holding potential along this function (Santos-Sacchi, 1989; Evans et al., 1989). The phase of the mechanical fundamental relative to the current fundamental differs by some 1.5 rad at these frequencies; this has been observed to be characteristic of a voltage-driven mechanical process (Santos-Sacchi, 1992). Note, however, that the phase of the mechanical second harmonic relative to the current second harmonic demonstrates a phase lag which decreases as frequency increases. This, as will be demonstrated below, is not characteristic of a directly driven voltage-induced mechanical response.

As a first step toward evaluating the data, the OHC is modeled to determine the currents and voltages generated under whole cell voltage clamp. The electrical characteristics of the OHC when ionic conductances are blocked can be modeled most simply as an electrode resistance (access resistance, R_s) in series with a parallel combination of a membrane resistance (R_m), a linear membrane capacitance (C_{lin}), and a voltage-dependent membrane capacitance (C_v) (Fig. 3 *a*).¹ The total membrane capacitance (C_m) at any given voltage is the sum of the linear and nonlinear capacitances,

$$C_m = C_v + C_{lin}, \quad (1)$$

¹ A residual resistive nonlinearity remains in OHCs despite considerable attempts to block ionic conductances (Santos-Sacchi, 1991). However, while this nonlinearity varies markedly in magnitude (essentially absent in some cells), the nonlinear capacitance is robust. Modeling the OHC with a resistive nonlinearity indicates that the capacitive nonlinearity dominates. Thus, any residual resistive nonlinearity is ignored in the model.

where C_v is defined as the first derivative of the Boltzmann function relating OHC nonlinear charge movement and voltage (see Santos-Sacchi, 1991). Thus,

$$C_v = \frac{(Q_{\max}(ze/kT))}{\exp\left(\frac{ze}{kT}\{V_m - V_h\}\right)\left[1 + \exp\left(\frac{-ze}{kT}\{V_m - V_h\}\right)\right]^2}, \quad (2)$$

where V_m is the membrane potential, V_h is voltage at half-maximal nonlinear charge transfer, e is electron charge, k is Boltzmann's constant, T is absolute temperature, z is the valence, and Q_{\max} is maximum charge transfer.

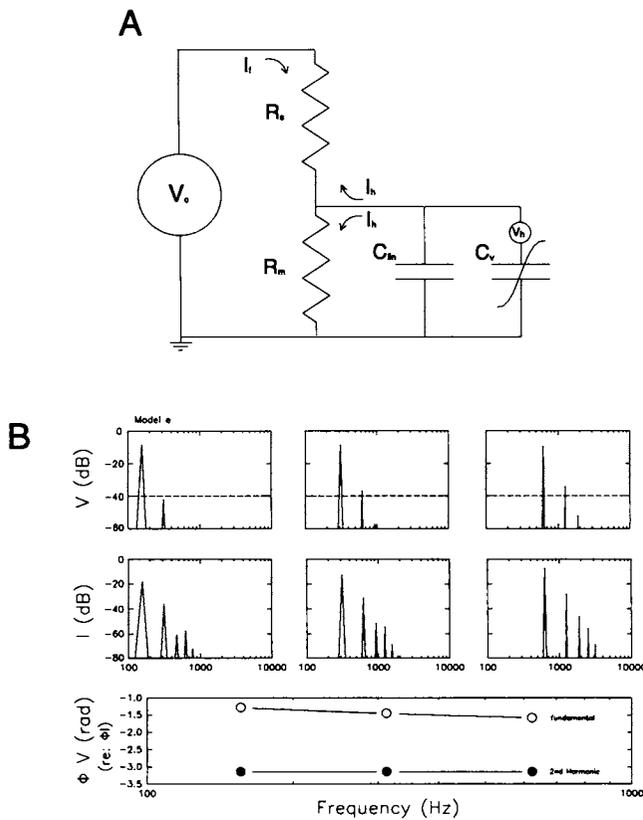

FIGURE 3 (A) OHC-clamp model used to determine the currents and voltages generated under whole cell voltage clamp. The model consists of an electrode resistance (access resistance, R_s) in series with a parallel combination of a membrane resistance (R_m), a linear membrane capacitance (C_{lin}), and a voltage-dependent membrane capacitance (C_v). V_c is the voltage clamp source and V_h is the source of the harmonic voltages within the voltage-dependent capacitance. I_i denotes the direction of fundamental currents through R_s elicited by the voltage clamp source. I_h denotes the direction of harmonic currents through R_s and R_m . (B) Solution of the model utilizing the parameter value (see Results): V_h , -30 mV; z , -1; Q_{max} , 2 pC; R_m , 100 M Ω ; R_s , 5 M Ω ; C_{lin} , 20 pF; T , 298K; V_{hold} , -80 mV; and V_c , 40 mV Pk. Upper panel depicts the membrane voltage (V_m) magnitude responses obtained by FFT for the stimulus frequencies of 156, 313, and 625 Hz. Middle panel depicts the current (I_{R_s}) magnitude responses. Note that fundamental and harmonic components are observed, as is expected in a nonlinear system under nonideal voltage clamp. Lower panel shows the phase of the voltage response fundamental relative to the driving current. As expected the phase of the fundamental voltage asymptotes near -1.57 rad, and the phase of the second harmonic voltage is 180° out of phase (-3.12 rad) with the phase of I_{R_s} .

Given an AC command voltage of V_c which is offset by a holding potential of V_{hold} , the current measurable under whole cell voltage clamp, I_{R_s} , is given as

$$I_{R_s} = I_{R_m} + I_{C_m} \quad (3)$$

or

$$\frac{([V_c + V_{hold}] - V_m)}{R_s} = \frac{V_m}{R_m} + C_m \frac{\delta V_m}{\delta t} \quad (4)$$

Numerical solutions were obtained with typical empirically determined parameter values (Santos-Sacchi (1991): V_h , -30 mV; z , -1; Q_{max} , 2 pC; R_m , 100 M Ω ; R_s , 5 M Ω ; C_{lin} , 20 pF; T , 298K; V_{hold} , -80 mV; and V_c , 40 mV Pk).

Fig. 3 b demonstrates, in the nonlinear electrical model of the OHC under voltage clamp, the current (I_{R_s}) and membrane voltage (V_m) responses due to sinusoidal voltage clamp stimulation. The model generates both fundamental and harmonic responses. Under whole cell voltage clamp, sinusoidal stimulation will elicit voltage harmonics across the nonlinear cell membrane since, due to the finite value of the series resistance, R_s , the clamp is less than ideal (if R_s were equal to zero then the voltage across the membrane would be solely the undistorted sinusoidal clamp voltage). As expected at these frequencies with the chosen typical component values, the phase of the fundamental of V_m lags that of I_{R_s} by about 1.57 rad or 90°. Note, however, that the phase of the second harmonic of V_m lags that of I_{R_s} by 3.14 rad. This derives from the fact that the input voltage clamp stimulus contains no harmonics, and the source of the second harmonic is within the voltage-dependent capacitance, C_v . Thus, at the second harmonic, current flows through R_s and R_m to ground. Keeping the current sign convention through R_s constant (see Fig. 3 a), it is apparent why the phase of I_{R_s} at the second harmonic is -3.14 rad relative to that of V_m (i.e., current lags voltage by 3.14 rad). Why, then, if OHC motility is voltage-dependent do the phase characteristics of the motility at the second harmonic differ from those of the voltage predicted by the model?

In order to explore this dilemma, an extension of the simple electrical model is generated whereby the voltage change across the OHC membrane is translated to changes in cell length and cell radius. This mechanical component of the model revolves around the assumption that the voltage-dependent charge movement measured in the OHC (Santos-Sacchi, 1991) corresponds to a conformational change induced by the movement of charged moieties within 10-nm particles known to reside within the OHC plasmalemma (Gulley and Reese, 1977; Saito, 1983; Forge, 1991). The conformational change is assumed to alter the surface area occupied by such particles within the membrane (Fig. 4). Kalinec et al. (1992) have observed depolarization-induced reductions in surface area of OHC lateral membrane patches. Given the constraints of constant cell volume (likely because the OHC mechanical frequency response probably extends beyond a 1-kHz cutoff (Santos-Sacchi, 1992)), and a fixed cell architecture, a change in length and radius will ensue following a change in cell surface area.

The diameter (d_p) of the membrane particle when the cell is fully elongate is taken as 10 nm. The particle area within the membrane is then,

$$A_p = \pi \left(\frac{d_p}{2} \right)^2, \quad (5)$$

and the change in diameter (δd_p) due to voltage-dependent conformation change results in a single particle area change of

$$\delta A_p = \pi \left(\frac{d_p + \delta d_p}{2} \right)^2 - \pi \left(\frac{d_p}{2} \right)^2. \quad (6)$$

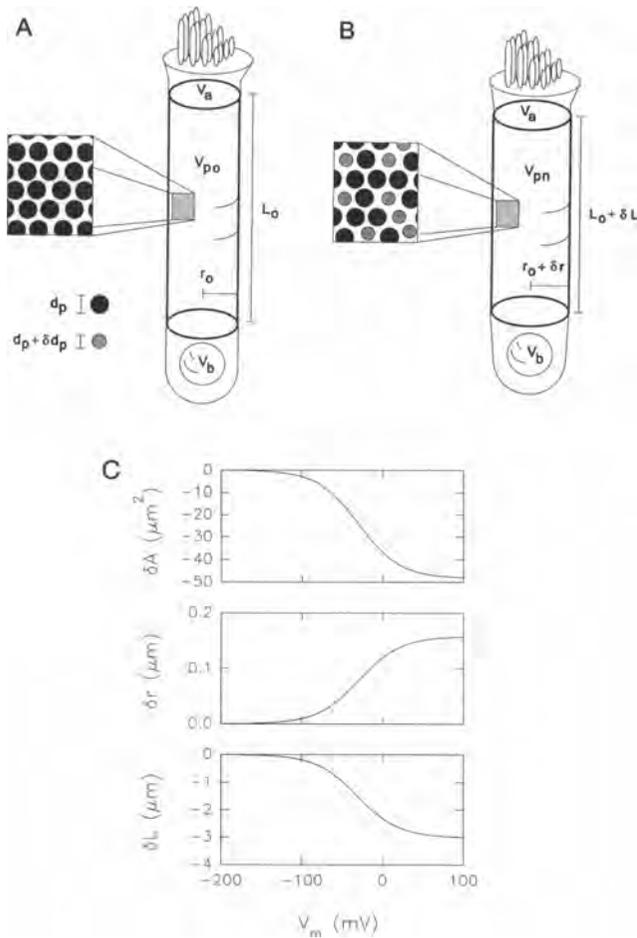

FIGURE 4 OHC mechanical model (see Results). (A) Hyperpolarized OHC in fully elongate state where all membrane particles (blow up) are in maximum surface area state. (B) Partially depolarized OHC where some particles are in minimum surface area state. Note that when cell is depolarized length is decreased and radius is increased. Drawing is not to scale. V_{po} , volume of portion of fully elongate cell which is bounded by active, particle containing region; r_o , radius of cell in fully elongate state; V_a , volume of apical region of cell not containing membrane particles; V_b , volume of basal region of cell not containing membrane particles; L_o , length of cell in fully elongate state; V_{pn} , volume of portion of partially contracted cell which is bounded by active, particle containing region; δr , change in radius due to depolarization; δL , change in length of cell due to depolarization; d_p , particle diameter in maximum surface area state; δd_p , change in particle surface area in minimum surface area state. (C) Predicted change in model OHC surface area, radius, and length as a function of transmembrane voltage. Changes in length and radius are similar to experimental observations under voltage clamp. Ratio of length to radial change is about 18.

The maximum change in cell surface area (δA_{\max}) depends upon the number of particles (N_i) in the membrane,

$$\delta A_{\max} = \delta A_p N_i. \quad (7)$$

The aggregate membrane surface area change ($\delta A(V_m)$) will be voltage-dependent and will display the same Boltzmann characteristics of the voltage-dependent charge movement alluded to above (Santos-Sacchi, 1991).

$$\delta A(V_m) = \frac{\delta A_{\max}}{1 + \exp\left(\frac{-ze}{kT}\{V_m - V_h\}\right)} \quad (8)$$

The architecture of an OHC is normally close to cylindrical,

and the following analysis adheres to that form; however, since it is known that length changes occur even when the cell has swelled into a spherical form (Holley and Ashmore, 1988a), an analysis assuming the form of a prolate spheroid was performed and similar results were obtained. Forces need not be considered directly, but are simply acknowledged to promote the maintenance of the cylindrical shape (or, in the case of a spheroid model, the spheroid shape). The existence of a cytoskeletal spring beneath the OHC plasmalemma (Holley and Ashmore, 1988b), in conjunction with intracellular pressure is taken to provide these forces. The force providing the change in surface area derives from the imposed transmembrane voltage.

For the cylindrical cell model (Fig. 4), the volumes of the particle containing region of the cell before (V_{po}) and after (V_{pn}) a change in length (δL) and radius (δr) are

$$V_{po} = \pi r_o^2 L_o, \quad (9)$$

and

$$V_{pn} = \pi (r_o + \delta r)^2 (L_o + \delta L), \quad (10)$$

where L_o and r_o are the cell length and radius in the fully elongate state.

The total cell volumes before (V_o) and after (V_n) are

$$V_o = V_{po} + V_{ab}, \quad (11)$$

and

$$V_n = V_{pn} + V_{ab}, \quad (12)$$

where V_{ab} is the sum of the volumes of the apical (V_a) and basal (V_b) regions of the cell which are devoid of the presumed membrane motor particles. To simplify matters, an assumption is made that V_{ab} remains constant. This assumption may be taken to indicate that the apical and basal compartments are either rigid or deformable to the extent that the sum of the volumes remains constant. Because total cell volume is constant for each condition,

$$\delta L = -\delta r L_o \frac{2r_o + \delta r}{r_o^2 + 2r_o \delta r + \delta r^2}. \quad (13)$$

The surface areas of the active, particle-containing regions under each condition are

$$A_o = 2\pi r_o L_o \quad (14)$$

$$A_n = 2\pi (r_o + \delta r)(L_o + \delta L), \quad (15)$$

The change in cell surface area, $\delta A(V_m)$, is then

$$\delta A(V_m) = A_n - A_o = \frac{\delta A_{\max}}{1 + \exp\left(\frac{-ze}{kT}\{V_m - V_h\}\right)}. \quad (16)$$

Given the Boltzmann dependence of $\delta A(V_m)$, the cell volume constraint, and the further constraint that $|\delta r| < |r_o|$, physically realizable values of δL and δr are obtained. Fig. 4c plots the solution to the equations as voltage is varied between -200 and 100 mV. The parameters used were: L_o , 50 μm ; r_o , 5 μm ; δd_p , -0.5 nm; and N_i , 4000/ μm^2 . The

number of particles derives not only from estimates based on the relation between charge movement and length changes in OHCs (Santos-Sacchi, 1991), but also from ultrastructural studies (Kalinec et al., 1992). The outcome of this model (Fig. 4 c) displays characteristics which are comparable to actual results obtained under whole cell voltage clamp (Ashmore, 1987; Santos-Sacchi and Dilger, 1988; Santos-Sacchi, 1989, 1991, 1992). For example, maximal length changes are about 20 times greater than radial changes, and while depolarization decreases cell length, cell radius is increased. More importantly for the present analysis, the model can be used to simulate the nonlinear effects evoked by sinusoidal voltage stimulation.

Fig. 5 illustrates the fundamental and harmonic structure of δL and V_m for the complete model (electrical and mechanical) when excited by those same frequencies used to collect the biophysical data. Several characteristics of the model output should be noted. First, it is obvious that phase relations are similar between model and data (Fig. 2). Second, the relative magnitudes of the fundamental and second harmonic mechanical responses resemble those of the actual mechanical data. Clearly, the relative magnitude of the second harmonic mechanical response is greater than would be predicted from the corresponding predicted voltage. Finally, note that while the magnitude of the voltage second harmonic increases with frequency, the magnitude of the mechanical second harmonic decreases with frequency. Overall, the

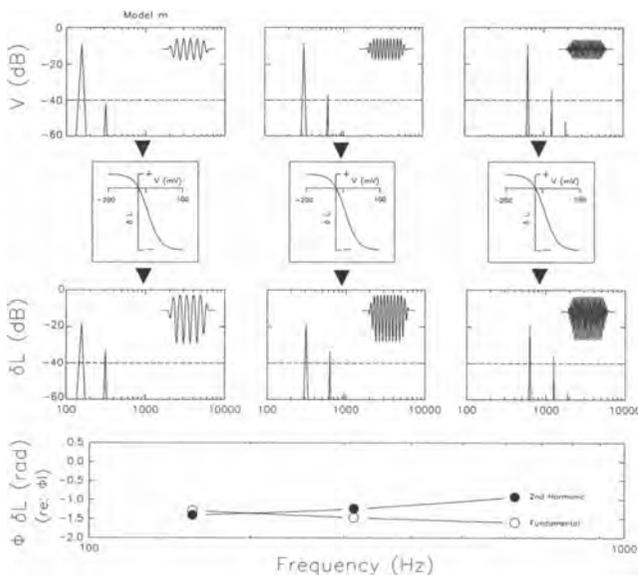

FIGURE 5 Combined electrical and mechanical model of OHC mechanical response under voltage clamp. Parameters as in Figs. 3 and 4. Upper panels depict the membrane voltage waveforms and magnitude responses obtained by FFT for the stimulus frequencies of 156, 313, and 625 Hz. Panels between arrowheads represent the V - δL function with parameters as in Results. Middle panels depict the mechanical waveforms and magnitude responses. Lower panel shows the phase of the mechanical response fundamental and second harmonic relative to the current phase. Phase is plotted versus fundamental frequency. Note that the mechanical second harmonic decreases with frequency unlike the voltage second harmonic. The phase response is similar to the actual biophysical data (Fig. 2).

model results are similar to the actual data in that they suggest that the second harmonic mechanical response is due to forces other than the second harmonic voltage.

Certainly, however, the voltage harmonics should induce mechanical responses at their respective frequencies. A model simulation was performed where the voltage from the nonlinear electrical cell model was stripped of its fundamental prior to evoking changes in membrane surface area. This was accomplished mathematically by zeroing the fundamental component of the voltage fast Fourier transform, followed by reverse transformation. Obviously, the fundamental component is absent in the mechanical response. Informatively, however, the voltage-dependent mechanical response at the second harmonic is unmasked. It mirrors the increase in magnitude which the second harmonic voltage displays. More importantly for this analysis, the phase of the mechanical response lags that of I_R by 3.14 rad, just as voltage does (Fig. 3).

It is shown in Fig. 6 that the fundamental component of the voltage, i.e., the voltage stripped of its harmonics (an ideal voltage clamp), induces a mechanical response which presents both fundamental and second harmonic structure. The magnitude of the second harmonic decreases with frequency less so than for the complete model (Fig. 5), and it appears to follow the similar slight decrease of the fundamental magnitude. The phase of the second harmonic relative to the current is somewhat similar to the complete model (Fig. 5), however, the phase lag is decreased at all frequencies. The apparent frequency dependence of the mechanical second harmonic phase is not real, but only reflects the frequency dependence of the I_R phase to which the mechanical

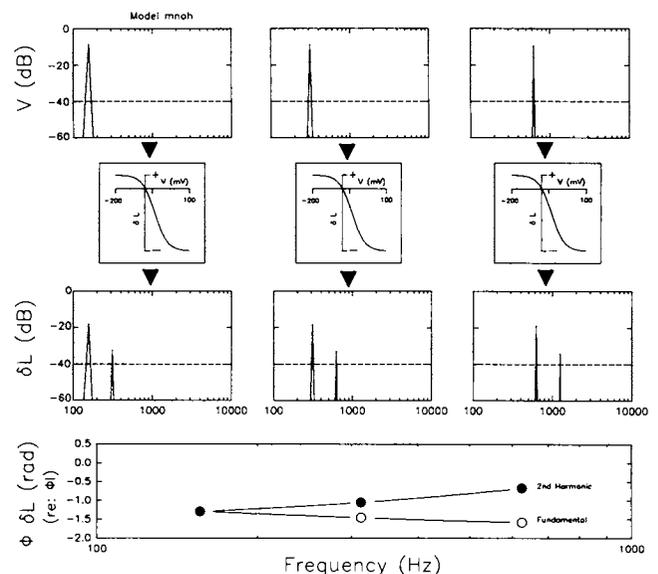

FIGURE 6 As in Fig. 5 except that the second harmonic voltage has been removed prior to generating the mechanical response. This is equivalent to an ideal voltage clamp, without the effects of series resistance. Note that mechanical second harmonics are generated due to the nonlinearity of the V - δL function. The phase is somewhat similar to the complete model (Fig. 5), but the second harmonic lag is slightly decreased at all frequencies (see Fig. 7).

phase is referenced. The phase of the mechanical second harmonic actually mirrors that of the fundamental, i.e., $\phi(\delta L_{f_2}) = \phi(\delta L_{f_1})/2$. The frequency independence of the mechanical second harmonic phase is demonstrated in Fig. 7, where the phase of the mechanical second harmonic of the fundamental-only model is plotted relative to that of the complete model (essentially, the phase reference to current is removed). Note, however, that a slight residual frequency dependence in this phase plot is revealed, showing a lag accumulating with frequency. This is totally attributable to the mechanical effects of the frequency-dependent increase in the magnitude of the voltage second harmonic of the complete model, given its phase lag of 3.14 rad. That is, in the complete model, and presumably in the actual data, although the second harmonic mechanical response is dominated by distortion in the mechanical transformation, voltage distortion plays a minor role.

DISCUSSION

In the present report, the higher harmonic components of the OHC voltage-dependent mechanical response were measured, and deduced through modeling to arise primarily from nonlinearities in the V - δL process. Voltage nonlinearities generated due to the OHC nonlinear capacitance (see Footnote 1), under nonideal voltage clamp, account for little of the mechanical harmonic distortion. Thus, while mechanical distortion can be induced by nonlinearities in the voltages of the OHC, the nonlinear nature of the mechanical transformation ensures distortion product generation under the present experimental conditions.

Effects of the V - δL function on evoked mechanical nonlinearities of the OHC

The form of the OHC V - δL function under voltage clamp can be fit by a two-state Boltzmann relation (Santos-Sacchi, 1991, 1992) and consequently the mechanical sensitivity of the cell, the slope of the V - δL function, varies depending upon resting potential. Because the normal resting potential

lies at the hyperpolarizing saturation knee of the V - δL function, sinusoidal voltage excitation elicits both DC and harmonic mechanical distortion. The production of DC mechanical components has been documented (Santos-Sacchi, 1989; Evans et al., 1989), and the polarity of this component has been shown to reverse, as expected, when the holding potential is shifted to values more positive than V_h (the voltage (~ -30 mV) at half-maximal length change (Santos-Sacchi, 1989, 1992)). Indeed, under voltage clamp, the DC component has been measured at stimulus frequencies as high as 3.2 kHz (Santos-Sacchi, 1992). Nevertheless, it was shown that the magnitude of the DC component is highly level-dependent, decreasing in size much more precipitously than the fundamental component as voltage level decreases (see Figs. 5 *c* and 10 *d* in Santos-Sacchi (1992)). This is a consequence of the inherent linearization of the V - δL function as stimulus amplitude is decreased. Modeling indicates that the same level dependence characterizes the mechanical harmonic components as well. In the intact, normal organ of Corti, these level-dependent effects will be expressed as auditory threshold is approached; that is, near auditory threshold, mechanically generated distortion will be several orders of magnitude smaller than the fundamental component, given a pure sinusoidal voltage stimulus.

In addition to level-dependent effects, mechanisms which alter the relationship between resting potential (operating point along the V - δL function) and V_h of the V - δL function will also influence the generation of nonlinearities. That is, shifts in either resting potential or V_h will modify the characteristics of mechanical distortion. For a two state Boltzmann process (namely, the V - δL function) which is symmetrical about its midpoint, V_h , the DC mechanical component theoretically will be abolished by superposition of the resting potential and V_h . Nonetheless, harmonic distortion will remain, and under these conditions predominantly odd harmonics will be generated. In the absence of superposition, level-dependent DC, odd and even harmonics are always expected. In the present study, harmonics above the second were probably below the noise floor.

Modeling the mechanism of OHC motility

The similarity between characteristics of OHC nonlinear charge movement (indicative of membrane-bound voltage sensors) and OHC motility has been suggested to indicate that an estimated $4000/\mu\text{m}^2$ membrane-bound voltage sensor-motor elements control OHC length (Santos-Sacchi, 1991, 1992). In the present report, the mechanism responsible for OHC motility was modeled as a modification of membrane surface area due to a two state voltage-dependent conformational change of an intrinsic membrane particle, representing the sensor-motor element. Intrinsic membrane particles, presumably membrane proteins, have been observed in the OHC lateral plasmalemma (Gulley and Reese, 1977; Saito, 1983; Forge, 1991; Kalinec et al., 1992). The density of particles is similar to estimates based on nonlinear charge data.

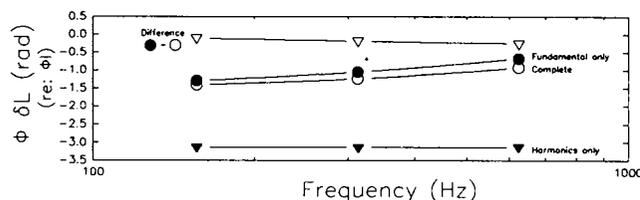

FIGURE 7 Relations between second harmonic mechanical phase data for the three model conditions: complete (fundamental and harmonic voltages, open circles), fundamental voltage only (closed circles), and harmonic voltage only (closed triangles). The difference between fundamental only and complete model (open triangles) essentially removes the reference to current and demonstrates the minimal frequency dependence of the mechanical phase. The remaining slight frequency dependence (increasing lag with frequency) is due to the effects of the mechanical response induced by second harmonic voltage, since this voltage driven response increases in magnitude with frequency, and has a phase lag of -3.12 rad.

Kalinec et al. (1992) have provided evidence that voltage-dependent OHC length changes continue to occur after subplasmalemmal cytoskeletal elements are disrupted with intracellular trypsin. In fact, they report that membrane patches change surface area when hyperpolarized or depolarized—hyperpolarization increases the membrane patch area, while depolarization decreases it. They have suggested that a rearrangement of membrane particles within the plasmalemma induces a change in membrane surface area, and a concomitant change in OHC length. Furthermore, these same investigators (Kalinec et al., 1993) have speculated that tetrameric anion exchangers in the lateral OHC membrane underlie OHC motility. However, according to their model, it is not clear how two-state tetrameric rearrangements of the observed membrane particles within the OHC membrane can account for the one-to-one correspondence between voltage sensor and motor element derived from nonlinear charge movement and motility data (Santos-Sacchi, 1991, 1992; Ashmore, 1992); that is, the reduced number of discrete motor elements (four per element rather than one per element; hence, one quarter the density of membrane particles) might predict results contrary to experimental observations relating nonlinear charge movement and motility.

Dallos et al. (1991a) have presented a model of OHC motility based on a “motor unit” of circumferentially arranged discrete sensor-motor elements which acts in series along the length of the OHC. The model accurately predicts motility data obtained with the partitioning microchamber technique (Dallos et al., 1991b). The motor elements are predicted to be anisotropic, providing a greater displacement in the longitudinal direction than in the radial direction. The putative alignment of the individual motor’s displacement vector ($\sim 20^\circ$) roughly corresponds to an early estimate of the angle of the circumferential filaments described by Holley and Ashmore (1988b). Newer estimates of the filament angle are closer to 9° , although the range is substantial (-55° to 74°) (Holley et al., 1992). It should be noted that recently Iwasa and Chadwick (1992) presented evidence that the active tension within the OHC plasma membrane is likely to be isotropic. Furthermore, they suggested that the presumed motors are not aligned within the plasmalemma.

The simple model developed in the present report is fundamentally isotropic, but evokes anisotropic shape changes in the OHC due to the geometric constraints of the cell architecture (see Results). The modifications in cell surface area are simply governed by changes in particle (protein) conformation and attendant reductions in the area of the particle within the lipid bilayer. The lipid bilayer is assumed to instantaneously occupy the potential void created by the particle’s reduced area; the particle need not be spherical as depicted. It is the simplest model available to fit the whole-cell voltage-clamped OHC, and its usefulness is evident from the similarity between model predictions and data.

Voltage nonlinearities of the OHC

As was demonstrated through modeling, nonlinear voltages will evoke voltage-induced mechanical responses. The de-

gree to which these voltage nonlinearities contribute to the measured mechanical nonlinearities will depend upon their magnitudes. Voltage nonlinearities will arise from several processes known to exist within distinct domains of the OHC plasmalemma. The very process that translates acoustically driven stereociliar movements into OHC receptor currents is nonlinear (Russell et al., 1986; Dallos, 1986). That is, opposite but equal displacements of the hair bundle from the resting position generate asymmetrical conductance changes, resulting in asymmetrical voltage responses. Whereas it is probable that the only channel in the apical membrane of hair cells is the stereociliary transduction channel, a variety of ionic channel types is found in the basolateral membrane, including voltage-dependent K^+ , and Ca^{2+} channels (Santos-Sacchi and Dilger, 1988; Ashmore and Meech, 1986; Nakagawa et al., 1991; Housley and Ashmore, 1992), as well as ligand gated channels (e.g., Housley and Ashmore, 1991). In addition to these nonlinearities, there exists the unique motility-related voltage-dependent capacitance of the OHC (Ashmore, 1989; Santos-Sacchi, 1990, 1992; Iwasa, 1993). Thus, the intrinsically nonlinear receptor potential registered in the OHC cell may be further affected by the nonlinear RC properties of the basolateral membrane.

It would be useful to have an estimate of the contribution of these basolateral membrane nonlinearities to the mechanical response in the *in vivo* state. Because the membrane nonlinearities which can potentially affect OHC motility on a cycle-by-cycle basis² are voltage and time-dependent, hence stimulus level and frequency-dependent, it is possible to rule out specific contributions based on stimulus parameters. That is, considering stimulus frequencies above 200 Hz and sound pressure levels below that required to generate 5-mV Pk AC receptor potentials,³ certain basolateral characteristics can be ignored. This is not an unreasonable approach, since the feedback effects of OHC motility are presumed to be most important at low stimulus magnitudes, where tuning is greatest. In order to evaluate whether a basolateral membrane characteristic can be ignored given these stimulus constraints, the time- and voltage-dependent nature of that characteristic must be considered. It becomes readily apparent, then, that the contribution of many of the basolateral conductances can be ignored in a model analysis at the typical *in vivo* resting potential of -70 mV (Dallos et al. (1982); see Footnote 3 in Santos-Sacchi (1989)). For example, the outward K^+ conductance, which dominates the basolateral membrane conductance, can be ignored because the activation time constant is on the order of tens of milliseconds at potentials near its activation voltage of about -50 mV (Santos-Sacchi and Dilger, 1988; Housley and Ashmore, 1992). The same rea-

² Ligand gated channels typically are slower in their action than voltage or mechanically gated channels, and may be considered to have mainly steady state effects on membrane potential and or V_h . For example, the effects of efferent transmitters on the OHC may produce hyperpolarization (Housley and Ashmore, 1991) or shifts of V_h (Huang and Santos-Sacchi, 1993).

³ A 5-mV Pk response from the OHC is obtained with moderate intensities at the cell’s characteristic frequency (Dallos, Santos-Sacchi and Flock, 1982).

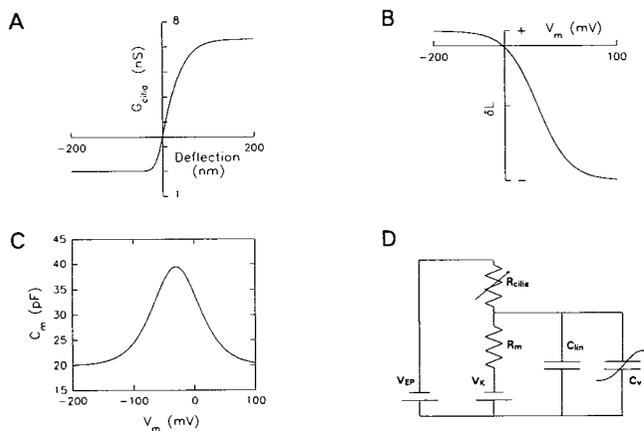

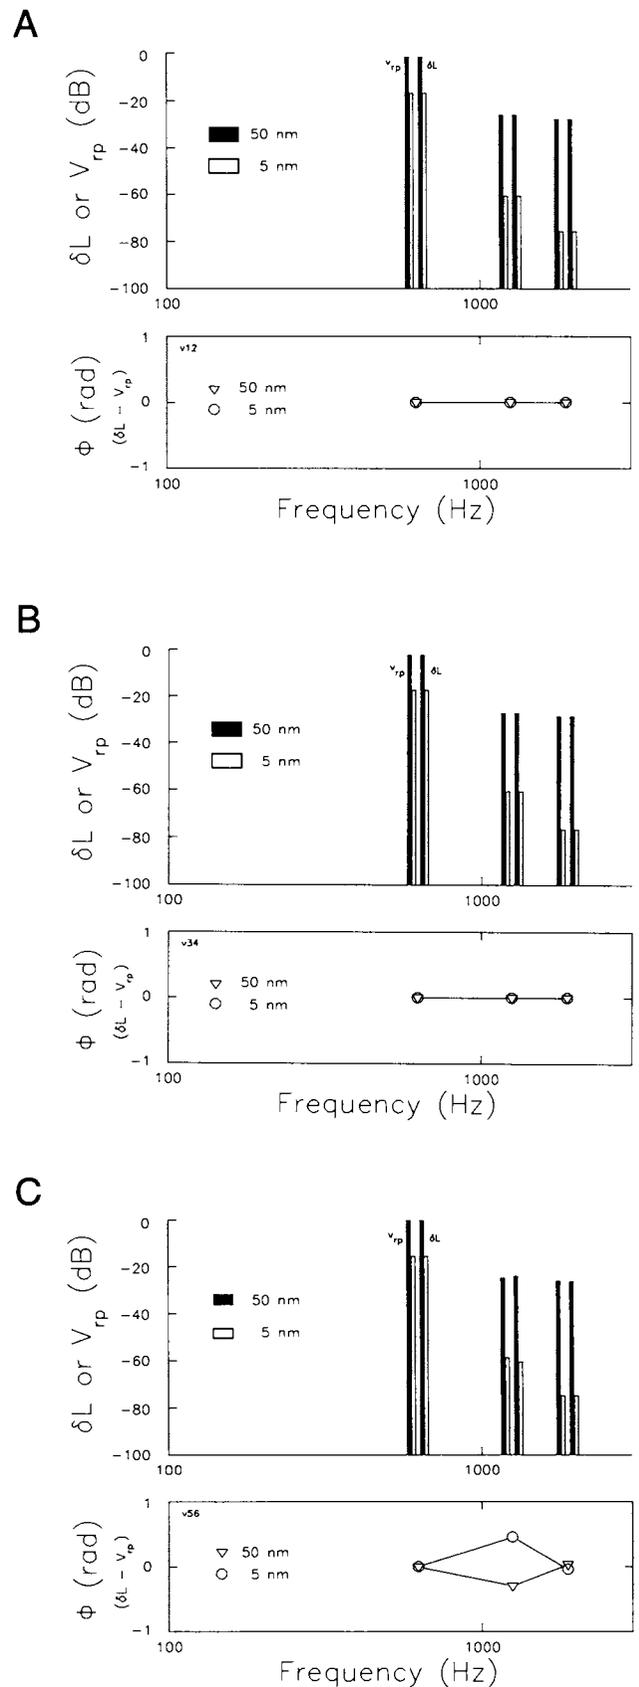

FIGURE 8 Nonlinearities of the in vivo model. (A) Conductance of the apical membrane of the OHC, including transducer conductance (max 5.3 nS) and leakage conductance (2 nS). The form is that observed by Kros et al. (1992). However, the resting conductance is shifted to the right so that about 25% of the transducer conductance is active. Under these conditions the model generates voltage responses which are similar to those obtained in OHCs from the 3rd turn of the guinea pig cochlea (Dallos, 1986). (B) V - δL function with parameters as in Results. (C) Voltage-dependent capacitance function with parameters as in Results. (D) In vivo electrical model. R_{cilia} , resistance of apical OHC membrane whose conductance is depicted in A; R_m , basolateral membrane resistance of 40 M Ω ; V_{ep} , endolymphatic potential of +90 mV; V_k , potassium reversal potential of -90 mV; C_{lin} , linear membrane capacitance of 20 pF; C_v , voltage-dependent membrane capacitance depicted in C. Stimulation of the model is via transducer conductance changes induced by sinusoidal deflection of the stereociliar bundle as in A. Resting potential under these conditions is near -67 mV.

soning holds for the basolateral Ca^{2+} conductance (Santos-Sacchi and Dilger, 1988; Nakagawa et al., 1991). While it is known that a nonlinear leakage conductance remains even after considerable attempts to block the OHC voltage-dependent conductances (Santos-Sacchi, 1991; Huang and Santos-Sacchi, 1993), the slope conductance near resting potential is fairly linear. In fact, Housley and Ashmore (1992), have shown that even with “normal” intra- and extracellular solutions the slope conductance between -50 and -85 mV is nearly constant for a given cell under voltage clamp, although it varies as a function of cell length. Thus, with the given stimulus parameter constraints, it seems acceptable to model the OHC as an electromechanical system comprised of only three nonlinearities—the transducer conductance, the voltage-dependent capacitance, and the V - δL function.

FIGURE 9 (A) Magnitudes and phases of receptor potentials (V_{rp}) and mechanical responses (δL) generated by sinusoidal stereociliar deflections of 5- and 50-nm PK in the in vivo model with only the transducer nonlinearity. A fixed membrane capacitance of 30 pF and a linear V - δL function were employed. Note the generation of fundamental, second, and third harmonics in the voltage and consequently in the mechanical response. Magnitudes (responses were scaled to set fundamentals equal) and phases are the same for voltage and mechanical response. (B) As above, except that the nonlinear capacitance has been introduced. At the voltages generated, little or no effect of the nonlinear capacitance is observed. (C) As above, except that the nonlinear V - δL function is added. Only slight changes in the magnitudes and phases of the harmonics are evident, indicating that the dominant nonlinearity which influences distortion in the mechanical response is due to the transducer function.

The forms of these nonlinearities and the *in vivo* electrical model are displayed in Fig. 8. The form of the transducer conductance of the OHC is that determined by Kros et al. (1992). However, the resting point has been shifted to the right to correspond more closely with *in vivo* measures (Fig. 8 in Dallos (1986)). Fig. 9 *a* presents a comparison between receptor potential (at 625 Hz) and induced mechanical responses when the voltage-dependent capacitance and $V\text{-}\delta L$ function are linearized. It is clear that harmonic distortion (evident as a second and third harmonic) is present in the receptor potential, and that mechanical response distortion simply mirrors this voltage distortion. In Fig. 9 *b*, the nonlinear capacitance is introduced. At the magnitudes of the receptor potential generated by the 50- and 5-nm Pk stereociliar displacements (~ 7 and ~ 1 mV peak-to-peak, respectively), the voltage-dependent capacitance induces minimal additional distortion in the voltages and mechanical responses (compare Figs. 9 *a* and 9 *b*). Finally, when the nonlinear $V\text{-}\delta L$ function is added (Fig. 9 *c*), it is observed that the mechanical response displays only slight differences in the magnitudes and phases of the mechanical response harmonics viz a viz the voltage. It is clear from this modeling effort that the dominant factor contributing to distortion production in the mechanical response *in vivo* will be the transduction process nonlinearity.

Patuzzi et al. (1989) have previously argued that the transducer mechanism nonlinearity of the OHC dominates in the *in vivo* cochlea. While this is in accord with the present modeling effort, it cannot be dismissed that the magnitude and/or effectiveness of the mechanical nonlinearity may be different *in vivo*. For example, it is clear that the position of the $V\text{-}\delta L$ function is not static—it can be shifted along the voltage axis (Santos-Sacchi, 1991; Huang and Santos-Sacchi, 1993; Evans et al., 1991). That is, the operating point can be placed in a more or less linear portion of the function. Clearly, *in vivo* estimates of this nonlinearity are necessary.

SUMMARY

The voltage-induced mechanical properties are believed to provide the means whereby the auditory system enhances its frequency sensitivity and selectivity (Dallos, 1992). Nonlinearity in the peripheral auditory system is believed to be the hallmark of the enhancement mechanism. It is demonstrated here that under voltage clamp, OHC mechanical responses possess nonlinear attributes. The mechanical harmonic components observed are effected by the nonlinear nature of the $V\text{-}\delta L$ function, since through modeling it is shown that the voltage harmonic distortion generated under nonideal voltage clamp of the OHC contributes minimally. While these conclusions hold for the data obtained with large voltage clamp stimuli, modeling efforts indicate that *in vivo*, at moderate sound pressure levels and below, the dominant factor which contributes to nonlinearities of the OHC mechanical response resides within the process that translates stereociliar movement into receptor potentials.

Voltage-dependent Ionic Conductances of Type I Spiral Ganglion Cells from the Guinea Pig Inner Ear

J. Santos-Sacchi

Sections of Otolaryngology and Neurobiology, Yale University School of Medicine, New Haven, Connecticut 06510

Type I spiral ganglion cells provide the afferent innervation to the inner hair cells of the mammalian organ of Corti and project centrally to the cochlear nucleus. While single-unit studies conducted over the past several decades have provided a wealth of information concerning the response characteristics of these neurons and, to some extent, their receptor targets, little is known about the neuron's intrinsic electrical properties. These properties undeniably will contribute to the firing patterns induced by acoustic stimuli. Type I spiral ganglion cell somata from the guinea pig inner ear were acutely isolated and the voltage-dependent conductances were analyzed with the whole-cell voltage clamp. Under conditions that mimic the normal intra- and extracellular ionic environments, type I spiral ganglion cells demonstrate fast inward TTX-sensitive Na currents (whose current density varied markedly among cells) and somewhat more slowly developing outward K currents. Resting potentials averaged -67.3 mV. Under current clamp, no spontaneous spike activity was noted, but short current injections produced graded action potentials with after hyperpolarizations lasting several milliseconds. The nondecaying outward K current activated at potentials near rest and was characterized by a pronounced rectification. The kinetics of the Na and K currents were rapid. Maximum peak inward Na currents occurred within 400 μ sec, between a voltage range of -10 and 0 mV, and inactivated within 4 msec. Recovery from inactivation was also rapid. At a holding potential of -80 mV, the time constant for recovery from an inactivating voltage step to -10 mV was 2.16 msec. Above -50 mV outward K currents reach half-maximal amplitude within 1.5 msec. In addition to these currents, a slow noninactivating TTX-sensitive inward current was observed that was blockable with Cd^{2+} or Gd^{3+} . Problems encountered with blocking the tremendous outward K current hampered the characterization of this inward current. Similarities between the kinetics of ganglion cell currents and some of the rapid temporal characteristics of eighth nerve single-unit activity confirm the notion that intrinsic membrane properties help shape auditory neuron responses to sound.

[Key words: spiral ganglion cell, inner ear, voltage clamp, organ of Corti, eighth nerve, ionic currents]

A tremendous amount of information has been gathered on eighth nerve single-fiber activity (for reviews, see Javel, 1986; Ruggero, 1992), and this information has aided in understanding much of what is known about mammalian inner ear function. The afferent innervation pattern of the organ of Corti provides an anatomical clue to the receptor dichotomy present in this sensory organ (see Dallos, 1988). Nearly all afferent fibers (up to 95%) innervate the inner hair cells; these fibers arise from type I spiral ganglion cells (Spoendlin, 1988). The remaining type II fibers contact outer hair cells. Because of the small number and diameter of type II eighth nerve fibers, the preponderance, if not all, of eighth nerve single-unit studies have necessarily focused upon type I cells. Consequently, early studies on type I units were often used to provide insights into the physiology of the inner hair cell. Subsequent, direct intracellular recordings from inner hair cells have corroborated some single-unit findings; for example, inner hair cells are as finely tuned as eighth nerve fibers (Russell and Sellick, 1978; Dallos et al., 1982). Unfortunately, the interpretation of some single-unit data is difficult because synaptic and neuronal influences are uncharacterized. Few recordings from inner hair cell afferent synapses have been made (Palmer and Russell, 1986; Siegel and Dallos, 1986; Siegel, 1992), and only preliminary information concerning mammalian type I spiral ganglion cell voltage-dependent ionic conductances is available (Santos-Sacchi, 1989a, 1990). I report here on some of the voltage-dependent ionic conductances of type I spiral ganglion cells that may underlie the generation of single-fiber activity.

Materials and Methods

General. Guinea pigs were anesthetized with halothane and killed by cervical dislocation. The temporal bones were removed, and spiral ganglion cells were obtained nonenzymatically by crushing the cochlear modiolus and bony spiral lamina, followed by trituration in nominally calcium-free medium. The supernatant was transferred to a 700 μ l perfusion chamber, and the cells allowed to settle onto a glass coverslip bottom. A modified Leibovitz medium (NaCl, 142.2 mM; KCl, 5.37 mM; $CaCl_2$, 1.25 mM; $MgCl_2$, 1.48 mM; HEPES, 5.0 mM; dextrose, 5.0 mM; pH 7.2) was used as the normal perfusate. Modifications to the extracellular medium are noted in figure captions, with NaCl adjusted to maintain osmolarity (300 mOsm). Extracellular solutions were changed via two methods. A chamber perfusion system was used to exchange fresh medium constantly (0.1 – 1 ml/min). A more rapid and direct pipette perfusion system was used to perfuse selectively single cells under voltage clamp during continuous exchange of bulk medium via chamber perfusion (Santos-Sacchi, 1991a). All experiments were performed at room temperature ($\sim 23^\circ C$). Cell diameter was determined for each cell by averaging three measures at different axes. A Nikon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical recording, and all experiments were taped with a Panasonic AG6300 video recorder.

Electrical recording. Type I spiral ganglion cell somata were whole-cell voltage clamped with a Dagan patch-clamp amplifier typically at holding potentials between -70 and -80 mV, unless otherwise noted.

Pipette solutions were composed of 140 mM KCl or CsCl, 5 or 10 mM EGTA or BAPTA, 2 mM MgCl₂, and 5 mM HEPES buffered to pH 7.2. Cell somata are normally myelinated, but over the course of the *in vitro* incubation the myelin is shed. The type I spiral ganglion cell outnumbered the type II cell by about 20:1, and type I spiral ganglion cells are about 20 μm in diameter while type II cells are about 15 μm. The average cell size in this study was about 19 μm (see Results). Given these facts and the fact that most recorded cells had residual myelin figures associated with the cell somata (only type I are myelinated), it is concluded that most, if not all, of the cells studied were type I.

Gigohm seals were made on the neuronal plasmalemma and electrode capacitance was compensated prior to whole-cell recording. Voltage-step studies were performed with an Axolab 1100 A/D and D/A board (Axon Instruments, Foster City, CA) with associated software (pCLAMP). The software was modified to provide a continuous display of clamp time constant (τ), cell capacitance (C_m), and resistance (R_m), and series resistance (R_s) between data collections. Leakage subtraction was performed with the P/−4 technique at holding potentials noted in figure captions. Currents were filtered with an 8-pole Bessel filter at 7 kHz.

Series resistance and cell capacitance were determined from capacitive transients induced by small voltage steps. The membrane resistance (200–800 MΩ) of spiral ganglion cells is not great enough to permit the use of a simple method (Marty and Neher, 1983) of determining series resistance and membrane capacitance under whole-cell voltage clamp. This problem of estimating series resistance was encountered by Yamaguchi and Ohmori (1990) while studying chick cochlear ganglion cells. The method employed here for these determinations is robust despite filter settings, and accurately takes into account the effects of series resistance on capacitance measures. It is based on the simple circuit model of the voltage-clamped cell, that is, an access resistance (R_s) in series with a parallel combination of a membrane capacitance (C_m) and resistance (R_m).

For the model, the steady state (I_∞) and instantaneous (I₀) current responses to a voltage step are defined as

$$I_{\infty} = \frac{V_c}{R_s + R_m}, \quad (1)$$

$$I_0 = \frac{V_c}{R_s}, \quad (2)$$

with the exponentially decaying capacitive current given as

$$I_{C_m} = (I_0 - I_{\infty})e^{-t/\tau}, \quad (3)$$

where

$$\tau = R_{\parallel} C_m, \quad (4)$$

$$R_{\parallel} = R_m R_s / R_{in}, \quad (5)$$

and

$$R_{in} = R_m + R_s, \quad (6)$$

the input resistance readily obtained at steady state.

The charge moved is then obtained by integration

$$\int_0^{\infty} I_{C_m} dt = Q = \frac{C_m R_m^2 V_c}{R_{in}^2}. \quad (7)$$

Solving for C_m,

$$C_m = \frac{R_{in}^2 Q}{R_m^2 V_c}, \quad (8)$$

and utilizing Equations 4 and 8, we obtain

$$R_s = \frac{R_{in} \tau V_c}{Q R_{in} + \tau V_c}. \quad (9)$$

The time constant (τ) of the exponentially decaying current, and the charge moved (Q) are little affected by filter settings as low as 2 kHz (8-pole Bessel). Equation 8 had been identified and used by Mathias et al. (1981) to evaluate alternative explanations of nonlinear gating charge movement, and it is, in fact, the proper evaluation of cell capacitance for the cell model when the ratio of R_s and R_m does not approach zero. In this article, series resistance was compensated electronically, and voltages were corrected for residual series resistance effects.

Steady state inactivation of Na currents was fit with a Boltzmann

function,

$$I_{\text{relative}} = \left[\frac{I_{\text{max}} - I_{\text{min}}}{1 + \exp[-ze(V - V_h)/kT]} \right] + I_{\text{min}}, \quad (10)$$

where V is the potential of an inactivating prepulse, V_h is voltage at half-maximal inactivation, e is electron charge, k is Boltzmann's constant, T is absolute temperature, z is the valence, I_{max} is maximum Na current induced by a fixed depolarization step, and I_{min} is minimum current.

Results

Type I spiral ganglion cells, including cell somata, are normally enveloped by a myelin sheath. Immediately after isolation by trituration, cell somata remain myelinated; however, over the course of tens of minutes many cells shed this coating (Fig. 1), making the neuronal plasmalemma accessible to patch pipettes. After whole-cell configuration is attained, and following a few minutes to allow equilibration of the normal KCl-containing pipette solution into the cells, resting potentials averaged −67.3 ± 5.7 mV (mean ± SD; n = 11). The capacitance of the cells averaged 10.14 ± 1.68 pF (n = 32) and agreed well with corresponding estimates (11.3 pF) based on surface area calculated from the average cell diameter of 19.01 ± 1.66 μm (n = 59).

Under conditions that mimic the normal intra- and extracellular environments, type I spiral ganglion cells demonstrate fast inward Na currents and more slowly developing outward K currents. Figure 2A illustrates the whole-cell currents under these conditions. Under current clamp, no spontaneous activity was noted, and brief current injections only produced graded spikes (Fig. 2B). Afterhyperpolarizations lasting several milliseconds followed the current induced depolarizations. Longer current injections did not produce repetitive spiking.

The magnitude of the fast inward Na currents varied greatly across cells, some cells demonstrating none. Figure 3 illustrates outward K currents in a cell in which no inward Na currents were evoked from the holding potential of −70 mV (a few cells were found that required holding potentials more negative than −80 mV to reveal Na currents). The outward K currents in spiral ganglion somata are blockable by extracellular tetraethylammonium (TEA), or Gd³⁺, or intracellular Cs (but see below) and display fairly rapid onset kinetics, with little or no inactivation. Raising extracellular K levels above 100 mM reverses the current polarity. Figure 4 illustrates responses from another KCl-loaded cell in which the fast inward Na currents were blocked with TTX. Outward rectification is pronounced and initiates near the resting potential. At −43 mV activation ensues within 360 μsec after step onset (Fig. 4D). The voltage dependence of current onset kinetics was estimated by measuring the time required to reach half-maximal current amplitude (Fig. 4C). Above −50 mV outward currents reach half-maximal amplitude within 1.5 msec.

Reduction of extracellular Ca had profound effects upon the neural membrane; an extreme example, where Ca-free extracellular medium containing 2 mM EGTA was perfused onto the cell, is illustrated in Figure 5A. Removal of Ca caused a reversible reduction of the K currents, a depolarizing shift in the zero current potential (opposite in sign to a potential charge screening effect), and an increase in the leakage conductance. [Armstrong and Miller (1990) showed that voltage-dependent K channels are adversely affected by removal of extracellular Ca, causing the cell to become leaky and the channels to become nonselective. However, they determined that in the presence of 1 mM extracellular K, this effect was absent. In the present

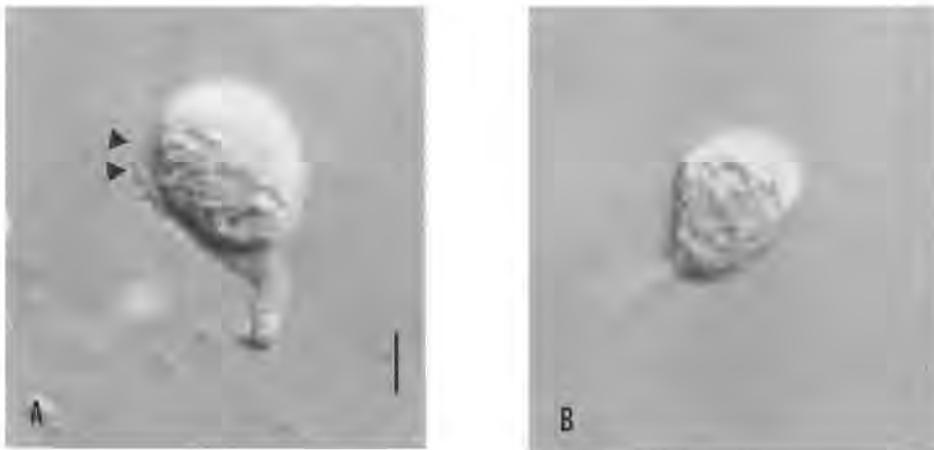

Figure 1. *A*, Spiral ganglion cell immediately after isolation. Myelin sheath can be observed enveloping the somata (arrowheads). *B*, Spiral ganglion cell that has lost its myelin sheath after incubation and whose neuronal plasmalemma is accessible to patch pipettes. Scale bar, 7 μm .

experiments, 5 mM K was present in the extracellular medium, and the type of effect noted by Armstrong and Miller probably does not occur. Indeed, outward rectification is still robust.] Gd^{3+} (50 μM) substantially blocked outward currents in ganglion cells (Fig. 5*B,C*).

Fast inward Na currents were readily isolated when outward currents were blocked, and the Na currents could be totally blocked with TTX (100–300 nM). Figure 6 illustrates the current–voltage relation for a spiral ganglion cell before and during

TTX perfusion. In addition, the fast inward current was abolished by replacement of extracellular Na by Tris or TEA. Maximum peak inward Na currents occurred within 400 μsec , between a voltage range of -10 and 0 mV, and inactivated within 4 msec. Single exponential fits to the decaying Na currents indicate a voltage-dependent inactivation (Fig. 7*A*). Averaged inactivation time constants for a group of spiral ganglion cells ranged from 0.8 msec at -23 mV to 0.3 msec at $+25$ mV. The time required for Na currents to reach half-peak levels was also

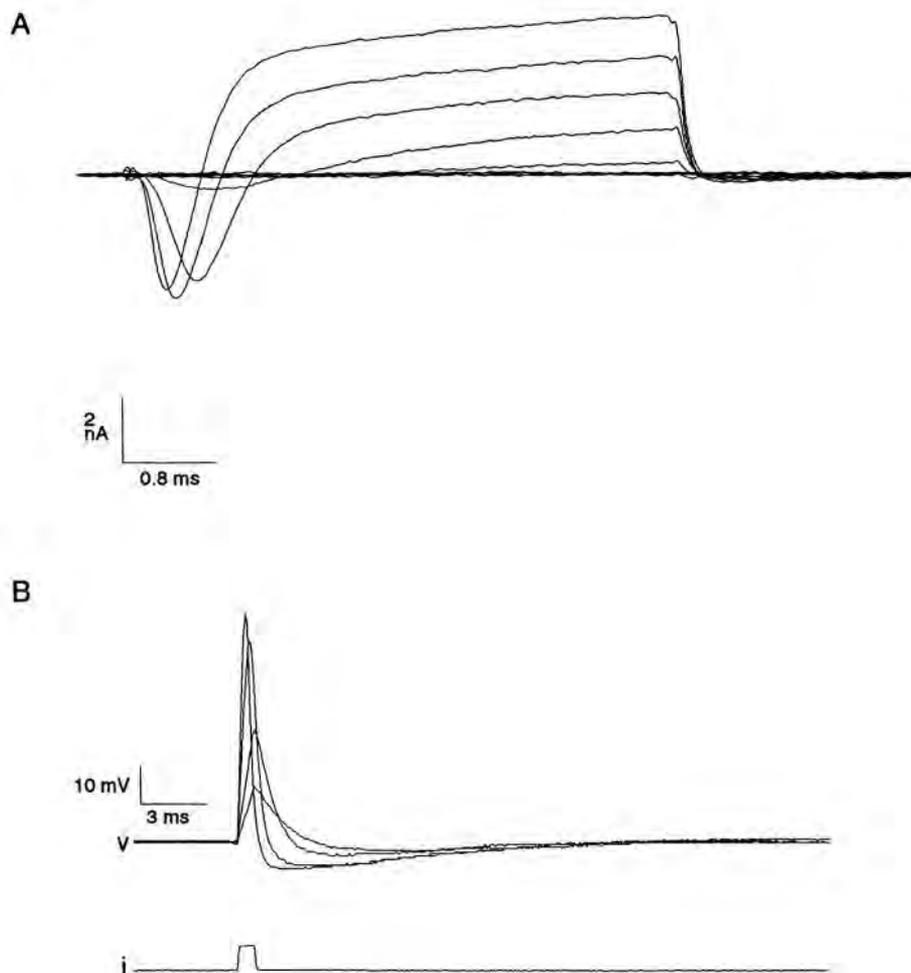

Figure 2. *A*, Isolated spiral ganglion cell under whole-cell voltage clamp. Pipette solution was normal KCl solution. Extracellular solution was modified Leibovitz. Cell was held at -80 mV and nominally stepped in 10 mV increments from -100 mV to -10 mV. Note fast inward Na currents followed by outward K^+ currents. Leakage subtracted. Clamp τ , 69 μsec ; series resistance, 6.1 $\text{M}\Omega$; holding current, -62 pA. *B*, Same cell under current clamp. Current pulse injection (*i*; 0.8 msec at 0.5, 1, 2.5, and 4 nA) initiated a depolarization (*v*) from the resting potential that was graded with step size. Respective times to peak depolarization were 0.72, 0.72, 0.56, and 0.40 msec. Note the increasingly rapid repolarization and afterhyperpolarization as a function of spike amplitude due to the inactivation of Na conductance and activation of K conductance. Membrane potential returned to baseline within about 18 msec. Voltage drop across electrode, based on the instantaneous step in voltage, was subtracted during pulse width. Resting potential was -64.4 mV.

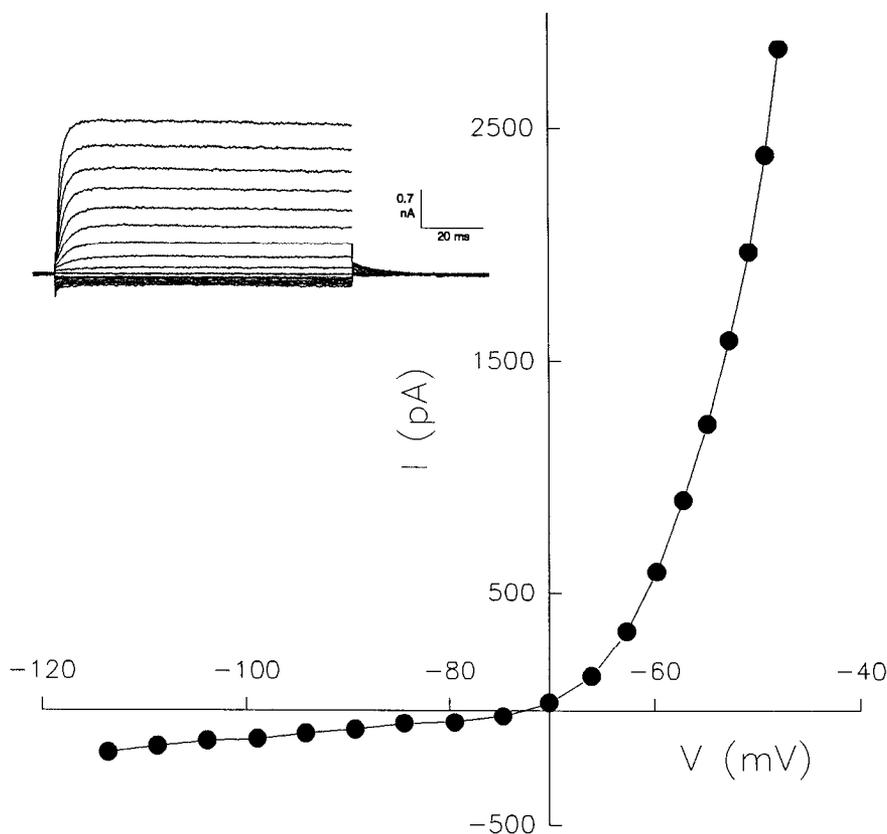

Figure 3. Isolated spiral ganglion cell under whole-cell voltage clamp. Cell was held at -70 mV and nominally stepped in 5 mV increments through the voltage range of -115 to -25 mV. Plotted outward K^+ currents were determined from the final 10 msec average of each trace (inset, upper left). KCl pipette, Leibovitz medium. Na currents were absent in this cell and may have been due partly to steady state inactivation at this holding potential (see Results). No leakage subtraction. Corrected for an uncompensated series resistance of 8 M Ω . Holding current, 37 pA.

voltage dependent (Fig. 7A), decreasing from 0.43 msec at -23 mV to 0.26 msec at $+25$ mV. The recovery of Na channels from inactivation due to a fixed depolarization was evaluated with the two-step protocol (Fig. 7B). At a holding potential of -80 mV, the time constant for recovery from an inactivating voltage step to -10 mV was 2.16 msec.

Figure 8 exemplifies the effects of holding potential on the Na current-voltage relation. Changing the holding potential from -80 to -60 mV inactivates nearly all Na channels. As mentioned, the maximum peak Na currents varied markedly among cells, and this variation conceivably may be related to differing degrees of steady state inactivation at the holding potential of the cells. For example, actual holding potentials may vary from the imposed voltage, depending upon series resistance values. This possibility was examined in cells that were particularly well voltage clamped (Fig. 9A). Despite fine voltage control, Na current densities show great variability. In addition, Figure 9B illustrates that voltage-dependent inactivation curves (h_{inf}) are similar for cells possessing large and small Na current densities. It is likely that current density differences arise from differing Na channel densities.

Another voltage-dependent inward current with slower onset kinetics was observed in CsCl-loaded spiral ganglion cells perfused with Leibovitz solutions, either with or without 10 mM TEA. The current had an activation time constant of several milliseconds, activated at potentials near -70 mV, did not inactivate during sustained depolarizations, and, surprisingly, reversed near -20 mV (Fig. 10). The reversal potential indicates that it is carried by multiple ionic species. Nearly identical $I-V$ curves were obtained with cells perfused with Na-free Tris/ 10 mM TEA solutions or in CsF-loaded cells. It seems likely that the tremendous outward K current was not completely blocked

under these conditions (see Discussion). This sustained inward current and associated tail current are shown in Figure 11 to be somewhat reduced in magnitude by 50 μ M Cd^{2+} and totally blocked by 50 μ M Gd^{3+} . Cobalt (2 mM) in the absence of extracellular Ca^{2+} also abolishes this current. These data provide evidence for a component calcium conductance that is activated near the resting potential. Interestingly, an increased intracellular Ca concentration prolongs the decay of the associated tail currents (which are TEA blockable) and reduced extracellular Ca speeds the decay, possibly indicating that K(Ca) channels may be involved in generating the tail currents.

It was observed that not only did TTX block fast inward Na currents but it reduced the magnitude of the slow inward currents in a reversible manner as well (Fig. 12a,b). The reduction was not due to a decrease in a noninactivating Na current, since replacement of extracellular Na by Tris abolished the fast inward Na current, but did not affect the sustained inward currents (Fig. 12c).

Discussion

Firing patterns and firing rates are considered important aspects of auditory frequency and intensity coding (Ruggero, 1992). The mammalian auditory nerve encodes very high-frequency information. Auditory sensitivity of the guinea pig extends above 40 kHz, and that of the bat above 100 kHz. Indeed, Javel (1986) has commented that within a few milliseconds after the initiation of an acoustic stimulus firing rates can approach 2000 spikes/sec in the cat. Average steady rates have been measured up to about 400 spikes/sec. Necessarily, eighth-nerve fibers must detect and process inner hair cell activity at a tremendous pace to faithfully transmit receptor potential information centrally. In this study, it is demonstrated that type I spiral ganglion cells

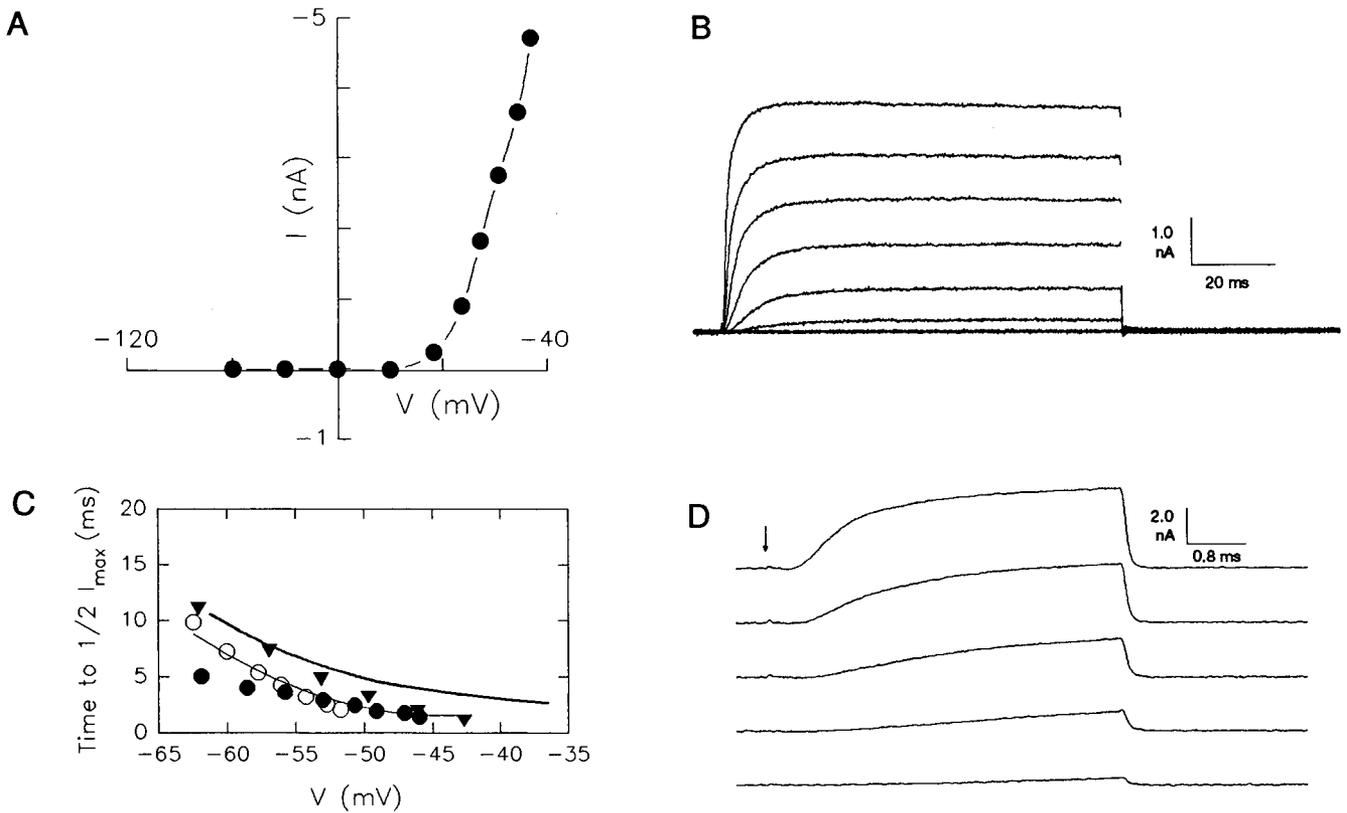

Figure 4. Isolated spiral ganglion cell under whole-cell voltage clamp. Cell was held at -80 mV and nominally stepped in 10 mV increments through the voltage range of -110 to -10 mV. I - V curve (*A*) is corrected for series resistance effects, and plotted outward K^+ currents were determined from the final 10 msec average of each trace (*B*). The times to reach half-maximal K current levels (*C*, plotted against corrected steady state voltage) were obtained from the traces in Figures 3-5 (symbols with thin fitted line). Marked voltage dependence is evident. The thick line represents data obtained from Yamaguchi and Ohmori (1990, their Fig. 3). Data collection at a higher sampling rate (*D*) illustrates delay in onset of outward currents. KCl pipette, Leibovitz medium with 100 nM TTX. Leakage subtraction. Corrected for an uncompensated series resistance of 7 M Ω . Clamp τ , 62 μ sec; holding current, 40 pA.

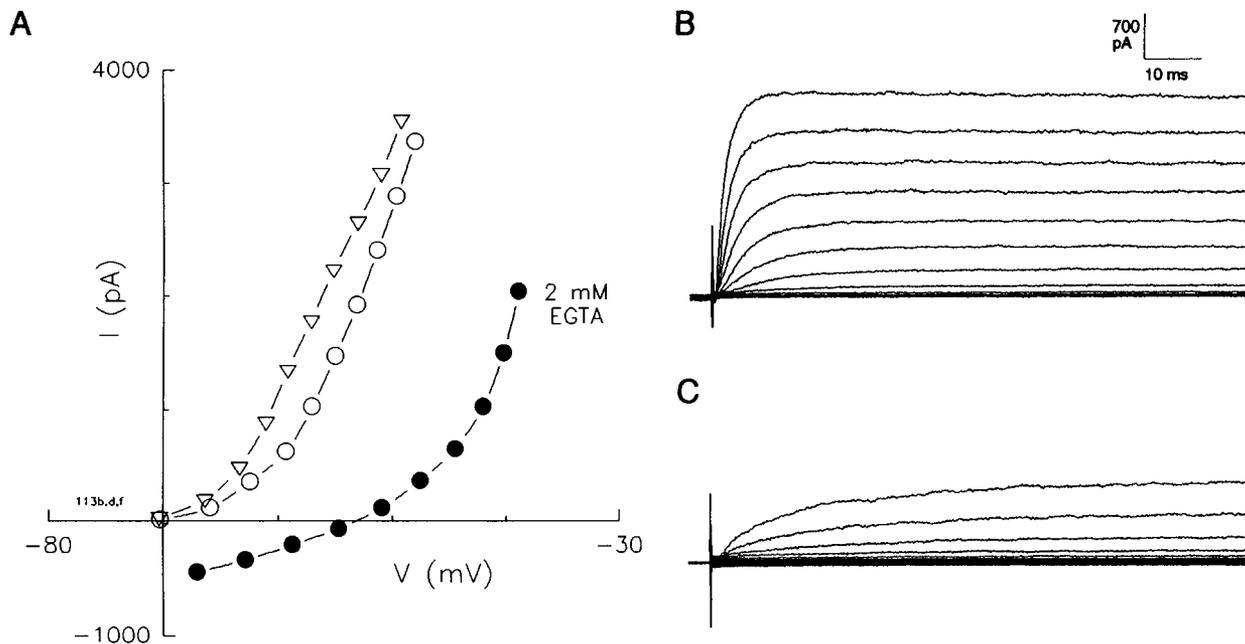

Figure 5. *A*, Isolated spiral ganglion cell under whole-cell voltage clamp. I - V plots of outward K^+ currents were determined before (open circles) and after (triangles) removal of extracellular Ca (solid circles; no added Ca and 2 mM EGTA), at a holding potential of -70 mV. Plotted outward K currents were determined from the final 10 msec average of each 100 msec trace. Note reversible drop in zero current potential and input resistance. No leakage subtraction. Corrected for an uncompensated series resistance of 6.8 M Ω . *B* and *C*, Traces depicting outward K currents in another ganglion cell after recovery from (*B*) and during (*C*) perfusion of normal extracellular medium supplemented with 50 μ M Gd^{3+} . Holding potential was -70 mV, and steps were from -100 to -30 mV (nominal). Holding current: *B*, -81.7 pA; *C*, -66.4 pA.

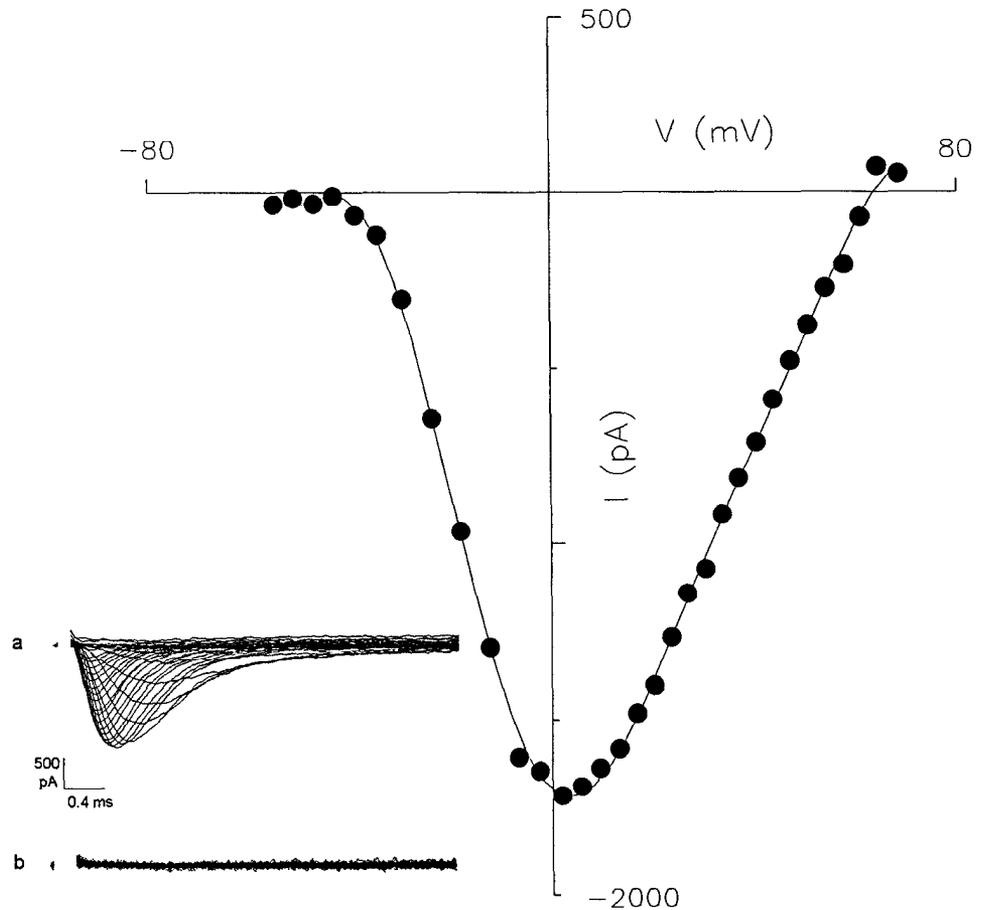

Figure 6. Fast Na currents from a spiral ganglion cell whose outward currents had been blocked. Intracellular solution contained 140 mM CsCl, supplemented with 5 mM NaCl. Extracellular solution contained 20 mM TEA, 20 mM CsCl, 2 CoCl₂, with no added Ca and NaCl appropriately adjusted. Peak inward currents occurred near 0 mV. Leakage subtracted. Corrected for an uncompensated series resistance of 4.98 M Ω ; voltage corrections were made based on nonleakage subtracted peak current magnitudes. Holding current was -43 pA; clamp τ was 29 μ sec. *Insets:* *a*, Na currents prior to block; *b*, block of Na currents by 300 nM TTX. Traces were digitally filtered for presentation at 3.2 kHz.

possess the required conductances and kinetics to account for such high-frequency phenomena.

Resting potential of spiral ganglion cells

Type I spiral ganglion cell somata have resting potentials near -70 mV when loaded with 140 mM KCl. Palmer and Russell (1986) measured membrane potentials in type I afferent terminals in the guinea pig, which ranged from -40 to -60 mV. The activation of K currents near these potentials and the observation that removal of extracellular Ca shifts zero current levels suggest that the resting potential may be maintained partly by a Ca-activated K conductance. The likelihood of the existence of a Ca-activated K conductance is strengthened by the observation of prolongation of TEA-blockable tail currents associated with increased levels of intracellular Ca. Single-channel Ca-activated K currents have been measured in cultured goldfish auditory ganglia (Davis et al., 1989). The effect of calcium removal on the ganglion cell is in marked contrast to the effects of extracellular calcium removal on outer hair cell outward K currents and zero current levels, where little or no effect is seen (Santos-Sacchi, 1989c). However, the block of ganglion cell outward K currents by Gd³⁺ is similar to the trivalent cation's effects on outer hair cells and Deiters cells from the organ of Corti (Santos-Sacchi, 1991a).

Na channels in spiral ganglion cell somata

The bipolar spiral ganglion somata have input resistances around 500 M Ω , and capacitances around 10 pF, giving a membrane

time constant of about 5 msec near -80 mV. This is similar to that observed in chick cochlear ganglion cells (Yamaguchi and Ohmori, 1990). This time constant is fairly slow, and might interfere with spike transmission through ganglion cell somata. Means must exist to permit the unobstructed transmission of spike activity containing timing information across the 20 μ m somata of the eighth-nerve fiber, as temporal coding is important for many aspects of auditory function, including sound localization. If resting potentials are more depolarized than -70 mV *in vivo* (see above), then the activation of the K conductance will dramatically reduce the membrane time constant and increase timing resolution. More notably, Na conductances are present in cell somata, indicating that the somata are excitable. Thus, while Na channels are usually restricted to neuronal nodal regions (Waxman and Ritchie, 1985; Black et al., 1990; Gilley et al., 1990), it is possible that Na channels are normally present in spiral ganglion cell somata and are required for fast throughput with little attenuation. Fast Na currents are also observed in chick cochlear ganglion cells (Yamaguchi and Ohmori, 1990) and acutely isolated cells of the cochlear nucleus (Manis and Marx, 1991).

It cannot be ruled out, however, that cell somata actually have few Na channels, and during isolation cellular processes are retracted into the somata with differing amounts of nodal membrane. The variability of Na channel density in cell somata is great, and differing degrees of nodal resorption may account for it. Another possibility is that Na channels destined for remote sites are incorporated into somata plasmalemma during isola-

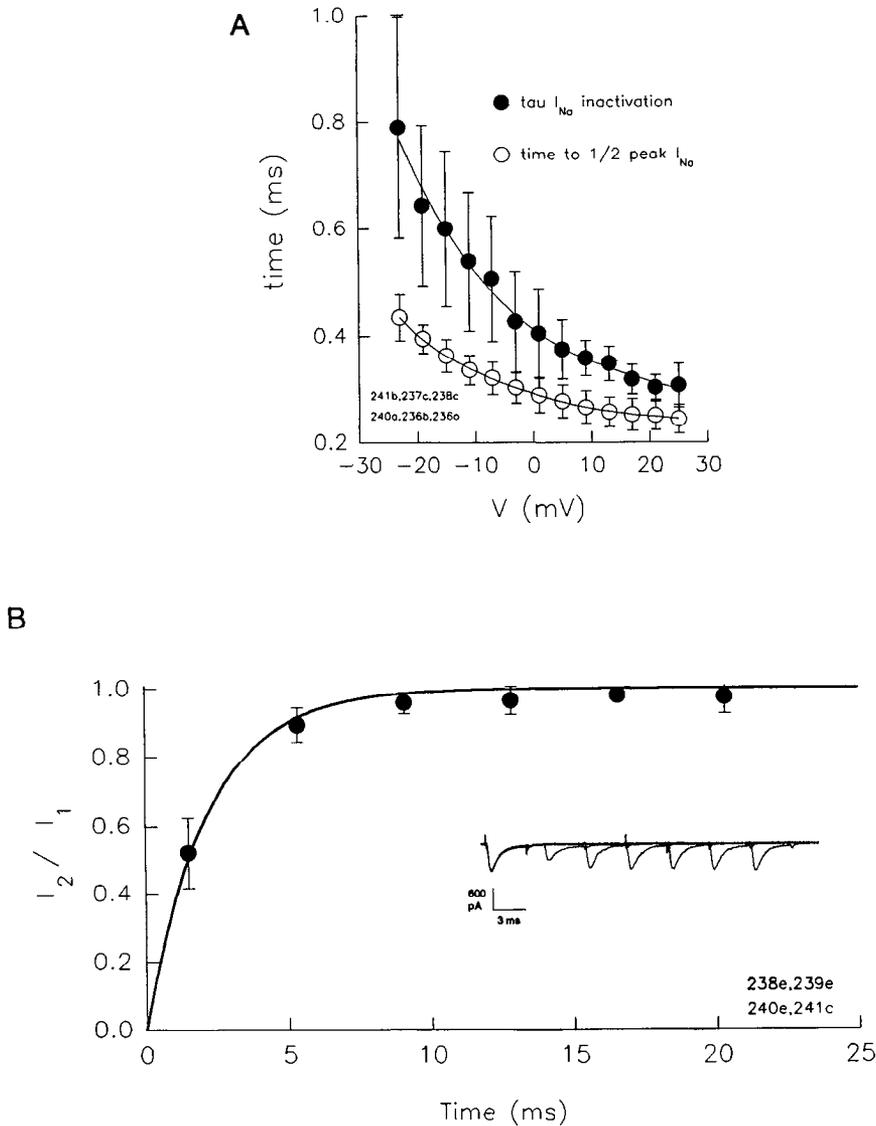

Figure 7. *A*, Averages and standard deviations ($n = 6$) of Na current inactivation (single exponential fit to decaying phase; *filled circles*) and time to half-peak inward Na current (*circles*) versus nominal step voltage. Intracellular solution contained 140 mM CsCl. Extracellular solution contained 20 mM TEA, 20 mM CsCl, 2 CoCl₂, with no added Ca and NaCl appropriately adjusted. Clamp τ was 0.033 ± 0.006 msec. Holding potential was -80 mV. *B*, Recovery of Na currents from inactivation. An initial 3.5 msec voltage step to -10 mV was followed at increasing time intervals by the same stimulus. Peak inward current magnitude evoked by the second pulse is plotted relative to the first response. Rest periods of 4 sec were given between each trial. Average and standard deviations are plotted ($n = 4$). Time constant of recovery was 2.16 msec. Holding potential was -80 mV. Solutions were as in Figure 7*A*. *Inset*, Example of current traces; six trials are superimposed.

tion. Variation in Na channel density may reflect differing degrees of Na channel production in the course of normal turnover, since spiral ganglion cells vary markedly in length.

Is the spiral ganglion cell soma simply another internode?

Because the type I cell soma of the guinea pig spiral ganglion is enveloped by a myelin sheath, one may conceive of it as an internode inserted along the course of the myelinated eighth-nerve fiber. The myelin sheath of the spiral ganglion cell is not characteristic of all mammalian species. For example, in the human there is typically no sheath (Ota and Kimura, 1980) and in the monkey it is very poorly developed (Kimura et al., 1987). In fact, the number of lamellae in those species having sheaths is considerably lower than that surrounding adjacent internodes (Kellerhals et al., 1967; Spöndlin, 1971; Robertson, 1976). These are not trivial observations. That is, since the number of lamellae is inversely proportional to internode capacity and directly proportional to internode resistance, it is not known how a partially myelinated soma (~ 20 μ m in diameter) affects conduction in auditory nerve fibers. Nevertheless, the concept that type I somata function as internodes should be considered

in understanding the ability of the fiber to transmit impulse trains across a potential somal filter. The distribution of ionic channels within mammalian myelinated fibers is not random—specific ionic conductances are restricted to distinct neurolemmal domains (Waxman and Ritchie, 1985). Whereas in mammals nodal regions possess only Na channels, myelinated internodal regions possess voltage-dependent K and possibly Na channels (Chiu and Schwartz, 1987). What effects might the voltage and kinetic characteristics of the spiral ganglion soma conductances have on somal impulse throughput? Indeed, if the conductances are representative of other internodal regions along the eighth-nerve fiber, what general consequences might their characteristics have for auditory neural transmission?

It has been speculated that the K conductance in the internodal region of the mammalian nerve fiber maintains the internodal and nodal resting membrane potential, especially if the conductance is active near rest (Chiu and Ritchie, 1984). The activation potential (near -70 mV) of the spiral ganglion cell K conductance is consistent with this scheme. A consequence of K channel activation near rest is a reduced membrane time constant, that is, a reduction of the filtering capacity of the

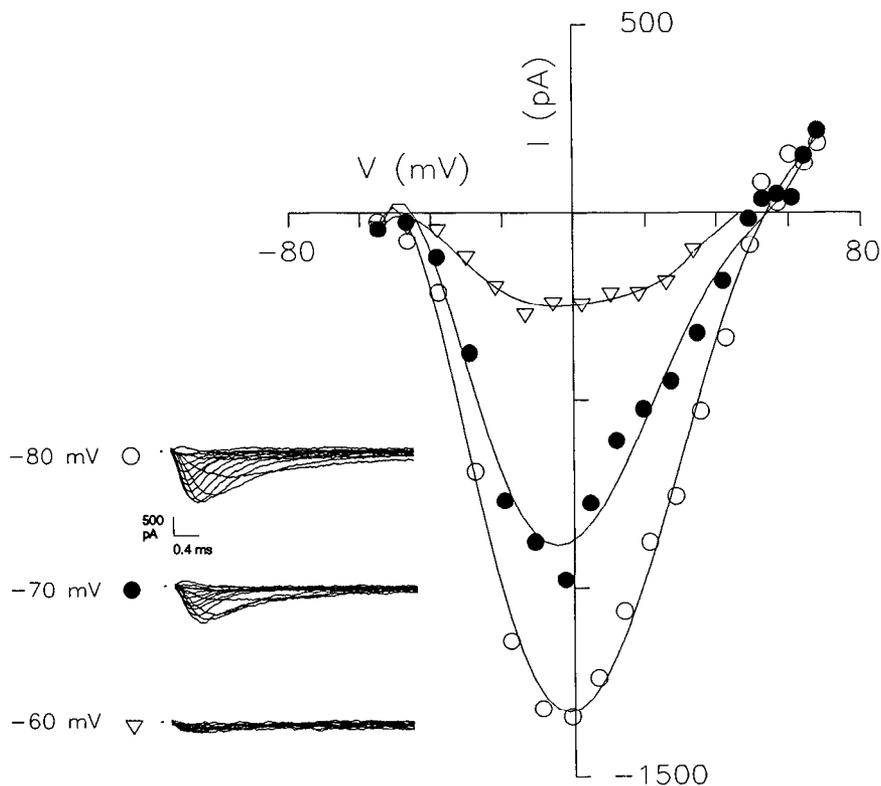

Figure 8. The effect of holding potential on Na current magnitude. Reducing holding potential from -80 mV to -60 mV inactivates nearly all Na channels in spiral ganglion cells. Voltage dependence remains constant. Holding current at -80 mV was -124.5 pA. Corrected for an uncompensated series resistance of 4.79 M Ω . Clamp τ was 0.031 msec. *Inset*, Current traces digitally filtered at 3.2 kHz for presentation.

internode. However, this resting conductance will also limit electrotonic spread between nodes, which is requisite for saltatory conduction.

A more important issue raised by Chiu and Ritchie (1984) is the contribution of internodal K conductances to the repolarization of nodal membrane. Following an action potential, the nodal membrane must repolarize to permit recovery from Na channel inactivation and restoration of excitability. These authors convincingly argue that electrotonic spread of depolarization from nodal to internodal membrane can activate voltage-dependent internodal K conductances that effectively repolarize nodal membrane. The characteristics of this conductance may help limit the duration of action potentials and reduce the possibility of repetitive afterspiking (Baker et al., 1987; Black et al., 1990). Currently, it is thought that discharge of capacitive current through leakage pathways between the myelin sheath and axonal membrane promotes an afterdepolarization following the action potential (Barrett and Barrett, 1982; Baker et al., 1987). This afterdepolarization is believed to promote repetitive spiking, as it will lower spike threshold. In fact, Black et al. (1990) have demonstrated that blockade of internodal K conductances elicits repetitive afterspiking, and David et al. (1992) have shown that action potentials can activate internodal K conductances. By evaluating the myelinated axon model of Barrett and Barrett (1982) it is clear that an increased conductance of internodal axonal membrane will limit the duration of this afterdepolarization. In fact, the more rapidly the conductances are activated, the more quickly the afterdepolarization is dissipated. For fibers that conduct information in the precise timing of action potentials, it is reasonable that K conductances should possess rapid activation kinetics, or else slow repolarization will distort the timing of later signals. In the eighth nerve, fibers are known to phase lock to acoustic frequencies as high as 4 kHz,

indicating that the temporal resolution must be great. Phase locking is known to be important for one mechanism of frequency discrimination (see Javel, 1986). The kinetics of spiral ganglion cell K conductances are faster than those of internodal membrane of rabbit myelinated sciatic nerve fibers, whose firing rates do not approach that of eighth-nerve fibers [e.g., at -25 mV, time to half-peak K current is about 5 msec in the sciatic nerve (Chiu and Ritchie, 1984), whereas at -43 mV the value is 1 msec for the spiral ganglion cell; temperatures are comparable]. The fast recovery of Na channel inactivation in the spiral ganglion cell also indicates that the effects of rapid K channel activation will be registered quickly. It appears, then, that even with the spiral ganglion cell soma viewed as an internode among other internodes, the voltage dependence and kinetics of the intrinsic membrane conductances contribute to the temporal characteristics of auditory nerve performance.

Comparison of spiral ganglion cell kinetics with those of other primary sensory neurons

The kinetics of ionic channels are temperature dependent (Hodgkin and Huxley, 1952; Frankenhaeuser and Moore, 1963). Thus, the results presented in the present report at room temperature ($\sim 23^\circ\text{C}$) should be interpreted accordingly. The temperature dependence of channel kinetics typically has a temperature coefficient (Q_{10}) of about 3 (Frankenhaeuser and Moore, 1963; Huguenard et al., 1991). Measures at higher, *in vivo*, temperatures will be faster by a factor of 3 for each 10°C increase. Keeping temperature effects in mind, it is illuminating to compare the kinetics of Na and K conductances of the guinea pig spiral ganglion cell to comparable results obtained from other mammalian primary sensory systems. In addition, a comparison is made to data obtained from a nonmammalian cochlear ganglion cell, that of the chick (Yamaguchi and Ohmori, 1990).

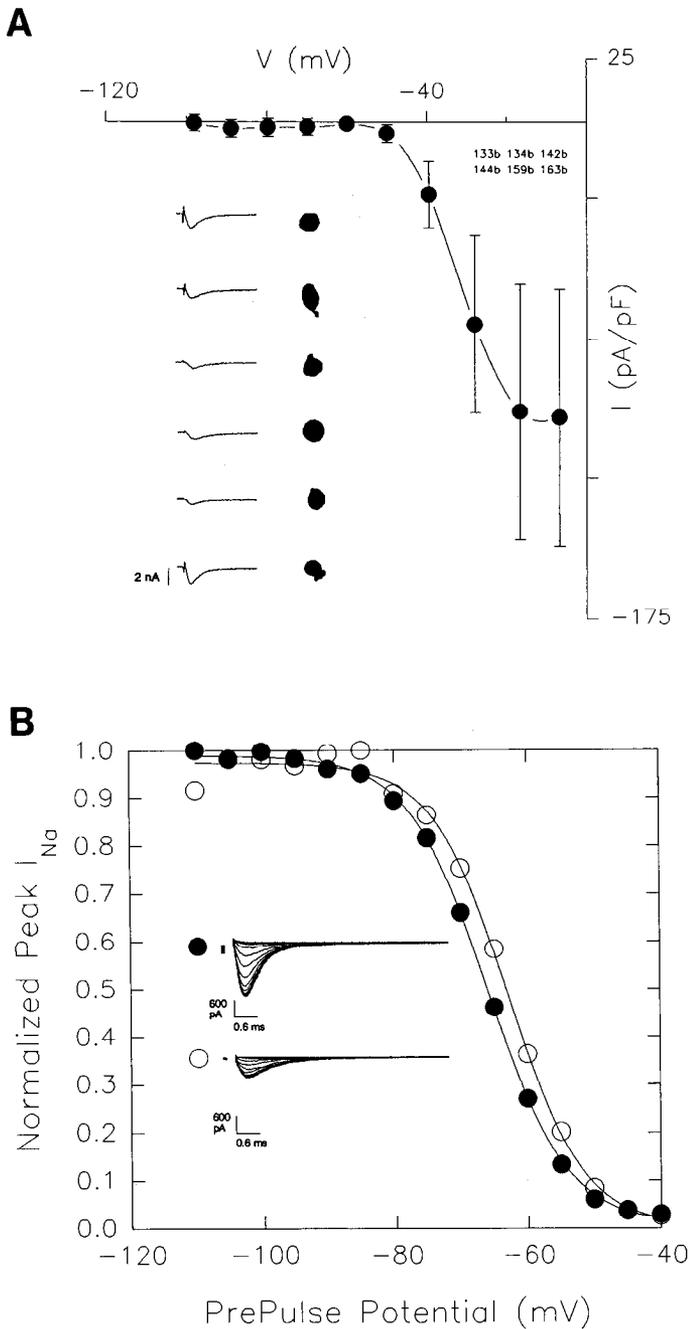

Figure 9. *A*, Variability of Na current magnitudes: averages and standard deviations of Na current densities versus voltage, for a group of cells ($n = 6$) that were particularly well voltage clamped. Intracellular solution contained 140 mM CsCl. Extracellular solution was modified Leibovitz with 10 mM TEA. Corrected for an uncompensated series resistance of $3.69 \pm 1.75 \text{ M}\Omega$; clamp τ , $38.73 \pm 25 \text{ }\mu\text{sec}$; C_m , $11.8 \pm 1.6 \text{ pF}$; R_{in} , $480 \pm 100 \text{ M}\Omega$. Voltage variations are within the symbol widths. Holding potential was -80 mV ; holding current was $-38 \pm 31 \text{ pA}$. *Inset*, Current traces in response to -10 mV steps, and outlines of associated cell somata. Scale is 2 nA or $15 \text{ }\mu\text{m}$. *B*, Steady state inactivation of Na currents. Two cells of high and low current densities are compared. Cells were held at -100 mV and prepulsed to various potentials (nominal) for 200 msec prior to step to -10 mV . Fits were made to a Boltzmann function. Inactivation characteristics are similar for both cells. *Open circles*: z , -4.55 ; V_h , -62.9 mV ; clamp τ , $24 \text{ }\mu\text{sec}$; R_s , $6.76 \text{ M}\Omega$. *Solid circles*: z , -4.34 ; V_h , -66 mV ; clamp τ , $24 \text{ }\mu\text{sec}$; R_s , $3.26 \text{ M}\Omega$. Intracellular solution contained 140 CsCl. Extracellular was modified Leibovitz with 10 mM TEA and 0.1 mM CdCl. *Inset*, Current traces for each cell.

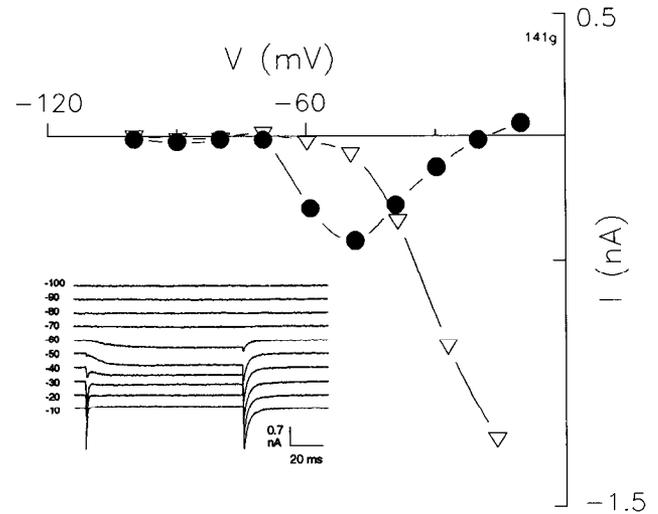

Figure 10. Simultaneous measurement of slow inward current (circles) and fast inward Na current (triangles) of spiral ganglion cell loaded with 140 mM CsCl, and perfused with 10 mM TEA Leibovitz solution. The slow inward current activates at a potential more negative than the Na current. Note the unusual reversal potential of the slow current (-20 mV), indicative of charge being carried by multiple ionic species. Also note the tail currents activated during return to the holding potential. Holding potential was -80 mV for each trace, and the cell was stepped to the potential noted on the left of the traces. Corrected for an uncompensated series resistance of $3.3 \text{ M}\Omega$.

In rat retinal ganglion cells at $\sim 23^\circ\text{C}$, peak Na currents reach half-maximal magnitude in about $500 \text{ }\mu\text{sec}$, and the inactivation time constant at -20 mV , for example, is 1.3 msec (Barres et al., 1989). These values are somewhat slower than those of the spiral ganglion cell (see Fig. 7A). Interestingly, these authors found that the kinetics of glial cells were considerably slower than retinal ganglion cells. While the K currents of spiral ganglion cells reach half-peak amplitude in 1 msec at -43 mV at room temperature, the whole-cell K currents in cat retinal ganglion cells required about 1.5 msec to reach half-peak values at -20 mV at 33°C (Lipton and Tauck, 1987). The time constant of recovery of Na currents from voltage-induced inactivation differs depending upon specific type of rat retinal ganglion cell, being less than or equal to 1 sec for X-cells and greater than 1 sec for W-cells (Kaneda and Kaneko, 1990). The average time constant of recovery for spiral ganglion cells is 2.16 msec .

Lynch and Barry (1991a) found in rat olfactory neurons that the major outward K conductance is a transient type that reaches half-maximal peak values within about 4 msec at $+20 \text{ mV}$ ($\sim 21^\circ\text{C}$). These same authors also found a smaller, more slowly activating K current (Lynch and Barry, 1991b). In a study by Trombley and Westbrook (1991), however, only a noninactivating K current was found that reached half-peak amplitude at 3.75 msec at a step potential of $+40 \text{ mV}$ (room temperature). These same authors measured fast inward Na currents that reached half-maximal peak magnitude at about $160 \text{ }\mu\text{sec}$. This is extremely fast and may indicate that the scale in their figure was mislabeled. In fact, the value is between 400 and $500 \text{ }\mu\text{sec}$ (P. Trombley, personal communication).

To my knowledge, there are no published voltage-clamp data on the conductances of mammalian taste cell primary afferents. However, in rat taste cells, some of which possess fast Na currents, half-maximal peak Na current is reached in about $450 \text{ }\mu\text{sec}$ (room temperature; S. M. Herness, personal communica-

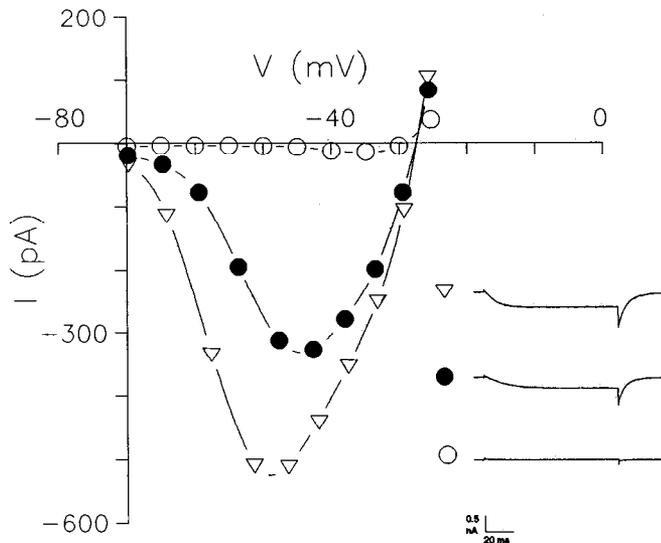

Figure 11. Reduction of slow inward currents by inorganic ions. Triangles and associated trace depict voltage dependence of sustained inward currents. Following perfusion with an additional $50 \mu\text{M Cd}^{2+}$ (solid circles) the current magnitudes were decreased and the peak current shifted in the depolarizing direction. Treatment with Gd^{3+} ($50 \mu\text{M}$; open circles) totally abolishes the inward currents. Cell was perfused with normal Leibovitz medium; note that reversal potential is near -30 mV , and does not change with Cd treatment. Inset. Traces depict current responses to voltage steps at -50 mV (nominal). Corrected for an uncompensated series resistance of $7 \text{ M}\Omega$. Holding potential -80 mV . CsCl pipette.

tion). Interestingly, recovery of Na currents from voltage inactivation is quite slow, having a time constant of about 56 msec. Delayed-rectifier outward K currents reach half-maximal levels at 12.5 msec at 0 mV.

It is clear from comparisons with spiral ganglion cell data that the channel kinetics of the cells from the mammalian visual, olfactory, and taste systems are comparatively slow. Kinetic differences probably relate to the type of stimulus each sensory system is required to detect, and the molecular method of detection (see Hille, 1992).

Yamaguchi and Ohmori (1990) studied the conductances of chick cochlear ganglion cells and observed outward K currents whose voltage dependence (if voltage corrections for series resistance are made for their data) is somewhat similar to the K conductance of the guinea pig. However, at temperatures comparable to that used in the present study, the onset kinetics of the chick's K currents are appreciably slower (see Fig. 4C). For example, voltage steps to levels above -50 mV require about twice as long to reach half-maximal current levels in the chick as compared to the guinea pig. While the extent of frequency sensitivity differs markedly in the guinea pig and the chick, the observed differences in the kinetics of outward K currents between mammalian and nonmammalian species may further reflect differences in maturity of the cells. Yamaguchi and Ohmori obtained ganglion cells from chicks between embryonic days 15 and 19, and it is possible that conductances may not exhibit adult characteristics. For example, Fuchs and Sokolowski (1990) have shown that chick cochlear hair cells do not acquire a Ca-activated K conductance until after embryonic day 19. Thus, beyond species differences, it may be difficult to make direct comparisons between potentially immature cells of the chick and acutely dissociated adult cells of the guinea pig. Neverthe-

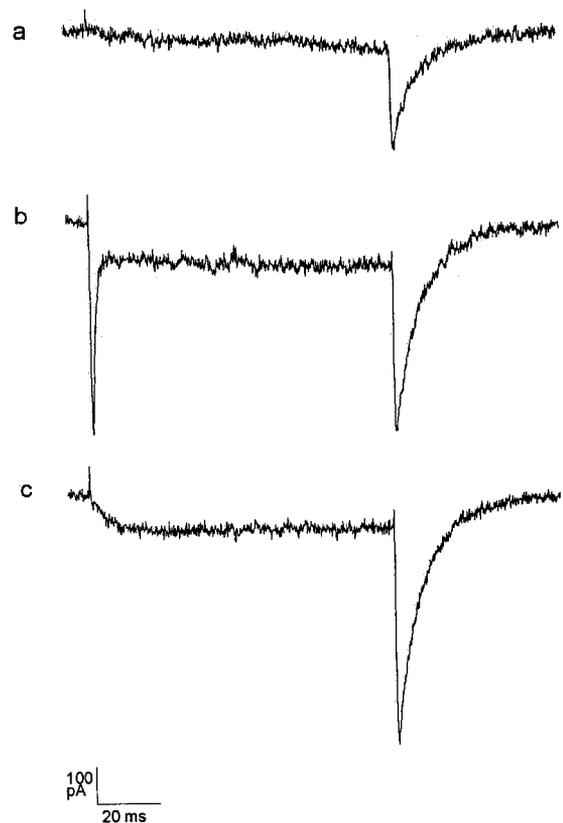

Figure 12. Effect of TTX and Na removal on fast and slow inward currents of a spiral ganglion cell. Cell was held at -80 mV and stepped to -40 mV (nominal). Trace *a* shows response during perfusion of $10 \text{ mM TEA Leibovitz}$ supplemented with 200 nM TTX . Trace *b* shows response with $10 \text{ mM TEA Leibovitz}$. Trace *c* shows response when Tris replaced all external Na. Digitally filtered at 0.1 msec . Note changes in magnitudes of tail currents. R_s , $2.26 \text{ M}\Omega$.

less, some characteristics of the studied currents appear similar, including voltage dependence of Na and K conductances and kinetics of the Na conductance. For example, Yamaguchi and Ohmori found that the time to half-peak Na current ranged from 0.57 to 0.26 msec within the voltage range of -23 to $+13 \text{ mV}$, and the present data ranged from 0.43 to 0.26 msec.

Relevance of spiral ganglion cell conductances to eighth-nerve activity

The electrical properties of auditory neurons help shape their response characteristics (Manis and Marx, 1991; Oertel, 1991). Indeed, the voltage dependence and kinetics of spiral ganglion cells conductances are probably highly influential. The rapidly activating K conductances of guinea pig spiral ganglion cells, occurring near the resting potential, will limit the duration of action potentials, and promote the rapid recovery of Na channels from inactivation, thereby potentially permitting higher average rates, and precise timing—traits that are requisite for auditory coding mechanisms such as phase locking.

Siegel (1992) has recorded spontaneous activity from guinea pig afferent terminals at the base of inner hair cells and speculated that possible relative refractory effects due to rapidly activated K conductances might account for the reduced EPSP size immediately following prior neural activity. [No spontaneous activity was found in isolated ganglion cells. Although spontaneous activity in eighth-nerve fibers can approach 140

spikes/sec in the absence of sound, it is likely that this activity is transmitter activated, since damage to inner hair cells or treatments designed to reduce receptor current decrease or abolish spontaneous activity (Kiang et al., 1976; Sewell, 1984.) Indeed, Siegel found that spike initiation and amplitude were also reduced. Under current clamp, in the present study, the occurrence of graded depolarizing spikes with increasing current pulse magnitude reflects the rapid onset and tremendous magnitude of the outward K currents generated in guinea pig spiral ganglion cells—the effect of Na conductance activation is rapidly curtailed, and afterhyperpolarizations lasting several milliseconds ensue. Clearly, such rapid activation of K conductances is congruent with Siegel's findings.

Investigations of acoustically evoked eighth-nerve adaptation also reveal temporal processes that may directly relate to some of the intrinsic refractory properties of spiral ganglion cells (Westerman and Smith, 1984; Yates et al., 1985; Lutkenhoner and Smith, 1986). Peristimulus time histograms (PSTHs) of eighth-nerve activity typically show a very high probability of spiking within the first few hundred microseconds following the onset of an acoustic stimulus. This is followed by a very short period of inactivity, probably reflecting the nerve's absolute refractory period. Interspike intervals in auditory nerve fibers can be as short as 0.7 msec (Kiang et al., 1965). In the gerbil, Westerman and Smith (1984) found two additional temporal components of activity decline during sustained acoustic stimulation. The rapid component had a time constant of 1–10 msec that was level dependent (decreasing with intensity), and the slower component, which was not level dependent, had a time constant of 60 msec. Similarly, Yates et al. (1985) found two temporal processes in the guinea pig, one ranging from about 2–25 msec that was sound-level dependent and another that had a time course greater than 100 msec. The fast form of adaptation may correspond to relative refractory periods of the spiral ganglion cell, that is, the kinetics of voltage-dependent inactivation and recovery of the Na conductance and K conductance-induced afterhyperpolarization. Another auditory neural phenomenon, forward masking, a paradigm where the response to a second tone is diminished by a prior tone, may also reflect the temporal characteristics of spiral ganglion cell ionic channel activation and inactivation. Harris and Dallos (1979) have shown that for short masking tones (2 msec) complete recovery of firing rate occurs within 20 msec. This process is also level dependent. While it is tempting to make comparisons between these fast level-dependent processes and the voltage-dependent characteristics of Na and K conductances in ganglion cells, the more slowly developing decline in fiber rate probably reflects synaptic events (transmitter rundown, hair cell calcium current kinetics) or discharge history effects (Smith and Brachman, 1982; Lutkenhoner and Smith, 1986; Kidd and Weiss, 1990). For example, it is conceivable that prior neural activity may increase extracellular K, thereby inactivating Na channels through depolarizing effects. Perhaps some of the longer adaptation time constants reflect the time constants of ionic recovery mechanisms, for example, pump activities and K sinking through supporting cells (Santos-Sacchi, 1991b).

Slow inward currents

The slow inward current observed in Cs-loaded cells may partially consist of a Ca component, since Cd^{2+} , Gd^{3+} , and Co^{2+} in the absence of Ca^{2+} are blockers. Gd^{3+} has been shown to block both sustained and transient Ca currents in cerebellar

granule cells (Slesinger and Lansman, 1991) but only transient Ca currents in NG108-15 cells (Docherty, 1988). Nonetheless, the sustained inward current displays many puzzling features, including its voltage dependence and reversal potential. One difficulty encountered in this study was the incomplete block of outward currents by Cs loading, even with the addition of 10 mM TEA extracellularly. While it is known that Cs can permeate Ca channels (Fenwick et al., 1982), and while this may be occurring to some extent in spiral ganglion cells, it appears that the use of Cs does not lead to complete isolation of Ca currents, as it does in some cell types (e.g., Kinnamon et al., 1989; Fuchs et al., 1990). Indeed, Dryer et al. (1991) have documented that Ca currents are not adequately isolated in chick ciliary ganglion cells when using intracellular Cs and extracellular K channel blockers. Ca conductances in the spiral ganglion cell of the guinea pig require further in-depth characterization, utilizing more aggressive current isolation techniques.

It is interesting to note that Wilson et al. (1991) have described a TTX-blockable voltage-dependent inward current in bag cell neurons of *Aplysia* that is activated by venom from *Conus textile*. It is carried mainly by Na, activates near -60 mV, and reverses near zero potential. This current appears to have some similarities with other Ca-activated nonspecific cation currents (Partridge and Swandulla, 1988). Despite the observation that the slow inward current in spiral ganglion cells is not Na dependent, it is noteworthy that it shares some of the characteristics of the bag cell neuron current; namely, it shares a similar TTX sensitivity, activation potential, and reversal potential, which indicates permeation by multiple ionic species.

Summary

It is becoming increasingly clear that the ability of the auditory system to process high-frequency acoustic events reflects the underlying rapid kinetics of the system's constituent cells. Within the sensory epithelium, mechanical events are remarkable. The mechanical transduction mechanism in hair cells utilizes one of the fastest gating processes known (Corey and Hudspeth, 1983), and outer hair cell voltage-dependent mechanical responses are measurable in the kilohertz range (Santos-Sacchi, 1992). The K conductance in inner hair cells is appropriately very rapid in onset (Santos-Sacchi, 1989b; Kros and Crawford, 1990), as are those in cells of the cochlear nucleus (Manis and Marx, 1991). It is no wonder that the observed membrane properties of the spiral ganglion cells that join peripheral receptors to central targets are also fast.

Short review

Cell coupling in Corti's organ

J. Santos-Sacchi *

Surgery (Otolaryngology) and Neurobiology, Yale University School of Medicine, BML 244, 333 Cedar St., New Haven, CT 06510, USA

Abstract

The mammalian organ of Corti is responsible for the initial analysis of sound; injury leads to hearing loss. During the last two decades, the characteristics of cellular coupling in this specialized epithelium have been studied. In this review, data on both electrical and mechanical coupling are covered. While electrical coupling likely contributes to homeostasis in the organ, this concept is far from proven. © 2000 Elsevier Science B.V. All rights reserved.

1. Introduction

The organ of Corti is a specialized, avascular sensory epithelium that rests on the basilar membrane of mammals.

Within this organ, mechanical energy is transduced into electrical activity. A variety of cell types populate the organ along the whole spiral length of the basilar membrane. The cells can be categorized into two major classes — hair cells and supporting cells. In order to appreciate the consequences of cell coupling in the organ, a brief account of our current concept of mammalian peripheral

* Corresponding author. Fax: +1-203-737-2502; e-mail: joseph.santos-sacchi@yale.edu

auditory physiology is presented (for additional information, see Ruggero and Santos-Sacchi [23]).

2. How the organ works

There are two types of auditory hair cells in mammals — inner hair cells (IHCs) and outer hair cells (OHCs). Each cell type generates receptor potentials when its stereociliar bundle is deflected by sound-induced basilar membrane vibration [5,24]. While OHCs outnumber IHCs by about four to one, it is the IHC type that receives up to 95% of the afferent innervation of the eighth nerve [38]. OHCs are mechanical effectors as well as receptors [1], and are capable of voltage-driven length changes in the acoustic frequency range [3,31,33]. Through their mechanical activity, OHCs provide a boost to basilar membrane motion that ultimately results in enhanced sensitivity and frequency selectivity in the output of IHCs. This physiologically labile enhancement has been termed the “cochlear amplifier” [6].

Hair cells are enveloped by supporting cells. IHCs have closely opposed supporting cells that provide a restricted interstitial fluid space. OHCs, on the other hand, lose close appositions with supporting cells during development; in the adult, the OHCs' lateral membranes are exposed to the large fluid spaces of Nuel. However, the supporting Deiters' cells retain close apposition at the apical and basal poles of the OHC.

The mechanism by which hair cells are excited is well characterized (see Pickles and Corey [22]). Bundle deflection modulates a standing cationic current through mechano-sensitive channels located in apical stereocilia tips. The current is predominantly carried by K^+ since the endolymphatic fluid which bathes the bundle is high in potassium (~ 140 mM; Ref. [25]). The driving force for transduction current derives from the voltage drop across the hair cell's apical membrane, i.e., the difference between the positive endolymphatic potential (+80 mV) and the cell's negative resting potential. An accessory epithelium, the stria vascularis, is responsible for the ionic content and potential of the endolymphatic space. The perilymphatic fluid that bathes the basolateral membranes of hair cells is similar to CSF. As a consequence of incessant hair cell and synaptic activity, potassium is continuously released into the extracellular spaces. In the case of the IHC, whose extracellular space is small, even slight increases in potassium may seriously impair hair cell and neural activity. Even though the OHC lateral membrane is exposed to the fluid spaces of Nuel, this membrane lacks voltage-dependent conductances that could contribute to potassium efflux [34]. Instead, voltage-dependent potassium conductances are restricted to the basal pole of the cell — where tight apposition of Deiters' cell cups provide a restricted fluid space with the potential for potassium accumulation. In either hair cell type, potassium-induced

depolarization will interfere with sound transduction since the driving force for transducer current will be reduced. Furthermore, normal transmitter release and afferent activity will be disrupted. In the OHC, however, additionally the mechanism responsible for cellular motility is directly susceptible to membrane potential [35]. Thus, the cochlear amplifier may be compromised.

3. Coupling between supporting cells

In the mid-1970's, a few groups characterized the ultrastructural extent of gap junctional contacts in the organ of Corti [11,12,14]. Based on structure, all supporting cells were found to potentially contribute to a syncytium of coupled cells. In 1983, Santos-Sacchi and Dallos [32] electrophysiologically confirmed that functional coupling was present in the organ of Corti. Using high impedance electrodes, they determined, both *in vitro* and *in vivo*, that current injection into one supporting cell produced voltage drops in adjacent cells (Fig. 1). Subsequently, it was shown that coupling ratios as high as 0.8 occur between adjacent Hensen cells [26]. Supporting cell coupling is sensitive to the effects of intracellular H^+ and Ca^{2+} , temperature, membrane tension and other uncoupling agents, such as octanol [27,28,31,41]. The sensitivity to intracellular pH is greater than that to intracellular calcium; calcium levels in the millimolar range are required to uncouple Hensen cells [36].

Supporting cells, as evidenced through Hensen cell studies, are so well coupled that voltage-dependent ionic conductances are effectively shared among coupled cells [31]. Outward K currents and inward rectifier currents from adjacent coupled cells are measurable under whole cell voltage clamp in one cell of a cell pair or group (Fig. 2). Uncoupling treatments reduce current magnitudes to single cell levels. This recruitment is believed to be important for the maintenance of the stable supporting cell

membrane potentials (~ -100 mV), since uncoupled single cells, which possess few K channels, are depolarized.

Cell coupling in Hensen and Deiters' cells has been studied with input capacitance measures and the double voltage clamp technique [31,36,41]. Because the supporting cells are so well coupled, input capacitance reflects the parallel combination of the coupled cells' capacitance. For example, visually confirmed single cells, pairs and triplets have average input capacitances of 31.0, 64.8 and 104 pF, respectively [41]. Using capacitance measures, junctional conductance was estimated to be nearly three orders of magnitude greater than single Hensen cell resting nonjunctional conductance [33]. Indeed, direct measurement under double voltage clamp provides an average conductance of about 50 nS, with some pairs exhibiting values above 500 nS (Fig. 3; Ref. [41]).

Although it was found in early studies that low temperature and CO₂ reversibly uncouple the supporting cell syncytium, reversible depolarization invariably accompanied such effects [27,28]. The direct effects of depolarization could not be fully evaluated in that type of preparation since neither the voltage nor the activities of H⁺ and Ca²⁺ could be adequately controlled. It is now known that gap junctional conductance in supporting cells is voltage dependent [40,41,43]. In fact, most cell pairs studied with the double voltage clamp technique exhibit transjunctional voltage dependence and/or nonjunctional membrane volt-

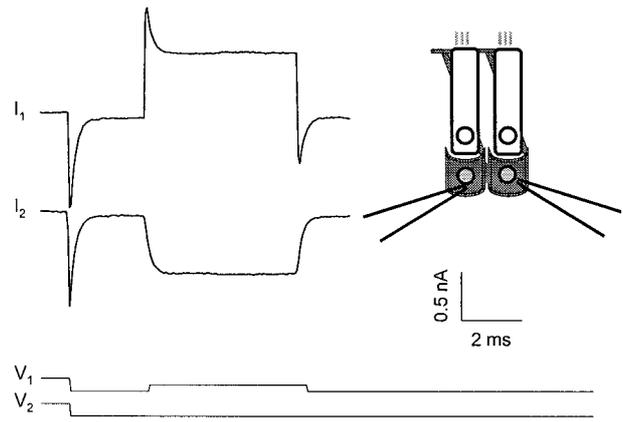

Fig. 3. Double voltage clamp of Deiters' cell pair. Ten millivolts test pulse delivered to cell 1. Junctional currents indicate a conductance, G_j , of about 75 nS. From Ref. [40].

age dependence. This dependence is observable through capacitance measures as well.

One of the most striking features of the voltage dependence in supporting cell pairs is its diversity. Fig. 4 illustrates two cases of Hensen cell pairs where G_j rectifies to opposite polarities as V_j is altered. In fact, cases are also found that exhibit symmetrical V_j dependence or an absence of voltage dependence [43]. Nonjunctional voltage dependence is just as variable. We have speculated that this variability is due to heterotypic or heteromeric junctional channels [43], since a variety of connexin subtypes, including Cx26, Cx30, Cx43, are localized to the organ of Corti [9,17,18]. Such combinatorial effects may give rise to directional intracellular pathways along the supporting cell syncytium.

Initial studies on dye coupling in supporting cells showed little or no spread of intracellularly injected dyes [32]. Subsequently, it was determined that junctional communication in supporting cells is highly sensitive to photoinactivation occurring during real time viewing of fluorescent dye injections. By using low light level viewing technology, it was possible to demonstrate pronounced

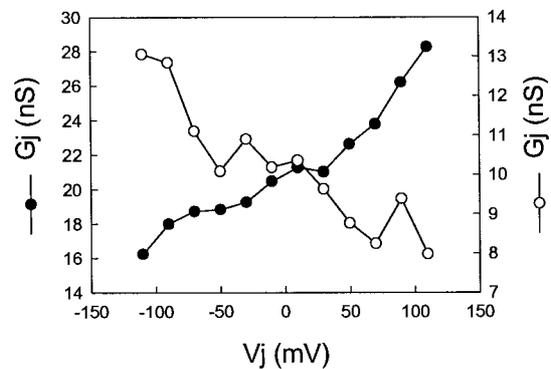

Fig. 4. Double voltage clamp of Hensen cell pairs indicating variability of transjunctional voltage dependence. In one case (open symbols), positive V_j in the voltage-stepped cell, caused a decrease in G_j , whereas in another cell pair (filled symbols) the opposite was found. From Ref. [43].

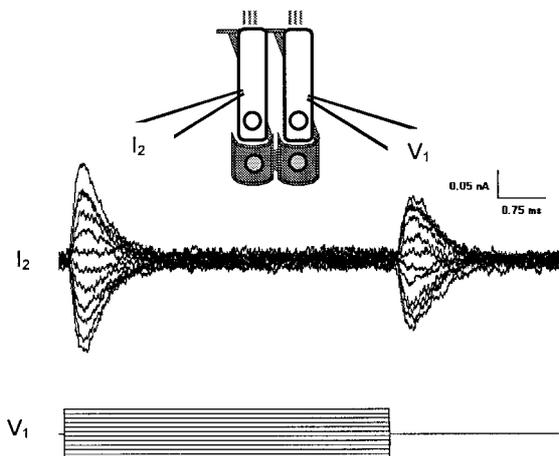

Fig. 5. Double voltage clamp of adjacent OHCs. Voltage steps in one OHC induced transient gating current in the adjacent cell. From Ref. [42].

dye coupling [29]. Recently, very interesting patterns of dye spread have been observed in the living animal, indicating that dye passage may be limited to preferential pathways [19].

4. Coupling between hair cells

In the mammal, there is no morphological evidence for gap junctional communication between hair cells or between supporting cells and hair cells. It is also clear from electrophysiological measures of sound-evoked hair cell activity that coupling is absent *in vivo*. Dallos and Santos-Sacchi [4] found that intracellularly recorded receptor potential cutoff frequencies for IHCs and OHCs were 340 and 1250 Hz, respectively. These equate to time constants of 0.47 and 0.13 ms, respectively. Considering that the membrane resistance obtained *in vivo* for either cell type is greater than 10 M Ω , membrane capacitances can be computed to be roughly in the low tens of picofarad range — single cell values. As we have shown before, a coupled cellular syncytium would be predicted to have much greater input capacitance. Additionally, as expected in the absence of hair cell to supporting cell coupling, receptor potentials in the guinea pig are larger in the hair cells and extracellular fluid spaces of the cochlea than in the supporting cells [2,5,20,21]. Contrary results have been obtained in the gerbil [44].

While gap junction-mediated coupling is absent between hair cells, we have recently found a mechano-electrical coupling between adjacent OHCs [42]. Because of the voltage-dependent mechanical activity of OHCs, voltage drops across the lateral membrane of an OHC will additionally cause deformation of physically adjacent cells. Since the motility voltage sensor in OHCs is sensitive not only to voltage but to membrane tension, gating currents are evoked in the adjacent cell (Fig. 5). The gating currents in adjacent OHCs result from a tension-induced shift in the

voltage dependence of gating charge movement [10,13,15]. Interestingly, the resulting charge-induced transient polarization of the adjacent OHC is opposite in polarity to that of the voltage in the stimulated cell — indicative of lateral inhibition. Furthermore, since the voltage dependence of the charge movement and the mechanical response are equivalent, the mechanical activity of any one OHC is directly influenced by that of its neighbors. We believe that sharpening of the basilar membrane response beyond that of Bekeasy's passive tuning results from this mechanical coupling.

5. What does it all mean?

Cell coupling in the organ of Corti is pronounced and diverse. It is likely that both the mechanical and electrical interactions reviewed here are important for the organ.

As far as gap junction-mediated coupling is concerned, the truth is that we have no direct indications what function it plays. Since the discovery of junctional coupling in the organ of Corti, we have contended that junctional coupling must be crucial for normal cochlear function [26,33]; however, only recently has this been shown. The occurrence of nonsyndromic deafness associated with connexin gene mutations, such as in Cx26, indicates the physiological requirement for these channels [7,8,16,39]. Yet, while we have argued for a role of coupling in K sinking and metabolic cooperation within the organ [27,29,31,41], there is no reason to believe that sensorineural deafness results solely from the disruption of these homeostatic mechanisms. For example, it is possible that the stria vascularis may be an important target [37]. These answers will only be obtained through further *in vivo* analysis of junctional coupling within the cochlea [30].

Functional motor microdomains of the outer hair cell lateral membrane

Received: 8 July 2002 / Accepted: 13 August 2002 / Published online: 6 September 2002
© Springer-Verlag 2002

Abstract The outer hair cell (OHC) of the mammalian inner ear is a highly partitioned neuroepithelial cell whose lateral membrane is devoted to electromotility, a fast mechanical length change owing to the motor protein, prestin. Spatially restricted measures of prestin-derived nonlinear capacitance or gating charge, using either electrical amputation or discrete membrane mechanical deformation, were used to determine that functional variation exists within the extensive lateral membrane of the cell. This was evidenced by variation in the motor's operating voltage range and sensitivity among microdomains within the lateral membrane. That is, localized regions of the membrane evidenced Boltzmann distributions of motor charge whose midpoint voltage and slope differed from those obtained for the whole cell. These data highlight the functional independence of microdomains and imply that measured whole cell characteristics may differ from the microscopic characteristics of elementary motors.

Keywords Motility · Gating charge · Membrane capacitance

Introduction

The outer hair cell (OHC) underlies the mammal's enhanced auditory abilities [5]. It is a cell that is functionally partitioned [10, 23], possessing regions of its plasma membrane that are predominantly devoted to the tasks of forward transduction (apical membrane), reverse transduction (lateral membrane) and neurotransmission (basal membrane). The lateral membrane houses the motors of the OHC, recently identified as prestin [16,

25, 30], which are responsible for the cell's electromotility [4]. The mechanical response of the cell is mirrored by a motor-associated gating charge movement (or nonlinear capacitance) [3, 20]; the voltage dependence of the nonlinear capacitance is the same as that of electromotility [14], allowing the former to be used to assess some aspects of the cell's mechanical activity.

While the OHC lateral membrane harbors an enormous number of identical prestin molecules (approx. $7,500/\mu\text{m}^2$ based on charge estimates [10]), the lateral membrane itself is composed of structural microdomains [15, 28]. This heterogeneity may underlie similar variability in the mechanical activity of the lateral membrane. For example, Kalinec and Kachar [15] observed local variation in the direction that microbeads moved along the surface of the electrically excited OHC. We hypothesize that the direction of forces arising from electrical stimulation of the lateral membrane results not only from cellular structural and mechanical constraints but also from intrinsic motor properties as well. Utilizing techniques to gauge motor characteristics from restricted regions (which we refer to as microdomains) of the OHC lateral membrane, we show that microdomains of molecular motors possess voltage characteristics that differ substantially from those obtained through whole cell measures.

Materials and methods

General preparation

Guinea pigs were overdosed with pentobarbital. The temporal bones were removed and OHCs were isolated from cochleas by gentle pipetting of the isolated top two turns of organ of Corti in Ca-free medium with collagenase (0.3 mg/ml). The cell-enriched supernatant was then transferred to a 700- μl perfusion chamber, and the cells were permitted to settle onto the coverglass bottom. All experiments were performed at room temperature ($\sim 23^\circ\text{C}$). A Nikon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical recording. A modified Lebovitz medium (NaCl, 142.2 mM; KCl, 5.37 mM; CaCl_2 , 1.25 mM; MgCl_2 , 1.48 mM; HEPES, 10 mM; dextrose, 5 mM;

adjusted to pH 7.2 with NaOH, and adjusted to 300 mosmol with dextrose) was used as the standard perfusion solution.

Electrical recordings

Cells were whole cell voltage-clamped with a Dagan 3900 (Dagan Corp., Minnesota) or Axopatch 200B amplifier (Axon Instruments, California). Gigohm seals were obtained at the supranuclear region of the OHC membrane prior to whole cell recording. Pipette solutions were composed of 140 mM CsCl, 10 mM EGTA, 2 mM MgCl₂, and 10 mM HEPES (buffered to pH 7.2 with CsOH, and adjusted to 300 mosmol with dextrose). In order to evaluate nonlinear capacitive gating currents in the absence of confounding ionic currents, the standard perfusion solution was replaced with an ionic blocking solution following seal formation (NaCl, 100 mM; tetraethylammonium, 20 mM; CsCl, 20 mM; CoCl₂, 2 mM; MgCl₂, 1.48 mM; HEPES, 10 mM; dextrose, 5 mM; adjusted to pH 7.2 with NaOH, and adjusted to 300 mosmol with dextrose [10, 20]). Data collection and analysis were performed with a Window's based whole cell voltage-clamp program, jClamp (Scisoft, Connecticut), utilizing a Digidata 1200 board (Axon Instruments). Series resistance effects on membrane voltage were corrected offline. All experiments were video taped.

Whole cell membrane capacitance was measured with two techniques: transient and AC. The former technique entailed the delivery of a stair-step voltage ranging from -160 to 120 mV, in 14 mV increments. Capacitive transients were integrated to obtain cell capacitance (C_m) measures as previously described [10]. The latter technique utilized a continuous high-resolution (2.56 ms sampling) two-sine voltage stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz), with subsequent fast Fourier transform-based admittance analysis [24]. These high frequency sinusoids were superimposed on voltage ramp, step or sinusoidal stimuli. Capacitance data were fitted to the first derivative of a two-state Boltzmann function [20].

$$C_m = Q_{\max} \frac{ze b}{kT(1-b)^2} + C_{\text{lin}} \quad (1)$$

$$b = \exp\left(\frac{-ze(V_m - V_{\text{pkcm}})}{kT}\right)$$

where Q_{\max} is the maximum nonlinear charge moved, V_{pkcm} is voltage at peak capacitance or half-maximal nonlinear charge transfer, V_m is membrane potential, C_{lin} is linear capacitance, z is valence, e is electron charge, k is Boltzmann's constant, and T is absolute temperature.

Two methods to measure motor characteristics in restricted regions of the OHC

A double voltage-clamp technique, fully described elsewhere [10, 23], was used to electrically amputate portions of the OHC membrane. Briefly, the OHC was placed in a tight-fitting glass microchamber and simultaneously whole cell voltage-clamped (see Fig. 1, inset). The voltages within the microchamber were either the same as those delivered to the whole cell or set to ground. When set to ground, the system functions as a simple whole cell voltage clamp, where the entire cell membrane's voltage-dependent activity is evaluated. However, when the microchamber voltage command is the same as that delivered to the whole cell, only that portion of the OHC membrane outside the microchamber experiences a voltage drop, thus permitting the inspection of a restricted region of the OHC. Changing between configurations was performed instantaneously by manually switching the microchamber to ground or to the whole cell command voltage. During these experiments C - V functions were obtained with the transient capacitance measurement technique.

A micropipette aspiration technique was used to stress restricted regions of the OHC lateral membrane, as fully described elsewhere [26]. Briefly, patches of lateral membrane were deformed with a

solution-filled glass pipette (2.5 μm diameter) fitted to a computer controlled piezoelectric driver (PZL, Burleigh Instruments, N.Y., USA). Membrane deformation near the middle of the cell was induced by movements of the driver's piston stepped in the negative direction (producing suction) of about 800 nm, controlled by the voltage magnitude delivered to the piezoelectric. Step stimuli produced motor-evoked currents that were measured as an rms response. Whole cell holding voltage was varied to obtain the current's voltage dependence. The data were fitted to Eq. 1 only to determine the voltage at peak current (V_{pkig}). During these experiments C - V functions were obtained with the AC capacitance measurement technique.

Results

For the double voltage-clamp technique, the nonlinear capacitance measured when the micro-chamber is grounded to the bath derives from all motor containing regions of the cell, since the voltage drop is impressed across the entire membrane of the cell. The capacitance measures are thus typical of whole cell conditions (Fig. 1A) and have characteristics similar to those of past reports [20].

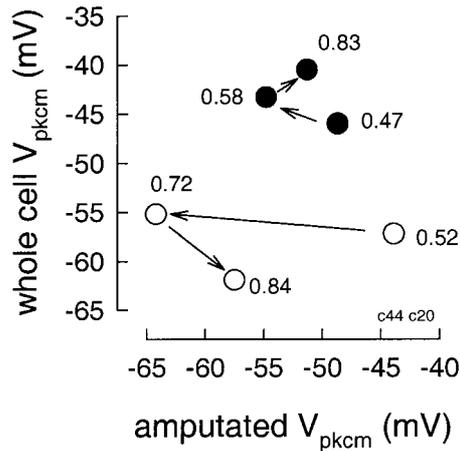

Fig. 2 Same as Fig. 1 except for two OHCs where three successive amputations were made (in the sequence of the *arrows*) following repositioning of the cell in the microchamber. Note that even though V_{pkcm} of the whole cell has shifted following repositioning, the region after amputation does not shift in parallel (neither in magnitude nor polarity), indicating its independence. The numbers indicate the degree of amputation at each measurement

Upon switching to amputation mode, the measured capacitance derives only from that portion of the cell that is outside the microchamber. The magnitude of linear as well as nonlinear capacitance is reduced (Fig. 1A), and there is an apparent shift in the V_{pkcm} to depolarized levels relative to whole cell V_{pkcm} . Figure 1B and C present V_{pkcm} data from ten cells. V_{pkcm} , which is the midpoint of the voltage range over which the motors work, differs between whole cell and the amputated region. The difference may be in the hyperpolarizing or depolarizing direction (Fig. 1B). Additionally, z , an indicator of voltage sensitivity, differs from whole cell estimates and z values can be greater or less than whole cell measures, as expected since they will sum to produce intermediate whole cell values (Fig. 1C). Pre- and post-amputation recordings were made within a few seconds of each other, in order to ensure both stationary conditions and that any experimentally induced forces, such as membrane tension imposed by the microchamber, would remain constant under each condition. Accordingly, the correlation between absolute ΔV_{pkcm} and degree of amputation was poor ($r^2=0.015$).

For the data just presented, the OHCs were inserted into the microchamber and remained unperturbed during the collection of pre- and post-amputation data. However, it is possible to reposition the OHC within the microchamber to obtain progressive amputations. In two cells where three successive amputations of differing magnitude were made, it was clear that whole cell V_{pkcm} changed during the repositioning (possibly due to changes in membrane tension or intracellular chloride), but that of the amputated portion tracked neither the amplitude nor the polarity of those changes (Fig. 2). For example, in one cell the initial pair of values (whole cell vs amputation) was -57.2 , -43.9 mV; after repositioning for the next

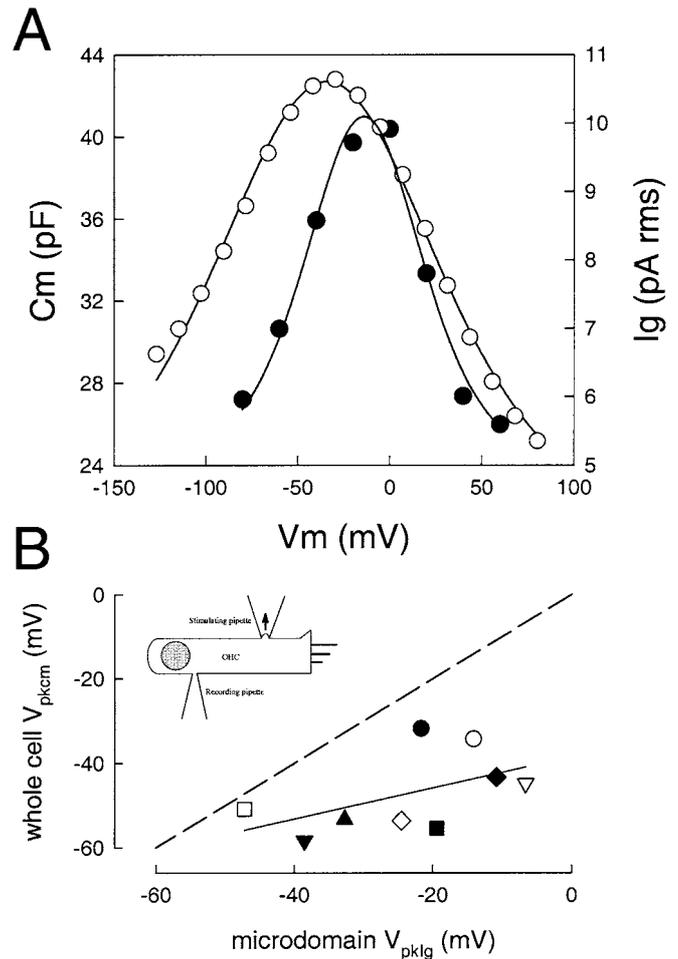

Fig. 3 **A** Whole cell capacitance (*open circles*) and microdomain stretch-induced gating currents. Note difference in voltage at peak response. **B** Comparison of voltage at peak response for 9 cells. *Dashed diagonal line* indicates equality. *Solid line* is linear fit to data. Note wide variability of V_{pkig} relative to V_{pkcm}

amputation the pair was -55.2 , -64.2 mV; and after repositioning for the final amputation, the pair was -61.9 , -57.5 mV. This is very strong evidence for the independent nature of OHC motor domains.

Mechanical stress of the lateral plasma membrane evokes a motor-generated displacement current (I_g) whose voltage dependence is bell-shaped like that of the cell's nonlinear capacitance (Fig. 3A). V_{pkig} is expected to be shifted to the right (in the depolarizing direction) of V_{pkcm} , since membrane stress shifts the underlying charge-voltage ($Q-V$) function to the right. That is, the evoked $I-V$ function results from the difference between the shifted $Q-V$ functions under the stressed and nonstressed conditions [9,29]. Figure 3B shows for nine cells that this expectation is met, as the data points fall to the right of the plot's dashed line of equivalence. However, the V_{pkig} of individually stressed microdomains varies widely relative to their respective whole cell V_{pkcm} . If the V_{pkcm} of the microdomains were the same as whole cell values then the two should be strictly correlated as V_{pkig} is

predicted to be midway between pre- and post-tension V_{pkcm} . Additionally, the variability is not due to differences in the degree of shift caused by the stimulus, since the correlation between peak I_g and shift magnitude was poor ($r^2 = 0.05$). This same poor correlation also indicates that any possible variability of d.c. tension introduced by sealing the loose pipette to the membrane was not influential, since we have previously shown that steady-state tension is directly related to the magnitude of I_g [26]. If steady-state membrane tension were responsible for the variability in the shift, we might have expected a good correlation between I_g and shift. The simplest explanation is that such wide variability reflects an underlying V_{pkcm} of the stressed microdomains that differs from that of the whole cell.

Discussion

The data presented here indicate that the mechanically active lateral membrane is functionally heterogeneous, showing variability in the voltage dependence of nonlinear capacitance or motor charge movement. The gain of the OHC's electrically evoked mechanical response depends on the position of its sigmoidal displacement voltage (or corresponding bell-shaped capacitance voltage) function along the voltage axis vis-à-vis the cell's resting potential [19]. V_{pkcm} , which defines the midpoint of these functions, and therefore the OHC's voltage of maximum piezoelectric-like sensitivity, is susceptible to a variety of agents including membrane tension [9, 12, 14], resting membrane potential [24], temperature [21], phosphorylation [8, 11] and intracellular [18, 22] or extracellular [22] chloride concentration. In many cases, it has been demonstrated that these effects arise from direct action on the OHC motor protein, prestin [16, 17, 18, 25]. It should be noted that efforts were made to avoid experimentally induced changes in the parameters that describe OHC charge movement; for example, measurements of whole cell V_{pkcm} and microdomain V_{pkcm} or V_{pkig} were obtained without perturbation of the preparation and within seconds of each other, thus ensuring stationary conditions. Additionally, unequivocal evidence of microdomain independence was found when multiple amputations were made; that is, in the face of whole cell V_{pkcm} changes during repositioning cells within the microchamber, nonparallel changes (in magnitude and polarity) of microdomain V_{pkcm} were found. This could not occur if the forces that changed whole cell measures during repositioning, e.g., membrane tension or chloride concentration, were acting on a uniform population of lateral membrane motors. We conclude that while molecular sensor/motors are restricted to the expansive lateral plasma membrane, this membrane actually harbors populations of sensor/motor microdomains whose characteristics are set by local forces. Independent microdomain characteristics sum to contribute to whole cell characterizations of OHC mechanical and electrical activity.

The existence of functionally distinct microdomains, whose voltage- and tension-dependent characteristics are locally set, may have important consequences for understanding the mechanism of OHC motility. Such diversity could promote differential activation of OHC motor elements resulting in mechanical forces other than in a predominantly axial direction. For example, at a given resting membrane potential, adjacent microdomains may be contracted to different extents because mechanical gains may be different; bending or twisting movements of the OHC might be expected. Indeed, Frolenkov et al. [7] have observed bending of the OHC in an external field, but provided an explanation based on differential stimulus distributions. Whether the causes of those nonaxial motions were due to motor or stimulus characteristics is arguable; however, the likelihood that even in the face of uniform lateral membrane stimulation nonaxial forces will be evoked is strengthened by evidence from these same authors who showed lateral membrane substructure and function [15]. In addition to observing local variation in the direction that microbeads moved on the surface of the OHC, they showed by freeze etch electron microscopy that the lateral membrane presented a mosaic of microdomains with differing orientations. The mechanism that produces this mosaic is unknown, but it is possible that forces derived from the variable motor characteristics that we observed result in structural correlates. It is well known that extrinsic, local membrane forces can initiate substantial rearrangement of membrane and submembrane structure over extended time periods [27]. Alternatively, the structural differences themselves could affect motor characteristics, for example, by inducing local membrane tensions.

Our data may also relate to theories on OHC motor function, since until now it has been tacitly assumed that elementary characteristics derived from whole cell measures of motility and/or gating charge apply to all motors in the lateral membrane. Under this assumption, it has been difficult to explain the observation that a decrease in membrane tension under whole cell conditions causes a negative shift in V_{pkcm} accompanied by an increase in peak C_m [9, 14]. It has been argued that changes in peak C_m arise from membrane tension working through an anisotropic cytoskeleton or working on an anisotropic motor [9, 13]; indeed, isolated patch recordings, where tension can be applied isotropically, show only a shift in V_{pkcm} [9, 16]. Nevertheless, even in OHCs that have become spherical due to intracellular trypsin treatment, and where applied tension should be isotropic, peak C_m is altered by turgor pressure [1, 14]. We noted that motor sensitivity to membrane stress appeared greater after cortical cytoskeleton destruction with trypsin [14]. Adachi and Iwasa [1] quantified this sensitivity change by degree of V_{pkcm} shift, and found that sensitivity was about six times greater than normal, i.e., 155 mV/kPa compared to normal whole cell values of 25 mV/kPa [2, 14], which may account for their observed step-like C_m decrease [1]. Our present data may provide an alternative explanation for the effects of stress on the whole cell as opposed to

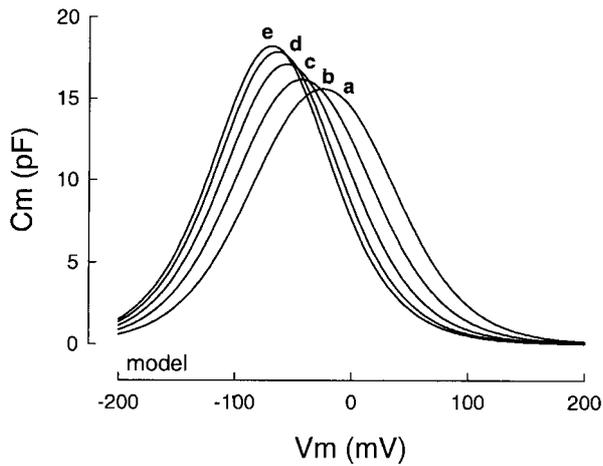

Fig. 4 Model of microdomain contributions to whole cell capacitance. In the model, each of 10 hypothetical microdomains experiences local tensions such that each V_{pkcm} is shifted 10 mV offset from each other, all of them to the right of -70 mV. The sum of these individual capacitances produces the whole cell capacitance trace *a*, and the other four traces are the result of graded decreases in tension under whole cell conditions. When tension is reduced, each microdomain V_{pkcm} shifts left towards -70 mV, the limiting V_{pkcm} [14]. As each microdomain tension is dissipated, its V_{pkcm} halts at -70 mV, and accumulates with other microdomain V_{pkcm} s producing larger peak whole cell capacitances (traces *b–d*). When all microdomain tensions are dissipated, all V_{pkcm} s reside at -70 mV and the peak capacitance is maximal (trace *e*). Q_{max} (0.25 pC) and z (0.75) were fixed and the same for each microdomain

patch nonlinear capacitance. First, we note that the negative shift of V_{pkcm} and increase in peak C_m during reduction of turgor pressure is asymptotic, each reaching fixed values when the OHC begins to collapse, despite continued reduction of turgor pressure [14]. The limiting negative potential is near -70 mV, close to the OHC's normal resting potential [6]. Because of this brick-wall effect, we suggest that microdomains that may have unchanging peak capacitance but variable V_{pkcm} will all shift to a single common V_{pkcm} as turgor pressure is reduced. As a result, at positive turgor pressure peak C_m will be depressed compared to negative pressure, but with increasingly negative pressures peak C_m will increase asymptotically as summation of the parallel microdomain capacitances occurs (Fig. 4). In this model we used a constant z of 0.66 across microdomains, yet fits of these model data to a single Boltzmann function indicate that apparent z is less than 0.66 initially, but increases to this level as turgor pressure is reduced. We have observed this behavior experimentally [14]. Nevertheless, the present observation that V_{pkcm} and z of microdomains are variable about whole cell values (Fig. 1 c) emphasizes that other forces besides tension influence the distribution of these parameters. Consequently, tension-induced changes in the form of the whole cell capacitance function may not necessarily provide insight into the microscopic characteristics of motor function. Spatially restricted patch capacitance measures, on the other hand, may provide a better sampling of microdomain characteristics.

New tunes from Corti's organ: the outer hair cell boogie rules

Joseph Santos-Sacchi

The amplification of acoustic stimuli is a feature of hair cells that evolved early on in vertebrates. Though standard stereocilia mechanisms to promote such amplification may persist in the mammal, an additional mechanism evolved to enhance high frequency sensation. Only in mammals, a special cell type, the outer hair cell, arose that possesses a remarkably fast somatic mechanical response, which probably endows the passive cochlea with a boost in sensitivity by a factor of 100 (40 dB), at least. Experiments conducted over the past few years have shed light on many aspects of outer hair cell electromotility, including the molecular identification of the motor, the effects of a knockout, and underlying mechanisms of action. A review of this remarkable progress is attempted.

Introduction

The organ of Corti, the auditory sensory epithelium of the mammal, houses two types of hair cells, the inner (IHC) and outer (OHC) hair cell. Both cell types transduce mechanical stimuli into electrical signals by modulating a standing cationic current in response to stereocilia displacement (forward transduction). This current induces a receptor potential across the basolateral membrane of the cell, the depolarizing phase of which may promote the release of neurotransmitter [1,2]. Evidence accumulated that an interaction between OHCs and IHCs promoted the highly selective and sensitive responses of the mammalian auditory system to high frequency acoustic stimulation [3–5]. However, a potential mechanism for such an interaction remained obscure until Brownell [6]

observed the twitching of outer hair cells in response to electrical stimulation. Following his discovery of reverse transduction [6], a re-evaluation of the classical concepts of mammalian hearing has been underway. Current theories that are concerned with the basis of the cochlear amplifier envision an acoustically evoked cycle by cycle feedback process between the OHCs and the basilar membrane (BM) [7–10]. That is, *in vivo*, the acoustically evoked electrical responses of the OHCs (receptor potentials) are assumed to effect rapid mechanical responses (length changes) by these cells, which boost the mechanical input to the IHC — the receptor cell that receives up to 95% of the afferent innervation [11].

Just three years ago, Dallos and colleagues identified the OHC lateral membrane motor, a protein of 744 amino acid residues that they called prestin, its primary structure classifying it as one of the newer anion transporter family members (SLC26A5) [12]. Subsequently, a flurry of manuscripts have appeared (most of which are review articles! — mea culpa) attesting to prestin's significant role in cochlear physiology. So many questions remain regarding the protein's workings; however, the recent production of a prestin knockout and the demonstration of a human non-syndromic deafness that is linked to a prestin mutation demonstrate the protein's requirement for OHC electromotility, and the devastating effects of its absence on the cochlea amplifier [13^{••},14[•]]. The knockout work also raised several more questions, including what proportional contribution does the cellular collection of motors make to the overall cochlea amplifier, and what other cellular and acellular structures direct its force into the organ? For example, in homozygotes, in which prestin was absent, threshold elevations ranged from 40 to 60 dB, but in heterozygotes, roughly a halving of the cellular motor number and activity (3.4 versus 2.3% cell length change) resulted in an apparent proportional (around 6 dB) decline in auditory performance. How might half the motor complement in the OHCs provide only for linear response (e.g. 8th nerve spike rate, BM displacement) growth near threshold, yet the full complement promote non-linear amplificatory growth above that? There are hints in the data that something more than a reduction in the motor number may be occurring. For example, the voltage-displacement function, which can be derived from their figure 3a [13^{••}], seems to show, in addition to the decrease in magnitude, a change in the voltage dependence between wild type and heterozygote. Such a shift denotes an adjustment in the gain of the remaining motor activity, that is, an alteration in the sensitivity of the remaining motors to voltage change. Additionally, could

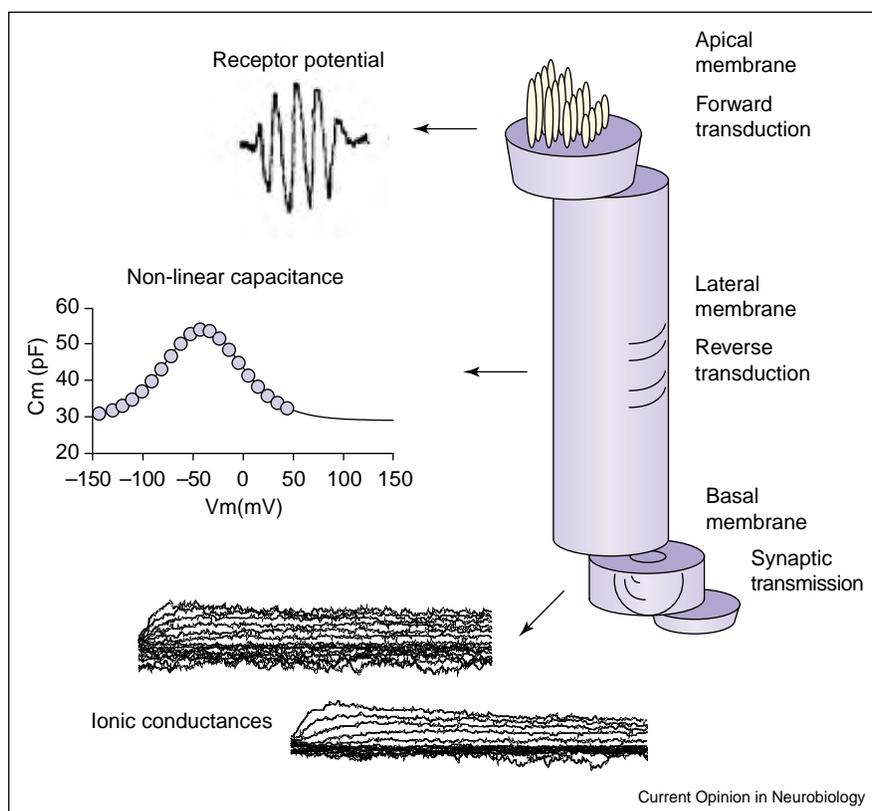

the change in cell length that accompanied the knockout have compromised normal interactions of OHCs with themselves [15] or the tectorial membrane (TM) superstructure [16]? Indeed, a knockout of a major TM protein, α -tectorin, which resulted in disruption of such interactions, proved detrimental to cochlea amplification [16]. Certainly, a molecular biological trick that could turn on and off prestin, or diminish its activity in a graded way, rather than removing it outright, could help to clarify matters. There is no doubt, however, that understanding the molecular aspects of the cells which form the basis of the cochlea amplifier will be far easier than putting together the whole picture. Here, I first review some basic properties of the OHC lateral membrane motor, and then look at some recent data that relate to the mechanism of OHC electromotility and its effects on cochlear performance.

Biophysical characterization of the outer hair cell lateral membrane motor

The steady-state behavior of the OHC lateral membrane motor is routinely evaluated by fitting a two state

Boltzmann function, a sigmoidal function typically used to relate charge displacement and voltage across a membrane, to measures of OHC length change (you can see a video of this length change evoked by a charming voltage stimulus delivered through a patch pipette at the Yale Ear lab website [17]) or non-linear charge movement of the motor's voltage sensor [18,19]. Alternatively, the charge movement is evaluated by fitting the cell's voltage-dependent or non-linear capacitance (NLC; Figure 1) with the first derivative of the same Boltzmann function. In each case, the parameters obtained are V_h (or V_{pkcm} , the voltage at half maximal charge transfer or peak capacitance), z (the unitary charge moved through some portion of the membrane field; otherwise interpreted as the motor's voltage sensitivity) and Q_{max} (the total charge moved across the membrane, indicative of the number of motors possessing unitary charge within the membrane). Typical values for an OHC isolated from the low frequency region of the cochlea are -40 mV, 0.75 , and 2.5 pC, respectively. Motor density, derived from non-linear charge density within the cell's lateral membrane has been estimated to be near $8000/\mu m^2$ [20,21]. Although

Figure 1

The OHC has a highly compartmentalized membrane. Apical, lateral and basal membranes possess characteristic integral membrane constituents with measurable electrical correlates. Of interest for the present review is the non-linear capacitance (NLC) that characterizes the lateral membrane motor. The voltage-dependent capacitance, which rides atop the linear (membrane surface area-dependent) capacitance, peaks at a voltage (V_h) near -40 mV that is modulated by a variety of biophysical forces. In addition to information on the state probability of the motor (contracted versus expanded) provided by V_h , measures of NLC also provide estimates of the motor's unitary charge or voltage sensitivity (z), and the total charge moved across the membrane (Q_{max}).

there is a consensus that non-linear charge movement and OHC mechanical activity are inextricably related, contrary to some claims [22], we do not know if charge movements or displacement currents mirror mechanical responses in time, as simultaneous mechanical and charge measures have not yet been made with sufficient time resolution [23–25]. Such measures could provide valuable information on the link between charge movement and OHC mechanical activity, the latter having been measured beyond 70 kHz [26].

Prior to the identification of prestin as the OHC motor [12], several biophysical attributes of the motor had been characterized. These included the effects of membrane tension (turgor pressure), preconditioning voltage, and temperature [27–34]. The main action of these biophysical forces is to set the steady state energy profile of the motor, perturbation effectively and reversibly shifting the operating voltage range over which the motors work in a time-dependent manner. Each of the following perturbations induces a 20–25 mV rightward (depolarizing) shift in V_h : an increase in OHC turgor pressure of 1 kPa (or circumferential membrane tension of 1 mN/m), a step in resting potential from +40 to –120 mV, and a 10°C increase in temperature. The sensitivity of the motor to these biophysical forces is likely to reflect as yet unraveled mysteries of the motor and underscores the susceptibility to insult of the cochlear amplifier. Recently, these same biophysical attributes have been identified in non-auditory cells transfected with prestin [35,36,37], confirming the identity of the lateral membrane motor. However, we did note that the effects were smaller in magnitude than those found in the native OHC [36], and thus, it is possible that prestin requires additional subunit interactions to achieve the desired amplification. Indeed, estimates of the unit magnitude of the motor stroke (area change) are also smaller in prestin transfected cells [38]. One possible interacting species is GLUT-5, an initial motor protein candidate [39].

A motor complex?

Although GLUT-5, a fructose transporter, presented some characteristics that indicated its similarity to the OHC motor [39], this hexose transporter took a back seat following the identification of prestin. GLUT-5 has a different time course of developmental expression than that of electromotility, whereas prestin expression correlates well [40]; indeed, the co-expression of GLUT-5 with prestin apparently has no effect on the activity of prestin [37]. Whether these observations mean that GLUT-5 is out of the picture or not is debatable, as preliminary indications are that in prestin knockout mice GLUT-5 is absent [41], and expression of prestin may promote fructose transport [42]. Could GLUT-5 and prestin expression be under some common control mechanism? Are they members of a motor complex?

At present we do not know if prestin functions alone or as multimers, or whether additional subunits are required for its activity or not. The initial subtractive screen between IHCs and OHCs that was used to identify prestin produced a large number of unique OHC proteins [12,43]. Presumably, some of these may interact with prestin. There has been one preliminary report of an interacting protein (termed couplin), which links prestin to structural members (pillars) of the OHC sub-membranous cytoskeleton [44]. However, on the basis of estimates of prestin density in the OHC, there are far too few pillars to suggest a one-to-one interaction of couplin with prestin. Couplin's function is unknown, but it is similar to the calponin homology (CH) domain, a superfamily of actin-binding domains. Interestingly, couplin is expressed in several tissues, indicating that potential interacting proteins of prestin may extend well beyond the number of unique OHC proteins identified in the initial differential screen. Indeed, interacting proteins may naturally exist in cell lines used for prestin transfections, possibly confounding our supposed view of prestin in isolation.

Prestin structure

The primary structure of prestin places it in a newly identified anion transporter family, SLC26. Prestin is the fifth identified member, SCL26A5. The nine members identified thus far [45] possess good sequence homology within the probable transmembrane region, but poor homology in the extreme carboxy and amino termini. Most of the SCL26 family members have a clear anion transport function [45–48], but prestin has yet to be fully evaluated, although preliminary evidence indicates that it may transport Cl^- and bicarbonate [42]. The topology of prestin, that is, the number of transmembrane regions and the location of carboxy and amino termini, has received some attention. The carboxy and amino termini are both located intracellularly as determined by antibody staining [37,49], indicating that the number of transmembrane domains is even. More detailed topology mapping is lacking, and the results of topology prediction programs are divided among 10 to 12 transmembrane domains. Nevertheless, the favored opinion is that prestin and SCL26A6, arguably prestin's closest relative [46], have 12 transmembrane domains [49]. This opinion is formed on the basis of the placement of conserved potential N-glycosylation sites within a putative second extracellular loop. The confirmation of prestin topology is important as site directed mutation studies have already been conducted that have observed effects on prestin activity.

Playing with prestin

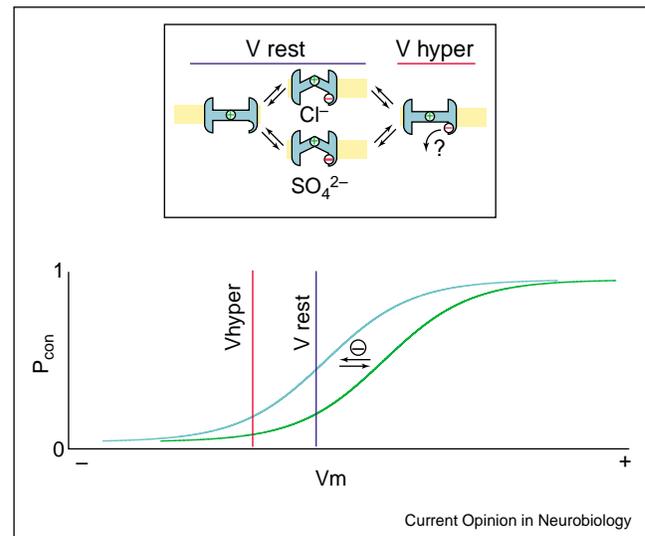

The first structural manipulations of prestin were designed to modify the polarity of non-conserved (among SLC26 members) charged amino acid residues that presumably reside within the voltage sensing transmembrane domain [50]. Such manipulation failed to

abolish non-linear charge movement under voltage stimulation, but shifted the value of V_h . Subsequently, it was found that full truncation of the carboxy terminus, distal to residue 590, results in absent voltage sensitivity, that is, immeasurable NLC [51]. However, in the absence of a functional protein it is difficult to prove correct plasma membrane targeting and/or folding; thus, it is imperative to also identify similar, yet active truncations. Recently, we [52] were able to produce highly restricted truncations of both carboxy and amino termini at their extreme ends (within 20 residues) that abolished NLC in a graded manner. Additionally, charge reversals of carboxy-terminal charged clusters produced marked shifts in V_h . Therefore, it is clear that the non-conserved (among SLC26 members) carboxy and amino termini of prestin, which are unable to sense the membrane field, are nevertheless important for its sensor function. This importance may relate to allosteric actions that these termini could have on prestin's voltage sensor through prestin–protein or prestin–anion interactions (see below). One other observation that is of interest in light of these data is the resistance of the motor to proteolytic destruction despite the presence of many potential cleavage sites [31,53,54]. Evidently, in the native OHC, the carboxy and amino termini are protected by either their own structural features or interactions with other proteins (or lipids).

Anion effects on prestin's voltage sensor

Two years ago, Oliver *et al.* [50^{••}] made the key discovery that prestin requires anions to function, notably Cl^- and bicarbonate, but not sulfate. They used membrane patches from prestin-transfected chinese hamster ovary (CHO) cells and rat OHCs to determine that NLC requires either of these physiologically abundant anions. The $K_{1/2}$ (concentration at half maximal response) for chloride and bicarbonate's ability to generate NLC was 6 and 44 mM, respectively. Additionally, they found that salicylate, a known ototoxic agent that modulates NLC on the inner aspect of the OHC plasma membrane [55,56], increased chloride's $K_{1/2}$. It was suggested that these anions function as prestin's extrinsic voltage sensor, in which an incomplete anion transport cycle moves negative charge through the membrane field, causing prestin to reside in the expanded state. Some of these data are consistent with previous work showing that only negatively charged lipophilic ions influenced motility and NLC in intact OHCs [57], and that furosemide, a chloride transporter antagonist, interfered with NLC [58]. Nevertheless, the outcome of more recent studies on the effects of mono and divalent anions on intact OHCs [59^{••}] offers an alternative to the extrinsic voltage sensor hypothesis. Notably, in intact OHCs, sulfate and other sulfonate-containing anions can promote significant non-linear charge movement in the absence of bicarbonate and chloride. Moreover, if sulfates were simply able to substitute for monovalent anions as prestin's extrinsic voltage sensor, the unit charge of the motor and Q_{max} would have

Figure 2

Effect of anions on OHC motor. Boltzmann functions describe the voltage-dependent probability of the motor being in the contracted state (P_{con}). At the fixed resting voltage (V_{rest} , blue line) and in the absence of bound anions (green Boltzmann), a small proportion of motors are in the contracted state. With the delivery and possible binding of Cl^- to a site (or sites) on the intracellular aspect of the membrane motor, the steady state energy profile is altered, resulting in a leftward shift in the probability function along the voltage axis (cyan Boltzmann). Consequently, at V_{rest} , an increased number of motors reside in the contracted state (inset, motors in cyan, membrane in yellow). A hyperpolarizing step to V_{hyper} (red line) restores the original distribution of motor states. Whether chloride or sulfate is bound, the slope (z), which is indicative of the voltage sensor's unit charge, remains the same, showing that the extrinsic anion does not serve as the voltage sensor [60].

doubled, as sulfate is divalent. However, the motor's valence, z , remained the same. Another issue that complicated the simple voltage sensor scheme of Oliver *et al.* [50^{••}] was the identification of large shifts in V_h as a function of chloride concentration, that is, an increase in intracellular chloride shifting V_h to negative potentials [59^{••},60]. Thus, chloride strongly influences the probability that prestin will reside in the compact or expanded state. In view of these observations, we proposed [59^{••}] that anions serve not as extrinsic voltage sensors but as allosteric modulators of prestin that upon binding shift prestin's voltage dependence into the physiological range, where intrinsic charge senses voltage perturbation (Figure 2). Thus, at any given voltage, the binding of chloride to prestin increases the likelihood of the motor being in the contracted state, which corresponds to cell shortening. Recently, chloride's effect on prestin's operational voltage range has been confirmed [61].

Targeting the lateral plasma membrane

The OHC motor is clearly restricted to the cell's lateral plasma membrane, which possesses a surface area of

greater than $2,000 \mu\text{m}^2$ in low frequency OHCs. This layout has been revealed through physiological tests of the motor's electro-mechanical activity [53,54,62] as well as its mechano-electrical activity [31]. Indeed, prestin has been mapped exactly to the location identified by those physiological measures by antibody labeling [40]. However, the lateral membrane is not uniform, but instead composed of structural and functional microdomains, in which local forces may impose on motor activity [63,64]. That is, the voltage range over which the motors work, and the sensitivity of the motors may not be uniform along the cell surface [64]. These microdomains can have an impact on the overall mechanical activity of the OHC. For example, movements of the cell along an axis other than the longitudinal one, as has been observed *in vitro* [65] and *in vivo (in situ)* [66], could arise from local characteristics of motor microdomains that provide for anisotropic (on the level of the whole cell) electromechanical properties. Thus, the evolving concept that the organ of Corti or parts of it deform in a non-rigid manner [66,67,68*,69] may be substantially derived from the mosaicism of the OHC lateral membrane.

The distribution of prestin along the lateral membrane, spanning from nuclear to sub-cuticular regions of the cylindrical cell, is apparently under thyroid hormone (TH) control. In TH deficient rats, prestin expression is delayed and the protein is distributed along the whole basolateral extent of the cell, never attaining restricted membrane targeting to the lateral membrane [70**]. Motor function, however, appears unaffected, as the absence of TH in *in vitro* explants of Corti's organ is not required for the development of electromotility [71]. The correct localization may not only depend upon targeting per se, possibly with helper proteins, but also on the limitation of lateral diffusion. In the normal OHC, the diffusion of lateral membrane motors into adjacent basal regions of the OHC membrane, in which ion channels are restricted [72], does not occur, even after cytoskeletal destruction with proteolytic enzymes [31]. The membrane-based barriers to diffusion across these membrane domains are unknown. However, within the lateral membrane proper, lateral diffusion of motors appears to occur at rates typical for untethered integral membrane proteins, namely at around $0.08 \mu\text{m}^2/\text{s}$ [73]. The diffusion coefficient of the lipid permeable dye di-8-ANNEPS within the OHC lateral membrane is faster, as expected for lipids, but interestingly, it is voltage-dependent and tension-dependent [74,75]. This may relate to the voltage and tension-dependence of the major protein prestin that is located in that membrane. However, another lipid soluble dye, SP-DiIC18, is relatively immobile but can redistribute within the membrane in a voltage-dependent manner, and this redistribution probably depends on prestin activity [63]. In light of these data, it is possible that the diffusion of prestin itself depends on the protein's voltage-dependent area state, an area that has yet to be explored.

Molecular motions

The whole cell mechanical response of the OHC (which can be seen at the Yale ear lab website [17]) is truly amazing. Movements as large as $30 \text{ nm}/\text{mV}$ have been measured [76]. One of the perplexing questions about prestin or its complex is how the voltage dependent conformational change, which we are able to observe microscopically through displacement current measures, results in cell movements? A variety of hypotheses have been tested, but two putative mechanisms remain entertained in the field. Following the observation that OHC membrane patches change surface area in response to membrane voltage change [53], molecular motor models incorporating two-state area changes appeared. These mechanical models naturally arose from the two-state Boltzmann models of non-linear charge transfer that preceded them [18,19], and suggested that unitary motors fluctuate among area states with an area difference ranging from 0.4 to 8 nm^2 [27,28,34,77–79]. Given the constraints imposed by a cylindrical shape, caused by the cortical cytoskeleton [80] and the fixed volume (especially expected at high acoustic frequencies), surface area changes are predicted to alter OHC length and diameter in line with physiological observations [77]. Of course, an alteration in surface area should cause a change in the cell's linear (specific) capacitance, which correlates with the number of motors that occupy each state, hyperpolarization favoring an increase in specific capacitance (expanded state). Indeed, such a phenomenon appears to occur [81].

The other motor mechanism currently favored is formed on the basis of membrane curvature and interfacial tension. Proponents of this mechanism maintain that prestin functions not as a motor but simply as an entity that provides the membrane with an enhanced capacitance (charge), which in turn amplifies a basic biophysical process that drives membrane motion [82*]. It has been argued that this flexoelectric property of membranes accounts for such phenomena as salicylate and chlorpromazine's (both amphipaths, which affect membrane curvature) actions on the magnitude and voltage dependence of OHC motility and NLC [83–86]. The theory appears solid, but there is disparity between the 'area motor' and 'membrane bending motor' camps over magnitude effects, polarity, and the precise requirements for helper charge that may point to the superiority of one hypothesis over the other. It is likely that each camp will fight until an experiment unequivocally reveals the truth [22,86]! We should not hold our breath, however, as it took nearly a decade to dissuade supporters of an electro-osmotic mechanism for OHC motility [87].

Another property of the OHC that may account for mechanical responses or help to modify them is its voltage dependent stiffness [88]. Two models have been proposed whereby mechanical activity could accompany a

stiffness change [89]; one invokes intrinsic and simultaneous changes in stiffness and the conformation of a motor unit, whereas the other derives from the consequences of a pure stiffness change under constant cellular preload (steady state application of cellular deformation). The results of preload effect (induced by turgor pressure) on OHC motility are contradictory [19,33]. Nevertheless, the conformational changes embodied in the area model of motility are predicted to evoke a voltage dependent compliance that peaks at V_h (corresponding to the voltage at maximal electrical compliance [capacitance], or mechanical voltage sensitivity), much as the stereociliar transduction channels sponsor a maximum bundle compliance when half the channels are open [90]. Iwasa [91] modeled this molecular inevitability and confirmed that motor activity should affect global OHC stiffness. However, as expected, at V_h stiffness is at a minimum, whereas neither the stiffness data nor the models of He and Dallos [88,89] show a minimum at V_h , but instead, a simple (sigmoidal) correspondence between stiffness and motility magnitude. In light of this, it is likely that the modulation of OHC stiffness additionally arises from mechanisms other than direct motor activity. Indeed, it is understandable that global OHC stiffness should derive from the combined structure of the OHC lateral wall (plasma membrane, cortical cytoskeleton, and subsurface cisternae) [92]. Thus, another means to alter global OHC stiffness would be through cytoskeletal effects of second messengers (e.g. cGMP [93], or calcium ions [94–97]) and other signaling pathways (e.g. those employing the small GTPases [98,99]). Neural efferent effects on cochlea mechanics may be mediated partly by modulation of OHC stiffness [100].

The consequences of direct motor effects (viewed through NLC measures) of chemical modifiers (e.g. phosphorylation) have been considered for some time [94,101]. Indeed, there are several sites identified within prestin that could be important targets for functional modification [12,49], including N-glycosylation and phosphorylation sites. There are some preliminary data of interest with regards to these sites. Mutation of two N-glycosylation sites at residues 163 and 166 produced no changes in NLC [102]. On the other hand, the PKC inhibitors, RO31-8220 and bisindolylmaleimide (BIM), shifted V_h in the depolarizing direction in prestin-transfected cells [103], although the PKC activator phorbol 12-myristate 13-acetate (PMA) had previously been shown to lack effect on OHC motility [93]. The compelling story of prestin's modulation by second messengers and the like is not yet available.

Hop or Hopf?

One of the raging controversies that concerns mammalian cochlea function is the relative importance of stereocilia versus somatic mechanics, each viewed as potential powerhouses for amplification [10,104,105]. The stereo-

cilia bundle may very well sit at or near a point of instability, at a Hopf bifurcation, where oscillation and amplification struggle to prevail [106]; but whether or not it rules in the mammalian system is difficult to reconcile with the obvious need for such a momentous evolutionary stride as the OHC lateral membrane. Certainly, the prestin knockout mouse has strengthened the case for the dominating role of OHC electromotility [13**]. Yet reasonable issues with this experiment remain, as noted above. To highlight one concern, could the structural changes (e.g. shortening) in the OHC that result from a reduction in prestin numbers have modified the interaction of the stereocilia with the TM, ultimately interfering with stereocilia feedback into the organ? That is, could stereocilia mechanics have been altered because, for example, of bundle biasing? Could this possible biasing have also altered their resting potentials? In addition, what is the consequence of missing GLUT-5? In any case, whether or not a Hopf bifurcation underlies the sensitivity, tuning and non-linearity of the mammalian auditory system may not necessarily point to one mechanism over another, as such an instability could conceivably reside within the soma, as well as the stereocilia (see annotation to Julicher *et al.* [107]). As far as the bifurcation concept itself goes, there is some quite heated debate [108**]! However, beyond the underlying principles of amplification, questions of speed persist and may ultimately help to decide which amplificatory mechanism will win. Clearly, stereocilia work at frequencies across the mammalian acoustic spectrum, indicating that the bundle's driving force for amplification is truly wideband; however, can the effector arm follow the input? Using realistic parameters, bundle amplificatory abilities have been modeled up to 5 kHz [105], still far short of mammalian needs. Unfortunately, the lateral membrane mechanism also faces difficulty.

How fast can fast be?

There is no doubt that the OHC motor is fast; as already noted, mechanical activity is measurable above 70 kHz [26], and in some mammals, such as bats, in which the cochlear amplifier presumably works, frequency sensation can extend well beyond 100 kHz. However, in all evaluations of the motor's frequency response, external voltage commands under the frequency and level control of the experimenter were used, thus avoiding one of the enigmatic problems facing the realization of voltage-driven cochlear amplification at high frequencies, the RC (resistor \times capacitor) membrane filter [24,109]. The OHC membrane's low pass filter is expected to seriously limit high frequency electromotility, and this difficulty is one of the key arguments employed by proponents of stereocilia-based cochlea amplification in the mammal [105]. The problem arises when one considers that because of the non-linear nature of the OHC electromotility function, the mechanical gain of the OHC is about one-tenth of its maximum (max: around 20 nm/mV) at the

cell's normal resting potential of -70 mV [109]. At this gain, receptor potentials near threshold would result in mechanical responses that fall short of threshold BM movements, making it unlikely that BM motion can be boosted. Since its identification, a few solutions for the apparent RC filter problem have been proposed. Dallos and Evans [110] suggested a mechanism that relies on stimulation of motor activity by wide-band extracellular voltages evoked by remote OHCs within the organ of Corti. Alternatively, we have suggested two cellular-based mechanisms whereby the problem could be alleviated. First, we found that the mechanical gain of the cell at its resting potential could be increased through reductions in turgor pressure [29]. Second, as we found that motor charge density is greater in higher frequency OHCs, we reasoned that the resultant electrical energy ($Q \cdot V$) delivered to the lateral membrane of high frequency OHCs could render the filter-induced drop in receptor potentials less detrimental [111]. The latest suggestions are based on modeling, one positing that the piezoelectric-like properties, that is, reciprocal electro-mechanical properties, of the OHC lateral membrane can provide for an enhanced receptor potential in high frequency OHCs [112], whereas the other suggests that the apparent inductance of ionic channels may enhance the cell's frequency response [113]. All of these arguments presuppose the existence of an RC filter problem due to prestin's voltage dependence. What if prestin were driven by something other than voltage?

The recent identification of a stretch-activated chloride conductance (termed G_{metL} ; [59^{••}]) in the OHC lateral membrane may indicate that the motor can react to currents evoked by mechanical perturbations of the lateral membrane accompanying acoustic stimulation *in vivo*. Indeed, sound induced deformations of the OHC have been observed in the intact cochlea [68[•]]. In this model, intracellular Cl^- oscillations located near prestin, driven by stretch-activated ac and/or dc Cl^- currents, would directly drive prestin transitions. Because the current or its integral, not the resultant voltage, directly modulates prestin, the mechanism is unencumbered by the RC membrane filter. If this model proves true, then the OHC soma has adopted a mechanism similar to that which stereocilia use to provide cochlea amplification in lower vertebrates. In that case, calcium ion entry through the mechanically-gated forward transduction channels modulates the channels themselves and thus stereocilia bundle mechanics, leading to amplification [104,105]. Nature's capitalization on such a primitive yet well-designed system may possibly have usurped the stereocilia's rule by elevating the OHC lateral membrane to function as both a forward and a reverse transducer.

Conclusions

Despite the advances made in understanding OHC function and its role in cochlear amplification, so many more

unknowns remain. In a way, OHC aficionados are faced with the excitement that ion channel biophysicists felt when molecular identifications of their sweetheart proteins were first made. A host of investigations that employ the now well-developed fields of molecular biology, protein biophysics, and the like, which have been successfully employed in other fields, are beginning to surface in our small field. This can be clearly observed when perusing the abstracts of international meetings, some of which have been highlighted here. Although the information gleaned in the past few years has truly been remarkable, I would bet that the next timely review of OHC electromotility will be astonishing by comparison.

Update

Two manuscripts of significant interest have appeared since this review was completed. In a follow-up to the published abstract [42] on sugar transport by prestin, Chambard and Ashmore [114] provide evidence that prestin and another SLC26 family member, Pendrin, can transport fructose. The ability to transport fructose was not assessed in other family members but conceivably could be a general trait. The full significance of the transport is not clear, but certainly it could influence turgor pressure regulation in OHCs.

Weber *et al.* [115] identify a few new SLC26 family members that are homologous to prestin in species that are distant from mammals, namely fish and insects. Nevertheless, the best homology is around 50% (or less) with prestin. It would not be considered unusual to find solute transporters in these species. Furthermore, it is unlikely that motor activity would arise from such homologues, as other members of the SLC26 family that have substantial homology to prestin lack this capacity. Nevertheless, investigation of motor activity (e.g. NLC) is certainly warranted.

- The authors used a mouse knockout of prestin to evaluate cochlear function *in vivo* and isolated OHC mechanical activity *in vitro*. In homozygotes auditory function was severely compromised, whereas in heterozygotes minimal dysfunction was realized. OHC mechanical activity was absent in homozygotes, and reduced to about half magnitude in heterozygotes. Cell length decreases resulted from the absence or reduction of prestin in the lateral membrane of OHCs. It remains to be clarified whether the absence of prestin function or the consequences of the removal of a major (structural) lateral membrane protein contributed to the results.

- The authors present a model of prestin topology formed on the basis of antibody localization of the carboxy and amino termini intracellularly, and placement of conserved sites (among SLC26 family members). Twelve transmembrane domains are suggested, but this topology has yet to be confirmed.
50. Oliver D, He DZ, Klocker N, Ludwig J, Schulte U, Waldegger S, Ruppertsberg JP, Dallos P, Fakler B: **Intracellular anions as the voltage sensor of prestin, the outer hair cell motor protein.** *Science* 2001, **292**:2340-2343.
- The authors present one of the first attempts to identify the voltage sensor region of prestin. Select charge neutralizations within presumed transmembrane domains failed to abolish NLC in transfected cells. This result led to the investigation of an extrinsic source as the carrier of sensor charge. Anions, including Cl⁻ and bicarbonate, but not sulfate, were found to promote charge movement. A model of prestin possessing an incomplete transport cycle was presented to account for its motor activity.

- The authors analyzed images of the organ of Corti within an intact cochlea explant during sound stimulation at high levels. Differential motion of the two surfaces of the organ (reticular lamina and basilar membrane) showed that OHCs sandwiched between them are deformed. Such deformation could gate a chloride conductance in the lateral membrane.

Determination of Cell Capacitance Using the Exact Empirical Solution of $\partial Y/\partial C_m$ and Its Phase Angle

Joseph Santos-Sacchi

Otolaryngology and Neurobiology, Yale University School of Medicine, New Haven, Connecticut 06510

ABSTRACT Measures of membrane capacitance offer insight into a variety of cellular processes. Unfortunately, popular methodologies rely on model simplifications that sensitize them to interference from inevitable changes in resistive components of the traditional cell-clamp model. Here I report on a novel method to measure membrane capacitance that disposes of the usual simplifications and assumptions, yet is immune to such interference and works on the millisecond timescale. It is based on the exact empirical determination of the elusive partial derivative, $\partial Y/\partial C_m$, which heretofore had been approximated. Furthermore, I illustrate how this method extends to the vesicle fusion problem by permitting the determination of $\partial Y_v/\partial C_v$, thereby providing estimates of fusion pore conductance and vesicle capacitance. Finally, I provide simulation examples and physiological examples of how the method can be used to study processes that are routinely interrogated by measures of membrane capacitance.

INTRODUCTION

Biological cells are typically modeled as simple parallel combinations of an electrical resistance and capacitance. Measures of membrane capacitance (C_m) based on this model under voltage clamp provide an informative view of such varied processes as fertilization (Jaffe and Schlichter, 1985), ionic channel gating (Fernandez et al., 1982), synaptic vesicle fusion (Neher and Marty, 1982), gap junctional coupling (Santos-Sacchi, 1991a), and receptor cell activity (Zhao and Santos-Sacchi, 1999).

A powerful feature of capacitance measures is the ability to monitor interactions between membrane-bound compartments, e.g., fusion of vesicles with the plasma membrane or cell coupling via gap junctions (Neher and Marty, 1982; Joshi and Fernandez, 1988; Santos-Sacchi, 1991a; Zhao and Santos-Sacchi, 1998), because these measures provide an estimate of membrane surface area (Fricke, 1925; Cole, 1971). Indeed, electrical measures of vesicular fusion (Alvarez De Toledo et al., 1993) have played a significant role in the development of one of the most controversial issues facing neurobiology today, namely, the occurrence of kiss-and-run synaptic vesicle transmitter release (Gandhi and Stevens, 2003; Aravanis et al., 2003). Single-frequency admittance analysis of membrane fusion, pioneered by Neher and Marty (1982), has been used by a number of investigators to gauge the time course of vesicular membrane fusion by monitoring the changes in the conductance of the fusion pore that initiates membrane fusion (Breckenridge and Almers, 1987; Alvarez De Toledo et al., 1993; Debus and Lindau, 2000; Klyachko and Jackson, 2002). Estimates of the pore's initial conductance hover near single-channel

conductance values (Breckenridge and Almers, 1987; Lollike et al., 1995).

Arguably the most widely used method to measure membrane capacitance (C_m) is the phase-angle method, variously termed, but all employing approaches to extract the current at a particular phase angle arising from small changes in C_m (Neher and Marty, 1982; Gillis, 1995). Such AC methods ostensibly provide excellent time resolution and sensitivity. Multifrequency approaches, which we and others have used (Fernandez et al., 1982; Santos-Sacchi, 1989; Zhao and Santos-Sacchi, 1999), are less in vogue, but offer potential protection from changes in admittance that can plague single-sine methods. Implementations of step, single-, and dual-sine techniques are available in a few software packages (jClamp, www.SciSoftCo.com; pClamp, www.Axon.com; Pulse Control, www.Instrutech.com, chroma.med.miami.edu/cap).

One of the key problems that challenges the validity of C_m measures, and thus our understanding of those cellular processes that are interrogated by C_m measurements, is the interference of those measures by changes in either patch electrode resistance (R_s) or cell membrane resistance (R_m), the latter often a natural corollary of those cellular processes (Gillis, 1995; Debus et al., 1995). An extensively discussed topic of the single-sine camp concerns the determination of the proper phase angle to utilize in measuring small changes in membrane capacitance. There are various mechanisms to determine an appropriate phase angle, but all estimates of capacitance employ simplifying assumptions and requirements, usually devised to limit the effects of uncontrollable R_s and R_m changes on C_m measures. Indeed, the traditional methodology of single-sine admittance analysis suffers from a number of assumptions and simplifications, especially those methods used to extract vesicle capacitance and conductance, and the fusion pore conductance. These

doi: 10.1529/biophysj.103.033993

assumptions cannot be met in all cases, and this quandary is clearly indicated by the posthoc manipulations of data that are often required (Lindau, 1991; Ratnov et al., 1998). In detailing these assumptions, I refer to the traditional electrical circuit models that are used to evaluate admittance data (Fig. 1). A nearly universal assumption is that $R_m \gg R_s$; additionally, for fusion vesicle analysis, $R_v \gg R_p$, and in some cases $R_v = \infty$. Below I illustrate through circuit analysis and modeling how these assumptions can lead to errors, and provide a method, based on the exact empirical identification of the partial derivatives $\partial Y/\partial C_m$ and $\partial Y_v/\partial C_v$, that offers solutions without compromising assumptions. The approach is referred to as the *eCm* method.

Theory

The phase of the capacitive current components evoked by a sinusoidal command voltage (V) across the simple models presented in Fig. 1 can be used to arrive at measures of the capacitive components themselves. Once the capacitive component values are obtained, the resistive component values are easily deduced. This can be appreciated from the

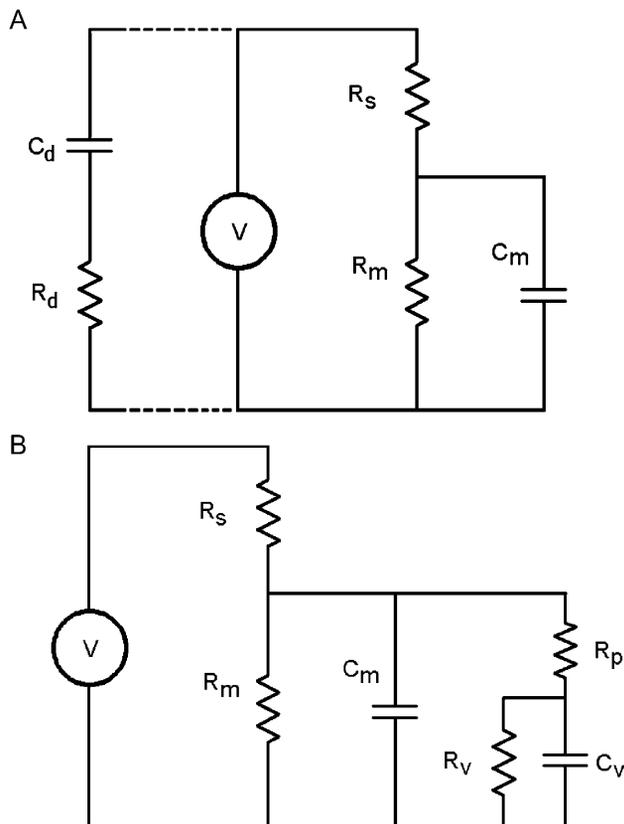

FIGURE 1 Circuit models. (A) The standard patch-clamp-cell model. Voltage (V) is set across the electrode (R_s) and cell membrane resistance (R_m)—capacitance (C_m). The series components between headstage and ground, R_d and C_d , model the whole-cell capacitance compensation circuitry when connected. (B) A vesicle is fused with the plasma membrane. C_v is vesicle capacitance, R_p is fusion pore resistance, and R_v is vesicle resistance.

following evaluation, which first deals with the model without a fusion vesicle and without capacitance compensation components (Fig. 1 A).

Two standard conditions must be met for successful use of the methods detailed here: 1), the patch-clamp system transfer function (which derives from all equipment that contributes to shaping the output current) must be corrected for. This is a trivial matter, where a pure resistor, say $1\text{ M}\Omega$, is used at the input of the headstage to determine the correction phase and magnitude at each frequency (see Gillis, 1995 for details); and 2), the pipette stray capacitance must be neutralized before establishing whole-cell configuration.

Absent vesicle fusion

The current measurable under voltage clamp (Fig. 1) is that through R_s , namely, I_{R_s} . According to Ohm's law, I_{R_s} is defined as the product of the clamp voltage (V) and input admittance (Y) of the circuit,

$$I_{R_s} = YV = (A_Y + jB_Y)V, \quad (1)$$

where A_Y and B_Y are the real and imaginary components of the admittance. Closer inspection of the circuit reveals that I_{R_s} is the sum of a resistive and a capacitive component induced by only that portion (V_m) of the clamp voltage (V), which drops across the cell membrane ($R_m \parallel C_m$),

$$I_{R_s} = I_{R_m} + I_{C_m} = \frac{V_m}{R_m} + j\omega C_m V_m. \quad (2)$$

These equations show that I_{R_s} can be represented as a frequency ($\omega = 2\pi f$) dependent complex number,

$$Y_m = \frac{(A_{I_{R_s}} + jB_{I_{R_s}})}{V_m}, \quad (3)$$

where Y_m is the membrane admittance, $A_{I_{R_s}}$ is the real component, and $B_{I_{R_s}}$ is the imaginary component of I_{R_s} . Plainly, this signifies that the phase relationship between capacitive (I_{C_m}) and resistive (I_{R_m}) membrane current components is 90° . It is important to realize that the magnitude of the series resistance (R_s), or its existence (i.e., $R_s = 0$), is irrelevant, and will not affect the phase relationship between I_{C_m} and I_{R_m} . Of course, for $R_s > 0$, the phase of I_{R_s} , relative to that of V , will vary as a result of any circuit parameter change, because the phase of I_{R_s} is dependent on that of V_m ,

$$\angle V_m = -\tan^{-1}(\omega\tau_{\text{clamp}}), \quad (4)$$

where τ_{clamp} , the actual clamp time constant, is

$$\tau_{\text{clamp}} = R_{\parallel}C_m = \frac{R_s R_m}{R_s + R_m} C_m = \frac{R_s R_m}{R_m} C_m. \quad (5)$$

Viewed relative to the phase of the command voltage (V), the capacitive current phase angle, Φ , will always reside at

$$\begin{aligned}\Phi &= \angle V_m + 90^\circ = \angle I_{R_m} + 90^\circ \\ &= -\tan^{-1}(\omega\tau_{\text{clamp}}) + 90^\circ.\end{aligned}\quad (6)$$

Thus, in the absence of R_s ($R_s = 0$), the angles of V_m and V are identical, and Φ will be orthogonal to the angle of V . However, as pointed out by Neher and Marty (1982), the introduction of R_s causes Φ to shift away from orthogonality with respect to the applied command voltage (V). The phase shift, θ , in the angle of I_{R_s} that accompanies changes in the circuit parameters is defined as

$$\begin{aligned}\theta &= \angle V_m - \angle I_{R_s} = \angle I_{R_m} - \angle I_{R_s} \\ &= -\tan^{-1}(\omega R_m C_m),\end{aligned}\quad (7)$$

and thus

$$\Phi = \angle I_{R_s} + \theta + 90^\circ.\quad (8)$$

Although it is apparent from Eq. 2 that the magnitude of the current at Φ , namely, I_{C_m} , can be used to extract C_m

$$|I_{C_m}| = \text{Re}(I_{R_s} e^{-j\Phi})\quad (9)$$

$$C_m = \frac{I_{C_m}}{j\omega V_m} = \frac{|I_{C_m}|}{\omega |V_m|},\quad (10)$$

neither absolute angle, θ nor Φ , can be determined from direct manipulation of the empirically obtained input admittance at any one frequency. Thus, in the face of changing circuit parameters, estimating C_m by directly measuring raw current at Φ appears unfeasible. Nevertheless, inspection of the current at Φ can be achieved by operating on the imaginary component of I_{R_s} , whose phase follows those phase shifts that result from parameter changes.

$$I_{C_m} = \text{conj} \left[\frac{\mathbf{B}_{I_{R_s}} V}{j V_m} \right].\quad (11)$$

Thus, the imaginary component of \mathbf{Y} (or I_{R_s}) can be used to find C_m . To obtain direct estimates of C_m from \mathbf{B}_Y , one needs to correct \mathbf{B}_Y with a noncomplex gain factor (H_c) that accounts for the relationship between inevitable changes in R_s , R_m , and C_m that occur during the course of an experiment.

$$C_m = H_c \mathbf{B}_Y,\quad (12)$$

where, after substitution and rearrangement,

$$H_c = \frac{(1 + \omega^2 \tau_{\text{clamp}}^2)}{\omega \left[1 - \frac{\tau_{\text{clamp}}}{\tau_{\text{cell}}} \right]^2},\quad (13)$$

and

$$\tau_{\text{cell}} = R_m C_m.\quad (14)$$

Note that τ_{cell} is the membrane time constant, and most importantly,

$$H_c^{-1} = \text{abs}(\partial \mathbf{Y} / \partial C_m).\quad (15)$$

Thus, to extract C_m from \mathbf{B}_Y , we must precisely evaluate the partial derivative, $\partial \mathbf{Y} / \partial C_m$. This is one of the enigmas facing cell capacitance aficionados.

There are two methods that are routinely used to provide estimates of $\partial \mathbf{Y} / \partial C_m$ and its phase angle; both involve dithering of circuit parameters, and typically require hardware modifications and/or manipulations (Fidler and Fernandez, 1989; Joshi and Fernandez, 1988; Neher and Marty, 1982). Series resistance dithering and capacitance compensation dithering each have shortcomings that have been discussed in detail (Joshi and Fernandez, 1988). Ultimately, these shortcomings stem from the untoward effects of series resistance, because as $R_m / R_{in} \rightarrow 1$, the circuit of Fig. 1 A approaches a simple parallel $R_m C_m$ configuration, and the estimates ultimately provide precise solutions. Regrettably, we are rarely so lucky during our experimental manipulations of cells to guarantee such relationships (Debus et al., 1995). Can this problem be resolved? That is, can the true magnitude and phase angle of $\partial \mathbf{Y} / \partial C_m$ be obtained, so that estimates of C_m are impervious to cell and clamp parameter changes? Furthermore, can this be accomplished without hardware additions and manipulations? Actually, it is a simple task, requiring, in addition to measures of \mathbf{B}_Y , the determination of the partial derivative, $\partial \mathbf{Y} / \partial \omega$ or correspondingly, $\partial I_{R_s} / \partial \omega$. As we shall see, such a determination ensures accurate measures of membrane capacitance.

$$\partial \mathbf{Y} / \partial \omega = \alpha_\omega e^{j\beta_\omega},\quad (16)$$

where the magnitude (α_ω) and phase (β_ω) are

$$\alpha_\omega = \frac{\mathbf{B}_Y}{\omega}\quad (17)$$

$$\beta_\omega = -\tan^{-1} \left[\frac{\omega^2 \tau_{\text{clamp}}^2 - 1}{2\omega \tau_{\text{clamp}}} \right].\quad (18)$$

Significantly, β_ω , the phase angle of $\partial I_{R_s} / \partial \omega$ and $\partial \mathbf{Y} / \partial \omega$, is identical to that of $\partial \mathbf{Y} / \partial C_m$, and also to the angle of

$\partial\mathbf{Y}/\partial R_m + 90^\circ$. This can be appreciated immediately by inspection of the partial derivatives.

$$\partial\mathbf{Y}/\partial\omega = \frac{\mathbf{Y}^2}{\mathbf{Y}_m^2} jC_m \quad (19)$$

$$\partial\mathbf{Y}/\partial C_m = \frac{\mathbf{Y}^2}{\mathbf{Y}_m^2} j\omega \quad (20)$$

$$\partial\mathbf{Y}/\partial R_m = -\frac{\mathbf{Y}^2}{\mathbf{Y}_m^2} \frac{1}{R_m^2}, \quad (21)$$

where

$$\frac{1}{\mathbf{Y}_m} = \frac{1}{\mathbf{Y}} - \frac{1}{G_s} = \frac{1}{\mathbf{Y}} - R_s, \quad (22)$$

It is this equivalence between the angles of $\partial\mathbf{Y}/\partial\omega$ and $\partial\mathbf{Y}/\partial C_m$ that forms the basis of the new *eCm* method of capacitance measurement that I report here. Given the angle, β_ω , and the real and imaginary components of \mathbf{Y} , the two time constants, τ_{clamp} and τ_{cell} , can be found. Each has two solutions, one of which will be realizable (positive) depending on the circuit parameters. For subsequent calculations the positive values must be used.

$$\tau_{\text{clamp}} = \left[-\tan(\beta_\omega) \pm \sqrt{1 + \tan(\beta_\omega)^2} \right] \omega^{-1} \quad (23)$$

$$\tau_{\text{cell}} = \frac{1 - \omega^2 \tau_{\text{clamp}}^2 - 2\eta\omega\tau_{\text{clamp}} \pm c}{\omega(-\eta + \eta\omega^2\tau_{\text{clamp}}^2 - 2\omega\tau_{\text{clamp}})} \quad (24)$$

where

$$c = \left[\sqrt{1 + \eta^2} + \sqrt{1 + \eta^2\omega^2\tau_{\text{clamp}}^2} \right] \quad (25a)$$

$$\eta = \tan \left[2 \tan^{-1} \left(\frac{\mathbf{B}_Y}{\mathbf{A}_Y} \right) \right] = \tan(\angle \partial\mathbf{Y}/\partial G_s). \quad (25b)$$

Finally, with τ_{clamp} and τ_{cell} in hand, H_c (Eqs. 13 and 15) can be obtained, thus revealing the exact solution for all clamp parameters, R_s , R_m , and C_m .

$$C_m = \mathbf{B}_Y H_c = \frac{\mathbf{B}_Y}{|\partial\mathbf{Y}/\partial C_m|} = \mathbf{B}_Y \frac{(1 + \omega^2 \tau_{\text{clamp}}^2)}{\omega \left[1 - \frac{\tau_{\text{clamp}}}{\tau_{\text{cell}}} \right]^2} \quad (26)$$

$$R_m = \frac{\tau_{\text{cell}}}{C_m} \quad (27)$$

$$R_s = \frac{-\tau_{\text{clamp}}\tau_{\text{cell}}}{C_m(\tau_{\text{clamp}} - \tau_{\text{cell}})}. \quad (28)$$

For completeness, the pertinent partial derivatives are provided in polar form (all parameters obtainable through a combination of measurement (that of \mathbf{Y} and β_ω ; see following) and calculation (as above)),

$$\partial\mathbf{Y}/\partial C_m = H_c^{-1} e^{j\beta_\omega} = \frac{\omega \left[1 - \frac{\tau_{\text{clamp}}}{\tau_{\text{cell}}} \right]^2}{(1 + \omega^2 \tau_{\text{clamp}}^2)} e^{j\beta_\omega}. \quad (29)$$

$$\partial\mathbf{Y}/\partial\omega = \frac{\mathbf{B}_Y}{\omega} e^{j\beta_\omega}. \quad (30)$$

The exact determination of β_ω

Several practical approaches to obtain β_ω via frequency manipulations are available. Ordinarily, the empirical determination of an angle of a partial derivative with respect to angular frequency, such as β_ω , is found by introducing a second voltage sinusoid (ω_1), in addition to the primary, ω_0 , at an infinitesimal interval of $d\omega$, which must be approximated with $\Delta\omega$. The angle of the resulting difference current will closely approximate β_ω . However, the determination of β_ω using digital techniques necessitates that the two frequencies be no closer than the minimum frequency interval, ω_{min} . This interval is determined by the number of points (*npts*) of the stimulus ($\omega_{\text{min}} = 1/(dt \text{ npts})$, where $dt = \text{sample clock}$) (see Oppenheim and Schaffer, 1975). Unfortunately, the rather large size of ω_{min} offered by a stimulus composed of, say, 128 points at 4 μs clock, will provide for a poor approximation of $d\omega$ by $\Delta\omega$ (f_{min} would be 1953.1 Hz). Of course, *npts* can be increased such that ω_{min} would be very small and permit a reasonable approximation of β_ω , but time resolution suffers. If high time resolution is not an issue, or if discrete determinations (as in ‘‘pause and dither’’ approaches) are acceptable, then determining the angle of the difference current at the primary frequency (ω_0) and secondary frequency (ω_1) at a very small interval will give β_ω .

Alternatively, a nondiscrete hardware implementation of this technique could easily allow $d\omega$ to be approached; furthermore, the magnitude of the second frequency could be quite small, because only the phase would be required. In fact, the stimulus could very well resemble a single sinusoid, thus limiting the cell’s stimulus exposure.

Notwithstanding these approaches to the determination of β_ω , our overriding intent is to obtain a method for C_m measurement without additional hardware or hardware manipulations, and to correct for parameter changes on a point-by-point (real time) basis. To this end, it is fortuitous that the need for an infinitesimal interval, $d\omega$, can be circumvented by acknowledging that for the linear component

model of Fig. 1 *a*, R_s or R_m may be considered frequency independent. That is, we may use either of the derivations of R_s or R_m provided by Pusch and Neher, 1988 (their Eqs. 5 and 6 reproduced below); also see Lindau and Neher (1988) to obtain an exact solution of β_ω at ω_0 .

$$R_s = \frac{\mathbf{A}_{\omega n} - b}{\mathbf{A}_{\omega n}^2 + \mathbf{B}_{\omega n}^2 - \mathbf{A}_{\omega n}b} \quad (31)$$

$$R_m = \frac{1}{b} \frac{(\mathbf{A}_{\omega n} - b)^2 + \mathbf{B}_{\omega n}^2}{\mathbf{A}_{\omega n}^2 + \mathbf{B}_{\omega n}^2 - \mathbf{A}_{\omega n}b}, \quad (32)$$

where $b = 1 / (R_s + R_m)$ and $n = 0, 1$.

Equating R_s (or R_m , either of which produce the exact same result) determined at two angular frequencies, ω_0 and ω_1 , provides two solutions for b (b_0, b_1 ; solutions not shown), and therefore two solutions for τ_{clamp} at ω_0 (obtained by utilizing Pusch and Neher's (1988) solution for C_m ; their Eq. 7),

$$\tau_{\text{clamp}_n} = \frac{\mathbf{A}_0 - b_n}{\mathbf{B}_0 \omega_0}. \quad (33)$$

Notably, however, either solution of τ_{clamp} , τ_{clamp_0} , or τ_{clamp_1} , when used to derive the angle of $\partial \mathbf{Y} / \partial \omega$, i.e., $\beta_{\omega 0}$, from Eq. 18 produces only one, unique result, namely

$$\beta_{\omega 0} = \tan^{-1} \left[\frac{1}{2} \frac{\mathbf{A}_1^2 - 2\mathbf{A}_1\mathbf{A}_0 + \mathbf{A}_0^2 - \mathbf{B}_0^2 + \mathbf{B}_1^2}{\mathbf{B}_0(\mathbf{A}_1 - \mathbf{A}_0)} \right], \quad (34)$$

where the subscripts denote the real (\mathbf{A}) and imaginary (\mathbf{B}) admittance components at any two angular frequencies, ω_0 and ω_1 . It should be pointed out that whereas two frequencies are required to obtain β_ω , the value itself is derived from $\partial \mathbf{Y} / \partial \omega_0$, whose location is exactly at ω_0 .

$$d_\omega \mathbf{Y} / d\omega_0 = \lim_{\Delta\omega \rightarrow 0} \mathbf{Y}_{\omega_0 + \Delta\omega} - \mathbf{Y}_{\omega_0} \quad (35)$$

$$\partial \mathbf{Y} / \partial \omega_0 \triangleq d_\omega \mathbf{Y} / d\omega_0, \quad (36)$$

that is, all three pieces of information, \mathbf{B}_Y , \mathbf{A}_Y , and β_ω that are used to measure C_m theoretically derive from single (ω_0), not dual, frequency inspection.

Present vesicle fusion

The fusion of independent membrane-bound compartments (vesicle to the plasma membrane or gap junctional coupling between two cells) can be evaluated with input capacitance measures, and modeled to obtain component values of the

applicable circuit (Fig. 1 *B*) (Zhao and Santos-Sacchi, 1998; Bigiani and Roper, 1995; Santos-Sacchi, 1991a). Below, I focus on vesicular fusion. If experiments are performed using the cell-attached mode it must be determined that the cell's input admittance is far greater than the patch admittance. Additionally, data must be corrected posthoc after determination of stray pipette capacitance (perhaps using the Sylgard bead-sealing technique (Sakmann and Neher, 1995)), which may be greater than patch capacitance. Thus, the application of this method under cell-attached mode is not straightforward. Nevertheless, in that case, or if vesicle fusion is monitored under whole-cell mode, the following applies; the subscript m denotes either patch or whole-cell characteristics. The input admittance before (\mathbf{Y}_b) and after (\mathbf{Y}_a) vesicle fusion differs.

$$\mathbf{Y}_b = [\mathbf{R}_s + \mathbf{Y}_m^{-1}]^{-1} \quad (37)$$

$$\mathbf{Y}_a = [\mathbf{R}_s + (\mathbf{Y}_m + \mathbf{Y}_v)^{-1}]^{-1}, \quad (38)$$

where

$$\mathbf{Y}_v = \left[R_p + \frac{R_v}{1 + j\omega R_v C_v} \right]^{-1}. \quad (39)$$

Typically, access to the circuit parameters defining the vesicle admittance (\mathbf{Y}_v : R_p , R_v , and C_v ; see Fig. 1 *B*) is obtained experimentally by making an inescapable assumption – that at the onset of fusion R_s , R_m , and C_m remain unchanged. Given the model, without this assumption estimates cannot be obtained with confidence.

The original and still common method to calculate vesicle parameters, including fusion pore conductance, employs capacitance compensation to estimate vesicle admittance (Breckenridge and Almers, 1987; Lindau, 1991; Ales et al., 1999). In this case, membrane admittance before fusion is removed by subtracting the \mathbf{Y}_m baseline determined by capacitance compensation dithering (Neher and Marty, 1982); the subsequent change in admittance after vesicle fusion is used to calculate vesicle components based on a simplified vesicle circuit model of C_v in series with R_p (Breckenridge and Almers, 1987). We can employ the *eCm* method to arrive at \mathbf{Y}_v , in a similar manner. First, \mathbf{Y}_m is extracted from \mathbf{Y}_b , the exact value of R_s having been obtained by analysis (see above) before fusion.

$$\mathbf{Y}_m = - \left[\frac{\mathbf{Y}_b}{\mathbf{Y}_b R_s - 1} \right]. \quad (40)$$

Consequently, the vesicle admittance, \mathbf{Y}_v , which includes the fusion pore, can be calculated (by substitution of Eq. 40 into Eq. 38) as a function of admittances measured before and after fusion,

$$\mathbf{Y}_v = \frac{R_s^{-2}(\mathbf{Y}_b - \mathbf{Y}_a)}{(R_s^{-1} - \mathbf{Y}_b)(R_s^{-1} - \mathbf{Y}_a)}. \quad (41)$$

From inspection of the vesicle circuit (Fig. 1 B), it is clear that

$$I_{Rp} = I_{Rv} + I_{Cv}, \quad (42)$$

that is, we have the analogous circuit conditions that we analyzed above in the absence of fusion. The parameters R_p , R_v , and C_v simply and, respectively, replace R_s , R_m , and C_m . Using the same analysis logic as above, the magnitude and angle of $\partial\mathbf{Y}_v/\partial C_v$ is obtained, thus enabling the solution of all vesicle circuit parameters. The following equations detail fusion event analysis.

$$C_v = H_{cv}\mathbf{B}_{Yv} = \frac{\mathbf{B}_{Yv}}{|\partial\mathbf{Y}_v/\partial C_v|} = \mathbf{B}_{Yv} \frac{(1 + \omega^2\tau_f^2)}{\omega \left[1 - \frac{\tau_f}{\tau_v}\right]^2} \quad (43)$$

$$R_v = \frac{\tau_v}{C_v} \quad (44)$$

$$R_p = \frac{-\tau_f\tau_v}{C_v(\tau_f - \tau_v)}, \quad (45)$$

where

$$\tau_f = [-\tan(\beta_{\omega v}) \pm \sqrt{1 + \tan(\beta_{\omega v})^2}] \omega^{-1} \quad (46)$$

$$\tau_v = \frac{1 - \omega^2\tau_f^2 - 2\eta\omega\tau_f \pm \left[\sqrt{1 + \eta^2} + \sqrt{1 + \eta^2\omega^2\tau_f^2} \right]}{\omega(-\eta + \eta\omega^2\tau_f^2 - 2\omega\tau_f)}, \quad (47)$$

and

$$\eta = \tan \left[2 \tan^{-1} \left(\frac{\mathbf{B}_{Yv}}{\mathbf{A}_{Yv}} \right) \right]. \quad (48)$$

Simulations and biological cell examples

I provide several approaches to evaluate the *eCm* method of parameter estimation, including mathematical modeling, physical modeling, and tests on biological cells. It is important to realize that tests on biological cells may provide important information on real-world capabilities, but cannot be used to truly verify the validity of an approach. For example, it is impossible to know if a certain time course of C_m change is truly occurring in cells, unless, of course, confirmation is obtained through other measures. However,

physical and mathematical model evaluations can confirm validity of an approach, and do provide confidence that the results from biological cells are sound. In the first set of evaluations, MatLab (Natick, MA) was used to model the circuit admittance and implement *eCm* strictly in the frequency domain. In the following mathematical and physical simulations, measures were made at an f_0 of 390.6 Hz and f_1 of twice that, delivered simultaneously, unless otherwise noted. Amplitudes at each frequency were set equal, at 10–20 mV peak. Fig. 2 presents a simple whole-cell mathematical model simulation where the circuit parameters are stepped to evaluate component interactions on C_m measures; comparisons are made of calculated component values using either the *eCm* method or other approaches that contain approximations. Clearly, *eCm* is superior, and is impervious to fluctuations in circuit component values. Fig. 3 presents another mathematical simulation in Matlab where vesicle fusion under whole-cell mode is evaluated, and compared with the standard methodology (Breckenridge and Almers, 1987; Lollike et al., 1995). Both methods are excellent even in the face of substantial R_s changes, but even with changes in vesicle resistance the *eCm* method produces an exact reconstruction of the model parameter changes. Although these model data highlight the exact nature of the *eCm* method, more demanding modeling efforts show the method's strengths. For the tests that follow, capacitance measures were obtained with *eCm* as implemented in the software package jClamp using a time resolution of 2.56 ms (i.e., f_0 of 390.6 Hz), unless otherwise noted.

Fig. 4 shows the results of a physical implementation of the simple model in Fig. 1 A under voltage clamp during a large step in capacitance, that was evoked by physically dislodging an additional capacitor that was placed parallel with C_m . Simultaneous measures of R_s and R_m remain essentially unperturbed. To evaluate large changes in R_m , this parallel approach did not work because of associated parasitic capacitances of the large resistances involved. Instead, Fig. 5 shows two separate measures where all circuit and measurement details remained exactly the same except that either a 50-M Ω or 800-M Ω R_m resistor was soldered into place. Again, there are minimal changes in C_m measures. Fig. 6 shows the effects of maladjustments of the amplifier's fast capacitive compensation on parameter estimates. The model cell was measured over 10 seconds at a resolution of 2.56 ms while changes in compensation were made. Stray R_s capacitance of ± 0.15 pF had little effect on C_m ($\pm 0.4\%$) or R_m ($< \pm 0.01\%$) parameter estimation. R_s estimates varied $\pm 1.8\%$.

Finally, in Figs. 7 and 8 biological cells are investigated. Fig. 7 shows measures of outer hair cell (OHC) capacitance obtained with jClamp using a time resolution of 512 μ s. Detrending of data before analysis was performed (Santos-Sacchi, 2002). The rapid relaxation in capacitance during a step voltage change is due to the shift of the cell's nonlinear Q - V function along the voltage axis (Santos-Sacchi et al.,

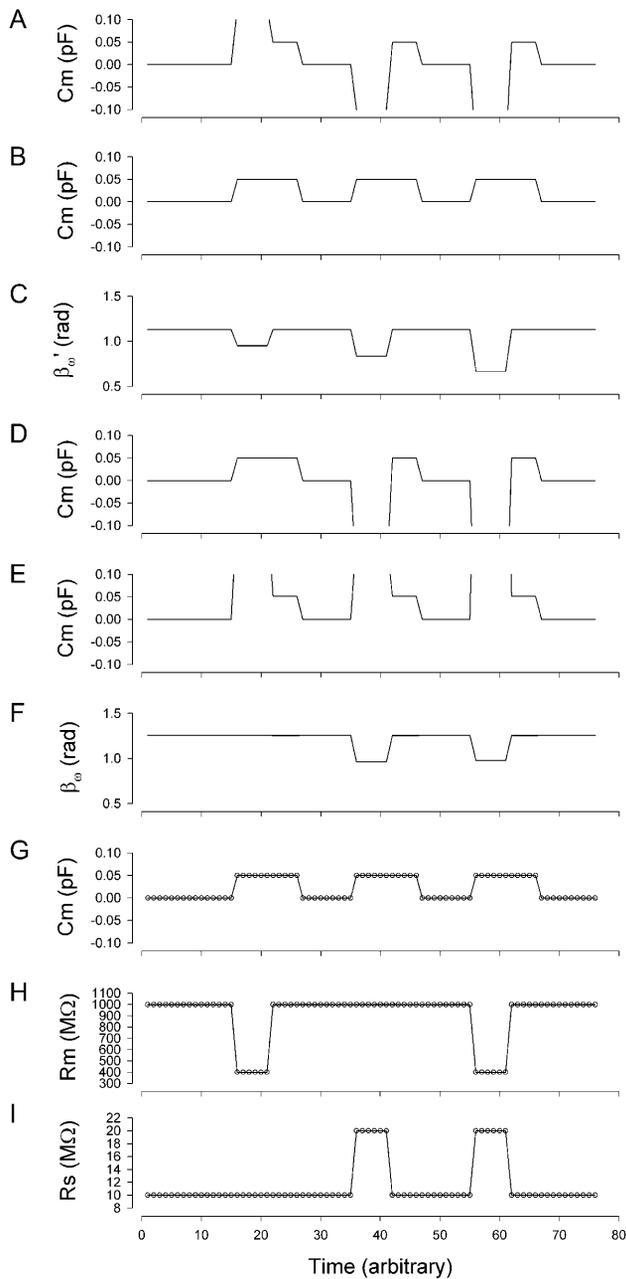

FIGURE 2 Simulation of capacitance changes in whole-cell mode. The component values of the model (R_s : 10 M Ω , R_m : 1 G Ω , and C_m : 6.5 pF) in Fig. 1 A were modulated out of phase with each other, with a C_m jump of 0.05 pF accompanied by either a 600-M Ω drop in R_m , or a 10-M Ω increase in R_s or all changes occurring simultaneously (see panels G–I). The stimulating frequency f_0 was the same for single-sine and eCm methods, with f_0 at 390.6 Hz and f_1 at twice that. In panels A–C, calculations are based on setting the PSD angle to an estimate (denoted by the prime) of β_ω , the angle of $\partial\mathbf{Y}/\partial G_s - 90^\circ$, $\beta'_\omega = (2 \tan^{-1}(\mathbf{B}_Y/\mathbf{A}_Y) - 90^\circ)$, to mimic R_s dithering. (A) A true piecewise linear approach was employed using this angle β'_ω in place of β_ω in Eq. 52. Whole-cell capacitance compensation was modeled by connecting and supplying the circuit components R_d and C_d (Fig. 1) with corresponding values of R_s and C_m , but with an overall negative admittance. PSD angle and gain corrections ($1/|\text{abs}(\partial\mathbf{Y}/\partial C_m)|$) were determined from whole-cell conditions at the zero time point and remained fixed throughout. It can be seen that when cell components are changed (G–I) the phase angle changes causing errors in C_m estimation (A). Even

1998). In that article, we confirmed through alternative measures that the time course of C_m relaxation corresponded to the shift. The shift signifies the very rapid change in the gain of OHC electromotility, a process that likely drives the mammalian cochlear amplifier (Santos-Sacchi, 2003). The solid shaded line is a triple exponential fit to the data. The three time constants are 1.04, 5.96, and 36 ms. This time course is over an order of magnitude faster than has been previously reported (Santos-Sacchi et al., 1998). The substantial noise levels in this trace derive from the huge nonlinear capacitance (>20 pF) and low input resistance (<300 M Ω) of the OHC. For comparison, Fig. 8 shows capacitance measures in a HEK cell transfected with prestin (Meltzer and Santos-Sacchi, 2001), where C_m noise was 5.5 fF (rms; 0.256 ms time resolution (f_0 : 390.6 Hz); see discussion on noise effects below). This cell possesses a nonlinear Q_{max} (by fitting the Q - V curve with a two-state Boltzmann function (Santos-Sacchi, 1991b)) of 63.7 fC, giving rise to a peak voltage-dependent capacitance at -101 mV of 420 fF. The figure shows a 30-fF step in capacitance when voltage was stepped from $+50$ mV to $+30$ mV. These data indicate that the sensitivity of the eCm method is well within the range required for fusion event analysis.

though the PSD angle is set to guard against R_s changes, a change from 10 to 20 M Ω (I) is too large to counter; such overpowering effects of parameter changes are well known (Lindau, 1991). However, if capacitance compensation is not employed and point-by-point resetting of new angle and gain factors are made and applied, absolute C_m is obtained without any errors (B). To make point-by-point corrections experimentally, the raw admittance (\mathbf{Y}) at each point was taken and the angle of β'_ω was calculated according to Zierler (1992), namely, $\beta'_\omega = (2 \tan^{-1}(\mathbf{B}_Y/\mathbf{A}_Y) - 90^\circ)$. The true gain factor, H_c , at each data point was calculated as $1/|\text{abs}(\partial\mathbf{Y}/\partial C_m)|$. With each new gain and angle, circuit parameters were calculated as in Eq. 52, by extracting the component of \mathbf{Y} at that phase angle and multiplying by that gain factor. Each admittance point was so treated to obtain circuit parameters. The reason this procedure works so well is that the value returned by this modified PSD analysis is the imaginary component of \mathbf{Y} ; thus, this method produces the same results as the eCm method as shown in panel G. This useful single-sine approach, employing the estimate of H_c provided by Gillis (1995), $H'_c = \omega/1 + \tan(\pi/2 - \mathbf{B}_Y)^2$, is implemented in jClamp. However, because this is an estimate of the true gain, $1/|\text{abs}(\partial\mathbf{Y}/\partial C_m)|$, relying on circuit approximations, C_m estimates are not fully immune from circuit parameter changes. In panels D–F, calculations are based on setting the PSD angle to the angle of $\partial\mathbf{Y}/\partial C_m$, namely β_ω , to mimic capacitance compensation dithering. (D) The true piecewise linear approach was employed as above in panel A. In this case, using β_ω , the large change in R_m does not affect the phase angle substantially (F), so C_m estimates are accurate and robust. However, R_s changes do interfere with angle and estimate, as expected (Joshi and Fernandez, 1988). Unlike the treatment above (B), panel E shows that applying a point-by-point correction as detailed above to the uncompensated admittance fails to provide error free C_m estimation, because the imaginary component of \mathbf{Y} is not returned in this case. Panels G–I show the results of the eCm method, where the calculated absolute values are depicted by the circles. Note an exact correspondence between actual parameter values (solid lines) and calculated estimates (\circ), with no parameter interactions. Simulation in MatLab.

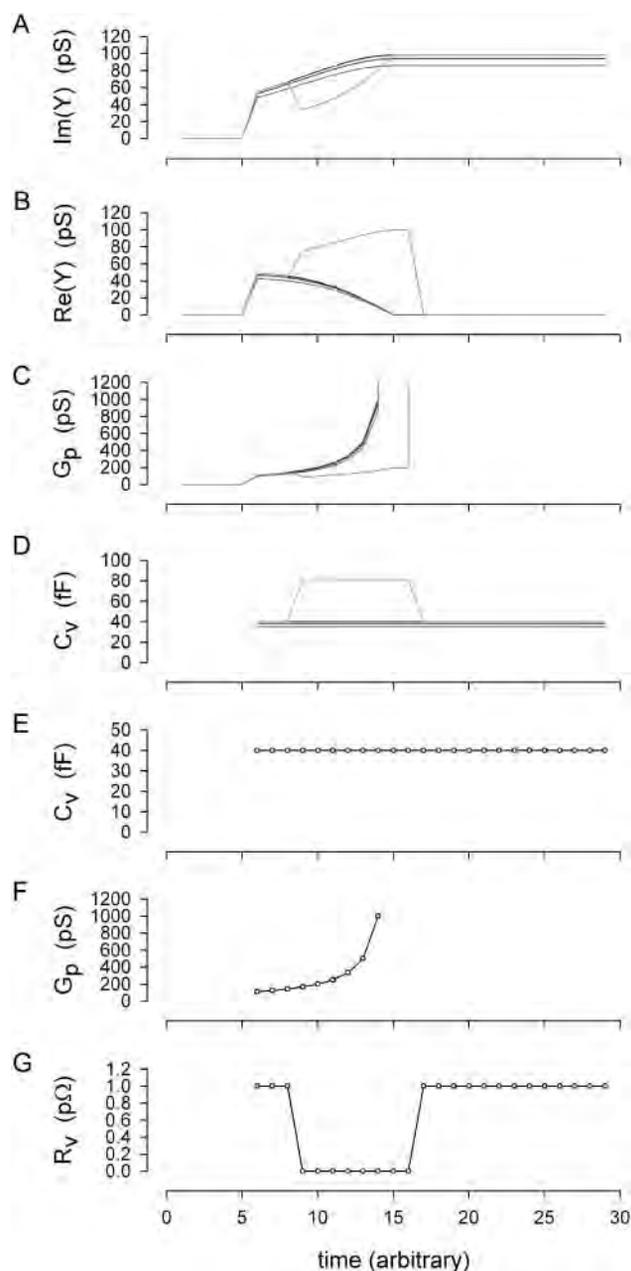

FIGURE 3 Simulation and analysis of vesicle fusion event. Whole-cell conditions remained constant throughout simulation at R_m : 1 G Ω , and C_m : 6.5 pF, with R_s : 1, 10, and 20 M Ω for dark traces (vesicle resistance, R_v , held constant at 1 p Ω (1e15 Ω)). For the shaded trace, R_s was 1 M Ω and vesicle resistance, R_v , was stepped transiently from 1 p Ω to 10 G Ω as shown in panel G. (A, B) Imaginary and real components of admittance determined according to Breckenridge and Almers (1987). (C, D) Vesicle pore conductance and capacitance extracted from admittance using standard methodology (Breckenridge and Almers, 1987; Lollike et al., 1995). Note very good correspondence between components of model even when R_s changes substantially (solid lines in panels E, F), but not when R_v is altered (shaded line). This discrepancy is not unanticipated because the standard methodology sets R_v as infinite (Breckenridge and Almers, 1987; Lollike et al., 1995). (E, F) Vesicle model parameters (solid lines) and estimates made with the *eCm* method (\circ). Correspondence is exact under all conditions. At time >5, vesicular fusion was simulated by linearly ramping the fusion pore resistance (R_p ; initially infinite) from 9 G Ω (111 pS) to 1 G Ω

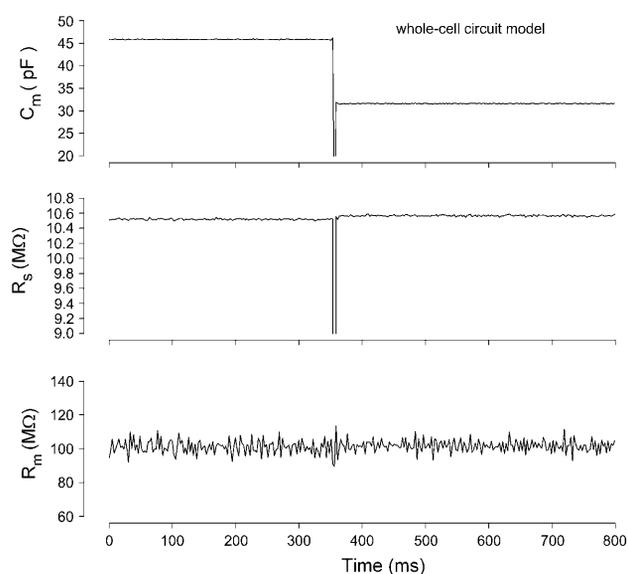

FIGURE 4 Effects of large C_m changes on parameter estimates with the *eCm* method. Nominal initial component values of R_s : 10 M Ω , R_m : 100 M Ω , and C_m : 33 pF \parallel 15 pF. A step decrease in capacitance was accomplished by suddenly removing the parallel 15 pF component. The three panels show the calculated values of the parameters using the *eCm* method at a sampling rate of 2.56 ms. Note large abrupt drop in capacitance (top) with virtually no effect on measures of R_s and R_m (middle and bottom). Model was voltage clamped with a PC clone, Axon 200 amplifier (Union City, CA) in resistive feedback mode ($\beta = 0.1$), 10-kHz Bessel filter, and Axon 1322A A/D D/A board.

DISCUSSION

Three pieces of information are required to determine the circuit parameters, R_s , R_m , and C_m of the traditional patch-clamp-cell model circuit (Fig. 1 A). The typical information obtained in a one-frequency (ω_0) measurement, namely, the real and imaginary components of the admittance, is insufficient. A third piece of information is required, and is usually obtained by exploring beyond ω_0 , that is, by utilizing information obtained at frequencies other than ω_0 . One popular solution is the “sine + dc” method (Pusch and Neher, 1988; Gillis, 2000), where a third piece of information, the input resistance ($R_{in} = R_s + R_m$), is extracted based on a priori knowledge of membrane reversal potential. This is basically a measurement at $\omega_1 = 0$. Alternatively, another non-dc piece of information, the admittance at $\omega_1 > 0$ ($\omega_1 \neq \omega_0$) can be used to extract R_{in} (Santos-Sacchi et al., 1998; Santos-Sacchi, 2002). The latter approach benefits from statistical modeling to obtain an optimal result (Barnett and Mislser, 1997). In this report, I have uncovered an additional piece of information at ω_0 , namely, β_{ω} , which can be used to determine all circuit parameters. Despite the location of β_{ω} precisely at ω_0 , the method does require two-frequency stimulation, and therefore analogous to the standard dual-sine method, it is

(1000 pS); the resulting pore conductance is shown in panel F (solid line). Fusion event analysis was implemented at that time.

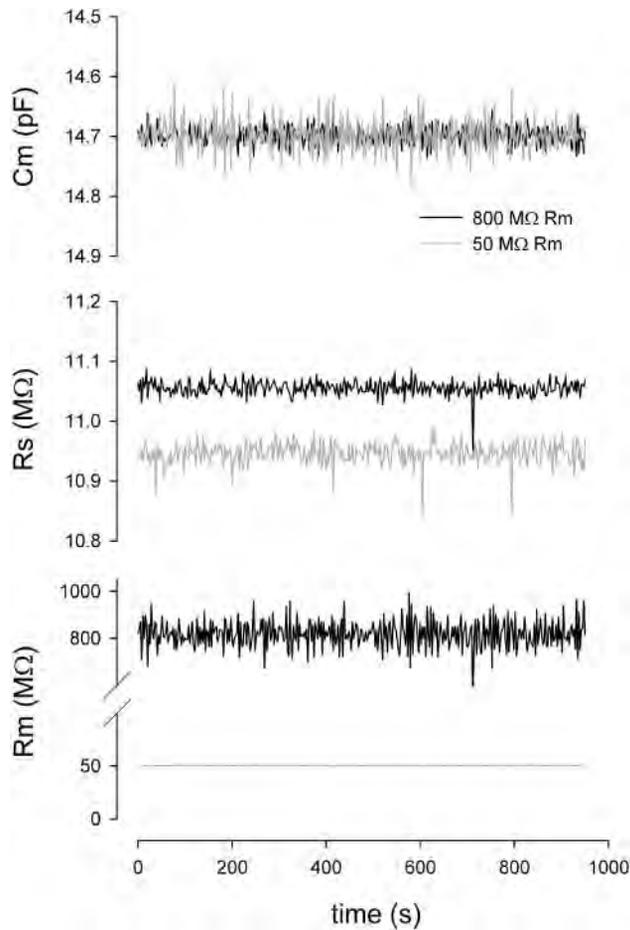

FIGURE 5 Effects of large R_m changes on parameter estimates with the eCm method. Nominal component values of R_s : 10 M Ω , R_m : 50 or 800 M Ω , and C_m : 15 pF. Note minimal interference with C_m and R_s estimates when a 50-M Ω resistor replaced the 800-M Ω resistor, other than changes in noise levels. PC clone, Axon 200 amplifier in capacitive feedback mode, 10-kHz Bessel filter, and Axon 1322A A/D D/A board were used.

reasonable to expect that optimal results could arise from further refinement (Barnett and Mislner, 1997). I should also note that because β_ω depends on τ_{clamp} , an alternative approach would be fitting of current transients induced by step voltage commands. Of course, any method that does not measure β_ω synchronously with the primary frequency component will be unable to correct for changes in cell parameters on a point-by-point basis. This will limit the utility of the technique, and this limitation is inherent in all “pause and dither” techniques. The eCm method benefits from point-by-point correction because gain and angle are redetermined and applied point-by-point at the f_0 rate.

Relation of the eCm method to traditional phase-tracking methods

The eCm method that I have developed here simply estimates absolute C_m by dividing the imaginary component of the input admittance (\mathbf{B}_Y) at a single frequency by the

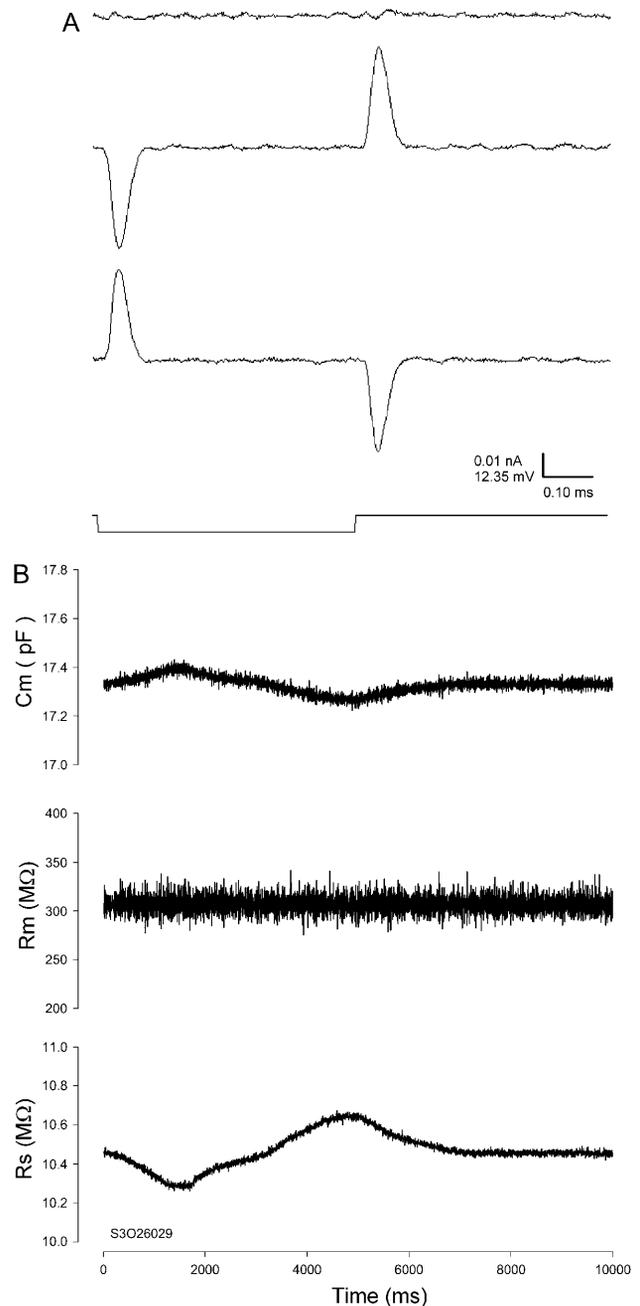

FIGURE 6 Effects of uncompensated stray capacitance on C_m measures with the eCm method. (A) Capacitive currents evoked by voltage step. Model R_s was in headstage but ungrounded. (Top) Fully compensated, (middle) undercompensated, and (bottom) overcompensated. The effect of these extremes was evaluated during parameter estimations after reassembly of the model circuit. (B) The three panels show model cell parameter estimates during manual under- and overcompensation of fast capacitance compensation. C_m was modulated $\pm 0.3\%$; R_s , $\pm 1.8\%$; and R_m , $< \pm 0.01\%$. The increase in C_m occurred during undercompensation. Nominal component values of R_s : 10 M Ω , R_m : 300 M Ω , and C_m : 18 pF. C_m noise: 14.6 fF rms; system noise with model 3.75 pA rms, 10-kHz Bessel filter, PC clone, Axon 200 amplifier in capacitive feedback mode, and Axon 1322A A/D D/A board.

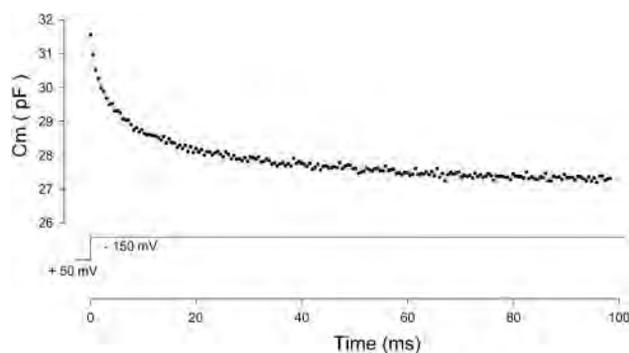

FIGURE 7 Measurement of outer hair cell nonlinear capacitance with the eC_m method. The rapid relaxation in capacitance during a step voltage change is due to the shift of the cell's nonlinear Q - V function along the voltage axis (Santos-Sacchi et al., 1998), and was confirmed through alternative measures. Cell was clamped with a PC clone, Axon 200B amplifier, 10-kHz Bessel filter, and Axon 1321A A/D D/A board with conditions described previously (Santos-Sacchi et al., 1998). See text for further details.

absolute value of the partial derivative $\partial \mathbf{Y} / \partial C_m$ at that same frequency. This method has an unforeseen relation to traditional phase-tracking techniques. The original phase-tracking method was devised to account for and limit the effects of resistive components on C_m measures (Neher and Marty, 1982; Joshi and Fernandez, 1988). It is a method that theoretically strives to determine C_m changes through measurement of changes in input admittance ($\Delta \mathbf{Y}$) as a function of changes in the circuit parameter, C_m .

$$\Delta I_{C_m} \approx \partial \mathbf{Y} / \partial C_m \Delta C_m V \quad (49)$$

$$\Delta C_m \approx \frac{1}{\partial \mathbf{Y} / \partial C_m} \frac{\Delta I_{C_m}}{V} \quad (50)$$

$$\Delta C_m \approx \frac{1}{|\partial \mathbf{Y} / \partial C_m|} \operatorname{Re} \left[\frac{\Delta \mathbf{Y}}{e^{j\beta_\omega}} \right] \quad (51)$$

$$\Delta C_m \approx H_c \operatorname{Re}(\Delta \mathbf{Y} e^{-j\beta_\omega}). \quad (52)$$

The latter equation is related to the nonsimplified form of Eq. 43 in Gillis (1995) and is addressed in a subsequent article of his (Gillis, 2000). However, heretofore, approximations of both β_ω and H_c have only been possible. The benefits and drawbacks of using particular parameter approximations have been discussed in detail (Joshi and Fernandez, 1988). Thus, phase-tracking paradigms that use estimates of the magnitude and angle of $\partial \mathbf{Y} / \partial C_m$ are recognized as better suited to systems where R_s is stable and R_m may fluctuate (Joshi and Fernandez, 1988). However, where the resistive components have the converse behavior, the angle of $\partial \mathbf{Y} / \partial G_s - 90^\circ$, namely, $2 \tan^{-1} (\mathbf{B}_Y /$

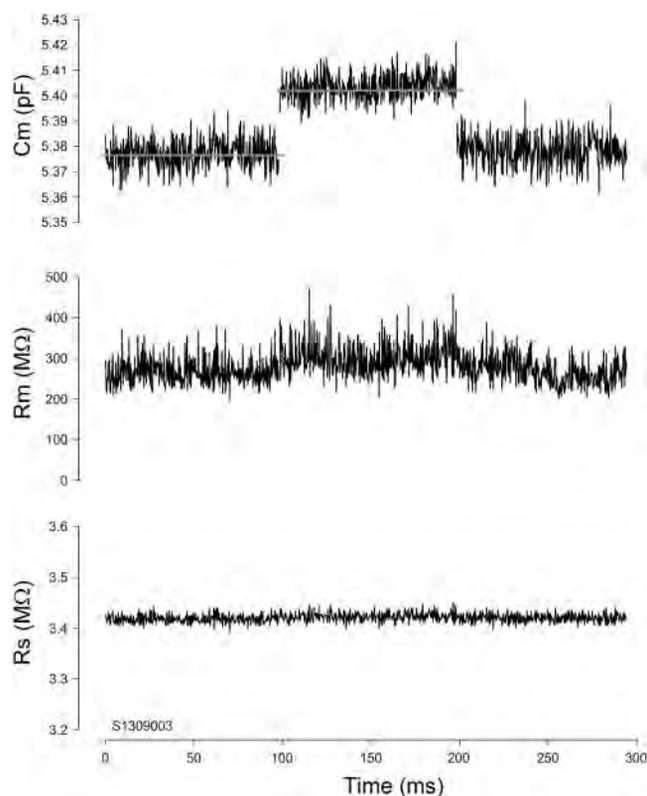

FIGURE 8 Measurement of capacitance step in prestin transfected HEK cell. Under voltage clamp a step voltage from +50 mV to +30 mV evoked a step increase in capacitance of 30 fF. C_m noise: 5.5 fF rms. PC clone, Axon 200B amplifier in resistive feedback mode, 10-kHz Bessel filter, and National Instruments (Austin, TX) PCI-6052E A/D D/A board were used.

$\mathbf{A}_Y) - 90^\circ$ as nicely provided by Zierler (1992), may be a better choice (Joshi and Fernandez, 1988). Unfortunately, where both resistive components simultaneously fluctuate, phase tracking is problematic. Despite these caveats, and even with the correct quantities I now provide, implementation of the phase tracking either by feeding the raw current output of the patch clamp into a hardware lock-in amplifier or a software phase detector (PSD) appears to be an inappropriate implementation of the phase analysis concept (Joshi and Fernandez, 1988; Neher and Marty, 1982; Fidler and Fernandez, 1989). That is, if the analyzed signal is \mathbf{Y} , then in contradistinction to Eq. 52,

$$\Delta C_m \neq H_c \operatorname{Re}(\mathbf{Y} e^{-j\beta_\omega}). \quad (53)$$

Consequently, the result of evaluating \mathbf{Y} (or I_{R_s}) directly should not provide an accurate picture of changes in C_m (i.e., ΔC_m).

The surprising fact is, however, that implementations using direct evaluations of \mathbf{Y} can, under certain conditions, provide very good estimates of absolute C_m .

It should be noted that applying capacitance and series resistance compensation at the onset of an experiment cannot be construed as providing a ΔI_{R_s} (i.e., $\Delta \mathbf{Y} V$) output from the

amplifier. This is simply a one-time subtraction that would have to be repeated, along with a new angle determination, every time a data point is collected. Additionally, only a two-element model is used by amplifiers for such compensation.

One reason for success with this direct approach would be if R_s were very small, i.e., as R_s approaches zero, $\beta_\omega \approx \Phi = 90^\circ$, and absolute values of I_{C_m} will be evaluated. Unfortunately, it is unlikely that R_s will be so low (and maintained so low) so as to approach this condition. Notwithstanding this apparent quandary, it is possible to implement phase-tracking paradigms with direct evaluations of \mathbf{Y} and still obtain excellent estimates of C_m in the face of very large changes in R_s and R_m . Surprising, the angle returned by series resistance dithering works better than that returned by capacitance compensation dithering.

Series resistance dithering

Dithering of the series resistance, championed by Joshi and Fernandez (1988), is used to return a close approximation of β_ω , namely $\angle \partial \mathbf{Y} / \partial G_s - 90^\circ$. This approximation, however, when used with a direct analysis of \mathbf{Y} , rather than $\Delta \mathbf{Y}$, and point-by-point (i.e., real time) gain and angle correction is surprisingly exact (see the simulations in Fig. 2 B). The outcome of such an implementation does not suffer from the caveats normally expected with the phase-tracking approach (Joshi and Fernandez, 1988)—namely, large changes in R_m (or R_s) have no effect on the measure of C_m . The reason for this is because the angle of $\partial \mathbf{Y} / \partial G_s$ is twice the angle of \mathbf{Y} (Zierler, 1992), and the PSD measurements are simply returning \mathbf{B}_Y ,

$$\mathbf{B}_Y = \text{Im}(\mathbf{Y}) \quad (54)$$

$$\mathbf{B}_Y = \text{Re}[\mathbf{Y} e^{-j(\angle \partial \mathbf{Y} / \partial G_s - \pi/2)}] = \text{Re}[\mathbf{Y} e^{-j(2\angle \mathbf{Y} - \pi/2)}]. \quad (55)$$

Thus, whereas Eq. 53 fails to provide ΔC_m estimates, simply replacing the angle $\angle \partial \mathbf{Y} / \partial C_m$ with $\angle \partial \mathbf{Y} / \partial G_s - 90^\circ$ results in an exact solution for absolute C_m , as shown previously in Eq. 26,

$$C_m = H_c \mathbf{B}_Y = H_c \text{Re}[\mathbf{Y} e^{-j(\angle \partial \mathbf{Y} / \partial G_s - \pi/2)}]. \quad (56)$$

Any complex number can be evaluated at twice its angle to return its real component and at twice its angle -90° to return its imaginary component. Thus, in this case, it turns out that the eCm method is simply being employed.

Capacitance compensation dithering

The initial work of Neher and Marty (1982) utilized capacitance compensation dithering to obtain an angle at which to evaluate, via PSD, changes in C_m . The angle provides an excellent approximation of β_ω when capacitance

compensation is in effect. This is shown by inspection of $\partial \mathbf{Y} / \partial C_d$ and its angle, based on the model of Fig. 1 A, now including the capacitance compensation components C_d and R_d (in series with each other, from headstage to ground).

$$\partial \mathbf{Y} / \partial C_d = \frac{-j\omega}{(R_d C_d \omega - j)^2} \quad (57)$$

$$\angle \partial \mathbf{Y} / \partial C_d = -\tan^{-1} \left[\frac{\omega^2 \tau_d^2 - 1}{2\omega \tau_d} \right], \quad (58)$$

where $\tau_d = R_d C_d$.

β_ω , the angle of $\partial \mathbf{Y} / \partial C_m$, remains unaffected by the addition of the capacitance compensation circuitry,

$$\beta_\omega = -\tan^{-1} \left[\frac{\omega^2 \tau_{\text{clamp}}^2 - 1}{2\omega \tau_{\text{clamp}}} \right], \quad (59)$$

thus indicating that when the clamp time constant (τ_{clamp}) and compensation time constant (τ_d) are equal, i.e., when compensation is in effect, the angle returned by dithering equals β_ω . Unlike the use of the angle returned by series resistance dithering, the use of this angle to measure C_m with direct evaluations of \mathbf{Y} is not as accurate (Fig. 2 E). It should be noted that these analyses only apply to direct measures of \mathbf{Y} that are corrected on a point-by-point basis for phase and gain changes, and not necessarily to the traditional use of the angle (Neher and Marty, 1982).

Validity, accuracy, and sensitivity of C_m measurement methods

There are several factors, including model validity, approximations, and noise that contribute to errors in the measurement of capacitance with sinusoidal analysis. Obviously, approximations lead to errors only if they fail; however, because approximations often remove a particular component, e.g., R_s or R_v , from the system of equations, it is impossible to gauge failure during an experiment. Thus, it is prudent to make as few simplifications and approximations as possible. The mathematical and physical modeling that I have presented clearly indicate that the eCm method benefits from this rule.

Noise, on the other hand, is an issue that affects all electrical measures of cell activity regardless of the method's validity. Even for a method that provides a valid measure of some electrical quantity in the absence of noise, the introduction of noise can prove devastating, or at least render it useless for a given task. Not surprisingly, some methods may be able to deal with system noise better than others.

The design of sinusoidal stimulus protocols has enormous impact on C_m measurement sensitivity in the face of real-world noise. Important issues such as stimulus frequency,

stimulus magnitude, stray capacitance, and unexpected conductance changes have been discussed in detail (Gillis, 1995; Barnett and Mislner, 1997; Thompson et al., 2001; Debus et al., 1995). Careful attention to these issues can lead to incredible sensitivity; for example, with very high-frequency stimulation and very large voltages, very good signal/noise ratios can be obtained, providing noise floors well below 1 fF (Klyachko and Jackson, 2002). One of the consequences of the equivalency between the *eCm* method and the phase-tracking method as typically employed, is that effects of noise on performance might be expected to be similar for each method. To evaluate issues like this, comparisons were made under varying noise conditions in model simulations.

In Fig. 9, a modeling approach is used to compare the effects of Gaussian noise levels on C_m estimate noise among a few common methods of C_m estimation. In this approach, the simple circuit of Fig. 1 A was modeled in the time domain using the RK4 method hardcoded in C within jClamp; the results were then independently analyzed by transient step analysis, single-sine analysis, dual-sine analysis, or the *eCm* method. Step analysis follows the method outlined in a prior publication (see appendix in Huang and Santos-Sacchi,

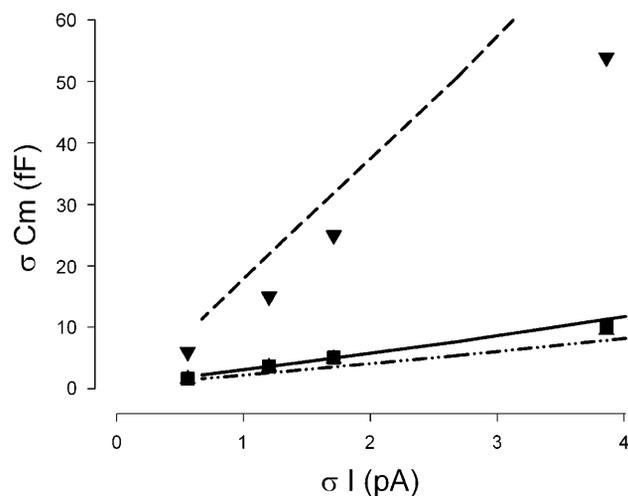

FIGURE 9 Effect of system noise on C_m estimate noise. Results from either mathematical modeling (lines) or physical modeling (symbols). Three methodologies, step (dashed line, ▼), *eCm* (dash-dotted line, ▲), and single-sine phase tracking (solid line, ■) are presented. For the software model, forced Gaussian noise levels were imposed, and the noise of C_m estimates calculated. For the physical model, system noise levels were 3.8 pA rms when the model was attached to the headstage. To obtain lower system noise levels, averaging was performed to produce the plotted noise levels. For the electrical model, a 10-kHz Bessel filter was used, and the frequency components of the remaining noise were likely different from the wideband noise used for the math model. This likely accounts for differences in math and electrical model results. In any case, the data from each model indicate that as system noise decreases, all of the methods become comparable. Nominal component values of R_s: 10 MΩ, R_m: 300 MΩ, and C_m: 18 pF. IBM T40 laptop in battery mode (Armonk, NY), Axon 200 amplifier in capacitive feedback mode, 10-kHz Bessel filter, and Quatech (Hudson, OH) DAQP 308 PCMCIA PC card A/D D/A board were used.

1993). Such an analysis is multifrequency, providing extended information similar to that obtained from “chirp” stimuli (Santos-Sacchi, 1991b; Santos-Sacchi, 1989), and wideband noise stimuli (Fernandez et al., 1982). Features of our step method included automatic clocking to reach steady state and utilization of exponential fitting after the initial onset transient, methodology recently reemphasized as important for the robust use of transient analysis for C_m measurement (Thompson et al., 2001). In our original implementation and in jClamp, a correction for errors introduced by the R_s/R_m voltage divider on Q, namely that C_m = (R_m + R_s)²/R_m² Q/V_m, is employed (Huang and Santos-Sacchi, 1993). To my knowledge, no other implementation accounts for this potential error. Single-sine analysis follows the approximation (for β_ω and H_c) method outlined in the Fig. 2 legend. The dual-sine method (Santos-Sacchi, 1992; Santos-Sacchi et al., 1998), follows the same fast Fourier transform-based determination of the real and imaginary components employed by the *eCm* method. In both cases estimates derived from both ω₀ and ω₁ are averaged (f₀: 390.6 Hz; f₁: 781.2 Hz). This averaging benefit must be kept in mind when comparing single-sine estimates. All methodologies are standard features in jClamp. In Fig. 9 the relation between measured C_m noise and imposed current noise is examined for each of the methodologies with either a 100-MΩ or 500-MΩ R_m. All methods work well under low-noise conditions, and this simply indicates that the true limitation for C_m estimation is the noise of the system at those frequencies used by the method. Indeed, under real-world conditions where system noise levels are well minimized, step, single-sine and dual-sine techniques can provide roughly equivalent C_m estimate noise levels (within ±10–30%) close to theoretical limits (Gillis, 1995; Barnett and Mislner, 1997; Thompson et al., 2001). However, under forced noise levels as in Fig. 9 the *eCm* and single-sine techniques appear better able to deal with higher noise levels than this step implementation. Because of the exact same implementation of frequency analysis and the absence of approximations for *eCm* and dual-sine approaches, sensitivities turn out to be essentially equivalent. Had β_ω been determined in another manner, e.g., by the dω approach, the results may have differed. Given the relation between the single-sine phase-tracking approach and the *eCm* method detailed above, it is not surprising that these two methods are roughly equivalent in handling noise. For each method, slightly better noise levels are achieved when β_ω is fixed during analysis to simulate a “pause and dither” approach; thus, recalculating β_ω for each sample introduces additional noise in the analysis that must be balanced with the increased validity afforded by point-by-point correction. The step analysis is particularly prone to high noise levels; this is especially obvious when low frequency (e.g., 60 Hz) interference is included, and is in marked contrast to sinusoidal approaches that can avoid extraneous spectral interference. The conclusions based on this mathematical

modeling effort were essentially confirmed with a physical implementation (see Fig. 9). From these results, it is clear that given a sufficiently low system noise or actually a sufficiently high signal/noise level, the *eCm* method will have the sensitivity to analyze fusion events, as clearly suggested by the physiological results shown in Fig. 8.

SUMMARY

The new *eCm* method that I outlined here provides another tool for analysis of cellular processes that can be interrogated by C_m measures. It is a method that works in the absence of usual simplifying assumptions and approximations of the traditional patch-clamp-cell model circuit. In detailing the approach, several new observations have been made. They include: 1), the imaginary component of the input admittance \mathbf{Y} , namely, \mathbf{B}_Y , can be worked on by $\partial\mathbf{Y}/\partial C_m$ to obtain absolute values of C_m ; 2), the angle of $\partial\mathbf{Y}/\partial C_m$, namely, β_ω , is the same as that of $\partial\mathbf{Y}/\partial\omega$ and therefore can be obtained from frequency manipulation alone; 3), given β_ω , the absolute value of $\partial\mathbf{Y}/\partial C_m$ can be determined; 4), frequency manipulation need not require an infinitesimal $d\omega$ to extract β_ω ; and 5), the traditional phase-tracking technique that evaluates raw amplifier currents, rather than difference currents, at the angle provided by series resistance dithering, works similar to the *eCm* method by simply returning estimates of \mathbf{B}_Y , not ΔI_{C_m} , and ultimately provides absolute, not delta, C_m estimates. Finally, it might be expected that enhancements of the *eCm* technique may arise from future implementations in hardware and by statistical optimizations.

I thank Peter Dallos, Fred Sigworth, and Alan Segal for looking at early drafts. I especially thank Peter Dallos for confirming some of the concepts presented in the manuscript, and identifying others that needed rethinking. Finally, I thank the reviewers for many helpful suggestions.

Thematic Issue

Membranes and Their Interacting Partners in Peripheral Auditory Function

J. Santos-Sacchi, Guest Editor

Foreword: Let's Hear It for the Membranes!

Joseph Santos-Sacchi

Otolaryngology, Neurobiology and Cellular and Molecular Physiology, Yale University School of Medicine, 333 Cedar St., New Haven, CT 06510, USA

Received: 20 February 2006

Membranes have always held a special place in my heart, having been entranced by their magic when I was a freshman at Columbia College in New York City in 1969. Of course not much was known about them then, and even less was known about how these organelles help us hear. During the next 35 years, auditory researchers worked hard to elucidate the role of membranes in inner ear function. Indeed, during that time, scores of (now) senior auditory biophysicists have shaped our knowledge of how the inner ear works. In this special issue of the *Journal of Membrane Biology*, I have broken from tradition, and chosen to enlist a large group of young (except for me, of course) independent investigators to collaborate in telling us about the importance of membranes and associated molecules in a variety of cell types within the auditory periphery. Seven review articles are presented which span the molecular workings of cells ranging from hair cells to primary afferents. We begin by looking at the first step in auditory processing, the stereocilia transduction apparatus housed in the apical stereocilia of hair cells. This unique organelle not only can convert sound-evoked mechanical stimuli into electrical signals (receptor potentials) that permit us to perceive sound, but, as well, may play an important role in a feedback mechanism that can amplify those incoming stimuli. Drs. Ricci, Kachar, Gale, and Van Netten provide us with a detailed description of these events. The hair cell does not simply cable the resultant receptor potentials to afferents, but instead shapes its

own responsiveness with the multitude of channel types within its apical and basolateral membranes. The next article in our special issue by Drs. Housley, Marcotti, Navaratnam, and Yamoah details what we know about these membrane constituents. In mammals, two hair cell types have evolved to aid in high-frequency discrimination, the inner and outer hair cells. The outer hair cell is both sensory receptor and mechanical effector, working to augment the mechanical responsiveness of the cochlea partition – cochlear amplification, as it is commonly called. Two reviews are devoted to this marvelous outer hair cell. In the first, Drs. He, Zheng, Kalinec, Kakehata, and Santos-Sacchi tell us about the experimental approaches which have led to understanding the so called electromotility of this cell and the electromechanical characteristics of the cell's lateral membrane, which houses the unique voltage-dependent motor protein, prestin (SLC26A5). The following review of OHC models by Drs. Spector, Deo, Grosh, Ratnanather and Raphael explains to the physiologists what their experiments mean! In fact, by modeling the OHC's electromechanical activity we can also glean things which experimentalists cannot yet appraise. Inner hair cells provide up to 95% of the afferent input to the CNS. The cell type that begins the transit of acoustic information to the CNS, the spiral ganglion cell, must reliably capture the activity of inner hair cells, and the synaptic events that lead to AP generation are of prime import in this process. Drs. Nouvian, Beutner, Parsons and Moser provide us with our current understanding of synaptic transmission between hair cells and eighth nerve. Of course, it is the spiral ganglion cell soma and processes that ultimately must pass this information

Correspondence to: J. Santos-Sacchi; email: joseph.santos-sacchi@yale.edu

centrally, and their membrane plays the most critical role in determining timing characteristics required for high frequency transmission. Drs. Dulon, Jagger, Lin, and Davis detail the unique characteristics of these important links to the CNS. Finally, the hair cells and nerve fibers that reside within the organ of Corti cannot stand alone. A variety of supporting-cells provide structural and metabolic support for the organ, and without them our mechanoreceptors would be useless. One of the most important aspects of supporting-cell physiology is the syncytial network provided by gap junctional communication. Muta-

tions of gap junctions account for a leading cause of deafness. Drs. Zhao, Kikuchi, Ngezahayo, and White review what we know about the role of gap junctions in cochlear homeostasis and pathology.

I think that this compilation of reviews underscores why membranes are important for peripheral auditory function. The wealth of information that these young investigators display in their reviews and the energy that these scientists bring to our field indicate that understanding membranes will remain an important goal for our community — for many years to come. Let's hear it for the membranes!

Cochlear Mechanics: No Shout but a Twist in the Absence of Prestin

Mammalian hearing is boosted by mechanically active auditory receptor cells, the outer hair cells which amplify the actions of incoming sounds. Recent evidence indicates that the molecular motor that drives this amplification, prestin, may do more than boogie.

Joseph Santos-Sacchi

About a half century ago, in experiments on the mammalian inner ear, Bekesy [1] observed acoustically driven, frequency-tuned responses of the basilar membrane, the cochlear structure which bears the sound-detecting organ of Corti. These tuned responses underlie tonotopicity, the mapping of characteristic frequency onto anatomical space throughout the auditory system. Modern measurements have shown that the peripheral auditory system response — involving sequentially the basilar membrane, hair cell and eighth nerve fiber — is nonlinear with intensity, at least at low intensities. Measures of basilar membrane motion near threshold are thus several orders of magnitude larger than Bekesy's atomic scale estimates [2]. This nonlinear response is the hallmark of cochlear amplification, and is vulnerable to metabolic insult. Metabolic lability issues from the fragile outer hair cell, one of two receptor cell types in the inner ear.

The outer hair cell employs, as Gold's 'negative resistance' hypothesis predicted [3], voltage-driven mechanical activity which helps counter cochlear fluid viscosity, thus enabling sharply tuned mechanical responses [4–6]. The identification of a unique motor protein [7], termed prestin, which is found exclusively in the outer hair cell, shed light on the molecular basis of this amplificatory process (Figure 1). As expected, elimination of prestin by knocking out its gene produced mice that were deaf, despite having normal stereociliar mechanisms [8,9], attesting to the

dominant role of prestin in mammalian cochlear amplification.

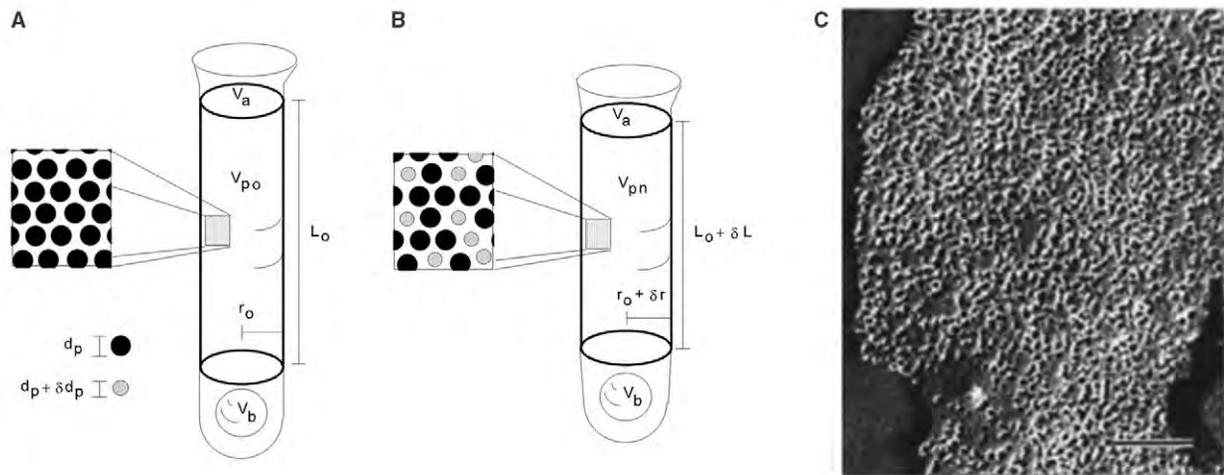

In all experiments to date in which normal outer hair cell function or specifically prestin function has been compromised, physiological measures have shown broadened frequency tuning, shifts in characteristic frequency to lower frequencies, and loss in auditory sensitivity. These experiments include studies that have also measured basilar membrane motion [10–12]. But the first measurements of basilar membrane tuning in prestin knockout mice, reported recently in *Current Biology* [13], have shown the story is more complex than suspected.

Mellado Lagarde *et al.* [13] observed that the effect on the peripheral auditory system was different when prestin was silenced by interfering with its function, for example with salicylate or anoxia, compared to when it was molecularly absent from the outer hair cell, as in the knockout mouse. In the former case, the sensitivity of both basilar membrane motion and eighth nerve activity are compromised, whereas in the latter case basilar membrane sensitivity is maintained, albeit at a shifted characteristic frequency with poor tuning, but eighth nerve activity is devastated. This is an interesting finding, as basilar membrane motions and eighth nerve fiber activity are expected to show a tight correspondence, at least in the characteristic frequency region [14]. The authors rightly point out that the dichotomy in response sensitivities between nerve and basilar membrane in the knockout mouse highlights the critical link between basilar membrane motion and inner hair cell stereociliar

shear, the drive for forward transduction and auditory sensation [15]. The inner hair cell is the other purely sensory cell that synapses with the majority of eighth nerve afferents. The paper [13] thus presents two interesting findings on the knockout mouse: first, that basilar membrane responses appear as acoustically sensitive as normal; and second, that despite the high sensitivity, coupling between basilar membrane and inner hair cell is lost. How can the absence of prestin do this?

We must revisit the effects of the prestin knockout on the outer hair cell itself. It is well known that prestin influences the static and dynamic mechanical properties of the outer hair cell [5,16–18]. There are several million prestin molecules within an outer hair cell membrane [19], and the absence of molecules reduces the membrane surface area and produces shorter cells [9]. This, in turn, affects the cell's mechanical properties. Cell stiffness also relies directly on the activity of prestin in the membrane ([17], but see [20]), possibly through cytoskeletal interactions. Collectively, these changes could alter cochlear partition impedance and account for the observed shifts in best frequency in the passive basilar membrane of the knockout mice; but can they account for the apparent increase in basilar membrane motion over that found in anoxic animals with normal prestin? Can a simple change in basilar membrane impedance and resonance overcome viscous damping effects? Or perhaps prestin did not evolve to overcome viscous damping.

Consider this evolutionary scenario that might help us understand the data. A passive cochlear with outer hair cells lacking prestin will have basilar membrane motion that we consider sensitive, but really it is just how things work in the presence of normal viscous damping. In this case, tuning at the passive characteristic frequency and coupling between basilar membrane

Current Biology

Figure 1. Prestin and outer hair cell function.

The outer hair cell soma is schematized in the fully elongated (A) and partially contracted (B) condition, corresponding to hyperpolarization and depolarization, respectively. (The abbreviations refer to a popular Boltzmann model of motility where motors fluctuate between two states: d_p , diameter of motor; δd_p , change in diameter when motor contracts; L_o , normal length of the lateral membrane; δL , change in length when motors contract; r_o , normal radius of the cylindrical cell; δr , change when motors contract; V_a and V_b , constant volume of apex and base, respectively; V_{po} and V_{pn} , volumes of motor-containing cell region during elongation and contraction, respectively.) The outer hair cell motor, prestin, is embedded within the lateral membrane of the cell, forming a dense array. Motors (dark and light circles in the blowup) are depicted in compact or expanded states, corresponding to the two-state model of their activity. Electrical measures of the motor's voltage sensor provide estimates of millions of motor molecules per cell. The lateral membrane (C) when viewed with freeze fracture electron microscopy, displays a dense array of 10 nm particles, which are believed to represent multimers of prestin. The dense packing must have substantial structural consequences beyond the dynamic activity of the protein. (Reproduced with permission from [19].)

and inner hair cell stereociliar shear are normally poor. Now, for mammals, there was a need for auditory sensitivity at higher frequencies. Prestin evolved to improve the coupling of basilar membrane motion to inner hair cell stereociliar shear and simultaneously shift characteristic frequency to higher frequencies, but in the process, the tightened mechanical coupling caused a reduction in the sensitivity of basilar membrane motion, thus necessitating an amplificatory mechanism to reestablish high sensitivity at the new higher characteristic frequency. In this scenario the passive presence of prestin enhances coupling, but is detrimental to basilar membrane motion, and the electrical activity of prestin amplifies the movements of the well coupled basilar membrane.

How could a protein within the lateral membrane of the outer hair cell work to couple basilar membrane motion into inner hair cell stereociliar shear? The organ of Corti is a mass of supporting cells and hair cells bounded apically by the reticular lamina/tectorial membrane and basally by the basilar membrane. Displacements of the

basilar membrane, induced acoustically, must be sensed at the apical region where stereocilia of inner hair cells and outer hair cells reside. It is possible that the increase in stiffness provided to the outer hair cells by the immense numbers of prestin protein in the lateral membrane reinforces or stiffens the cellular link between basilar membrane and reticular lamina.

If this is true, we might predict that a knock-in of a nonfunctional prestin into the knock-out mouse would produce a basilar membrane response at lower characteristic frequency, as we see in the knock-out, but with a reduced sensitivity that would reflect an enhanced coupling between basilar membrane and inner hair cell stereocilia. We know how long it takes to get a new mutant mouse. So it may be a while before we get at the deeper significance of the new data reported by Mellado Lagarde *et al.* [13].

Chemical Coevolution: Host–Parasite Arms Race Runs Hot and Cold

Coevolution is a major process operating across biological communities at a range of spatial scales. Rapid ecological change makes it vital that we understand how coevolution proceeds if we are to conserve genetic diversity, combat disease and predict the effects of species invasions.

Duncan E. Jackson

Coevolution is a reciprocal evolutionary change in the genetic composition of one species in response to change in another interacting species. We can only invoke coevolution as an explanation when the observed traits of two species have evolved through ongoing interaction between the two species. Research has shown that coevolution is a dynamic process that can continually change the nature of inter-specific interactions over broad geographic ranges [1]. The current rapid environmental change makes it essential that we understand coevolutionary processes if we are to predict the changing dynamics of biological communities, conserve biodiversity and combat disease [2]. Some of the best examples of coevolution are found in mutualisms, especially flowers and their pollinators, but several ‘coevolutionary arms races’ are well-documented in the context of predator–prey and host–parasite relationships. Nash *et al.* [3] have recently shed fresh light on dynamic coevolutionary processes with a long-term study of the relationship between the parasitic Alcon blue butterfly (*Maculinea alcon*) and its *Myrmica* ant host. They have shown that Alcon blue caterpillars adopt a chemical disguise, matching that of ant larvae, to

mediate their ‘adoption’ into *Myrmica* nests, and that local variations in ant chemistry are closely matched by their caterpillar parasites.

Unlike the familiar examples of mutualistic coevolution seen in flowering plants and their pollinators, coevolving parasites and their hosts are engaged in an antagonistic process. The most important property of a parasite that is attributed to coevolution is its virulence. A more virulent parasite will reduce a host's fitness more quickly, relative to an unparasitised host. Clearly selection must favour highly virulent parasites, those which more quickly exploit host resources, but this process might lead to the death of all potential hosts. However, if a parasite is so virulent that it kills its host before transmission of the parasite's offspring then this will select for a reduction in parasitic virulence, as well as more resistant hosts. The best-cited example of how parasitic virulence can decline is that of myxomatosis among European and Australian rabbits during the 1950s. An initially maximally virulent myxoma virus (100% kill) declined rapidly, accompanied by sharp increases in host resistance, such that the disease was seldom seen after less than 20 years. The myxoma virus still persists in populations in an attenuated form, although on occasions more

virulent strains appear causing short-lived, localised outbreaks.

Antagonistic coevolution can lead to static equilibria where an optimal situation is reached, such as may be the case with the myxoma virus, but also dynamic equilibria where adaptive improvement is always possible. Dynamic equilibria are known as the ‘Red Queen hypothesis’ because, as

Figure 1. An Alcon blue butterfly (*Maculinea alcon*) lays her eggs on marsh gentian (*Gentiana pneumonanthe*) flower heads.

After 2–3 weeks of feeding on flower heads the caterpillar lowers itself to the ground using a silken thread and awaits discovery by foraging *Myrmica* ants. Alcon blue caterpillars are chemical mimics of *Myrmica* ant larvae, an attribute which tricks ants into carrying caterpillars back to their nest (‘adoption’) where they become social parasites. The speed limit of outer hair cell electromechanical activity

Introduction

The outer hair cell (OHC) is one of two receptor cell types within the organ of Corti, the other being the inner hair cell (IHC). Since Corti's description of the cellular components of the mammalian inner ear in 1851 ([5]; **Fig. 1**), the role of the cylindrical OHCs he observed has been debated. For example, why are there three times as many OHCs as IHCs? We now know that the IHC functions as the primary sensor of acoustic stimulation, centrally relaying its activity via 95% of the eight nerve fibers [30]. The OHC is supportive, in a sense, in that it basically modulates gain of cochlear output via the IHCs. That modulation, however, is quite significant and amounts to a sensitivity gain of 40–60 dB ($\times 100$ –1000). Of course, in their absence this translates to a hearing loss of equal magnitude. These cells, thus, provide cochlear amplification that arises from their electromechanical activity, the OHC being electromotile [4, 14], and the mechanics driven by receptor voltages across the OHC lateral membrane [12, 22].

» Prestin is the molecular motor of OHCs

Given their role, it is likely that OHCs outnumber IHCs in order to provide a more powerful feedback into the cochlear partition. The voltage-dependence of this mechanical activity necessarily involves gating charge movements (or nonlinear capacitance [NLC]) that arise during displacement of charged voltage sensors of the OHC lateral membrane molecular motors [2, 19, 21]. NLC is a bell-shaped

function of voltage, with its peak occurring at a characteristic voltage (V_h). The molecular motor has been identified as prestin [31]. One of the early issues that captivated auditory scientists following the discovery of electromotility was its frequency cut-off; since mammals have very high frequency hearing, it was expected that cochlear amplification would require OHCs to work at equivalent high speeds. This short review (readers are expected to seek original referenced articles for more detail, or email me with questions!) will focus on the historical quest to determine the OHC *Geschwindigkeitsbegrenzung* (speed limit).

Early history

The early observation on OHC electromotility by Brownell [3] was merely descriptive, and subject to initial skepticism from the research community. Only when the alternating length changes induced by sinusoidal currents were

captured on video and analyzed was it clear that these cells were remarkably mechanically active for electrical stimulation frequencies of 1–30 Hz [14]. Of course, those early video studies were made at very low frequency video frame rates (~ 60 Hz), so that no estimate of the cell's frequency response could be made (**Fig. 2**). The earlier demonstration of otoacoustic emissions at acoustic frequencies [15] foretold that the OHC would move much faster.

In 1987, Ashmore measured the frequency response of OHC electromotility under whole-cell voltage clamp using a photodiode technique allowing for high-frequency observations [1]. As shown in **Fig. 3**, the measured frequency response was low pass with dual Lorentzian cut-offs of 67 and 664 Hz; nevertheless, the cell response could be measured into the kilohertz range, albeit at low magnitudes. It was likely that the voltage clamp time constant was a limiting factor, since it will impose

limitations to the delivery of voltages to the OHC at high frequencies.

Into the 1990s

In 1992, also using the whole-cell voltage clamp and a photodiode approach, Santos-Sacchi [20] was able to overcome to some extent the clamp time constant and extend the frequency response of voltage delivery to the cell. Given a wider stimulation bandwidth, OHC electromotility frequency cut-offs near 1 kHz

were obtained (■ Fig. 4). Still, the voltage clamp time constant was a limiting factor. In 1993, Zenner and colleagues [18] extended the study of electromotility by utilizing stroboscopic techniques to enhance video analysis of movements evoked by high-frequency transcellular current stimulations across the organ of Corti in situ. They showed reticular laminar movements into the kilohertz range, with reported roll-offs of 40 dB at 15 kHz, not unlike Ashmore's results in the voltage-clamped single cell [1]. Of

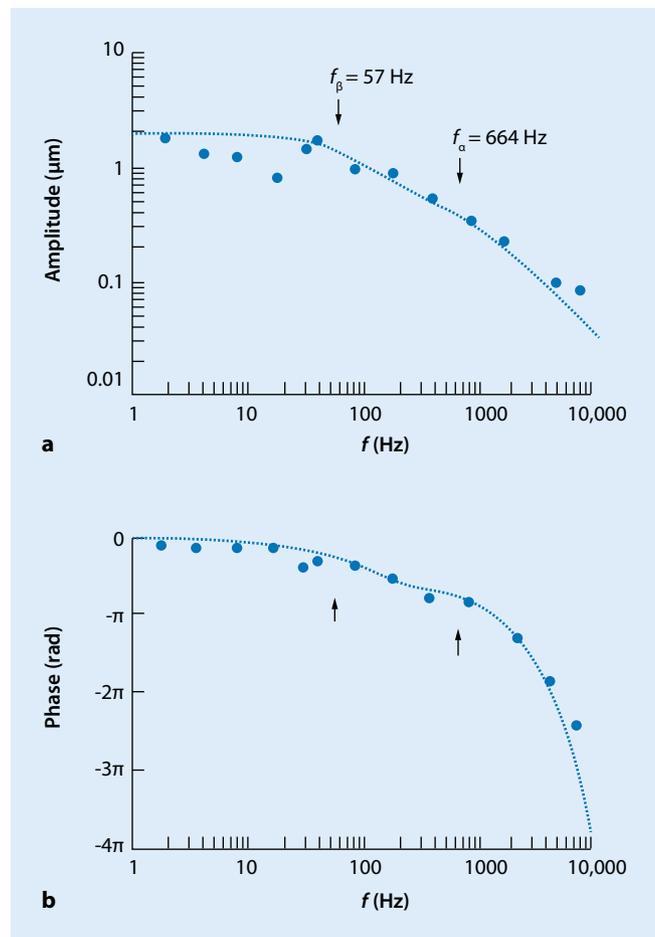

Fig. 3 ▲ Outer hair cell electromotility evoked under whole-cell voltage clamp. The response exhibited a dual Lorentzian roll-off at 57 and 664 Hz. See original paper for detailed description. **a** Magnitude response of OHC, **b** Phase response. (Adapted from [1])

course, current stimulation will involve substantial voltage stimulation roll-off across the OHC membranes owing to the membrane resistor \times capacitor (RC) filter. In any case, at this point in time, it was clear that the OHC responded to electric stimuli well into the audio-frequency range, but better estimates of the isolated OHC cut-off frequency were essential.

With a technical advancement designed to extend the frequency response of voltage delivery to the OHC, Dallos and Evans [6] measured the OHC frequency response out to at least 10 kHz (■ Fig. 5). They utilized a large microchamber glass pipette into which an OHC was inserted to deliver currents across the cell; this approach provides a capacitive divider that limits the negative effect of the OHC capacitance on

Abstract · Zusammenfassung

voltage delivery. Nevertheless, even this approach has limitations that arise from the series resistance of the microchamber, which in combination with the cell capacitance controls frequency delivery bandwidth just as in the whole-cell voltage clamp technique. Furthermore, in that study a voltage clamp configuration was not used, but instead the cell was driven by a low-output impedance waveform generator. With that configuration, it was impossible to monitor membrane currents to directly estimate the fidelity of voltage delivery, as can be done under voltage clamp. In 1999, Frank et al. [8] used the microchamber technique under voltage clamp to obtain a ground-breaking result. Outer hair cell electromotility was measured using an interferometer and found to be flat to beyond 50 kHz for short portions ($\leq 25 \mu\text{m}$) of the OHC that extruded from the microchamber! Of course, this was the frequency response following corrections for the estimated frequency roll-off of voltage delivery (■ Fig. 6). In their in-house-developed voltage clamp, no capacitance compensation circuitry was included to remove stray capacitance (e. g., from the amplifier, electrode holder, and glass microchamber), so that this stray capacitance *may have* interfered with estimates, based on measured currents, of voltage delivery across the OHC membranes. That is, stray capacitance does not influence the bandwidth of voltage delivery under voltage clamp, but it will interfere with measures of membrane currents that are used to estimate voltage delivery. For nearly two decades, these data have driven our concepts of cochlear amplification.

Present day

In 2018, Santos-Sacchi and Tan [28] revisited this issue. This was instigated by a series of previous studies showing that prestin possesses slow kinetics that were influenced by chloride anions [24–26, 29]. These data led to a kinetic model—the *meno presto* model—of prestin that includes slow intermediary transitions between chloride binding and a voltage-enabled configuration. What this meant was that sensor charge move-

The speed limit of outer hair cell electromechanical activity

Abstract

The outer hair cell of Corti's organ provides mechanical feedback into the organ to boost auditory perception. The fidelity of voltage-dependent motility has been estimated to extend beyond 50 kHz, where its force generation is deemed a requirement for sensitive high-frequency mammalian hearing. Recent investigations have shown, however, that the frequency response is substantially more low pass at physiological membrane

potentials where the kinetics of prestin impose their speed limit. Nevertheless, it is likely that the reduced magnitude of electromotility is sufficient to drive cochlear amplification at high frequencies.

Geschwindigkeitsbegrenzung der elektromechanischen Aktivität der äußeren Haarzellen

Zusammenfassung

Von der äußeren Haarzelle des Corti-Organs gibt es zur Verstärkung der Hörwahrnehmung eine mechanische Rückkopplung. Die Genauigkeit der spannungsabhängigen Motilität wurde auf über 50 kHz geschätzt, wobei ihre Krafterzeugung als Voraussetzung für das empfindliche Hochfrequenzhören der Säugetiere angesehen wird. Neuere Untersuchungen haben jedoch gezeigt, dass die Frequenzantwort bei physiologischen Membranpotenzialen, bei denen sich die

Geschwindigkeitsgrenze der Kinetik von Prestin auswirkt, wesentlich niedriger ist. Es ist jedoch wahrscheinlich, dass das verringerte Ausmaß der Elektromotilität ausreicht, um die Cochleaverstärkung bei hohen Frequenzen zu steuern.

Corti-Organ · Auditorische Wahrnehmung · Cochlea · Membranpotenziale · Rückkopplung

ments were low pass in nature. Since sensor charge movements correspond to conformational changes in prestin, it was expected that electromotility would likewise demonstrate this low-pass behavior.

» Sensor charge movements are low pass in nature

The study by Santos-Sacchi and Tan [28] confirmed this. In their experiments, electromotility was measured using a microchamber under voltage clamp with high-speed video at frame rates of 50 kHz (■ Fig. 7). The Phantom camera (Vision Research, Berwyn, PA, USA) can actually record at frame rates exceeding 400 kHz (with its smallest pixel resolution), but because electromotility was measured out to 12.5 kHz, that frame rate was sufficient. Stray capacitance was removed with amplifier compensation circuitry, so that

measured membrane current relaxations could be used to estimate the clamp time constant. It was found, after corrections for voltage delivery roll-off, that electromotility frequency response depends on OHC resting membrane potential relative to $NLC V_h$. When the OHC resting membrane potential is held at V_h , electromotility shows dual Lorentzian behavior with a large roll-off at frequencies below 1 kHz. Away from V_h , the response is relatively flat, but quite reduced in magnitude. The frequency cut-off of the fastest Lorentzian component was about 8.7 kHz. This compares with a 33-kHz cut-off obtained by Frank et al. [8] with a similar experimental configuration, namely, degree of OHC extrusion. Thus, it is likely that differences between the work of Frank et al. [8] and Santos-Sacchi and Tan [28] arise from experimental differences, possibly including how stray capacitance is dealt with, and certainly the OHC holding volt-

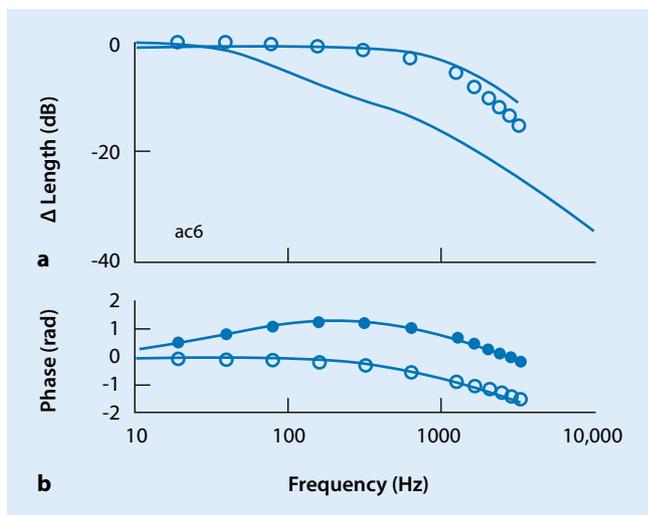

Fig. 4 ▲ Outer hair cell (OHC) electromotility evoked under whole-cell voltage clamp. For this OHC, the response exhibited a roll-off near 1 kHz. The mechanical response (*circles*) was lower pass than the predicted membrane voltage (*solid line*). **a** Magnitude response of OHC, **b** phase response. See original paper for detailed description. *ac6* label that identifies the particular cell studied. (Adapted from [20])

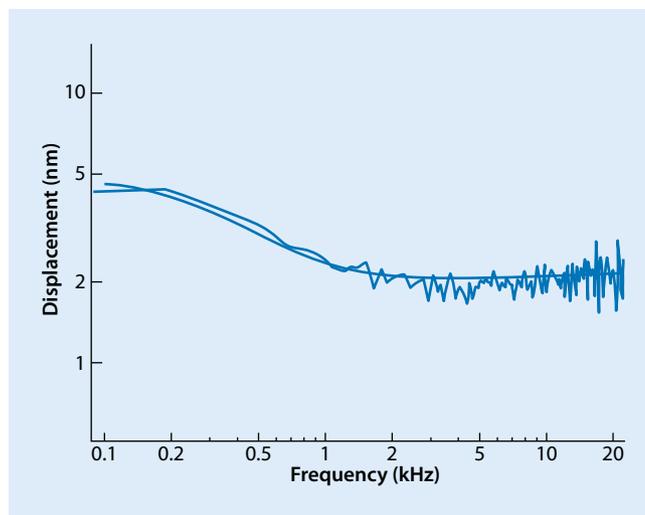

Fig. 5 ▲ Outer hair cell (OHC) electromotility evoked with the microchamber technique. For this OHC, the response exhibited an initial roll-off near 300 Hz, but stabilized past 10 kHz. See original paper for detailed description. (Adapted from [6])

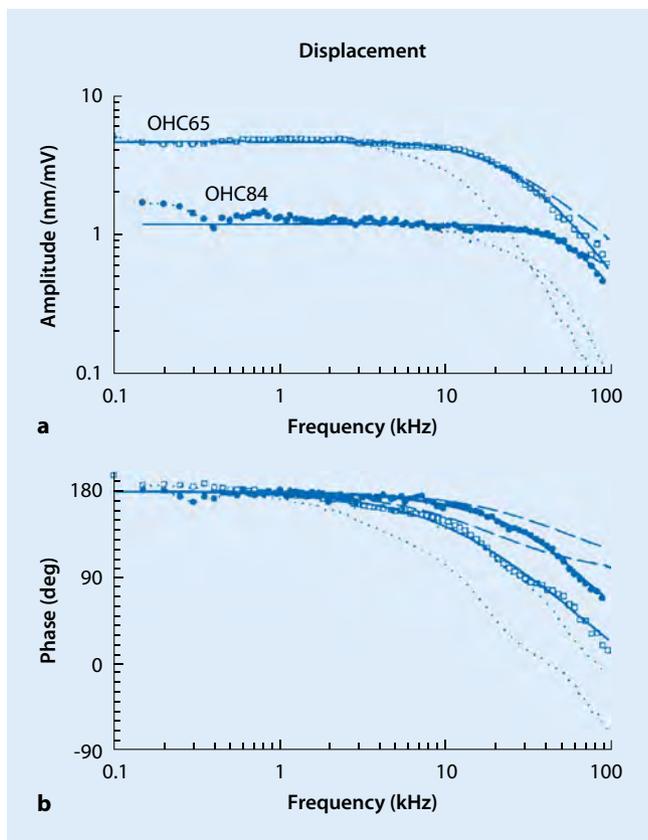

Fig. 6 ▲ Outer hair cell (OHC) electromotility evoked with the microchamber technique. Data from two OHCs are shown. In **a** the *dotted lines* depict electromotility magnitude *prior* to corrections for system voltage roll-off, and the *other symbols* show the same after corrections for voltage roll-off. In **b** the phase response of the cells is shown. See original paper for detailed description. (Adapted from [8])

age at which electromotility measures are made—both Frank et al. [8] and Dallos and Evans [6] had OHC holding voltage set far away from V_h (we estimate about 68 mV away from $NLC V_h$). After correcting for effects of experimental temperature (from 25 to 37 °C), the fastest cut-off component of electromotility from Santos-Sacchi and Tan [28] was about 20 kHz, and interestingly is similar to the temperature-corrected NLC cut-off of Gale and Ashmore [10]. That the two should correspond makes sense since NLC defines the speed of prestin conformational change, the basis of electromotility.

Summary

The remarkable ability of the OHC to respond mechanically to voltage (i.e., sound-induced receptor potentials), relying on prestin and in a manner distinct from usual mechanisms of cellular motility, forms the basis of cochlear amplification [7, 27]. Consequently, the frequency response of electromotility is pertinent, and over the years its assessment has benefitted from technological refinements, providing estimates of cut-off frequencies that have incrementally grown. However, prior to the work of Santos-Sacchi and Tan [28], these assessments had not taken into account the possible influence of prestin's voltage-

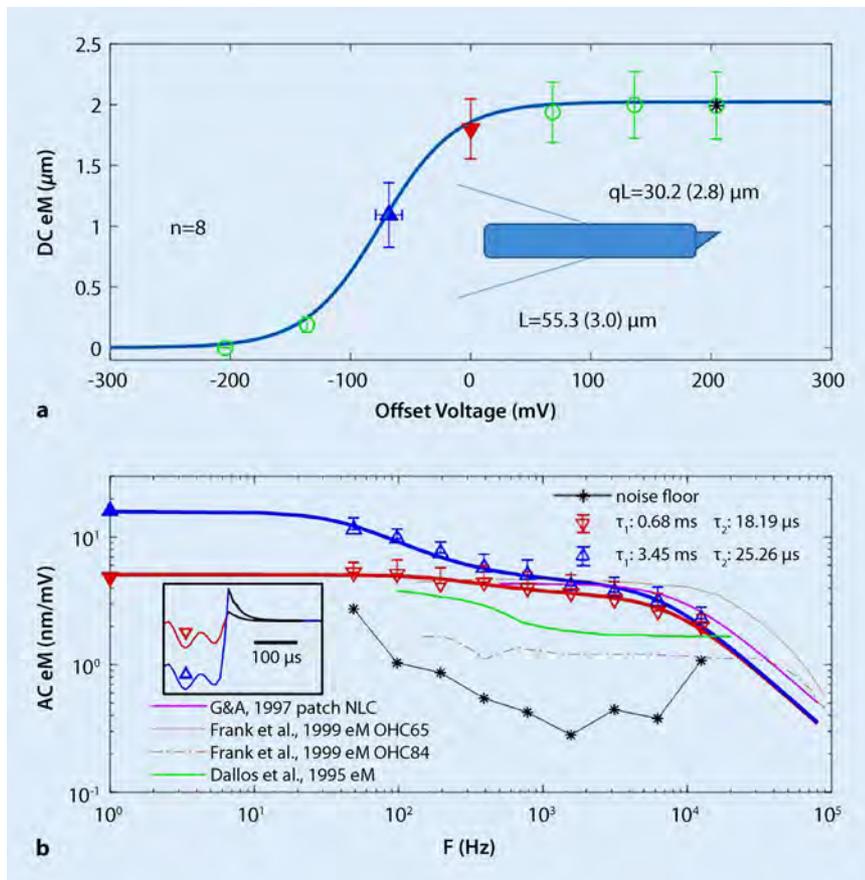

Fig. 7 ▲ Outer hair cell (OHC) electromotility evoked with the microchamber technique. Average data from eight OHCs positioned midway in the microchamber are shown. In **a** the DC movements are shown for different offset holding voltages. In **b** the frequency response at V_h (blue line) shows low- and high-pass behavior, but away from V_h (red line) the response is faster with a flatter frequency response. See original paper for detailed description. (Adapted from [28])

dependent kinetics on the frequency response. Thus, at a resting membrane potential near V_h (which itself is susceptible to a variety of biophysical influences [9, 11, 13, 16, 17, 23, 26]), electromotility is predominantly low pass, with a faster component extending to about 20 kHz. Clearly, the magnitude of electromotility will be a fraction of its response at very low frequencies. Nevertheless, it is obvious that this is sufficient to provide amplification in the high-frequency regions of mammalian audition. How this might be accomplished requires new cochlear models incorporating these new observations.

Practical conclusion

- The outer hair cells of Corti's organ provide mechanical feedback to the organ to boost auditory perception.

- Voltage-dependent motility has been measured beyond 50 kHz, where its force generation is needed for sensitive high-frequency mammalian hearing.
- Recent studies report that the frequency response is substantially more low pass at physiological membrane potentials where the kinetics of prestin enforce their speed limit.
- The reduced magnitude of electromotility is likely sufficient to drive cochlear amplification at high frequencies.

MODERATOR

Tamala S. Bradham, Ph.D., CCC-A, is an assistant professor at the Vanderbilt Bill Wilkerson Center in Nashville, Tenn., and the associate director of quality, protocols, and risk management. She is the coordinator for the Steering Committee of the American Speech-Language-Hearing Association (ASHA) Special Interest Group 9: Hearing and Hearing Disorders in Childhood. She is also the former director of the MUSC Cochlear Implant Center in Charleston, S.C., and the past president of the South Carolina Academy of Audiology and the AG Bell South Carolina Chapter. Bradham has published in the areas of cochlear implants, newborn hearing screening, and early intervention. She received her doctorate in Speech and Hearing Sciences and her master's degree in Audiology at the University of South Carolina.

THE QUEENS OF AUDITION

BY JOSEPH SANTOS-SACCHI, PH.D., YALE SCHOOL OF MEDICINE

Alexander Graham Bell would have been amazed to find out how the ear uses the outer hair cell (OHC) to boost our sensitivity to sounds. The OHC does this by providing mechanical feedback into the organ of Corti, thus enhancing the input to the inner hair cells, which predominantly send information to the central nervous system. Prestin is the protein that drives the OHC mechanical response, and we have learned much since its discovery in the year 2000. Notably, we now know that the cochlear amplifier is controlled by anions interacting with prestin. The upshot is that the OHC evolved to use very primitive constituents to do exquisite things. There is still more to learn.

When I was a teenager I damaged my right ear by standing too close to fireworks on the 4th of July. Tinnitus and hearing loss persist to this day, only enhanced by an additional 45 years of auditory abuse. The culprit of my problem is the hair cell, probably the outer hair cell (OHC). Hair cells that enable us to perceive sound are fragile, and when lost do not regenerate, causing permanent hearing loss (and sometimes ringing in the ear). They are amazing machines, and the whole of the ear—outer ear, middle ear, inner ear and the auditory brain—is devastated without their sustenance. They are the Queens of Audition!

PRE-AMPLIFICATION

My Ph.D. thesis was concerned with blood capillary function in the inner ear, an attempt to understand how, at the electron microscopic level, blood-borne molecules enter the inner ear (Santos-Sacchi & Marovitz, 1980). The inner ear is a privileged site that blocks most molecular entry, just as the brain does. I convinced myself (and my doctoral committee) that this was good for the inner ear—namely that the ear protects its hair cells.

Two years later I pursued a postdoc in Peter Dallos' lab at Northwest-

ern University. I was able to directly investigate what the OHCs were doing by recording electrical activity from them through microelectrodes in living guinea pigs. Research at that time showed that OHCs are sharply tuned to particular frequencies based on the location along the cochlea (Dallos, 1985; Dallos, Santos-Sacchi, & Flock, 1982; Russell & Sellick, 1983). Hair cells in the basal part of the cochlea respond best to high frequency sounds and those in the apex of the cochlea respond best to low frequency sounds. The frequency selectivity and sensitivity of hair cells along the cochlea were predicted based on basilar membrane and eighth nerve fiber measurements (Ruggero & Santos-Sacchi, 1997).

Also during my postdoc research, Dallos and I showed that the supporting cells were electrically coupled by gap junctions (Santos-Sacchi & Dallos, 1983), presaging subsequent independent studies that suggested connexon-based communication among supporting cells was important for potassium sinking and metabolic maintenance within the organ of Corti—two phenomenon that are required for hair cell survival and proper functioning (Santos-Sacchi, 1985). Not surprisingly, connexon mutations are now known to underlie

a major proportion of genetically based hearing loss (Kelsell et al., 1997).

POST-AMPLIFICATION

Something special happens in the inner ear to provide such fine frequency tuning and sensitivity. The momentous identification of otoacoustic emissions (OAE; emissions of sound from the ear canal) by Kemp (1978) did not subdue Brownell's amazing discovery of OHC electromotility (Brownell, Bader, Bertrand, & de Ribaupierre, 1985). Indeed, the observation that OHCs are not only receptors of sound, but can respond mechanically, and the identification of OAEs prompted a paradigm change in auditory research. I joined the electromotility club early on, providing evidence that electromotility was driven by the voltage across the OHC membrane (Santos-Sacchi & Dilger, 1988). Since then I have focused on the biophysical and molecular aspects of OHC motility.

THE AMAZING OHC

The OHC is more specialized than its neighbor, the inner hair cell (IHC). Similar to the IHC, however, OHCs have an apical region of the cell that houses the sound transduction apparatus, a collection of yet-to-be-identified mechanically activated (MET) channels that

reside in the membrane tips of stereocilia. Stereocilia are tall membrane extrusions that are stiff because they contain a tightly packed core of actin filaments. Movement of the stereociliar bundle permits MET channels to allow potassium to enter the cell, and the resulting receptor potential depolarizes the cell's membrane. For the IHC, the main purpose of this depolarization is to evoke neurotransmitter release at the bottom part of the cell where auditory eighth nerve fibers synapse. OHCs also have synapses with the eighth

nerve but are dwarfed in number by those of the IHC. Thus, the main job of sending acoustic information to the brain centrally falls to the IHC.

It's the middle part of the OHC, which IHCs do not have, that piqued my interest. Research has shown that the membrane in this region houses the molecular motors responsible for electromotility (Figure 1). One of the ways to study the activity of the motors is to measure its conformational change (shape change) within the membrane

when voltage across the membrane is altered, as might occur when receptor potentials are generated. The conformational change is associated with the restricted movement of motor-bound charges within the membrane that can be measured as a nonlinear capacitance (NLC).

Capacitance is the ability to store charge, and normally a membrane will have a capacitance proportional to its area, just like an electrical capacitor component. The membrane capacitance, defined as the change in charge divided by the change in membrane voltage (dQ/dV_m), is the same at any membrane potential in IHCs, i.e., it is linear because this cell lacks the charged molecular motors found in the OHC. The OHCs, however, have a voltage-dependent capacitance that is bell-shaped riding atop a flat linear capacitance (Figure 2). The peak of the NLC occurs at a membrane voltage where the voltage sensitivity of motor conformational activity, and consequently, electromotility, is greatest (called V_p). The range over which NLC extends across V_m is the operational range of the motor. Research in the previous two decades has established that NLC and electromotility share such common characteristics.

In 2000, Dallos and colleagues discovered the motor protein responsible for electromotility (Zheng et al., 2000). They called it prestin because it is fast. When artificially expressed in non-auditory cells, it displays all the characteristics that the native OHC displays, including a NLC with a voltage dependent mechanical response of the membrane. Prestin has been shown to display additional qualities that were previously identified in the native OHC (reviewed in Santos-Sacchi, 2003). Shared qualities include 1) a piezo-electric-like phenomenon, where not

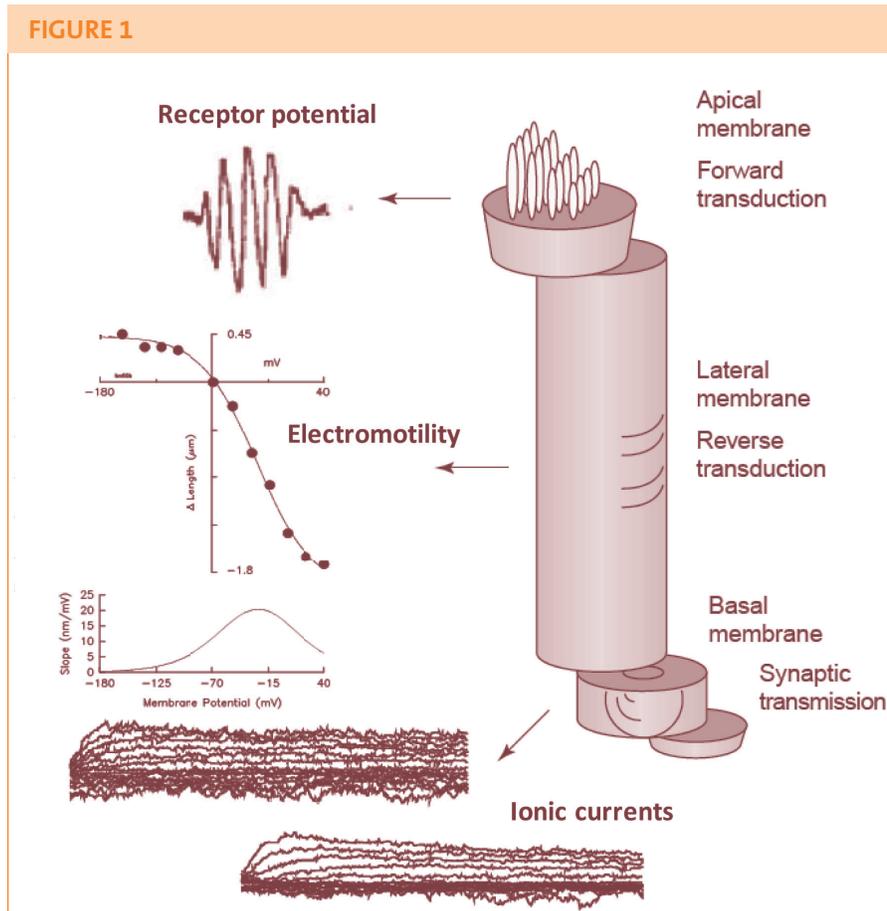

Figure 1. The OHC is a highly partitioned cell. The apical portion houses the stereocilia where receptor potentials are generated, and the base houses synaptic machinery and voltage-dependent ionic channels that allow information to be sent to the brain. The middle of the cell is the most interesting part! Here there are molecular motors embedded in the lateral membrane that underlie electromotility, a voltage dependent length change that can occur at acoustic rates. The mechanical response is sigmoidal versus voltage, and its maximum sensitivity is at voltage V_p , which is at the mid-point of the sigmoid or at its maximum first derivative with voltage. Notice that the sensitivity curve looks like the NLC curve in Figure 2.

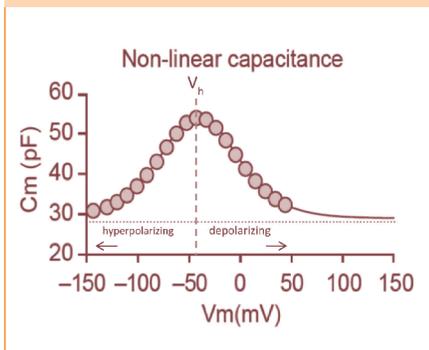

FIGURE 2

Figure 2. The molecular motors in the OHC lateral membrane produce a restricted charge movement in the membrane that can be measured as a NLC. The curve can shift along the voltage axis in the hyperpolarizing or depolarizing direction in response to a variety of biophysical forces, indicating that the operational voltage range is not stable for electromotility. V_h of NLC generally coincides with V_h of electromotility; however, see text for new observations

only does voltage induce a mechanical response, but reciprocally membrane deformation induces an electrical response; 2) marked temperature sensitivity; 3) a dependence of the protein's operational voltage ranges on resting potential; and 4) a dependence on intracellular chloride.

The latter characteristic, chloride dependence of the motor, has been a topic of focus for 12 years now. The anion appears to work by binding to prestin and affecting the protein's ability to change conformation within the membrane when voltage is modulated. This chloride sensitivity is not totally unexpected since prestin is part of a family of proteins that transports anions across the membrane. What is surprising is that the protein, unlike its family members, has evolved to aid in cochlear amplification. This was very apparent when, in collaboration with Fred Nuttall's research group, we were able to reversibly reduce basilar membrane motion in the guinea pig by manipulat-

ing chloride levels bathing the OHCs (Santos-Sacchi, Song, Zheng, & Nuttall, 2006). The defeat of cochlear amplification was reversible upon restoring normal chloride levels (Figure 3).

One of the characteristic properties of chloride on prestin is to shift the motor's operating voltage range; should intracellular chloride levels decrease from normal, a shift of the electromotility function in the depolarizing direction will follow, effectively making the receptor potential incapable of generating mechanical responses. In another demonstration of the importance of prestin's operating voltage range, Dallos and colleagues (Dallos et al., 2008) were able to knock-in genetically modified prestin molecules into the OHCs of the living mouse. The new prestin was engineered to have its op-

erating range shifted in the depolarizing direction, thus preventing the OHC receptor potential from evoking mechanical responses. Of course, in this case, the hearing loss was irreversible. Experiments such as these support the notion that, in mammals, cochlear amplification results from prestin activity, and not other mechanisms.

While we know the effects of anions on the NLC of OHCs and predict their effects on electromotility in vivo, little work has been done on OHC mechanics directly. Our predictions assume that NLC exactly characterizes electromotility. Could chloride be working in ways other than changing the OHC operating range? Lately, we have been re-investigating the coupling between prestin motor conformational change and electromotility. It turns out that the

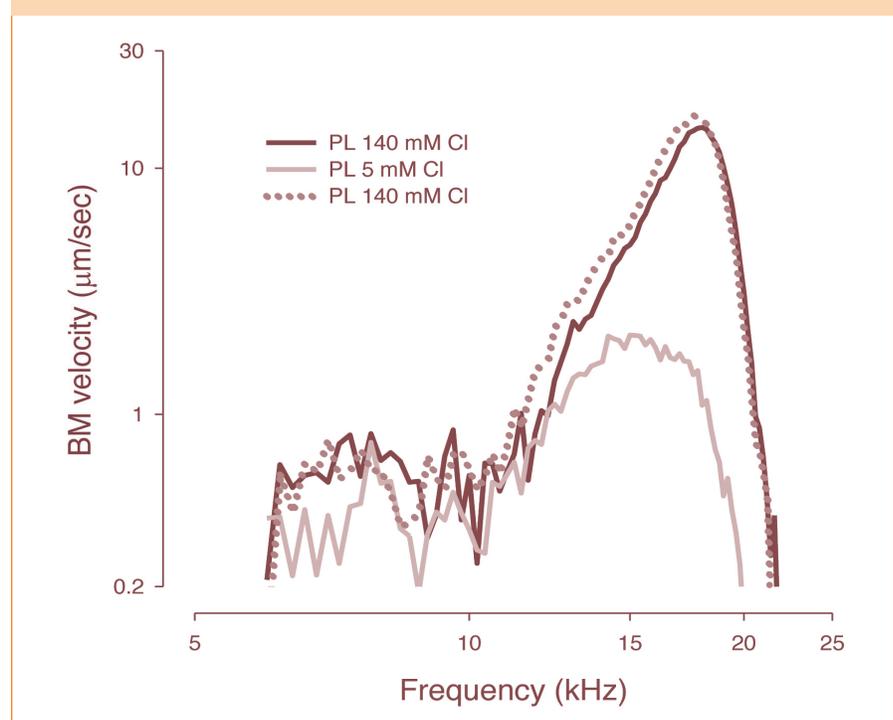

FIGURE 3

Figure 3. Basilar membrane measures are considered the classic assessment of cochlear amplification. Here we show that sharp tuning (dark solid line) under normal 140 mM chloride bathing solution is severely reduced by replacement with 5 mM chloride solution (light solid line). Return to 140 mM chloride solution restores hearing and basilar membrane motion in the guinea pig by manipulat-

two are variably uncoupled depending on concentration of intracellular chloride; that is, the operating voltage ranges appear to be separately modifiable (Song & Santos-Sacchi, 2012).

To further explain, within the organ of Corti, in order for OHCs to effectively promote enhanced basilar membrane motion, they must exert their forces at the proper moment during sound induced basilar membrane vibration. This is akin to pushing with your child's movements on a swing, not against her. That is, the timing, or phase of, energy injection must be appropriate. In the past, cochlear modelers have resorted to various strategies to generate enough phase delay between receptor potentials and OHC forces for their models to reasonably describe experimental data. The physiological basis for such delays was always removed from the OHC. We think that the variable couplings between conformational changes of prestin (NLC) and electromotility results from a time delay between the two, and we suggest that the mechanical forces of the OHC can be tuned to the requirements of the cochlea by chloride homeostasis. Thus, we believe that anions have a preeminent role in how we hear.

SUMMARY

Over the years that I have been working on the mechanics of hearing, I have learned about many things that the supporting cells and hair cells do right. Unfortunately, these are the same things that can be disturbed and have, I'm sure, contributed to my own hearing problems. But I am convinced that with a better understanding of how things work, we will ultimately know what and how to repair. So tell me more Queens of Audition, I'm listening!

ABOUT THE AUTHOR

Joseph Santos-Sacchi, Ph.D., is a professor in the Department of Otolaryngology at Yale School of Medicine. He has an undergraduate degree in psychology from Columbia College and a Ph.D. in audiology from Columbia University. He joined Yale University in 1991. Prior to that, Santos-Sacchi worked in labs at the City College of New York, Northwestern University and the University of Puerto Rico. He has been funded continuously by NIH/NINCDS/NIDCD since 1984 to study hair cell and supporting cell physiology. More information can be found on his website www.YaleEarLab.org.

SPEECH PERCEPTION AND HEARING LOSS

BY JONT B. ALLEN, PH.D., ANDREA TREVINO, AND WOOJAE HAN, PH.D.,
UNIVERSITY OF ILLINOIS, URBANA-CHAMPAIGN

Over 150 years after the early research of Alexander Graham Bell, it remains unclear how the auditory system decodes speech, both in individuals who have “normal ears” and those who have “non-normal ears.” Recent research has shown that normal ears can decode isolated consonants without error. However, when the inner ear is damaged, such as with sensorineural hearing loss where hair cells and synaptic connections are not properly functioning, speech can be heard but not understood. In these cases, two seemingly-normal articulated utterances of the same consonant can result in totally different responses. Such specific and consistent confusions uniquely depend on the auditory system’s function and the utterance. This presentation will discuss the differences between how the auditory systems of normal ears and non-normal ears receive and decode speech.

INTRODUCTION

Existing clinical methods for diagnosing speech disorders in individuals with damaged inner ears seem fundamentally broken. Today when patients go to an audiology clinic, their pure-tone hearing thresholds are first measured. Based on the degree of tonal hearing loss, a hearing aid may be prescribed, which is subsequently adjusted to partially compensate for the pure-tone loss. This may or may not improve the ear’s speech loss (Walden & Montgomery, 1975). But since the speech loss is infrequently measured (or worse, the method of measurement is ineffective), the change is not quantified.

Based on the evidence available, it has been shown that speech testing has not been successful in fitting hearing aids (Walden & Montgomery, 1975). This seems counterintuitive since the main purpose of wearing a hearing aid is to improve speech understanding. Due to historically poor understanding

of the fundamentals of speech perception, it has proven difficult to resolve this inconsistency. First, researchers may not understand the process of learning speech, which typically takes place in the first one to two years of life. Second, due to middle ear infections, young children can temporarily lose their hearing, which can interfere with learning spoken language. It is not until the first year of school when the child is learning how to read that the child’s ability to hear consonants is first fully tested.

Children who cannot accurately decode consonants may have increased difficulty with orthography. For example, if an ear cannot hear the distinction between /b/ and /d/ or between /t/ and /f/, the child is likely to misunderstand the importance of the shape of the letter [loop at bottom, closing to the left (d) or right (b), and curl at top (f) or bottom (t)]. The classroom teacher assumes that if a child’s hearing is normal, then the child can hear the consonant distinctions.

However, this assumption can be wrong and if so, the child’s consonant decoding deficiency will go undetected (it will not show up in a pure-tone hearing test). When the child passes a hearing screen it is assumed, incorrectly, that they can decode syllables. What is needed is a targeted consonant discrimination test to predict these reading disorders.

Clinical audiologists can also make the same assumptions about adult speech perception, and research has shown that many of these assumptions can be wrong. The most serious assumption has been that consonants are homogeneous. Research has shown that for “normal ears,” confusions systematically depend on the consonant (Phatak & Allen, 2007; Phatak, Lovitt, & Allen, 2008; Singh & Allen, 2012). For “non-normal ears,” the errors dramatically increase, again depending on the ear, the noise-level, and, most significantly, the utterance.

If consonants were homogeneous, the

confusions, as a function of the noise level, would be the same from one consonant to the next. This is not the case, since consonant confusions are highly dependent on the utterance (Han, 2011; Singh & Allen, 2012). While normal ears give similar confusions for a given utterance as a function of the noise, non-normal ears are idiosyncratic in their error patterns. The idiosyncratic nature of the speech scores implies that they may not be averaged. It is this inappropriate averaging that has led clinicians to believe that speech is not a reliable measure for fitting hearing aids.

In the last few years, the Human Speech Research (HSR) group at the Beckman Institute for Advanced Science and Technology at the University of Illinois, Urbana-Champaign, has determined some key elements in this chain that seem to enlighten responses from both normal and non-normal ears. For our purposes, “normal ears” are defined as those with pure-tone thresholds less than 20 dB-SPL, and “non-normal ears” are defined as having pure-tone thresholds greater than 20 dB-SPL.

Until very recently, it was not understood that the normal ear can detect speech with essentially zero error, down to -10 dB SNR (three times more speech-shaped noise than speech) (Phatak et al., 2008). As the noise increases, the error goes from zero to chance performance over a small signal-to-noise ratio (SNR) range. These new results totally change the understanding of what is happening in normal ears because it means consonant perception is binary (Singh & Allen, 2012).

The focus of this presentation is to describe this difference in performance between the normal and non-normal

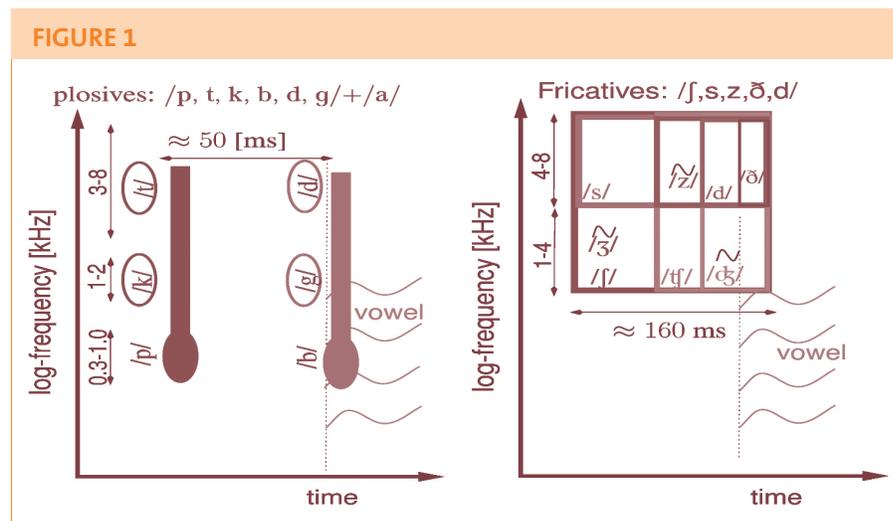

Figure 1. Time-frequency allocation of the plosives and the fricatives. Mapping these regions into perceptual cues required extensive perceptual experiments (Li et al., 2010). Once the sounds have been evaluated, it is possible to prove how the key noise-robust perceptual cues map to acoustic features. In the cases of the three voiced consonants indicated with a tilde (/z, ʒ, dʒ/), the frication noise is modulated at the pitch frequency.

ear at the utterance level. The paper will explain what the HSR group has found, and then predict where this research will go in the next few years. In addition, we will discuss a speech test that teases out such natural occurring idiosyncratic speech confusions, which we argue will eventually be useful for fitting hearing aids.

HOW DOES SPEECH PERCEPTION FAIL?

The challenge remains to understand the auditory processing strategy of the auditory cortex, which is wired to non-normal ears. To understand how normal ears decode consonants, the HSR group repeated the classic consonant perception experiments of Fletcher (1922) and Miller and Nicely (1955), among others. This gave us access to important new data and the ability to reassess many widely held assumptions. The first lesson of this research is the “sin of averaging”—while audiology is built on averaging measures, most of the interesting information is lost in these averages. We have shown, for example, that averaging across consonants distorts the measure as does averaging across

talkers for a given consonant. We have also found that entropy (a probabilistic measure of consistency) is more robust than the average error.

In 1970-80, a number of studies explored the role of the transitional and burst cues in a consonant-vowel (CV) context. In a review of the literature, Cole and Scott (1974) argued that the burst must play at least a partial role in perception, along with transition and speech energy envelope cues. Explicitly responding to Cole and Scott (1974), Dorman and colleagues (1977) executed an extensive experiment using natural speech made up from nine vowels preceded by /b, d, g/. The experimental procedure consisted of truncating the consonant burst and the devoiced transition (following the burst) of a CVC, and then splicing these onto a second VC sound, presumably with no transition component (since it had no initial consonant). Their results were presented as a complex set of interactions between the initial consonant (burst and devoiced cue) and the following vowel (i.e., coarticulations).

FIGURE 2

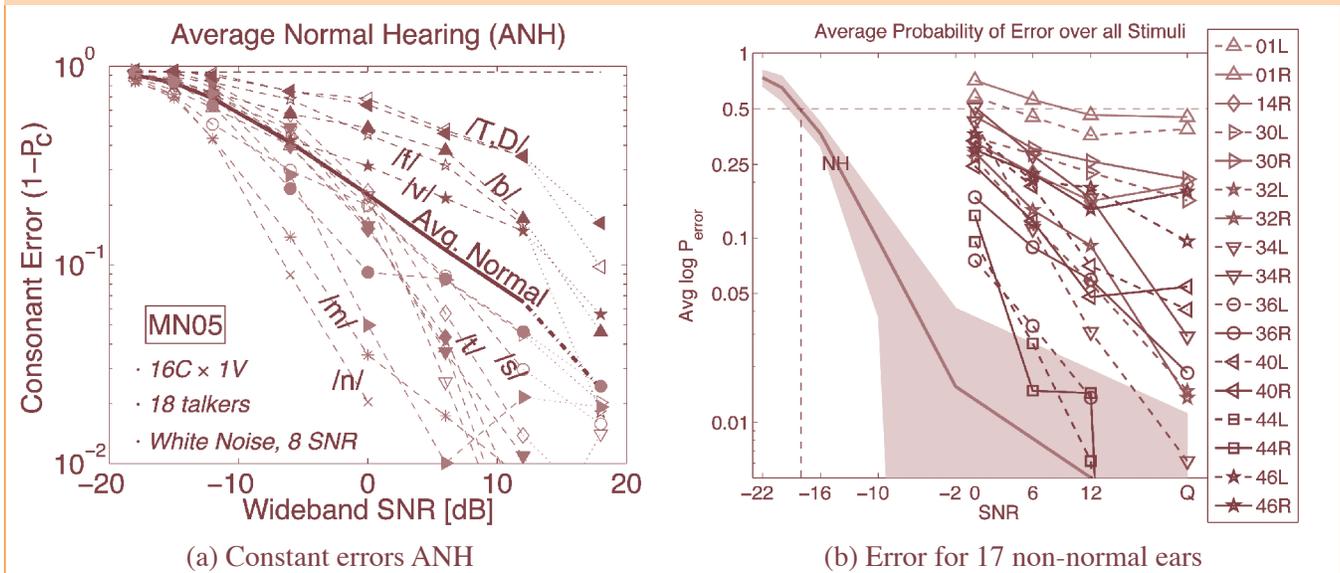

Figure 2. LEFT: Shown here is the average error (log scale) for 16 CV consonants as a function of the relative intensity of constant-spectrum-level masking noise (Phatak et al., 2009). The solid black curve labeled “Avg. Normal” shows the average across all the consonants. Note the large variation in error. RIGHT: This family of curves compares the average consonant error for 14 normal and 17 non-normal ears in speech shaped masking noise. For the non-normal ears, there is a large spread in scores due to the variation in hearing loss as compared to listeners with normal hearing (gray region), all of whom are similar in their average performance.

The same year Blumstein and colleagues (1977) published a related /b, d, g/ study using synthetic speech that also presented a look at the burst and a host of transition cues. They explored the possibility that the acoustic cues were *integrated* (acted as a whole). This study was looking to distinguish the *necessary* from the *sufficient* cues, and first introduced the concept of *conflicting cues* in an attempt to pit one type (burst cues) against the other (transition cues).

While these three key studies highlighted the relative importance of the two main types of acoustic cue, burst and transition, they left unresolved the identity and relative roles of these cues. No masking noise was used in the studies, ruling out any form of information analysis. Masking is key to an information theoretic analysis of any communication channel (Allen, 1994, 1996; Fletcher, 1922; Shannon, 1948). As discussed by Allen (2005), based on

the earlier work of Fletcher and Galt (1950), Miller and Nicely (1955), and inspired by Shannon’s source-channel model of communication, the HSR group repeated many of the classic experiments (Li & Allen, 2009; Phatak & Allen, 2007; Phatak et al., 2008). The data resulting from our several experiments will be discussed in the remainder of the paper.

IDENTIFYING PERCEPTUAL CUES

Li and colleagues (2010) first described a method to robustly identify speech cues for a variety of naturally produced CV speech sounds. This method uses a 3-dimensional psychophysical approach using a variety of noise levels, time-truncation, and high and low pass filtering. These experiments made it possible, for the first time, to reliably locate the subset of perceptually relevant cues in time and frequency, while the noise-masking data characterizes the cue’s masked threshold (i.e., its strength).

Figure 1 describes the resulting consonant maps. Not surprisingly, the perceptual cues associated with fricative sounds are quite different from the plosives. Timing and bandwidth remain important variables. For the fricative sounds, the lower edge of the swath of frication noise is the perceptual cue.

Briefly summarized in Figure 1, the CV sounds /ta, da/ are defined by a burst at high frequencies, /ka, ga/ are defined by a similar burst in the mid frequencies, and /ba, pa/ were traced back to a wide-band burst. As noise is added, the wide-band burst frequently degenerates into a low frequency burst, resulting in low-level confusions. The recognition of burst-consonants further depends on the delay between the burst and the sonorant onset, defined as the voice onset time (VOT). Consonants /t, k, p/ are voiceless sounds, occurring about 50 [ms] before the onset of F0 voicing while /d, g/ have a VOT <20 [ms]. Plosive /b/ may have a negative VOT.

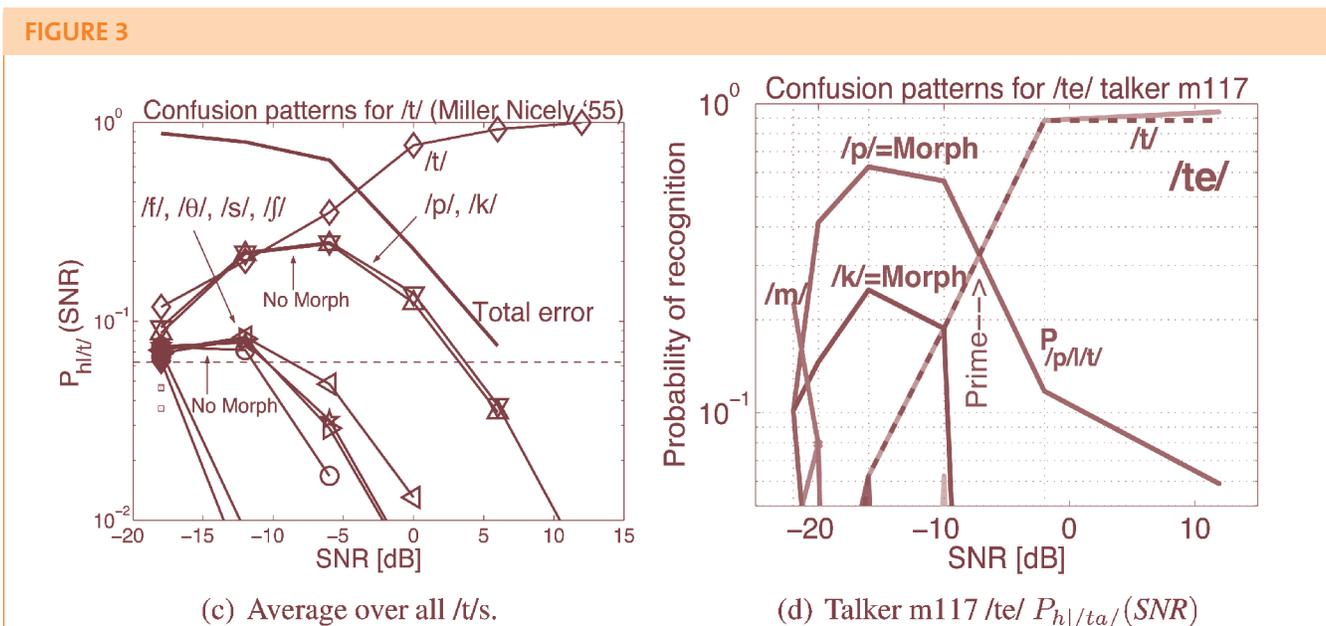

Figure 3: The “sin of averaging” extends to the utterance level. On the left (a) we see confusion patterns for the average score for /ta/ from Miller and Nicely (1955) (white masking noise). On the right (b) we show the confusion patterns for male talker 117 saying /te/ (speech shaped noise). Based on data with the same masking conditions, and as concluded in Figure 2, averaging across utterances removes critical information from the ANH scores. The confusion error is a function of the SNR in dB. As we shall see, this “sin” is much worse for non-normal ears at the utterance level. The arrow at -8 dB and 30% shows the priming point, defined as where a listener reports one of a small set of sounds (Li & Allen, 2011).

Based on the results of Li and colleagues (2010), this study, along with a host of verification experiments on the ~100 CV utterances in the HSR database (Kapoor & Allen, 2012; Li & Allen, 2011; Régnier & Allen, 2008), we have conclusively demonstrated that these features uniquely label the indicated consonant.

METHODS

Isolated CVs were taken from naturally produced speech from 18 talkers. Noise was added to the speech with a range from -26 dB to quiet (Q). Both uniform and speech weighted spectrum level noise was added to the speech. The listener corpus consisted of more than 200 normal and 45 non-normal ears, with 9-16 consonant and 8 vowel sounds. To assure the estimates of the error are reliable, a minimum of 10 trials per utterance and SNR are required (Han, 2011; Phatak, Yoon, Gooler, & Allen, 2009; Singh & Allen, 2012). The difference between these new experi-

ments and their classic counterparts is that the utterances of each consonant are not averaged.

RESULTS

In Figure 2, the average probability of the error $P_e(SNR)$ is shown (for speech-weighted noise the SNR is the same as the articulation index). On the left (a), the “average normal hearing” (ANH) score $P_e(SNR)$ (black line), along with the score for each heard consonant /h/, given spoken consonant /s/ as a function of the SNR for flat-spectrum masking noise (Phatak et al., 2009). There is a huge variation in scores across the consonants: the SNR corresponding to the 50% point ranges from -12 dB [m, n/] to +8 dB [θ, ð/] [shown as /T/ and /D/ in Figure 2)]. Such a large range of scores is not captured by an average. Not shown here, each utterance in the HSR database has a wide range of scores, varying in error from zero to chance depending on the masking

noise intensity (Singh & Allen, 2012). The right panel (b) shows the average scores for the 17 non-normal ears as compared to the average scores of the participants with normal hearing in speech-shaped masking noise. One of the best ears in terms of average error is 36R. Not shown is that his error for /ba/ reaches 100%, while the remaining 13 consonants tested had zero error. Thus, the reported performance is highly distorted, again due to the “sin of averaging.”

A second major conclusion is that when characterizing a listener with hearing loss, one must look at the individual confusions. In Figure 3, confusion patterns (CPs) are compared to SNR. The CP is a graphical display of the confusion probabilities as a function of the intensity of the masking noise relative to the speech. To estimate a CP requires a totally different clinical measure than is being applied today. CPs allow one to

visualize the confusions of each sound as a function of the SNR. From the CP it is easy to identify a sound that primes, meaning that it can be heard as one of several sounds with equal probability by changing one's mental bias. In this case the CPs show subject responses that are equal (the curves cross each other), similar to the CP of Figure 3(b) at -8 dB where one naturally primes /p/, /t/, and, to a lesser extent, /k/ (at -10 dB).

When asked, most clinicians report that they do not have the time to make detailed measures. In our opinion, this is more a reflection of old habits than actual time constraints. The confusion sets, and their dependence on the noise, are not predictable without such tests. Utterance confusions and their masked dependence are important because they reveal the mix of underlying perceptual cues being confused with the target sound.

When using an utterance confusion measure, each non-normal ear consistently makes large errors on a small subset of utterances. Furthermore, for a given utterance, there are patterns in these errors across listeners with hearing loss. In other words, normally spoken utterances are heard idiosyncratically by non-normal ears, yet with correlated error patterns.

CONFUSIONS IN NON-NORMAL EARS

As a direct extension of earlier studies (e.g., Phatak et al., 2009), four experiments were performed (Han 2011), two of which will be reported on here. In Experiment 1 (Exp-1), full-rank confusion matrices for the 16 Miller-Nicely CV sounds were determined at 6 SNR [Q, 12, 6, 0, -6, and -12 dB] for 46 non-normal ears (25 subjects). In Experiment 2 (Exp-2), a subset of 17 ears were remeasured, but with the total number of trials per SNR per consonant raised from 2–8 (Exp-1) to as high as

FIGURE 4

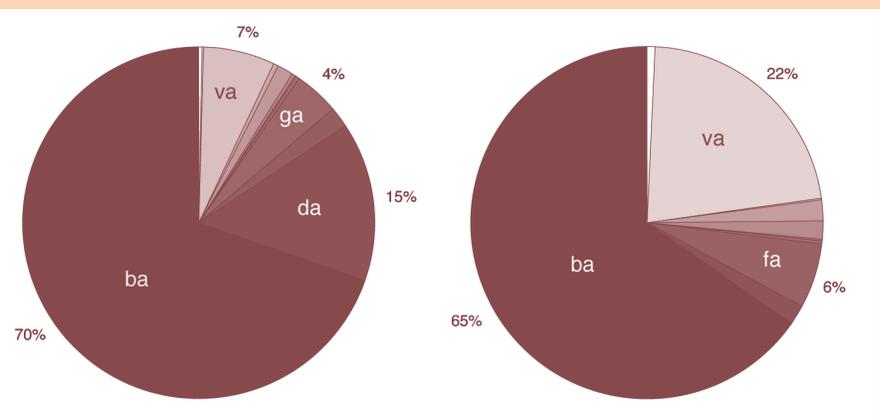

Figure 4: These pie charts show the proportion of confusions for two different /ba/ utterances, as reported by all of the 17 non-normal ears. The most common error for the /ba/ on the left is /da/ and then /va/, while the one on the right is most frequently heard as /va/ and then /fa/. The one on the left is almost never heard as /fa/ and the one on the right almost never as /da/. These two /ba/ sounds are reported correctly by normal ears.

20 (Exp-2) to statistically verify the reliability of the subjects' responses in doing the task.

Figure 4 shows that listeners with hearing loss are using a common strategy that depends systematically on the utterance. Clearly, if such very different scores for the two /ba/ sounds were to be averaged together (i.e., present clinical practice), the idiosyncratic (i.e., the most important) information about the ears would be lost. As discussed earlier, the average score is a distorted metric due to its high variance a) across consonants, b) across utterances for each consonant, and c) across subjects with hearing loss. Entropy gives a direct measure of consistency and is insensitive to mislabeling errors (e.g., consistently across a voicing error, as in reporting /d/ given /t/). Given the observed increased mislabeling of sounds in non-normal ears, a high-consistency measure (i.e., entropy) seems to be a better measure.

SUMMARY

This article has reviewed some of what the HSR group has recently learned about speech perception of consonants, and how this knowledge might im-

pact understanding of nonlinear (NL) cochlear speech processing. However, the role of outer hair cell (OHC) processing of speech is still poorly understood (Allen, 2008; Allen & Li, 2009). It is now widely accepted that OHCs provide dynamic range and are responsible for much of the NL cochlear speech signal processing, thus the common element that links all the NL data (Allen, Régnier, Phatak, & Li, 2009). OHC dynamics must be understood before any model can hope to succeed in predicting basilar membrane, hair cell, neural tuning, and NL compression. Understanding the OHC's two-way mechanical transduction may be the key to solving the problem of the cochlea's dynamic range and dynamic response (Allen, 2003).

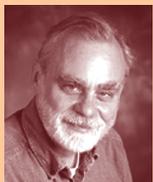

However, the perception of speech by the non-normal ear does not seem to be consistent with the above commonly held view. For example, the large individual differences seem inconsistent with the OHC as the tying link, and seem more likely related to synaptic dead regions (Kujawa & Liberman, 2009). Continued analysis of these confusions will hopefully provide further insights into this important question.

The detailed study of how a complex system fails can give deep insights into how the normal system works.

The key open problem here is, “How does the auditory system (e.g., the NL cochlea and the auditory cortex) process human speech?” There are many applications of these results including speech coding, speech recognition in noise, hearing aids, and cochlear implants as well as language acquisition and reading disorders in children. If we can solve the *robust phone decoding problem*, we will fundamentally change the effectiveness of human-machine interactions. For example, the ultimate hearing aid is the hearing aid with built in robust speech feature detection and phone recognition. While researchers have no idea when speech-aware hearing aids will come to be, and the time is undoubtedly many years off, when it happens, it will be a technological revolution of some magnitude.

THE RESTORATION OF SPEECH UNDERSTANDING BY ELECTRICAL STIMULATION OF THE AUDITORY SYSTEM

BY MICHAEL DORMAN, PH.D., ARIZONA STATE UNIVERSITY

The first cochlear implant surgery was performed over 50 years ago and allowed a patient to hear “sounds.” Today, professionals expect high levels of speech understanding for adults who are post-lingually deaf and who receive a cochlear implant, and for children who are congenitally deaf—if the children receive a cochlear implant early and if they receive intensive listening and spoken language intervention. This presentation will provide a broad view of the technology underlying cochlear implants and describe possible next steps in the evolution of these devices.

Over 50 years ago, William House, M.D., performed the first cochlear implant surgery. The results were modest—the patient reported hearing “sounds.” Today, professionals expect that the majority of adult patients who are late-deafened, when fit with a cochlear implant, will achieve 80–100% correct scores on tests of sentence understanding in quiet (Wilson & Dorman, 2008). Professionals expect that many children who are congenitally deaf, if fitted with a cochlear implant before the age of 3 and if given extensive (re)habilitation, will perform near the level of their age-matched peers who have typical hearing on tests of speech understanding when in elementary school. These results, for adults and children, underlie the claim that cochlear implants are one of the miracles of modern medicine.

After 50 years of effort, cochlear implantation is now a mature discipline—professionals expect good results for most patients. Nonetheless, researchers continue their work and new developments extend the promise of even higher levels of speech understanding for individuals with hearing loss.

BETTER HEARING BY “HYBRID” STIMULATION

One innovation, a relatively simple one at that, is combining electric stimulation

with acoustic stimulation. The majority of patients who qualify for a cochlear implant in one ear have some low-frequency acoustic hearing in the other. Researchers at Arizona State University have found that patients with hearing only at 125 Hz and 250 Hz, i.e., at very low frequencies, can use the information carried by these frequencies to improve speech understanding via their implant. This low-frequency information is especially useful in noise, which is fortunate because cochlear implants alone do not provide high levels of speech understanding when speech is presented against a background of noise.

A recent surgical innovation, hearing preservation surgery, allows surgeons to implant an electrode array and to preserve low-frequency hearing. This provides much better speech understanding via the implanted ear and provides the listener with two partially hearing ears—the ear opposite the implant and the ear with the implant. Having two partially hearing ears is of benefit in listening environments where noise surrounds the listener.

Hearing preservation surgery allows patients with substantial low-frequency hearing and speech understanding to receive a cochlear implant and to benefit from “hybrid” hearing. Research-

ers working on this technique expect to see, in the near future, patients with up to 60% word scores by hearing alone to qualify for a cochlear implant. The logical extension of this idea is cochlear implantation for the “common variety” of high-frequency hearing loss. Of course, the greater the amount of hearing and speech understanding, the greater the consequences of losing both, if hearing is not preserved. The calculation for or against cochlear implant surgery for these individuals will not be simple.

Hearing preservation surgery will also create patients with a cochlear implant in each ear and low-frequency hearing in each ear. Researchers have tested several patients like this and, when tested in complex listening situations, find that they benefit from having two implants versus one and having two partially hearing ears versus one.

BETTER HEARING THROUGH CHEMISTRY

The odds of retaining low-frequency hearing following cochlear implant surgery can be improved by the administration of protective drugs during the surgical procedure. Studies have shown that some drugs, such as dexamethasone, can prevent inner-ear cell damage from exposure to very loud noises, similar to the noise produced by surgical

drilling for cochlear implants. The same drug can rescue cells 24 hours after exposure to loud noises or other drugs that destroy hearing. These results have stimulated researchers to create electrode arrays that both deliver a drug and provide electrical stimulation to the cochlea. The delivery of drugs during cochlear implant surgery and in the weeks and months post-surgery via the electrode array will allow for the maximum conservation of residual hearing in the implanted ear.

This same technology of combined drug delivery and electrical stimulation holds tremendous promise for young children receiving cochlear implants. Research has shown that administration of a class of drugs called neurotropic drugs can stimulate the growth of neurons (Sinohara et al., 2002) and could even promote the growth of neural fibers up the chemical gradient to the electrode that is releasing the drug. If this can be achieved in very young children, then professionals will have a method of preserving the neural elements in the child's cochlea and a method of getting neural elements very close to the electrode array. The latter would allow very low levels of current to be used for stimulation and should result in much better frequency resolution. Better frequency resolution would lead to better speech understanding and, perhaps, better appreciation of music.

BETTER HEARING FROM EARLY STIMULATION

Brain wiring is determined by both intrinsic factors of biology and by environmental stimulation. In the absence of auditory stimulation early in development, the auditory brain will not develop typically and will not have the usual connections to other areas of the brain that process speech and language (Kral & O'Donoghue, 2010). Indeed, in the absence of auditory stimulation,

some auditory areas can be usurped by other sensory modalities, such as vision or touch. Thus, early stimulation of the auditory pathways is critical to driving a developing brain into the configuration shown by infants with typical hearing. At issue for parents is, how early is "early" and how late is "late?" If a child has had no auditory stimulation for the first seven years of life, then the odds of achieving reasonable levels of speech understanding via a cochlear implant are poor. A child who receives a cochlear implant by age 2-3 years will have better odds of a good outcome (Svirsky et al., 2007), and age 1 year is now a standard for most children who receive cochlear implants. There is some evidence that receiving a cochlear implant under the age of 1 provides some advantages (Houston & Miyamoto, 2010), but very early implantation must be weighed against surgical risks and other factors (Cosetti & Roland, 2010).

The need for early stimulation to shape connections within and among different areas of the auditory brain puts parents, who wish to wait for something better than a cochlear implant for their child, in a difficult position. Imagine a therapy, for example, based on stem cells that could regenerate the cell bodies and related structures in the cochlea that are absent in a child who has a profound hearing loss. And imagine that this therapy is still 10 years away. What would

speech understanding be like for a child with regenerated cells in the cochlea but who had been without stimulation for 10 years? Because the brain would not have developed typical connections within and between brain areas that subserve hearing and language, the value of having new cells in the cochlea could be very small. Early restoration of function should be the hope of parents who wish their child to experience typical or near typical development of speech and language skills.

ABOUT THE AUTHOR

Michael Dorman, Ph.D., is a professor in the Department of Speech and Hearing Sciences at Arizona State University. He received his Ph.D. in experimental child and developmental psychology (with a linguistics minor) from the University of Connecticut in 1971. He is a Fellow of the Acoustical Society of America and the author of over 150 publications in areas including speech perception by infants, adults, listeners with hearing loss and listeners fit with cochlear implants; cortical lateralization of function; and neural plasticity. His work on cochlear implants has been supported continuously by the National Institutes of Health since 1989.

SPOKEN LANGUAGE DEVELOPMENT IN INFANTS WHO ARE DEAF OR HARD OF HEARING: THE ROLE OF MATERNAL INFANT-DIRECTED SPEECH

BY TONYA R. BERGESON-DANA, PH.D., INDIANA UNIVERSITY

How do children learn spoken language? Most children with typical hearing learn from infancy the sound of their mother's voice, a type of speech researchers call infant-directed speech. Mothers, fathers and most adults speak to infants in a sing-song manner, exaggerating the melody and rhythm of their speech. But what happens when this connection is broken, such as with a child who has hearing loss? This article will discuss the importance of infant-directed speech, and how infants with hearing loss respond to such talk in comparison to infants with typical hearing.

How do children learn spoken language? In children who are developing typically, this feat is accomplished more or less naturally through active experiences with caregivers and the child's environment. Parents don't enroll infants and toddlers in spoken language classes; instead, they model, encourage, and stimulate their speech and language attempts by responding to the cries and coos of infants and holding simple conversations with toddlers. In fact, caregivers across the world actually speak to their infants and young children using a special style of speech commonly known as "babytalk" or "motherese." Researchers and scholars call this *infant-directed speech*. Mothers, fathers, and even strangers off the streets speak to infants in a sing-song manner, exaggerating the melody and rhythm of their speech (e.g., Ferguson, 1964; Fernald, 1989). Caregivers are flexible with this speech style, adjusting the levels of exaggeration according to the social context and their infant's age (e.g., Kitamura, Thanavishuth, Burnham, & Luksaneeyanawin, 2002; Stern, Spieker, Barnett, & MacKain, 1983). This speech style is now known to contribute in many ways not only to

infants' social-emotional development, but also to their speech, language, and cognitive development (e.g., Liu, Kuhl, & Tsao, 2003).

Sometimes that natural connection between caregivers and infants can be disrupted. For example, caregivers who suffer from depression have difficulty connecting with their children, speaking to them in monotones with flat affect. Researchers have shown that infants of mothers who are depressed have a difficult time learning new associations from such speech (Kaplan, Bachorowski, Smoski, & Hudenko, 2002), which likely has cascading effects on the development of spoken language and cognition. Moreover, children in families with low socioeconomic status are at a serious disadvantage compared to children in families with high socioeconomic status in terms of both spoken language input quantity and quality. Researchers have found that caregivers with fewer financial and educational resources use fewer words in their infant- and child-directed speech than caregivers with greater financial and educational resources (Hart & Risley, 1995). This effect later translates to

language abilities, with children from low income homes exhibiting much worse language skills compared to children from high income homes (Hart & Risely, 1995). These studies, among others, highlight the importance of caregivers' speech to infants as they develop spoken language.

What happens, then, if infants have a hard time hearing their caregivers? How do children who are deaf or hard of hearing learn spoken language? With the advent of new technologies, such as cochlear implants and state-of-the-art hearing aids, children with hearing loss now have the most access to sound and spoken language in their environment than ever before. Because of this, we would expect caregivers to speak to their infants and children with hearing loss just the same as those with typical hearing. And children with hearing loss who use hearing aids or cochlear implants should demonstrate similar spoken language development as children with typical hearing. Children who are deaf or hard of hearing *can* achieve speech and spoken language abilities on par with their typically developing peers with the use

of such assistive devices (e.g., Peterson, Pisoni, & Miyamoto, 2010). However, there are large individual differences among these children; not all children with hearing loss benefit to the same degree from cochlear implants or hearing aids (Pisoni, Cleary, Geers, & Tobey, 1999; Pisoni et al., 2008). As recently as 10 years ago, researchers could only guess at why this is the case because there were no pre-amplification predictors of outcome and benefit. However, recent studies have shown potential predictors of children who will succeed with hearing aids or cochlear implants that are related to early auditory experience (e.g., Bergeson & Pisoni, 2004).

CHILD PERCEPTION OF INFANT-DIRECTED SPEECH

The focus of this paper is one of the most important factors that can determine infants' benefit and success in spoken language development via amplification: early auditory experiences from infants' interactions with their caregivers, or infant-directed speech. The first question addressed is, do infants who have hearing loss for the first part of their life pay the same kind of attention to infant-directed speech as infants with typical hearing do? This is one way to determine if infants with hearing loss are reinforcing caregivers' use of infant-directed speech.

To answer this question, let's first review what is known about infant attention to maternal speech in typical development. At least two types of infant behaviors have been established by researchers. First, infants with typical hearing, from birth to 12 months old, prefer to listen to infant-directed speech over adult-directed speech (Fernald & Simon, 1984; Fernald et al., 1989; Grieser & Kuhl, 1988; Kitamura et al., 2002; Kuhl et al., 1997). Infants are especially responsive to the melodic quality of infant-directed speech

(Fernald & Kuhl, 1987). Infants' increased attention to infant-directed speech might actually help them process and understand speech and language. For example, infants find it easier to pick out new words from a spoken passage when listening to infant-directed speech rather than adult-directed speech (Thiessen, Hill, & Saffran, 2005). Mothers tend to highlight new words when speaking to infants much more so than when speaking to adults.

Second, infants with typical hearing recognize and prefer to listen to their own mothers' voice (DeCasper & Fifer, 1980). Amazingly, preference for maternal voices seems to develop even before infants are born. One study found that infants in the womb have different heart rate patterns in response to their mother's voice as compared to a stranger's voice (Kisilevsky et al., 2003). These findings also highlight the important effects of very early auditory experience on infants' speech perception abilities.

But what about infants and toddlers who have congenital hearing loss and receive hearing aids or cochlear implants? Do they pay the same type of attention to speech as infants with typical hearing? Research from the Babytalk Research Laboratory has been addressing this very question. One of the difficulties of assessing attention in this population is that the research participants are preverbal. That is, we cannot simply ask the infants and toddlers, "What do you think about this speech? Do you like this type of speech better than the other?" Instead, we use tried-and-true methods taken from the field of developmental psychology. Infants sit on their caregivers' laps inside a large sound-proof booth. We draw their attention to a TV monitor in front of them, and then present various

audio-visual stimuli. Previous research has shown that infants will naturally look longer towards a visual display near a sound source if they're interested in what they're hearing.

In one particular study, we measured infants' looking time to a red-and-white checkerboard pattern on the TV monitor while listening to four different mothers speaking in either an infant-directed or adult-directed style of speech. The study also included silent trials to determine how much infants prefer speech in general to silence. Infants with typical hearing attended much longer to speech trials than silent trials, and generally preferred infant-directed to adult-directed speech. Infants with mild-to-moderate hearing loss who use hearing aids showed similar patterns, but it took a little longer for them to develop their preferences than infants with typical hearing. Finally, infants with cochlear implants did not show a preference for infant-directed speech over adult-directed speech until approximately 9-12 months post-implantation. And even then, they did not attend any longer to the adult-directed speech than to silence! These findings have major implications for child-caregiver interactions and spoken language development.

There are some studies about recognition of voices in children who are deaf or hard of hearing. Several studies have shown that cochlear implant users find it difficult to distinguish the voices of different talkers, particularly if the talkers are the same sex (Cleary & Pisoni, 2002; Cleary, Pisoni, & Kirk, 2005; Fu, Chinchilla, & Galvin, 2004). However, one recent study showed that children ages 5-15 years old who use cochlear implants can tell apart their own mother's voice from other men, children, and even other women, although

their performance is not as good as that of children with typical hearing (Vongpaisal, Trehub, Schellenberg, van Lieshout, & Papsin, 2010).

The Babytalk Research Laboratory is in the midst of conducting another study to determine whether infants with congenital hearing loss can distinguish their own mother's voice from a stranger's voice. This study uses a habituation paradigm, in which a series of different women reciting passages in an infant-directed speech style is presented to infants who have about one year of hearing aid or cochlear implant experience. The idea is that infants will again pay attention to a checkerboard pattern on the TV monitor directly ahead of them when they are interested in the speech sounds. In a habituation paradigm, it is also expected that infants will start off with a high amount of interest and gradually become bored as the same category of sound (i.e., women's infant-directed speech) is repeated. Two test trials are presented once they reach a criterion point of boredom: one is their own mother's voice and the other is a stranger's voice. If they recognize their mother's voice, infants should theoretically pay more attention than to the last habituation trial and the test trial with the stranger's voice. If they do not recognize their mother's voice, then they should pay equal attention to all three trials. Data have been collected from a handful of infants and toddlers who are deaf or hard of hearing who have used a hearing aid or cochlear implant for approximately one year. These children have not yet shown recognition of their own mother's voice from that of a strange woman. Future studies will likely be needed to determine how infants and toddlers learn to recognize their mother's voice with additional hearing aid or cochlear implant use.

CAREGIVER PRODUCTION OF INFANT-DIRECTED SPEECH

Thus far, research has shown that infants and young children who are deaf or hard of hearing do not pay attention to infant-directed speech, or even speech in general, in the same way as children with typical hearing until they've had at least 9-12 months of auditory experience. Imagine now parents interacting with infants who are deaf or hard of hearing. If their infants are not paying active attention to their attempts to entertain or soothe using infant-directed speech, how must this affect caregivers' further use of this special speech style? That is, do caregivers speak in the same or different ways to young children with and without hearing loss?

To date there has been very little research on caregiver speech to infants with hearing loss who use hearing aids and cochlear implants. One reason is that, prior to state-mandated universal newborn hearing screening programs, infants were typically not diagnosed with hearing loss until 2-3 years of age (Meadow-Orlans, Spencer, & Koester, 2004). The existing literature suggests that an infant's hearing status may affect the way in which caregivers speak to their infants. One study of speech to infants with hearing loss showed that mothers with typical hearing tend to increase their use of vocal exaggeration when they first discover their infant's hearing loss, but gradually decrease the amount of vocal exaggeration over time (Wedell-Monnig & Lumley, 1980). Other studies of mother-child interactions have revealed that mothers tend to be more controlling, more repetitive, and less responsive in their interactions with children who are deaf or hard of hearing than with children who have typical hearing (Cheskin, 1981; Goss, 1970; Henggeler & Cooper, 1983). Mothers also produce fewer and less complex

verbal utterances but more nonverbal attention-getting behaviors when interacting with children with hearing loss than children with typical hearing (Goldin-Meadow & Saltzman, 2000; Koester, Brooks, & Karkowski, 1998; Koester, Karkowski, & Traci, 1998). Some researchers have shown, however, more similarities in mothers' speech styles to both sets of children when the children were matched by linguistic age rather than chronological age (Cross, Nienhuys, & Kirkman, 1985; Nienhuys, Cross, & Horsborough, 1984).

The Babytalk Research Laboratory recently investigated the effects of infant age and hearing loss on several prosodic characteristics of mothers' speech to infants with typical hearing and infants with hearing loss who use cochlear implants (Bergeson, Miller, & McCune, 2006; Kondaurova, Bergeson, & Xu, 2012). The results of these studies revealed that mothers do use infant-directed speech when interacting with their infants with cochlear implants, and that their vocal styles are more similar to mothers of infants with typical hearing when infants are matched by hearing experience rather than chronological age. Thus, these mothers adapt their prosodic speech style to the hearing experience and linguistic abilities of their infants who are deaf or hard of hearing.

Researchers have proposed that one of the functions of infant-directed speech is to help infants learn about language (e.g., Fernald, 1992). For example, infant-directed speech actually exaggerates certain cues to sentence structure. Caregivers will change the pitch of their voice from the end of one sentence to the beginning of another when speaking to an infant. They will also tend to linger on the last syllable of a sentence and take an exaggerated pause before starting a new sentence. In a recent

analysis of maternal speech, we found that mothers use similar sentence boundary cues when interacting with their infants who are profoundly deaf and use cochlear implants (Kondaurova & Bergeson, 2011).

Infant-directed speech might also help infants learn about the sound structure of their language. One study found that mothers potentially help their infants with typical hearing and infants with hearing loss discriminate among vowel categories (e.g., “ah,” “ee,” and “oo”) by exaggerating the differences among them (Dilley & Bergeson, 2010). Another study measured mothers’ exaggeration of cues that commonly distinguish tense vowels (e.g., “sheep”) and lax vowels (e.g., “ship”) in their speech to infants with profound hearing loss. There are two cues to this vowel contrast, one of which should be easily encoded with cochlear implant technology (duration of the vowel) and the other which is more problematic for cochlear implant users (spectrum of the vowel). Results showed that mothers exaggerated duration but not spectrum cues in speech to infants with hearing loss compared to speech to adults (Kondaurova, Bergeson, & Dilley, in press).

Taken together, these studies suggest that mothers’ speech is sensitive to their young children’s linguistic and hearing levels. In other words, mothers seem to be providing their infants and toddlers who are deaf or hard of hearing with speech cues tailored to their individual abilities. These findings are important given previous research that shows that the features of infant-directed speech have significant effects on language and cognitive development (Hart & Risley, 1995; Kaplan et al., 2002; Liu et al., 2003; Meadow-Orlans & Spencer, 1996; Pressman, Pipp-Siegel, Yoshinaga-Itano, & Deas, 1999; Spencer & Meadow-Orlans, 1996).

Nevertheless, there are still several unanswered questions regarding the acquisition of speech and language skills in both populations. Which aspects of infant-directed speech make it particularly beneficial for language acquisition? It could be that infant-directed speech is most beneficial because the vowel/consonant categories are clearer or more exaggerated. Or it could be the case that more general exaggeration (e.g., higher pitch or slower speaking rate) in mothers’ speech to infants elicits and maintains infants’ attention, which then allows the infants to pay attention to particular sounds or sentence structures. Moreover, infants with hearing loss may benefit from different features of infant-directed speech than infants with typical hearing. What is the best way for a mother (or a speech-language pathologist) to speak to an infant, and is this the same for infants who use a hearing aid or a cochlear implant? Preliminary data in the Babytalk Research Laboratory shows that some features of mothers’ speech to infants with hearing loss, such as use of repetition, is associated with their infants’ ability to learn new words and other speech and language outcomes. Answers to these questions will provide valuable new information to parents and clinicians of infants who are deaf or hard of hearing and use hearing aids and cochlear implants.

ABOUT THE AUTHOR

Tonya R. Bergeson-Dana, Ph.D., is an associate professor, Philip F. Holton Investigator, and co-director of the Babytalk Research Laboratory in the Department of Otolaryngology-Head & Neck Surgery at the Indiana University School of Medicine in Indianapolis, Ind. She received undergraduate degrees in music

theory and psychology from Northwestern University, and an M.A. and Ph.D. in cognitive psychology from the University of Toronto. Bergeson is currently interested in three areas of research: the effects of hearing loss and subsequent amplification via hearing aids or cochlear implants on mothers' speech to infants with mild to profound hearing loss; the development of multimodal perception skills in infants who are deaf following amplification; and the effects of cochlear implantation and hearing experience on music perception and production in infants, children, and adults. She is particularly interested in the effects of early experience on developing language and auditory perception.

Abstract Measures of membrane capacitance (C_m) can be used to assess important characteristics of voltage-dependent membrane proteins (e.g., channels and transporters). In particular, a protein's time-dependent voltage-sensor charge movement is equivalently represented as a frequency-dependent component of C_m , telling much about the kinetics of the protein's conformational behavior. Recently, we have explored the frequency dependence of OHC voltage-dependent capacitance (aka nonlinear capacitance, NLC) to query rates of conformational switching within prestin (SLC26a5), the cell's lateral membrane molecular motor¹. Following removal of confounding stray capacitance effects, high frequency C_m measures using wide-band stimuli accurately reveal unexpected low pass behavior in prestin's molecular motions.

INTRODUCTION

The outer hair cell (OHC) powers a feedback process within the cochlea that augments hearing sensitivity by 40 to 60 decibels, termed cochlear amplification². The molecular basis of this process resides within the lateral plasma membrane of that cell, where millions of unusual motor proteins, known as prestin (SLC26a5)³, contribute to force generation. Activation of the motor protein by voltage (*in vivo*, the receptor potential) evokes two characteristic, measurable responses; these are a mechanical response called electromotility (eM)⁴⁻⁷, and a corresponding electrical response. The latter is commonly called NonLinear Capacitance (NLC), and results from the restricted charge movement of the motility voltage sensor within the plasma membrane, normal to membrane's electric field^{8,9}. This phenomenon is similar to gating/sensor charge movements driving opening/closing of voltage dependent ion channels¹⁰. NLC has been used as a surrogate of OHC mechanical activity because of its relative ease of measurement; since eM has been measured beyond 80 kHz¹¹, sensor movement effecting eM is expected to be extremely rapid.

Though the usefulness of membrane capacitance (C_m) measurement dates from the time of Frick¹², its general applicability has grown tremendously since patch clamp technology blossomed¹³. Because of the widespread interest in neurotransmitter release, techniques were developed to assess vesicle membrane fusion by monitoring the surface area of the membrane during fusion. Because the plasma membrane acts as a linear capacitor (C_{lin}) proportional to

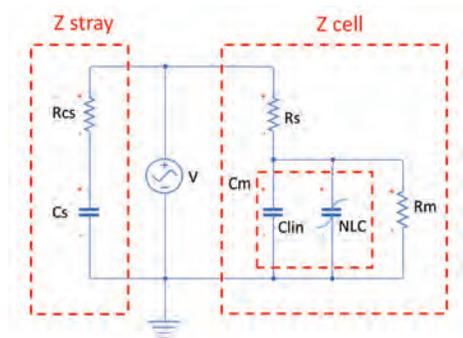

FIGURE 1. Electrical model of patch-clamped OHC. Electrode resistance (R_s), membrane resistance (R_m), membrane capacitance (C_m), composed of linear (C_{lin}) and nonlinear capacitance (NLC). Stray capacitance is modeled as series of R_{cs} and C_s . Model is stimulated with sinusoidal voltage, V .

surface area, synaptic vesicle fusion can be monitored by focusing on changes in linear membrane capacitance^{14, 15}. C_m measures have also been useful for estimating electrical coupling of cells through gap junctions^{16, 17}.

Linear C_m Measurement Approaches

Figure 1 shows the standard simple schematic of a voltage-clamped biological cell, in the case of an OHC, with an additional parallel voltage-dependent capacitance (NLC). The electrode resistance (R_s) limits the voltage (V) imposed across the cell membrane in time and magnitude. Roughly, the speed with which a voltage command can be delivered to the membrane is limited in time by $R_s * C_m$, the clamp time constant (τ_{clamp}), with a step voltage command slowly rising to a maximum of $R_m / (R_s + R_m) * V$. The actual τ_{clamp} is $C_m * (R_s * R_m / (R_s + R_m))$, but since R_s is usually much less than R_m the approximation may hold. Thus, in evaluating the effectiveness of the voltage command, τ_{clamp} and attenuation by the voltage divider effect must be considered. Additionally, stray capacitance (e.g., from the pipette and holder, and residual within the patch clamp amplifier), modelled in **Fig. 1** as a series combination of R_{cs} and C_s , needs to be cancelled by patch amplifier compensation circuitry. With just R_s , R_m and C_m , the circuit is simple, and assuming linear components (no NLC), C_m can be estimated accurately.

One method to estimate surface area under voltage clamp relies on monitoring the capacitive currents that arise from changes in membrane capacitance, namely, the AC voltage-evoked currents measurable at the phase angle of the partial derivative $\delta Y / \delta C_m$. Since the introduction of admittance analysis of C_m , the phase angle of $\delta Y / \delta C_m$ had been estimated by techniques requiring dithering of either patch clamp capacitance compensation circuitry (effectively altering C_s) or by dithering an R_s increment to arrive at estimates of the proper phase angle¹⁸. These methods provide measuring angles that are only estimates, and consequently changes in resistive currents (i.e., resulting from changes in membrane or electrode resistances) may influence attempts to measure capacitive currents. In 2004¹⁹, a simple method not relying on dithering and providing the exact identification of $\delta Y / \delta C_m$ and its angle was developed. This was based on the identity between the angles of $\delta Y / \delta C_m$ and $\delta Y / \delta \omega$. Thus, using two simultaneous voltage frequencies to measure membrane currents, the angle of $\delta Y / \delta C_m$ at one of those frequencies can be obtained and used to measure capacitive currents directly and accurately. However, a calibration during experiments is required to get at absolute C_m values.

Another method, which I developed in 1991, also used dual frequency stimulation²⁰. The method arose in a proposal to measure OHC C_m *in vivo*, and the following description is taken from my funded NIH grant proposal (R01 DC02003, submitted in 1992).

.... In the present experiment, a discrete frequency analysis will be attempted. Pusch and Neher (1988) have used a single "tone" (sine wave, actually) technique to determine cell characteristics under whole cell voltage clamp. By injecting a sinusoidal voltage into a cell, and measuring the current response, they calculated from the system's impedance, the cell capacitance, resistance and electrode resistance.

.... with the use of one "tone" (ω), it is necessary to obtain an independent estimate of the input resistance (b). However, the utilization of a "two tone" (ω_1 and ω_2) stimulus allows one to determine all parameters, given the signal and response. That is, b need not be determined independently, and can be solved for, since, for example, R_s is the same at any two frequencies. The evaluations should work under voltage clamp or current clamp ...

The component solutions at the harmonic angular frequencies ω_n , $n=0, 1$ are

$$R_{sn} = \frac{a_n - \beta}{a_n^2 + b_n^2 - a_n \beta} \quad (1)$$

$$R_{mn} = \frac{1((a_n - \beta)^2 + b_n^2)}{b(a_n^2 + b_n^2 - a_n \beta)} \quad (2)$$

$$C_{mn} = \frac{1}{(\omega_n b_n)} \frac{(a_n^2 + b_n^2 - a_n \beta)^2}{((a_n - \beta)^2 + b_n^2)} \quad (3)$$

where from the measured input admittance Y_{in} we obtain

$$Y_{cell\omega_n} = Y_{in\omega_n} - Y_{stray\omega_n}, n = 0,1 \quad (4)$$

$$a_n = Re(Y_{cell\omega_n}) \quad (5)$$

$$b_n = Im(Y_{cell\omega_n}) \quad (6)$$

$$c_n = a_n^2 + b_n^2 \quad (7)$$

$$\beta = -0.5 \times \frac{-c_1 + c_0 + \sqrt{c_1^2 - 2c_1c_0 + c_0^2 - 4a_1a_0c_1 + 4a_1^2c_0 + 4a_0^2c_1 - 4a_0a_1c_0}}{a_1 - a_0} \quad (8)$$

Thus, membrane currents evoked by two voltage frequencies can be used to solve for R_s , R_m and C_m , even in the face of resistive changes, but only in the absence of stray capacitance. Nevertheless, it is prudent, if not imperative under many circumstances, that ionic conductances be blocked when actually measuring C_m .

In 2006, Farrell, Do Shope and Brownell²¹ devalued this electrical dual-sine admittance approach²⁰ for estimation of C_m at high frequencies given the standard model of the patch-clamped cell, without stray capacitance (**Fig.1**). This devaluation has hindered the application of such admittance measures to high frequencies. They reasoned that as angular frequency (ω) increases, estimates of C_m derived from the imaginary component of circuit admittance, $Im(Y)$, namely $Im(Y)/\omega$, provides inaccurate estimates of C_m . Only when $R_m \gg R_s$ and $\omega \rightarrow 0$ does *this* calculation provide reasonable values, as expected. But, this estimate of model C_m across stimulating frequency is inappropriate. We previously showed¹⁹ that, with no circuit simplifications, $Im(Y)$ must be divided by the absolute value of the partial derivative $\delta Y / \delta C_m$ to obtain correct values of C_m , regardless of model component values and interrogating frequency.

Figure 2A illustrates the interrogating frequency dependence of these measurement techniques in a model cell (R_s : 10 M Ω ; R_m : 100 M Ω ; C_m : 30 pF) without stray capacitance; only $Im(Y)/\omega$ provides incorrect estimates. **Figure 2B** shows the effects of stray capacitance on dual-sine estimates. In fact, not only is C_m erroneously estimated but R_s is, as well. Thus, in order to evaluate frequency-dependent effects on linear and nonlinear components of C_m , we must remove stray capacitance at each of our interrogating frequencies, else our estimates are wrong. The linear component of C_m , i.e., C_{lin} , as well as R_s , should be frequency invariant.

OHCs and Models with NLC

Using small signal analysis where the sinusoidal voltage perturbation is small relative to inherent nonlinearities, C_m , including C_{lin} and NLC, at any given holding voltage can be measured. Subsequent Boltzmann fits of C_m vs. holding voltage can then accurately assess the voltage dependence of NLC⁹, which rides atop the linear (surface-area dependent) C_{lin} . In order to glean frequency dependent behavior, wideband stimuli (e.g., voltage chirps) are delivered to the cell and the real and imaginary components of the current response extracted by FFT. Harmonic components across frequency are analyzed with the dual-sine approach. **Figure 3** shows NLC extracted across stimulating frequency in an OHC, using sums of

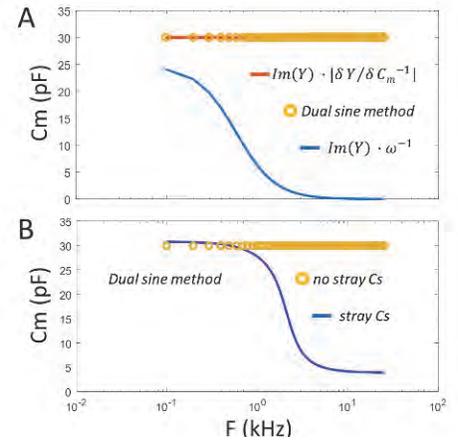

FIGURE 2. Robust frequency measures of model C_m . A) $Im(Y)/\omega$ is inappropriate to extract C_m across stimulation frequency for a model lacking stray capacitance. B) Stray capacitance must be removed to accurately measure C_m with dual-sine approach.

discrete sinusoidal (A) or chirp (B) stimuli. We balance out stray capacitance with patch clamp capacitance compensation controls to ensure that linear capacitance at depolarized holding potentials, where NLC is minimal, is linear across frequency, as required. Note that contrary to prevailing dogma, the results indicate that prestin sensor charge movements has low pass behavior. Indeed, we have developed a kinetic model that very nicely accounts for these data, and incorporates an essential chloride binding step preceding voltage dependent transitions in prestin¹ that underlies its low pass characteristics.

OHCs are fragile, and extreme voltage excursions during experiments (± 200 mV) required for full characterization of prestin's shallow voltage dependence can cause loss of recordings. Indeed, the requirement to balance out stray capacitance prior to frequency interrogation involves holding the cell at very depolarized levels where C_{lin} dominates. Cells are often compromised by such procedures. Fortunately, corrections for stray capacitance can be done post-hoc. To illustrate, we present such an approach in a MATLAB Simulink model that incorporates both NLC and stray capacitance.

Figure 4 illustrates model C_m magnitude versus voltage across frequency obtained by chirp analysis, as above. In **Fig. 4A**, NLC capacitance is modeled as the first derivative of a 2-state Boltzmann Q-V function, with no inherent frequency dependence. While prestin NLC involves molecular kinetics that engender frequency dependence, the present electrical model (**Fig. 4B**) provides frequency dependence of NLC by an additional series resistance, R_f . This electrical modelling approach has been used previously to characterize frequency dependence of Na channel voltage sensor charge movement²² and OHC NLC⁹. Consequently, C_m shows a low pass characteristic. In **Fig. 4C**, stray capacitance is introduced and this seriously distorts the measurements deriving from

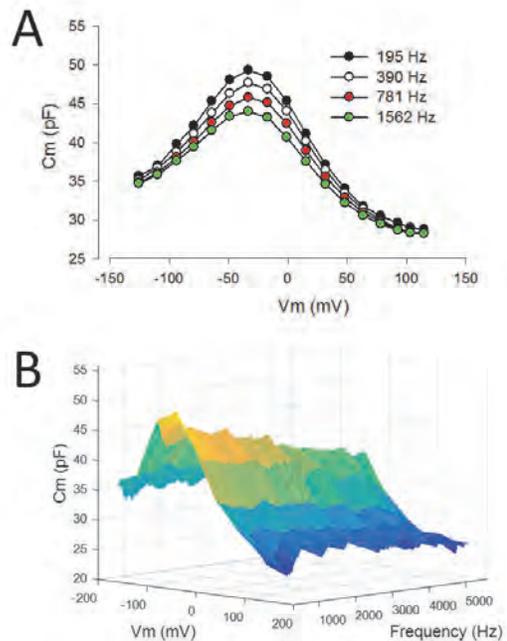

FIGURE 3. Frequency dependence of OHC NLC is revealed using the dual-sine measurement approach. A) Discrete sinusoidal stimulation shows reduction of peak NLC while C_{lin} remains constant. B) Chirp analysis provides better frequency resolution and limits stimulation times, which preserve cellular health during an experiment. No averaging.

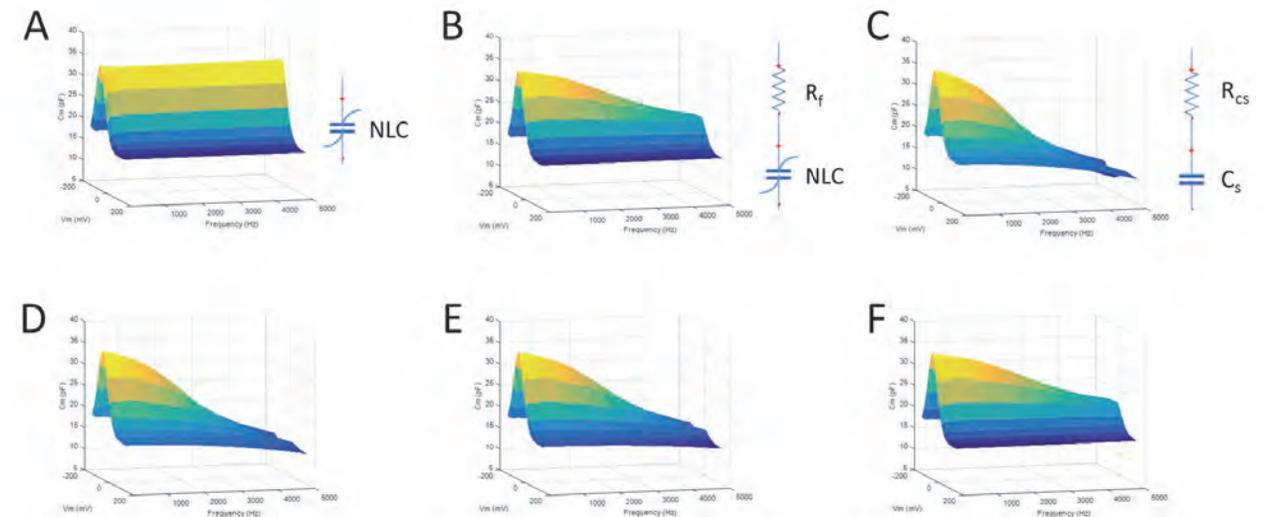

FIGURE 4. Model C_m frequency dependence can be extracted by correcting for stray capacitance post-hoc. See text for details.

dual-sine measures. In order to remove the effects of stray capacitance, and restore dual-sine measurement accuracy, estimates of stray capacitance are subtracted from the input admittance until the slopes of both R_s and C_m vs. frequency at the most depolarizing holding potential are zero. An automated fitting process accomplishes this. In **Figs. 4D** and **4E**, plots are shown depicting improvements in correction until in **Fig. 4F**, successful compensation for stray capacitance is achieved, as indicated by favorable comparisons between plots **Figs. 4B** and **4F**.

SUMMARY

Contrary to prevailing thought²¹, NLC can be measured accurately across stimulating frequency to extract the molecular kinetics of prestin. The ability to do so enables us to directly compare voltage-sensor charge movement, eM and force generation within a single OHC across frequency. Such studies are underway.

Intercellular communication in the supporting cells of the organ of Corti

Joseph Santos-Sacchi * and Peter Dallos

Auditory Physiology Laboratory (Audiology) and Department of Neurobiology and Physiology, Northwestern University, Evanston, Ill., U.S.A.

(Received 28 June 1982; accepted 25 October 1982)

We have directly tested the concept that the supporting cells of the organ of Corti are functionally coupled through gap junctions. *In vitro* and *in vivo* preparations were evaluated. Electrical measurements clearly show that the cells are coupled ionically. Voltage drops measured in neighboring cells in response to intracellular current injections indicate that current spread decays rapidly. Despite the existence of electrical coupling, fluorescent dye injection studies revealed no dye spread into adjacent cells, other than a few instances which were clearly artifactual. However, it is possible that dye spread is very slow and that dye in adjacent cells is diluted below visual detectability. In any case, dye coupling is remarkably poor compared to other electrically coupled tissues. The role of coupling in the supporting cells may be nutritive, considering the avascular nature of Corti's organ.

Key words: electrical coupling; dye coupling; organ of Corti.

Introduction

Over twenty years have passed since Furshpan and Potter [10] demonstrated that cytoplasmic communication can occur between individual cells. Subsequently, numerous studies have elucidated various details governing direct intercellular communication (for summaries see [17,22,14]). Indeed, in a variety of cell systems the existence of electrical as well as metabolic coupling has been established.

The cellular organelle thought to be responsible for such information transfer is the gap junction [11]. Its ultrastructure has been extensively studied by means of specific electronmicroscopic techniques, including freeze fracture and interstitial lanthanum infiltration [24,23,19]. However, despite the good correlation between intercellular coupling and the presence of gap junctions, the existence of gap junctional structures is not proof of electrical and/or metabolic coupling. For example, it is known that gap junctional structure is maintained following certain

treatments which electrically uncoupled cells (e.g. glutaraldehyde, DNP, Li) ([25]; however, see [21]). Furthermore, Gulley and Reese [12], using freeze-fracture techniques, were able to find structures normally associated with gap junctions on the lateral walls of outer hair cells, which were exposed to the fluid filled spaces of Nuel. Clearly, as has been cautioned by Detwiler and Hodgkin [7], the electronmicroscopic demonstration of gap junctions is not sufficient to establish the existence or degree of intercellular coupling.

Several studies have indicated the presence of gap junctions in the adult mammalian inner ear [16,15,12]. An extensive array of gap junctions was demonstrated between all the supporting cells of the chinchilla and guinea pig organ of Corti. Freeze fracture revealed typical plaque-like structures and expansive areas of intramembranous particles. These results led to the conclusion that the supporting cells of the organ of Corti are electrically and metabolically coupled – a significant concept considering the metabolic demands and electrical activity of the organ. However, a direct evaluation of this proposal has never been attempted. We report here the results of experiments designed to evaluate such presumed intercellular coupling.

Materials and Methods

Animal preparations

In vivo. Young adult albino guinea pigs were used. This preparation has been previously described [5]. Briefly, after induction with urethane anesthesia, the animals were tracheotomized and the cochleas exposed through a ventrolateral approach. A fenestra was made in the bone over the stria vascularis in the third turn of the cochlea. Microelectrodes were inserted through the stria vascularis and the endolymphatic space into the supporting cells of the organ of Corti.

In vitro. Animals were decapitated after anesthetic induction and their cochleas removed. Two methods were employed to obtain specimens. Individual turns of the cochlea (stria vascularis removed) were microdissected out for study. Alternatively, only the bony capsule from the two apical most turns was removed. In this case the cochlea in toto, endolymphatic duct intact, was incubated in a microscope perfusion chamber. Electrode penetrations were made through Reissner's membrane into the supporting cells of the organ of Corti under visual control.

Electrophysiology

Electrodes were fabricated with a Brown–Flaming puller. Resistance of electrodes when filled with 3 M KCl ranged from 50 to 225 M Ω , with the mode around 120 M Ω . Lucifer Yellow, Procion Yellow, Niagara Sky Blue and 6'-carboxyfluorescein-filled electrodes were used for dye injection studies. Current pulses (–0.25 to –4 nA) were used to inject the fluorescent dyes.

For in vivo electrical coupling studies, double-barreled electrodes were made with tip-to-tip distances of 15–30 μ m. One electrode was bent according to the method of Hudspeth and Corey [13] so that the two electrode shanks could be placed parallel to

each other and epoxied together. This enabled us to penetrate adjacent Hensen's cells (diameter 15–25 μm) despite the inability to directly visualize the cells hidden beyond the stria vascularis. A stepping motor drive (Transvertex AB., Sweden) was used to advance the electrode assembly through the stria vascularis and into the organ of Corti's supporting cells.

For *in vitro* electrical coupling studies, separate micromanipulators were used to place the electrodes into neighboring supporting cells. Tissue was perfused with M199 culture medium (Gibco, Long Island, N.Y., U.S.A.) with modified Hank's salts (1.3 mg/100 ml Na_2HCO_3 , 10 mM Hepes, adjusted to pH 7.4 after equilibration with 5% CO_2 /95% O_2). The microscope perfusion chamber was maintained at $37 \pm 1^\circ\text{C}$. The cells were visualized and photographed with a Zeiss Standard microscope, equipped for epifluorescence.

Recordings and dye injections were made with either a commercial high-input impedance, capacitance-compensated amplifier (Mentor) or a dual-channel device constructed according to Fein [8] utilizing AD545 operational amplifiers (Analog Devices, Mass., U.S.A.). Both devices are capable of recording during current injection. Data were plotted on a strip chart recorder and in some instances electrical coupling was analyzed using a signal averager (Nicolet).

Cell input resistance was measured by injecting small negative currents (-0.25 to -1 nA) through the recording electrode and measuring the voltage drop across the cell membrane. Electrode resistance was linear in this current range. Current pulses from -1 to -10 nA were used to evaluate cell coupling. Coupling indices include coupling ratio (voltage drop in cell 2/voltage drop in cell 1, in response to current injected into cell 1; [1]) and mutual resistance (voltage drop in cell 2/current injected into cell 1; [7]).

Hensen's cells remained in good condition for up to several hours *in vitro*, as evidenced by interference optics and resting potentials. Experiments were completed before swelling and autolysis occurred, and they typically lasted from 1 to 2 h.

Light microscopy

For *in vivo* experiments, cochleas were fixed from 1 to 2 h after dye injection. Fixative was either 4% paraformaldehyde in 0.1 M phosphate buffer, pH 7.4, or 2% glutaraldehyde in 0.1 M cacodylate buffer, pH 7.2. Desired portions of the cochlea were dissected out in buffer and either examined in surface mount or dehydrated in alcohols, embedded in Spurr and serially sectioned at about 12 μm . Injected cells were visualized with epifluorescence, using a BP450-490 nm exciting filter with a high-pressure mercury lamp. Photographs were taken with Kodak Ektachrome (ASA 200) and developed with the E-6 process (Unicolor). *In vitro* dye injection was monitored during experiments with brightfield and epifluorescence.

Results

In vivo

Upon passage through the stria vascularis in the *in vivo* preparation, the positive

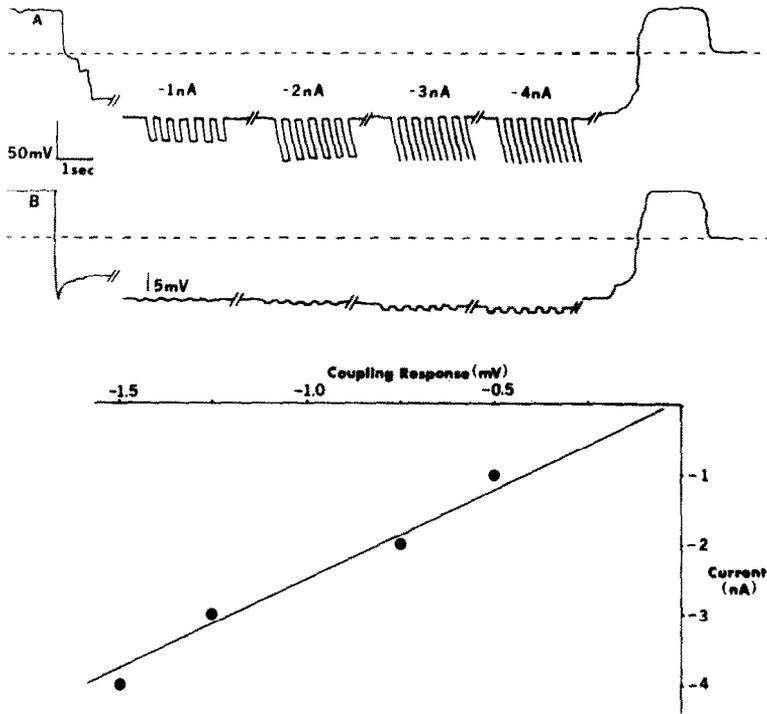

Fig. 1. Record of in vivo electrical coupling between adjacent Hensen's cells. Trace begins with electrode in endolymphatic space where the potential is near +70 mV. The sudden reversal of sign indicates that Hensen's cells are penetrated. Negative current pulses were injected in cell A at magnitudes of 1, 2, 3 and 4 nA. Bridge unbalancing in trace A indicates that cell A has an input resistance of 35 M Ω . Responses in cell B are linearly dependent upon current injection magnitude. Mutual resistance of these cells is 0.5 M Ω . The endolymphatic potential is again observed upon removal of electrodes from the cells, and after removal from the cochlear duct the potential drops to zero.

endocochlear potential is encountered (Fig. 1). After advancing the electrodes about 100–150 μ m further, the Hensen's cells are contacted. The stable membrane potentials averaged -70 ± 13 mV ($n = 87$). Input resistances are on the order of 35 ± 24 M Ω ($n = 37$). *

Fig. 1 illustrates the measurement of electrical coupling between adjacent Hensen's

* There is some evidence that the use of the single electrode technique to measure input resistance may overestimate the actual value by a factor of eight [27]. Apparently, the problem is that the resistance of the electrode must be taken into account in the calculations. Electrode resistance may increase preferentially inside the cell, thereby providing incorrect estimates of cell resistance. It would appear that if the electrode resistance does change preferentially inside the cell, the value of that change might be dependent upon the initial resistance of the electrode. A positive correlation between electrode resistance and Hensen's cell resistance might than be expected if the electrode were influencing the measurements. However, no such correlation was found in our measurements (Pearson $r = 0.013$).

cells. Membrane potentials of the cells are near -80 mV. Negative current pulses in cell A produce a voltage drop in that cell, proportional to its input resistance. Simultaneously, a voltage drop is noted in cell B. In this instance the voltage drop in cell B is considerably smaller than that in cell A, indicating a small but measurable coupling. The mutual resistance (see Materials and Methods) here is about 0.5 M Ω . Mutual resistances of up to about 1 M Ω have been found in the *in vivo* preparation. Mutual resistances with the current injecting electrode intracellular and the recording electrode immediately extracellular are typically less than 0.2 M Ω , indicating that spread is not through extracellular pathways. Fig. 1 also demonstrates that increasing the magnitude of the current injection produces a corresponding and proportional increase in cell B's response.

Despite the existence of electrical coupling, dye studies have failed to show spread into adjacent cells (Fig. 3a, b). Over 75 cells have been marked. Dye spread has occurred only on rare occasions when obvious mechanical trauma, i.e. from microdissecting prior to fixation, had been causal. Perhaps artifactual cytoplasmic bridges had formed between cells [4].

In vitro

An *in vitro* preparation was considered important in order to evaluate dye coupling fully. The direct visualization of dye injection under fluorescence microscopy eliminates the uncertainty associated with the processing required after *in vivo* injections. Initially, preparations for *in vitro* studies were obtained by microdissecting free the apical or third turn of the cochlea, after removing the stria vascularis. An

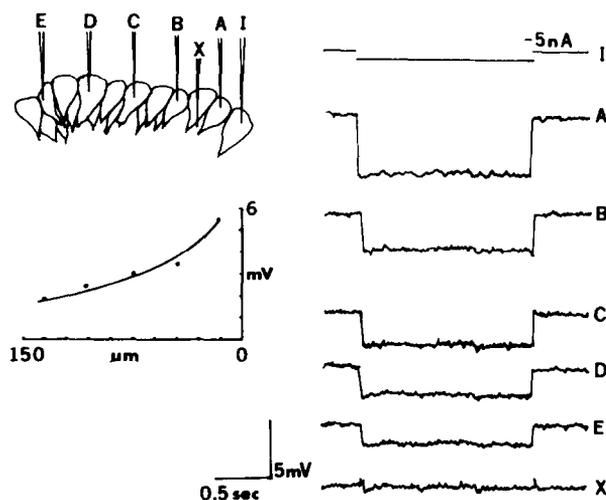

Fig. 2. Spatial analysis of electrical coupling in Hensen's cells *in vitro*. Current electrode *I* remained stationary while a roving electrode sampled intracellular responses to -5 nA current pulses at various inter-electrode distances. Responses were signal averaged. Response magnitudes indicate a fairly rapid decay as a function of inter-electrode distance, with a decay to one-third the adjacent cell response at about 130 μ m in this instance.

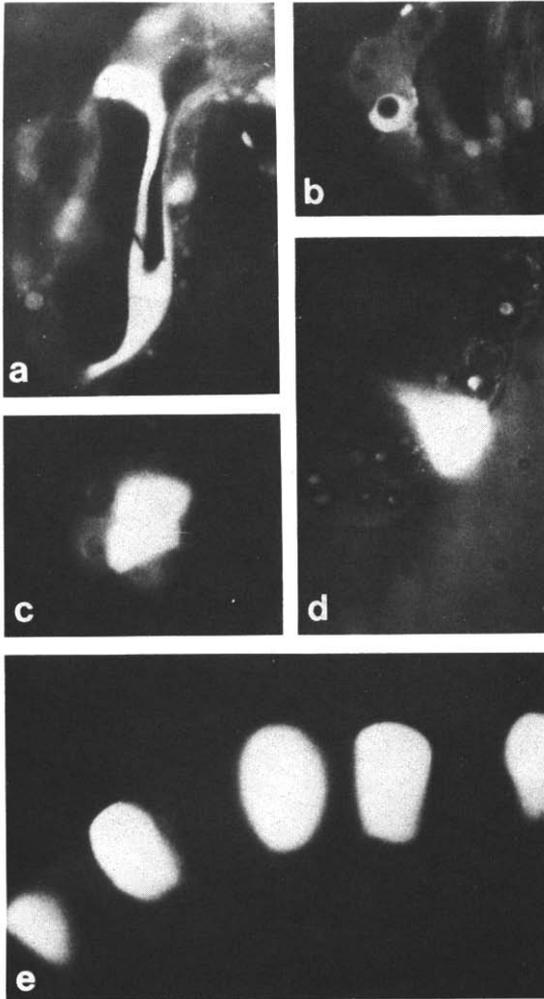

Fig. 3. (a) In vivo Procion Yellow injected outer pillar cell. Adjacent supporting cells above, below and in the plane of section were not stained. $800\times$. (b) In vivo Procion Yellow injected Hensen's cell. Note lipid vacuole is unstained. Adjacent cells demonstrate no detectable dye fluorescence. $470\times$. (c) In vitro Hensen's cells exhibiting Lucifer Yellow spread from a single injected cell. Five cells are stained. No spread was noted during dye injection (ca. 5 min). However, upon rebound of cells after difficult electrode removal, dye spread occurred within seconds. No further equilibration of dye occurred. $600\times$. (d) In vitro Lucifer Yellow injected Hensen's cell. Note lack of dye spread. This was typical of such experiments. Brightfield and epifluorescence. $600\times$. (e) In vitro preparation of Hensen's cells individually injected over a period of about 30 min. Each Lucifer Yellow injected cell is separated by an uninjected cell. $1000\times$.

analysis of these preparations revealed that cell potentials were depolarized as compared to in vivo preparations. Dye injections in these cells never demonstrated spread, except when physical trauma, e.g. difficult electrode removal, caused dye to enter adjacent cells (Fig. 3c).

By using a whole cochlea preparation, it is possible to maintain the functional integrity of the supporting cells of the inner ear. With endolymphatic duct intact, penetrations into Hensen's cells through Riessner's membrane permitted recordings of resting potentials (-63 ± 10 mV; $n = 111$) that were similar although statistically significantly different in magnitude to those measured in vivo (Student's *t*-test: $P < 0.001$). Electrical coupling was also similar to that in the in vivo preparation. Fig. 2 demonstrates coupling between Hensen's cells, as a function of inter-electrode distance. These data represent one of the better examples of spatial current spread. Current injecting electrode I remained stationary while the recording electrode sampled responses from cells at about 40 μm steps distal. The magnitude of the voltage drop in neighboring cells (Fig. 2A–E) in response to current injections (-5 nA, 1.5 s on–off) is dependent upon the distance from the current injected cell; the coupling response decays fairly rapidly as a function of increasing distance. The mutual resistance of the immediately adjacent coupled cells is about 1.0 $\text{M}\Omega$. Mutual resistances up to 2.0 $\text{M}\Omega$ have been found in this type of preparation. Note that the voltage drop in the extracellular space is miniscule (Fig. 2, X). Input resistance of these cells was also similar to that of cells in vivo.

Dye injections of Lucifer Yellow and 6'-carboxyfluorescein in over 75 cells demonstrated no dye spread into adjacent cells (Fig. 3d). The cells were observed for over an hour after injection. It was often possible to inject a row of single cells separated by uninjected cells (Fig. 3e).

Discussion

Electrical measurements clearly indicate that ionic coupling in the supporting cells of the organ of Corti is present both in vivo and in well maintained in vitro preparations. Coupling characteristics are similar for both preparations, showing mutual resistances around 1–2 $\text{M}\Omega$ for immediately adjacent Hensen's cells. Difficulty arises when attempts are made to determine coupling ratios because a single electrode was used to deliver current and measure voltage drops simultaneously. If the single electrode resistance measures were correct, this would mean that coupling ratios are poor. A comparison of mutual resistances of Hensen's cells and turtle retinal cones, for example [7], would seem to substantiate this contention. In these experiments, mutual resistances in better penetrations of neighboring cones averaged about 29 $\text{M}\Omega$ at a mean separation of 20 μm ; input resistance of cones were reported to be 24 $\text{M}\Omega$. Thus, turtle cones are much better coupled than Hensen's cells, if indeed measures of Hensen's cell input resistance are valid. *

* It is possible to obtain information on coupling ratios by comparing coupling responses in neighboring cells distal to the current electrode. That is, with a stationary current electrode and a roving measuring

Another indication of coupling efficiency is the analysis of spatial characteristics of intercellular current spread. At distances ranging from 2 to 9 Hensen's cell diameters ($\approx 45\text{--}130\ \mu\text{m}$) from the current injecting electrode, the coupling response is already about $1/3$ the response in the immediately adjacent cell. Sachs et al. [26] found a 50% reduction in coupling response magnitude from 3 to 5 cells distal in isolated gastric tubules. In contrast, Shueteze and Goodenough [29] demonstrated in the embryonic chick lens that the magnitude of the coupling response remained the same up to $80\ \mu\text{m}$ removed from the current injecting electrode. Furthermore, dye spread of intracellularly injected Lucifer Yellow is rapid and pervasive; it was reported that the whole chick lens can be stained given a sufficient length of time. Similar strong coupling has been found in other cell systems, e.g. insect gland epithelium and rat liver [18,20]. In rat liver, fluorescent dye spread occurs rapidly in over a dozen cells. This is in marked distinction from our dye studies.

About a decade ago it was thought that embryonic cells during certain developmental stages could maintain electrical coupling despite the inability to permit dye transfer [28,2,30]. A careful re-evaluation of this phenomenon has led Bennett et al. [4] to conclude that dye transfer does occur if cells are electrically coupled. The inability to observe dye spread, despite the presence of electrical coupling, in the supporting cells of the organ of Corti may represent a very slow passage of dye. However, it should be emphasized that observations were made up to several hours after dye injection. Yet it cannot be ruled out that such a slow spread would allow for dye dilution below visual detectability. Dye was observed in cells other than the injected ones only in those cases where supporting cells were physically traumatized, i.e. roughly manipulated. Spread in these instances was very rapid (less than 1 min) and may have been due to the artifactual formation of cytoplasmic bridges, although pathways through gap junctions cannot be dismissed. Nevertheless, dye coupling in the inner ear is clearly not at all like that in other well coupled cell systems, i.e. liver or lens.

Recently, Fraser and Bode [9] have shown that previous studies which demonstrated a lack of dye coupling in epithelial cells of *Hydra* [6] were due to dye injections into cellular vacuoles. It is important to note that this was not the case in our Hensen's cell studies. Although Hensen's cells in the apical and third turn of the guinea pig cochlea do contain large lipid vacuoles, cell penetrations always showed high negative resting potentials, and furthermore, after injection of dyes whole cells were filled but vacuoles were unstained.

The significance of electrical coupling in the supporting cells of the mammalian organ of Corti is obscure. Weiss et al. [31] have presented indirect evidence that hair

electrode, it has been found (e.g. Fig. 2) that voltage attenuation between Hensen's cells can be relatively low. Coupling ratios can be determined from this information and are found to average greater than 0.6. This indicates that input resistance of Hensen's cells may be *lower* than that measured directly with a single electrode. Attempts to measure input resistance with two electrodes have been difficult, but in a few presumably successful cases, measures have shown resistances below $10\ \text{M}\Omega$. In these cases adjacent cells have coupling ratios of about 0.5. Of course, it is possible that the penetration of cells the size of Hensen's cells with two electrodes may be injurious and reduce input resistance.

cells and supporting cells in the alligator lizard cochlea are electrically coupled. Thus, lateral hair cell interactions may be mediated through supporting cells in this case. However, in mammalia effects upon sensory transduction are apparently non-existent; no gap junctions are present between hair cells and supporting cells in the adult [16,15,12]. Furthermore, we have shown [5] that the magnitudes of receptor potentials of mammalian hair cells (inner and outer) are much larger than potentials recorded in any supporting cell type. Indeed, responses in intercellular spaces are also larger than in supporting cells, indicating that responses to sound in the latter are picked up from the extracellular space. The fact that spatial spread of current through supporting cells is not great further limits possible interactions.

A more likely role for intercellular communication in the organ is nutritive or metabolic. Such cooperation among the supporting cells may be requisite considering the avascular nature of Corti's organ proper. In fact, this may account for the continued survival of supporting cells under adverse conditions which destroy uncommunicating hair cells. A difficulty with this nutritive hypothesis is the consistent finding that dye spread is absent. The molecular weights of the fluorescent dyes used in this study are similar to those of many metabolites. Again, the inability to find dye spread may be due to very slow dye passage and dilution of dye below visual detectability. Further investigations are required to resolve this issue.

(Received 8 March 1988; accepted 8 May 1988)

Outer hair cells (OHCs) exhibit electrically induced cell movements which are considered to enhance the frequency selectivity and sensitivity of basilar membrane vibration. Using simultaneous whole cell voltage clamp and video analysis, we demonstrate that the mechanical response of OHCs is not altered by agents which alter membrane currents under voltage clamp. Thus the underlying mechanism of OHC movements appears to be dependent upon membrane potential, rather than transmembrane currents.

Outer hair cell; Whole cell voltage clamp; Membrane current; OHC mechanical movements

Introduction

Major differences are known to exist between the two types of hair cells which populate the organ of Corti (see Dallos, 1985a). Whereas *in vivo* intracellular recordings have clearly shown that both inner and outer hair cells (OHCs) are capable of generating receptor potentials in response to acoustic stimulation (Dallos et al., 1982; Russell and Sellick, 1983), it is becoming increasingly clear that OHCs additionally function as effectors. The electrical activity of the OHCs is thought to modify the mechanical properties of these same cells and in turn influence organ of Corti micromechanics (Mountain, 1980; Siegal and Kim, 1982; Brown et al., 1983; Nuttall, 1985). Thus, an indirect micromechanical interaction between outer and inner hair cells may account for the exquisite tuning characteristics and sensitivity of the eighth nerve fibers, which predominantly innervate inner hair cells. It has been established that OHCs are capable of slow K^+ induced length changes (Zenner et al., 1985), and fast electrically induced, reversible cell movements on the order of micrometers (Brownell, 1983, 1984; Brownell et

al., 1985; Ashmore, 1986). Studies using isolated OHCs have shown that cell elongation or contraction begins within 200 μs of an applied voltage clamp stimulus, and that the direction of movement is polarity dependent (Brownell, 1983, 1984; Brownell and Kachar; Ashmore, 1986). Time- and voltage-dependent currents have been identified in OHCs using whole cell voltage clamp recording (Ashmore, 1986, Ashmore and Meech, 1986a, b; Santos-Sacchi and Dilger, 1986, 1988). It has been suggested that transmembrane currents are coupled to the fast mechanical responses of OHCs (Ashmore, 1986; Ashmore and Meech, 1986). We have directly tested this hypothesis by recording OHC whole cell currents under voltage clamp while simultaneously monitoring cell movement. We report here that manipulations which drastically reduce or reverse transmembrane current during voltage clamp, do not interfere with the OHC mechanical response, which remains a nearly linear function of applied voltage over much of its dynamic range.

Methods

OHCs were non-enzymatically isolated from guinea pig cochleas by gentle pipetting of the isolated top two turns of the organ of Corti. The cells were then transferred to a 700 μL perfusion chamber with a cover glass bottom. A Nikon

Correspondence to: J. Santos-Sacchi, Laboratory of Otolaryngology, UMDNJ-New Jersey Medical School, Newark, NJ 07103, U.S.A.

Diaphot inverted microscope, with Hoffmann optics, was used to observe the cells during electrical recording. Tissue culture Medium 199 with Hanks salts (GIBCO, NY; major ions: NaCl 137 mM, KCl 5.4 mM, CaCl₂ 1.3 mM, MgSO₄ 0.8 mM, with HEPES or bicarbonate buffer, pH 7.2) was used as the control perfusate. The same ion concentrations were used in test solutions except that NaCl was reduced to maintain osmolarity. Patch electrodes had initial resistances of 3–5 MΩ. Series resistance was typically between 10 and 15 MΩ, and was partially compensated during recording. Residual series resistance was estimated from current transients at the onset of voltage pulses and was corrected for during analysis (Marty and Neher, 1983). Pipette solutions were composed of 140 mM KCl or CsCl, 1 mM or 5 mM EGTA, 2 mM MgCl₂, and 5 mM HEPES buffered to pH 7.0–7.2. Both borosilicate and flint glass electrodes were used; flint glass provided better sealing. Giga-ohm seals were obtained at a location slightly above the nuclear level of the OHC membrane prior to whole cell recording.

OHCs were clamped to holding potentials near –60 mV, using a Dagan patch clamp amplifier. Under computer control, hyperpolarizing and depolarizing voltage pulses (50–500 ms), ranging from –100 to +100 mV, were used to elicit membrane currents and mechanical movements. Current records, filtered at 2 kHz with an 8 pole Bessel filter, were digitized and stored on a Data 6000 waveform analyzer, and saved to disk for off-line analysis. Simultaneously, cell movements were taped with a Panasonic AG6300 video recorder for later evaluation. OHC displacement reaches steady state several milliseconds after a voltage clamp step (Ashmore, 1986). Displacements of the cuticular plate region were measured from the video monitor after they had reached steady state. Two methods were employed, either manual measurement from digital still frames using a Toshiba digital VHS (14800 × monitor magnification) or measurement during playback using differential optoresistors (output filtered at 50 Hz) placed across the image of the cuticular plate on the monitor (2800 × monitor magnification). Still frame measurements were repeated at least five times and averaged. Standard deviations of these repeated measurements were about 0.16 μm. The

position of the cuticular plate was measured before, during, and after each voltage step. The linearity of the optoresistor method was confirmed by measuring the video taped movement of the tip of a microelectrode driven by a piezoelectric bimorph element. For the optoresistor method, absolute values were determined from manual measurements of cell displacements in response to the largest depolarizing voltage pulse. The movement of the cuticular plate is relative to the stationary insertion point of the electrode, which was typically near the nuclear region. However, upon depolarization, both the apical and basal ends of the OHC move towards the electrode insertion point. Thus, in order to account for total cell length change, the measured displacements of the cuticular region were multiplied by the ratio of total cell length to the electrode-cuticular plate distance, under the assumption that movement is linearly related to length of the cell.

Results

The resting membrane potential of isolated OHCs ranged from –10 to –68 mV with a mean

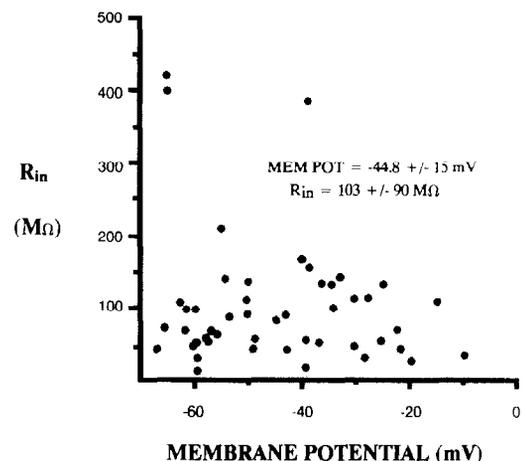

Fig. 1. Input resistance and membrane potential (+/- S.D.) for isolated OHCs whole cell recorded using pipettes containing 140 mM KCl solution. Input resistance was determined at a holding potential near –60 mV using –10 mV voltage steps. Membrane potential was determined by finding zero current level under voltage clamp or alternatively by directly measuring under current clamp. Measures were made a few minutes after the establishment of whole cell recording, i.e., following exchange of pipette and intracellular fluids.

A

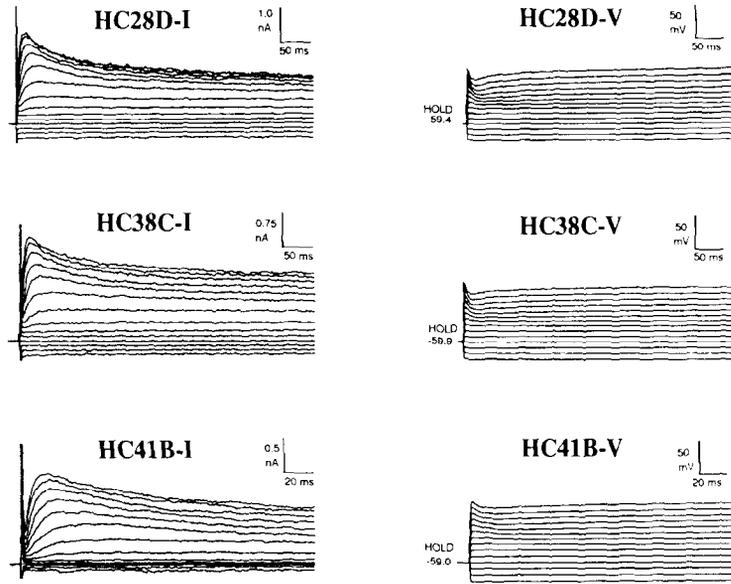

Fig. 2a. Examples of whole cell voltage clamp recordings from three isolated OHCs. Patch electrode contained 140 mM KCl solution. On the left are current traces in response to voltage steps from a holding potential near -60 mV (actual voltage listed in figure). Outward current is upward. On the right are the voltage step magnitudes corrected for estimates of residual series resistance. Depolarization is upward. Upon depolarization above -40 mV, a delayed outward current develops, the magnitude of which is voltage- and time-dependent. Current peaks within 20 ms after the onset of the voltage step, and inactivates slowly over hundreds of milliseconds. Note differences in time and current scales. Membrane potential (determined at zero current level) and input resistance (determined at the holding potential) of each cell: HC28D: -57 mV, 70 m Ω ; HC38C: -60 mV, 100 m Ω ; HC41C: -38 mV, 380 m Ω .

B

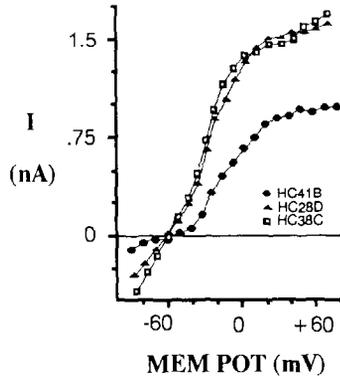

Fig. 2b. I-V plot for the three cells in Fig. 1a. Total transmembrane currents (no leak subtraction) measured at 200 ms. Note the outward rectification upon depolarization from the holding potential. The I-V curves begin to saturate above -10 mV.

C

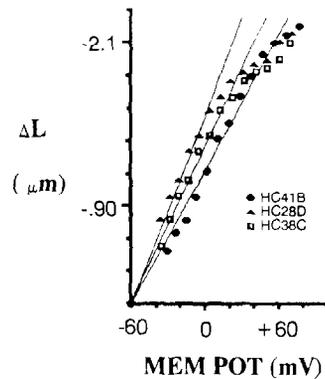

Fig. 2c. Mechanical responses (contractions) of the same three OHCs in response to depolarizing pulses from the holding potential. Mechanical responses from the three cells essentially overlap. Individual cell lengths and percent maximal contraction: HC41C: 64 μm , 3.8% , HC28D: 74 μm , 3.2% , HC38C: 83 μm , 2.7% .

value of -45 mV (Fig. 1). This is similar to the membrane potentials obtained in vivo for apical OHCs (Dallos et al., 1982). Upon establishment of whole cell recordings, membrane potentials often

increased over the course of a few minutes. This type of behavior has occasionally been observed from OHCs recorded in vivo using high resistance

electrodes (Dallos, 1985b). With whole cell recording this behavior may arise from the exchange of pipette and cytoplasmic solutions, possibly indicating that isolated OHCs have a reduced internal K^+ concentration. This phenomenon suggests that the membrane potential is dependent upon K^+ conductance. However, we have recorded from OHCs having membrane potentials near -60 mV from the onset of whole cell recording. The conductance of these cells at the holding potential of about -60 mV was also variable (2.4 to 62 nS), having a mean of 9.2 nS.

Under voltage clamp, OHCs exhibit time- and voltage-dependent outward currents upon depolarization from -60 mV (Fig. 2). These currents rise sigmoidally to peak values within 10 to 20 ms (with a voltage-dependent time constant) and partially inactivate on a somewhat longer time scale. Leak-subtracted peak outward currents typically show saturation at pulse potentials above

$+40$ mV, and begin to roll over about $+60$ mV. Steady state current (no leak subtraction, measured at 200 ms, Fig. 2b) begins to saturate above $+10$ mV.

OHCs, but not supporting cells, clearly exhibit mechanical movements in response to step changes in holding potential (Fig. 2c). The magnitude of cell concentrations induced by depolarization increases as the size of the voltage step is increased, and in most cells studied the linear relationship between voltage and contraction is lost at high voltage step levels, where the mechanical response falls off. Our largest calculated mechanical response about the -60 mV holding potential was 29 nm/mV. The electrically induced contraction of cells is not limited to any region of the cell; both basal and apical regions contract towards the point of electrode insertion in the supranuclear region. Hyperpolarization causes elongation of the cell, but quantitative measurements of these move-

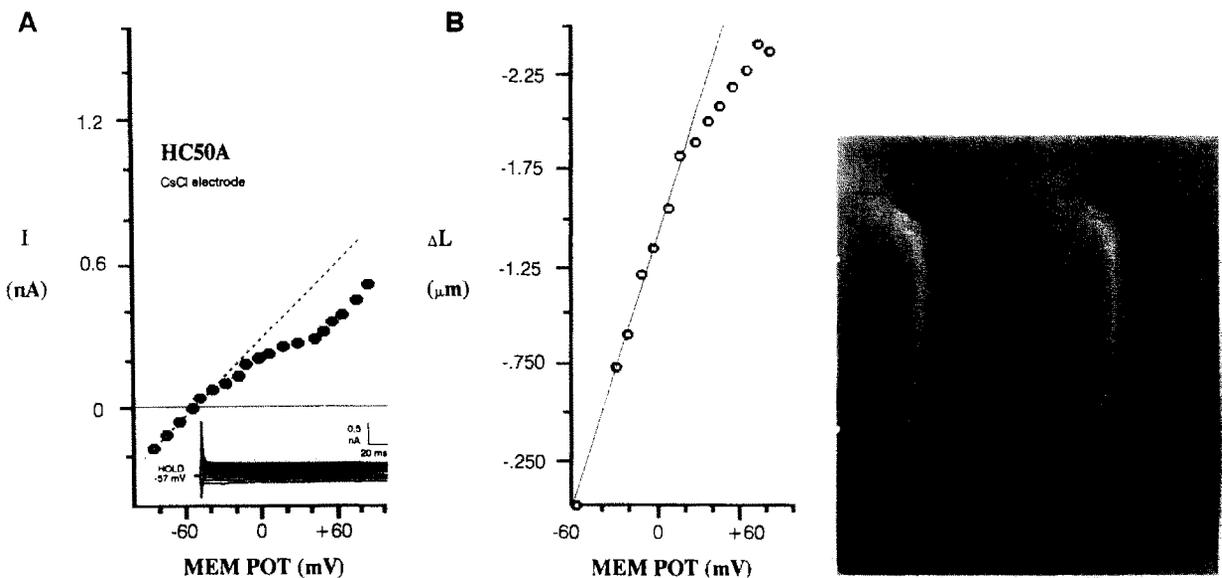

Fig. 3a. I-V curve measured at 200 ms after voltage step for an OHC in which the outward currents were blocked by using a patch pipette containing 140 mM CsCl isolation. Dotted line indicates leakage current. Leakage current subtraction (not shown) revealed inward currents at depolarizations greater than -30 mV, probably indicative of Ca^{2+} influx. Inset shows current traces associated with voltage steps from a holding potential of -57 mV.

Fig. 3b. Mechanical responses of the same OHC in response to step depolarizations from a holding potential of -57 mV. Despite the reduction in outward current the voltage induced mechanical response of the cell is as robust as those exhibiting normal I-V characteristics (see Fig. 1c). In this case, the mechanical response about the holding potential is 23 nm/mV.

Fig. 3c and d. Photographs of video images of same OHC. (c) during the 200 ms pulse of $+81$ mV, and (d) upon return to the holding potential of -57 mV. Vertical scale: $4.8 \mu\text{m}$.

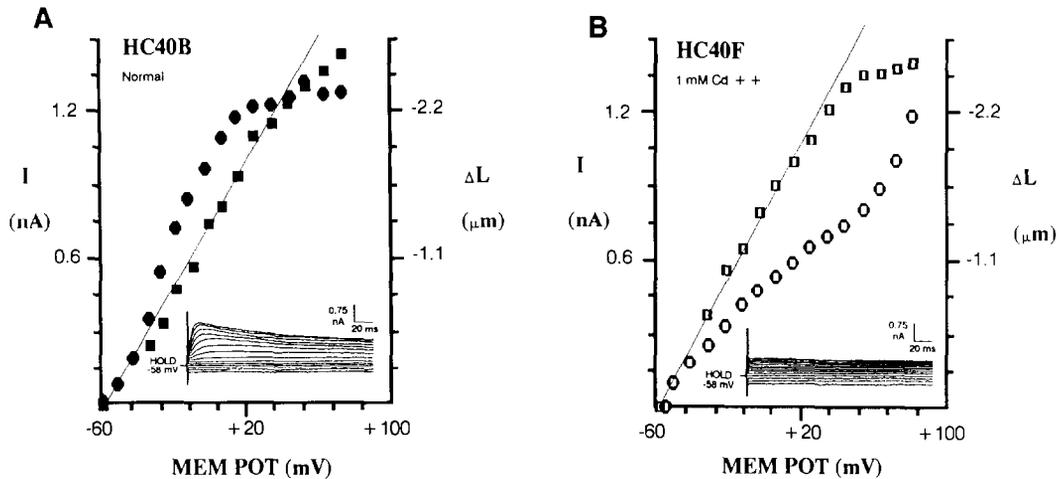

Fig. 4. Steady state current (measured at 200 ms), and mechanical response of an isolated OHC before and after addition of 1 mM CdCl_2 to the extracellular perfusate. Pipette contained 140 mM KCl. No leakage current subtraction. Despite reduction of outward current, mechanical responses remain unaltered. (a) Normal extracellular medium. Steady state current: closed circles; mechanical response: closed squares. Mechanical response is 23 nm/mV about the holding potential. Inset: Current traces associated with voltage steps from the holding potential. (b) Normal extracellular medium + 1 mM CdCl_2 . Steady state current: open circles; mechanical response: open squares. Mechanical response is 25 nm/mV about the holding potential. Inset: current traces associated with voltage steps from the holding potential.

ments were not possible for the small range of hyperpolarizations examined in this study.

Outward currents in OHCs are blocked by various manipulations which are generally considered to suppress K^+ currents in cells. Replacing intracellular K^+ with Cs^+ (Fig. 3a) eliminates most of the outward current. However, mechanical responses are robust despite the reduction of outward current (Fig. 3b). Other treatments which block the outward current including extracellular additions of 25 mM TEA, 10 or 50 mM Ba^{2+} , or 1 mM Cd^{2+} do not interfere with the electrically induced OHC movements. Figs. 4a and b illustrate the effects of 1 mM extracellular Cd^{2+} on OHC currents and mechanical movements. Although the time- and voltage-dependent outward current is reduced by this treatment, the mechanical response is left intact. One mechanism by which Cd^{2+} may suppress outward current is by blocking Ca^{2+} entry through voltage gated Ca^{2+} channels, thus preventing the opening of Ca^{2+} -activated K^+ channels. A voltage-dependent inward current can, in fact, be measured when outward currents are reduced (see Fig. 3). This inward current is Cd^{2+} sensitive and its magnitude is increased when the bath contains 50 mM Ba^{2+} and no Ca^{2+} (Fig. 5). Thus, a link between Ca^{2+}

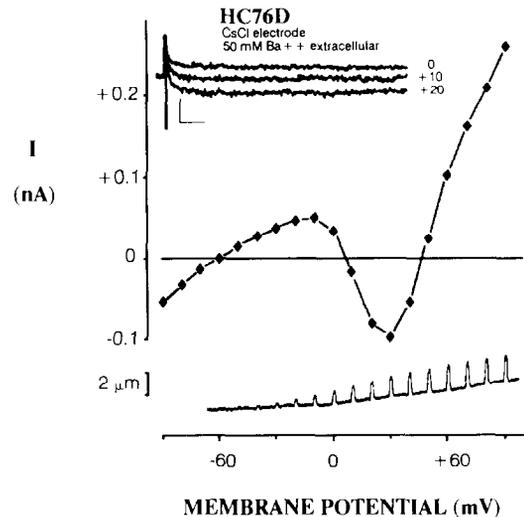

Fig. 5. I-V curve of an isolated OHC, obtained with a pipette solution of 140 mM CsCl, and extracellular solution in which 50 mM Ba^{2+} replaced Ca^{2+} . Note the reversal of net current as the cell is depolarized to levels between +10 and +40 mV. At the top, current traces are depicted at depolarizations of 0, 10, and 20 mV, from a holding potential of -60 mV (insert: horizontal scale 20 ms, vertical scale 0.1 nA). Note the absence of inactivation during the 200 ms pulses. At the bottom, the magnitude of cellular contractions is presented for depolarizing pulses. In this case the responses were recorded with the use of differential optoresistors to measure apical cell movements directly off a video monitor. Note that the cell continues to contract in a graded fashion during net current reversal.

influx and OHC movements can be ruled out. In addition to the inability of extracellular Cd^{2+} or Ba^{2+} to inhibit cell movements, OHC movements persist when the extracellular Ca^{2+} is reduced to zero (either due to omission of Ca^{2+} or chelation with EGTA).

Finally, in the presence of high extracellular Ba^{2+} concentrations there is a net inward current during depolarizing voltage clamp steps to +10 through +40 mV (Fig. 5); yet, the cells still contract rather than elongate, as might have been expected if the direction of movement were dependent upon the direction of current across the membrane.

Discussion

The mechanical response of OHCs has been postulated to be coupled to the magnitude and direction of transmembrane current in the cell (Ashmore, 1986; Ashmore and Meech, 1986). Ashmore (1986) initially reported that replacing intracellular K^+ with Na^+ under whole cell voltage clamp blocked outward K^+ currents and altered OHC mechanical responses, suggesting that outward K^+ current is important for OHC movements. Subsequently, it was postulated that the sensory stimulus to the outer hair cell is directly coupled to the cell mechanical response via these large basolateral outward currents (Ashmore and Meech, 1986). Indeed, this concept prompted others (Gitter et al., 1987) to analyze single K^+ channel kinetics of OHCs in an effort to account for the speed of OHC movements. The data presented here clearly demonstrate that OHC movements are not dependent upon outward K^+ currents, since blocking them with a variety of treatments does not affect movements. Recently, Ashmore (1987) reported that, in fact, replacing intracellular K^+ with Na^+ does not affect OHC movements, and suggested that his initial reports to the contrary were due to the small range of voltages studied and pipette series resistance changes.

While outer hair cells *in vivo* have resting potentials near -70 mV (Dallos, et al., 1982; Russell et al., 1986), and values of up to -68 mV were observed in this and other studies (Ashmore and Meech, 1986; Zenner et al., 1985), it is clear that potentials *in vitro* are variable and often

poorer than *in vivo*. Many studies have evaluated mechanical responses of OHCs under current clamp or by means of extracellular current stimulation without simultaneously accounting for changes in cell membrane potential (Brownell et al., 1985; Kachar et al., 1986; Evans, 1988). Under these conditions, the variability of membrane potential and input resistance *in vitro* may place limitations upon the interpretation of certain aspects of the measured mechanical responses, since we show that mechanical responses are not dependent upon total transmembrane current.

We demonstrate here that OHCs possess a voltage dependent Ca^{2+} current, but that this inward current is not required for mechanical responses. OHCs continue to contract in response to depolarizations when inward Ca^{2+} currents are blocked by Cd^{2+} or when extracellular Ca^{2+} is absent. This result indicates that fast electrically induced OHC movements are not dependent upon an actin-myosin system, as has been suggested for the slow movements of OHCs (Zenner, 1986). This notion is strengthened by the fact that OHCs continue to respond mechanically when intracellular Ca^{2+} is buffered to below 10 nM (Ashmore, 1987), and when metabolic inhibitors are present (Kachar et al., 1986). Furthermore, the frequency response of OHC movements, measured up to 8 kHz, is unlikely to be accounted for by a muscle-like system (Ashmore and Brownell, 1986; Ashmore, 1987).

The average input conductance of OHCs in this study was 9.2 nS (108 M Ω). This contrasts with the range of conductances (25–50 nS; 40–20 M Ω) reported by Ashmore and Meech (1986) for OHCs isolated using trypsin. These authors have suggested that inclusion of the Ca^{2+} chelator BAPTA in the patch pipette solution is necessary to obtain cells with high resistances and membrane potentials. It is difficult to understand how a reduction in internal calcium levels would increase the cell's membrane potential when such measures would be expected to reduce the cell's Ca^{2+} -activated K^+ conductance. In a cell whose membrane potential is dependent upon K^+ conductance, a reduction in the conductance would cause depolarization. We find that with our non-enzymatic isolation technique, cells with high resistances and membrane potentials are obtained with or without Ca^{2+} che-

lators in the pipette solution. Furthermore, the presence of time- and voltage-dependent outward currents was not dependent upon the inclusion of a Ca^{2+} chelator in the pipette solution.

The resting input resistance of OHCs is low compared to hair cells from other systems, where values can be an order of magnitude greater (Ohmori, 1984; Corey and Hudspeth, 1979). This difference is not due to the methods employed in this study since similar measures on isolated Hensen cells (having comparable membrane surface area) demonstrate an average input resistance of 1.1 G Ω (Santos-Sacchi, 1988). The OHC leakage conductance is probably not due to transduction channel activity in the stereocilia since many of the cells studied lacked stereocilia as a result of the isolation procedure. Induced mechanical movements in these cells were indistinguishable from movements of cells with stereocilia. Still, the average input resistance reported here is higher than that determined *in vivo* (30–50 M Ω , Dallos, et al., 1982; Russell et al., 1986). These *in vivo* measures probably underestimate true values because they were made with high impedance micro-electrodes whose electrode-to-membrane seal resistance is considerably less than that obtained with the patch electrode technique.

Currently, a major effort is being made to elucidate the roles played by inner and outer hair cells in the organ of Corti. The discovery that OHCs can rapidly alter their cell length in response to electrical stimulation (Brownell et al., 1985) fits well with models incorporating active bi-directional transduction processes (mechanical to electrical and vice versa) to account for the high sensitivity and sharp tuning of basilar membrane vibration (Kim, 1986; Geisler, 1986; Mountain, 1986; Jen and Steele, 1987). The elucidation of the mechanism of OHC movements will aid in the understanding of OHC-IHC interactions and pathologies which compromise these interactions. At present, the mechanism of this mechanical response is unknown. The data presented demonstrate that the mechanical response is not dependent upon either the specific ionic currents blocked here or the direction and magnitude of total transmembrane current. Furthermore, studies using the Cl^- channel blocker SITS indicate that a Cl^- current is not involved (Santos-Sacchi, unpub-

lished). While it is possible that movements are dependent upon some unidentified current which is masked by the residual leakage conductance, we believe that a membrane potential dependence is more likely. This may not conflict with Brownell's electro-osmotic theory (Brownell, 1986) of OHC movement if an axial potential gradient is present along the cell. Axial potential gradients are conceivable under physiologic conditions. Under voltage clamp, however, the existence of such a gradient is dependent upon the ability to adequately space clamp the cell. Ashmore has estimated (see comments after Brownell, 1986) that under voltage clamp, the cell is isopotential to within 1%. Of course, this value will depend upon the cable properties of the cell during stimulation, i.e., the magnitude and spatial distribution of basolateral conductances during depolarization. Presumably, in the present study, cells whose basolateral conductances were blocked would have been better space clamped than those under normal conditions. Yet, no differences in mechanical responses were observed. In preliminary experiments (Santos-Sacchi and Brownell, unpublished), voltage clamping OHCs with two patch electrodes, one at the cell apex and one at the cell base, in order to reduce axial potential gradients did not abolish the mechanical movements due to depolarization. Further studies of this sort are necessary.

Whatever underlying mechanism is responsible for the OHC's mechanical response, the results presented here indicate that it is associated with the magnitude of transmembrane potential, and potential differences less than a millivolt produce mechanical responses on the same scale as basilar membrane movements near threshold. It is conceivable that the effects of OHCs on the mechanical properties of the cochlear partition may be influenced by both intracellular and extracellular voltage responses associated with acoustic stimulation.

INDUCTION OF THE ACROSOME REACTION IN GUINEA PIG SPERMATOZOA BY cGMP ANALOGUES

J. SANTOS-SACCHI and MILDRED GORDON

From the School for Biomedical Education, The City College, New York 10031

ABSTRACT

The effect of cyclic nucleotide analogues upon the immediate induction of the guinea pig acrosome reaction (AR) was studied. Dibutyryl (dB) cGMP and 8-bromo-cGMP, when added to sperm suspensions after varying periods of preincubation in glucose-free BWW medium (NaCl 94.59 mM, KCl 4.7 mM, CaCl₂ 1.71 mM, KH₂PO₄ 1.19 mM, MgSO₄ 1.19 mM, NaHCO₃ 25.07 mM, pyruvate 0.25 mM, lactate 21.58 mM, and bovine serum albumen 1 g/liter), induced the AR in a large proportion of spermatozoa relative to controls. The proportion of ARs induced upon the addition of dB cGMP or 8-bromo-cGMP (10 mM) at 1 h was equivalent to that obtained after a 5-h incubation in glucose-free BWW alone. The effect of cGMP analogues was concentration dependent over the tested range of 2–12 mM (<1–20%). The simultaneous addition of imidazole (10 mM), a cAMP phosphodiesterase stimulator, potentiated the effect (imidazole + 12 mM 8-bromo-cGMP: 73%). cAMP analogues were without effect. The presence of extracellular Ca⁺⁺ was required, and it is suggested that a rise in the cGMP/cAMP ratio triggers Ca⁺⁺ influx and the AR.

The acrosome reaction (AR) is a massive exocytosis of the acrosome vesicle which occurs in capacitated sperm before fertilization. Early studies claimed that pretreatment of spermatozoa with exogenous cAMP analogues enhanced capacitation as evidenced by increased rates of egg penetration (2, 15, 18). Recently, however, Garcia and Rogers (3, 12) determined that the incubation of guinea pig spermatozoa for 4 h within a capacitating medium, Minimum Culture Medium (MCM), containing dibutyryl (dB) cAMP (10 mM) or phosphodiesterase inhibitors reduced the acrosome reaction percentage as compared to controls (10 vs. 50%). On the other hand, the presence of imidazole, a cAMP phosphodiesterase stimulator, increased the numbers of ARs over controls (90 vs. 50%). The effects of these agents were concentration dependent over the tested range of 1–10 mM.

The data reviewed thus far suggest that capacitation may involve a rise in intracellular cAMP levels, but the subsequent AR may be associated with a reduction in cAMP levels.

In accord with this hypothesis are the results of cAMP effects upon other secretory systems. For example, incubation of neutrophils, basophils, and mast cells in media containing agents that promote a rise in cAMP levels inhibits the release of secretory granule contents (for reviews, see references 10 and 11). On the other hand, an increase in cGMP levels promotes the release of secretory granule contents in these same cells. Calcium ion influx is requisite for such secretory activity, and apparently plays a significant role in modulating intracellular levels of cGMP (5). One interpretation of such data is that cGMP and cAMP control opposing cellular function (Yin-Yang hypothesis,

reference 6). The fact that extracellular Ca^{++} is required for the AR and that its influx parallels or precedes the occurrence of the AR (16, 19) may be related to cyclic nucleotide flux. Indeed, cAMP and cGMP may control opposing cellular functions in sperm as they apparently do in other secretory systems. It may be possible, then, that a rise in the intracellular cGMP/cAMP ratio is associated with the mammalian AR. Accordingly, in this report, the effects of cyclic nucleotide analogues on the AR of guinea pig spermatozoa were investigated.

MATERIALS AND METHODS

Guinea pig epididymal spermatozoa were extruded into 0.9% NaCl in H_2O , disaggregated by pipetting, and washed two times by centrifugation (1,000 g, 4 min each). Spermatozoa were then suspended in glucose-free BWB medium (NaCl 94.59 mM, KCl 4.7 mM, CaCl_2 1.71 mM, KH_2PO_4 1.19 mM, MgSO_4 1.19 mM, NaHCO_3 25.07 mM, pyruvate 0.25 mM, lactate 21.58 mM, and bovine serum albumen 1 g/liter) at a final concentration of $1-1.5 \times 10^7$ spermatozoa/ml and were incubated at 37°C for 5 h in screw-capped tubes under an air atmosphere. Calcium ion-free medium was also employed. Media were prepared daily, immediately before use. The initial pH was adjusted to 7.55, and throughout the experiments it remained <8.00 .

At 0 and 1 h after the suspension of spermatozoa, db cAMP, 8-bromo-cAMP (0.001–10 mM), dB cGMP, 8-bromo-cGMP (0.001–10 mM), AMP, 8-bromo-AMP (10 mM), GMP, or bromo-GMP (10 mM) was added to sperm samples. Butyrate (0.1 and 10 mM) was also tested as a control for possible butyrate contamination of the dibutyl cyclic nucleotides. After a 20-min incubation with these agents, ARs were assessed. In this report, direct counts of acrosome-reacted spermatozoa were made by hemocytometer,¹ six to eight chambers (0.5 mm^3 each) being counted for each condition. ARs were not induced artifactually by the use of the counting apparatus. Counting was rapid and was facilitated because activated, acrosome-reacted spermatozoa tend to remain within confined areas. Care was taken, however, to

¹ We have chosen not to use the method of Rogers and Yanagimachi (14) to assess the percentage of ARs. Their technique involves placing an aliquot of sperm upon a slide and counting the number of ARs in a sample of 100 motile sperm. The validity of such a sampling technique is directly dependent upon a random distribution of sperm in which each sperm has an equal likelihood of being chosen. Because guinea pig sperm autoagglutinate spontaneously in physiologic media (16, 1) and because these agglutinated sperm, although motile, are non-acrosome reacted, there exists a nonrandom distribution of sperm. Thus, if a sperm is sampled from an aggregate, a priori, it will be unreacted. On the other hand, the chances of sampling an acrosome-reacted sperm from the freely motile pool are very high, because the majority of non-acrosome-reacted sperm are agglutinated. Whenever we have attempted to use this technique, we obtained spuriously high AR scores, with high variability as compared to the hemocytometer technique.

focus through the 0.1-mm counting chamber depth so as not to overlook cells. Standard errors of the mean averaged $<20\%$. The results are reported as a percentage of AR in the total motile sperm population ($\%AR^{\text{tot}} = [\text{concn of AR spermatozoa}/\text{concn of total spermatozoa} - \text{concn of immotile spermatozoa}] \times 100$). Sperm samples were also qualitatively evaluated in wet mounts without coverslips by light and differential interference microscopy. The speed of onset of ARs as well as the incidence of autoagglutination over time was determined. For electron microscopy, spermatozoa were prepared as described previously (7) and examined with a Philips 300 electron microscope at 80 kV.

cAMP levels were determined by the protein binding technique (cAMP Assay Kit, Amersham Corp., Arlington Heights, Ill.) and were corroborated by the antibody technique (cAMP Assay Kit, New England Nuclear, Boston, Mass.). After rapid centrifugation for 30 s, cell pellets were sonicated in 2 ml of absolute ethyl alcohol. After centrifugation, the supernate was evaporated to dryness at 75°C with a stream of air, and the residue was resuspended in buffer for assay. Counts were made with a Beckman LS-250 Liquid Scintillation System (Beckman Instruments, Inc., Fullerton, Calif.) or Nuclear-Chicago gamma counter (Nuclear-Chicago Corp., Des Plaines, Ill.). Recovery of cAMP was $\sim 59\%$.

RESULTS

Suspension of washed guinea pig spermatozoa in either Ca^{++} -deficient or Ca^{++} -containing, glucose-free BWB resulted in head-to-head agglutination within a matter of minutes (Fig. 1). Incubation in glucose-free BWB from 0 to 5 h (Fig. 2) resulted in a gradual increase in the absolute number of activated, acrosome-reacted spermatozoa, although a large proportion of aggregated, non-acrosome-reacted spermatozoa remained throughout incubation. All agents were without pronounced effect upon AR induction when added at 0 h (Table I). Whereas dB cAMP, 8-bromo-cAMP, AMP, 8-bromo-AMP, GMP, 8-bromo-GMP, and butyrate remained ineffective upon addition at 1 h, dB cGMP or 8-bromo-cGMP (10 mM) was able to induce a large proportion of ARs, being roughly equivalent to the $\%AR^{\text{tot}}$ score obtained after a 5-h incubation in glucose-free BWB alone.

Dose-response data were collected to determine the relationship between analogue concentration and $\%AR^{\text{tot}}$ scores (Fig. 3). Incremental increases from 2 to 12 mM 8-bromo-cGMP produced increasingly higher numbers of ARs, reaching 20.46% for the highest concentration tested (12 mM). In addition, the simultaneous addition of 10 mM imidazole, a cAMP phosphodiesterase stimulator, caused a dramatic potentiation of the 8-bromo-cGMP effects (Fig. 3). For example, the addition at 1 h of imidazole with 12 mM 8-bromo-cGMP produced a phenomenal 73.94% AR^{tot} score, nearly fourfold greater than 8-bromo-cGMP alone and 112-fold greater than the no-addition

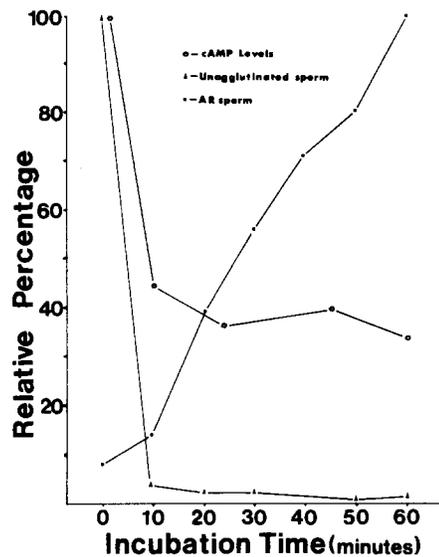

FIGURE 1 The relationship among db cGMP-induced AR, sperm agglutination, and cAMP levels over a 1-h incubation period in glucose-free BWW. Intracellular cAMP levels were assayed 0, 10, 25, 45, and 60 min after suspension of sperm in glucose-free BWW at 37°C. The number of unagglutinated sperm was determined by hemocytometer over the 1-h incubation. Sperm were induced to acrosome react by the addition of 10 mM dB cGMP at 0, 10, 20, 30, 40, 50, or 60 min, and counts were made after a 20-min incubation with the cyclic nucleotide. AR are reported relative to the 60-min score. Sperm concn: 1.5×10^7 /ml; cAMP at 0 h: 17 pmol/ 10^7 sperm; %AR^{tot} score at 1 h: 12.71.

control. Imidazole alone was ineffective.

The addition of 10 mM dB cGMP but not dB cAMP at 0 h appeared to inhibit agglutination of spermatozoa and did not elicit ARs. If, however, 10 mM dB cGMP was added after agglutination had begun, ARs were induced. This suggested a correlation between agglutination and the ability of spermatozoa to acrosome react. To further evaluate the time dependence of dB cGMP effects, additions of dB cGMP (10 mM) to sperm samples were made at 10-min intervals over a 1-h incubation period and ARs were assessed as described previously (Fig. 1). Results show a time-dependent increase in the ability of dB cGMP to induce ARs. In addition, it was found that, over the 1-h incubation period, sperm cAMP levels decreased from 17 pmol/ 10^7 sperm to nearly 30% of the initial level and that this decrease was accompanied by a rapid rise in the number of autoagglutinated spermatozoa (Fig. 1).

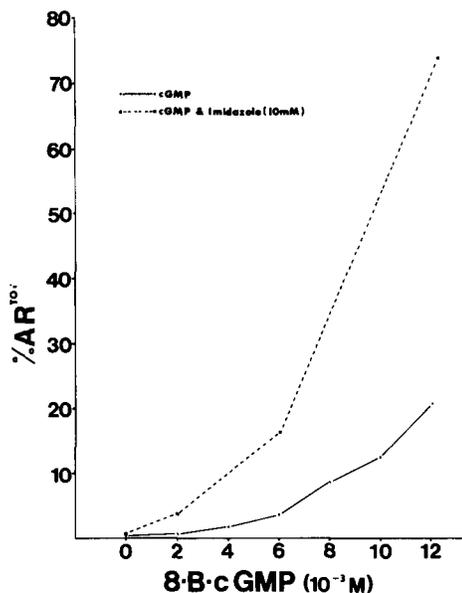

FIGURE 3 Dose-response curves for the induction of ARs by 8-bromo-cGMP or 8-bromo-cGMP + 10 mM imidazole, a cAMP phosphodiesterase stimulator. Sperm were incubated for 1 h at 37°C in glucose-free BWB before addition of drugs. ARs were assessed after an additional 20-min incubation at 37°C in medium containing drugs as indicated.

Typically, within a matter of minutes after the addition of cGMP analogues, vigorous flagellar activity of aggregated spermatozoa ensued. After 5–10 min, freely motile acrosome-reacted spermatozoa were observed attended by an activated pattern of motility (19), and by 15–25 min, a maximum was reached. Activated, acrosome-reacted spermatozoa remained motile for periods up to 2 h, after which an increasingly large number became immotile. ARs were judged physiological as evidenced by differential interference and electron microscopy (Fig. 4).

ARs could not be induced in Ca^{++} -deficient media. In addition, EGTA (2 mM) and nucleotide 5'-triphosphates (ATP, GTP, ITP, UTP; 10 mM) when previously added to Ca^{++} -containing media inhibited AR induction by dB cGMP, and this inhibition could be reversed by a subsequent and sufficient increase in Ca^{++} concentration.

DISCUSSION

A role for cGMP as an effector of the mammalian AR has not been previously considered. Perhaps this is because of the proposal of Gray et al. (9) that guanylate cyclase activity is absent in dog and

human spermatozoa. However, their results may have been caused by limitations of their assay procedure, because others (4) have shown that bovine sperm cGMP levels increase more than cAMP levels in the presence of pyruvate and the phosphodiesterase inhibitor, caffeine. Furthermore, cGMP has been localized immunocytochemically within rat spermatids (17). It seems probable that mammalian spermatozoa do possess an active guanylate cyclase.

In a given population, spermatozoa are not in maturational synchrony (8). This is also borne out by the observation that under in vitro conditions known to promote the AR, only a small percentage of the total sperm population will undergo the acrosome reaction at any point in time (Fig. 2). Because sperm nucleotide levels probably fluctuate on an individual basis, the high levels of analogues employed herein were considered necessary to compensate for this individual variability and to produce a large-scale synchronous AR. In addition, there is the possibility of poor membrane permeability of these analogues.

The facts that exogenous cGMP analogues but not cAMP analogues produced an almost immediate AR in a large proportion of spermatozoa and that these spermatozoa were motile for at least 2 h thereafter, lend credence to the idea that an increase, or perhaps a relative increase over cAMP in the levels of intracellular cGMP, promotes the AR. This is further substantiated by the potentiating effect of the cAMP phosphodiesterase stimulator, imidazole. These cyclic nucleotide fluctuations probably initiate Ca^{++} influx, because the absence of Ca^{++} or the presence of agents that chelate calcium ions (EGTA, nucleotide 5'-triphosphates) inhibits the induction of ARs by cGMP analogues. In this regard, the reduction of sperm ATP levels as sperm capacitate (13) may be functionally important, because this reduction may increase the availability of calcium ions, which are requisite for the AR.

The time-dependent effects of dB cGMP upon AR induction indicate that physiologic preparation for the AR, such as capacitation, is occurring. Furthermore, the results reported here suggest that the basis of dB cGMP's increased effectiveness over time may be related to a concomitant decrease in sperm cAMP levels. In effect, then, the cGMP/cAMP ratio increased over time, although the amount of added dB cGMP remained constant at 10 mM. Whether sperm autoagglutination is truly related to the decrease in cAMP levels, as is

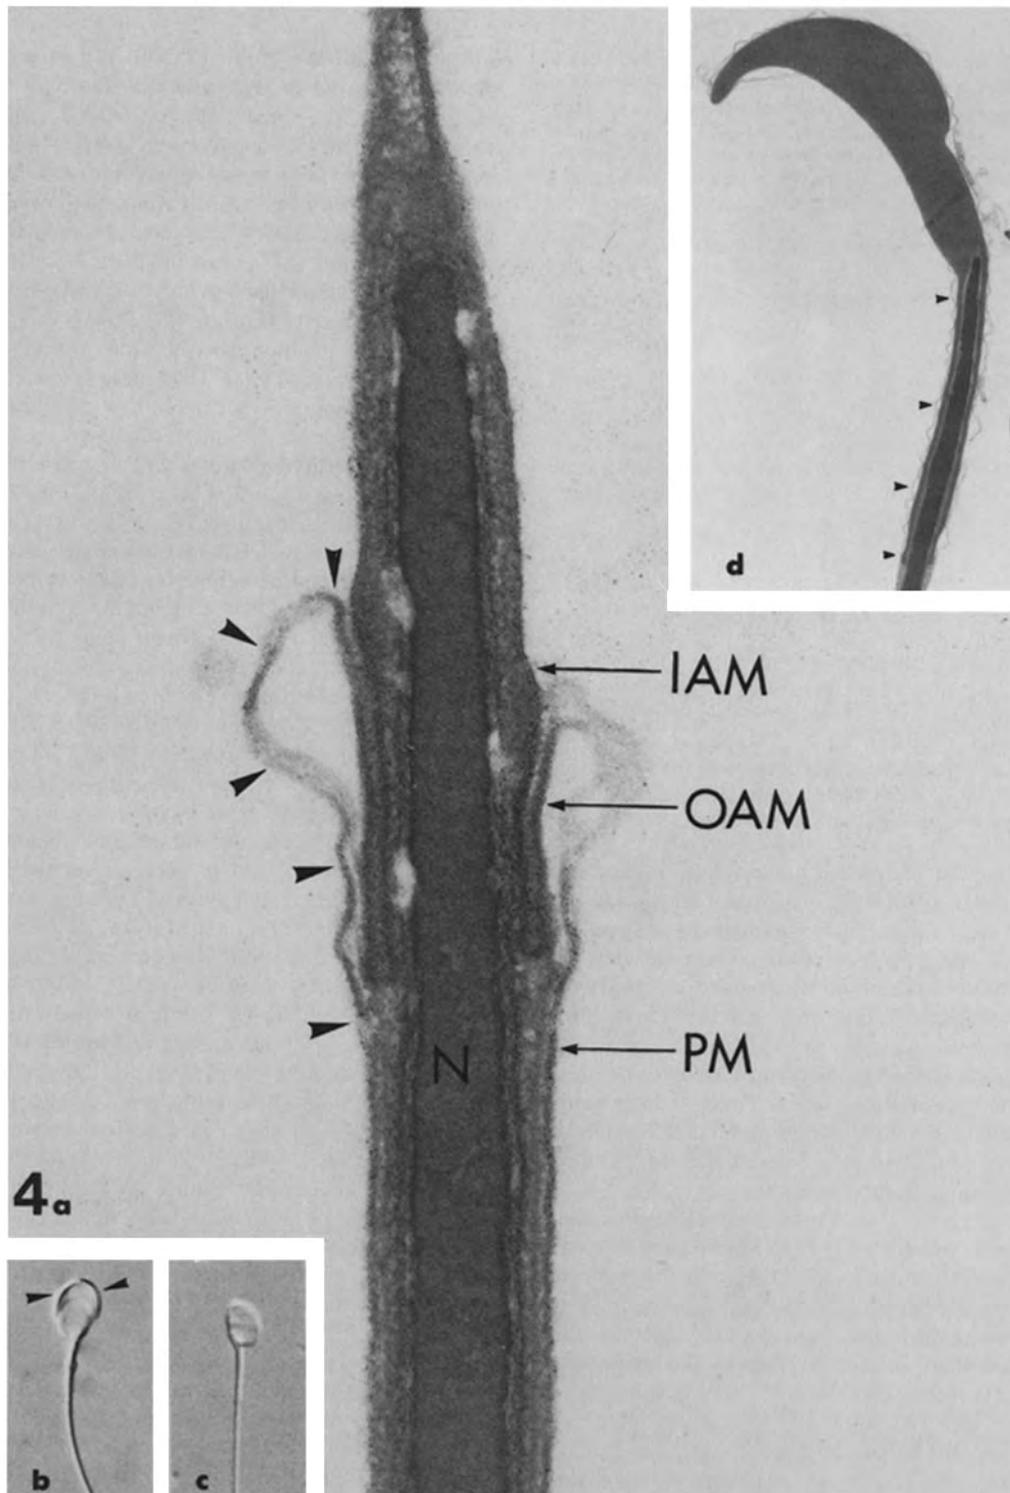

FIGURE 4 (a) Electron micrograph of acrosome-reacted guinea pig sperm fixed 20 min after the addition of 10 mM dB cGMP. suggested by their inverse correlation, remains to be proven. However, it is plausible that sperm agglutination indicates surface modifications concomitant with capacitation (8).

In sum, the previously reported results that dB cAMP inhibits the AR (3, 12) and those reported here seem to suggest that an increase in the cGMP/cAMP ratio promotes the guinea pig AR.

The Effect of ATP Depletion upon the Acrosome Reaction in Guinea Pig Sperm

J. SANTOS-SACCHI* AND MILDRED GORDON

From the School for Biomedical Education, The City College, New York, New York

The suspension of guinea pig spermatozoa in substrate-free medium results in the cessation of sperm motility and a 94% reduction in adenosine triphosphate (ATP) levels within minutes. ATP depletion was not deleterious to spermatozoa since motility was fully restored by the addition of pyruvate. In addition, sperm were able to synthesize ATP by metabolizing pyruvate. Following incubation for 0, 30, and 60 minutes in medium without substrate, acrosome reactions were measured before and after motility restoration. ATP depletion induced a large percentage of acrosome reactions relative to controls ($32.29 \pm 1.22\%$ compared with $0.63 \pm 0.02\%$ at 60 minutes). Ca^{2+} was required for the effect. It is suggested that ATP depletion inactivates a Ca^{2+} -dependent ATPase expulsion mechanism for Ca^{2+} , thereby permitting Ca^{2+} influx and the acrosome reaction.

Key words: sperm motility, ATP depletion, acrosome.

Calcium was originally implicated in fertilization mechanisms in invertebrates (Dan, 1956). The demonstration of a Ca^{2+} -dependent ATPase on the outer acrosomal membrane of rabbits, humans (Gordon, 1973), guinea pigs (Gordon et al, 1974), mice, and rats (Gordon, unpublished observations) implicated Ca^{2+} as a potent factor in the mammalian acrosome reaction. Calcium was invoked both as a prerequisite for membrane fusion (Gordon, 1973) and as an activator of acrosomal enzymes which are necessary for sperm passage through egg investments (Williams et al, 1974). Subsequently, it was established that the mammalian acrosome reaction is dependent upon the

presence of external Ca^{2+} (Yanagimachi and Usui, 1974) and that Ca^{2+} influx precedes or parallels its occurrence (Singh et al, 1978).

Mechanisms of Ca^{2+} entry into the sperm head are still not definitely known. However, based on observations of the activity of plasmalemmal and acrosomal membrane transport enzymes, Gordon (1973) considered that a Ca^{2+} -dependent ATPase on the outer acrosome membrane is inactive until the plasmalemma is modified during capacitation (Gordon et al, 1974), when Ca^{2+} levels rise in the periacrosomal fluid. At this point, Ca^{2+} is transported into the acrosome.

Most cells maintain low Ca^{2+} levels by active extrusion and mitochondrial sequestration (Kretzinger, 1979). It is clear that sperm Ca^{2+} must be kept low to prevent premature acrosome reactions. Since intracellular Ca^{2+} levels are dependent upon passive membrane permeability and an active Ca^{2+} -dependent ATPase, an alteration in either processes will result in altered Ca^{2+} flux. Oleate, lysolecithin, and Cd^{2+} , agents that increase Ca^{2+} membrane permeability (Hasselbach, 1972; Hurwitz et al, 1977), can induce the acrosome reaction in the presence of external Ca^{2+} (Gordon, unpublished observation). In the present study, the authors have examined the effect of depletion of ATP, and thus decreased activity of the Ca^{2+} -dependent ATPase expulsion mechanism, upon the guinea pig acrosome reaction.

Materials and Methods

Guinea pig spermatozoa were extruded from the cauda epididymidis into 0.9% NaCl in H_2O . After

Submitted for publication January 15, 1981; revised version received June 18, 1981; accepted for publication August 18, 1981.

washing three times by centrifugation (1000 g; 4 minutes each) spermatozoa were suspended in substrate-free BWB medium (NaCl 94.6 mM, KCl 4.7 mM, CaCl₂ 1.71 mM, KH₂PO₄ 1.19 mM, MgSO₄ 1.19 mM, NaHCO₃ 25.07 mM, and bovine serum albumin 1 g/l), pH 7.55, at a final concentration of 1×10^7 sperm/ml. Pyruvate-containing medium (10 mM) and Ca²⁺-free medium were also employed. Spermatozoa were incubated at 37 C under air.

After suspension of spermatozoa in the substrate-free BWB, ATP was assayed at 0, 15, 30, 45, and 60 minutes. At 60 minutes, either glucose (8 mM) or pyruvate (8 mM) was added and ATP was assayed 15 minutes later. Assays were performed on two occasions. The caudae of three guinea pigs were pooled to perform each assay. According to the method of Cole et al (1967), ATP was extracted from aliquots of spermatozoa with perchloric acid and was measured by the luciferase assay as described by Stanley and Williams (1969).

Acrosome reactions were assessed by use of a hemocytometer (four chambers, 0.1 mm³ each) after 0-, 30-, and 60-minute incubations (Santos-Sacchi and Gordon, 1980). For spermatozoa incubated in the absence of energy substrates, acrosome reactions were counted before and after motility restoration by 10 mM pyruvate. Acrosome reaction indices for spermatozoa incubated in medium with pyruvate from 0 time were based upon motile spermatozoa only. Spermatozoa were examined by light and phase contrast microscopy. Motile sperm are sperm with an active flagellar beat, including those freely swimming and those whose heads have attached

to the slide during the counting procedure. The following formulae were used to calculate acrosome reaction (AR) responses: %AR = (AR spermatozoa/total spermatozoa) × 100; %AR^{tot} = [(AR spermatozoa/(total spermatozoa - immotile spermatozoa))] × 100 (Santos-Sacchi and Gordon, 1980).

Results

Within 15 minutes after suspension in substrate-free BWB, over 95% of the spermatozoa become immotile. Figure 1 demonstrates the concomitant rapid decrease in sperm ATP levels, which dropped to about 6% of initial values (2.14 μg/10⁸ cells) within 15 minutes. Pyruvate restores motility to a large proportion of spermatozoa (Fig. 2, insert), but glucose does not. A difference in the ability of ATP-depleted spermatozoa to utilize these substrates was also observed (Fig. 1). Whereas pyruvate increases sperm ATP levels to nearly half their initial levels within 15 minutes, glucose is essentially ineffective. The inability of pyruvate to restore motility to all spermatozoa was not the result of damage to spermatozoa by the absence of substrate, since approximately the same percentage of motile spermatozoa were present in controls where pyruvate had been present from 0 time (Fig. 2, insert).

Figures 2 and 3 show the effect of incubation

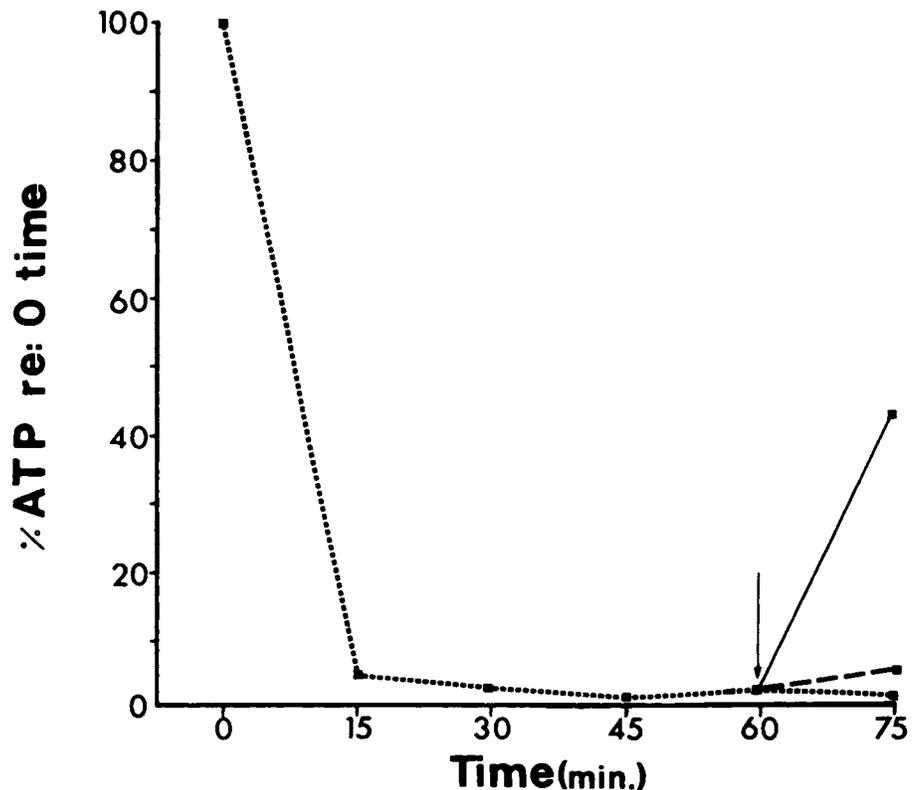

Fig. 1. Sperm samples were assayed for ATP at 15-minute intervals after suspension in substrate-free BWB (-----). At 60 minutes pyruvate or glucose (8 mM) was added (arrow) to samples, and ATP was assayed 15 minutes later (pyruvate —; glucose ---). The ATP levels determined at 0 time for the first and second assay were 2.22 μm/10⁸ sperm and 2.14 μm/10⁸ sperm, respectively. The 15-minute levels were reduced to 2.95% and 6.4% of initial values, respectively. The average of the two assays is reported here as a percentage of the 0 time value.

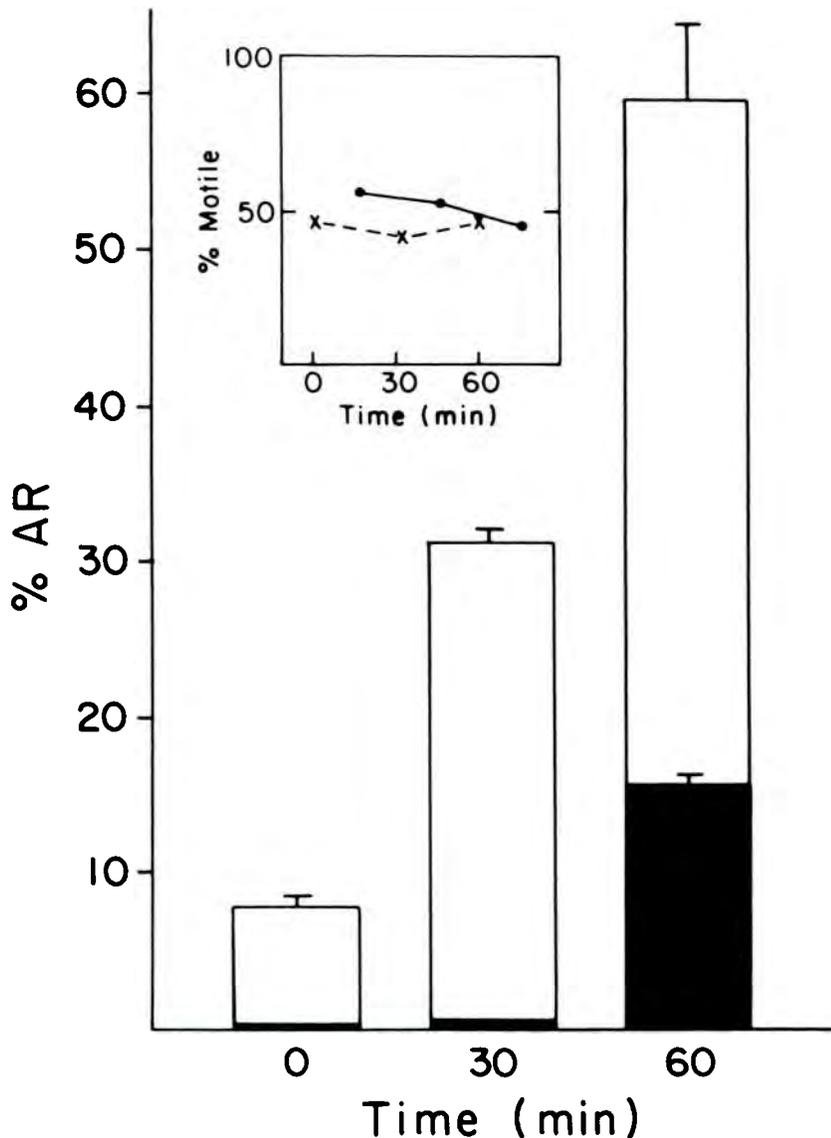

Fig. 2. Sperm were incubated in substrate-free BWW medium, and the percentages of acrosome reactions were determined prior to restoration of motility (light bars). The dark bars show the percentages of acrosome-reacted sperm whose motility was restored by pyruvate addition (10 mM). Insert: the percentages of sperm that remained motile during incubation in the presence of pyruvate from 0 time (—) and the percentages of sperm incubated in substrate-free BWW whose motility was restored by the addition of pyruvate (10 mM) at 0, 30, and 60 minutes (---).

time upon the induction of acrosome reactions. In the presence of Ca^{2+} , a time-dependent increase in the $\%AR^{\text{tot}}$ score is observed for spermatozoa incubated with or without an energy substrate. However, the $\%AR^{\text{tot}}$ scores for those spermatozoa incubated without substrate are dramatically higher than for those incubated in the presence of pyruvate (1 hour: $32.29 \pm 1.22\%$ vs. $0.63 \pm 0.02\%$) (Fig. 3). The number of immotile acrosome-reacted spermatozoa that became motile upon the addition of pyruvate also increases over time (Fig. 2). Because pyruvate was added to restore sperm motility prior to determining the $\%AR^{\text{tot}}$ scores, it was necessary to establish whether pyruvate induced the acrosome reaction. The pyruvate effect

on motility is not related to the acrosome reaction, because an increase in the number of *immotile acrosome-reacted spermatozoa* is found prior to pyruvate addition (Fig. 2). Furthermore, microscopic examination showed that acrosome-reacted and non-acrosome-reacted spermatozoa regain motility immediately (within 2 minutes) after pyruvate addition, with the acrosome-reacted spermatozoa exhibiting an "activated" pattern of motility (Yanagimachi and Usui, 1974).

In the absence of Ca^{2+} , the $\%AR$ score is very low relative to that in the presence of Ca^{2+} . After a 2-hour incubation in Ca^{2+} -free medium, only $27 \pm 4\%$ immotile acrosome-reacted spermatozoa are found. Pyruvate *did not* restore motility of

acrosome-reacted spermatozoa but did restore the motility of non-acrosome-reacted spermatozoa, indicating that acrosome degeneration occurred after the death of these sperm. The 2-hour %AR^{tot} score for spermatozoa incubated from 0 time with pyruvate in Ca²⁺-free medium was also very low, equivalent to that obtained after 30 minutes in the Ca²⁺-containing control.

Osmolality differences between substrate and substrate-free conditions were not responsible for the observed results, since glucose (5 mM) could replace pyruvate if added at the initiation of incubation. Under such circumstances, osmolality differences between substrate and substrate-free conditions were insignificant (5 mOsmol).

Discussion

Gordon (1973) originally suggested that an outer acrosome membrane Ca²⁺-dependent ATPase initiates the acrosome reaction by actively increasing acrosomal Ca²⁺ concentration. Green (1978), however, suggested that influx of calcium during the acrosome reaction is a result of passive diffusion. The induction of the acrosome reaction after ATP depletion suggests passive Ca²⁺ influx. Thus, rather than activity of the ATPase, the entry of Ca²⁺ for initiation of membrane fusion and exocytosis may be due to inhibition of an active Ca²⁺-dependent ATPase expulsion mechanism for calcium. The consistent demonstration of an active Ca²⁺-dependent ATPase on the outer acrosome membrane in epididymal and seminal spermatozoa (Gordon, 1973) lends support to this idea. The demonstration that plasmalemmal glycoproteins (Gordon et al, 1974) and enzymes (Gordon and Dandekar, 1977) are modified during capacitation of rabbit sperm may now be interpreted as a prerequisite to inactivation of the acrosomal membrane Ca²⁺-dependent ATPase. Thus loss of plasmalemmal integrity may affect the functional properties of the outer acrosomal membrane. In fact, Gordon et al (1978) demonstrated that the loss of Ca²⁺-dependent ATPase on the acrosome surface was correlated with destabilization of the plasma membrane of guinea pig sperm.

It is interesting to note that ATP levels decrease during capacitation (Rogers and Morton, 1973). A decrease in acrosomal membrane ATPase activity could be due to a decrease in substrate availability as well as to a decline in enzyme activity. Stores of ATP could be depleted within cellular compartments located near the acrosome independently of

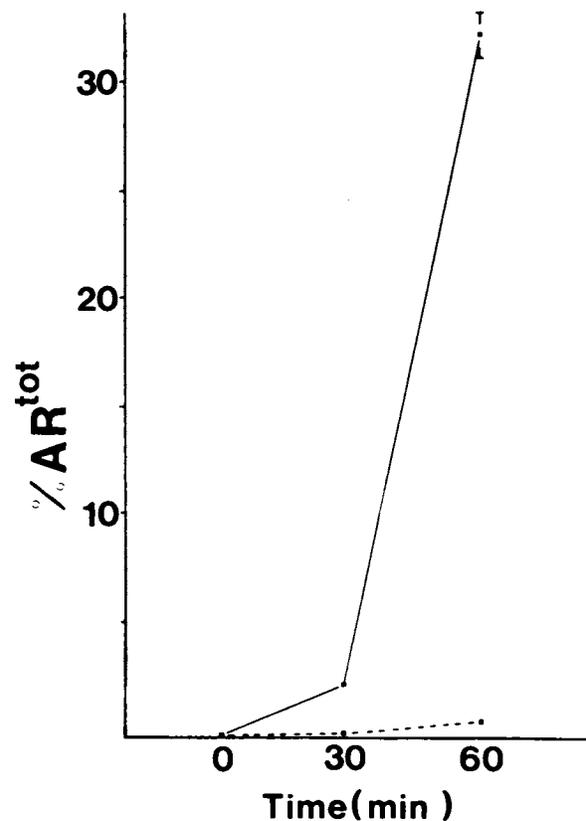

Fig. 3. The percentages of motile acrosome-reacted sperm as a function of incubation time. The motility of sperm incubated in substrate-free BWB (—) was restored by pyruvate addition (10 mM) at 0, 30, and 60 minutes, whereupon acrosome reactions were assessed. Sperm incubated in the presence of pyruvate from 0 time were assessed as well (---).

axonemal ATP. The sperm head is effectively isolated from the flagellum by a tight membrane junction (Fawcett, 1975). Therefore, the acrosome reaction may occur as a result of localized ATP depletion, despite intense flagellar "activation." In this study, ATP depletion produced immotility. Since pyruvate fully restored motility, ATP depletion does not damage the flagellar-mitochondrial system. The inability of glucose to restore motility is probably due to the ATP requirement for glucose utilization, since glucose alone can maintain motility if present at onset of incubation, ie, when ATP levels are high.

The consequences of ATP depletion on cAMP production may be significant. If cAMP generation is reduced or abolished, this may affect Ca²⁺ flux and the acrosome reaction. It has been shown that exogenous cAMP inhibits (Garcia and Rogers, 1978; Rogers and Garcia, 1979) and exogenous cGMP in the presence of Ca²⁺ induces the guinea

pig acrosome reaction (Santos-Sacchi and Gordon, 1980; Santos-Sacchi et al, 1980).

The rate of induction of acrosome reactions by ATP depletion is slower than that induced by changes in membrane Ca^{2+} permeability. For example, after a 1-hour incubation in glucose-free BWW, the addition of $4.5 \mu\text{g}$ oleate/ 10^7 spermatozoa induces a high percent acrosome reaction within a few minutes (Gordon, unpublished observations). This difference in induction time can be explained by the intrinsically poor Ca^{2+} permeability of plasma membrane (Lee and Shin, 1979). It appears that inhibition of Ca^{2+} -dependent ATPase in an otherwise intact membrane will not increase the rate of passive Ca^{2+} permeation but will permit a slow equilibration due to the inability to extrude Ca^{2+} . Agents that increase the passive Ca^{2+} permeability, on the other hand, result in a rapid influx of Ca^{2+} , despite the presence of an active Ca^{2+} -dependent ATPase (Hasselbach, 1972). Hence the rapidity of onset of Ca^{2+} -dependent events is related to the particular mechanism disrupted, whether passive or active.

The spermatozoon is a terminal cell. Irreversible changes in the sperm surface during capacitation prepare the sperm for the acrosome reaction. Thus the breakdown of a Ca^{2+} expulsion mechanism associated with the external acrosome membrane would follow the breakdown of the sperm surface membrane barrier. The fluid compartment between the plasma membrane and acrosome would facilitate such a sequence of membrane changes.

Although the exact mechanism of acrosome reaction induction needs further study, the present findings suggest that Ca^{2+} concentration can increase in the acrosome as a result of ATP depletion. Decreased activity of a Ca^{2+} expulsion mechanism may therefore be the cellular mechanism that initiates the acrosome reaction and prepares the sperm for fertilization.

Received 22 July 1997; revised 25 October 1997; accepted 28 October 1997

Abstract

The temperature dependence of outer hair cell motility-related gating current and capacitance was evaluated under whole-cell voltage clamp. Temperature change caused a shift of these voltage-dependent functions along the voltage axis, with a decrease in temperature causing a negative shift in the voltage at peak capacitance (V_{pkcm}) of 19.2 mV per 10°C. Gating current kinetics showed only mild temperature dependence, the Q_{10} being about 1.5. Temperature is speculated to affect outer hair cell (OHC) mechanical gain and frequency response by alterations in lateral membrane viscoelastic properties. Such temperature-dependent effects on the OHC may mediate known temperature effects on in vivo cochlear physiology. © 1998 Published by Elsevier Science B.V.

1. Introduction

The discovery that outer hair cells (OHC) can change their length in response to electrical stimuli profoundly influenced the study of cochlear physiology (Brownell et al., 1985). OHC motility is dependent upon transmembrane voltage (Santos-Sacchi and Dilger, 1988; Iwasa and Kachar, 1989); hyperpolarization elongates and depolarization shortens the cylindrically shaped cell. The mechanism underlying this shape change which occurs at acoustic frequencies is unknown. However, it is not based on typical cellular mechanisms of motility (Kachar et al., 1986; Santos-Sacchi and Dilger, 1988; Holley and Ashmore, 1988). In fact, current indications are that the force generating mechanism resides solely within the lateral plasma membrane (Kaliniec et al., 1992; Huang and Santos-Sacchi, 1993, 1994), possibly corresponding to the 8–10 nm intramembranous particles observed ultrastructurally (Gulley and Reese, 1977; Forge, 1991).

The mechanical activity of the OHC is mirrored by an electrical signature, a voltage-dependent capacitance

or, equivalently, a gating charge movement (Ashmore, 1989; Santos-Sacchi, 1990, 1991; Iwasa, 1993), which indicates that membrane-bound voltage sensor-motor elements control OHC length (Santos-Sacchi, 1990, 1991, 1993; Ashmore, 1989, 1992; Dallos et al., 1991; Iwasa, 1994). In this report we measure the effects of temperature on the OHC motility-related gating currents and nonlinear capacitance. We report that both the kinetics and voltage dependence of nonlinear charge movement are affected. Preliminary accounts of this work have been presented (Santos-Sacchi, 1990; Santos-Sacchi et al., 1995).

2. Materials and methods

Guinea pigs were overdosed with halothane. The temporal bones were removed, the apical two turns of the organ of Corti micro-dissected free, and OHCs isolated enzymatically with collagenase (0.3 mg/ml for 10 min followed by gentle reflux through a tapered polyethylene pipette tip) in medium 199 with Hanks' salts (Gibco). The cell enriched supernatant was then transferred to a 700 μ l perfusion chamber, and the cells permitted to settle onto the cover glass bottom. A Ni-

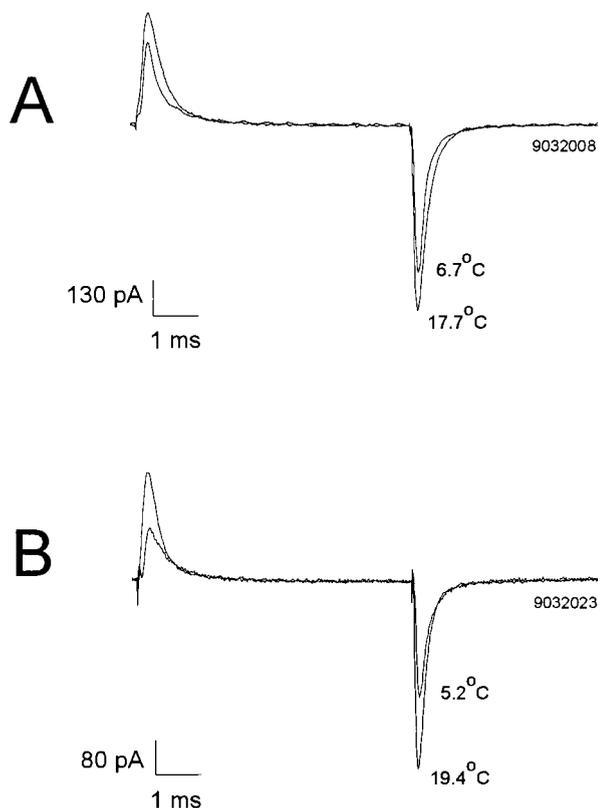

Fig. 1. Two OHCs were clamped to -80 mV and gating currents were extracted with the $\pm P$ protocol (40 mV about the holding potential). A drop in temperature decreased both the gating charge moved and the exponential time constant of the current decay. A: Larger amplitude trace: 17.7°C ; Q_{off} : 240 fC; τ_{off} : 0.21 ms. Smaller amplitude trace: 6.7°C ; Q_{off} : 162 fC; τ_{off} : 0.24 ms. B: Larger amplitude trace: 19.4°C ; Q_{off} : 144 fC; τ_{off} : 0.18 ms. Smaller amplitude trace: 5.2°C ; Q_{off} : 98 fC; τ_{off} : 0.26 ms. The effects were reversible.

kon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical recording. A modified Leibovitz medium (NaCl 100 mM, KCl 5.37 mM, CoCl_2 2.0 mM, MgCl_2 1.48 mM, 20 mM TEA, 2 μM TTX, 20 mM CsCl, HEPES 5.0 mM, dextrose 5.0 mM, pH 7.2) was used in order to block ionic conductances which might otherwise interfere with capacitive current measures. OHCs maintained normal appearance in this solution for up to 1 h. Osmolarity was adjusted to 300 mOsm with dextrose.

OHCs were whole-cell voltage clamped with a Dagan 8900 patch clamp amplifier at a holding potential of -80 mV, similar to the resting potential recorded in vivo (Dallos et al., 1982). Pipette solutions were composed of 140 mM CsCl, 10 mM EGTA, 5 mM TEA, 2 mM MgCl_2 , and 5 mM HEPES buffered to pH 7.2. Osmolarity was adjusted to 300 mOsm with dextrose. Gigohm seals were obtained at the nuclear level of the cell membrane; electrode capacitance and series resistance were compensated. A modified version of Clampex (Axon Instruments, CA) utilizing the Labmaster board (Axon) was used to collect data which were saved to

disk for off-line analysis. Current was filtered at 5 kHz with an 8-pole Bessel filter. Temperature was controlled with a custom-built Peltier recording chamber, and measured with a micro temperature probe (Sensortek, NJ) placed within 0.5 mm of the recorded cells. In addition, data were confirmed using pre-cooled or pre-warmed solutions in the absence of the Peltier device.

Detailed evaluation of the bell-shaped OHC membrane capacitance function was made at different potentials by transient analysis of currents induced by a voltage stair step stimulus. Step duration was adjusted on-line to $15\times$ the time constant of the capacitive transient to ensure steady-state conditions. The capacitance function was fit to the first derivative of a two-state Boltzmann function relating nonlinear charge to membrane voltage ($\delta Q/\delta V$; Santos-Sacchi, 1991; Huang and Santos-Sacchi, 1993),

$$C_m = Q_{\text{max}} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}} \quad (1a)$$

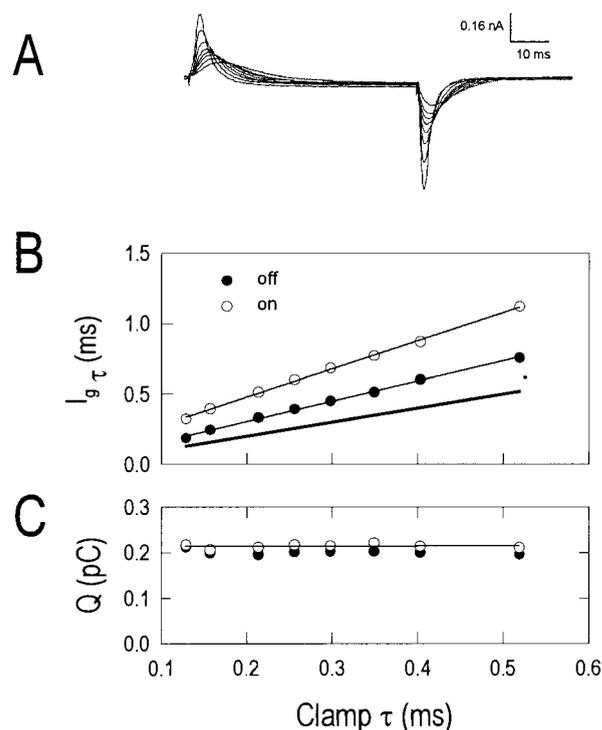

Fig. 2. A: The time constant of OHC gating current decay was modified by altering the speed of the voltage clamp via series resistance compensation. Gating currents were obtained as in Fig. 1. B: Gating charge time constant followed that of the voltage clamp. The thick solid line represents a one-to-one correspondence between clamp τ and gate τ . C: However, changing the gating time constant does not modify total charge moved. The charge is simply redistributed over time. The change in charge moved as a function of temperature (Fig. 1) is therefore not due to a simple effect on the time constant of the clamp amplifier.

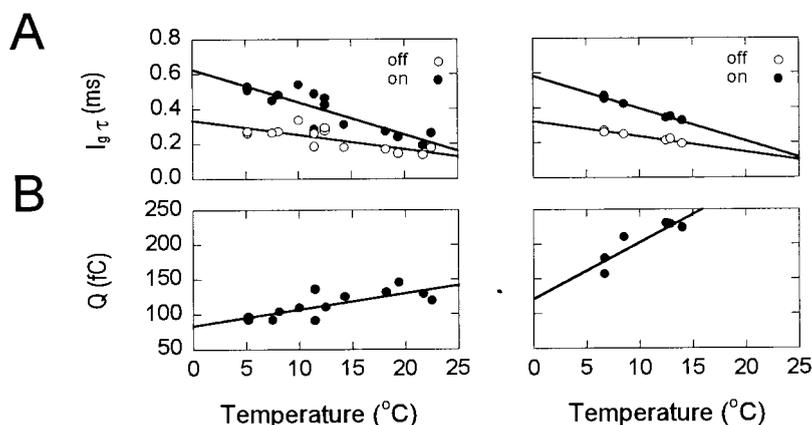

Fig. 3. The effects of temperature on gating currents are presented in detail for two OHCs (left and right panel). A: The time constant of on and off gating current relaxation as a function of temperature. Note the differences between on and off time constants. Left panel: $\tau^{-1} Q_{10}$ on: 1.55; off: 1.4. Right panel: $\tau^{-1} Q_{10}$ on: 1.62; off: 1.45. B: The average of on and off charge moved as a function of temperature. On and off charge were essentially equivalent.

where

$$b = \exp \frac{-ze(V - V_{\text{pkcm}})}{kT} \quad (1b)$$

Q_{max} is the maximum nonlinear charge moved, V_{pkcm} is voltage at peak capacitance or equivalently, at half maximal nonlinear charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. Gating currents were extracted online with the $\pm P$ procedure (± 40 mV; Armstrong and Bezanilla, 1973) about a holding potential of -80 mV, or with the $P/-5$ protocol, at a subtraction potential of -160 mV (Armstrong and Bezanilla, 1977). All data analysis was performed with the software package MATLAB (Mathworks, MA). In some experiments, V_{pkcm} was monitored during temperature changes using a previously developed tracking procedure (Kakehata and Santos-Sacchi, 1995). Cell turgor pressure was either maintained constant by pipette pressure, or cells were collapsed so that pressure-induced shift in V_{pkcm} did not interfere with analysis of temperature effects (Kakehata and Santos-Sacchi, 1995). Q_{10} was determined as in Kimura and Meves (1979). The use and treatment of animals was approved by the Yale University animal care committee.

3. Results

Nonlinear gating currents associated with the mechanical responses of OHCs are induced at the onset and offset of voltage steps. Fig. 1 illustrates these currents in two cells obtained at a holding potential of -80 mV, each at two different temperatures. The effect of temperature change is to alter the total amount of

charge moved and the time constant (τ_{on} and τ_{off}) of the current decay. Both the rate and quantity of charge moved are decreased as temperature is decreased. Note also that τ_{on} and τ_{off} differ, with τ_{on} being slower. It has been previously shown that the clamp time constant affects the speed of OHC charge movement (Santos-Sacchi, 1990, 1992). However, changing the clamp time constant does not alter the amount of charge moved (Fig. 2). Thus, any affects of temperature upon clamp time constant (Santos-Sacchi, 1990) would not be

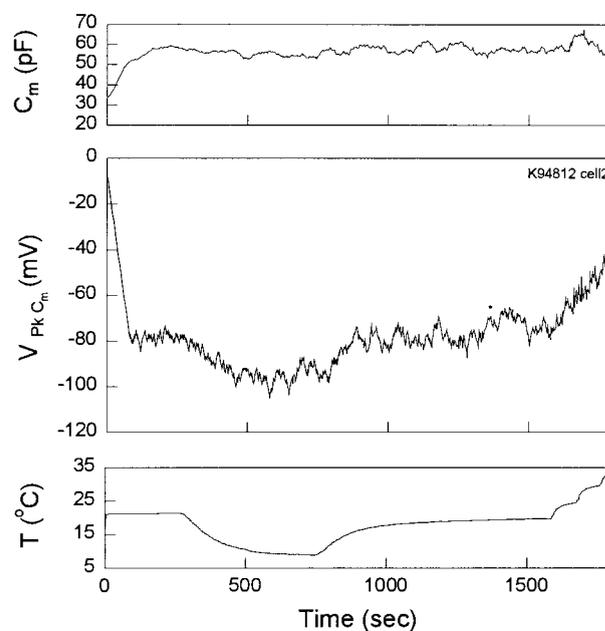

Fig. 4. The voltage at peak capacitance (V_{pkcm}) follows changes in temperature. A tracking procedure developed previously (Kakehata and Santos-Sacchi, 1995) was used to follow changes in C_{mpk} and V_{pkcm} as temperature was reversibly modified over the course of minutes. Tracking initiated at 0 mV. Note close correspondence between changes in temperature and V_{pkcm} .

expected to modify the total charge moved. In Fig. 3, a detailed analysis of the temperature effects is presented for two cells. It can be seen that the gating current time constants (τ_{on} and τ_{off}) and charge movement (Q) are proportional to temperature. The τ_{off} appears less affected by temperature than does τ_{on} . In each cell, the Q_{10} for τ_{on}^{-1} and τ_{off}^{-1} was about 1.6 and 1.4, respectively.

The OHC possesses a bell-shaped voltage-dependent capacitance function as a consequence of its membrane-bound nonlinear charge movement. The voltage where capacitance is maximal (V_{pkcm}) corresponds to the voltage where half maximal charge movement occurs, and where OHC motility is most sensitive to voltage fluctuations. Fig. 4 illustrates with a real time tracking technique that V_{pkcm} closely follows changes in temperature. Decreasing temperature causes a negative shift in V_{pkcm} and visa versa. Detailed capacitance evaluations support these tracking observations. Fig. 5A illustrates a family of capacitance functions obtained from a single OHC during temperature plateaus at 25, 21, 14, 8 and 6°C. V_{pkcm} shifted 26.8 mV between temperature extremes. Peak capacitance also decreased in this case, accompanied by a decrease in valence, z . Average results ($n=6$) are depicted in Fig. 5B. Q_{max} showed little significant systematic change. The valence, z , showed a change of 0.12 per 10°C, and V_{pkcm} changed 19.2 mV per 10°C.

Gating currents were also evaluated using the P/−5 protocol, which more effectively extracts gating currents (Armstrong and Bezanilla, 1977). Fig. 6 provides examples of gating currents from the same OHC evaluated in Fig. 5A. Fig. 6A,B show currents elicited by stepping from −120 mV to −30 and −60 mV, respectively. In both cases, decreasing temperature causes a decrease in the rate and quantity of charge moved. The average ($n=4$) $\tau_{\text{on}}^{-1} Q_{10}$ was 1.50 ± 0.06 (mean \pm S.E.M.). The $\tau_{\text{off}}^{-1} Q_{10}$ was 1.55 ± 0.08 . These results are in accord with the magnitudes obtained with the \pm P technique used above; differences between on and off time constant Q_{10} are not significant.

Finally, an attempt was made to obtain gating currents from giant patches of OHC membrane (Hilgemann, 1989). Unfortunately, patch pipettes with tip diameters near 5 μm consistently broke through the membrane to yield whole-cell configurations with poor seals. Nevertheless, recordings under these conditions were sometimes capable of garnering gating current information. Fig. 7 presents such an example, where the cell was held at 0 mV and gating currents extracted with the \pm P technique. The very fast time constant of the clamp amplifier under these conditions permitted recording of gating current time constants down to about 50 μs . Deiters cells under the same configuration showed no gating current. As in regular whole-cell configuration, decreases in temperature caused a reduction

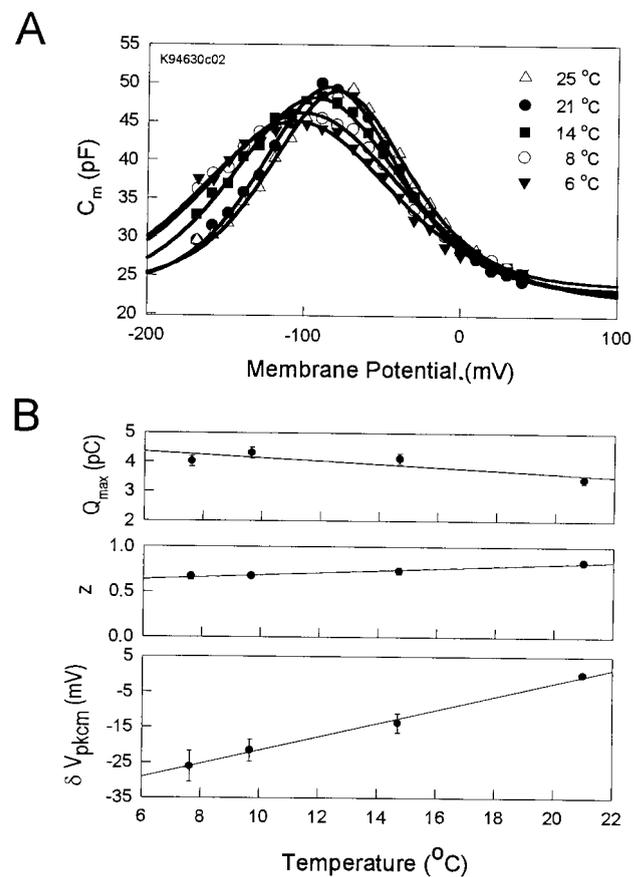

Fig. 5. Effect of temperature on OHC nonlinear capacitance. A: Capacitance was evaluated with the stair step protocol. As temperature is decreased from 25°C to 6°C, the functions shift in the hyperpolarizing direction. Solid lines are fits to Eq. 1. 25°C: V_{pkcm} : −78.8 mV; z : 0.87; Q_{max} : 2.99 pC; C_{lin} : 23.75 pF; 21°C: V_{pkcm} : −84.3 mV; z : 0.87; Q_{max} : 3.1 pC; C_{lin} : 23.12 pF; 14°C: V_{pkcm} : −93.1 mV; z : 0.71; Q_{max} : 3.74 pC; C_{lin} : 22.3 pF; 8°C: V_{pkcm} : −100.5 mV; z : 0.61; Q_{max} : 4.14 pC; C_{lin} : 21.7 pF; 6°C: V_{pkcm} : −105.6 mV; z : 0.62; Q_{max} : 3.77 pC; C_{lin} : 22.4 pF. B: Average results from six OHCs showing changes in parameters Q_{max} , z and V_{pkcm} . Error bars are \pm S.E.M. Q_{max} remains fairly stable with temperature, although a slight increase below 21°C may be significant. z changes slightly with temperature. V_{pkcm} is significantly susceptible to temperature, showing a 1.9 mV change per degree centigrade.

of OHC nonlinear charge moved, but had little effect on rate of charge movement.

4. Discussion

The OHC voltage-dependent charge movement or capacitance is sensitive to alterations in temperature. The most prominent effect appears to be on the position of these functions along the voltage axis, with a decrease in temperature causing a reversible negative shift in V_{pkcm} of 19.2 mV per 10°C. At a fixed holding and step potential, such a shift would be expected to result in a change in magnitude of charge moved. This is illustrated through modeling in Fig. 8. A small com-

ponent of the decrease in charge movement noted in gating current records as temperature is decreased may also be due to a redistribution in time beyond the experimental recording period, since steady-state indications from capacitance measures show little change in total charge moved (Q_{\max}). The whole-cell capacitance determinations from stair step stimuli were robust since integrations were made over intervals greater than 15 times the capacitive current time constants (Huang and Santos-Sacchi, 1993). Gating current kinetics are sensitive to temperature, as well, but show only a mild temperature dependence, the Q_{10} being about 1.5. The Q_{10} of ion channel gating current kinetics, on the other hand, is typically between 2 and 3 (Bezánilla and Taylor, 1978; Kimura and Meves, 1979; Adams and Gage, 1979; Schauf and Bullock, 1979; Collins and Rojas, 1982). It should be emphasized, however, that OHC motility-related gating current kinetics are faster than clamp time constants obtainable under whole-cell configuration (Santos-Sacchi, 1990, 1992), and are thus constrained by clamp characteristics. Nevertheless, at least for ion channels, a temperature-dependent shift in the voltage dependence of conformational state often accompanies a temperature dependence of the underlying molecular kinetics. For example, in batrachotoxin treated Na channels, a 7 mV per 10°C shift in the open probability function accompanied a Q_{10} of about 2.3 for mean open times

(Correa et al., 1992). For a two-state model, while a shift in steady-state probability reflects a change in the difference between open and closed steady-state energy levels, changes in kinetics are governed by alterations of the activation energy barrier height relative to those steady-state energy levels. Thus, changes in steady-state energy levels which effect shifts in the two-state probability function may also lead to changes in the relative height of the activation energy barrier, thereby affecting gating kinetics. Under the assumption that ionic channel and OHC molecular motor characteristics are similar, it is best to cautiously acknowledge that the large shift in OHC V_{pkcm} may be accompanied by a Q_{10} for the underlying kinetics which is greater than the measured value of 1.5, and that this value is a limitation of clamp speed. Temperature effects on OHC mechanical responses are also probably constrained by clamp speed (Holley and Ashmore, 1988). Recently, Ashmore and Gale (1997) found that gating current kinetics in OHC membrane patches, while remarkably fast (down to 7 μs τ), still evidenced Q_{10} s below 1.5. This is similar to results obtained with very fast clamp characteristics as in Fig. 7. However, they found no change in gating charge magnitude vs. temperature. This may indicate that, unlike our whole-cell results, V_{pkcm} did not shift in their membrane patch recording configuration, or just like our whole-cell results, clamp speed remained limiting.

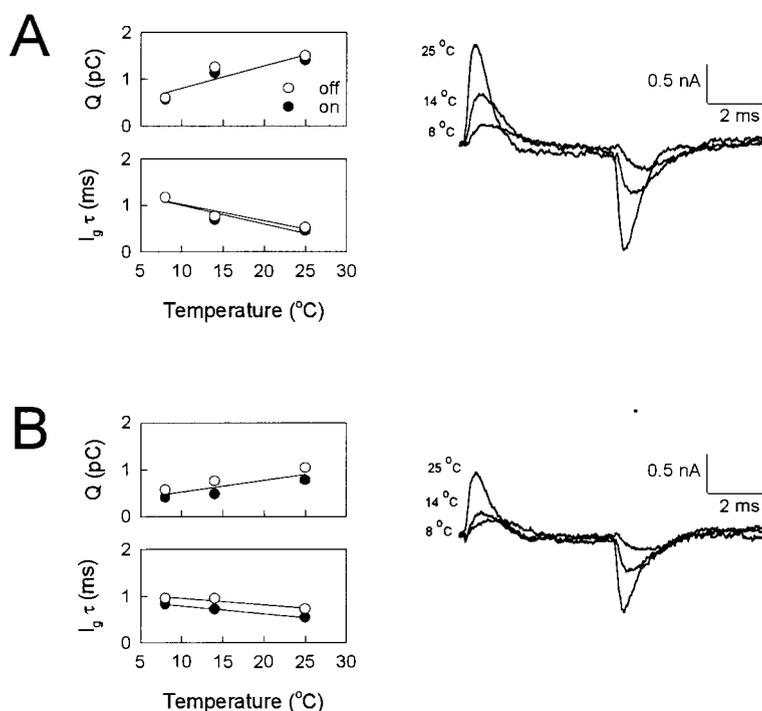

Fig. 6. Effect of temperature on gating currents obtained with the P/–5 protocol. Same cell as in Fig. 5A. A: Step voltage from –120 to –30 mV. A decrease in temperature from 25°C to 8°C decreases both charge moved and rate of movement. Q_{10} determined from the line fits for on and off gate τ was 1.61 and 1.49, respectively. B: Step voltage from –120 to –60 mV. Similar decreases were obtained. Q_{10} for on and off gate τ was 1.26 and 1.18, respectively.

A likely factor which might underlie the effects of temperature upon the kinetics of OHC lateral membrane motors, is a temperature dependence of OHC membrane viscosity. Membrane particle kinetics are governed by frictional forces within the medium, which are proportional to the medium's viscosity and particle size (see Rojas and Keynes, 1975). Interestingly, membrane viscosity may also underlie a component of the double exponential time course in voltage-induced V_{pkcm} shifts that we have recently found (Santos-Sacchi et al., 1996, 1997). It should be the case, then, that factors in addition to temperature, e.g. lipid composition, which influence OHC membrane viscosity or fluidity will have profound effects on OHC function.

OHC voltage-dependent capacitance is known to mirror characteristics of the OHC's mechanical activity (Ashmore, 1989, 1992; Santos-Sacchi, 1990, 1991, 1992; Kakehata and Santos-Sacchi, 1995). Given this relationship, temperature is expected to modify OHC motility and its physiological consequences, namely its contribution to the 'cochlear amplifier'. In this regard it is known that decreases in temperature are able to adversely affect *in vivo* cochlear frequency selectivity and sensitivity (e.g. Brown et al., 1983). Temperature change will alter the frequency response of OHC motility. In addition, a temperature-dependent shift in the OHC motility function along the voltage axis, which is indicated by the observed shift in V_{pkcm} , will alter the gain of OHC motility. Such effects may be sufficient to explain the *in vivo* results. However, it has also been shown that temperature modifies the resting length of isolated OHCs, which conceivably could modify basilar

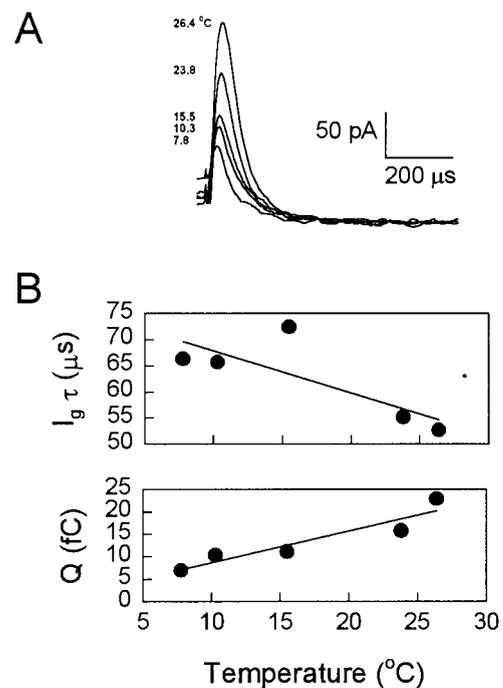

Fig. 7. A: Effect of temperature on gating currents obtained with very fast clamp time constant. During an attempt at giant patch formation with a 5 μm patch electrode tip, whole cell configuration was established. The trace shows off gating currents extracted with the $\pm P$ technique at 0 mV holding potential. The actual order of temperature change was 26.4, 10.3, 7.8, 15.5, and 23.8°C. B: Gate time constant and charge movement as a function of temperature. Charge moved decreases with temperature. Gating time constant is little effected by temperature; the fitted line represents a Q_{10} of about 1.2.

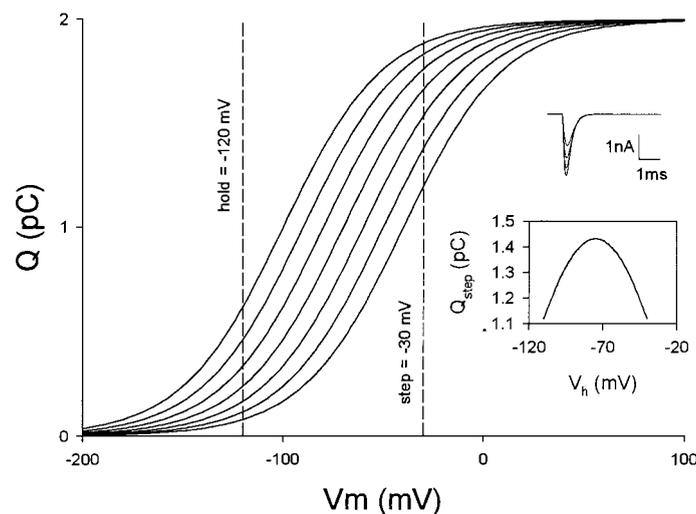

Fig. 8. Model illustrating the expected change in charge moved as a function of V_{pkcm} (V_h) shift. Cell model was as in Santos-Sacchi (1992), with R_s : 5 $\text{M}\Omega$, R_m : 100 $\text{M}\Omega$, C_m : 29 pF, Q_{max} : 2 pC, z : 1, V_{pkcm} (V_h): -40 to -100, in steps of 10 mV. Charge is plotted vs. membrane potential for each value of V_{pkcm} . The dotted lines indicate the holding potential and step potential used to obtain the off gating currents in the inset, which were obtained with the P/5 technique as for the biophysical data. The traces are plots only from V_{pkcm} of -70 to -100 mV, charge decreasing as V_{pkcm} shifts negatively. Scale: 1 ms, 1 nA. The inserted figure plots charge at the -30 mV step vs. V_{pkcm} (V_h), and illustrates that increases and decreases in charge moved can be obtained depending upon the relationship between holding, step and V_{pkcm} potential.

membrane tension in vivo (Gitter, 1992; LeCates et al., 1995). In addition to affecting the gain of OHC motility, a change in resting length at a fixed resting potential is expected from a shift in V_{pkcm} . This occurs because a displacement of the length vs. voltage function along the voltage axis (i.e. shift in V_{pkcm}) while holding the membrane potential constant will change the degree of contraction of the OHC. Given an OHC mechanical response of 20–30 nm/mV (Santos-Sacchi and Dilger, 1988), the temperature dependence of V_{pkcm} will provide for a resting length change of 0.04–0.06 $\mu\text{m}/^\circ\text{C}$. However, both Gitter (1992) and LeCates et al. (1995) found values nearly an order of magnitude larger, which indicates that something other than a direct effect on the membrane motor was responsible for their observations.

In sum, we provide additional evidence that physical modification of the environment which harbors the molecular motors for OHC motility can profoundly modify the cell's electromechanical behavior. Previously, it had been shown that membrane tension, either externally applied (Iwasa, 1993; Gale and Ashmore, 1994; Kakehata and Santos-Sacchi, 1995) or intrinsically generated by the molecular motors themselves (Santos-Sacchi et al., 1996, 1997), can alter the voltage dependence of OHC capacitance/motility. Taken together, these data attest to the OHC's, and, indeed, the cochlea's, exceptional susceptibility to functional perturbation.

AN EVALUATION OF NORMAL STRIAL CAPILLARY TRANSPORT
USING THE ELECTRON-OPAQUE TRACERS
FERRITIN AND IRON DEXTRAN

J. Santos-Sacchi¹ and William F. Marovitz²

From the ¹Center for Biomedical Education and ²Dept. of Otolaryngology,
Mount Sinai School of Medicine, City University of New York, New York

(Received March 14, 1979)

Abstract. Enzymatic tracer techniques to study normal and pathologic stria capillary transport pose various problems. The use of electron opaque tracers can circumvent many of these problems. Iron dextran (mol. diam 20–70 Å) and ferritin (mol. diam 110 Å) were injected intravenously and the mice sacrificed at intervals of $\frac{1}{2}$, 1, 2, 5, and 24 h. The iron dextran results were unusual in that from $\frac{1}{2}$ to 5 h after administration the tracer was present within the cytoplasmic matrix of endothelia, but by 24 h it had been cleared out. No transendothelial exchange was noted. The ferritin results were in conflict with previous results using horse-radish peroxidase. Transport of ferritin was minimal regardless of time sacrificed. No more than a few molecules were scattered about the capillary basal lamina. Those molecules transported across capillaries were apparently delivered by means of the micropinocytotic system. The results suggest a blood-stria barrier similar to the blood-thymic and blood-myenteric barriers. Experimental as well as control animals exhibited stria light cells which contained ferritin-like particles within their cytoplasmic matrices. These light cells are probably reticulo-endothelial type cells. Ferritin may be useful to gauge stria capillary transport alterations associated with auditory pathologies.

The functional role of the stria vascularis, which includes the production of the endocochlear DC potential and ionic composition of the endolymph, is important for normal inner ear function (Honrubia & Ward, 1969; Konishi et al., 1966). The stria vascularis lines the lateral wall of the cochlear duct and is composed of three cell layers, termed marginal, intermediate and basal (Smith, 1957). The tissue is effectively a separate compartment sealed off from the endolymphatic space and spiral ligament by zonulae occludens which occur between the cell membranes of abutting marginal cells and abutting basal cells

(Jahnke, 1976). This tight junctional seal around the stria limits the nutrient inflow from neighboring sources; therefore, the high stria metabolic requirements (Chou & Rodgers, 1962) must be met essentially by intrinsic capillary networks (Reale et al., 1975). Thus the permeability functions of the stria capillaries are paramount when considering the survival and function of the stria cells; accordingly, stria capillary permeability is important for normal cochlear function.

Tracer molecules have been used to map the transport of materials through stria capillaries (Yamamoto & Nakai, 1964; Duvall et al., 1971; Winther, 1971; Gorgas & Jahnke, 1974). Tight junctions have been found to exist between stria endothelial cells as have been found to exist between capillary endothelia of most CNS tissue (Duvall et al., 1971; Gorgas & Jahnke, 1974; Reese & Karnovsky, 1967). Tight junctional seals are known to prevent the passage of lipid insoluble materials through intercellular clefts. Therefore, passage of lipid insoluble materials through the capillaries of the stria vascularis appears to be limited to the micropinocytotic vesicular system (Duvall et al., 1971; Gorgas & Jahnke, 1974). By means of the vesicular system, transport of the tracer molecule horseradish peroxidase (HRP, mol. wt. 43 000, mol. diam 55 Å) is very rapid. As early as 1–2 min following HRP injection, Duvall et al. (1971) observed the HRP reaction product distributed through stria capillary basal lamina. In muscle, however, more than

5 min following HRP injection were required before Karnovsky (1967) found capillary basal lamina densely stained. Although transport of HRP in muscle capillaries was primarily by means of pinocytosis, intercellular cleft transport also occurred.

In contrast with other permeability studies, Osako & Hilding (1971) have reported that HRP is transported across strial capillaries by a route between endothelial cells and that micropinocytotic vesicles are absent within strial endothelia of both Ames Waltzer mice and normal Swiss strain mice.

Yamamoto & Nakai (1964) studied strial capillary transport in the Guinea pig using iron dextran. At no time point after injection (10 min to 72 h) was the tracer observed in capillary basal lamina, although membrane bound accumulations were frequently found within endothelia. While these authors determined the size of iron dextran to be 100 Å in diameter, others have shown that the diameter of this tracer ranges from 20–70 Å (Muir & Goldberg, 1961; Richter, 1959). Molecules this size should be transported across strial endothelia if indeed the HRP results are sound. In fact, if one considers that the transport rate of HRP (mol. diam 55 Å) is more rapid through strial than muscle capillaries and that transport in both cases primarily involves pinocytosis, then it is difficult to account for the iron dextran results in light of the successful transport of molecules as large as ferritin (mol. diam 110 Å) across muscle endothelia (Bruns & Palade, 1968). Clearly, the literature on strial capillary permeability is in conflict.

It should be noted that the use of HRP as a tracer to study strial capillary permeability has certain drawbacks. For example, the enzyme HRP was noted by Duvall et al. (1971) to cause strial capillary alterations, consisting of intraluminal protrusions of endothelial cell membranes and pores within capillary walls. Cell protrusions have been known to occur in injured cells (Trump & Arstila, 1974). The artifactual production of pores in strial capillaries could have resulted in the release of HRP

to the basal lamina. Such changes do not occur in adjacent spiral ligament vessels, where no HRP exists. Whether strial capillary alteration is a manifestation of HRP toxicity to select portions of the inner ear is not clear; however, it has been found that perilymphatic perfusion of HRP in vivo is acutely ototoxic (Ross et al., 1977).

Other problems of HRP use include: (1) the enzyme must retain its catalytic activity until and throughout incubation; (2) quantitative analysis of transported tracer substance cannot be performed since a) the HRP itself is not directly visualized and b) the quantity and quality of the reaction product is dependent upon the quality of both the enzyme preparation and incubation medium, the penetration of the medium into the tissue and the duration of the incubation; (3) histamine, which affects vessel permeability and strial capillary blood flow, is released in some species in response to HRP injection; (4) an endogenous peroxidase reaction exists which may interfere with the interpretation of experimental findings.

These problems are especially troublesome when evaluating capillary permeability changes in experimentally induced pathologies. For example, Duvall et al. (1974) used the tracer substance HRP to evaluate strial capillary permeability after intense noise exposure. They suggested that some of their unusual experimental results may have been due to the degradation of the protein HRP by lysosomal enzymes. Of course, if HRP is inactivated by lysosomal hydrolases, then the electron dense HRP reaction product, which indicates the presence of HRP, will not be produced. Therefore, the transport of the tracer cannot be determined.

Certainly, then, HRP and similar enzymatic tracers pose serious problems when used as a means to gage strial capillary transport during pathologic as well as normal conditions. A reliable method of evaluating the function of strial capillaries without the limitations imposed by the use of an enzymatic tracer would be beneficial.

Table I. Number of mice per experimental condition

Tracer	Post injection sacrifice time (h)				
	1/2	1	2	5	24
Ferritin	6	4	3	4	7
Iron dextran	2	2	2	2	2

Many non-enzymatic, electron-opaque tracers have been used to study capillary transport at the ultrastructural level. In particular, ferritin has been successfully used to delineate certain aspects of transendothelial exchange in a variety of tissues (Farquhar et al., 1961; Bruns & Palade, 1968; Clementi & Palade, 1969). There are many reasons why ferritin may be considered an ideal tracer (Bruns & Palade, 1968) especially for strial capillaries. They include: (1) ferritin (mol. wt. 460 000; mol. diam 110 Å) is the size required for a probe molecule of the large pore transport system, which is reportedly the only system in strial capillaries; (2) it is a biological substance, similar in nature and in size to most plasma proteins; (3) high blood concentrations are well tolerated by experimental animals; (4) individual molecules can be identified within ultrathin sections and therefore a direct measure of transport is possible; (5) ferritin is resistant to lysosomal hydrolases (Drysdale & Munro, 1966; Coffey & DeDuve, 1968) and therefore may be useful in pathologic conditions.

The advantage which the electron opaque tracer molecule ferritin may provide over enzymatic tracers warranted its evaluation. In addition, because the iron dextran results reported by Yamamoto & Nakai (1964) are in conflict with other strial capillary permeability studies, a reevaluation was judged necessary. Therefore, it was the purpose of this study to evaluate strial capillary permeability with the electron-opaque tracer molecules ferritin and iron dextran.

MATERIALS AND METHODS

Tracer substances

Iron dextran (Imferon, Lakeside Labs, Milwaukee, Wis.) was dispersed in physiological saline with 0.5% phenol as a preservative, and contained the equivalent of 50 mg elemental iron per ml.

A 10 ml stock solution of 100 mg of cadmium crystallized ferritin per ml of physiological saline was obtained (Nutritional Biochemicals, Cleveland, Ohio). To remove the cadmium, the solution was dialysed against 3.7% ethylenediamine tetraacetic acid (EDTA) in 0.2 M phosphate buffer, pH 7.0, at 0–4°C for two changes (48 h each). Following two additional changes in buffer alone (24 h each), the ferritin solution was dialysed against physiological saline (24 h) and then passed through a 0.45 micrometer millipore filter into a sterile 10 ml injection vial.

Animals

Young adult male mice, BALB c/J (Jackson Labs, Bar Harbor, Maine) ranging in weight from 15 to 20 g and showing positive Preyer reflexes to finger snaps were used. The animals were screened for middle ear infection by direct examination during temporal bone removal.

Methods

All animals received subcutaneous injections of sodium pentobarbital 2 mg/20 g body weight, prior to injection of tracer. Anesthesia was reached within 15 min, and lasted for 2–3 h for those animals allowed to recover. Under anesthesia, either the jugular vein or the inferior vena cava was exposed and was injected with 1 ml per 100 g body weight of ferritin or iron dextran solution. The injection was delivered through a 30 gauge needle over a period of 1–2 min. Animals were sacrificed by decapitation 1/2, 1, 2, 5, or 24 h after injection. Twelve control animals received anesthetic injection only and were sacrificed immediately after induction. The number of

animals per experimental condition is noted in Table 1.

Cochleae were fixed either in 1% osmium tetroxide or 2% glutaraldehyde in 0.2 M Cacodylate buffer, pH 7.4. Within 1 min after decapitation, the right temporal bone of each animal was excised, fractured open and immersed in about 5 ml of primary fixative. After 2 h of primary fixation at 0–4°C, all cochleae were briefly washed in buffer. Those ears fixed in glutaraldehyde were then osmicated for an additional 2 h. However, from each cochlea of those animals injected with iron dextran, pieces of stria were removed while in buffer and were not osmicated. At the completion of osmication, the specimens were again briefly washed in buffer. In ferritin injected animals, specimens were selected from basal, mid and apical portions of the cochlear duct. After the striae were microdissected free from the cochleae in 70% acetone, dehydration was completed in graded acetone, and the tissue embedded in Epon at 60°C for 24 h.

Ultra-thin sections were cut on glass and diamond knives using either the Sorvall MT 1 ultramicrotome or an LKB Ultratome. Section interference colors ranged around silver. Sections were picked up on copper grids and most were examined unstained so that electron dense tracer particles could be unequivocally identified. Some sections were stained with lead citrate (Reynolds, 1963). Contrast was significantly enhanced by the use of projector field diaphragms with the Zeiss 9S-2 EM.

RESULTS

Those animals allowed to recover from anaesthesia had positive Preyer reflexes. None of the experimental ears showed evidence of middle ear infection upon direct examination using a dissecting microscope.

The ultrastructural appearance of the stria vascularis was typical of the fixation procedure employed (Merck et al., 1974; Santos-Sacchi, 1978*a* and *b*). One noteworthy difference between the two fixation procedures

was the decreased concentration of tracer particles within capillary lumina in primary osmium fixed specimens as compared to primary glutaraldehyde fixed tissues.

Iron dextran

The plasma concentration of iron dextran decreased over time. In the 1/2 h specimens, capillaries were observed which contained iron dextran only within endothelial pinocytotic vesicles (Fig. 1). However, more frequently, and in all animals beyond 1/2 h up to 5 h, the iron dextran appeared free as well as in vesicles within the cytoplasm of endothelia (Figs. 2 and 3). In fact, the tracer was occasionally observed within the nucleoplasm of some endothelia. By 24 h after injection, however, the iron dextran was absent from endothelia (Fig. 4). The passage of the tracer to the basal lamina was found to be almost nil, since rarely were any electron dense particles found in the basal lamina at any time point after injection. No tracer was observed within stria cells.

Ferritin

The appearance of ferritin within various spaces of the tissues studied was indicative of its passage from the circulatory system into the stria vascularis. The results are reported in terms of compartments within which ferritin was observed.

Capillary lumen

From 1/2 to 24 h following injection, ferritin was present within the capillary lumina of the stria in all areas studied. However, the concentration of ferritin within the blood plasma varied with time. By 24 h after ferritin administration the plasma concentration was considerably lower than its initial level. Ferritin was never present within capillary lumina of control animals.

Endothelial tunic

From the earliest to the latest time points after administration, ferritin labeled pinocytotic

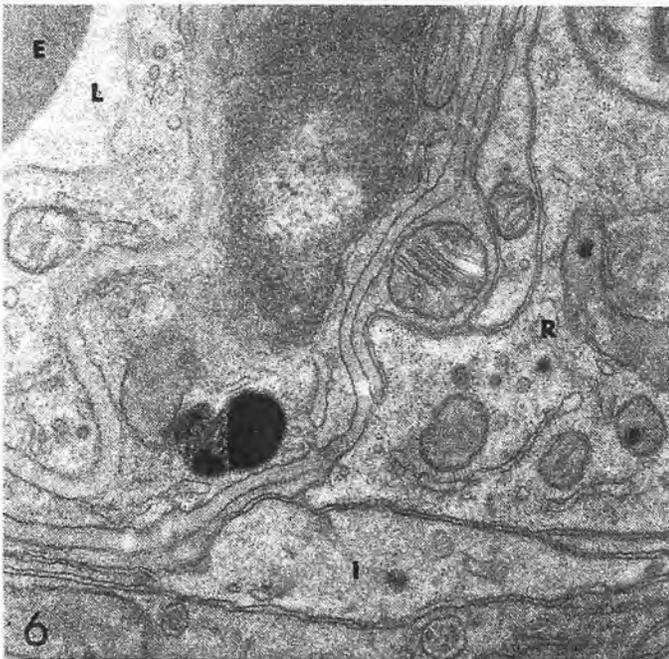

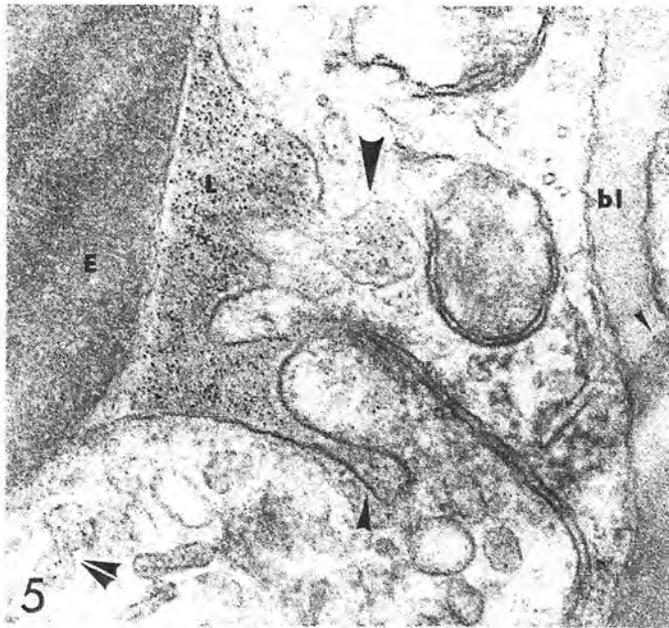

Fig. 5. Large arrow indicates open-mouthed vacuole containing large amount of ferritin on luminal front. Medium arrow indicates luminal tubular invagination containing ferritin. Double arrow indicates fusion of two labeled pinocytotic vesicles. Ferritin molecule can be seen in basal lamina (small arrow). $\frac{1}{2}$ h post injection. Glutaraldehyde and osmium fixed. Unstained. Mid portion of cochlear duct. $\times 90\,025$.

Fig. 6. Control animal (uninjected) showing light cell (R) with abundant supply of endogenous ferritin-like granules. Osmium fixed. Unstained. $\times 39\,600$.

vesicles were observed within endothelial cells (Figs. 5, 7, 8 and 9). Labeling of any pinocytotic vesicles was limited to no more than a few molecules of ferritin. In any section, the number of such labeled vesicles per endo-

thelial cell varied from none to a few, with no discernible relation to time after injection or area of cochlear duct. At times, the number of unlabeled vesicles was great. Although endothelial vesicles opening to the tissue front were

often empty, on occasion ferritin could be visualized within the basal lamina either just in front of the opening or not far away (Fig. 9). Nevertheless, there were direct observations of ferritin within vesicles opened upon the luminal and tissue fronts (Figs. 7, 8 and 9), as well as in those within the endothelial cytoplasm. Labeled vesicles within the endothelial cytoplasm were encountered more frequently. It cannot be ruled out that ferritin within open-mouthed vesicles diffused out during fixation.

Another occasional phenomenon was the appearance of tubular invaginations from luminal and tissue surface membranes of endothelial cells (Fig. 5). These structures were only encountered in thick portions of endothelia. Ferritin was found within some luminal invaginations, but direct connections from luminal to tissue fronts were never observed.

There appeared to be a relation between the time after injection and the accumulation of ferritin within vacuoles of endothelia. At the earlier time points, vacuoles containing ferritin in fairly large amounts were occasionally observed (Fig. 8). Rarely large vesicles with high concentrations of ferritin were seen open to the plasma front as if in the process of loading (Fig. 5). With increasing time, larger and denser cytoplasmic vacuoles were noted within which individual ferritin granules could be observed (Fig. 11). Pinocytotic vesicles labeled with ferritin were seen fused with large ferritin containing vacuoles (Fig. 8) or with each other (Fig. 5). Multi-vesicular bodies were also seen, that is, single membrane vacuoles within which were found labeled as well as unlabeled pinocytotic-like vesicles (Fig. 10).

Ferritin was neither seen in pinocytotic or other structures within endothelia of control animals, nor was it observed free in the endothelial cytoplasm of experimental or control animals.

Basal lamina and intercellular spaces

The basal lamina was not heavily infiltrated with ferritin molecules at any time point after

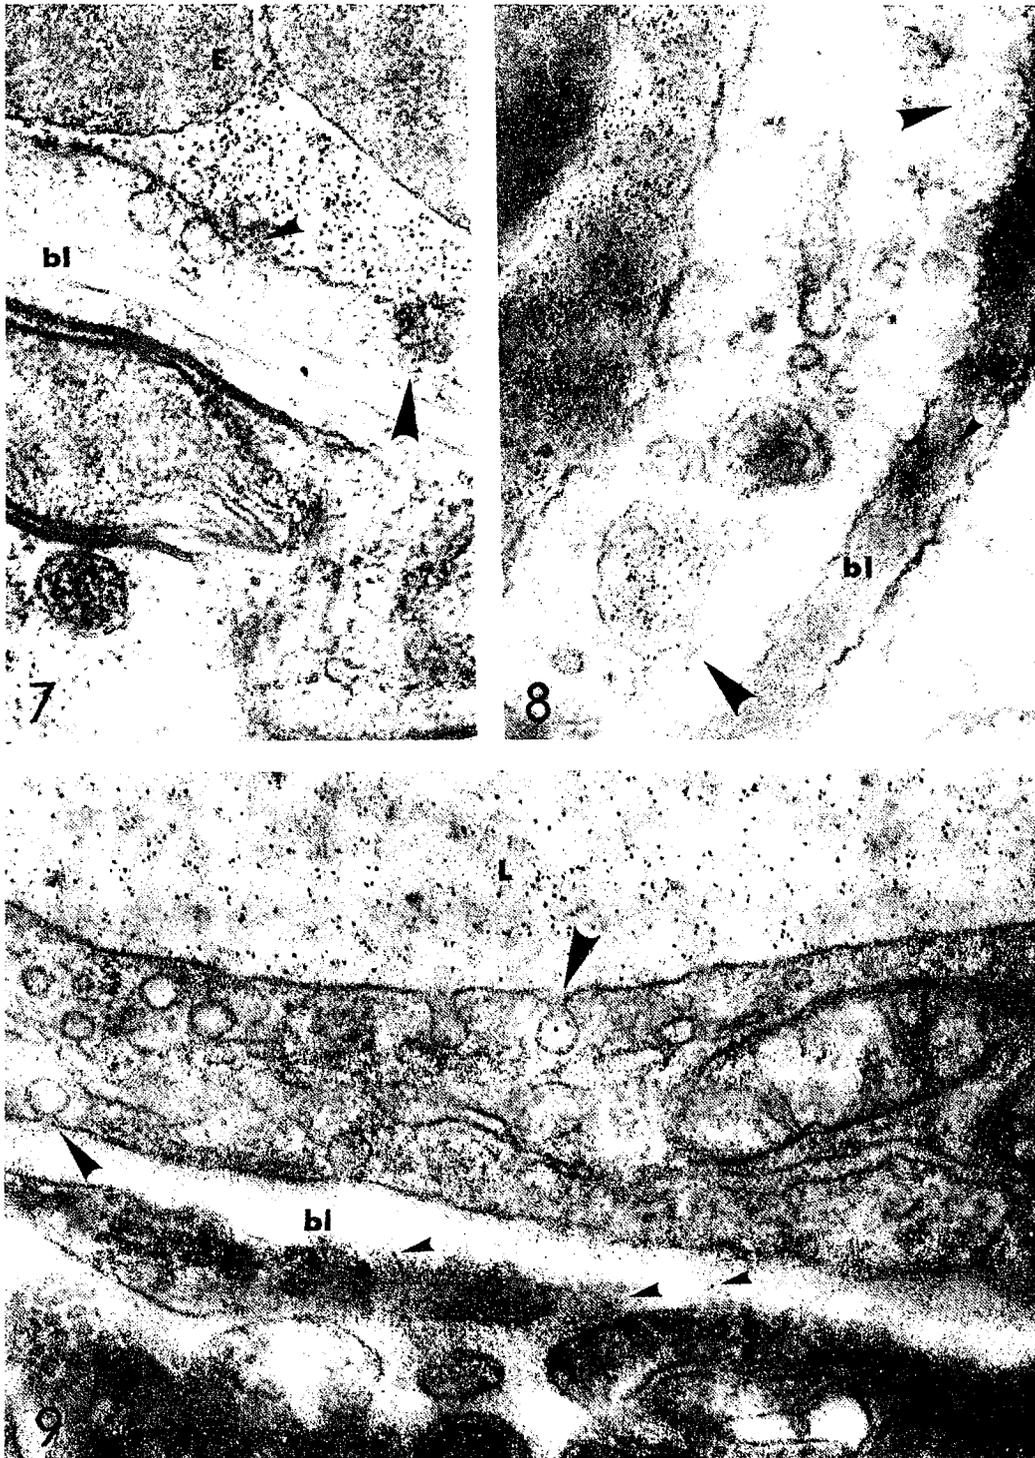

injection. In the earlier specimens observed, molecules were either absent, or present at extremely low concentrations, singly scattered about the perimeter of the capillary (Figs. 5 and 8). No accumulation of ferritin within the basal lamina at particular points around the capillary was noted, save one instance. This occurred in a capillary of an animal sacrificed 1/2 h after injection (Fig. 12). An apparent leak within a discrete portion of a single capillary allowed a relatively large quantity of ferritin to escape into the basal lamina. This was the only occurrence of this kind in all specimens studied, and adjacent strial capillaries within the same section did not exhibit this profuse transendothelial passage of ferritin. This phenomenon was clearly not typical of normal strial capillary function.

In the 5 and 24 h specimens, accumulation of ferritin appeared slightly greater around some capillaries than in earlier specimens. However this was not the rule since other capillaries at the same time periods showed little or no ferritin present within the basal lamina. The overall picture revealed that ferritin labeling of the basal lamina was variable at all time points studied and that labeling even at its greatest was scant.

Fig. 7. Large arrow indicates numerous labeled pinocytotic vesicles within endothelium. Smaller arrow indicates open-mouthed vesicle upon luminal front which appears to have ferritin molecules within neck portion of vesicle. 1 h post injection. Osmium fixed. Stained with lead citrate. Mid portion of cochlear duct. $\times 92\,325$.

Fig. 8. Note numerous open-mouthed pinocytotic vesicles upon tissue front. Medium arrow indicates a ferritin labeled one. A ferritin molecule can be seen in the basal lamina (small arrow). Within the endothelial cell a pinocytotic vesicle can be seen fused with a large vacuole containing numerous ferritin molecules (large arrow). 5 h post injection. Glutaraldehyde and osmium fixed. Unstained. Basal portion of cochlear duct. $\times 88\,635$.

Fig. 9. Large arrow indicates open-mouthed pinocytotic vesicle containing two ferritin molecules on luminal front. A ferritin molecule can be seen at the opening of a pinocytotic vesicle at the tissue front (medium arrow). Small arrows indicate ferritin molecules within basal lamina. 2 h after injection. Osmium fixed. Unstained. Mid portion of cochlear duct. $\times 92\,470$.

Ferritin molecules within the intercellular spaces of the stria vascularis were not observed, and presumably the size of the molecule limited its penetration into such spaces. Ferritin was not seen within the basal lamina of control animals.

Strial cells

Ferritin was not seen within the marginal cells. However, large accumulations of electron dense particles closely resembling ferritin in size and shape were often found in specific cell processes of light cells (Fig. 6). In fact, the particles within these cells and the injected ferritin molecules appeared indistinguishable. The particles were found in high concentration free in the cytoplasm often accompanied by lysosomes containing the same particles. This phenomenon was found throughout all time periods studied, and *in control animals as well*. Further description and analysis of these cells will be the subject of another report (Santos-Sacchi and Marowitz, in preparation). No pinocytotic uptake of injected ferritin by these light cells was seen, although light cells occasionally possessed open-mouthed vesicles on the basal lamina. Also, no spectacular accumulation of ferritin within vacuoles was ever observed in these cells. There were no apparent differences in cytoplasmic ferritin-like concentration between experimental and control animals.

DISCUSSION

Iron dextran

The iron dextran results were perplexing. Iron dextran was present within strial endothelial cytoplasm from 1/2 to at least 5 h, but was apparently absent by 24 h. This did not seem to be a fixation artifact. It was concluded that the tracer initially entered the endothelia by means of pinocytotic uptake, since in some 1/2 h specimens and in the endothelia of a control animal (killed immediately after injection) iron dextran was present within vesicles and

absent within the cytoplasmic matrix. The occurrence of iron dextran within the cytoplasmic matrix of endothelia is difficult to explain, since it is generally acknowledged that macromolecules have no route by which to enter the "membrane protected" cytoplasm. Although molecules the size of iron dextran are unable to pass through intact membranes, similar observations of free intracytoplasmic iron dextran following administration have been reported. Richter (1959), after injecting iron dextran intraperitoneally, studied the fate of that substance within liver and spleen. After 1 h he found accumulations of iron dextran within macrophages and sinusoidal endothelia of both organs. There were non-membrane bound aggregates of iron dextran within the cytoplasmic matrices, as well as numerous free particles. This is similar to the results of the present study. However, in Richter's study, by the fourth hour following injection, aggregates were enclosed by limiting membranes. Further, iron dextran was discernible within the cells up to 6 days after administration. In this regard, Richter's results differ from the present study, because iron dextran was absent from 24 h. However, it should be recalled that in the only previous study of iron dextran permeability in strial capillaries (Yamamoto & Nakai, 1964) the molecules remained within endothelia, reportedly within vacuoles, for 5 h, but by 24 h and beyond iron dextran was absent from endothelia. It seems that strial endothelia have an ability to remove or possibly metabolize iron dextran, so that by 24 h very little or none remains observable. Yamamoto and Nakai reported no transendothelial passage of iron dextran into the stria. Although this appears to be the case for the present study as well, the possibility exists that passage of some degraded form of the original molecule occurred which could not be visualized electronmicroscopically. Richter's experiment suggests that mouse cells may be able to metabolize the partially depolymerized dextran sufficiently to abolish the colloidal stability of the iron dextran preparation.

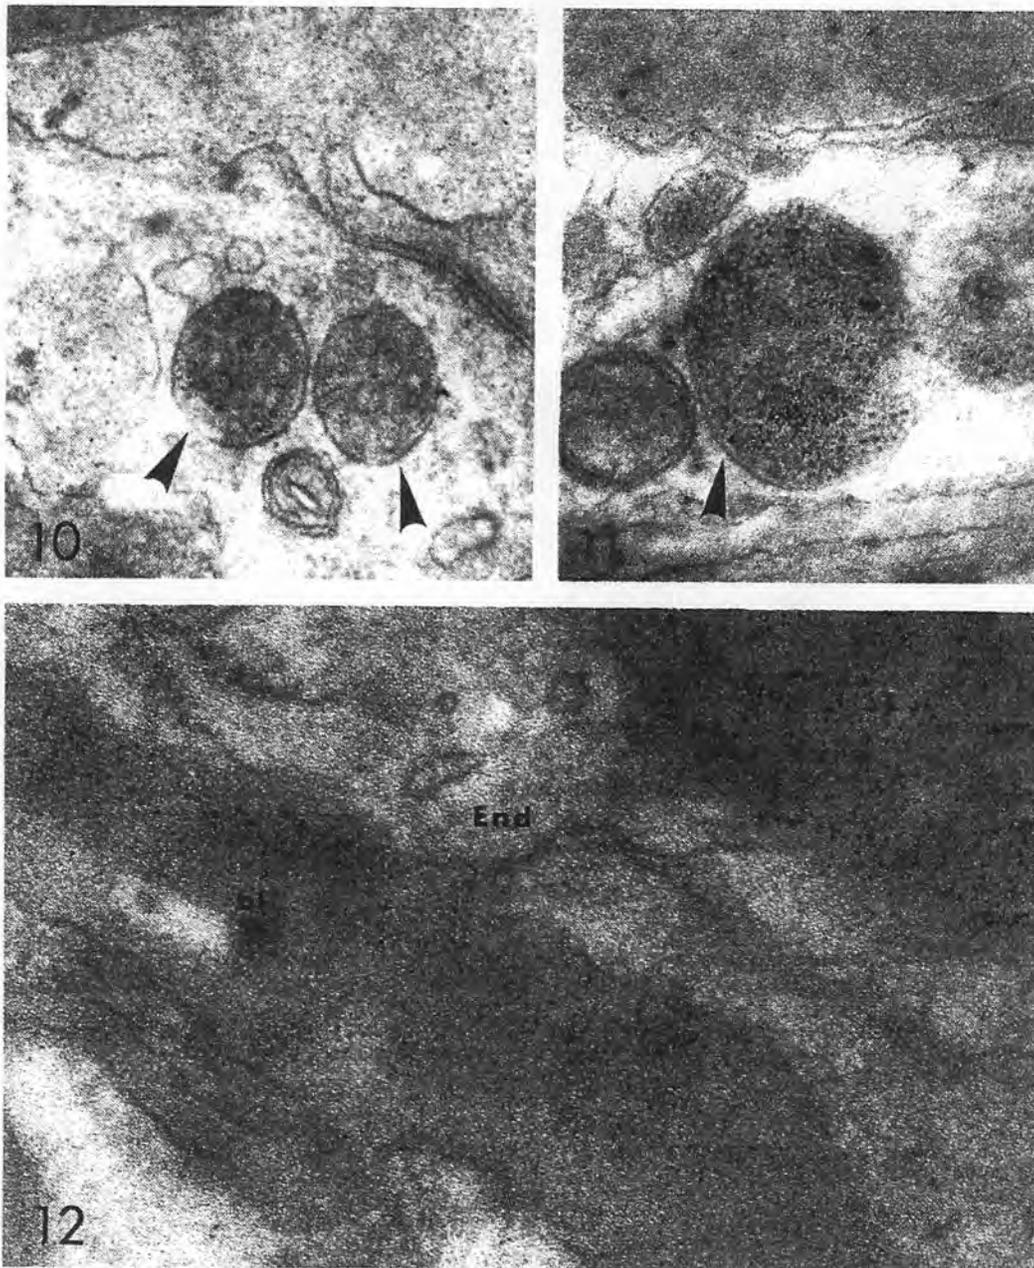

Fig. 10. Arrows indicate multivesicular bodies of labeled and unlabeled pinocytotic-like vesicles within endothelial cell. 24 h post injection. Glutaraldehyde and osmium fixed. Unstained. Apical portion of cochlear duct. $\times 85\,500$.

Fig. 11. Large lysosome containing ferritin within an endothelial cell (arrow). 5 h post injection. Glutaraldehyde and osmium fixed. Unstained. Basal portion of cochlear duct. $\times 88\,065$.

Fig. 12. Note large accumulation of ferritin within basal lamina. This was the only occurrence of its kind throughout all specimens. It is not typical of normal strial capillary transport, but highlights the possibility of such leakage. $\frac{1}{2}$ h post injection. Glutaraldehyde and osmium fixed. Unstained. Basal portion of cochlear duct. $\times 118\,000$.

Of course, diffuse iron in ionic form or bound in low concentrations to carrier substances cannot be seen (Muir & Goldberg, 1961).

Clearly then, the use of iron dextran as an electron opaque tracer molecule for strial capillary transport is obviated by the possibly unique treatment it receives by strial endothelia which apparently results in the intracytoplasmic sequestration and eventual removal of iron dextran.

Ferritin

Although ferritin transport across strial capillaries had not been evaluated prior to the present study, HRP transport had been examined. The transport of the enzyme through strial vessels is very rapid. Within a few min after HRP injection, the basal lamina and intercellular spaces are densely stained with reaction product (Duvall et al., 1971; Winther, 1971). These results are more similar to those obtained with muscle capillaries than to those obtained with CNS capillaries, except that intercellular cleft transport of HRP is reportedly absent in strial capillaries. However, the results of the present study, which suggest minimal capillary transport, indicate that the permeability function of the strial capillaries is more similar to that of the CNS vessels. Thus, even by 24 h post injection, transport of ferritin across endothelia is scanty as determined by basal lamina labeling. Although transport of lipid insoluble substances certainly increases as molecular weight decreases, the evidence evaluated by Renkin (1964) suggests that transport rates of molecules in excess of about 60 000 Daltons remains constant. If the micro-pinocytotic transport system is the sole means of transendothelial passage of lipid-insoluble material within the stria, then the passage of HRP (whose molecular weight is close to Renkin's cut off size) should not be drastically different from that of ferritin. This may especially be true if, as some researchers believe (Balint & Nagy, 1971), HRP binds to B-globulin and IgG within plasma, thereby increasing

the particle size and bringing it closer to the size of ferritin. Thus by size comparison it is difficult to explain the similarity of HRP results and the dissimilarity of ferritin results between strial and muscle capillaries. Certainly, the very small number of labeled strial capillary pinocytotic vesicles could account for the smaller amount of ferritin transport in strial as compared to muscle capillaries. Moreover, the dissimilarity of transport suggests that some other factor may play an important role in the rapid transport of HRP across strial endothelia. It is here that the established ototoxicity of HRP may come to bear (Ross et al., 1977). Perhaps the transport of HRP is rapid in strial capillaries because the HRP *itself* alters strial capillary permeability. Such a hypothesis would explain the similarity of HRP results in muscle and strial capillaries, and would not conflict with the ferritin results.

Research on the permeability of continuous type capillaries in other tissues also leads to the conclusion that the strial HRP results are unusual, i.e. in the light of this study's findings with ferritin. Raviola & Karnovsky (1972) evaluated thymic capillary transport using a variety of enzymatic tracers, including HRP. They also used the tracer molecule ferritin, so that it is possible to compare the permeabilities of both HRP and ferritin in the same capillary system. One must note however that the thymus contains both continuous and fenestrated capillaries. For the present purpose, only the continuous capillaries' permeability functions are of significance, since these capillaries, are structurally comparable to strial capillaries. Interestingly, these continuous capillaries, located within the cortical areas of the thymus, present a blood-thymic barrier. As in the stria and CNS, circumferential tight junctions halt extravascular leakage through endothelial intercellular clefts. At all time periods, from 1–24 h after ferritin injection, minimal amounts of the electron opaque tracer had traversed the thymic capillary endothelia. Labeling of pinocytotic vesicles was variable, but represented a very

small fraction of the whole vesicle population. Within the basal lamina only isolated or small groups of 2-3 ferritin molecules were scattered along the circumference of the capillaries. These findings are surprisingly similar to those of the present study. However, despite the similarities in capillary structure and ferritin transport, the transendothelial passage of HRP is vastly different between strial and cortical thymic capillaries. Raviola and Karnovsky (1972) demonstrated that the amount of HRP transport across cortical thymic capillaries is comparable to that of ferritin. That is, from 2-20 min post injection only limited vesicular transport of the enzymatic tracer occurred through endothelia; vascular adventitia was free of peroxidase reaction product. Apparently then, the transport of both ferritin and HRP is similar for a given capillary bed, provided that the micropinocytotic transport system is the sole means of transendothelial passage. The similar transport characteristics of HRP and ferritin agree well with the conclusions of Renkin (1964).

Another blood-tissue barrier has been reported which is similar to the thymic one (Gershon & Bursztajn, 1978). The myenteric plexus is supplied with continuous-type capillaries. Using HRP, Gershon & Bursztajn (1978) demonstrated minimal transport of the tracer, presumably by the pinocytotic pathway, since intercellular cleft transport was impossible due to tight junctional seals. Extravascular accumulation of the HRP reaction product in the myenteric plexus was undetectable, as Raviola and Karnovsky reported for cortical thymic tissue. However, in both tissues—thymus and myenteric plexus—it was concluded that some transport has occurred because perivascular phagocytes contained vacuolated tracer substance.

In the present study, the ferritin results appear to indicate the existence of a blood-strial barrier which is closer in nature to the blood-thymic and blood-myenteric plexus barriers than to the blood-brain barrier.

Another phenomenon which might account

for the observed minimal transport of ferritin across strial capillaries is the phagocytotic activity of strial endothelial cells. Within these cells were observed large vacuoles and multivesicular bodies containing ferritin similar to those reported by Raviola & Karnovsky (1972). Apparently, one means of such vacuole formation was by pinocytotic vesicular fusion, since with increasing time, larger and denser ferritin containing bodies (presumably lysosomes) were present. It appeared that once ferritin conglomerates formed, the ferritin was immobilized within endothelia until degraded. In essence then, the phagocytotic activities of strial endothelia in conjunction with minimal pinocytotic transport and endothelial tight junctions contribute to the formation of a blood-strial barrier at least for molecules the size of ferritin.

Previous studies have suggested that intermediate cells may serve as macrophages within the stria. Such cells have been found to have open-mouthed pinocytotic vesicles and intracytoplasmic vacuoles labeled with HRP reaction product after a sufficient interval of time following HRP administration (Duvall et al., 1971; Winther, 1971). Also at the light microscopic level, Nomura (1961) found that intravenously injected trypan blue was phagocytized by certain strial cells scattered about the capillaries. Similarly, transported tracer substances within cortical thymic and myenteric plexus blood-tissue barrier systems were incorporated within perivascular phagocytic cells (Raviola & Karnovsky, 1972; Gershon & Bursztajn, 1978). The possibility exists that in this study some ferritin-like particles within the light cells of experimental animals may be exogenous ferritin; that is, perhaps the cytoplasm of these cells serves as a sink for transported exogenous ferritin. However, the fact that such particles were located, for the most part, free within the light cell cytoplasmic matrix argues against an exogenous source, since macromolecules of this size are not able to enter free cytoplasm. Further, it should be noted that there were no obvious differences

between control and experimental animals in regard to concentration of intracytoplasmic ferritin-like particles. Nevertheless within the cytoplasm of liver cells there is *de novo* apoferritin production within a few h following administration; subsequently, iron sequestration by apoferritin occurs, producing ferritin (Drysdale & Munro, 1966). In the present study, since the injected tracer contains iron, the *de novo* production of endogenous ferritin by experimental strial light cells might occur if indeed they phagocytized transported exogenous ferritin. The problem is made more difficult because the horse spleen ferritin tracer is very resistant to lysosomal breakdown (Coffey & DeDuve, 1968). Thus, although ferritin may accumulate within lysosomes, elemental iron may not be able to enter the cytoplasm because of the hydrolytic resistance of the protein. On the other hand, there is some evidence that the iron may enter and leave the apoferritin shell without protein disintegration (Mazur & Carleton, 1963). In this regard, it is noteworthy that in other permeability studies using ferritin as a tracer (Bruns & Palade, 1968; Raviola & Karnovsky, 1972), after 24 h, perivascular macrophages did exhibit intracytoplasmic ferritin granules. Presumably, they were endogenously produced, after the phagocytes accumulated the ferritin tracer within lysosomes. In the present study, since numerous lysosomes containing ferritin were found in control animals, a normal turnover mechanism may be deduced. However, it cannot be totally dismissed that the select light cells in experimental animals also contain exogenously injected ferritin within lysosomes. Finally, it should be noted that although light cells often exhibited open-mouthed vesicles upon the basal lamina, no ferritin labeling of these vesicles in experimental animals was found. Certainly, the scanty accumulation of ferritin within the basal lamina offered little probability of finding ferritin within such open-mouthed vesicles.

The central nervous system of mammals appears to require an unusually stable internal

environment in order to function effectively (Katzman, 1972). Clearly, the blood-brain barrier affords such an environment. In a like manner, thymic and myenteric plexus blood-tissue barriers serve their own physiologic purposes. The finding that the transport of ferritin across strial endothelia is scanty may indicate that the internal milieu of the stria must be carefully regulated. The probable existence of strial phagocytic cells may also be important in this regard. Normal strial function may very well depend upon an intact blood-strial barrier.

The ferritin labeling technique used in this study of normal animals may be useful in determining altered strial capillary transport possibly associated with various auditory pathologies. It is known that under pathologic conditions of inflammation, extravascular leakage of high protein content fluid occurs (Florey, 1964). Indeed, this is known to occur in brain tissue, and involve a breakdown of the blood-brain barrier (Katzman, 1972). Certainly, under some deleterious influences, strial tissue becomes edematous, e.g. in response to ethacrynic acid or noise exposure. In the present study, only one instance of abundant ferritin accumulation within the basal lamina was observed. Since adjacent capillaries within the same section, and all other capillaries did not exhibit such abundant transport, the phenomenon was judged atypical of strial capillary transport. However, this occurrence indicates that the tracer molecule ferritin may be useful in determining altered strial transport. Ferritin is highly resistant to lysosomal hydrolases (Coffey & DeDuve, 1968). Therefore, if large amounts did traverse the endothelial tunic they would no doubt be detected within some "compartment" of strial tissue, assuming, of course, that the tight junctional seal delimiting the stria vascularis remains intact. However, the possibility of light cell incorporation of exogenous tracer, and the difficulty in differentiating between endogenous and exogenous electron dense particles should be kept cognizant.

ZUSAMMENFASSUNG

Enzymatische Tracermethoden für die Erforschung normales und pathologisches Kapillartransports der Stria stellen verschiedene Probleme vor. Die Verwendung opaker Elektronentracer kann viele von diesen Problemen verhüten. Eisendextran (mol. Dm. 20–70 Å) und Ferritin (mol. Dm. 110 Å) wurden intravenös eingespritzt, und die Mäuse wurden nach Zwischenzeiten von $\frac{1}{2}$, 1, 2, 5 und 24 Stunden geopfert. Die Eisendextran-Ergebnisse waren ungewöhnlich, weil der Tracer von $\frac{1}{2}$ bis 5 Stunden nach der Einspritzung in der zytoplasmatischen Matrize der Endothelen zugegen war, aber gegen die 24. Stunde war er ausgeräumt worden. Kein transendothelialer Austausch wurde bemerkt. Die Ferritin-Ergebnisse widersprachen vorhergehenden Ergebnissen, die Meerrettichperoxidase benutzten. Der Transport von Ferritin war ungeachtet der verstrichenen Zeit minimal. Nur ein paar Molekeln wurden um die Basalkapillarlamina bestreut. Die quer durch Kapillaren übergeführten Molekeln wurden anscheinend mittels des mikropinozytotischen Systems überbracht. Die Ergebnisse deuten eine Blut-Stria-Sperre an, die den Blut-Thymus- und Blut-Myenterus-Sperren ähnlich ist. Versuchs- sowie auch Kontrolltiere wiesen Lichtzellen der Stria auf, die Ferritin-ähnliche Partikeln in ihren zytoplasmatischen Matrizen enthielten. Diese Lichtzellen sind wahrscheinlich Zellen des reticuloendothelialen Types. Ferritin könnte nutzbar sein, um die auf Gehörpathologien bezogenen Änderungen des Kapillartransports der Stria abzuschätzen.

ACKNOWLEDGEMENTS

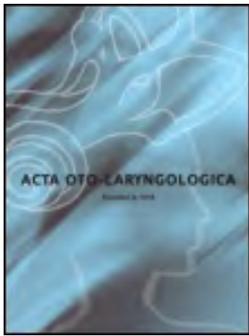

The authors wish to thank Prof. I. M. Ventry and Prof. O. R. Anderson, Teachers College, Columbia University, for their support of this work. Portions of this work were taken from the dissertation submitted by J. S.-S. in partial fulfillment of the requirements of the Ph.D. degree, Columbia University, 1978. This work was supported in part by a Grant-in-Aid of Research from Sigma Xi, The Scientific Research Society of North America and by a grant from the Deafness Research Foundation. Thanks to Celeste Conway for help in the preparation of this manuscript.

A Ferritin-containing Cell Type in the Stria Vascularis of the Mouse Inner Ear

J. SANTOS-SACCHI¹ and WILLIAM F. MAROVITZ²

From the ¹Department of Surgery, Section of Otolaryngology, UMDNJ-New Jersey Medical School and the ²Department of Anatomy and Otolaryngology, Mt. Sinai School of Medicine, City University of New York, New York, USA

Santos-Sacchi J, Marovitz W. F. A ferritin-containing cell type in the stria vascularis of the mouse inner ear. *Acta Otolaryngol (Stockh)* 1985; 100: 26-32.

This report describes a new cell type within the stria vascularis of the mouse inner ear. The cell is similar ultrastructurally to the classically described intermediate cell. However, it can be distinguished by the presence of dense vacuoles, presumably lysosomes, within which can be visualized electron dense particles resembling ferritin molecules. In addition, the ferritin-like particles are present throughout the cytoplasm and occasionally within the endoplasmic reticulum. These cells characteristically abut capillary basal lamina. Electron probe analysis of the dense vacuoles revealed the presence of iron. It is suggested that these cells may sequester iron released from dying erythrocytes in the strial capillary system, whereupon the iron is conserved through ferritin synthesis.

J. Santos-Sacchi, Department of Surgery, Section of Otolaryngology, UMDNJ-New Jersey Medical School, 100 Bergen St., Newark, NJ 07103, USA.

The stria vascularis, located on the lateral wall of the cochlear duct, is classically described as a three-cell layered tissue—marginal, intermediate, and basal (Smith, 1957). The marginal cell layer, which is ectodermal in origin, lines the lateral endolymphatic space and interdigitates laterally with the two other fibroblastic-like cell layers. The stria is important for normal cochlear function, and is unique in that capillaries (continuous type) maintain intimate contact with this epithelium; that is, in the adult there is no epithelial basal lamina. Various studies have noted the phagocytic activity of pericapillary strial light cells (Ruedi, 1951; Nomura, 1961; Duvall et al., 1971; Winther, 1971).

The monocyte-phagocyte system is considered crucial in iron metabolism (MacSween & MacDonald, 1969). The chief storage form of iron is ferritin, a protein which may be found in high concentrations in the cytoplasm of liver and spleen phagocytic cells. Intracellular iron storage as ferritin can be induced by the administration of exogenous iron compounds (Richter, 1959; Muir & Goldberg, 1961; Drysdale & Munro, 1966). Within hours of iron administration, ferritin molecules can be visualized electronmicroscopically within phagocytic cells which have incorporated the exogenous iron compound. Such induced phagocytic sequestration and ferritin synthesis mimics the normal mechanism of iron conservation. Considering the high capillary density and hematocrit of strial tissue, it might be expected that phagocytotic light cells would incorporate iron released from dying erythrocytes.

Recently, in a report on strial capillary permeability, we commented on the presence of a strial cell type which contains endogenous intracytoplasmic ferritin-like granules (Santos-Sacchi & Marovitz, 1980). This report presents a detailed analysis of these cells.

METHODS

Twelve young adult male mice, BALB/cJ (Jackson Labs, Barr Harbor, Maine) showing positive preyer reflexes were killed by decapitation. Within one minute of death, the right

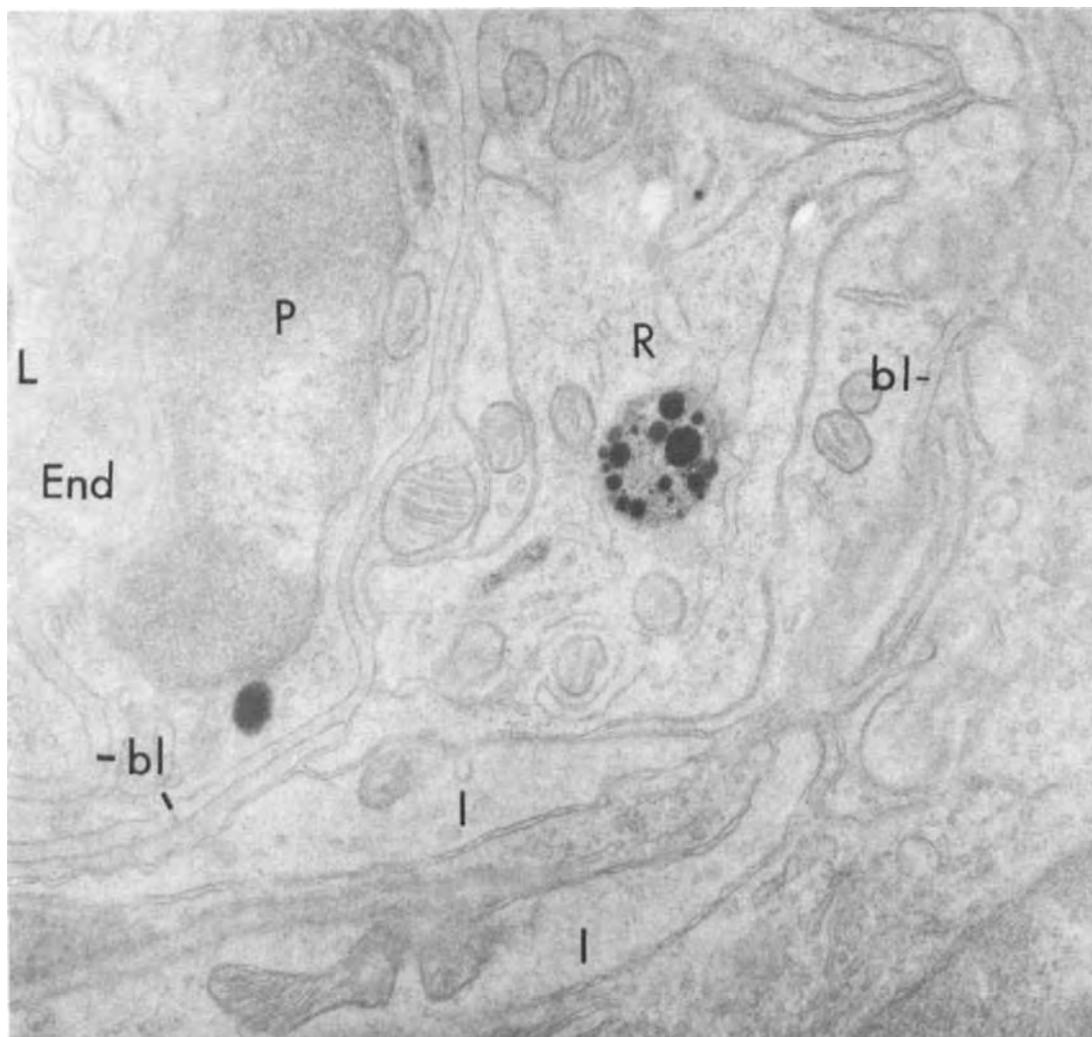

Fig. 1. Light cell abutting basal lamina near strial capillary. Note abundant supply of intracytoplasmic electron-dense granules and dense cored lysosomes. Adjacent intermediate cells lack granules. Unstained. $\times 30\,500$. *L*, capillary lumen; *End*, endothelial cell; *P*, pericyte; *I*, intermediate cell; *bl*, basal lamina; *R*, ferritin-containing cell; *M*, marginal cell; *Ly*, lysosome; *ER*, endoplasmic reticulum.

temporal bone was excised, fractured open and immersed in a primary fixative of either 2% glutaraldehyde or 1% osmium tetroxide, buffered with 0.2 M cacodylate, pH 7.4 (4°C for two hours). After a brief rinse in 0.2 M cacodylate buffer, those cochleas fixed in glutaraldehyde were post-fixed with osmium. The cochleas were again washed in buffer and dehydrated in a graded series of acetone. While in 70% acetone the striae were microdissected from surrounding tissue and after dehydration was complete, embedded in Epon 812 at 60°C. Grey-silver sections (50–80 nm) were cut with an LKB Ultratome, picked up on copper grids and examined with a Zeiss 9S-2 EM or Phillips 300 EM. Sections were examined unstained or lightly stained by lead citrate.

Because certain monocyte-phagocyte cells show endogenous peroxidase activity, this enzyme was assessed by the diaminobenzidine (DAB) technique, according to the modifi-

cation of Widmann et al. (1972). Electron probe elemental analyses were performed upon thin sectioned material using a JEOL JEM 100CX EM. Iron determinations were performed using a window of 6.190–6.550 KeV.

RESULTS

At low magnifications and in spite of the absence of normal staining the three known strial cell types were distinguished: marginal, intermediate and basal. However, at higher magnification, careful analysis of unstained strial tissues reveals the presence of ferritin-like particles within the cytoplasm of certain light cells (Figs. 1, 2, 3). At very high magnifications, the electron dense particles presented the characteristic appearance of ferritin (Fig. 3). The dimension of the electron dense ferritin core is slightly less than the thickness of the unit membrane, or approximately 50–60 Å.

These presumptive ferritin containing cells characteristically abut the basal lamina of strial capillaries, and possess electron dense vacuoles consistent with ferritin containing monocyte-phagocyte cells (Figs. 1, 2, 4). The electron density of these vacuoles is not dependent upon heavy metal staining as demonstrated in Fig. 4: tissues fixed only in glutaraldehyde and viewed with the electronmicroscope possess electron opaque va-

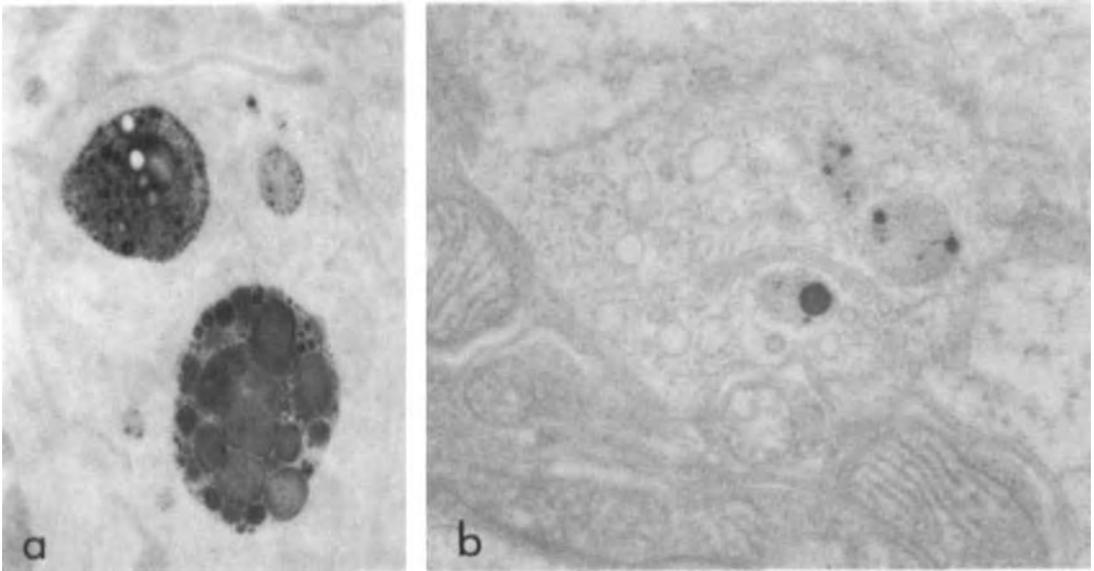

Fig. 4. (a) Note electron opacity of strial light cell vacuoles despite absence of postossification or heavy metal stains. Glutaraldehyde fixation only. $\times 17\,400$. cuoles. Electron probe elemental analysis of these vacuoles revealed iron in roughly equivalent concentration to that measured in a nearby erythrocyte, and significantly higher than in intermediate cell cytoplasm or Epon alone (Fig. 5). Interestingly, the chloride content of the lysosome and red cell was similar indicating a chloride shift within the lysosome.

Although ferritin granules are observed free within the cytoplasm as well as within certain membrane bound structures, i.e. endoplasmic reticulum and lysosomes (Figs. 1, 2, 4), they were never observed within mitochondria or nuclei. The cytoplasmic concentration of ferritin was variable; some cell processes exhibited sparsely scattered molecules while others, particularly when accompanied by lysosomes, contained an abundant supply. Except for the presence of ferritin, electron dense lysosomes and substantial amounts of membranous structures, including Golgi bodies, the ultrastructural detail of these cells is very similar to the typical intermediate cell. Strial capillary pericytes typically showed no accumulation of ferritin.

Light and electron microscopic cytochemical analysis of endogenous peroxidase activity within the stria vascularis failed to demonstrate reaction product within ferritin-containing cells. Strial capillary erythrocytes were the only structures which demonstrated positive staining with this technique.

DISCUSSION

Ferritin-containing strial light cells do not demonstrate endogenous peroxidase activity as do Kupffer cells (Widmann et al., 1972). However, species differences may be involved here. Whereas macrophagic cells in the rat and guinea pig are peroxidase positive (Fahimi et al., 1970; Widmann et al., 1972; Wisse, 1974), mature macrophages in the mouse are not (van Furth et al., 1970).

The stria's high capillary density and hematocrit provide an environment rich in iron.

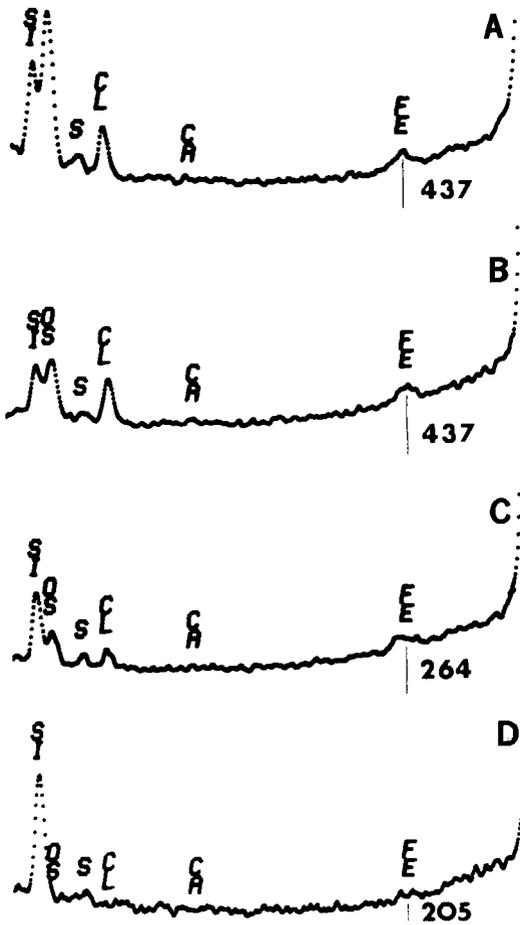

Fig. 5. Electron probe analyses of selected areas of a single thin section. Iron content measured with a window of 6.190–6550 KEV over a 658 sec period. (A) Dense core of light cell lysosome. Net count: 437. Also note high chloride content. (B) Adjacent red cell cytoplasm. Net count: 437. Note high chloride content. (c) Intermediate cell cytoplasm. Net count: 264. (d) Epon alone. Net count: 205. Silicon due to silicious probe element.

Possibly hemoglobin from dying erythrocytes is transported across strial capillaries and taken up preferentially by the light cells described herein. Lysosomal degradation coupled to ferritin synthesis would then ensue. The process of acquiring ferritin stores by this means would appear to be a slow one, considering the slow transendothelial passage of electron-dense tracers (Santos-Sacchi & Marovitz, 1980). This is confirmed by preliminary results which indicate the absence of intracellular light cell ferritin in the postnatal mouse.

Nomura (1961) demonstrated at the light microscopic level the uptake of trypan blue from guinea pig strial capillaries by sparsely scattered cells which rested near the capillaries. It was necessary for him to induce capillary leakage with intravenous injection of histamine and acetic acid. We have been unable to correlate the uptake of trypan blue and the presence of ferritin in mouse strial cells due to the inability to induce trypan blue extravascular leakage, even after acetic acid treatment. Horseradish peroxidase which has been shown to leak through strial capillaries has been demonstrated within pinocytotic and phagocytic vacuoles of strial intermediate cells (Duvall et al., 1971; Winther, 1971).¹

¹ Recently, Duvall (ARO Midwinter Meeting, 1981) reported that the HRP capillary transport in the normal preparation may have been due to dissection artifact. Thus the supposed phagocytic incorporation of HRP by light cells may actually have been staining of these cells by reaction product after the cells were killed by fixation.

However, these investigators suggest that the ability to phagocytize HRP is general among intermediate cells. Thus the ability to produce and store ferritin may be differentiated from simple phagocytotic functions, since only very few intermediate type cells exhibit detectable amounts of intracellular ferritin.

The storage of iron in the stria vascularis may have functional significance; e.g., it may be utilized by metalloenzymes within the stria or inner ear. Alternately, the storage may simply be a general response to high local levels of iron. Studies are planned to evaluate this issue.

Voltage-dependent changes in specific membrane capacitance caused by prestin, the outer hair cell lateral membrane motor

Received: 4 December 2001 / Revised: 23 January 2002 / Accepted: 23 January 2002 / Published online: 20 February 2002
© Springer-Verlag 2002

Abstract In the outer hair cell (OHC), membrane capacitance principally derives from two components – that associated with lateral membrane sensor/motor charge movement, and that proportional to the membrane surface area (C_{sa}). We used measures of membrane capacitance to test a model hypothesis that OHC lateral membrane molecular motors, recently identified as the protein prestin, fluctuate between two area states. By measuring membrane capacitance in native OHCs or prestin-transfected HEK cells at extreme voltages (± 200 mV) where motor-derived charge movement is small or absent, we observed that C_{sa} depends on the state of the motors, or correspondingly on membrane voltage. Deiters cells or control HEK cells, which lack motors, do not show this dependence. We modeled the voltage-dependent change in C_{sa} as a Boltzmann process with the same parameters that describe the charge movement of the motors' voltage sensors. C_{sa} is 3.28 ± 0.75 pF (mean \pm SD; $n=23$) larger during extreme hyperpolarization, and the number of motors in OHCs and prestin-transfected HEK cells correlates with the magnitude of ΔC_{sa} ($r=0.78$). Although these data are consistent with the area motor model, the corresponding area change, assuming $0.5 \mu\text{F}/\text{cm}^2$ under constant membrane thickness, is unphysiologically large, and indicates that the capacitance change must result from changes not only in lateral membrane area but also specific capacitance. Thus, we conclude that a conformational change in the lateral membrane motor, prestin, additionally alters the dielectric constant and/or thickness of the lateral plasma membrane.

Keywords Gating charge · Membrane capacitance · Motility

Introduction

The capacitance per unit area of plasma membrane, i.e., specific capacitance (C_{sp}), is determined by the membrane's dielectric constant and thickness. It is a robust quantity that Cole [5] described as “largely independent of cell physiology, pathology and pharmacology, and probably life itself”. Based on this property, the magnitude of an individual cell's membrane capacitance ($C_m = \text{surface area} \times C_{sp}$) may be considered fixed, invariant with changes in membrane voltage. In that same essay, however, Cole realized that his view could be modified by future investigations; it is now known that deviations from the expected invariant behavior provide information on such varied processes as ionic channel gating [10], synaptic vesicle fusion [29], gap junctional coupling [36], and, in the case of the outer hair cell (OHC), its lateral membrane motor's activity [2, 37]. In the OHC, such deviation arises from restricted charge movement during conformational change in a membrane motor protein [2, 37], the recently identified lateral membrane protein, prestin [26, 41, 48]. Consequently, membrane capacitance (C_m) in the OHC is characterized as a bell-shaped, voltage-dependent capacitance (C_v) that rides atop a parallel capacitance (C_{sa}) whose magnitude is proportional to cell surface area [2, 16, 37]. Peak motor-associated capacitance can range up to nearly twice that of the cell's C_{sa} [39].

One of the model mechanisms whereby the lateral membrane motor can effect whole-cell mechanical responses is by changing the surface area that it occupies within the lateral plasma membrane [17, 18, 38], although other models have been proposed [7, 14, 22, 33]. We reasoned that if the integral lateral membrane motors fluctuate in area between two states, as the model suggests, we should be able to observe whole-cell changes in C_{sa} due to changes in the cell's surface area. Indeed, one of the major criticisms of the area-motor model has been the apparent absence of effects on C_{sa} [33]. According to the model, depolarization, which is predicted to drive the motors into the compact state and reduce the

area occupied by them within the bilayer, should in turn reduce total membrane surface area and C_{sa} , whereas hyperpolarization should do the opposite. In order to test this prediction, we measured capacitance over an extreme voltage range in isolated OHCs and prestin-transfected human embryonic kidney cells under whole-cell voltage-clamp conditions. At extreme voltage polarities where motor-derived charge movement is small or absent, we find that C_{sa} depends on the state of the motors, or correspondingly on membrane voltage. During extreme hyperpolarization, when the motors cause the cylindrical OHC to elongate, C_{sa} is increased – a prediction of the area motor model of OHC motility [17, 18, 38]. Nevertheless, the predicted area change based on typical, fixed values of specific membrane capacitance is unphysiologically large, and must be accounted for by additional mechanisms such as membrane thinning or alterations in the membrane's dielectric properties.

Materials and methods

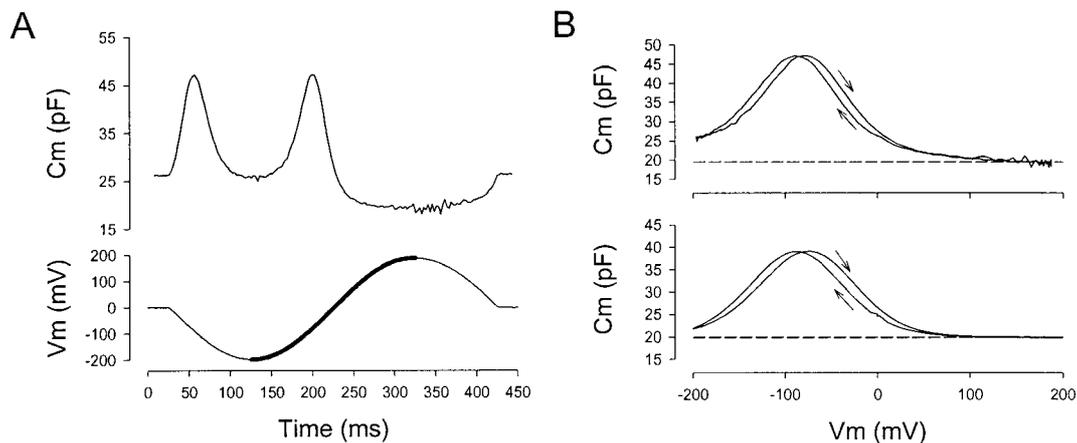

Guinea pigs were decapitated following anesthetic overdose with halothane, in accordance with the guidelines of Yale University's Animal Care and Use Committee. OHCs were freshly isolated from the guinea pig cochlea using dispase (1 mg/ml) followed by trituration. Transient transfection of human embryonic kidney (TSA201) cells with gerbil prestin was performed as previously described [48]. Co-expression of green fluorescent protein (GFP) provided visual identification of transfected cells. Only isolated, single HEK cells were studied. Cells were whole-cell voltage clamped at room temperature using an Axon 200B amplifier. Membrane voltages were corrected for the effects of residual series resistance, which ranged from 3–5 M Ω . Ionic blocking solutions were used with all cell types to remove voltage-dependent ionic conductances so that capacitive currents could be analyzed in isolation [37]. Extracellular solution: 100 mM NaCl, 20 mM TEA, 20 mM CsCl, 2 mM CoCl₂, 1.48 mM MgCl₂, 2 mM CaCl₂, 10 mM HEPES, and 5 mM dextrose, adjusted to pH 7.2 with NaOH, and adjusted to 300 mosmol/l with dextrose; in some cases CaCl₂ and MgCl₂ were omitted. Pipette solution: 140 mM CsCl, 10 mM EGTA, 2 mM MgCl₂, and 10 mM HEPES, adjusted to pH 7.2 with CsOH, and adjusted to 300 mosmol/l with dextrose. In some experiments, the extracellular solution was also used in patch electrodes. For experiments with 10 mM sodium salicylate, NaCl was reduced to maintain osmolarity. In a few experiments, 50 μ M GdCl₃ was included in the extracellular solution to decrease residual currents. At this concentration, gadolinium has an insignificant effect on OHC capacitance [21]. Capacitance was

measured with a continuous high-resolution (2.56 ms) two-sine voltage stimulus protocol (20 mV peak at both 390.6 and 781.2 Hz), and subsequent FFT-based admittance analysis [40], utilizing the parameter derivations provided by Pusch and Neher [32]. These small, high-frequency sinusoids were superimposed on voltage sinusoids that spanned ± 200 mV. OHCs that showed evidence of instability at the extremes were not included (see Results). All data collection and most analyses were performed with an in-house-developed Windows-based whole-cell voltage-clamp program, jClamp (SciSoft, CT), utilizing either an Axon Instruments Digidata 1320 board or a National Instruments PCI-6052E board. Matlab (Natick, Mass., USA) was used for fitting the capacitance data. Fits were made with the Nelder-Mead algorithm, and the minimization metric employed was $s = \sum \sqrt{(C_m - \text{fit})^2}$. In some cases, we used Sigmaplot (Jandel Scientific, California, USA) to fit model data, and determine standard errors.

Results

Under whole-cell voltage-clamp, OHCs do not tolerate extreme voltages that are abrupt in onset. We have only been able to record consistently from cells using a low-frequency sinusoidal stimulus whose range was limited to ± 200 mV (not including the superimposed high frequency two-sine stimuli – see Materials and methods). Whole-cell voltages more extreme than that usually resulted in loss of recordings. In a separate study we determined that breakdown in the membranes of the OHC oc-

Fig. 1A, B Outer hair cell (OHC) capacitance shows hysteresis and asymmetry at voltage polarity extremes. **A** Stimulation with a wide-ranging voltage sinusoid reveals a voltage-dependent capacitance. The highlighted portion of the voltage stimulus and associated capacitance are used in subsequent fits of the membrane capacitance (C_m) data as in Fig. 3. **B** *Top panel*: C_m versus voltage function from **A**. Note hysteresis. Direction of voltage change is shown by *arrows*. Additionally, note that the function is asymmetrical, with C_m at the hyperpolarized extreme never approaching the value of membrane surface area (C_{sa}) found at depolarized potentials. This is more rigorously shown in the fits of Fig. 3. *Dashed line* shows minimum capacitance at depolarized levels. *Lower panel*: model results using the wide-ranging voltage sinusoid (based on model fully described in Santos-Sacchi et al. [40]). *Dashed line* shows minimum capacitance at depolarized levels. The result indicates that the hysteresis is due to dependency on prior voltage, but the asymmetry is not, since model C_{sa} at hyperpolarized levels eventually reaches the same minimum magnitude as at depolarized levels

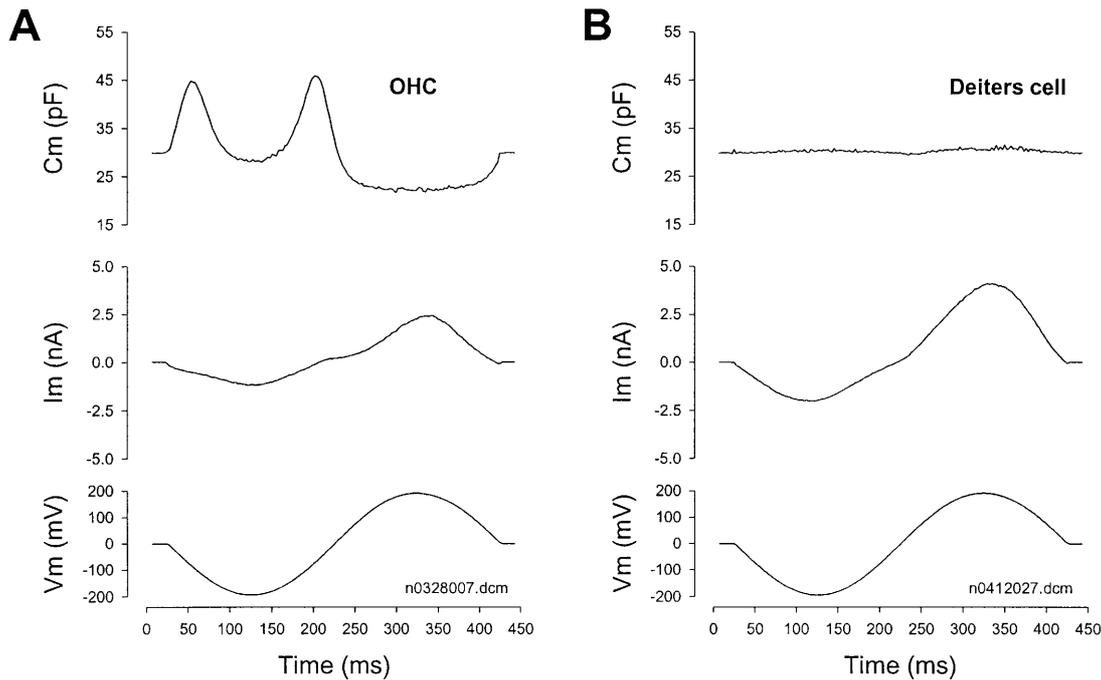

Fig. 2A, B Residual nonlinear current does not influence capacitance measures. **A** Residual nonlinear currents are evoked in the OHC despite our attempts to block membrane conductances. Note that this does not influence the measurement of capacitance, since similar though larger current nonlinearities generated in Deiters' cells (**B**) do not compromise the measurement of its voltage-independent capacitance

cur at absolute membrane potentials greater than 380 mV [27], far greater than the voltage extremes used here; thus, the loss of cells that we experienced with voltages above 200 mV under whole-cell conditions was probably due to compromised pipette-membrane seals resulting from robust mechanical activity of the OHC. We found that deflating the OHC by applying negative pipette pressure, which is known to abolish OHC motility [37], decreased the chances of loss. The results we report here were not affected by reducing OHC turgor pressure. Figure 1A illustrates the membrane capacitance changes that occur with our type of stimulation. During the hyperpolarizing phase of the stimulus, membrane capacitance presents as a double peaked response, and during the depolarizing phase a monophasic minimum is reached. A plot of membrane capacitance (C_m) versus membrane voltage (Fig. 1B, upper panel) shows the bell-shaped capacitance function characteristic of OHCs. However, in this case, two previously unobserved features are found. First, C_m shows hysteresis; namely, C_m magnitude depends on the prior voltage value and, thus, on the direction of voltage change. Second, the bell-shaped C_m function is asymmetrical, indicating that C_{sa} at extreme hyperpolarizations is larger than at extreme depolarizations. The hysteresis is fully predictable since it is known that there is a voltage-dependent shift in the capacitance function that is adequately modeled as a voltage-dependent, motor-induced change in membrane

tension [40, 41]. Membrane tension effectively shifts the capacitance function along the voltage axis [11, 17, 20, 47]. Fig. 1B (lower panel) shows the result of that model simulation using our extreme sinusoidal voltage stimulus. The hysteresis is similar to the biophysical data. However, whereas the model output indicates that hysteresis results from voltage-induced shifts in the C_v function, it cannot produce and therefore cannot account for the asymmetry in the C_m function. Additionally, the asymmetry was not related to the initial direction of voltage change, i.e., it did not matter whether the large sinusoid's phase was initially hyperpolarizing (as presented in the figures) or depolarizing. Rate of voltage change was also not influential, as sinusoids from 200 to 800 ms in duration produced the same asymmetry.

Despite the use of ionic blocking solutions, substantial currents are evoked by our extreme voltage protocol (Fig. 2). In order to assure ourselves that large currents or residual current nonlinearities did not confound our measurements, we compared OHC responses to those of supporting Deiters' cells, which lack membrane motors. In Fig. 2 we plot C_m , I_m , and V_m of a typical OHC and typical Deiters' cell. In each case, nonlinear currents are evidenced, notably larger in the Deiters' cell. Yet, Deiters' cells present a linear capacitance largely independent of variations in membrane voltage and current. These control experiments show that unblocked currents do not influence our capacitance measurements. Additionally, we have preliminary data [35] indicating that even in the presence of intracellular and extracellular solutions containing only large impermeant ions, where residual currents are less than 100 pA, capacitance remains asymmetrical. Furthermore, prestin-transfected HEK cells, which display small linear currents, show similar capacitance functions as OHCs (see below). Thus, residual currents and corresponding changes in membrane resistance can-

not account for our C_m data. We also ruled out potential increases of membrane surface area via incorporation of intracellular membrane by recording with high-BAPTA (10–20 mM) or pronase-containing (500 $\mu\text{g}/\text{ml}$) intracellular solutions, treatments known to block membrane fusion [16, 43]. Under these conditions C_{sa} asymmetry is still observed. As an additional check on our admittance technique, we used a standard stair step, transient analysis protocol to confirm the admittance measures within individual OHCs [16]. Although we were unable to provide such extreme voltages as the sinusoidal stimulus because of cell loss, capacitance values measured within the fairly wide range of -160 to 100 mV overlaid the admittance-based values (data not shown). We conclude that the asymmetry evidenced in the OHC C_m is real. This asymmetry is illustrated more rigorously through fits of the C_m data.

In order to gauge the asymmetry in our C_m data, we fit the data to the first derivative of a two-state Boltzmann function that has been used routinely to fit OHC C_m data [12, 17, 37].

$$C_m = C_v + C_{sa}$$

$$C_m = Q_{max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{sa}$$

$$b = \exp\left(\frac{-ze(V_m - V_{pkcm})}{kT}\right) \quad (1)$$

where C_v is the motor's voltage sensor-associated capacitance, C_{sa} is parallel capacitance proportional to membrane surface area, Q_{max} is the maximum nonlinear charge moved, V_{pkcm} is voltage at peak capacitance or half-maximal nonlinear charge transfer, V_m is membrane potential, z is valence, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. Figure 3A, B show, for two different cells, that this symmetrical function does not adequately describe our C_m data, although the equation had proven sufficient previously [12, 17, 37]. In those previous studies, voltage stimulation was substantially more restricted than employed here, typically not extending beyond ± 125 mV, and fits were understandably less constrained. In order to obtain a better understanding of our data, a modified equation was developed, where the state of lateral membrane motors contributes to the magnitude of C_{sa} . We reasoned that the contribution of a putative motor area change would be voltage dependent, and that the relationship should follow a sigmoidal two-state Boltzmann function identical to that of the sensor motor's nonlinear charge movement or the cell's mechanical response [37]. Depolarization, which drives the motor into its compact state, should decrease membrane surface area and C_{sa} . Thus, C_{sa} is described as a sigmoidal function

$$C_{sa} = \frac{\Delta C_{sa}}{(1+b^{-1})} + C_0 \quad (2)$$

where C_0 is defined as the capacitance of the membrane when all motors are in their compact state, the minimum

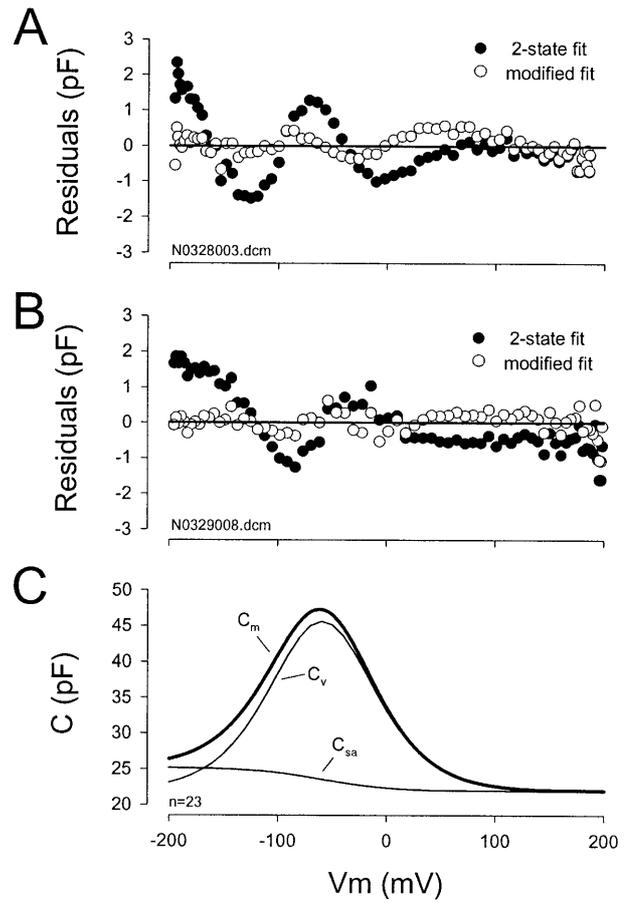

Fig. 3A–C OHCs present two types of voltage-dependent capacitance. **A, B** Plots show residuals of fits to capacitance of two OHCs as a function of membrane voltage. In each case, the C_m data were fit either with an equation based on a simple two-state Boltzmann function (*filled circles*, Eq. 1) or with an additional voltage-dependent C_{sa} component (*open circles*; modified by Eq. 2). Note the poor fit with the simple equation (**A**, *filled circles*: $s=8.11$ pF; **B**, *filled circles*: $s=8.62$ pF), and the good fit with the modified one (**A**, *open circles*: $s=2.81$ pF; **B**, *open circles*: $s=2.69$ pF), especially at negative voltages. **C** OHC capacitance derives from the sum of C_{sa} and C_v to produce C_m . Plots are from fitted parameters of the modified equation for 23 cells (averaged $s=3.96$ pF). Fitted parameters: Q_{max} : 3.09 ± 0.53 pC; V_{pkcm} : -59.4 ± 17.8 mV; z : 0.79 ± 0.10 ; C_0 : 21.9 ± 1.6 pF; ΔC_{sa} : 3.28 ± 0.75 pF. Average residuals for the two-state fit was $s=8.13$ pF

membrane capacitance, ΔC_{sa} is the maximum increase in capacitance that occurs when all motors change from compact to expanded state, and b is as above. The residuals in Fig. 3A, B illustrate the goodness of fit of this modified equation to the C_m data; the average sum of the residuals was halved with the fit to the modified equation ($s=8.13$ pF for the two-state fit; $s=3.96$ pF for the modified fit). The significantly better fit substantiates our contention that C_{sa} increases during hyperpolarization, and aids in quantifying the magnitude of change. In Fig. 3C, we plot capacitance functions based on averages of the fitted parameters for 23 cells. The difference in C_{sa} between conditions where all motors exist in either the compact or expanded states is 3.28 ± 0.75 pF (mean \pm SD;

see Fig. 3C legend for other fitted parameters and statistical comparisons). The plot further illustrates how this voltage-dependent change in C_{sa} results in an asymmetrical C_m function.

Capacitance asymmetry may arise from multi-state models of motor activity; however, Iwasa [19], using realistic values for OHC charge parameters found little evidence of asymmetry in model capacitance functions (his Fig. 3). We also fit our data to the sum of two bell-shaped Boltzmann derivatives, each providing distinct parameters for z , V_{pkcm} , and Q_{max} . In this case however, the fitted parameters of the second underlying Boltzmann are unrealistic; for example, V_{pkcm} is unphysiologically negative in magnitude, showing values as great as -780 mV, with Q_{max} up to 15 pC. Of course, this type of fit describes a function that mimics that of Eq. 2 within the voltage range that we studied.

What evidence is there that ΔC_{sa} results from the activity of OHC lateral membrane motors? This is an important point since recently, Kilic and Lindau [24] have found an asymmetrical bell-shaped membrane capacitance, similar in form to the one we observe here, that they attribute to Na channel gating charge in nerve terminals. In fact, they find voltage-dependent changes in their control C_m recordings (in the absence of Na channel activity) that mimic the form of our Eq. 2. In order to determine whether the activity of the lateral membrane motor accounts for ΔC_{sa} , we measured capacitance in Deiters' cells and HEK cells that were either successfully or unsuccessfully (based on the generation of nonlinear capacitance) transfected with the gene for prestin. Prestin has recently been identified as the OHC motor protein, since when expressed in HEK cells it displays the electro-mechanical signature of the OHC motor [41, 48]. We do not observe voltage-dependent C_m in control cells that lack the motor. Figure 4A shows that Deiters' cells, which lack lateral membrane motors, or human embryonic kidney cells *unsuccessfully* transfected with prestin do not evidence C_m differences at voltage extremes. More telling, those non-auditory cells *successfully* transfected with prestin present asymmetrical capacitance functions matching those of OHCs (Fig. 4B). Additional evidence arises from the direct correlation between the number of membrane motors based on charge estimates ($N=Q_{max}/ze$) and the magnitude of ΔC_{sa} (unconstrained fit, solid line; $r=0.78$; Fig. 4C). A unit capacitance change of 0.11 aF per motor is obtained. With the fit constrained to the origin (Fig. 4C, dashed line), 0.13 aF per motor is obtained. These data were derived from mature OHCs of different lengths ($n=23$), from prestin-transfected cells with differing expression efficiencies ($n=6$), and from published data on developing OHCs ($n=2$) [30]. Finally, we note that the generation of nonlinear capacitance, in and of itself, is not responsible for the asymmetry we find. That is, treatment with lipophilic ions is able to induce a bell-shaped capacitance in Deiters cells and an augmented capacitance in OHCs. However, we found no evidence that this additional gating charge either produced or augmented the asymmetry

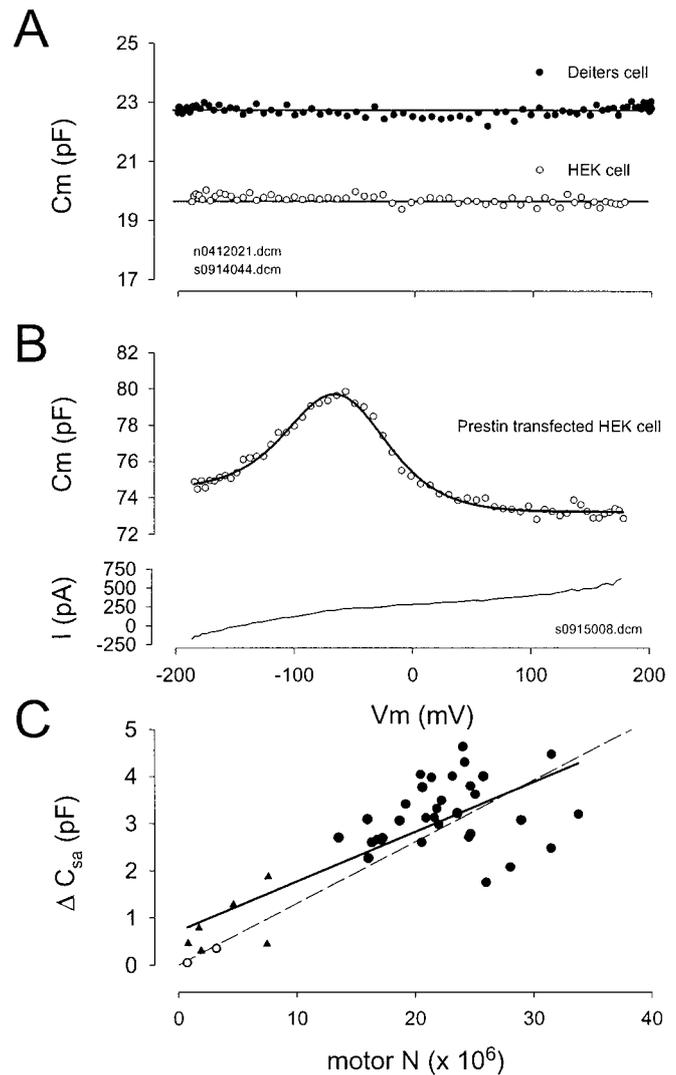

Fig. 4A–C The increase in C_{sa} at hyperpolarized potentials arises from the lateral membrane motor protein, prestin. **A** Neither Deiters' cells (*filled circles*), which do not express prestin, nor human embryonic kidney cell unsuccessfully transfected with prestin (*open circles*) give evidence of an increase in C_{sa} with hyperpolarization. *Lines* are straight horizontals. **B** Prestin-transfected human embryonic kidney cells show the same asymmetrical C_m function as OHCs. *Fitted solid line*: Q_{max} : 0.90 pC; V_{pkcm} : -65.0 mV; z : 0.66 ; C_0 : 73.2 pF; ΔC_{sa} : 1.25 pF. **C** The maximum change in C_{sa} (ΔC_{sa}) is correlated with the estimated number of motors ($N=Q_{max}/ze$). The *filled circles* are adult OHCs, the *filled triangles* are prestin-transfected cells, and the *open circles* are obtained from fits to the developmental OHC data of Oliver and Fakler (their Fig. 1, P6, P11; limited voltage range but low noise traces) [30]. The *dotted line* is a linear regression through the origin (slope of 0.13 aF/motor), whereas the *solid line* is an unconstrained regression, with a slope of 0.11 aF/motor and an r of 0.78

in OHC capacitance [46]. All these data strongly suggest that ΔC_{sa} arises from the activity of lateral membrane motors.

Finally, we explored the effect of the widely used drug, salicylate, on OHC C_{sa} . Salicylate, which can cause temporary hearing loss and tinnitus, has been found to reduce OHC motor-derived capacitance and

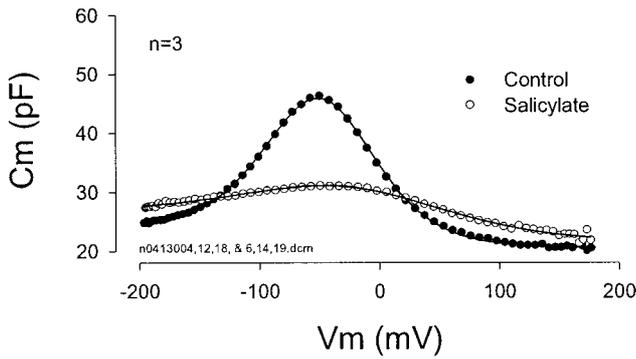

Fig. 5 Salicylate reduces C_v but increases C_{sa} . Averaged responses from three cells before and after extracellular salicylate treatment (10 mM). Three minutes after obtaining the whole-cell configuration control measures were made; following an additional 3 min of superfusion with salicylate the measures were repeated. Note the reduction in motor-derived capacitance, but an increase in C_{sa} . Fitted parameters for control: Q_{max} : 2.93 pC; V_{pkcm} : -48.9 mV; z : 0.83; C_0 : 20.5 pF; C_{sa} : 3.6 pF. Fitted parameters for salicylate: Q_{max} : 1.6 pC; V_{pkcm} : -23.2 mV; z : 0.44; C_0 : 21.2 pF; C_{sa} : 5.4 pF

motility [21, 42, 44]. Deiters' cell capacitance, on the other hand, is unaltered by salicylate treatments (data not shown). However, the effect on the OHC is not simply to reduce capacitance uniformly across voltage. The averaged data ($n=3$) in Fig. 5 shows that whereas peak capacitance is substantially reduced, capacitance on either side of the peak actually increases, and this is partially owing to a reduction in the steepness of the voltage dependence, as indicated by the fits to the C_m data (see Fig. 5 legend). Interestingly, the fit with our new model demonstrates that C_{sa} in the hyperpolarized region increases by about 2 pF above controls. Since salicylate has no effect on the capacitance of cells that lack the lateral membrane motor, and since there is a simultaneous effect on C_v and C_{sa} , this result additionally identifies ΔC_{sa} as arising from the activity of lateral membrane motors.

Discussion

In the OHC, membrane capacitance (C_m) arises from two superimposed components; one component (C_v) derives from gating charge movement owing to voltage-dependent activity of motor proteins within the lateral plasma membrane, while the other component (C_{sa}) derives from the intrinsic dielectric properties of all segments of its plasma membrane [2, 8, 37]. The latter component, often termed “linear” membrane capacitance, though typically considered independent of voltage, may co-vary with mechanisms, including voltage-dependent ones, that alter the underlying characteristics which define whole-cell capacitance, namely the membrane's surface area, dielectric constant, or thickness. We find that the activity of the lateral membrane motor, prestin, either in native OHCs or expressed in nonauditory cells influences the magnitude of the plasma membrane's C_{sa} , providing a clue to the motor's mechanism of action.

What fraction of ΔC_{sa} may arise from voltage-induced, OHC lateral membrane area change?

The change in C_{sa} that we observe resulting from fluctuations in the state of lateral membrane motors may arise from corresponding fluctuations in the area occupied by the motors within the lipid bilayer. Direct modifications of membrane surface area by integral proteins can be accomplished by a variety of molecular mechanisms. For example, reversible insertion of proteins or protein regions within the plasma membrane could serve to change membrane surface area [25]. The insertion of the bactericidal colicin protein into the lipid bilayer is voltage dependent, with at least 68 amino acid residues reversibly inserting into the bilayer [23]. Obviously, such a phenomenon will displace lipid, and alter membrane surface area. Alternatively, integral membrane proteins could change surface area by rearrangement of subunits, as may occur in gap junctions [45].

Based on our set of measures, the average number of motors [$N=Q_{max}/(ze)$] per cell is 25.7 ± 4.3 million. Thus, we estimate that each motor contributes ≈ 0.13 aF to C_{sa} as the motor changes from the compact to the expanded state. We previously determined the OHC-specific membrane capacitance to be $8 \text{ fF}/\mu\text{m}^2$, accounting for additional membrane area ($\approx 30\%$; see [6]) due to rippling that is unobservable at the light microscopic level [16]. More recent and rigorous attempts to account for membrane folding provide estimates in other cell types of $5 \text{ fF}/\mu\text{m}^2$ [43]. Using the latter value, we arrive at a motor area change of $\approx 26 \text{ nm}^2$. Based on our estimates of C_0 (21.9 pF), the area of the lateral membrane can be estimated to be $3134 \mu\text{m}^2$, after correcting for the capacitance of those membrane regions devoid of motors (6.23 pF; [16]). The density of motors within the lateral membrane is then $8168/\mu\text{m}^2$, similar to our previous estimates obtained from low-frequency OHCs [16, 39]. Given these values, the estimated area change in the lateral membrane, if ΔC_{sa} fully reflects area changes, would be about 21%. This large area change is in contrast with results of modeling. We had previously determined that the OHC area motor model could account for physiological length and diameter changes by a lateral membrane surface area modification of about 3%. Indeed, even the unit motor area change that we now obtain, 26 nm^2 , is much larger than estimates previously made ($\approx 8 \text{ nm}^2$ [38]; $2\text{--}7 \text{ nm}^2$ [1, 17, 18]; 0.37 nm^2 [11]). We conclude that ΔC_{sa} does not simply reflect changes in the membrane surface area.

Kalinec et al. [22] found voltage-induced surface area changes up to 8% in lateral membrane patches utilizing voltage pulses between ± 80 mV. Since this voltage excursion is less than the motor's range of voltage sensitivity, it might be expected that their measured area changes were sub-maximal. Considering the Boltzmann characteristics of the mechanical response [37], their data are reconcilable with a maximal area change of 10.9%. While our capacitance data may be viewed as arising from changes in membrane characteristics other than ar-

ea, the direct measures of Kalinec et al. [22] must be taken at face value and supersede model predictions. It should be noted that the OHC plasma membrane area is not increased by stretch but instead by supplementation; consequently, an area increase above that typically considered to cause membrane breakdown by stretching ($\approx 4\%$; [9]) is not unrealistic. Thus, we consider that a portion of ΔC_{sa} arises from a 10.9% change in lateral membrane surface area, amounting to 1.7 pF, and the remainder (1.6 pF) reflects changes in either the membrane's dielectric constant or thickness. That is, the specific membrane capacitance changes from 5.0 to 5.37 fF/ μm^2 when all prestin motors change from the compact to the extended state.

How might an integral membrane protein, such as prestin, alter specific membrane capacitance?

Membrane dielectric

The dielectric constant of the lipid bilayer is about 2. Proteins possess a higher dielectric constant, and thus they may be expected to alter the overall dielectric properties of the membrane when inserted within the bilayer. Indeed, many investigators have found changes in capacitance upon insertions of proteins into lipid bilayers, although in some cases the changes were transient [4], or may have been attributed to channel gating capacitance [34]. A direct test with exogenously expressed glycine receptors in HEK cells did not alter the specific membrane capacitance [13], although only about 20,000 receptors were expressed per cell. In the adult OHC from the low-frequency region of the cochlea, 25 million motors are expressed, increasing the likelihood of the protein's effect on the membrane dielectric. Voltage-dependent movement of charged regions of the protein prestin into or out of the hydrophobic membrane domain could affect the membrane dielectric. Alternatively, binding of anions to prestin could change the protein's dielectric [31].

Membrane thickness

Transmembrane voltage may affect membrane thickness directly. Indeed, one of the mechanisms whereby voltage-induced membrane breakdown is thought to occur is via electro-compressive forces [28]. Regardless, it is unlikely that the magnitude of voltages we employed here is capable of inducing sufficient changes in membrane thickness to significantly alter its capacitance, since in control Deiters' and HEK cells, membrane capacitance was not affected by voltage. Interestingly, in pure lipid bilayers, membrane capacitance was shown to be voltage dependent, presumably as a result of membrane compression [3]. Voltage-induced increases in capacitance up to 100% were found. However, those results were attributable to the solvent content of the bilayer. More ger-

mane to our data, the action of membrane proteins may also affect bilayer thickness. For example, the anti-microbial peptide, proegrin-1, resides as a membrane surface adsorbed structure (residing within the polar head group region) or as a transmembrane spanning structure [15], depending on the concentration. In the former state, the peptide thins the membrane, whereas in the latter state the membrane is thickened. Little is known about the secondary and tertiary structure of the integral membrane protein prestin, and it may be that some voltage-dependent mechanism akin to the concentration-dependent activity of proegrin-1 is occurring. The possibility cannot be dismissed that the presence of the highly hydrophobic prestin molecule within the lateral membrane provides for an effect similar to the solvent effects observed by Benz and Janko [3]; for example, by altering lipid packing at the protein-lipid interface. In these scenarios, voltage-dependent, prestin-induced perturbations of the bilayer could permit fluctuations of membrane thickness either as a result of the direct compressive action of voltage on a susceptible bilayer or through voltage-induced protein conformational changes. In this regard, salicylate, a drug capable of modifying lipid packing and bilayer mechanics [33], may function to increase the effectiveness of prestin in altering membrane thickness. It should be noted that in either scenario membrane surface area would also change as a function of thickness.

Chloride Anions Regulate Kinetics but Not Voltage-Sensor Q_{\max} of the Solute Carrier SLC26a5

Joseph Santos-Sacchi^{1,2,3,*} and Lei Song¹

¹Department of Surgery (Otolaryngology), ²Department of Neuroscience, and ³Department of Cellular and Molecular Physiology, Yale University School of Medicine, New Haven, Connecticut

ABSTRACT In general, SLC26 solute carriers serve to transport a variety of anions across biological membranes. However, prestin (SLC26a5) has evolved, now serving as a motor protein in outer hair cells (OHCs) of the mammalian inner ear and is required for cochlear amplification, a mechanical feedback mechanism to boost auditory performance. The mechanical activity of the OHC imparted by prestin is driven by voltage and controlled by anions, chiefly intracellular chloride. Current opinion is that chloride anions control the Boltzmann characteristics of the voltage sensor responsible for prestin activity, including Q_{\max} , the total sensor charge moved within the membrane, and V_h , a measure of prestin's operating voltage range. Here, we show that standard narrow-band, high-frequency admittance measures of nonlinear capacitance (NLC), an alternate representation of the sensor's charge-voltage (Q - V) relationship, is inadequate for assessment of Q_{\max} , an estimate of the sum of unitary charges contributed by all voltage sensors within the membrane. Prestin's slow transition rates and chloride-binding kinetics adversely influence these estimates, contributing to the prevalent concept that intracellular chloride level controls the quantity of sensor charge moved. By monitoring charge movement across frequency, using measures of multifrequency admittance, expanded displacement current integration, and OHC electromotility, we find that chloride influences prestin kinetics, thereby controlling charge magnitude at any particular frequency of interrogation. Importantly, however, this chloride dependence vanishes as frequency decreases, with Q_{\max} asymptoting at a level irrespective of the chloride level. These data indicate that prestin activity is significantly low-pass in the frequency domain, with important implications for cochlear amplification. We also note that the occurrence of voltage-dependent charge movements in other SLC26 family members may be hidden by inadequate interrogation timescales, and that revelation of such activity could highlight an evolutionary means for kinetic modifications within the family to address hearing requirements in mammals.

INTRODUCTION

Typically, voltage-sensor charge movement in membrane proteins rapidly follows voltage perturbations, producing capacitive-like gating/displacement currents (1,2). However, intrinsic properties of the protein or interactions of the protein with other membrane constituents (protein or lipid) can influence the movement's time course (3). In essence, gating currents may be low-pass filtered relative to the actual driving voltage, often exhibiting multiexponential behavior that depends on the timing of intramolecular and/or intermolecular interactions. Thus, interrogation of charge at other than infinite timescales (or zero frequency) may produce inaccurate quantification of the total charge

moved (Q_{\max}) across a given cell membrane's electric field where the protein's voltage sensor resides. This issue was recently highlighted by the discovery that previously unidentified slow charge movements, revealed by utilizing longer integration times of 300 ms, account for an apparent charge immobilization in *Shaker* ion channels (4). Importantly, cellular events that result from charge movements may correspondingly be inaccurately assessed.

The family of SLC26 solute carriers functions to maintain gradients of anions across the membranes of a variety of cells (5). However, SLC26a5 (prestin) has been recruited by the outer hair cell (OHC) in Corti's organ to function as a motor protein that underlies cochlear amplification, a mechanical feedback process that boosts auditory sensitivity by 100- to 1000-fold (6,7). OHCs have been shown to produce voltage-dependent length changes (electromotility (eM)) in the audio frequency range (8–10), extending out at least to 80 kHz at room temperature (11). On the other hand, prestin's sensor charge movement, measured as a voltage-dependent or nonlinear capacitance (NLC), displays

a limiting frequency, with a cutoff of ~ 10 kHz at room temperature (12). Thus, the frequency response of the motor protein prestin has differed depending on whether sensor charge or mechanical activity of the protein is evaluated. The expectation that each metric (NLC or eM) should be equivalently fast is based on the assumption that prestin's electromechanical responsiveness to voltage is governed by a direct ultrafast two-state process, switching molecular conformations between compact and expanded states. Thus, technical issues affecting each of these measures could have contributed to the mismatch.

The activity of prestin and its effects on cochlear amplification are strongly dependent on chloride (13–17); it has been shown that alteration of perilymphatic chloride reversibly abolishes cochlear amplification (16). Recently, we observed a dissociation between the eM and NLC magnitude and voltage operating range that we attributed to slow intermediate transitions between prestin's chloride-binding and voltage-enabled states (18). This discrepancy arose because each was evaluated within different frequency regimes (eM at near steady state and NLC at high frequency), under the assumption that the two should have been equivalent. Here, we simultaneously evaluate prestin's charge movement with measures of high-frequency alternating-current (AC) capacitance and step-induced charge integration. We find that quantification of charge is highly dependent on frequency of interrogation, pointing to behavior in prestin that is inconsistent with a simple ultrafast two-state process. Consequently, prestin charge distribution, the rate of which we show to be chloride-dependent, has been wrongly estimated by standard high-frequency AC admittance measures. Voltage-evoked, frequency-dependent eM measurements within the same bandwidth used for NLC measurements confirm these observations. These data reveal that prestin activity is low pass in this frequency domain, and that chloride does not influence Q_{\max} , the total prestin charge within the membrane. Our results have significant implications for our current understanding of prestin behavior and cochlear amplification.

MATERIALS AND METHODS

Whole-cell patch-clamp recordings were made from single isolated OHCs from the organs of Corti of Hartley albino guinea pigs. After animals were overdosed with isoflurane, the temporal bones were excised and the top turns of the cochleae dissected free. Enzyme treatment (1 mg/mL Dispase I for 10 min) preceded trituration, and isolated OHCs were placed in a glass-bottom recording chamber. An inverted Nikon (Tokyo, Japan) Eclipse TI-2000 microscope with a $40\times$ lens was used to observe cells during voltage clamping. Experiments were performed at room temperature. Direct-current (DC) voltages were corrected for series-resistance (R_s) effects, and AC currents were corrected for system roll-off, as previously described (19,20). Series and membrane resistance determined from step analysis were similar for the two chloride groups. For the 140 mM Cl group, $R_s = 9.37 \pm 0.31$ M Ω and $R_m = 337 \pm 45.9$ M Ω for $n = 21$ OHCs; for the 1 mM Cl group, $R_s = 8.39 \pm 0.47$ M Ω and $R_m = 365 \pm 40.5$ M Ω for $n = 6$ OHCs. Fig. 5, G and H, shows that our measurement system, after corrections for R_s effects, is flat out to 5 kHz, within which bandwidth our data arise (see the Appendix

in the Supporting Material). All data collection and analysis was done with the software program jClamp (<http://www.scisoftco.com>).

Solutions

Intracellular chloride levels were set to either 140 or 1 mM, levels that bracket the intracellular concentration found in intact OHCs, namely, ~ 10 mM (16). An ionic blocking solution was used to remove ionic currents to ensure valid measures of membrane capacitance. The extracellular-base high-Cl solution contained 100 mM NaCl, 20 mM TEA-Cl, 20 mM CsCl, 2 mM CoCl₂, 1 mM MgCl₂, 1 mM CaCl₂, and 10 mM Hepes. In some cases, 1 μ M Gd³⁺ was included in the bath solution to block stretch channels and assist in gigohm seal formation. We had previously shown that Gd³⁺ three orders of magnitude greater can block NLC. At the concentration used, no effects on NLC were observed. The intracellular-base solution contained 140 mM CsCl, 2 mM MgCl₂, 10 mM Hepes, and 10 mM EGTA. Lower chloride concentrations were set by substituting chloride with gluconate. Intracellular chloride levels in the subplasmalemmal space of the OHC, where prestin's chloride-binding site resides, were guaranteed by setting both intracellular and extracellular chloride concentrations equal. All chemicals used were purchased from Sigma (St. Louis, MO).

Cell capacitance

An Axon Instruments (Foster City, CA) 200B amplifier was used for whole-cell recording. To measure both AC capacitance and integrated charge movement, a simple voltage protocol was designed that included both step stimulation and dual sine stimulation at a range of dual-sine interrogation frequencies (Fig. 1, A and B). For AC admittance analysis, real and imaginary components of currents were corrected for the recording-system frequency response (19). No averaging was used with this protocol.

Membrane capacitance (C_m) was measured using a continuous dual-frequency (discrete sinusoidal frequencies at f_1 and f_2 , where $f_2 = 2 \times f_1$) voltage-stimulus protocol (19,21). Simultaneous AC C_m sampling resolutions (5.12, 2.56, 1.28, and 0.064 ms) were achieved by stimulating with a summed multisine voltage (the multi-dual-sine approach) whose phases were the same. Primary frequencies (f_1) were 195.3, 390.6, 781.3, and 1562.5 Hz; all frequencies (10 mV peak) were superimposed onto steps from -160 to $+100$ mV for a duration of 700 ms at a clock sample period of 10 μ s. We limited our voltage delivery to -160 to 100 mV because with this protocol, larger voltages caused cell recordings to be lost or unstable. On return from each step to a sinusoidal-free holding potential of 0 mV for at least 40 ms (see Fig. 1, where only a portion of the protocol is plotted), voltage-sensor displacement currents are extractable. Thus, this approach provided both multifrequency AC capacitance and step-induced charge movement measures within one protocol, an important approach that ensures that the preparation is quasistationary in time.

After gigohm seal formation, stray capacitance was cancelled with amplifier compensation controls, as is usually done. Since stray capacitance is frequency dependent, it is important to ensure that it is cancelled out at each recording frequency. The existence of stray capacitance causes an apparent frequency dependence of linear capacitance, which should *not* be frequency dependent. Measures of R_s are similarly affected. Consequently, in the whole-cell configuration, residual stray capacitance at each of the recording frequencies was cancelled with further manipulations of amplifier compensation by ensuring that cell linear capacitance (or, equivalently, R_s) was constant across frequency. This was done at very positive voltages, where OHC capacitance is dominated by linear capacitance. Removal of stray capacitance is necessary to meet C_m estimation algorithm requirements (19). We have used this compensation approach to ensure accurate measures of hair cell synaptic vesicle release at high interrogating dual-sine frequencies (20,22). The Supporting Material Appendix expands on our approach.

For each cell, capacitance data were fit to the first derivative of a two-state Boltzmann function with an additional component describing the

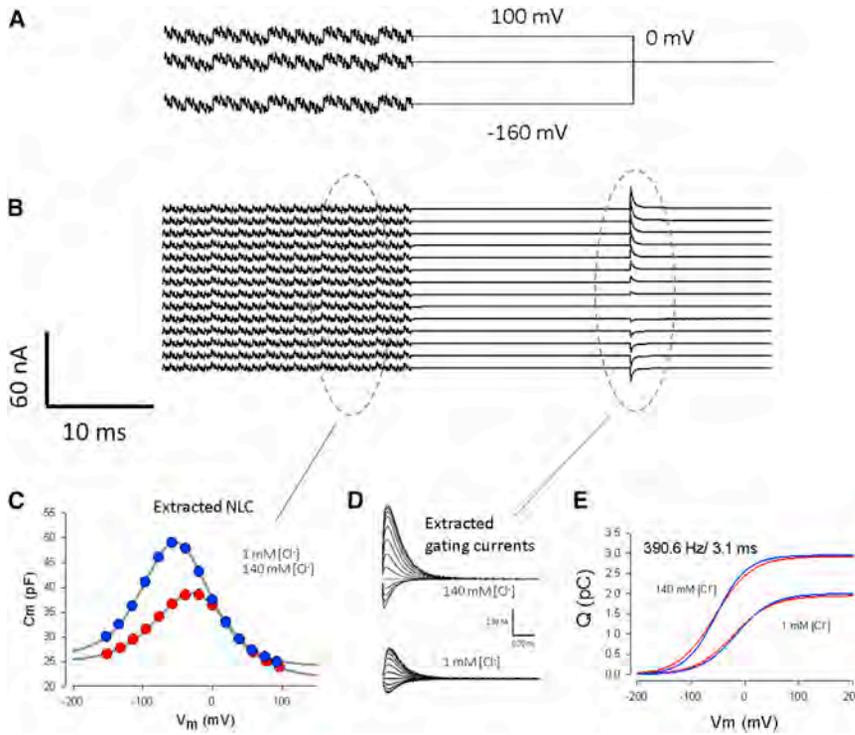

FIGURE 1 Stimulus and analysis paradigms. (A) Traces of voltage protocol. Step voltages (-160 mV to $+100$ mV by 20 mV increments) were delivered for 700 ms followed by a return to a holding potential of 0 mV for 40 ms. Superimposed on the steps were summed discrete dual-sine frequencies 655 ms in duration (see [Materials and Methods](#)). (B) Elicited currents (offset for easy visualization), AC and step-induced, were used to extract capacitance and integrated charge movements (dashed ovals), respectively. (C) Averaged NLC traces of OHCs with intracellular chloride clamped to 1 or 140 mM chloride. NLC was estimated from the latter half of the dual-sine stimulation duration. (D and E) Corresponding displacement currents extracted by linear capacitive current subtraction (D) and extracted Q - V curves (E) at 1 mM and 140 mM chloride conditions for an equivalent interrogation time based on fits of NLC with Eq. 1 (blue traces) or on fits of integrated off charge with Eq. 2 (red traces) give comparable results, as expected (see [Materials and Methods](#) for details). To see this figure in color, go online.

changes in specific membrane capacitance generated by prestin state transitions (23). The occupancy of prestin in the expanded state contributes ~ 140 zeptofarads/motor (δC_{sa}) to the linear capacitance, producing an apparent voltage-dependent change in linear capacitance at hyperpolarized levels (23,24). This equation is called the two-state- C_{sa} equation.

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + \frac{\Delta C_{sa}}{(1+b^{-1})} + C_{lin}, \quad (1)$$

where

$$b = \exp\left(\frac{ze}{kT} U\right) \text{ and } U = V_h - V_m.$$

Q_{\max} is the maximum nonlinear charge moved, V_h is the voltage at peak capacitance or, equivalently, at half-maximum sensor charge transfer, V_m is the membrane potential, z is valence, e is the electron charge, k is Boltzmann's constant, and T is absolute temperature. C_{lin} is defined as the linear capacitance of the membrane when all prestin motors are in their compact state, the minimum membrane capacitance evident at depolarized voltages; ΔC_{sa} is the maximum increase in capacitance that occurs when all prestin motors change from the compact to the expanded state, each motor contributing a unit response of δC_{sa} . From such fits, voltage-dependent NLC (C_v) is calculated from estimates of Q_{\max} , i.e., $C_v = Q_{\max}/(4 kT/ze)$ (25).

To confirm AC admittance estimates of sensor Q_{\max} , we integrated capacitive currents evoked at the end of voltage steps (exponentially decaying currents of each trace, with the baseline set to current relaxations at 20 ms). Residual ionic currents that remained after our ionic blocking conditions are time independent and thus were excluded for the most part from integrations of the exponentially decaying currents. The integration time window, starting at voltage offset, was varied from 3 to 20 ms. Previously, we and others used a similar approach that we developed to extract NLC during stair-step protocols by integrating total capacitive current at each step and fitting the resulting C_m - V_m data to a two-state Boltzmann deriva-

tive plus a linear capacitance (26,27). Here, Q - V curves were fit to the integral of Eq. 1 with respect to V_m , yielding

$$Q_{\text{tot}} = \left[\frac{Q_{\max} \times b + C_{lin} \times (U + U \times b)}{b + 1} + \frac{\Delta C_{sa} \times \log(b + 1)}{ze/kT} \right] + \text{off}. \quad (2)$$

The constant of integration (off) depends on the return holding voltage and accounts for a vertical offset in the Q_{tot} - V_m function. For fitting, we fixed linear capacitance to the average value obtained from AC admittance measures for each chloride group, since these measures provided robust, constant estimates across all frequencies (see [Fig. 3](#)). Additionally, we only report measures of integrated charge after 3 ms (10 times our clamp time constant), since earlier charge distribution at the voltage-pulse offset would be influenced by our clamp time constants of $< 300 \mu\text{s}$ ($\sim R_s \times C_m$). With this approach we essentially removed linear capacitive charge contamination from the total integrated charge. [Fig. 1 E](#) illustrates the equivalence of AC and time-domain estimates of Q_{\max} .

Higher resolution of prestin's frequency-dependent behavior was obtained by stimulating OHCs with voltage chirps (linear increasing frequency), with a frequency resolution of 24.41 Hz, and analyzing dual-frequency admittance, obtained by fast Fourier transform, at each component dual frequency (f_1 and $2 \times f_1$). The stimulus consisted of voltage steps (-160 to 160 mV by 40 mV increments) superimposed with voltage chirps of 10 mV peak (4096 points at a $10 \mu\text{s}$ sampling rate, giving an F_{\max} of 50 kHz). One benefit of the chirp signal is that it is a multifrequency stimulus whose individual frequency components are equal in amplitude, this being accomplished by varying the phase of each frequency. Another benefit is that duration of the chirp can be easily changed (although the duration used here was only 40.96 ms). Admittance at one frequency and its harmonic were analyzed in exactly the same way as the dual-sine approach, above (see the [Supporting Material Appendix](#)). We do that at all frequencies within the chirp at a primary frequency increment of 24.41 Hz. With this

protocol, filtered responses (10 kHz four-pole Bessel) were averaged three times for each cell to reduce noise. The first chirp response during a step was discarded, since it contains a transient response. We were able to balance out stray capacitance up to a frequency of ~5 kHz. This approach enabled us to construct 3D images of NLC across frequency using averages of all individual cell responses, thereby confirming and expanding on the resolution of the multi-dual-sine approach detailed above.

eM measures

OHC eM data derive from our recent study on the phase relationships of eM and membrane voltage (28). Here, we present the magnitude data transformed into mechanical gain (nm/mV) so that they can be compared to sensor charge movements, i.e., NLC. Briefly, cells were whole-cell voltage clamped and eM was elicited with voltage bursts of frequency ranging from 0.024 to 6 kHz. A photodiode technique was used to measure movements of the apex of the cell, with the cell bound at its basal pole by the patch electrode. Full details can be found in (28).

Kinetic model

A full description of the *meno presto* model of prestin activity is provided in our recent publications (24,28). Briefly, the model is multistate; after chloride binding, a slow intermediate transition leads to a voltage-enabled state, which generates sensor charge movement. The delays afforded by its multistate nature underlie the model's frequency dependence. The only parameter that was modified to fit (by eye) the data in Fig. 4 was the model's forward transition rate constant, k_1 , for Cl^- binding. The kinetic diagram and description are reproduced in Fig. 2 (reproduced from our previous work (24)).

RESULTS

Fig. 1 C shows the group-averaged NLC determined from admittance measures (5.12 ms sampling rate) for OHCs recorded under 140 mM and 1 mM intracellular chloride conditions. NLC fits for the 1 mM Cl group yield $V_h = -26.3$ mV, $Q_{\max} = 2.2$ pC, $C_{\text{lin}} = 21.84$ pF, $z = 0.71$, and $\Delta C_{\text{sa}} = 3.2$ pF; those for the 140 mM Cl group yield

$V_h = -52.3$ mV, $Q_{\max} = 3.1$ pC, $C_{\text{lin}} = 24.24$ pF, $z = 0.80$, and $\Delta C_{\text{sa}} = 2.1$ pF. Fig. 1 D shows voltage-sensor displacement currents after the offset of voltage steps extracted by subtraction of scaled difference currents evoked between the potential of +80 and +100 mV, in an attempt to remove linear capacitive currents, as is required for gating/displacement current extraction (29). Clear chloride differences exist, consistent with expectations. However, because C_m plots show that substantial NLC resides at these subtraction voltages, these displacement currents are inaccurate. We and others have studied OHC/prestin displacement currents for decades (12,30–33); however, because of the shallow voltage dependence of prestin ($z \sim 0.75$), extracted waveforms and estimates of Q_{\max} using P/N subtraction holding potentials, typically 40–50 mV, were adversely affected in those studies. Extraction of the sensor charge using Eq. 2 (see Materials and Methods) overcomes this problem in determining Q_{\max} . Fig. 1 E shows that determining Q_{\max} with either AC analysis or this time-domain approach produces equivalent results.

Fig. 3, A and B, shows group averages of both peak NLC (C_v) and linear capacitance as a function of interrogation frequency. Our success at stray capacitance compensation is borne out by the frequency independence of OHC linear capacitance provided by fits to the C_m data (Fig. 3 B). Interestingly, however, NLC shows a marked frequency dependence, with larger magnitudes as interrogating frequency decreases (Fig. 3 A). In fact, the frequency-dependent trend in C_m data suggests that NLC at frequencies lower than our lowest primary interrogating frequency of 195.3 Hz would be larger. The Boltzmann parameters V_h and z are stable across frequency (Fig. 3, C and D).

To better compare our measures across cells within the two chloride conditions, we converted our measures to specific nonlinear charge (Q_{sp} in pC/pF), thereby normalizing for surface area and prestin content. In Fig. 4 A, we plot AC-derived (Eq. 1) and integration-derived (Eq. 2) sensor charge over a range of interrogation times. Admittance interrogation time refers to the geometric mean of sampling periods of both primary and secondary sinusoids, whereas for integration estimates of sensor displacement charge, interrogation time refers to an integration window increasing up to 20 ms. It can be seen, as predicted from admittance measures alone, that as interrogation time increases, Q_{sp} continuously increases. Integration times >20 ms suffered from excess low-frequency noise, since no averaging could be performed during data collections. Electrode seals were routinely lost after the demanding protocol, since the OHC is quite mechanically active, with responses up to ~30 nm/mV (34) and on average 15 nm/mV (35). To extend our estimates of sensor charge beyond 20 ms, we resorted to measures of averaged electromotility (28), which were analyzed by fast Fourier transform, providing much better signal/noise ratios. Since it is established that eM is voltage-dependent (8,34), sensor charge

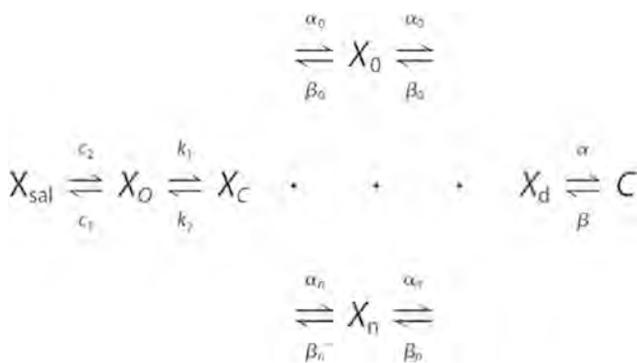

FIGURE 2 Kinetic model of the *meno presto* model. The X_{sal} state is bound by salicylate, but in this manuscript, salicylate is absent. The X_o state is unbound by an anion. The X_c state is bound by chloride, but the intrinsic voltage-sensor charge is not responsive to the membrane electric field. A slow, multiexponential conformational transition to the X_d state via X_n states enables voltage sensing within the electric field. Depolarization moves the positive sensor charge outward, simultaneously resulting in the compact state, C , which corresponds to cell contraction. Parameters and differential equations are provided in (24).

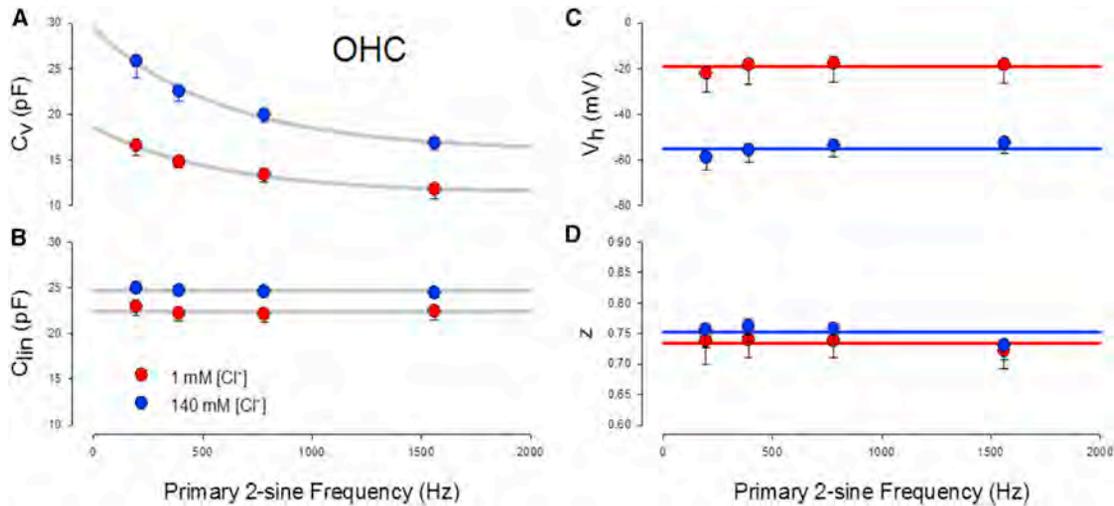

FIGURE 3 Voltage-dependent (C_v) and linear (C_{lin}) components of OHC capacitance simultaneously measured with the multi-dual-sine approach. (A) C_v displays a low-pass frequency dependence, which is unexpected for a fast two-state Boltzmann process. Differences between 1 mM (red circles, $n = 6$) and 140 mM (blue circles, $n = 17$) chloride conditions also show chloride-dependent frequency effects. (B) C_{lin} is flat across frequency, as expected. The frequency independence of C_{lin} demonstrates that calibration of system responsiveness was accurately performed. (C and D) V_h and z are also stable across frequency. Error bars depict the mean \pm SE, which in some cases is obscured by symbols. The solid lines in (A) are exponential, and those in (B)–(D) are linear fits for presentation. To see this figure in color, go online.

must correspond to eM magnitude. In Fig. 4 B, we plot eM gain as a function of the stimulating-frequency period and show that it corresponds to measures of AC-determined sensor charge. Indeed, eM magnitude continues to grow substantially as interrogation time increases, clearly indicating that sensor charge for both the 140 and 1 mM conditions trends toward equivalence with longer interrogations. These data indicate that total sensor charge movement, Q_{max} , is not directly linked to chloride concentration; rather, only a frequency-dependent, *apparent* Q_{max} is linked, depending on the kinetics of prestin's conformational transitions. It is not necessary to model these data to draw these conclusions.

To understand molecular mechanisms that may underlie this phenomenon, we simulated the *meno presto* model (initially developed in (18) and expanded with full details in (24)) with the same protocol (Fig. 4 B, gray lines). As

with the biophysical data, charge magnitude is dependent on interrogation time and chloride level. The model fits the data quite well, with increasing integration times (up to 200 ms in the model) incrementally increasing the charge measured. Importantly, for the model, estimated charge at either chloride level asymptotes at the actual set Q_{max} , with the time course depending on prestin's transition rates. Modification of our model parameters (24) was limited to one parameter, namely, a reduction of the model's forward transition rate constant, k_1 , for Cl^- binding (from $1e5$ to $0.7e4$). These results derive from the multiexponential kinetics of sensor charge movement in the *meno presto* model, some slowly moving charge contributions being missed due to shorter interrogation times, and the fact that only an *apparent* Q_{max} was provided. Such behavior corresponds to our biophysical observations of OHCs and complements the biophysical data, which show that total sensor charge

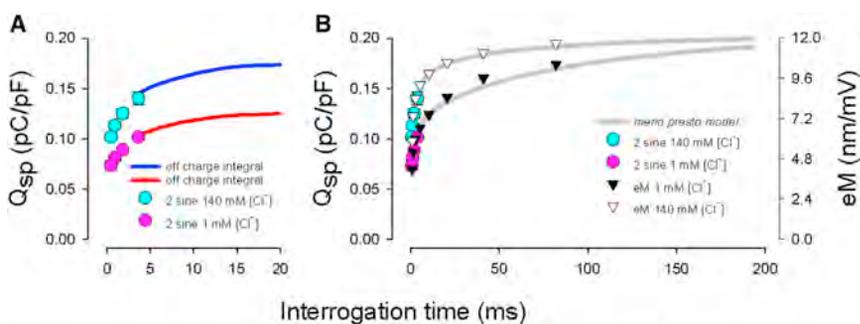

FIGURE 4 Sensor charge movements estimated from two-sine admittance analysis, off-current integration, or eM show low-pass frequency characteristics. (A) The AC measured specific sensor charge (Q_{sp}) corresponds to the integrated off-charge and shows that discrete measures of charge movement by AC admittance provide underestimates of the total prestin charge. (B) Q_{sp} (circles) and eM (triangles), which is known to be driven by voltage, display magnitudes that correspond to the predictions of the *meno presto* model (gray lines). Interrogation time is the geometric average

of periods of the dual-sine protocol, the integration time of sensor charge, or the eM fundamental frequency period (see Results). The biophysical data and model indicate that regardless of chloride concentration (but at above-zero concentrations), positive voltage will move prestin into the compact state, asymptoting at the maximum sensor charge dictated by prestin membrane content. Data are derived from averages of multi-dual-sine currents (circles) and eM (triangles) from $n = 5$ –8 OHCs. To see this figure in color, go online.

movement is not directly linked to chloride concentration, but rather is misestimated due to prestin kinetics, in contradistinction to long-held concepts.

Finally, to measure prestin's frequency-dependent behavior in finer detail and expand on our data set, we measured NLC using chirp stimuli. Fig. 5 shows averaged results from another group of cells under each of the two chloride conditions (five to six cells per condition). NLC increases with a reduction of interrogating frequency, approaching that expected from zero-frequency or infinite-integration estimates of sensor charge (Fig. 5, A and B). The meno presto model produces similar results (Fig. 5, C

and D), whereas a fast two-state Boltzmann model and a linear electrical resistor-capacitor (RC) model show no indication of frequency- or voltage/frequency-dependent capacitance, respectively (Fig. 5, E, G, and H). Appropriately setting the rate constants in a two-state model (forward/backward rate constants of $0.5e3\text{ s}^{-1}$) can produce a frequency-dependent roll-off within the measured bandwidth (Fig. 5 F); however, the resulting single-exponential transitions produce a different form of frequency dependence as compared to either the biophysical data or the meno presto model. These data confirm the validity of multi-dual-sine analysis of both linear electrical models and OHC NLC,

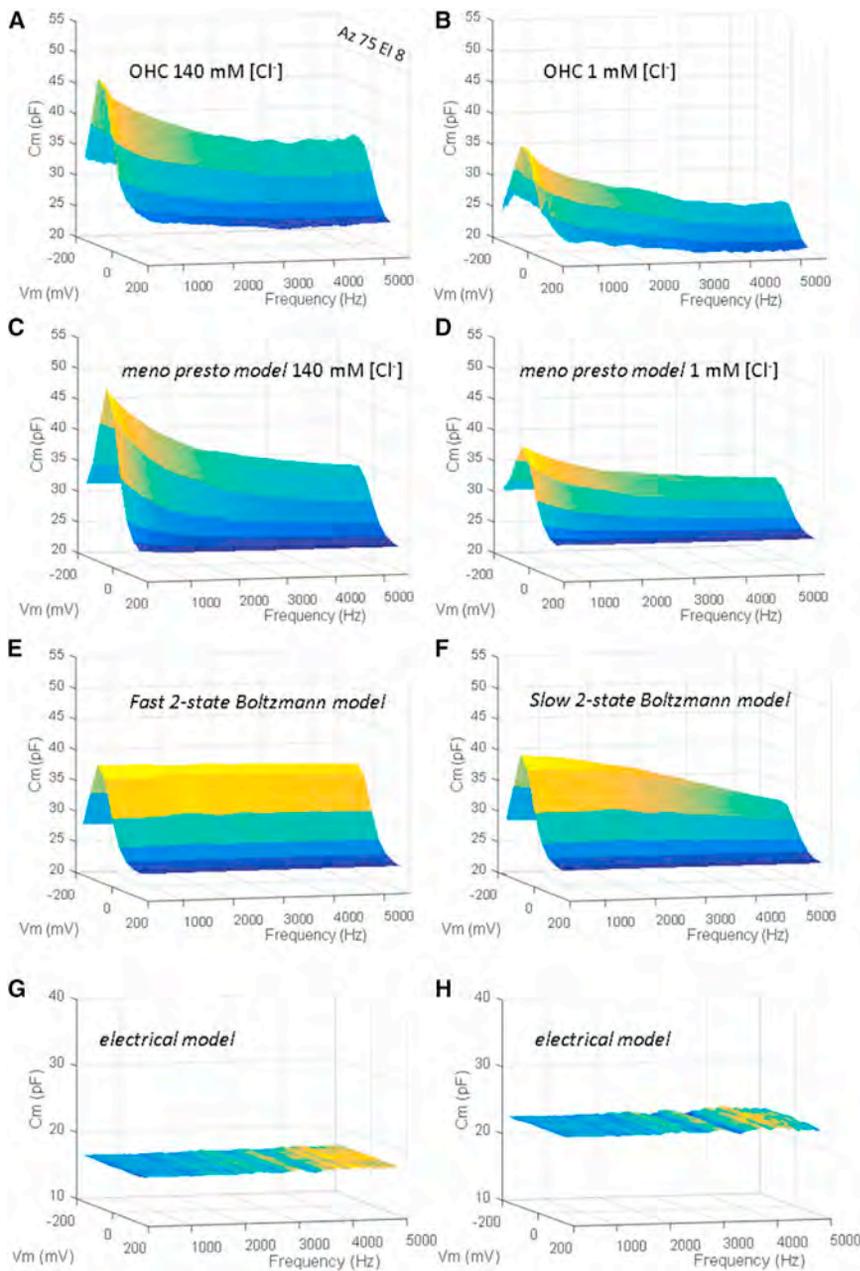

FIGURE 5 Membrane capacitance versus frequency measured by high-resolution frequency-dependent NLC of OHCs, the meno presto model, the fast two-state model, and the electrical model. (A) Averaged OHC NLC ($n = 5$) measured using the chirp protocol between 300 and 5000 Hz with 140 mM intracellular chloride. Note the rapid decline of peak capacitance. (B) Another group average of OHCs with 1 mM intracellular chloride ($n = 6$). The peak NLC decline is also evident in this condition. (C and D) C_m versus frequency as measured by the meno presto model at 140 mM and 1 mM chloride, respectively. The stimulus protocol and analysis were the same as the biophysical measures. Note the similarity to the biophysical data. (E) C_m versus frequency as measured by the fast two-state Boltzmann model (forward/backward rate constants of $1.5e5\text{ s}^{-1}$). Note the absence of NLC decline across frequency. (F) C_m versus frequency as measured by the slower two-state Boltzmann model (forward/backward rate constants of $0.5e4\text{ s}^{-1}$). Note the gradual roll-off due to reduced single-exponential transitions. (G) C_m versus frequency as measured by the electrical cell model with $R_s = 10\text{ M}\Omega$, $R_m = 300\text{ M}\Omega$, $C_m = 17\text{ pF}$, all nominal. Note the flat C_m response across frequency and voltage. (H) C_m versus frequency as measured by the same electrical model, with an additional 5 pF C_m switched in using a magnetically activated reed relay with minimal additional stray capacitance. highlighting, in the case of the OHC, the need to consider interrogation frequency effects when assessing prestin's voltage-sensor Q_{\max} , namely, total sensor charge in a given cell.

DISCUSSION

Characterizing sensor-charge movement in voltage-sensitive proteins provides a host of important information on protein function, including operating voltage range and maximum charge moved (Q_{\max}). The latter metric aids in quantifying protein content within the membrane, and our data indicate that prestin may be present at densities higher than the long-held estimates (26,36). For over a decade, chloride has been believed to be a key player in prestin function (13–16), influencing the quantity of measured sensor charge. However, our new data point to a role of chloride in controlling prestin kinetics and not in limiting the quantity of charge movement. Indeed, we previously showed that the maximum OHC eM magnitude, which is expected to correspond to the charge moved, since eM is voltage-driven, is little affected by chloride (18).

Does chloride underlie prestin's voltage-driven charge movement?

Zheng et al. (7) identified the OHC molecular motor as the fifth member of the mammalian SLC26 family of anion exchangers, of which 10 members have been identified (5,37). These anion exchangers facilitate the transmembrane movements of monovalent and divalent anions; however, prestin's transport capabilities are controversial, with some studies showing transport capabilities and others not (38–43). It is interesting to note that the influence of anions on NLC had been observed before the identification of prestin. For example, lipophilic anions, but not cations, were shown to influence OHC eM and NLC (44), and it has been known since the mid 1990s that the anion salicylate blocks NLC and eM, working on the intracellular aspect of the OHC (45,46). Notwithstanding the controversy of anion transport, the existence of voltage-dependent displacement currents, or NLC, has been taken to indicate an evolutionary change that enables eM, since SLC26a5's closest mammalian homolog, SLC26a6, lacks this capability, as assessed by standard high-frequency admittance techniques (13). Whether other SLC26 family members actually possess NLC is a subject for future investigation, since our data indicate that we must now consider the occurrence of charge movements that are slower than typically expected. Should other family members possess slow voltage-sensor charge movements, a scenario wherein kinetic modifications within the family underlie prestin's change to a molecular motor would be compelling. Interestingly, zebra fish prestin shows a lower-pass frequency response than rat prestin (33).

In 2001, Oliver et al. (13) identified the chloride anion as a key element in prestin activation by voltage. They speculated that extrinsic anions serve as prestin's voltage sensor (17), moving only partially through the membrane. Our observations and those of others over the ensuing years have challenged this concept, and we have suggested that chloride works as an allosteric-like modulator of prestin. These observations are as follows. 1) Monovalent, divalent, and trivalent anions, which support NLC, show no expected changes in z or Q_{\max} (47). 2) A variety of sulfonic anions shift V_h in widely varying magnitudes and directions along the voltage axis (47). 3) The apparent anion affinity changes depending on the state of prestin, with anions being released from prestin upon hyperpolarization, opposite to the extrinsic sensor hypothesis (48). 4) Mutations of charged residues alter z , our best estimate of unitary sensor charge (41). 5) Prestin shows transport properties ((40,41,43); however, see (39,42)). Despite these challenges, the extrinsic voltage-sensor hypothesis is still entertained. For example, Geertsma et al. (49) used their recently determined crystal structure of SLC26Dg, a prokaryotic fumarate transporter, to speculate on how prestin's extrinsic voltage sensor might work. They reasoned that a switch to an outward-facing state could move a bound anion a small distance within the membrane. Unfortunately, there are no data showing an outward-facing state, only an inward-facing one. Indeed, if prestin did bind chloride but was incapable of reaching the outward-facing state (a defunct transporter), no chloride movements would occur upon voltage perturbation. Furthermore, the fact that the anion-binding pocket is in the center of the protein would mean that if an outward-facing state were achieved with no release of chloride, the monovalent anion would move a very small distance through the electric field of the membrane. However, z , from Boltzmann fits, indicates that the anion moves three-quarters of the distance through the electric field. Unless the electric field is inordinately concentrated only at the binding site, it is difficult to envisage this scenario. The data presented here clearly indicate that no direct relation between chloride level and Q_{\max} exists, further suggesting that chloride does not serve as an extrinsic voltage sensor for prestin. Nevertheless, our recent work and *meno presto* model indicate that chloride binding to prestin is fundamental to the activation of this unusual motor. The model and data indicate that a stretched exponential intermediate transition between the chloride binding and the voltage-enabled state imposes lags that are expressed in whole-cell mechanical responses (28). This intermediate transition also accounts for our frequency- and chloride-dependent effects on measures of total charge movement, Q_{\max} . Indeed, based on site-directed mutations of charged residues, we favor intrinsic charges serving as prestin's voltage sensors (41).

Recently, Gorbunov et al. (50), used cysteine accessibility scanning and molecular modeling to suggest structural homology of prestin to UraA. Notably, the crystal structure

of SLC26Dg (49) supports Gorbunov et al.'s structural interpretations of prestin. Given the deduced structure, Gorbunov et al. identified possible chloride-binding residues within prestin's central permeation pathway. When those residues were mutated, the protein became anion-insensitive, yet maintained NLC. For example, in the rPres mutation, R399S, which maintains NLC, salicylate inhibition of NLC was abolished. These data are in line with our observations that truncated Cl^- movements are not responsible for voltage sensing, namely, the generation of NLC.

We suggest, instead, that various anions differentially modulate the transition rates of prestin, likely as a consequence of their different binding affinities, thereby influencing V_h (i.e., the distribution of compact and expanded states of prestin) and the *apparent* Q_{max} obtained via discrete frequency admittance measures. This concept may explain the wide variability in prestin's Boltzmann parameters that we and others have found with various anions (13,47).

Some of prestin's voltage-dependent characteristics are inadequately assessed using admittance analysis

The prevailing concept of prestin activity has been that of an ultrafast two-state Boltzmann process. This is not surprising, since the OHC can change its length at acoustic rates up to 80 kHz (8–11). Consequently, this reasoning has guided our assessment method of prestin activity, where AC NLC measures have usurped the more tedious gating-current methods that were utilized early on (32,35,51). Nevertheless, even gating-charge evaluations have suffered from problems associated with inadequate integration times and the shallow voltage dependence of prestin, which makes adequate linear leakage subtraction nearly impossible. Our data now show that AC capacitance measures do not correspond to full motor capability (18). The inaccuracies that fast single or dual AC measurements provide needn't preclude their use, however, now that we have uncovered their limitations. Thus, by measuring C_m with a range of frequencies, with proper calibration for stray capacitance effects and including long interrogation times, valid measures of Q_{max} can be obtained.

We previously noted that Boltzmann fits to the Q - V function of prestin cannot reliably predict unitary motor charge, Q_m , since even Langevin fits are reasonable, which would place Q_m values 3 times higher relative to two-state fits (26). This has been clearly emphasized by the Gummer group (52). One outcome of our study indicates that regardless of unitary charge magnitude (which remains stable across frequency, as indicated by invariant z values), the larger Q_{max} estimates from long interrogation times point to a higher density of prestin within the OHC lateral membrane. Consequently, the changes in prestin charge density observed in previous studies by narrow-band admittance

techniques may have been due to the effects of altered kinetics rather than prestin membrane content.

Frequency dependence of OHC charge movement

The frequency dependence of OHC charge movement has been investigated previously (12,31). Using the methodology of Fernandez et al. (53), we showed that capacitive reactance of the OHC with 140 mM intracellular solution in the whole-cell voltage-clamp configuration was voltage- and frequency-dependent, rising as zero frequency was approached (31). Subsequently, Gale and Ashmore (12) measured NLC in OHC membrane patches, where clamp time constants were better suited to high-frequency assessment. They found flat responses out to ~10 kHz at room temperature. Importantly, the direct effects of temperature on OHC displacement currents and NLC have been evaluated and shown to substantially affect NLC V_h (indicative of transition-rate effects) of both OHC and prestin-transfected cells when the bath temperature is altered (30,54,55). Shifts of ~20 mV/°C were found. Additionally, temperature jumps using an infrared laser on prestin-transfected cells (56) induced C_m changes attributable to NLC as well as linear C_m , as originally described by Shapiro et al. (57). NLC V_h shifted with rates up to 14 V/s over the course of a 5 ms infrared pulse. Thus, it is clear that temperature will influence the frequency dependence of OHC NLC. Consequently, after correcting for temperature, Gale and Ashmore (12) arrived at a 25 kHz cutoff for NLC, still far below the eM cutoff observed at room temperature (11). We suggest that these incompatible measures arise from technical issues. Considering the characteristics of our recently espoused *meno presto* model (24,28), we further suggest that sufficiently long stimulations of the OHC will drive substantial numbers of prestins into the chloride-bound, voltage-enabled state where they may rapidly respond to voltage perturbations with cutoff frequencies possibly unencumbered by the chloride-binding step. Thus, the performance of the OHC may modulate between two frequency regimes, high and low; the latter likely related to a slow transport function of the protein (40,41,43).

Recently, Homma et al. (58) have measured the frequency dependence of OHC NLC using our dual-sine approach, but only with discrete dual-sine frequencies and without presentation of linear capacitance data. Interestingly, they found that NLC in control mouse OHCs was frequency *independent* with high intracellular iodide solutions, but frequency *dependent* with high intracellular chloride conditions. The latter results are similar to our results under high-chloride conditions. Thus, we concur that anions are influential in controlling prestin kinetics, and we now must consider the effects of chloride substitutes on prestin kinetics. Here, we used gluconate—previously confirmed to be similar to aspartate substitution (18)—to lower chloride to near

physiological levels (16). Whether any of the effects of iodide were due to chloride reductions remains to be investigated.

Interestingly, Albert et al. (33) also presented data showing low-pass NLC activity in rat prestin using single-sine measurements (see their Fig. 3 E), which they attributed to their recording equipment. Yet they note very fast clamp speeds, and furthermore, they do not claim any untoward influences on the low-pass nature of zebra fish prestin in that same study.

How can low-pass prestin sensor charge movement that directly drives eM underlie cochlear amplification?

Cochlear amplification provides a boost to auditory sensitivity ranging from 100- to 1000-fold. It is thought to be maximal at high acoustic frequencies, in the tens of kilohertz range. There is ample evidence that prestin-driven OHC electromechanical activity underlies cochlear amplification, yet how can a voltage-dependent process that relies on a low-pass voltage sensor to drive mechanical activity work? We have previously estimated that mechanical responses at high acoustic frequencies would be markedly smaller than basilar motion, based on the cell's RC time constant. This problem has been addressed by many investigators, and many ostensible resolutions to the RC time-constant problem have been proposed (15,25,59–62). However, we must now consider the slow kinetics of prestin at physiological chloride levels that we have uncovered. This can only make matters worse. To be sure, we have recently found that eM magnitude rolls off faster than membrane voltage (28), and now we show that this roll-off corresponds to sensor charge activity (Fig. 4 B). It is possible that eM is not the main player and that OHC voltage-dependent stiffness, for which there is a wealth of evidence (63–65), is important.

On the other hand, we have found that the low-pass kinetic features of prestin can have high-frequency effects that could influence its ability to interact with basilar membrane/cochlear partition mechanics. Notably, we recently found a frequency-dependent phase lag in eM (re voltage) that is chloride dependent and is attributable to prestin's multistate kinetic features (28). Interestingly, phase lags are also predicted based on an electrodiffusion model of prestin (66), although the group that made that prediction suggested through additional modeling that power-law viscoelastic properties of the membrane could counter the effects of such lags (67). Whether such unusual viscoelastic properties characterize prestin's membrane environment is not known; however, our measured eM phase behavior in OHCs suggests no countering effects of viscoelasticity in the frequency range we studied. We propose that an accumulating phase lag at the molecular level could have a significant influence on the OHC's ability to inject power into

the cochlear partition, despite an associated magnitude roll-off dictated by low-pass sensor charge movement.

Removal of stray capacitance at C_m measuring frequencies

We use an Axon 200B patch clamp amplifier to measure OHC capacitance. Methodology was coded in jClamp and utilizes admittance measures at 2 frequencies to measure capacitance (1, 2). A linear cell model is depicted below, where R_s , R_m and C_m at each frequency (ω_0 , ω_1) are derived from the following equations.

$$\begin{aligned} a_0 &= \text{real}(Y) @ w_0 \\ a_1 &= \text{real}(Y) @ w_1 \\ b_0 &= \text{imag}(Y) @ w_0 \\ b_1 &= \text{imag}(Y) @ w_1 \end{aligned}$$

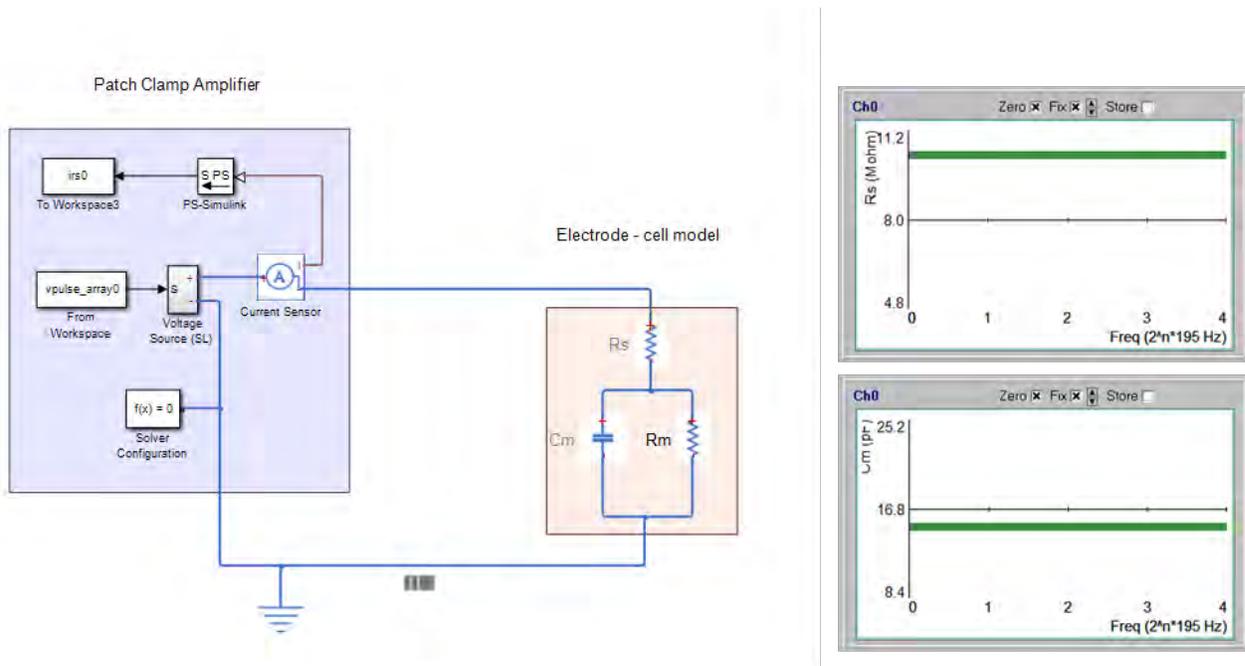

$$\begin{aligned} c_0 &= a_0^2 + b_0^2; \\ c_1 &= a_1^2 + b_1^2; \end{aligned}$$

$$b = (-0.5) * (-c_1 + c_0 + \sqrt{c_1^2 - 2 * c_1 * c_0 + c_0^2 - 4 * a_1 * a_0 * c_1 + 4 * a_1^2 * c_0 + 4 * a_0^2 * c_1 - 4 * a_0 * a_1 * c_0}) / (a_1 - a_0);$$

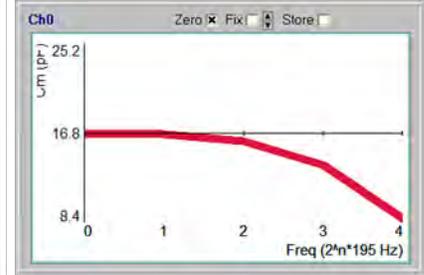

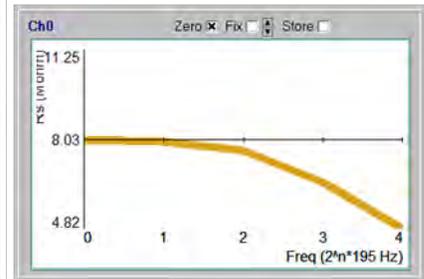

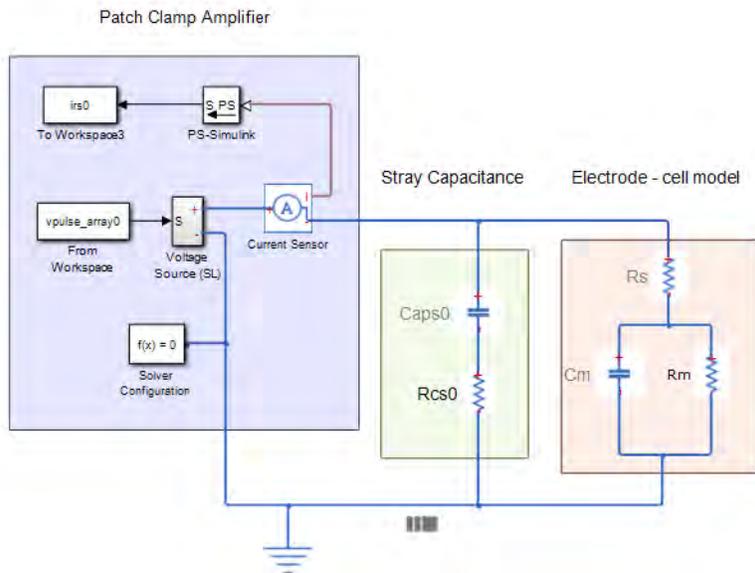

$$\begin{aligned} R_{s0} &= (a_0 - b) ./ (a_0.^2 + b_0.^2 - a_0 * b); \\ R_{m0} &= 1/b * ((a_0 - b).^2 + b_0.^2) ./ (a_0.^2 + b_0.^2 - a_0 * b); \\ C_{m0} &= (1 ./ (w_0 * b_0)) .* ((a_0.^2 + b_0.^2 - a_0 * b).^2) ./ ((a_0 - b).^2 + b_0.^2); \end{aligned}$$

$$\begin{aligned} R_{s1} &= (a_1 - b) ./ (a_1.^2 + b_1.^2 - a_1 * b); \\ R_{m1} &= 1/b * ((a_1 - b).^2 + b_1.^2) ./ (a_1.^2 + b_1.^2 - a_1 * b); \\ C_{m1} &= (1 ./ (w_1 * b_1)) .* ((a_1.^2 + b_1.^2 - a_1 * b).^2) ./ ((a_1 - b).^2 + b_1.^2); \end{aligned}$$

An example of our approach to remove stray capacitance is shown below using jClamp interfaced to a MatLab Simulink model. First, the model is evaluated without stray capacitance, where $R_s = 10$ Mohm, $R_m = 200$ Mohm, $C_m = 15$ pF.

Note that the solutions (R_s and C_m plotted) provide exact parameter estimates regardless of frequency of stimulation (or, in fact, regardless of component values). However, real world recording includes parasitic capacitances, termed stray capacitance, the inclusion of which is modeled below.

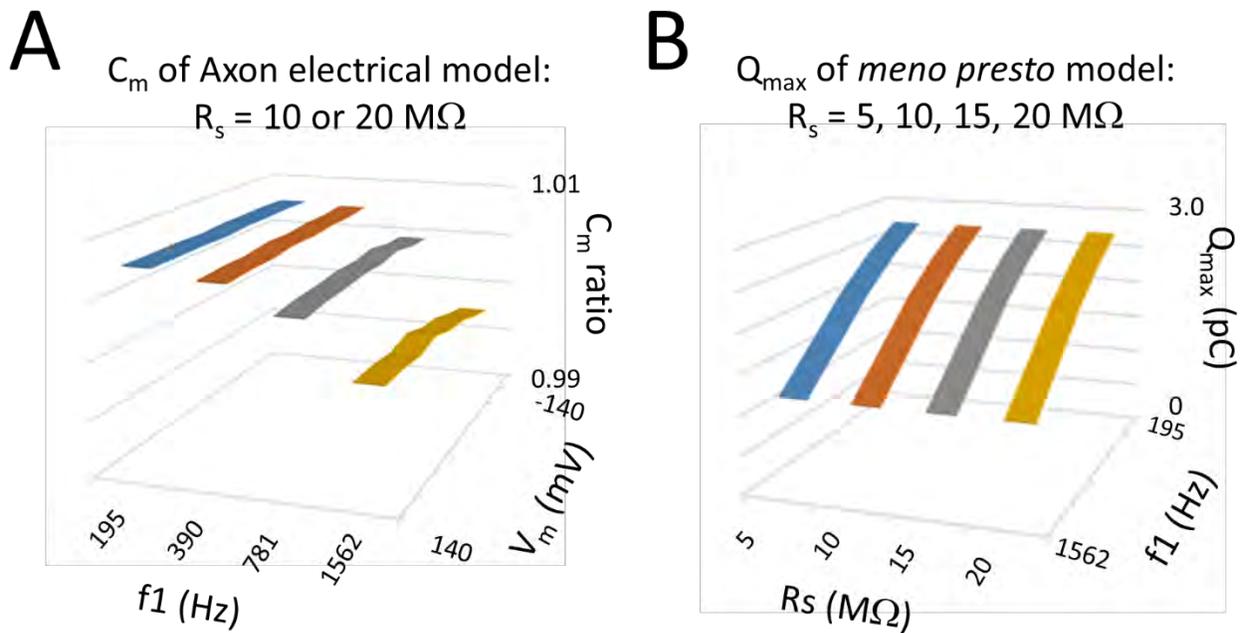

Here, utilization of the exact solutions above provides inaccurate measures, showing both R_s and C_m decreasing with increasing frequency. Both R_s and C_m are linear, and as defined are neither frequency nor voltage dependent. It behooves us then to remove stray capacitance effects during our recordings, since only without stray capacitance are our equations valid. Typically, stray capacitance effects (e.g., due to pipette holder and pipette – we use thick wall borosilicate glass pipettes coated with M-coat to reduce stray capacitance) are cancelled following gigohm seal formation during patch clamp recording by utilizing Axon 200B amplifier capacitance compensation controls. Unfortunately, this balancing procedure (using voltage steps in the time domain to cancel capacitive spikes) often is imperfect and stray capacitance effects can remain at our measurement frequencies. We attempt to overcome this problem after establishing whole cell configuration by stimulating in the frequency domain with a multi-frequency protocol that defines our interrogating frequencies. We then further fine balance with amplifier controls until calculated linear C_m and R_s are flat across frequency, as they should be. Any change in stray capacitance during the course of a recording session can be cancelled in this manner, e.g., if bath fluid levels changes. For our studies on synaptic activity (3-5), we can remove stray capacitance at any holding potential since the membranes of cells we study have no large intrinsic voltage dependent capacitance. However, in order to balance out stray capacitance for OHCs we hold the cell at positive potentials where linear capacitance dominates. Having succeeded in minimizing confounding effects of stray capacitance on linear membrane capacitance measurements across frequency, we then can investigate the frequency dependence of **NLC**. As detailed in the *Methods* section of our manuscript, C_m is measured at a range of holding potentials to generate a C_m - V_m plot that is fit with eq. 1, enabling extraction of Boltzmann characteristics, Q_{max} , V_h , and z . When sensor charge (Q_{max}) is plotted versus frequency of interrogation, we find that **NLC** is frequency dependent but linear capacitance is frequency independent (Fig. 2), confirming stray capacitance cancellation at our measuring frequencies. Our modelling indicates that the frequency dependence of **NLC** relates to the transition rates between conformational states of prestin.

R_s effects on membrane voltage drop and clamp time constant are removed with our methodology

Equipment frequency response (magnitude and phase of amplifier and associated equipment in the recording path) is corrected for by generating a calibration table across measurement frequencies, which is applied post-hoc to correct data for system response characteristics. This is a standard approach in all areas of system identification, including patch clamp assessment of C_m (6).

Our dual-sine analysis fundamentally corrects for effects of R_s , since it works by finding the parameter solutions of the total admittance of the patch clamp-cell circuit (as modelled above), given a known voltage across the total admittance. Thus, C_m derivation by this method takes into account the voltage drop across R_s at any frequency, providing true measures of C_m across frequency. Fits to C_m - V_m (or Q - V_m , in the case of current integrations) are made using corrected V_m values based on measured R_s , namely, $V_m = V_{com} - I_{rs} * R_s$, where the cell has been held sufficiently long to reach steady state voltage levels (in our case, for hundreds of ms before C_m analysis). Below, we show with electrical and mathematical models that R_s effects do not interfere with our C_m measures.

- A) An electrical model cell was used to measure C_m , following stray capacitance cancellation as above. Model parameters were $R_s=10$ or $20 \text{ M}\Omega$, $R_m = 500 \text{ M}\Omega$, $C_m = 33 \text{ pF}$. The plot shows that the ratios of $C_m@20 \text{ M}\Omega / C_m@10 \text{ M}\Omega$ measured at a range of holding potentials and frequencies (primary f_1 frequency of dual-sine stimulus shown) are essentially identical (ratio ~ 1), regardless of R_s value. This indicates that R_s (with its influence on clamp time constant) does not affect our C_m frequency response measures in the absence of stray capacitance. Average C_m across voltages at 195 Hz was 33.0 pF for $10 \text{ M}\Omega R_s$ and 33.2 pF for $20 \text{ M}\Omega R_s$. At 1562 Hz values were 33.1 pF for $10 \text{ M}\Omega R_s$ and 33.0 pF for $20 \text{ M}\Omega R_s$. Differences arise from variability in stray capacitance cancellation, as is evident from model evaluations in B) in the absence of stray capacitance.
- B) The *meno presto* model (7) was used to measure C_m - V_m functions that were fit to extract Q_{max} . R_s ranging from 5 - $20 \text{ M}\Omega$ has no effect on the magnitude or frequency response of NLC (Q_{max}), which is frequency-dependent due to model transition rates. Frequency is (plotted on a linear scale). Chloride set to 140 mM . $R_m=200 \text{ M}\Omega$, $C_{lin}=20 \text{ pF}$.

Article

Chloride-driven Electromechanical Phase Lags at Acoustic Frequencies Are Generated by SLC26a5, the Outer Hair Cell Motor Protein

Joseph Santos-Sacchi^{1,2,3,*} and Lei Song¹¹Surgery (Otolaryngology), ²Neurobiology, and ³Cellular and Molecular Physiology, Yale University School of Medicine, New Haven, Connecticut

ABSTRACT Outer hair cells (OHC) possess voltage-dependent membrane bound molecular motors, identified as the solute carrier protein SLC26a5, that drive somatic motility at acoustic frequencies. The electromotility (eM) of OHCs provides for cochlear amplification, a process that enhances auditory sensitivity by up to three orders of magnitude. In this study, using whole cell voltage clamp and mechanical measurement techniques, we identify disparities between voltage sensing and eM that result from stretched exponential electromechanical behavior of SLC26a5, also known as prestin, for its fast responsiveness. This stretched exponential behavior, which we accurately recapitulate with a new kinetic model, the *meno presto* model of prestin, influences the protein's responsiveness to chloride binding and provides for delays in eM relative to membrane voltage driving force. The model predicts that in the frequency domain, these delays would result in eM phase lags that we confirm by measuring OHC eM at acoustic frequencies. These lags may contribute to canceling viscous drag, a requirement for many models of cochlear amplification.

The outer hair cell (OHC) is one of two receptor cell types in the organ of Corti, but unlike the inner hair cell it displays electromotile behavior distinct from any other form of cellular motility (1–4). OHC electromotility (eM) arises from the concerted action of millions of molecular motors embedded in the lateral membrane of the cell. They respond directly to membrane voltage and evidence reciprocal activity; namely, they are piezoelectric-like (5–7). Indeed, there is clear evidence that surface area changes accompany state transitions in the motor [see (8)]. The identification of these motors as members of the anion transporter family SLC26 (9), of which prestin is the 5th member (a5), underscores an interesting molecular evolution designed to boost the performance of auditory sensitivity and selectivity. This enhancement is known as cochlear amplification (10).

A class of cochlear models requires an electromechanical phase disparity for effective cochlear amplification (11–13), OHC eM lagging receptor potentials. Traditionally, these models assign the mechanism to processes other than the OHC itself. The phase lag provides for the properly timed injection of mechanical force into the cochlear partition to counter viscous detriment. Most molecular models of prestin behavior envision tightly coupled interactions between membrane voltage and eM, arising from sensor charge movements obeying Boltzmann statistics (14–20). Thus, Boltzmann characteristics of sensor charge and eM, namely Q_{\max} / eM_{\max} and $Q / V_h / eM / V_h$, are commonly believed to tightly correspond. However, we recently showed significant uncoupling of these character-

istics depending on rate and polarity of voltage stimulation and on intracellular chloride level (21). We showed that a slow intermediate transition placed between prestin's chloride binding transition and the voltage dependent transition responsible for eM could qualitatively account for the data, and we surmised that a molecularly based phase lag should arise. In this study we test this hypothesis by measuring eM at acoustic frequencies and find that indeed substantial frequency dependent phase lags are produced between membrane voltage and eM, showing chloride dependence. An enhanced stretched-exponential kinetic model, termed the *meno presto* model of prestin, nicely fits the data, whereas a model lacking the intermediate transitions fails.

METHODS

Whole cell recordings were made from single isolated OHCs from the organ of Corti. Hartley albino guinea pigs were overdosed with isoflurane, the temporal bones excised and the top turns of the cochleae dissected free. Enzyme treatment (1 mg/ml Dispase I, 10 min) preceded gentle trituration, and isolated OHCs were placed in a glass-bottom recording chamber. Either a Nikon E600-FN microscope with 40× water immersion lens or an inverted Nikon Eclipse TI-2000 microscope with 40× lens was used to observe cells during voltage clamp. Experiments were performed at room temperature.

Solutions

Chloride levels were set to surround the 10 mM intracellular level in intact OHCs (22). Valid measures of membrane capacitance required an ionic blocking solution to remove ionic currents. The base high Cl solution contained (in mM): NaCl 100, TEA-Cl 20, CsCl 20, CoCl₂ 2, MgCl₂ 1, CaCl₂ 1, and Hepes 10. Lower chloride concentrations (10, 1, and 0.1 mM) were achieved by substituting chloride with gluconate. Base intracellular solutions contains (in mM): CsCl 140, MgCl₂ 2, Hepes 10, and EGTA 10.

To unequivocally set intracellular chloride levels in the subplasmalemmal space of the OHC, both intracellular and extracellular chloride concentrations were set equal. All chemicals used were purchased from Sigma (Sigma-Aldrich, St. Louis, MO).

Cell capacitance and mechanical response

An Axon (Molecular Devices, Sunnyvale, CA) 200B amplifier was used for whole cell recording. Coupled voltage ramps (depolarizing followed immediately by hyperpolarizing ramp) of 100 and 500 ms were delivered to the cells from a holding potential of 0 mV. No averaging was done.

Nonlinear capacitance was measured using a continuous high resolution (2.56 ms sampling) two-sine stimulus protocol (10 to 20 mV peak at a primary frequency of 390.6 and harmonic of 781.2 Hz) superimposed onto the voltage ramps (23,24). It is mandatory that ionic conductances be blocked to insure accurate results, and imperative that system calibration be performed, as specified in our software design, jClamp (Sciosoft, Ridgefield, CT). Capacitance data were fit to the first derivative of a two-state Boltzmann function (15) as follows:

$$C_m = Q_{max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin},$$

$$b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right)$$

providing Q_{max} , the maximum nonlinear charge moved; V_h , the voltage at peak capacitance or equivalently, at half maximum charge transfer; z , the valence; and C_{lin} , the linear membrane capacitance.

Simultaneous eM measurements were made either with fast video recording or photo diode. A Prosilica GE680 camera (Allied Vision Technologies, Exton, PA) was used for video measures, and details can be found in a previous publication (21). For photodiode measures, the image of the OHC apical region was projected onto a photodiode to measure cell movement, in a similar fashion to the method of Clark et al. (25). Two aligned, same optical axis, microscope cameras (Logitech webcam C650, Newark CA) were used: one to image the cell during patch recording and the other to ensure proper image placement. The inner camera (Fig. 1 A, 1) sensor area (white bordered quadrangles), upon which a 1.1×2.67 mm photodiode (SD076-11-31-211, Advanced Photonics, Ann Arbor, MI) was mounted (yellow boxed area), monitored only the OHC apex, whereas the other camera (Fig. 1 A, 2) sensor region (which actually viewed the whole cell) was used for patch electrode placement and monitoring image rotation and x-y shifts utilizing a dove prism and gimbaled mirror, respectively. Video capture was made with the wide field camera to determine actual cell displacement magnitude. With either the Prosilica camera or the photo diode approach, the edge of the cuticular plate was used to track OHC length change, the patch electrode providing a fixed point at the basal end of the cell. For photodiode measures, calibration was additionally made by movements of the OHC image via gimbaled mirror tilt (see Fig. 5). Sigmoidal fits (four parameters) provided estimates of V_h , maximal movement, and slope factor, b . Shift of motility against NLC (NonLinear Capacitance) is calculated by subtracting NLC V_h from eM V_h .

AC analysis of membrane currents (I_m) and eM were made by stimulating cells with voltage bursts at harmonic frequencies from 12.207 to 6250 Hz, with a $10 \mu s$ sample clock. Voltage bursts were ramped on and off to avoid transients. Magnitude and phase of responses were computed by FFT (fast Fourier transform) in jClamp. Fits in Matlab were made using least squares simultaneously on the transformed real and imaginary components of all spectral components of both eM and I_m . The effects of turgor pressure and magnitude of voltage stimulation on eM phase were also investigated. Turgor pressure was modified by applying pressure to the patch pipette using an ALA's High Speed Pressure Clamp, HSPC-1 (Westbury, NY).

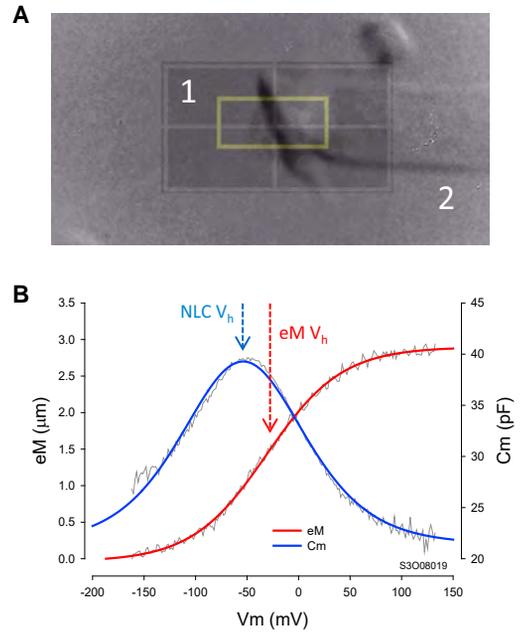

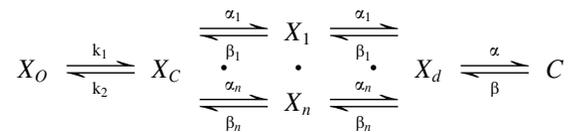

FIGURE 1 Electromechanical measures of prestin activity. (A) Image of OHC apical region was projected onto a photodiode to measure cell movement. (B) Simultaneous measures of OHC NLC and eM, measured via photodiode. No averaging. Note that NLC V_h and eM V_h differ (arrows) with that of eM shifted rightward. Chloride level was 1 mM. Model assessment

A kinetic model, termed the *meno presto* model of prestin, was used to fit the eM data. The *meno presto* model (Fig. 3) was assessed using Matlab Simulink in conjunction with jClamp. It is an extension of the simple model in Song and Santos-Sacchi (2013) that now introduces stretched exponential behavior in the intermediate transition between chloride binding and voltage dependency.

X_o state is unbound by anion. X_c state is bound by anion but intrinsic voltage sensor charge is not responsive to membrane electric field. A slow, multi-exponential conformational transition to X_d state via X_n states enables voltage sensing within the electric field. Depolarization moves positive sensor charge outward, simultaneously resulting in compact state C, which corresponds to cell contraction. The differential equations are as follows:

$$\frac{dX_o}{dt} = X_c \cdot k_2 - X_o \cdot [Cl^-]k_1$$

$$\frac{dX_c}{dt} = X_o \cdot [Cl^-]k_1 + \sum_{n=1}^{27} X_n \cdot \beta_n - X_c \cdot k_2 - \sum_{n=1}^{27} X_c \cdot \alpha_n$$

$$\frac{dX_n}{dt} = X_c \cdot \alpha_n + X_d \cdot \beta_n - X_n \cdot \alpha_n - X_n \cdot \beta_n$$

$$\frac{dX_d}{dt} = C \cdot \beta + \sum_{n=1}^{27} X_n \cdot \alpha_n - X_d \cdot \alpha - \sum_{n=1}^{27} X_d \cdot \beta_n$$

$$\frac{dC}{dt} = X_d \cdot \alpha - C \cdot \beta$$

where $\alpha_n = A \cdot (\exp(-(n-1)))^w$, $\beta_n = \alpha_n$, $w = 0.6$, $A = 2.5e4$ for $n = 0.25$, $k_1 = 1.5e5$, $k_2 = k_1 \cdot k_d$, $k_d = .012$, $z = 0.7$, $nPres = 25e6$, $\alpha = 1.3e6 \cdot \exp((z \cdot F \cdot V_m / (2 \cdot R \cdot T)))$, $\beta = 7.7e4 \cdot \exp((-z \cdot F \cdot V_m / (2 \cdot R \cdot T)))$. Equivalence of α_n and β_n transition rates assures detailed balance of the reaction scheme (26). Parameters were varied until a good approximation of the data was obtained. We used 27 intermediate transitions to get as many exponential components such that a range of frequencies could be fit by the model. A single exponential intermediate transition will only influence one small frequency range, as we showed in our PNAS paper (21). Basically the prestin model is frequency sensitive, showing effects across our measured frequency range.

jClamp provides an automation link to Matlab that allows voltage stimuli to be delivered to and current responses to be obtained from Simulink models. Solutions were obtained with the ode45 (Dormand-Prince) solver at a fixed absolute tolerance of 10^{-6} . The *meno presto* model was interfaced to jClamp via a model of the patch clamp amplifier and OHC. The linear component of the patch-cell model was composed of R_s (pipette resistance) in series with a parallel combination of R_m (membrane resistance) and C_{lin} (linear capacitance). For the AC data fits, an additional uncompensated stray pipette capacitance modeled as a series combination of resistance (R_p) and capacitance (C_p) was included (24). Given the above *meno presto*

model parameters, fits of AC data were made with patch clamp parameters of $R_s = 6.1 \text{ M}\Omega$, $R_m = 275 \text{ M}\Omega$, $C_{lin} = 23 \text{ pF}$, $R_p = 15 \text{ M}\Omega$, $C_p = 0.4 \text{ pF}$ for the 140 mM chloride condition, and $R_s = 6.6 \text{ M}\Omega$, $R_m = 265 \text{ M}\Omega$, $C_{lin} = 26.5 \text{ pF}$, $R_p = 10 \text{ M}\Omega$, and $C_p = 0.4 \text{ pF}$ for the 1 mM chloride condition. The exact same voltage stimuli and exact same analysis of model data were performed as with the biophysical data. For comparison purposes, a model emulating a fast two-state Boltzmann, with the intermediate transitions removed and k_1 rate constant set to $1.5e10$, was evaluated, as well. Mechanical contraction data of the model, namely eM, was taken as the accumulated residence in the C state (see Fig. 3).

RESULTS

Under whole cell voltage clamp, OHCs change length when membrane voltage is altered. Fig. 1 B shows an example of an OHC mechanical response (eM) measured with photodiode during a voltage ramp. Simultaneously, a bell-shaped nonlinear capacitance (NLC) is measured, an estimate of prestin's voltage sensor charge movement. Note that the arrows depicting NLC V_h and eM V_h are separated, with eM shifted rightward along the voltage axis. This disparity underscores an uncoupling between voltage sensor and eM.

The magnitude of this V_h disparity is dependent both on the polarity of the voltage ramp that is used to obtain C_m - V_m functions and on intracellular chloride level. Hyperpolarizing ramps (Fig. 2 A) produce a maximal disparity

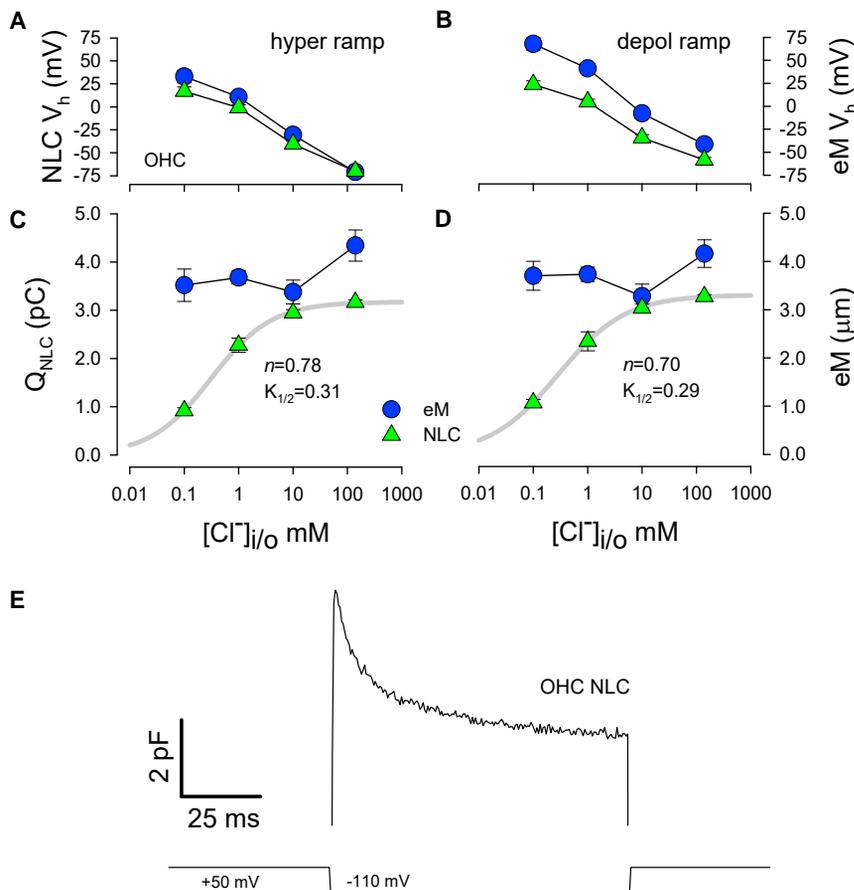

FIGURE 2 Chloride dependence of Boltzmann characteristics of eM and NLC as a function of depolarizing and hyperpolarizing ramps. (A) NLC V_h disparities arise as chloride levels are decreased, with effects being larger on eM, and larger disparities being observed with depolarizing ramps (B). (C) Q_{max} , determined from NLC fits, decreases as chloride levels are lowered. Hill coefficient (n) and $K_{1/2}$ are shown. Contrarily, eM magnitude is little affected. Similar results are obtained with depolarizing ramps (D). Plots are of average (\pm se) results from combined responses to 100 ms and 500 ms ramps. ($n = 5$ to 15). (E) Stretched exponential changes in OHC NLC occur during a constant voltage step from +50 mV to -110 mV. 4 μsec clock, C_m inspection resolution 0.512 ms. To see this figure in color, go online.

appreciably less than depolarizing ramps (Fig. 2 B), each polarity, however, showing larger disparities as chloride levels are reduced. Plots show means and se (5 to 15 cells per point) of the average responses to 100 and 500 ms ramps. At the 0.1 mM chloride level, eM V_h was 32.9 ± 6.9 mV and NLC V_h was 16.9 ± 4.8 mV for hyperpolarizing ramps, whereas for depolarizing ramps eM V_h was 67.8 ± 6.6 mV and NLC V_h was 23.8 ± 3.9 mV ($n = 5$). In individual cells with faster ramps, we have observed such disparities greater than 60 mV. Similarly, disparities in Q estimates and eM measures are found as chloride levels are lowered (Fig. 2 C and D). Whereas estimates of Q from NLC are highly chloride dependent, showing a $K_{1/2}$ of 0.3 mM from Hill fits, eM changes very little across chloride levels. These data indicate an uncoupling between sensor charge movement determined from NLC and OHC mechanical activity. In simple two-state models of electromotility, no disparities are expected.

Thus, we believe that this uncoupling results from an additional slow molecular transition in prestin that derives from a more complicated molecular scheme (21); this slow process is readily evidenced as a stretched exponential component of OHC C_m when membrane voltage is stepped. Fig. 2 E illustrates the resulting complex behavior in C_m during a fixed step from +50 mV to -100 mV, showing an initial rapid rise in C_m followed by a multi-exponential decay with tau components ranging from millisecond to seconds (27). Unfortunately, our recently developed model (21), which introduces an intermediate transition between chloride binding and voltage-dependent mechanical activity, cannot account for the observations shown in Fig. 2 because it provides only a single exponential transition. To more accurately account for our experimental findings, we expanded on this model to give stretched exponential behavior. A cartoon of the new *meno presto* model is shown in Fig. 3 and is described in detail in the Methods section. As can be seen in Fig. 4, the model results show marked simi-

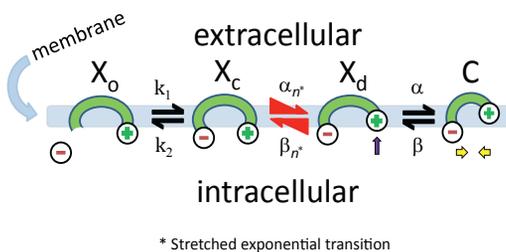

FIGURE 3 Stretched kinetic model of prestin activity within the plasma membrane. X_o state is unbound by anion. X_c state is bound by anion but intrinsic voltage sensor charge is not responsive to membrane electric field. Slow, multi-exponential conformational transition to X_d state via X_n state enables voltage sensing of electric field. Depolarization moves positive sensor charge outward, simultaneously resulting in compact state C, which corresponds to cell contraction. Equivalence of α_n and β_n transition rates assures detailed balance of the reaction scheme. To see this figure in color, go online.

larities to the biophysical data, with V_h disparities showing chloride dependence and depolarizing ramps producing larger disparities (Fig. 4 A and B). $K_{1/2}$ values for NLC-derived Q are quantitatively similar to those in OHCs (Fig. 4 C and D), and importantly, stretched exponential behavior of C_m arises during step voltages (Fig. 4 E). To reiterate, these results are not observed with our previous single exponential model (21). Thus, we believe that an intermediate transition with stretched exponential kinetics is required to recapitulate the biophysical data.

To appreciate the impact of prestin's complex behavior on audition, we measured the magnitude and phase of OHC eM at acoustic frequencies. We stimulated cells with a nominal 50 mV peak AC voltage command under whole cell voltage clamp. Such magnitudes allowed us to generate eM magnitudes easily measurable via photodiode with fairly low number of averages to ensure maintenance of patch recording and limit cell damage. Because we were especially interested in phase behavior of the OHC eM, we ensured that phase behavior was not stimulus magnitude dependent (Fig. 5 A). We also determined that phase behavior was not dependent on steady-state turgor pressure, because this may vary among cells (Fig. 5 B). Though turgor pressure did not affect phase, magnitude of eM increased with pressure. Thus, cell magnitudes are reported as relative to lowest frequency response. Fig. 6 shows the average (\pm se; $n = 5$ to 8) magnitude and phase of both measured membrane current (I_m , blue symbols) and eM (red symbols) for two groups of cells under (A) 140 mM chloride and (B) 1 mM chloride conditions. The correspondingly colored solid lines are fits with the *meno presto* model, quantitatively falling within the standard errors for each condition at every frequency. Model parameters are reported in the Methods section. The thick solid green lines depict the membrane voltage magnitudes and phases. The striking observation is that there is a frequency dependent phase lag between V_m and eM, for both low and high chloride conditions, with the lag being significantly larger at several frequencies in the low chloride condition (asterisks in Fig. 7). Furthermore, the eM magnitude roll-off is greater than that of V_m , showing some chloride level dependence. For comparison, the V_m and eM magnitude and phase of a simple fast kinetic model (see Methods) is plotted (eM, red square symbols; V_m , dark green dashed line) and demonstrates neither phase lags nor magnitude disparities between the two. Indeed, the phase and magnitude of biophysical data cannot be fit by such simple models. We conclude that a slow, stretched exponential behavior of prestin generates the disparities between membrane voltage/sensor charge movement and electromotility.

DISCUSSION

Our data show marked uncoupling of OHC eM, voltage sensor charge movement and membrane voltage. The

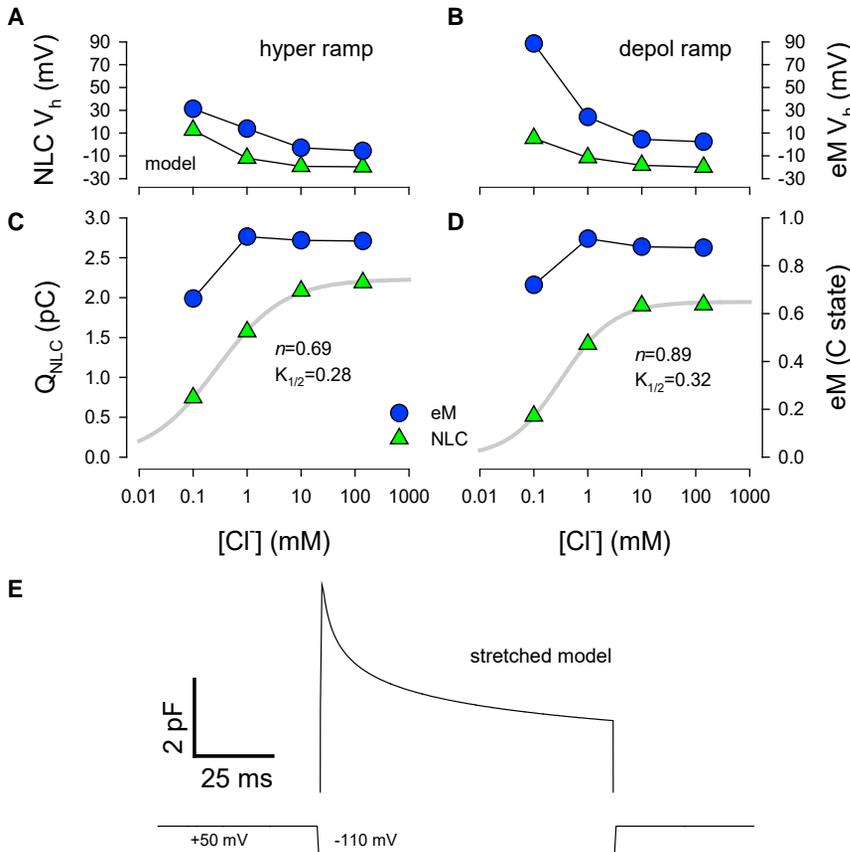

FIGURE 4 Stretched kinetic model recapitulates Boltzmann characteristics of eM and NLC. (A) In the model, NLC V_h disparities arise as chloride levels are decreased, with effects being larger on eM, and larger disparities being observed with depolarizing ramps (B). (C) Q_{NLC} , determined from NLC fits, decreases as chloride levels are lowered. Hill coefficient (n) and $K_{1/2}$ are shown. Contrarily, eM magnitude is little affected. Similar results are obtained with depolarizing ramps (D). (E) Stretched exponential changes in model NLC occur during a constant voltage step from +50 mV to -110 mV. 4 μs clock, C_m inspection resolution 0.512 ms. To see this figure in color, go online.

ensuing disparities in those measures are chloride dependent, with lower chloride levels producing greater uncoupling. In the frequency domain, these disparities display as a differential roll-off in magnitude and a phase lag between membrane voltage and electromotility. The *meno presto* kinetic model that we developed fits the data quantitatively, and illustrates how molecular delays introduced by multi-exponential transitions can influence OHC electro-me-

chanics. A simple model without a stretched-exponential intermediate transition cannot account for our data.

Chloride and the OHC

Prestin is a member of the SLC26 solute carrier family and as such is expected to bear archetypal interactions with anions. Indeed, early experiments on OHC NLC pointed in this

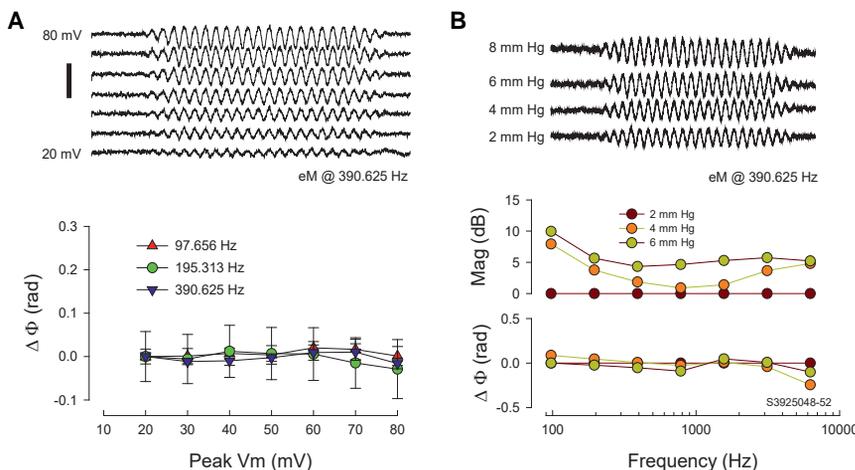

FIGURE 5 Effects of V_m magnitude and turgor pressure on eM phase. (A) Command magnitude was varied from 20 to 80 mV peak at 98, 195, and 391 Hz. Example traces are in top panel; average (\pm se) phase (re: 20 mV response) is plotted in bottom panel. No differences in phase were found. (B) Turgor pressure was varied from 0 to 8 mm Hg via the patch pipette. Though magnitude increased with pressure, phase remains unaffected. Example traces are in top panel (low frequency responses to left of eM response were calibration movements of the image). Note that smart averaging (see Methods) was performed for each trace, hence the different noise levels. An example of frequency dependence is in bottom panel. No changes were observed. Average results for three cells at 390 Hz (mean \pm se @ 4, 6, and 8 re: 2 mm Hg condition) are -0.063 ± 0.02 , -0.055 ± 0.04 , and -0.019 ± 0.06 , respectively. All phase analysis was via FFT. Scale bar: 3 μm . Chloride is 140 mM. To see this figure in color, go online.

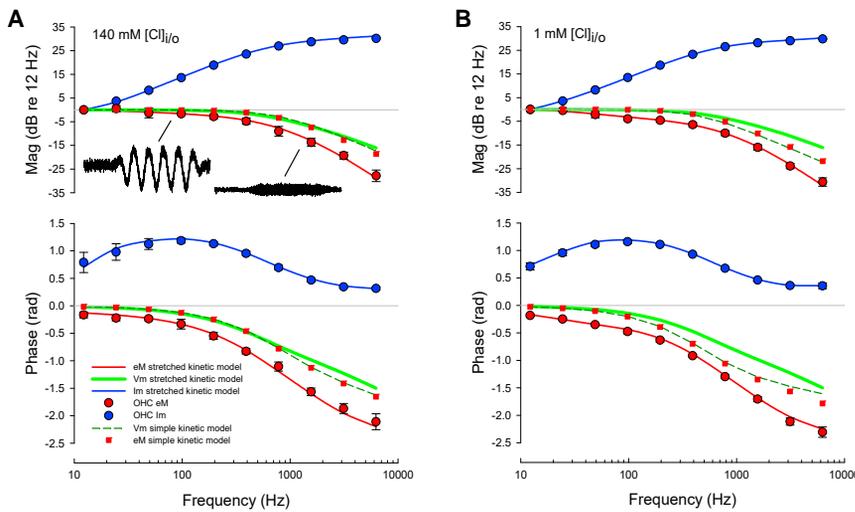

FIGURE 6 Chloride effects on magnitude and phase of simultaneously measured membrane current and eM. High frequency mechanical responses were measured with a photodiode under whole cell voltage clamp. eM waveforms shown are averaged responses to sinusoidal voltage bursts of 98 (1.9 μm pk-pk response) and 1563 Hz. Frequency response was measured up to 6.25 kHz and subsequently analyzed by FFT. Smart averaging in jClamp (see Methods) assured that a minimum number of averages was performed to establish a given signal-to-noise ratio, thereby limiting cell stimulation. Because of robust mechanical response, repeated stimulation can cause loss of cell recording. In these examples, the 98 Hz response was averaged eight times, and the 1563 Hz response was averaged 64 times. (A) 140 mM condition. Fundamental magnitude and phase of OHC I_m (blue) and eM (red) are plotted. Standard errors are given and mostly fall within

symbol size. Solid red and blue lines are model fits (see Methods). The solid green line is the membrane voltage of the patch clamp-kinetic model. Note frequency dependent phase lag between membrane voltage and eM, and faster roll of eM magnitude than membrane voltage. For comparison, a fast simple kinetic model without intermediate transitions is plotted. V_m and eM of that simple model show neither phase nor magnitude differences, as expected for a simple 2-state model of prestin activity. (B) 1 mM chloride condition. Notable differences from (A) include a greater magnitude roll-off in eM vs. V_m and a greater frequency dependent phase lag. The simple model again shows no differences between V_m and eM magnitude and phase. To see this figure in color, go online.

direction. In the mid-1990s, the anion salicylate was shown to interfere with NLC and eM, working intracellularly with a Hill coefficient of 1 (28,29). Additionally, the anionic, lipophilic molecule tetraphenylborate (TPB⁻), unlike its cationic counterpart tetraphenylphosphonium (TPP⁺), modulates NLC (30). Thus it was not totally unexpected that normally residing intracellular anions, including chloride and bicarbonate, were found to influence prestin activity (31). We have amassed evidence that chloride ions modulate prestin in an allosteric-like manner, where intrinsic residue

charge provides for voltage sensing (21,32–37). In some ways, the *meno presto* model, which fashions chloride as an enabler of voltage sensitivity, possesses qualities of an allosteric process whereby binding of a ligand to a remote site (or in response to other biophysical forces) induces a conformation state change that promotes the primary function of the protein (38,39), in our case electromotility. Though the occurrence of anion transport in prestin is a controversial issue (33,40–43), we believe that the slow intermediate transition that we have identified is related to prestin's ancestral transporter legacy.

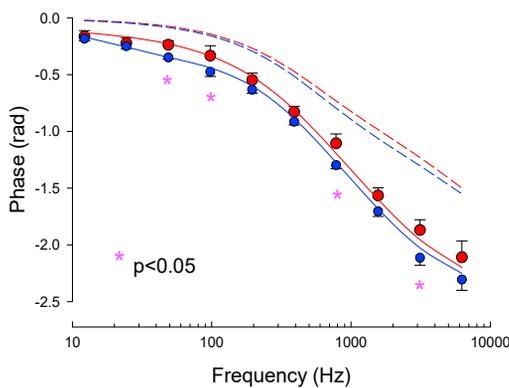

FIGURE 7 Expanded, overlapped plot of phase from high and low chloride conditions. Red symbols are from OHCs with 140 mM Cl intracellular pipette solutions, and blue symbols with 1 mM Cl solutions. Asterisks denote significantly different phases ($p < 0.05$, t -test, 2-tailed). Red dashed line is estimated membrane voltage phase under high chloride condition, and the blue dashed line under the 1 mM Cl condition. Regardless of chloride condition, the stretched exponential behavior of prestin results in phase lags in eM versus membrane voltage. Data from Fig. 6. To see this figure in color, go online.

Coupling between charge movement and electromotility

Our data show an apparent dissociation between voltage sensor charge movement and electromotility. For example, V_h of the two during depolarizing ramps under 0.1 mM chloride conditions can differ by greater than 60 mV, and NLC Q_{max} is reduced by one-third with little effect on eM. The reason for the disparity is the existence of an intermediate transition between chloride binding and mechanical response. The delays afforded by the stretched exponential transition may appear to separate sense and effect, but do not indicate that the two are unrelated. An analogy between voltage-dependent ion channels can be made where the current onset after a step voltage is delayed (44). The greater the number of intermediate states before pore opening, the greater is the delay in current onset. In our case, we observe the mechanical response delayed relative to sensing; however, according to our *meno presto* kinetic model the delay

need not be imposed between charge movements per se and eM (C state occupancy). In fact, in a linked reaction scheme, all transitions (including voltage-independent ones) influence each other (45–47). Thus, what appears to be an event before voltage sensing (chloride binding and an exponential evolution into voltage dependence) does in fact alter the balance of transition rates between states X_d and C, thereby altering V_h during fast ramps. Indeed, the hysteresis and charge immobilization that we initially observed in the Q - V_m response of OHCs (23) and in prestin expressing cells (48) must arise from a process that is not expected of simple fast two-state Boltzmanns, such as previous models of prestin (14–20). Consequently, because of the real complexity of prestin kinetics phase lags between V_m and eM will ensue.

Phase behavior of OHC electromotility

The phase of OHC eM has been studied previously. In 1992, in an effort to confirm voltage vs. current dependence of eM, we measured magnitude and phase in a similar manner to our experiments here (49). We concluded that the phase of eM followed predicted V_m under whole cell voltage clamp. This complemented our previous work showing eM voltage dependence (4). However, whereas there was apparent correspondence between V_m and eM phase, perusal of the phase data in our previous manuscript clearly indicates a significant phase lag in all cells studied. In fact, we had corrected for some phase discrepancies by introducing delays in the fits, and in low frequency data by shifting V_m and eM to overlap (see Fig. 5 A in (49)). Our current work indicates that those delays were actually correcting for the kinetic behavior of prestin. Indeed, our present eM phase data can be approximated by a delay that is inversely proportional to frequency. In this study, unlike our previous work, we did not use series resistance compensation, which can introduce lags in measured phase. Frank et al. (50) measured magnitude and phase of OHC eM using an extracellular microchamber technique, which although allowing for extended frequency perturbation, provides for neither direct membrane voltage control nor measures of membrane current (51). They provided corrected zero lag phase plots that were flat out to tens of kilohertz. Still, to fully account for the frequency response they needed to model the response with an electrical and mechanical component, showing second-order resonant effects to fit their data. Though the microchamber effectively produces a simple capacitive divider for the linear-membrane capacitance, any effects on a frequency-dependent, voltage-dependent and polarity dependent capacitance such as that resulting from OHC sensor charge movement is presently unresolved. Thus, they may have been inadvertently correcting for prestin-based phase characteristics. It will be interesting to see how simulations of the *meno presto* model compare with their data when inserted into a microchamber model. Regardless, the ability to simultaneously fit both actual I_m

magnitude and phase, and eM magnitude and phase, as we have done in this study (and cannot be done with the microchamber approach), is important for accurately modeling eM data. We are confident that the correspondence of our *meno presto* model responses to the measured frequency response of eM, to the measured stretched exponential behavior of NLC, and to the measured chloride dependence of NLC and eM indicate a successful understanding of prestin behavior on OHC electromechanical behavior.

Our identification of substantial eM phase lag leads us to concur with early modelers on its role in cochlear amplification. A preponderance of cochlea models find that a phase lag between receptor potential and eM is required for effective cancellation of viscous drag expected from the cochlea environment (11–13). Indeed, the dependence of phase on prestin's stretched exponential behavior that we find must also be significant, because it augments the phase lag toward the 90 degree requirement of cochlear modelers. We have previously shown that altering perilymphatic chloride levels, which effectively alters intracellular chloride concentration via the lateral membrane chloride conductance, G_{metL} (36), can reversibly modify cochlear amplification (22). Because we have shown here that the magnitude of eM is little affected by chloride level, we conclude that phase characteristics provided by the evolution of chloride-bound prestin into a voltage-enabled state predominantly underlie the OHC's role in contributing to hearing sensitivity and selectivity by cochlear amplification. Furthermore, contrary to all cochlear models, we place a significant component of the phase lag not on cochlear partition super structures, but within the OHC motor itself. Finally, we note that implications of our in vitro observations for in vivo performance, where additional loads may impinge on the OHC requires further exploration. In fact, any biophysical study of hair cells in isolated or explant conditions in the absence of in vivo structures, such as those evaluating electro-mechanics or stereociliary transduction mechanisms, require cochlear modeling to assess physiological impact.

This research was supported by NIH NIDCD grant DC00273 to JSS.

Background: The SLC26a5 outer hair cell motor drives electromechanical behavior of this sensory/effector cell.

Results: A kinetic model fits the combined effects of salicylate and chloride on prestin-associated membrane capacitance.

Conclusion: Data support a theory whereby prestin differentially changes area state upon binding of chloride and salicylate.

Significance: The model of prestin activity points to the molecular underpinnings of electromotility in outer hair cells.

The outer hair cell is electromotile, its membrane motor identified as the protein SLC26a5 (prestin). An area motor model, based on two-state Boltzmann statistics, was developed about two decades ago and derives from the observation that outer hair cell surface area is voltage-dependent. Indeed, aside from the nonlinear capacitance imparted by the voltage sensor charge movement of prestin, linear capacitance (C_{lin}) also displays voltage dependence as motors move between expanded and compact states. Naturally, motor surface area changes alter membrane capacitance. Unit linear motor capacitance fluctuation (δC_{sa}) is on the order of 140 zeptofarads. A recent three-state model of prestin provides an alternative view, suggesting that voltage-dependent linear capacitance changes are not real but only apparent because the two component Boltzmann functions shift their midpoint voltages (V_H) in opposite directions during treatment with salicylate, a known competitor of required chloride binding. We show here using manipulations of nonlinear capacitance with both salicylate and chloride that an enhanced area motor model, including augmented δC_{sa} by salicylate, can accurately account for our novel findings. We also show that although the three-state model implicitly avoids measuring voltage-dependent motor capacitance, it registers δC_{sa} effects as a byproduct of its assessment of C_{lin} , which increases during salicylate treatment as motors are locked in the expanded state. The area motor model, in contrast, captures the characteristics of the voltage dependence of δC_{sa} , leading to a better understanding of prestin.

The piezoelectric-like motor molecule SLC26a5 (prestin) underlies the ability of OHC² to enhance hearing (1–3). This boost in performance is driven by a voltage-dependent mechanical response, termed somatic electromotility (4–6).

² The abbreviations used are: OHC, outer hair cell; NLC, nonlinear capacitance; F, farads.

Associated with the mechanical response is a bell-shaped nonlinear capacitance (NLC), which results from the voltage sensor activity of the motor (7, 8). Long before the molecular identification of the motor, two-state Boltzmann models of the motor incorporating state-dependent surface areas were developed (9–12). These were founded on experimental evidence that surface area in the OHC is voltage-dependent (13). In support of these models, we measured changes in specific membrane capacitance that corresponded to the distribution of motors, evidencing an increase in linear capacitance as more motors were driven into the expanded state by hyperpolarization (14). Membrane capacitance necessarily depends on membrane surface area and/or associated changes in membrane thickness. A derived equation based on that observation, termed the two-state C_{sa} model equation, is far superior in fitting NLC data than is a simple two-state one. Recently, Homma and Dallos (15) proposed a three-state Boltzmann model that rivals the two-state C_{sa} model in the data-fitting precision of salicylate-treated OHCs, but that additionally challenges the existence of a voltage-dependent area change accompanying the conformational transitions of prestin. Here we provide further evidence that an area motor model better describes the biophysical behavior of the motor. Through modeling, we show how salicylate competition with chloride may result in state-dependent modification of specific membrane capacitance.

EXPERIMENTAL PROCEDURES

The methods for single hair cell recordings were the same as described previously in detail (16). Hartley albino guinea pigs were sacrificed with halothane. Temporal bones were excised, and the top three turns of the cochleae were dissected for enzyme treatment (0.5 mg/ml dispase I, 10–12 min). Individual outer hair cells were isolated by gentle trituration. Isolated single outer hair cells were then studied under whole cell voltage clamp and were held at 0 mV to eliminate the electrical drive for chloride across the lateral membrane. A custom made Y-tube perfusion system was used to deliver experimental solutions to isolated OHCs. The base extracellular solution contained, in mM, 140 NaCl, 2 CaSO₄, 1.2 MgSO₄ and 10 Hepes. Chloride concentration was adjusted from 1 to 140 mM by substituting chloride with gluconate. Final solutions were adjusted to ~300

Active Surface Area of SLC26a5

mOSM with D-glucose and adjusted to pH 7.2–7.3 with NaOH. Pipette solutions (same as extracellular solution except with the addition of 10 mM EGTA) contained chloride ranging from 1 to 140 mM. The extracellular perfusion solution (1–140 mM chloride) also contained graded concentrations of salicylate (1 μ M to 10 mM).

Nonlinear capacitance was measured using a continuous high resolution (2.56-ms sampling) two-sine stimulus protocol (10-mV peak at both 390.6 Hz and 781.2 Hz) superimposed onto a voltage ramp from –150 to +140 mV at a clock sample period of 10 μ s (17, 18). Capacitance data were fit to the first derivative of a two-state Boltzmann function with an additional component describing the changes in specific membrane capacitance generated by motor state transitions (14). This equation is termed the two-state C_{sa} model equation.

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + \frac{\Delta C_{sa}}{(1+b^{-1})} + C_0 \quad (\text{Eq. 1})$$

where

$$b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right) \quad (\text{Eq. 2})$$

Q_{\max} is the maximum nonlinear charge moved, V_h is voltage at peak capacitance or equivalently, at half-maximum charge transfer, V_m is membrane potential, z is valence, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. C_0 is defined as the capacitance of the membrane when all motors are in their compact state, the minimum membrane capacitance; ΔC_{sa} is the maximum increase in capacitance that occurs when all motors change from compact to expanded state, each motor contributing a unit response of δC_{sa} . Voltage-dependent NLC was calculated from estimates of Q_{\max} , namely $NLC = Q_{\max}/(4kT/ze)$. The number of motors is: $N = Q_{\max}/ze$.

Alternatively, NLC was fit with the three-state model equation, possessing two sets of Boltzmann parameters ($z_1, V_{h1}, z_2, V_{h2}, N = N_1 + N_2$) of Homma and Dallos (15).

$$C_m = NkT \times \frac{\alpha_1^2 K_{12} + (\alpha_1 + \alpha_2)^2 K_{12} K_{23} + \alpha_2^2 K_{12}^2 K_{23}}{(1 + K_{12} + K_{12} K_{23})^2} + C_0 \quad (\text{Eq. 3})$$

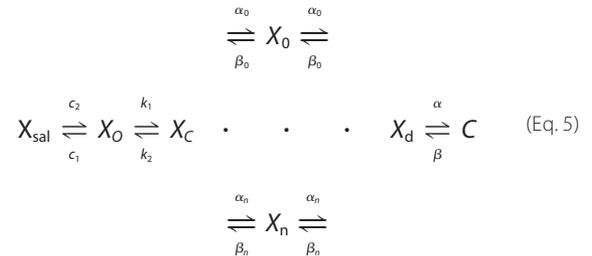

where

$$\alpha_1 = \frac{z_1 e}{kT}, \alpha_2 = \frac{z_2 e}{kT}, K_{12} = \exp(V_m - V_{h1}), K_{23} = \exp(V_m - V_{h2}) \quad (\text{Eq. 4})$$

Fits and plots were made in SigmaPlot. Data points from published plots were extracted using Plot Digitizer version 2.0 (University of South Alabama).

A kinetic model describing prestin activity, which we used previously to explain chloride-dependent coupling between prestin charge movement and electromotility (19) and the effects of thermal jumps on prestin voltage dependence (20), was extended to provide competitive binding of salicylate to the chloride binding site of the protein. The model was assessed using MATLAB Simulink in conjunction with jClamp. The new

model, which includes a stretched exponential transition that accounts for stretched exponential behavior of NLC (21) and accurately reproduces magnitude and phase behavior of the electromotility frequency response,³ is presented below with the new salicylate binding component.

X_{sal} state is bound by salicylate. X_o state is unbound by anion. X_c state is bound by chloride, but intrinsic voltage sensor charge is not responsive to the membrane electric field. A slow, multiexponential conformational transition to X_d state via X_n states enables voltage sensing within the electric field. Depolarization moves positive sensor charge outward, simultaneously resulting in compact state C , which corresponds to cell contraction. The differential equations are

$$\frac{dX_{\text{sal}}}{dt} = X_o \times [\text{Sal}]c_1 - X_{\text{sal}} \times c_2 \quad (\text{Eq. 6})$$

$$\frac{dX_o}{dt} = X_c \times k_2 + X_{\text{sal}} \times c_2 - X_o \times [\text{Cl}^-]k_1 - X_o \times [\text{Sal}]c_1 \quad (\text{Eq. 7})$$

$$\frac{dX_c}{dt} = X_o \times [\text{Cl}^-]k_1 + \sum_{n=0}^{25} X_n \times \beta_n - X_c \times k_2 - \sum_{n=0}^{25} X_c \times \alpha_n \quad (\text{Eq. 8})$$

$$\frac{dX_n}{dt} = X_c \times \alpha_n + X_d \times \beta_n - X_n \times \alpha_n - X_n \times \beta_n \quad (\text{Eq. 9})$$

$$\frac{dX_d}{dt} = C \times \beta + \sum_{n=0}^{25} X_n \times \alpha_n - X_d \times \alpha - \sum_{n=0}^{25} X_d \times \beta_n \quad (\text{Eq. 10})$$

$$\frac{dC}{dt} = X_d \times \alpha - C \times \beta \quad (\text{Eq. 11})$$

where $\alpha_n = A \times (\exp(-n))^w$, $w = 0.6$, $A = 2.5 \times 10^4$ for $N = 0.25$, $\beta_n = \alpha_n$, $k_1 = 1.5 \times 10^5$, $k_2 = k_1 \times \text{Clk}_{d^*}$, $\text{Clk}_d = 0.012$, $c_1 = 3 \times 10^8$, $c_2 = c_1 \times \text{Salk}_{d^*}$, $\text{Salk}_d = 30 \times 10^{-7}$, $\alpha = 1.3 \times 10^6 \times \exp((z \times F \times V_m)/(2 \times R \times T))$, $\beta = 7.7 \times 10^4 \times \exp((-z \times F \times V_m)/(2 \times R \times T))$, $z = 0.7$, $n_{\text{Pres}} = 25 \times 10^6$, or in the case of Fig. 5, N determined from fits to the biophysical data. The

equivalence of α_n and β_n transition rates assures detailed balance of the reaction scheme (22).

jClamp provides an automation link to MATLAB, which allows voltage stimuli to be delivered to and current responses to be obtained from Simulink models. Thus, biophysical and model data are analyzed exactly the same. Solutions were obtained with the ode45 (Dormand-Prince) solver at a fixed absolute tolerance of 10^{-6} . The *meno presto* model was interfaced to jClamp via a model of the patch clamp amplifier and OHC. The linear component of the patch-cell model was composed of R_s in series with a parallel combination of R_m and C_{lin} . Given the above *meno presto* model parameters, model results were obtained with patch clamp parameters of $R_s = 6.1$ megohms, $R_m = 275$ megohms, and $C_0 = 23$ pF. To reiterate, the exact same voltage stimuli and exact same analysis of model data were performed as with the biophysical data. Model responses were allowed to reach steady state prior to ramp perturbations.

RESULTS

We previously showed that the effectiveness of salicylate inhibition of NLC is chloride-dependent (3). Fig. 1A shows NLC traces of an OHC with 140 mM intracellular chloride. Increasing concentrations (0.001, 0.01, 0.1, 1, 10 mM) of salicylate reduce the magnitude of NLC and shift its voltage dependence in the depolarizing direction. The traces were fit to the two-state C_{sa} model equation (Equation 1) and the three-state model equation (Equation 3) (see "Experimental Procedures"). Note that each fit is indistinguishable without statistical analysis. In fact, Homma and Dallos (15) found that Equation 1 gave a $4\times$ better fit. Nevertheless, it is not the quality of the fit that is of concern here; it is the underlying mechanism. In Fig. 1B, the 0.1, 1, and 10 mM traces are replotted with the subcomponents of the two equations shown. In the *left panels*, two *independent* Boltzmann functions underlie the full fit. In the *right panels*, a single Boltzmann function and a *coupled* sigmoidal function, sharing the same V_n and number of motors, contribute to the full fit. Within the data region, each fit is quite reasonable. However, whereas the two-state C_{sa} fit shows an increasing membrane surface area/reduced membrane thickness, reflected in C_m , as the motors redistribute to the extended state, the three-state fit indicates no such changes. Similar results are found when intracellular chloride is set to 5 mM (Fig. 1, C and D). Note, however, that with reduced chloride there is a different dose-dependent effect of salicylate on ΔC_{sa} as compared with the 140 mM chloride condition. As with the 140 mM chloride data, the three-state model shows no differences in linear capacitance at voltage polarity extremes. A more telling evaluation of the two models is shown in Fig. 2, where both equations are used to fit the data of Santos-Sacchi and Navarrete (14) who utilized extreme voltages of ± 200 mV to measure NLC. Those fits indicate that one Boltzmann component of the three-state model may actually serve as a surrogate for the sigmoidal component of the two-state C_{sa} model equation. Below we evaluate the interaction of salicylate and chloride effects on prestin to explore the appropriateness of the two models.

To help understand the effects of salicylate, we extended a kinetic model of prestin we are currently working on, termed

the *meno presto* model because it includes a slow, stretched exponential intermediate transition between chloride binding and the voltage-enabled state (Fig. 3). We have used this model previously to explain chloride-dependent uncoupling between prestin charge movement and electromotility (19) and the effects of thermal jumps on prestin voltage dependence (20). Because we will use this model to evaluate the interaction of salicylate and chloride on ΔC_{sa} , we first confirm its ability to reproduce known chloride-dependent salicylate effects on NLC (3). Fig. 4A shows the model results illustrating that the IC_{50sal} reduces when intracellular chloride is reduced. Five publications report on salicylate effects on NLC (all reporting at least the 140 mM chloride condition), and from those we estimate IC_{50sal} by fitting Hill functions with the coefficient n set to 1 (Fig. 4B), as experimentally determined (23). Three values arise from studies on guinea pigs (3, 23, 24), being 1.67, 1, and 1.42 mM; a value of 0.64 mM comes from rat prestin-transfected cells (25), and a value of 0.22 mM comes from mouse OHCs (15). These values are plotted in Fig. 4C along with the extended measures of IC_{50sal} reported in Santos-Sacchi *et al.* (3). The model IC_{50sal} data (*open white triangles*) from Fig. 4A shows chloride dependence similar to our previous biophysical data (*filled black circles*) (3), indicating that our model may be useful in characterizing any chloride-dependent behavior of ΔC_{sa} .

Homma and Dallos (15) uncovered behavior of ΔC_{sa} that they believed was incompatible with our two-state C_{sa} area motor model (see their Fig. 2H). They found that ΔC_{sa} increases with salicylate concentration before it decreases. Because we determined that the conformational switch of the motor from compact to expanded state results in a 130 zF/motor (δC_{sa}) increase in C_m (23), they reasoned that as salicylate removed motors from the active pool there should only be a decrease in ΔC_{sa} with increasing salicylate concentration. This reasoning disregards our published observation that salicylate increases ΔC_{sa} above that measured in its absence. Thus, we contend that when salicylate binds to a motor, either its surface area is greater than an unbound expanded motor and/or the membrane thickness is reduced when bound. We and others have shown that salicylate in the absence of prestin has no measurable effects on membrane capacitance (23, 24). Homma and Dallos (15) also show this. Clearly, then, the salicylate effect results from interaction with prestin. Fig. 5A shows the effects of salicylate with 140 mM intracellular chloride on ΔC_{sa} . The data have been normalized by motor number, N , in the absence of salicylate for comparisons ($\Delta C_{sa}/N_{sal=0}$). A non-monotonic increase followed by a decrease is similar to the Homma and Dallos data (15). At this chloride concentration, in the absence of salicylate, a unit δC_{sa} per motor is calculated to be 141 zF, similar to our previous estimates (14). In our model, to account for the salicylate dose-response function, each salicylate-bound motor unit δC_{sa} had to be factored by 1.9 (*solid line*), in line with our previous observations (14). We also observed similar behavior when chloride levels were reduced; however, the salicylate dose-response function shifted leftward along the concentration axis with reduced chloride. With a fixed unit δC_{sa} scale factor of 1.9 for salicylate-bound motors, the model response also shifted when chloride was reduced, and exhibited appropriate response magnitude.

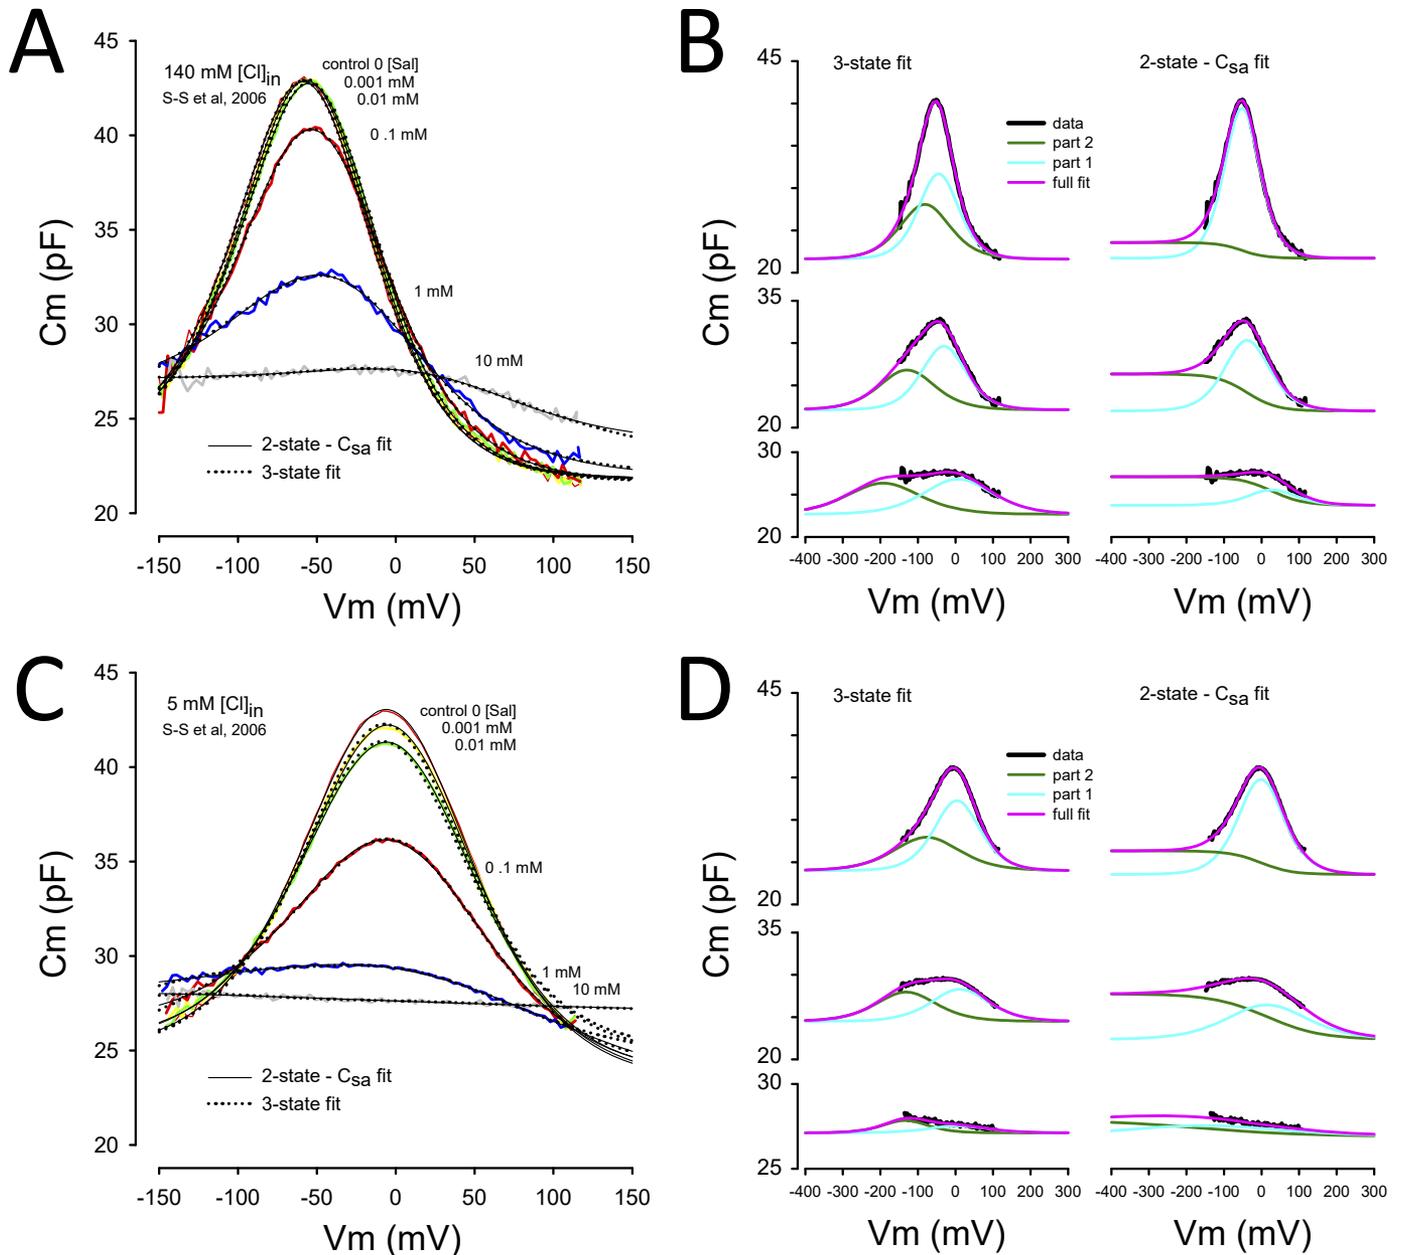

FIGURE 1. Model-dependent differences in salicylate effects on the NLC of prestin. Contributions of area fluctuations in prestin differ with the three-state model of Homma and Dallos (15) or the two-state C_{sa} model of Santos-Sacchi and Navarrete (14). **A**, data from Fig. 1B of Santos-Sacchi *et al.* (3) (S-S *et al.*, 2006) showing effects of different salicylate concentrations on NLC at an intracellular chloride level of 140 mM. Each trace was fit with both models, each providing near equivalent fit quality. **B**, details of fits by each model for the 0.1, 1, and 10 mM salicylate conditions, *top*, *middle*, and *bottom* panels, respectively. Each model is composed of two components, labeled *part 1* and *part 2*. Essentially, the sum of each component produces the full fit. Although the two-state model gives an offset in C_m at hyperpolarized levels, the three-state model does not. **C**, data from Fig. 1A of Santos-Sacchi *et al.* (3) with an intracellular chloride level of 5 mM showing an enhanced effect of salicylate. As above, fits of both models were made, both showing good correspondence. Some small differences are noted at depolarized levels. **D**, fit components of both models. Again, an offset in C_m arises at hyperpolarized levels for the two-state model, but not the three-state model. Note that for each chloride condition, the offset in C_m (ΔC_{sa}) increases and then decreases with increasing chloride concentration.

We previously showed that the effects of externally applied salicylate (1 mM) on NLC required about 60 s to reach steady state (23). Because Homma and Dallos (15) used a 1-min perfusion to change salicylate from 0 to 1.5 mM, during which time they evaluated NLC, steady state effects were only achieved before and after perfusion. For this reason, we evaluate the data from their supplemental Fig. S3A (140 mM chloride, intracellular) where salicylate concentration was set definitively. Interestingly, those data (Fig. 5B) required that the salicylate K_d

($Salk_d$) or equivalently the rate constant c_2 of our model be reduced by an order of magnitude, in line with their more sensitive estimated IC_{50sal} (Fig. 4B). Additionally, the δC_{sa} scale factor had to be increased to 3. It must be emphasized that the $Salk_d$ and Clk_d in our model do not necessarily correspond in magnitude to IC_{50} values of NLC effects that we and others have measured, because through our experiments on NLC we neither inspect these directly, nor should IC_{50} values necessarily agree with K_d values in other than a simple two-state system.

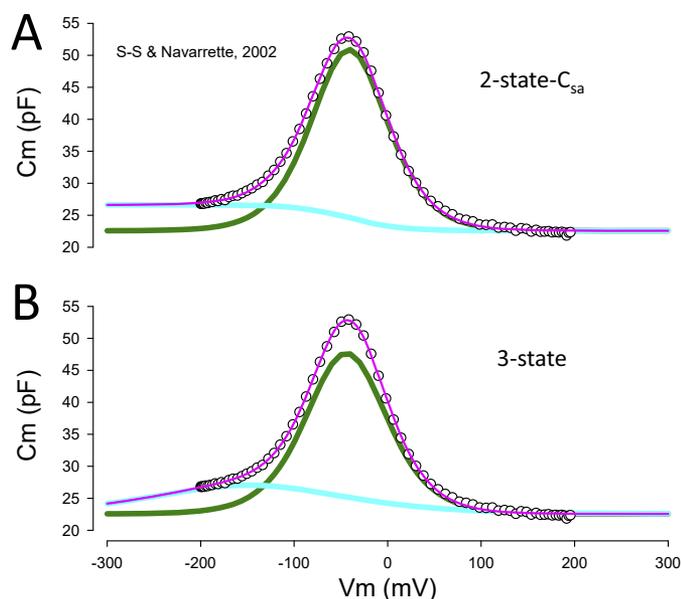

FIGURE 2. **Two-state C_{sa} and three-state fits of NLC determined over a very wide voltage range.** *A*, two-state C_{sa} fit, showing underlying components. *B*, three-state fit with underlying components. Note that the unconstrained fit of the three-state equation found one component V_h that effectively placed a sigmoidal-like C_m function at the hyperpolarized extreme, mimicking the two-state C_{sa} model's constrained fit of its single V_h . Data are from Santos-Sacchi and Navarrete (14) (S-S. & Navarrete, 2002).

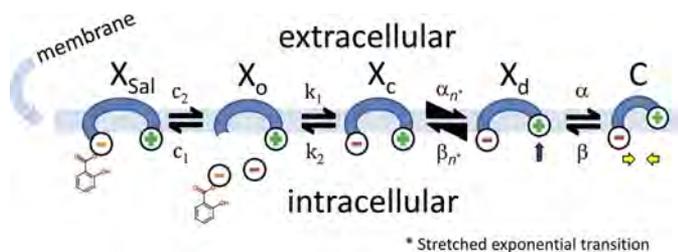

FIGURE 3. **Extension of the stretched kinetic model of prestin activity to provide salicylate competition with chloride.** X_{sal} state is bound by salicylate. X_o state is unbound by anion. X_c state is bound by chloride, but intrinsic voltage sensor charge is not responsive to membrane electric field. Slow, multiexponential conformational transition to X_d state via X_n states enables voltage sensing of electric field. The α_n and β_n transitions are multiexponential (see "Experimental Procedures"). Depolarization moves positive sensor charge outward, simultaneously resulting in compact state C, which corresponds to cell contraction. Equivalence of α_n and β_n transition rate constants assures detailed balance of the reaction scheme.

The utilized k_d values, however, produce IC_{50} values for NLC that are consistent with our experimental observations.

Finally, we investigated the behavior of C_{lin} . For the two-state C_{sa} model equation, C_{lin} is the linear capacitance, which is the minimum capacitance at extreme depolarized voltages where all motors are in the compact state. For the three-state model equation, C_{lin} is equivalently the capacitance at either hyperpolarized or depolarized extremes. Similar to Homma and Dallos (15), we find a monotonic increase in C_{lin} in our data when fit with the two-state C_{sa} equation (Fig. 5C). It reaches an asymptote when ΔC_{sa} vanishes, that is, when salicylate binds to all motors and locks them in the expanded state. Thus, C_{lin} tells about the state residence of motors, just as ΔC_{sa} does; the measures are reciprocal. Importantly, just as ΔC_{sa} is dependent on the interaction of salicylate and chloride (Fig. 5A), so too is C_{lin} (Fig. 5C). In Fig. 5D, we plot C_{lin} that arises from three-state fits

of our model data that explicitly incorporate motor-generated δC_{sa} . As expected, and in agreement with Homma and Dallos (15), C_{lin} rises monotonically to an asymptote, until all motors are in the salicylate-bound extended state. Unfortunately, Homma and Dallos (15) only report on salicylate effects on C_{lin} using a 1-min perfusion of extracellular salicylate, so we cannot unequivocally determine intermediate concentrations of salicylate from their data (see their Fig. 2C) except at the onset of perfusion (zero salicylate) and at the steady state end of perfusion (1.5 mM salicylate). Thus, we only plot those two points, and they lie on our model prediction curve. Thus, although the three-state model cannot identify the voltage-dependent nature of prestin-associated capacitance change, it nevertheless reports on it as C_{lin} .

DISCUSSION

The area motor model of OHC motor activity was based on biophysical evidence that OHC surface area increases upon hyperpolarization (13). Given the constraints of a cylindrically shaped cell and a constant cytoplasmic volume, alterations in surface area result in cell length changes that correspond to measured characteristics of OHC electromotility (9, 11). Although various models of OHC electromechanical activity have arisen, including electro-osmosis (26, 27) and membrane flexo-electricity (28), several arguments against them have been made (29–31), chief among them the identification of the voltage-dependent motor protein prestin (1). Considering the vast number of prestin motors embedded in the OHC lateral membrane, whose membrane residence contributes markedly to OHC surface area (32, 33), unit area changes, ranging from 0.4 to 8 nm² (9, 11, 12, 34, 35), will have substantial effects on membrane surface area. Linear membrane capacitance is expected to change when either membrane surface area or associated changes in membrane thickness occur.

Recently, Homma and Dallos (15) have developed a three-state model of prestin activity, which challenges those earlier area motor models. In their model, no changes occur in linear capacitance at extreme hyperpolarizations or depolarizations despite very nice fits of NLC data within a restricted voltage range. In contrast, fits with the two-state C_{sa} model equation (14) predict that linear capacitance increases when motors redistribute into the expanded state, reaching an asymptote, ΔC_{sa} , at extreme hyperpolarizations where all motors reside in the expanded state. There are two reasons why Homma and Dallos (15) championed their new model over the area model, despite a better fit by the latter model. First, they observed that when fitting with the two-state C_{sa} model equation there is a non-monotonic change in ΔC_{sa} as salicylate concentration rises, an increase followed by a decrease. It was assumed that salicylate simply removes motors from the active pool, and thus motor contribution to area changes should monotonically decrease. However, we previously showed that salicylate increases ΔC_{sa} above that measured in its absence (14), implying that salicylate-bound motors are augmented in surface area and/or decrease membrane thickness. To be sure, we and others have shown that salicylate in the absence of prestin has no measurable effects on membrane capacitance (15, 23, 24). Consequently, when we use our new *meno presto* model incorpo-

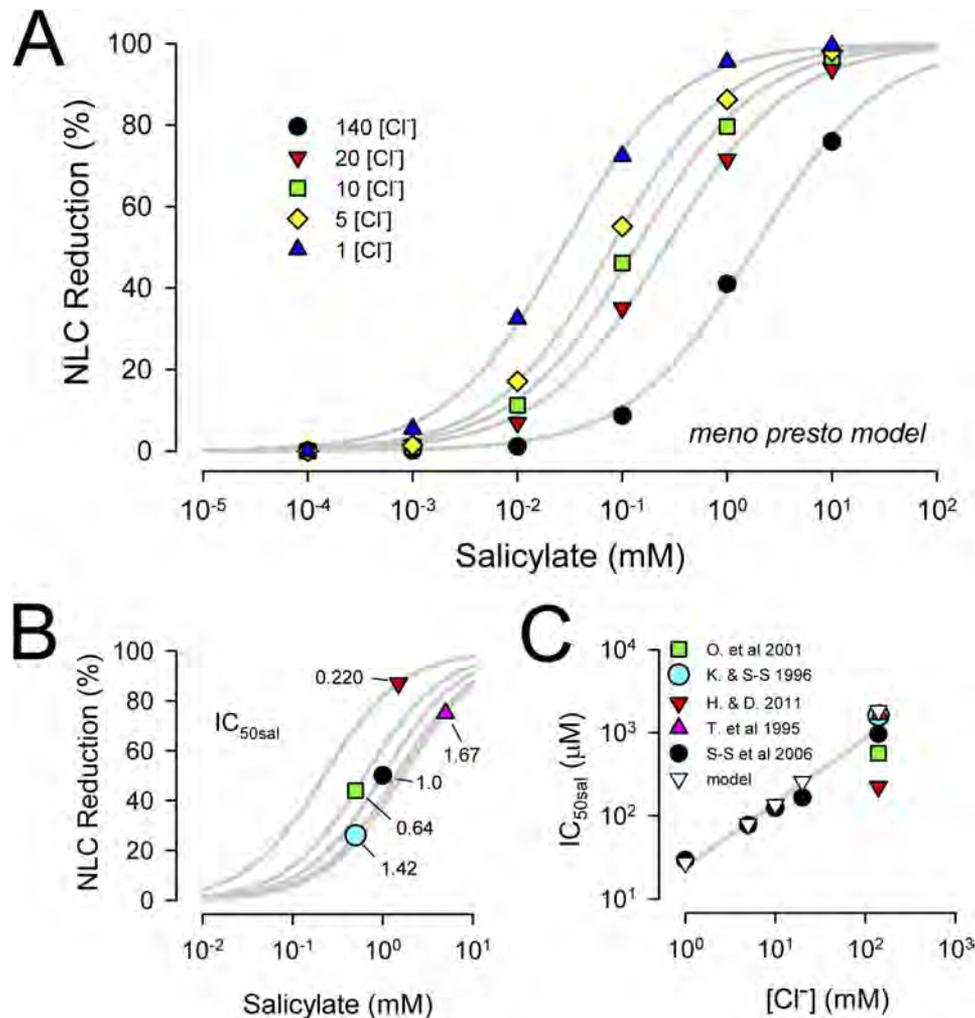

FIGURE 4. Model results of salicylate effect on NLC correspond to biophysical data. *A*, model predicts chloride dependence of salicylate effects, showing that reduced IC_{50sal} as chloride is lowered, as determined experimentally by Santos-Sacchi *et al.* (3) (see their Fig. 2). *B*, comparison of IC_{50sal} from different studies. Because only one study fully evaluated the chloride dependence of IC_{50sal} , IC_{50sal} was estimated by fitting a Hill function through the single data points obtained at 140 mM chloride with the Hill slope, n , fixed at 1, as experimentally determined (3). Biophysical data points were from guinea pig OHCs (Tunstall *et al.* (24), extracted from their Fig. 5C; Kakehata and Santos-Sacchi ((24)), extracted from their Fig. 1C; Santos-Sacchi *et al.* (3), extracted from their Fig. 2); rat prestin transfected HEK cells (Oliver *et al.* (25), extracted from their Fig. 5b); and mouse OHCs (Homma and Dallos (15), extracted from their Fig. 2). *C*, comparison between model and biophysical data shows that the model recapitulates biophysical data. Straight line fit is through model points. Legend: O. *et al.* 2001, Oliver *et al.* (25); K. & S-S 1996, Kakehata and Santos-Sacchi ((24)); H. & D. 2001, Homma and Dallos (15); T. *et al.* 1995, Tunstall *et al.* (24); S-S *et al.* 2006, Santos-Sacchi *et al.* (3).

rating salicylate effects on the motor, we satisfactorily fit the non-monotonic ΔC_{sa} behavior caused by salicylate. Furthermore, we show that this non-monotonic biophysical behavior varies with chloride level, with the model capable of describing the chloride dependence. Curiously, the three-state model accurately identifies a biophysical change in linear capacitance that is salicylate-dependent, which is precisely expected of that model should surface area increase due to increasing residence of prestin in the expanded state. Thus, although that model is built to ignore the voltage-dependent surface area changes due to prestin, it unavoidably detects that surface area change as a voltage-independent one.

The other reason why Homma and Dallos (15) favor their three-state model is that the coupling between sensor charge movement and electromotility is not tight, with zero charge extrapolations giving non-zero mechanical responses, regardless of the model equation. We previously observed uncoupling between sensor charge and electromotility (23, 36, 37). Indeed,

we had shown that salicylate even at 10 mM, whereas nearly abolishing NLC, had much less of an effect on electromotility (23). Recently, we determined that the discrepancy between charge movement, measured with the dual sine admittance approach (17, 18) (also coded into jClamp), and electromotility is chloride-dependent (19), and thus, considering its competition with chloride, salicylate-dependent. Furthermore, we showed that a model incorporating slow intermediate kinetics between chloride binding and a two-state Boltzmann process substantially predicted disparities between sensor charge and electromotility (19). The *meno presto* model presented here, which integrates characteristics of the two-state C_{sa} model, possesses this capability as well. It should be noted that the three-state model, as is, can neither reproduce this result nor generate stretched exponential kinetics that is evident in OHC NLC (18, 21, 39) and prestin-transfected cell NLC (40). The *meno presto* model exhibits stretched exponential kinetics in capacitance measures similar to biophysical observations. One

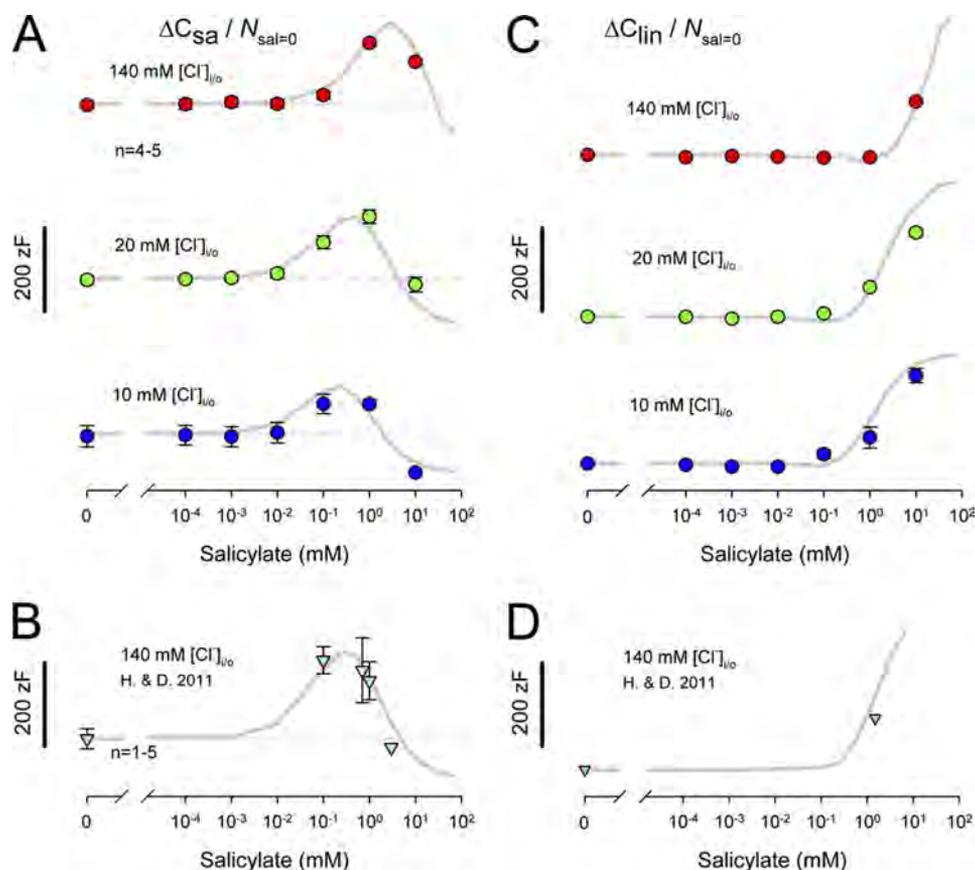

FIGURE 5. Chloride and salicylate dependence of specific membrane capacitance. ΔC_{sa} is normalized by dividing by $N(Q_{max}/ze)$ at 0 salicylate conditions. *A*, dashed lines show initial ΔC_{sa} for each chloride condition in the absence of salicylate: upper panel, 140 mM chloride, 141 zF; middle panel, 20 mM chloride, 110 zF; lower panel, 10 mM chloride, 88 zF. Note that in each case ΔC_{sa} is stable until a particular concentration of salicylate induces an increase in ΔC_{sa} followed by a decrease. The onset of salicylate effects is chloride-dependent, arising at lower salicylate levels as chloride is reduced. The *meno presto* model, which incorporates prestin-dependent changes in C_m arising from changes in motor surface area/membrane thickness, follows this pattern. *B*, data from Homma and Dallos (15) (*H. & D. 2011*); see their supplemental Fig. S3A (140 mM [chlorine] internal). The dashed line shows an initial ΔC_{sa} of 96 zF. A similar pattern of ΔC_{sa} change is observed when salicylate concentration is changed. Both the salicylate K_d and the ΔC_{sa} scaling factor for salicylate bound motors required adjustment to fit their data and are related to the higher salicylate sensitivity of mouse prestin (see “Results” for details). *C*, Clin also depends on the interaction between salicylate and chloride, showing a leftward shift along the salicylate concentration axis as chloride is reduced. The area motor model (gray lines) recapitulates this behavior. *D*, Homma and Dallos (15) Clin data are well described by the area motor model (see “Results”).

other point should be mentioned about the three-state model. Although the two-state C_{sa} model derives from biophysical evidence showing voltage-dependent surface area changes, the rationale for two independent Boltzmann processes in the three-state model is curiously lacking a rationale, other than its ability to fit NLC data within a restricted voltage region. In this regard, it is not at all clear why the V_h of each Boltzmann process should shift in an opposite direction during salicylate treatment (15). Even if salicylate could charge screen the membrane (41), voltage-dependent processes should shift in the same direction. The mechanism whereby the three-state model works is especially clear in the absence of salicylate when extended voltage ranges are used to measure NLC as in Fig. 2. One underlying Boltzmann process is simply shifted such that it mimics the sigmoidal nature of ΔC_{sa} generation that is revealed by the two-state C_{sa} model.

Interestingly, inspection of the literature on salicylate inhibition of prestin shows that mouse prestin appears more susceptible to inhibition than guinea pig prestin, with the guinea pig IC_{50sal} being ~ 1 – 1.5 mM and mouse IC_{50sal} being ~ 0.2 mM. Consequently, our new *meno presto* model was able to fit the mouse data of Homma and Dallos (15) by the reducing the

forward rate constant, c_2 (see “Experimental Procedures”), by an order of magnitude. Although homology is high between the two species, perhaps some key residue differences could account for this. Alternatively, chloride and/or salicylate concentration may differ within the minute space between plasma membrane and subsurface cisternae among species. This femtoliter compartment is exactly where interactions between anions and prestin occur. Thus, it may be interesting to compare salicylate sensitivity among OHCs from a wide range of species.

In summary, we find that an area motor model, such as our *meno presto* model, accurately accounts for interactions between salicylate and chloride on the OHC motor, and that models that do not explicitly incorporate a motor-dependent area change will nevertheless detect one as an increase in linear capacitance. To be sure, it is crucial that a model be appropriate to understand the elementary nature of a voltage-dependent molecule (38).

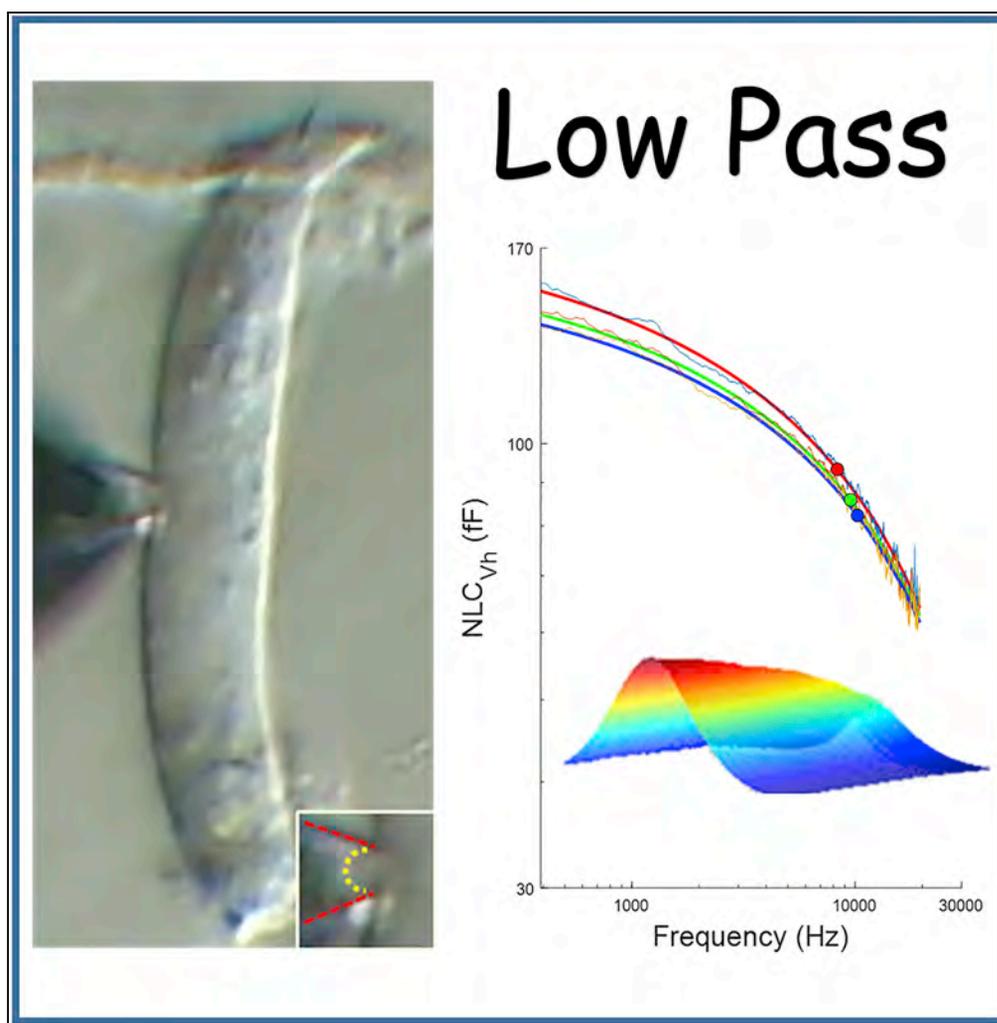

Acknowledgment—We thank Fred Sigworth for discussions on the salicylate and chloride microscopic binding efficiencies of the model relative to the observed effects on nonlinear capacitance.

Voltage Does Not Drive Prestin (SLC26a5) Electro-Mechanical Activity at High Frequencies Where Cochlear Amplification Is Best

Joseph Santos-Sacchi, Winston Tan

joseph.santos-sacchi@yale.edu

HIGHLIGHTS

Outer hair cells (OHC) boost auditory sensation for very high acoustic frequencies

We studied the frequency response of OHC's electromechanical nonlinear capacitance

The response is incommensurate with cycle-by-cycle feedback at very high frequencies

OHCs likely use another mechanism to drive cochlear amplification at high frequencies

Article

Voltage Does Not Drive Prestin (SLC26a5) Electro-Mechanical Activity at High Frequencies Where Cochlear Amplification Is Best

Joseph Santos-Sacchi^{1,2,3,4,*} and Winston Tan¹

SUMMARY

Cochlear amplification denotes a boost to auditory sensitivity and selectivity that is dependent on outer hair cells from Corti's organ. Voltage-driven electromotility of the cell is believed to feed energy back into the cochlear partition via a cycle-by-cycle mechanism at very high acoustic frequencies. Here we show using wide-band macro-patch voltage-clamp to drive prestin, the molecular motor underlying electromotility, that its voltage-sensor charge movement is unusually low pass in nature, being incapable of following high-frequency voltage changes. Our data are incompatible with a cycle-by-cycle mechanism responsible for high-frequency tuning in mammals.

INTRODUCTION

In some mammalian species, hearing capabilities can extend out to 60–160 kHz (Heffner and Masterton, 1980; Castellote et al., 2014; Szymanski et al., 1999; Heffner et al., 2001). Indeed, tuned hair cell receptor potential-derived cochlear microphonic potentials have been measured beyond 60 kHz in the bat (Pollak et al., 1972). Underlying this electrical behavior are sharp frequency tuning and enhanced cochlear partition vibration, which are susceptible to outer hair cell (OHC) damage; studies in laboratory rodents provide such evidence, e.g., in the mouse sharp basilar membrane tuning is measurable beyond 60 kHz (MelladoLagarde et al., 2008). This enhancement over Bekesy's passive partition vibration (von Bekesy, 1960) is termed cochlear amplification (CA) (Davis, 1983) and amounts to an apparent gain of 100–1000 at best frequency locations along the cochlear duct. DC and AC trans-membrane voltages are sensed by the membrane protein prestin (SLC26a5) (Santos-Sacchi and Dilger, 1988; Iwasa and Kachar, 1989), a special member of the SLC26 family of anion transporters (Zheng et al., 2000), that populates the OHC lateral membrane at molecular densities up to 8,000/ μm^2 (Santos-Sacchi et al., 1997; Gale and Ashmore, 1997b). Voltage is thought to faithfully govern prestin's conformational state, evoking rapid switching between expanded and contracted molecular conformations that leads to rapid length changes (termed electromotility; eM) (Ashmore et al., 2010). Current dogma has it that evoked OHCeM provides mechanical feedback into the organ of Corti on a cycle-by-cycle basis to power CA. In fact, Frank et al. measured high-fidelity OHC AC eM responses beyond 80 kHz (Frank et al., 1999). During the last few years, however, the kinetics or frequency dependence of prestin's electromechanical capabilities have been reassessed in OHCs (Santos-Sacchi and Song, 2014; Santos-Sacchi, 2019). Both the frequency of prestin charge movement (measured as a nonlinear capacitance [NLC]) and that of its associated eM were found to be low-pass, precipitously rolling off within the bandwidth of human speech (200–8000 Hz) (Santos-Sacchi and Tan, 2018; Santos-Sacchi et al., 2019). However, those data must be viewed cautiously because measures were made in whole cell mode. In fact, being a piezoelectric-like protein (Iwasa, 1993; Gale and Ashmore, 1994; Kakehata and Santos-Sacchi, 1995), where reciprocal influences of mechanical load and voltage are at play, whole cell measures of OHC electromechanical activity may fail to establish the actual frequency capabilities of prestin. Here we address this issue by measuring the frequency response of prestin's NLC with on-cell and excised macro-patches from the cell's lateral membrane where isolation from external whole cell loads can be achieved. The macro-patch is the preferred methodology to gauge fast charge movement in voltage sensitive membrane proteins (Lu et al., 1995). Our patch data in mouse and guinea pig show low pass, voltage-driven electromechanical behavior of the protein, whose frequency response alters over time but still falls far short of its expected influence on cochlear amplification at very high frequencies, leading us to question prestin's role in this process.

RESULTS

Our recording system response (Figures S1A and S1B), and results on an electrical model of a membrane patch (Figures S1C–S1F), confirming our capability to measure capacitance flat out to 20 kHz, is provided

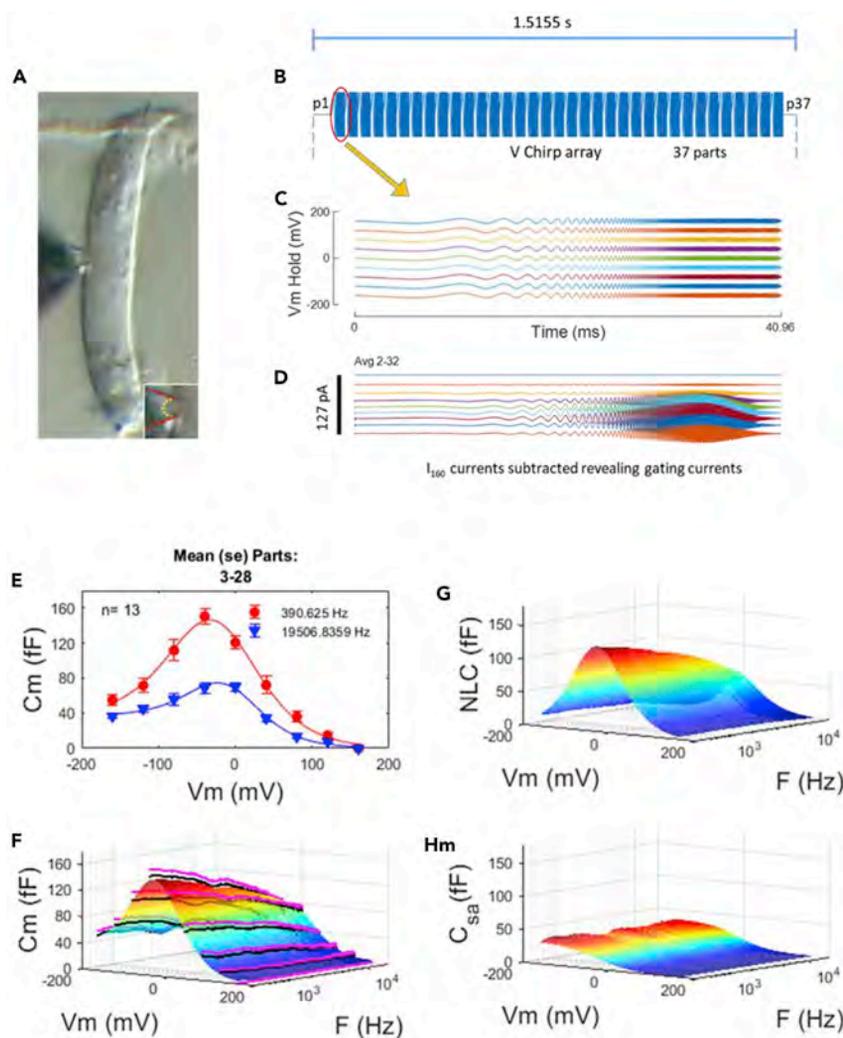

Figure 1. Measures of NLC in Macro-Patches from Outer Hair Cells (OHC)

(A) An image of an OHC (10 μm wide) showing a patch pipette sealed to the lateral membrane. Inset: enlarged view of patch. Red lines outline pipette, dotted yellow line outlines membrane patch.

(B) Section of command voltage stimulus, composed of 35 repeats of a chimp stimulus of 10 mV peak.

(C) Expanded view of individual chimp stimuli at the range of holding potential delivered to the patch (–160 to 160 mV).

(D) Extracted AC displacement (“gating”) currents, representative of voltage sensor charge movements during conformational changes in prestin. Evoked raw currents at each holding potential were averaged from parts 2–32, then the averaged current at 160 mV, where prestin activity is absent, was subtracted from all raw currents at each holding potential, revealing prestin displacement currents. Here, for illustration, we plot the average of currents from all cells, but for subsequent data analysis each cell was individually analyzed to provide statistics. The magnitude of AC currents peaks near V_h , where prestin charge movement vs. voltage is maximal. The displacement currents were used to analyze for nonlinear capacitance (NLC).

(E) Extracted membrane capacitance at two stimulating frequencies, (390 Hz [red circles]) and 19,500 Hz [blue triangles]). Mean \pm SE. Solid lines are fits based on Equation 1 (see [Methods](#)).

(F) Membrane capacitance as a function of voltage and frequency. Black lines are averages from 13 patches, and pink lines show mean \pm SE. Smooth multicolored surface is fit to averaged data.

(G) Extracted NLC. Note the roll-off in peak NLC magnitude as frequency of stimulation increases from 390 to 20,000 Hz.

(H) C_{sa} component of fit. Note frequency independence.

in the [Transparent Methods](#) section of the supplement. [Figures 1A–1D](#) illustrate our basic experimental strategy. Macro-patches (3.5–4 μm inner diameter) were made on the lateral membrane of OHCs ([Figure 1A](#)) and a voltage chimp array delivered to the patch superimposed on stepped holding voltages (–160 to 160 mV) to

extract prestin displacement currents (Figure 1D), following subtraction of currents at +160 mV where NLC is absent (Santos-Sacchi and Navarrete, 2002). Single-sine or dual-sine admittance analysis of the displacement currents provides estimates of NLC. Figure 1E shows average (\pm SE) cell capacitance data fitted with Equation 1 (see Methods) at 2 frequencies (390 and 19,500 Hz). Note the substantial drop in peak membrane capacitance at the higher frequency. Figure 1F displays in a 3D rendition all frequencies studied across holding voltage. Black lines are average data and pink lines are mean +SE, whereas the multicolored plot shows fits. The extracted NLC is shown in Figure 1G and illustrates the continuous roll-off of NLC with increasing frequency. Figure 1H shows the largely frequency independent component of membrane capacitance (C_{sa}) at negative holding potentials that we previously attributed to membrane surface area/thickness changes during prestin's conformational changes between compact and expanded states (Santos-Sacchi and Navarrete, 2002). The clear roll-off differences between NLC and this C_{sa} response (Figures 1G and 1H) indicate that our previous interpretation of the C_{sa} component may need reevaluation.

NLC at V_h reflects the charge distribution where an equal amount of voltage sensor charge resides on either side of the plasma membrane. Furthermore, that characteristic voltage (V_h) is a reflection of the ratio of forward and backward rates of prestin transitions, providing a voltage at which to measure the characteristic rate or frequency of sensor charge movement. The coupling of charge movement and eM (Santos-Sacchi and Tan, 2018) also indicates that at this voltage OHCeM gain (cell length change/membrane potential) is maximal. In Figure 2A, we plot the frequency response of NLC at V_h (mean: blue line; mean +SE: light blue dotted line). The roll-off is precipitous commencing at the lowest measured frequency. It is clear that our data, collected at 24.4 Hz resolution, requires a multi-Lorentzian (double in this case), or a power function fit (Figure 2B). The double Lorentzian fit indicates a slow and fast component with frequency cut-offs (F_c) at about 1.5 and 16.2 kHz, respectively. For the power fit, we estimate a cut-off at one-half magnitude of 11.3 kHz. Figure 2C indicates that the frequency response of NLC is the same with on-cell or immediately excised macro-patches in the guinea pig. In Figure 2D, we show that the frequency response of NLC in mouse patches is similar to that of the guinea pig. Half-magnitude cut-off of the power fit is at 10.5 kHz. For comparison, we plot the chloride dependent capacitance frequency response of GAT1 (triangles) (Lu et al., 1995), and its power function fit (green line), indicating that it is somewhat faster than the frequency response of prestin. The guinea pig response (pink line) is replotted in the figure along with scaled eM data (OHC 65: magenta solid line; OHC84: dashed magenta line) from Frank et al. (1999) (Figure 2A), showing that the speed of prestin conformational transitions falls far below OHC mechanical responses. In other words, the drive for eM (voltage-dependent conformational changes in prestin) does not correspond to their measured eM. Can NLC frequency response be augmented?

We have previously shown that NLC is not stationary in time (Santos-Sacchi et al., 2009). Step changes in voltage evoke initial rapid changes in NLC, which immediately alter in magnitude in a stretched exponential fashion, accompanied by shifts in V_h . In Figure 3, we explore the frequency response of NLC along the duration of our holding potential steps. Figure 3A shows the regions of chirp currents that were averaged for comparison. The extracted NLC from the three regions are shown in Figure 3B, and for the first region (p3-8) a red line is plotted along the slope of NLC at V_h across frequency. That same red line is recast onto the two other plots of regions p13-18 and p23-28, showing alterations in the frequency response of NLC as duration of the step increases. A quantification of the frequency responses is made in Figure 3C. Power fits indicate that low frequency components are reduced over time such that the frequency cut-off effectively increases over time. Figures 3D-3G plot the fitted parameters of the power fit across holding potential duration, showing reductions in NLC_0 , and time-dependent changes in the power parameters that control frequency dependence, with frequency cut-offs increasing over time.

It has been observed that patch size can change during the course of experiments (Sokabe et al., 1991). It is unlikely that patch size alterations across the duration of our voltage protocol account for the changes in frequency responses that we find because such changes would likely alter the size of NLC across the full frequency range (e.g., see Figure 2D, where smaller mouse patches simply shift all components of NLC downward relative to guinea pig patches). Indeed, Figures 3H and 3I illustrate that NLC across holding potential duration exhibits shifts in V_h that correspond to the nonstationary behavior of NLC that we previously found (Santos-Sacchi et al., 2009), rather than changes in patch area.

Salicylate is a known intracellular blocker of NLC (Kakehata and Santos-Sacchi, 1996; Tunstall et al., 1995), working in a competitive fashion on chloride binding (Oliver et al., 2001). Chloride anions are *not* extrinsic

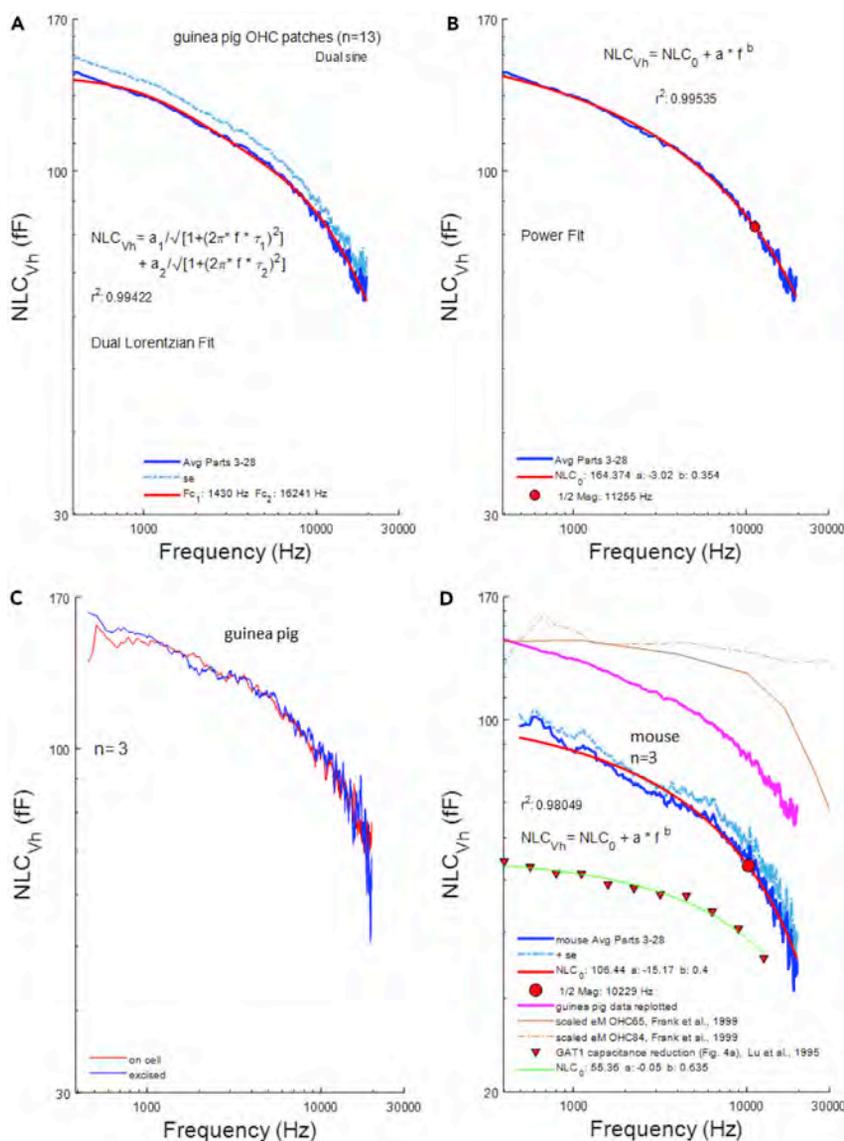

Figure 2. Frequency Response of NLC at V_h

(A) Blue line indicates mean NLC, dotted light blue line shows mean +SE. We require at least a double Lorentzian fit that indicates low and high pass components.

(B) Power fit of our data illustrating the continuous roll-off of NLC across frequency. One-half magnitude (red circle) is near 10.5 kHz.

(C) Average of three patches before and after inside-out patch excision, illustrating similar frequency response for each.

(D) Mouse NLC frequency response (mean, mean +SE, blue line, dotted light blue line, respectively) is similarly low pass compared with guinea pig response (pink line). Red circle shows one-half magnitude at 10.5 kHz. For comparison, we plot the capacitance function of Lu et al. (1995) (Figure 4A) for GAT1, fitted with a power function (solid green line). Also, for comparison, the scaled electromotility for the two presented cells from Frank et al. (1999) (Figure 2A) is shown. Note prestin's voltage-driven charge movements are remarkably lower-pass than eM.

voltage sensors for prestin but instead likely work allosterically (Song and Santos-Sacchi, 2010; Rybalchenko and Santos-Sacchi, 2003) (also see our comment #1 on Walter et al. [2019]—<https://elifsciences.org/articles/46986>). In Figure 4, we explore the effects of salicylate on NLC frequency response. Blue symbols denote responses after salicylate treatment, and red symbols denote response before treatment. Extracellular perfusion of high concentrations of salicylate (10 mM) substantially reduces NLC but not completely (Figure 4A). The effect results from intracellular loading of the ionized form of the molecule, working in the micromolar range (Kakehata and Santos-Sacchi, 1996). In order to gauge salicylate effects

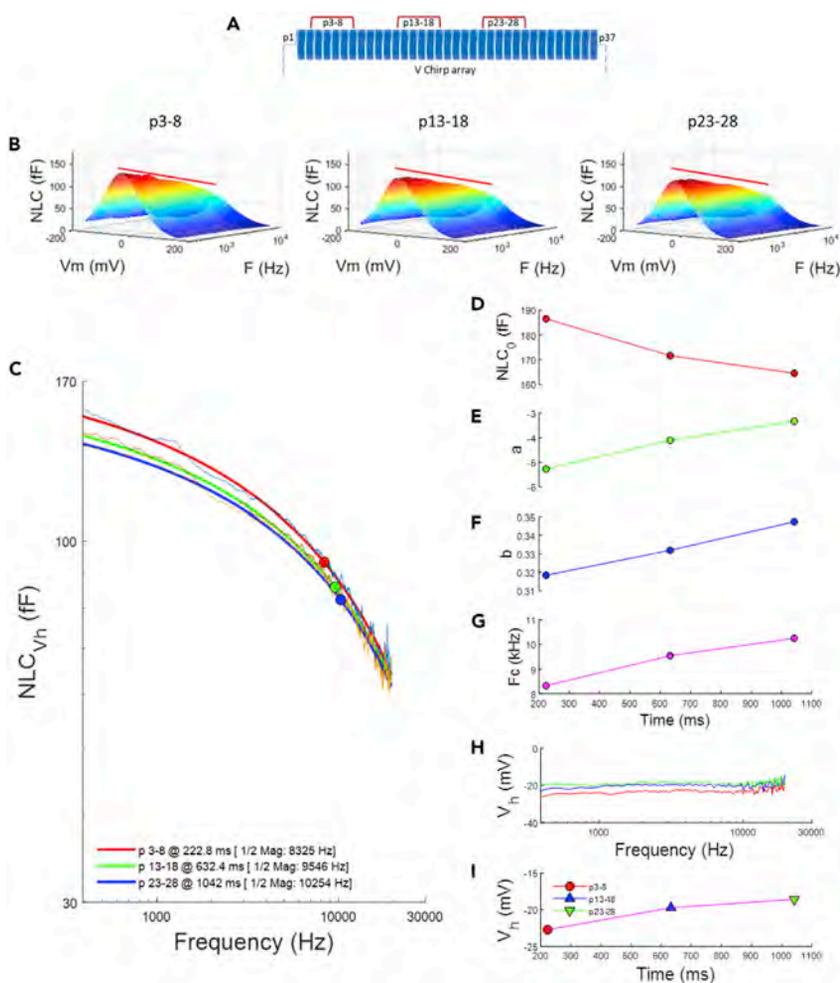

Figure 3. NLC Frequency Response Alters Over Time

(A) Currents were averaged at three time regions, six chirp responses each, over the duration of holding potential, p3-8, p13-18, and p23-28, and NLC was extracted for each region.

(B) NLC for the three durations is shown. The red line demarks the slope of NLC at V_h for the first region (p3-8) and is recast on the others. Note the change in NLC as duration of holding voltage increases.

(C) The frequency response of NLC at V_h is fit with a power function and shows that low-frequency regions of the response decreases over time. Circles depict one-half magnitude, which increases over time.

(D–G) Plots show the parameters of the power fits ([D] NLC_0 , [E] a , [F] b , and [G] F_c) that alter over time.

(H and I) V_h shifts over the duration of holding voltage steps. (H) V_h across frequency (colors correspond to those in [C]).

(I) Mean V_h across frequency corresponding to data and colors in (H).

on NLC frequency response, we utilized lower concentrations (10 μ M), assessing the response before (Figure 4B, top panel) and after (Figure 4B, bottom panel) treatment. Figure 4C shows that low-frequency components of NLC were reduced by 10 μ M salicylate, effectively increasing the frequency cut-off. None of the NLC frequency modulations we observed, due to time dependence or salicylate interference with chloride binding, sufficiently increased the response to promote very high frequency electromechanical activity.

DISCUSSION

The identification of AC electromotile responses of the OHC (Kachar et al., 1986) offered a clue to the OHCs' ability to promote high-frequency enhancement of hearing in mammals (Dallos, 2008). The subsequent identification of the response's voltage dependence and associated voltage-sensor activity (Santos-Sacchi, 1990, 1991; Santos-Sacchi and Dilger, 1988; Ashmore, 1990) suggested that OHC receptor potentials, evoked by acoustic stimulation, drive feedback of mechanical energy into the cochlear partition. It is current dogma that this feedback is cycle-by-cycle, working best at high frequencies, where tonotopic

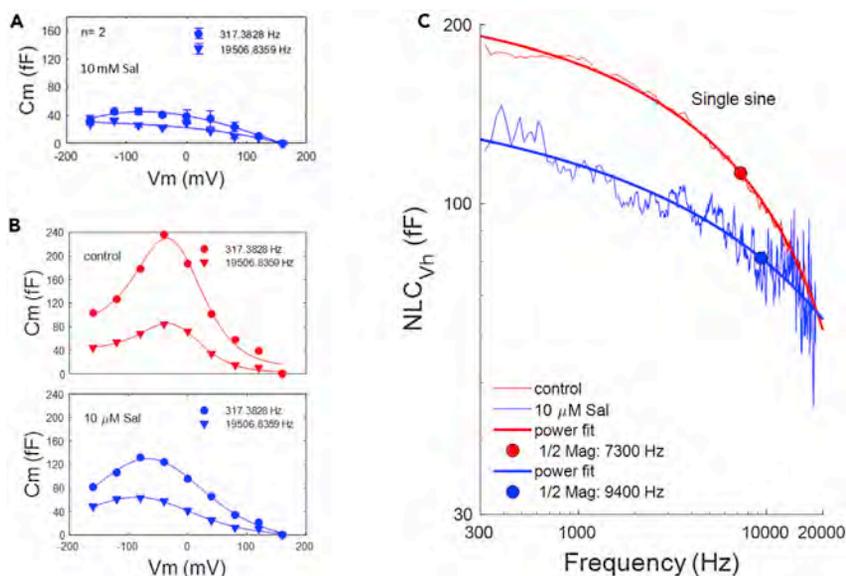

Figure 4. Salicylate Blocks NLC by Reducing Low Frequency Components

Blue color denotes responses after salicylate treatments. Red color denotes control prior to treatment.

(A) NLC is substantially reduced by 10 mM salicylate.

(B) *Top panel*: control before and *bottom panel*: after application of 10 μ M salicylate to a single patch to provide partial block of NLC.

(C) The resultant partial inhibition of fit extracted NLC illustrates a low-frequency block, which effectively increases NLC frequency response.

frequency tuning is best (Ashmore et al., 2010). Indeed, OHC eM had been measured in a whole-cell micro-chamber configuration to work without attenuation beyond 80 kHz at room temperature (Frank et al., 1999), this in spite of initial studies showing more limited charge movement (Gale and Ashmore, 1997a). More recent investigations on whole cells have challenged the concept of OHC high-frequency electromechanical activity, with both NLC and eM exhibiting significant low-pass behavior below 10 kHz (Santos-Sacchi, 2019; Santos-Sacchi et al., 2019; Bai et al., 2019). Our current data on excised and on-cell macro-patch measures of NLC, where whole-cell mechanical loads on the piezoelectric-like protein prestin are absent, directly show continuous roll-off of prestin's conformational activity and indicate that attenuation of sensor-charge movement in both mouse and guinea pig is not single Lorentzian in nature, but instead fit well by a power function of frequency. This frequency response is not very different from that of capacitance measures in the GAT1GABA transporter (Lu et al., 1995). Mechanisms that we find to enhance the frequency response of prestin, namely, time-dependence or motor block with salicylate, do not increase its high-frequency behavior, but simply work by reducing the magnitude of low-frequency components. These observations place a severe restraint on the effectiveness of voltage (i.e., receptor potentials) to drive electromechanical responses of the OHC at very high acoustic frequencies where several mammals possess hearing in the 60–160 kHz range. That is, there can be little or no OHC mechanical feedback in the absence of prestin sensor charge movement at high frequencies, assuming that prestin works as an AC motor driven by AC voltage. Interestingly, *in vivo* indications of OHC electromechanical activity in the gerbil obtained with OCT show low pass behavior, as well (Vavakou et al., 2019). Those authors considered the RC filter problem (Santos-Sacchi, 1989), where OHC receptor potentials are expected to be attenuated at very high frequencies by more than 20 dB relative to partition movements, and thus not be able to drive prestin. Our data show that the RC filter problem is inconsequential, in as much as the ability of prestin to follow wide-band voltage perturbations is insufficient in and of itself.

There is no doubt that normal prestin activity is involved in the process that enhances hearing capabilities (Dallos et al., 2008; Santos-Sacchi et al., 2006). Knock-in of prestin mutations that alter its voltage operating range (i.e. V_h) or manipulations of OHC chloride, known to influence prestin activity, are catastrophic to cochlear amplification in the mouse, the latter in a reversible manner. How can a slow motor protein work to enhance high-frequency hearing? Could low pass eM actually be countering low-frequency acoustic responses in order to “highlight” high-frequency input to the cochlea? Intriguing results on basilar

membrane tuning have been obtained in prestin knock-out/in mice that may point to possible mechanisms of OHC action (MelladoLagarde et al., 2008). Alternatively, a rectified DC component of prestin activity (Evans et al., 1991; Santos-Sacchi, 1989) could contribute to effects on high-frequency tuning, as Vavakou et al. (Vavakou et al., 2019) have intimated. Finally, global hydromechanical influences of the OHC may be at play (He et al., 2018). In any case, the long-held cycle-by-cycle hypothesis of cochlear amplification at very high frequencies is directly countered by our present observations.

Limitations of the Study

Ion concentrations in pipette and cell over the timescale of recording are likely fixed; however, conceivably, as in any macro-patch experiment, ion depletion or accumulation on the patched membrane could influence electrical measures.

METHODS

All methods can be found in the accompanying [Transparent Methods supplemental file](#).

Transparent Methods

OHCs were isolated from guinea pig and mouse as described previously (Santos-Sacchi et al., 2019; Santos-Sacchi and Tan, 2018). Briefly, animals were killed by anesthetic overdose, the cochleas removed and the organ of Corti of the top two coils dissected out. Following 5 minutes of enzymatic digestion with trypsin (0.5mg/ml), the OHCs were isolated by gentle trituration and placed in a petri dish on a Nikon Eclipse TI-2000 microscope for recording. Extracellular solution was (in mM): NaCl 100, TEA-Cl 20, CsCl 20, CoCl₂ 2, MgCl₂ 1, CaCl₂ 1, Hepes 10, pH 7.2. Extracellular solution was in the patch pipette. Macro-patches on the OHC lateral membrane were made near the middle of the cylindrical cell; since prestin density/activity is uniform within the lateral membrane (Dallos et al., 1991; Huang and Santos-Sacchi, 1993), they provide representative information. For the guinea pig on-cell macro-patch approach we used pipette inner diameters of 3.38 +/- 0.20 μm (electrode resistance in bath 1.46 +/- 0.06 M Ω , n=13), with M-coat applied within about 20 μm of the tip to minimize pipette capacitance. Hemispheric estimate of patch surface area was 179 fF. Mouse pipette tip size was smaller at 2.29 +/- 0.024 μm (n=3). In order to establish Gohm seals (5.54 +/- 0.59 G Ω , n=13) we supplemented extracellular solution with 5-7.5 μM Gd⁺³; we have shown previously that these low concentrations help to form seals without affecting NLC (Santos-Sacchi and Song, 2016; Santos-Sacchi et al., 2019). **Fig. 1A-D** illustrates our protocol to measure high frequency NLC. Voltage steps from -160 mV to 160 mV were superimposed with an array of voltage chirps. We have previously shown that breakdown of prestin expressing membrane occurs at voltages greater than 300 mV (Navarrete and Santos-Sacchi, 2006). Nevertheless, patches where instabilities of the membrane produced erratic currents at the largest potentials were removed from our data set. An Axon 200B amplifier was used with jClamp software (www.scisoftco.com). An Axon Digidata 1440 was used for digitizing at 10 μs (Nyquist frequency of 50 kHz). Currents were filtered at 10 kHz with a 4-pole Bessel filter. The voltage chirps were generated in the software program jClamp (www.scisoftco.com) using the Matlab logarithmic “chirp” function (10 mV pk; pts=4096; F0=24.4141 Hz; F1=50 kHz; t1=0.04095 s). Subtraction of currents at very depolarized potentials (160 mV) where NLC is absent (Santos-Sacchi and Navarrete, 2002), provided prestin-associated nonlinear currents, absent stray capacitive currents. Subsequently, these subtracted nonlinear membrane currents were used

for dual-sine or single-sine based capacitance estimation by evaluating real and imaginary components of the differential input admittance (Y_{diff}) derived from the subtracted currents (Santos-Sacchi, 2004; Santos-Sacchi et al., 1998). The removal of stray capacitance is required for the application of membrane capacitance algorithms (see below). Briefly, real and imaginary components of the nonlinear membrane admittance at all chirp frequencies were determined by FFT in jClamp, and corrected for the roll-off of recording system admittance (Gillis, 1995). That is, the frequency response of the system, including all components (AD/DA, amplifier and filter) was assessed by placing a small shielded resistor, 10 M Ω , into the head stage input. Stray capacitance was balanced out with amplifier circuitry prior to grounding the resistor. Then, following grounding, voltage chirps (frequency span from 3.05 to 50 kHz, 32768 points at 10 μ s clock) were delivered, and currents recorded to provide system admittance. The magnitude and phase of our system response is shown in **Figure S1 A and B**. That system admittance is used to correct experimental data admittance. The necessity for such corrections are shown in **Figure S1 C-D**, where an electrical cell model (R_s : 10 M Ω , R_m : 2 G Ω , and C_m : 1 pF) was analyzed similar to macro-patches, after stray capacitance compensation with amplifier circuitry. It can be seen, for both the dual sine and single sine analysis, that uncorrected responses are aberrant, but following correction for system magnitude and phase (i.e., dividing the complex response admittance by system admittance at each stimulus frequency), the subsequently estimated capacitance is flat at about 1 pF across frequency, regardless of holding potential. Thus, our methodology permits us to measure capacitance with high fidelity out to 20 kHz across holding potentials. We and others have previously used such an approach, though at lower interrogating frequencies, to measure NLC, as well as capacitance associated with synaptic vesicle release (Santos-Sacchi, 2018; Schnee et al., 2011b; Schnee et al., 2011a; Santos-Sacchi et al., 1998).

For the dual sine method, the solution of the standard electrode-cell model is obtained from the admittances at 2 interrogating frequencies (Santos-Sacchi et al., 1998; Santos-Sacchi, 2018), based on the original single sine solution of Pusch and Neher (Pusch and Neher, 1988). The component solutions at harmonic angular frequencies ω_n , where $n=0, 1$ and $\omega_n=2\pi f_n$, are

$$R_{s_n} = \frac{a_n - \beta}{a_n^2 + b_n^2 - a_n \beta}$$

$$R_{m_n} = \frac{1((a_n - \beta)^2 + b_n^2)}{b(a_n^2 + b_n^2 - a_n\beta)}$$

$$C_{m_n} = \frac{1}{(\omega_n b_n)} \frac{(a_n^2 + b_n^2 - a_n\beta)^2}{((a_n - \beta)^2 + b_n^2)}$$

where from the measured input admittance Y_{in} we obtain

$$Y_{cell\omega_n} = Y_{in\omega_n} - Y_{stray\omega_n}, n = 0,1$$

$$a_n = Re(Y_{cell\omega_n})$$

$$b_n = Im(Y_{cell\omega_n})$$

$$c_n = a_n^2 + b_n^2$$

$$\beta = -0.5 \times \frac{-c_1 + c_0 + \sqrt{c_1^2 - 2c_1c_0 + c_0^2 - 4a_1a_0c_1 + 4a_1^2c_0 + 4a_0^2c_1 - 4a_0a_1c_0}}{a_1 - a_0}$$

Thus, membrane currents evoked by two voltage frequencies can be used to solve for R_s , R_m and C_m , even in the face of resistive changes, *but only in the absence of stray capacitance*. This applies to measures of patch capacitance, as well. We report on C_m measures derived from f_n , where $n=0$.

For single sine analysis, capacitance was estimated from the imaginary component of the admittance, $C_m = Im(Y_{diff}) / \omega$, where $\omega = 2\pi f$, after minimizing the real component of admittance by rotating the phase angle of the complex admittance. Single and dual sine frequency response estimates were essentially the same (for example, see **Figure S1 D and F**).

To extract NLC at each frequency, we fit V_m - C_m data to the following *eq. 1* (Santos-Sacchi and Navarrete, 2002). This equation extracts NLC based on a 2-state charge movement (Boltzmann) model, which predicts symmetrical NLC on either side of V_h . In fact, measured membrane capacitance in OHCs or prestin-expressing heterologous cells is greater at hyperpolarized potentials than at depolarized potentials. This voltage-dependent sigmoidal offset is removed by the fit (see **Fig. 1H**). The equation has been routinely used to evaluate NLC (Santos-Sacchi and Song, 2014; Homma and Dallos, 2011; Duret et al., 2017; Chessum et al., 2018; Harasztosi and Gummer, 2016).

eq. 1

$$C_m = Q_{max} \frac{ze}{kT} \frac{b}{(1+b)^2} + \frac{\Delta C_{sa}}{(1+b^{-1})} + C_0$$

where

$$b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right)$$

Q_{max} is the maximum nonlinear charge moved, V_h is voltage at peak capacitance or equivalently, at half maximum charge transfer, V_m is membrane potential, z is valence, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. C_0 is defined as the capacitance of the membrane when all motors are in their compact state, the minimum membrane capacitance; ΔC_{sa} is the maximum increase in capacitance that occurs when all motors change from compact to expanded state, each motor contributing a unit response of δC_{sa} .

Data are presented as mean +/- standard error (SE). Data points from previous publications were extracted from plots using the application Grabit (written by Jiro Doke) in Matlab.

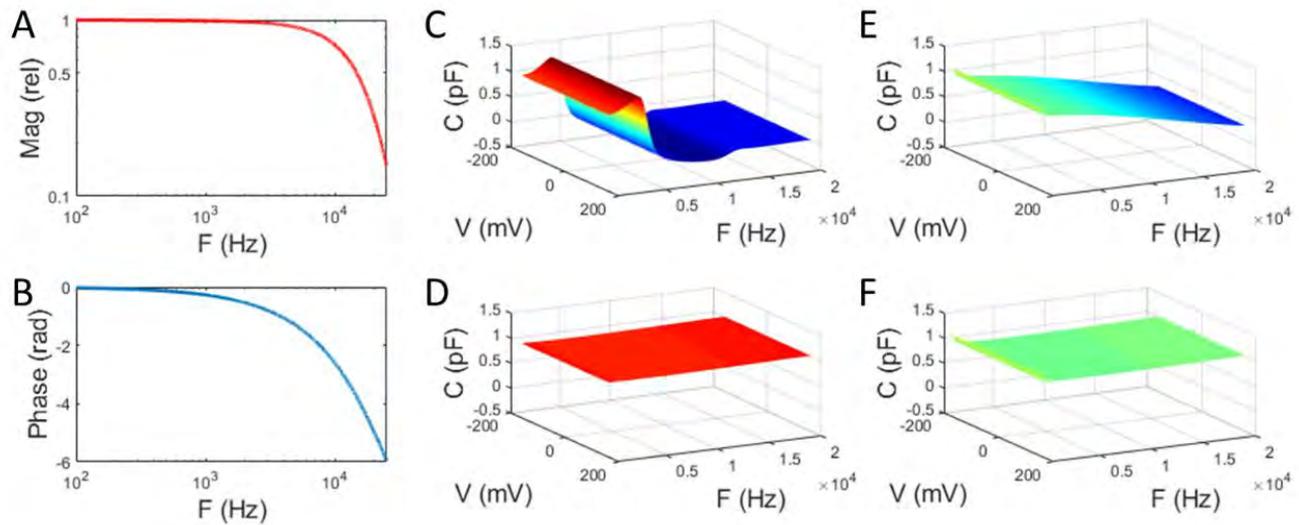

Figure S1 Requirement to correct for the frequency response of the patch clamp system prior to capacitance estimation, Related to Figure 1 and 2. A) Magnitude and B) phase of the system. Determination is detailed in the Methods. In C-D, a model electrical patch (R_s : 10 M Ω , R_m : 2G Ω , C_m : 1 pF) is used to confirm proper system performance. C,D) illustrate capacitance measures utilizing dual sine analysis and E,F) using single sine analysis as detailed in Methods. In C) and E) capacitance measures are not corrected for system frequency response. Responses are aberrant. In D) and F) corrections are made to the measured model patch admittance based on measured system admittance. Following corrections, capacitance measures are flat out to 20 kHz, across holding potentials of -160 to 160 mV.

The voltage-dependent protein SLC26a5 (prestin) underlies outer hair cell electromotility (eM), which is responsible for cochlear amplification in mammals. The electrical signature of eM is a bell-shaped nonlinear capacitance (NLC), deriving from prestin sensor-charge (Q_p) movements, which peaks at the membrane voltage, V_h , where charge is distributed equally on either side of the membrane. Voltage dependencies of NLC and eM differ depending on interrogation frequency and intracellular chloride, revealing slow intermediate conformational transitions between anion binding and voltage-driven Q_p movements. Consequently, NLC exhibits low-pass characteristics, substantially below prevailing estimates of eM frequency response. Here we study in guinea pig and mouse of either sex synchronous prestin electrical (NLC, Q_p) and mechanical (eM) activity across frequencies under voltage clamp (whole cell and microchamber). We find that eM and Q_p magnitude and phase correspond, indicating tight piezoelectric coupling. Electromechanical measures (both NLC and eM) show dual-Lorentzian, low-pass behavior, with a limiting (τ_2) time constant at V_h of 32.6 and 24.8 μ s, respectively. As expected for voltage-dependent kinetics, voltage excitation away from V_h has a faster, flatter frequency response, with our fastest measured τ_2 for eM of 18.2 μ s. Previous observations of ultrafast eM ($\tau \approx 2 \mu$ s) were obtained at offsets far removed from V_h . We hypothesize that trade-offs in eM gain-bandwidth arising from voltage excitation at membrane potentials offset from V_h influence the effectiveness of cochlear amplification across frequencies.

Key words: capacitance; cochlear amplification; electromotility; membrane proteins; outer hair cell; sensor charge

Significance Statement

Of two types of hair cells within the organ of Corti, inner hair cells and outer hair cells, the latter evolved to boost sensitivity to sounds. Damage results in hearing loss of 40–60 dB, revealing amplification gains of 100–1000 \times that arise from voltage-dependent mechanical responses [electromotility (eM)]. eM, driven by the membrane protein prestin, may work beyond 70 kHz. However, this speed exceeds, by over an order of magnitude, kinetics of typical voltage-dependent membrane proteins. We find eM is actually low pass in nature, indicating that prestin bears kinetics typical of other membrane proteins. These observations highlight potential difficulties in providing sufficient amplification beyond a cutoff frequency near 20 kHz. Nevertheless, observed trade-offs in eM gain-bandwidth may sustain cochlear amplification across frequency.

Introduction

The voltage-dependent protein SLC26a5 (prestin) underlies outer hair cell (OHC) electromotility (eM; Zheng et al., 2000; Liberman et al., 2002), considered to be responsible for cochlear amplifica-

tion in mammals (Santos-Sacchi et al., 2006; Dallos et al., 2008). This mechanism provides 40–60 dB gain in our perceptions of sound. eM has been characterized biologically as ultrafast, exhibiting no attenuation beyond 70 kHz (Frank et al., 1999), and such uniform mechanical activity across frequencies is assumed to be required for cochlear amplification by some mammalian species that have hearing capabilities well beyond the range of human frequency detection.

While cochlear amplification clearly results from the voltage-dependent mechanical activity of the OHC, it behooves us to understand frequency-response characteristics of eM, since amplification may extend to very high frequencies in some mammals. There are at least two independent influences on eM frequency response. The first is the ability of the cell to provide

the drive for eM, namely, the attenuating influence of the membrane resistive–capacitive (RC) time constant on receptor potentials at high frequency; the second is the ability of the prestin motor protein to follow voltage changes at high frequencies. It is this second issue, the focus of the pioneering work of Dallos and Evans (1995) and Frank et al. (1999), that we explore here.

The electrical correlate of eM is a bell-shaped nonlinear capacitance (NLC; Ashmore, 1990; Santos-Sacchi, 1991), which peaks at the membrane voltage (V_h) where the prestin voltage-sensor charge (Q_p) is equally distributed across the OHC membrane field in a way that is analogous to voltage-dependent ion channel capacitance/gating behavior (Armstrong and Bezanilla, 1974; Kilic and Lindau, 2001). We recently determined that the apparent, simultaneously evaluated, voltage dependence of NLC and eM differs depending on intracellular chloride level and interrogation frequency, revealing slow (multiexponential) intermediate conformational transitions between required anion binding and Q_p movements (Song and Santos-Sacchi, 2013). Consequently, analysis of NLC across frequency has revealed significant low-frequency roll-off (Santos-Sacchi and Song, 2014, 2016) that is incompatible with the demonstration of ultrafast eM lacking any evidence of low-pass components (Frank et al., 1999). Additionally, disparities that we and others have reported between electrical and mechanical properties (Gale and Ashmore, 1997) of the OHC motor appear to challenge the concept of tight electromechanical coupling in OHCs, namely, its piezoelectric-like behavior (Iwasa, 1993; Gale and Ashmore, 1994; Mountain and Hubbard, 1994; Kakehata and Santos-Sacchi, 1995; Dong et al., 2002).

Here we study simultaneously evoked prestin electrical (both NLC and Q_p) and mechanical (eM) responses, synchronously measured across frequencies to quantify electromechanical coupling in OHCs. We find that while Q_p and eM are indeed tightly coupled, NLC reports not on the frequency response of eM, but only on the limiting kinetics of eM. Finally, we identify two frequency components of NLC and eM (one slow, one fast), and show that trade-offs between frequency response and gain of eM, similar to the gain–bandwidth product optimization used in operational amplifiers, may be obtained by excitation of the OHC at a resting voltage offset from V_h . We conclude that voltage-dependent eM is intrinsically low-pass, in line with behavior of most voltage-dependent proteins, relative to the highest frequencies perceivable by certain mammals. However, we hypothesize that mechanisms that provide stimulus offsets from V_h , either shifts in resting potential or prestin's voltage dependence, may actually work to enhance the bandwidth of cochlea amplification.

Materials and Methods

Whole-cell recordings were made from single isolated OHCs from the apical turns of organ of Corti of guinea pigs and mice of either sex. Since prestin's identification in 2000 (Zheng et al., 2000), there is no evidence that prestin itself or its behavior differs in long or short OHCs from different regions of the cochlea (Santos-Sacchi et al., 2017). An inverted Nikon Eclipse TI-2000 microscope with a 40× lens was used to observe cells during voltage clamp. Experiments were performed at room temperature. Blocking solutions were used to remove ionic currents, thus limiting confounding effects on NLC determination and voltage delivery under voltage clamp (Santos-Sacchi, 1991; Santos-Sacchi and Song, 2016). Extracellular solution was as follows (in mM): 100 NaCl, 20 tetraethylammonium-Cl, 20 CsCl, 2 CoCl₂, 1 MgCl₂, 1 CaCl₂, 10 HEPES. Intracellular solution was as follows (in mM): 140 CsCl, 2 MgCl₂, 10 HEPES, and 10 EGTA. Contamination of prestin NLC by ion channel gating current is negligible since channel charge movement is orders of magnitude smaller than the OHC charge due to prestin (2–4 pC; Santos-Sacchi, 1991). All chemicals were purchased from Sigma-Aldrich.

Cell capacitance, prestin charge, and mechanical response. An Axon 200B amplifier was used for whole-cell (head stage $\beta = 1$) and microchamber (head stage $\beta = 0.1$) recording with jClamp software (www.scisoftco.com). A National Instruments 6550 AD/DA or Axon Digidata 1440 was used for digitizing. To avoid time-dependent influences on our measures, no averaging was done, except where noted. AC analysis of membrane currents (I_m) and eM were made by stimulating cells with individually delivered or summed voltages at harmonic frequencies from 48.8 to 12,500 Hz (depending on recording configuration) with a 10 μ s sample clock. Magnitude and phase of responses were computed by FFT in Matlab. Integration of AC currents to extract charge was performed in the frequency domain ($Q_p = I_m/j\omega$; $\omega = 2\pi f$; $j = \sqrt{-1}$). Since prestin charge movement has very shallow voltage dependence ($z \approx 0.85$), charge at very positive voltages where NLC is minimized (+50 or +130 mV) was subtracted following scaling to estimated values at 300 mV ($\times 0.875$ – 0.9), based on two-state Boltzmann fits, thereby removing charge generated by linear capacitance. Capacitance was measured using dual-sine analysis at harmonic frequencies (Santos-Sacchi et al., 1998; Santos-Sacchi, 2004). To extract Boltzmann parameters, capacitance-voltage data were fit to the first derivative of a two-state Boltzmann function as follows:

$$C_m = Q_{max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin} \text{ where } b = \exp\left(\frac{-ze(V_m - V_{pkCm})}{kT}\right)$$

Q_{max} is the maximum nonlinear charge moved, V_{pkCm} or V_h is voltage at peak capacitance or equivalently, at half-maximum charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature.

NLC determination requires stray capacitance removal due to analysis constraints (viz, admittance solutions assume no stray capacitance; Santos-Sacchi et al., 1998; Santos-Sacchi and Song, 2016). NLC was not measured following changes in series resistance compensation circuitry because phase lags introduced by compensation circuitry invalidate the system calibration used to correct for the system's frequency response. The system response is required for NLC measures. Patch pipettes were coated with M-coat (Micro Measurements) to reduce stray capacitance. Remaining stray capacitance was removed by amplifier compensation circuitry before whole-cell configuration. If necessary, additional compensation was applied under whole-cell conditions (Schnee et al., 2011a,b) and/or through a software algorithm to ensure expected frequency-independent linear capacitance (Santos-Sacchi, 2018).

Simultaneous eM measures were made with fast video recording or a photo diode system. The photo diode measurement details have been published (Santos-Sacchi and Song, 2014). Briefly, we stimulated with 50 mV peak discrete AC bursts across harmonic frequencies (12.2–6250 Hz) to explicitly excite the OHC eM nonlinearity and generate fundamental and harmonic responses. For video analyses, a Phantom 110 camera (Vision Research) was used for video measures at frame rates of 25 kHz (whole cell) or 50 kHz (microchamber). For whole cell, stimuli were the sum of nine 15 mV peak harmonic frequencies (48.8–12,500 Hz). Additional magnification was set to provide 176 nm/pixel. The bright edge of the cuticular plate was used to track OHC length change by fitting a Gaussian to the peak of the image, providing subpixel resolution of movements (see Fig. 2A). The fitted line (five pixels wide) was drawn to encompass the cuticular plate at right angles, the number of points (pixels) depending on the image thickness of the plate, which can vary from cell to cell. Only a single peak was chosen for tracking.

The patch electrode or microchamber provided a fixed point at the basal end or middle of the cell, respectively. For cells studied with video analysis under whole-cell mode, charge-movement magnitude was corrected for the magnitude roll-off of the 10 kHz Bessel filter. Series resistance (R_s) was determined from voltage step-induced whole-cell currents (Huang and Santos-Sacchi, 1993, their appendix). For the microchamber, a 30 kHz filter (external Frequency Devices 9002 filter with 200B open filter) was used to collect current data, but because of the complexity of charge movements (moving in opposite directions in each part of the partitioned cells), no analysis was performed. Resultant movements

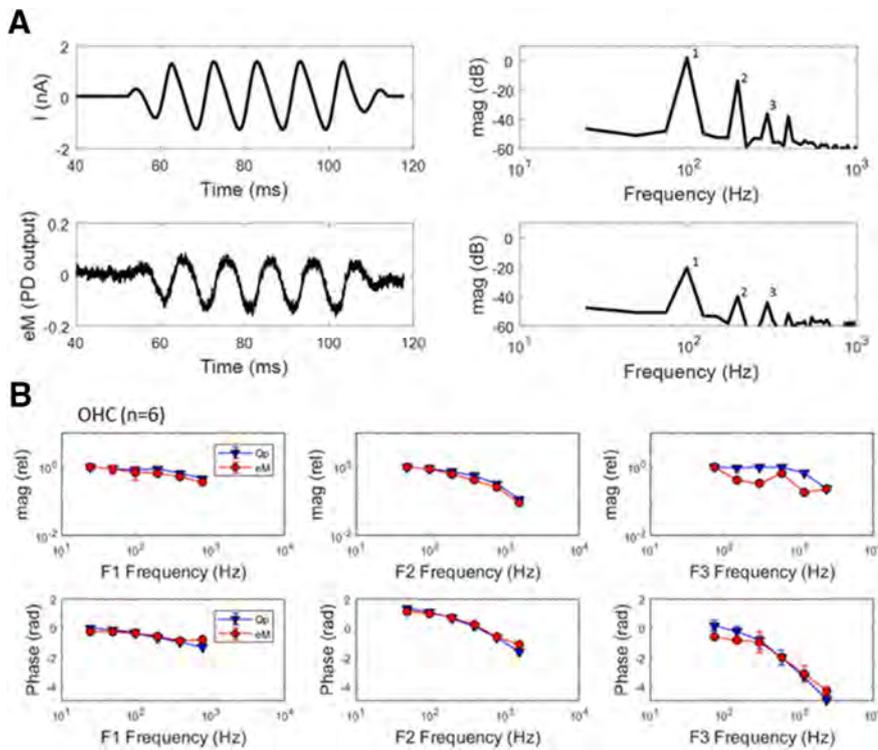

Figure 1. Gating charge and eM are coupled. **A**, Example of currents and eM at 97.7 Hz. Harmonics (1, 2, 3) are generated by nonlinearities in the process generating mechanical responses. **B**, Comparison of average ($n = 6$) relative magnitude and phase of eM and prestin sensor charge (Q_p) for harmonics 1, 2, and 3, illustrating tight coupling between the two measures of prestin activity across frequencies. Responses were time averaged 8–64 times to achieve an equal signal-to-noise ratio across frequencies. Fifty millivolt peak discrete AC bursts across harmonic frequencies were delivered to explicitly excite the OHC eM nonlinearity and generate fundamental and harmonic responses.

were analyzed by FFT in Matlab. The colors in surface plots were generated in the Matlab plotting routine `surf` with shading set to `<interp>`. This procedure allows contours to be readily observable. No relation to 3 dB breakpoint is intended.

For the microchamber, voltage across the membrane of the extruded length of the cell, qL , is estimated as the imposed microchamber voltage, V , factored by $1 - q$, q being extent (0–1) of extrusion (Dallos et al., 1993; Frank et al., 1999). The calculated correction is 0.4539, since our average $q = 0.546$. Shunt resistance could also be influential (Dallos et al., 1991; Huang and Santos-Sacchi, 1993); our average was $4.97 \pm 0.8 \text{ M}\Omega$ ($n = 8$), approximately estimated from voltage steps. With this shunt resistance, the calculated correction is quite accurate as shown by near equivalence of the Boltzmann z parameter for both eM and NLC (see Fig. 10). For the microchamber, AC stimuli were the sum of nine 30 mV peak harmonic frequencies (48.8–12,500 Hz), and given the correction factor above 0.4539, 13.62 mV was delivered to the extruded cell membrane, similar to whole-cell conditions. Microchamber eM responses were corrected for extrusion factor to equate to whole-cell measures (eM/q ; Frank et al., 1999).

At other than DC, the frequency cutoff [f_c , 3 dB down point, or time constant τ ($1/2\pi f_c$)] of voltage delivery will be determined, as in whole-cell voltage clamp, by R_s and predominantly cell capacitance, since for the OHC, cell capacitance dominates any stray capacitance of the macropipette. Additional lumped stray capacitance of the amplifier, pipette holder, etc., will not influence clamp τ since it only influences the circuit as a current divider (see Fig. 9). It is typically compensated electronically (e.g., in whole-cell mode) only to limit amplifier saturation, not to extend voltage-clamp frequency response. Thus, given a voltage-clamp amplifier that can provide sufficient current to the microchamber, voltage delivery across R_s in series with cell impedance will be immune to this stray capacitance. Thus, f_c will chiefly depend on q , where at $q = 0.5$, a balanced capacitance divider can be achieved (assuming inserted and extruded membrane τ 's are equal), and provide a maximally flat fre-

quency response for voltage delivery. The f_c will increase in a U-shaped manner on either side of $q = 0.5$, but will depend critically on R_s (see Fig. 11). We compensated stray capacitance with our amplifier (Axon 200B) compensation circuitry before recording to limit amplifier saturation. eM was corrected for microchamber clamp time constant effects based on voltage-induced transient responses of measured currents following AC stimulation (see Figs. 9, 10). Measurement noise floor was estimated from the saturated AC eM responses at +200 mV offset. Cells displaying maximum steady-state (DC) microchamber eM responses $< 1.0 \mu\text{m}$ were discarded, since such small responses may be a sign of reduced turgor pressure, which can reduce eM (Santos-Sacchi, 1991). Models were implemented in Matlab Simulink and Simscape, as detailed previously (Song and Santos-Sacchi, 2013; Santos-Sacchi and Song, 2014). Data points from previous publications were extracted from plots using the application Grabit (written by Jiro Doke) in Matlab.

Statistics. R_s -corrected V_m versus NLC, Q_p , and eM data were fit with the first derivative of a two-state Boltzmann function to provide comparable Boltzmann parameters z and V_h for each measure (Santos-Sacchi, 1991). Data are presented as mean \pm SE. Regressions were performed in Matlab. Using SAS 9.4 (SAS Institute), the mean phase data in Figure 9C were tested for significance from zero. A one-group t test was used to test the null hypothesis. The results are reported in the figure.

Results

In whole-cell mode, we simultaneously measured the first (fundamental), second, and third harmonic of both eM and membrane current I_m using single sinusoidal bursts of voltage (Fig. 1A). For the OHC under voltage clamp, the following equations apply:

$$I_m = i_{R_s} = i_{R_m} + i_{C_{lin}} + i_{NLC}$$

$$I_m = \frac{V_m}{R_m} + C_{lin} \frac{dV_m}{dt} + NLC \frac{dV_m}{dt}$$

$$i_{NLC} = \frac{dQ_p}{dt}$$

where Q_p is prestin charge. In our experiments, NLC is the dominant nonlinearity, since nonlinear ionic membrane currents are blocked. Nonlinear harmonic currents thus predominantly represent voltage-driven displacement currents arising from prestin sensor charge movements normal to the membrane field. Prestin charge at these harmonic frequencies, Q_p , is obtainable by integration of current, signifying that the phases of harmonic charge components will lag current phase by 90° .

While the nonlinear harmonic currents arise from prestin charge movements alone, those of the fundamental have additional contributions from linear components (C_{lin} , R_m) of the cell. To remove those linear components, so we can additionally compare electrical and mechanical responses at the fundamental, we note that the relationship between second harmonic eM and second harmonic nonlinear current should hold for the fundamental re-

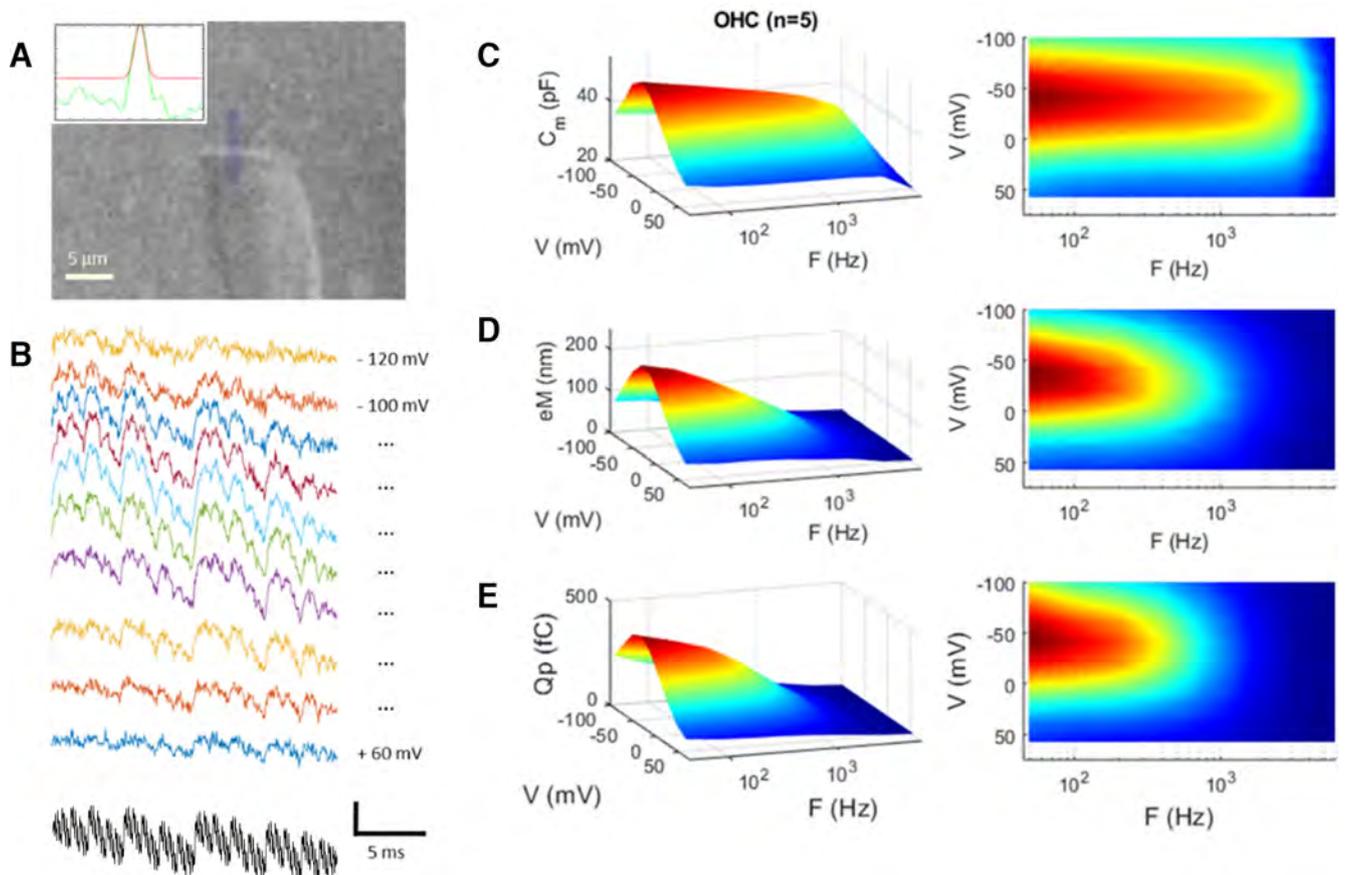

Figure 2. Low-pass electromechanical behavior of the OHC under whole-cell voltage clamp. **A**, Video frame of an OHC whose eM was measured by tracking the edge of its cuticular plate. Inset, Bright edge (green line) is fitted with a Gaussian (red line) and tracked across frames (25,000 fps). **B**, Raw eM responses (colored traces) generated by the multifrequency voltage stimulus (black trace) summed to differing holding potentials. eM responses are arbitrarily offset and colored for easy visualization. Vertical scale bar is 0.45 μm for eM and 50 mV for voltage (sum of 9 15 mV peak harmonic frequencies starting at 48.8 Hz). **C**, NLC, in contrast to linear capacitance, is frequency dependent, showing low-pass behavior. Rightmost panels show alternative view of surface plots to appreciate frequency response. **D**, eM shows lower-pass behavior compared with NLC. **E**, Prestin sensor charge (Q_p) shows behavior similar to eM. eM and Q_p frequency-response time constants at V_h are statistically indistinguishable by t test ($p = 0.134$). Average responses from five cells.

sponses (confirmed through modeling). Thus, the complex ratio of eM and current at the second harmonic will approximate that at the first harmonic (fundamental), expressed as follows:

$$\frac{eM_{f_2}}{Im_{f_2}} \approx \frac{eM_{f_1}}{Im_{f_1} - Im_{f_1lin}}$$

The linear component of Im_{f_1} , namely, Im_{f_1lin} , was solved for and subtracted from Im_{f_1} . These manipulations only affect fundamental frequency comparisons. The underlying premise to be confirmed is that the electromechanical activity of the OHC is piezoelectric-like, and that prestin sensor charge movements (Q_p) correspond to eM, despite recently identified phase differences between V_m and eM (Santos-Sacchi and Song, 2014), and previously identified timing disparities between Q_p and eM (Gale and Ashmore, 1997; Santos-Sacchi and Song, 2014). In our kinetic models, we assume eM corre-

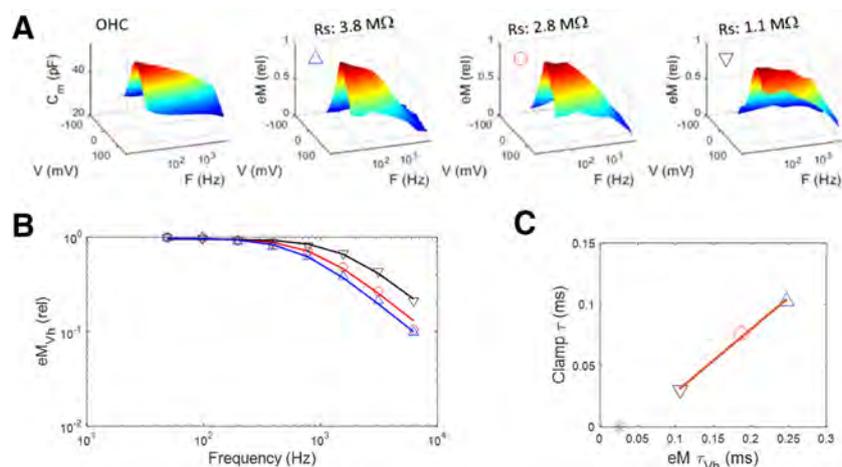

Figure 3. Whole-cell clamp time constant limits eM frequency response. **A**, Left panel shows NLC in an OHC, whose eM was measured at three different values of R_s (achieved through amplifier R_s compensation circuitry). As clamp time constant is decrementally reduced (clamp $\tau \approx R_s * C_m$), eM frequency response approaches that of NLC. Symbols correspond to all plots. **B**, Magnitude–frequency plot illustrating enhanced frequency response of eM at V_h . **C**, Linear relationship between eM and clamp time constants. eM τ_{Vh} approaches this cell’s NLC τ_{Vh} , determined from a single exponential fit (blue asterisk). Stimulus was 15 mV peak at each frequency.

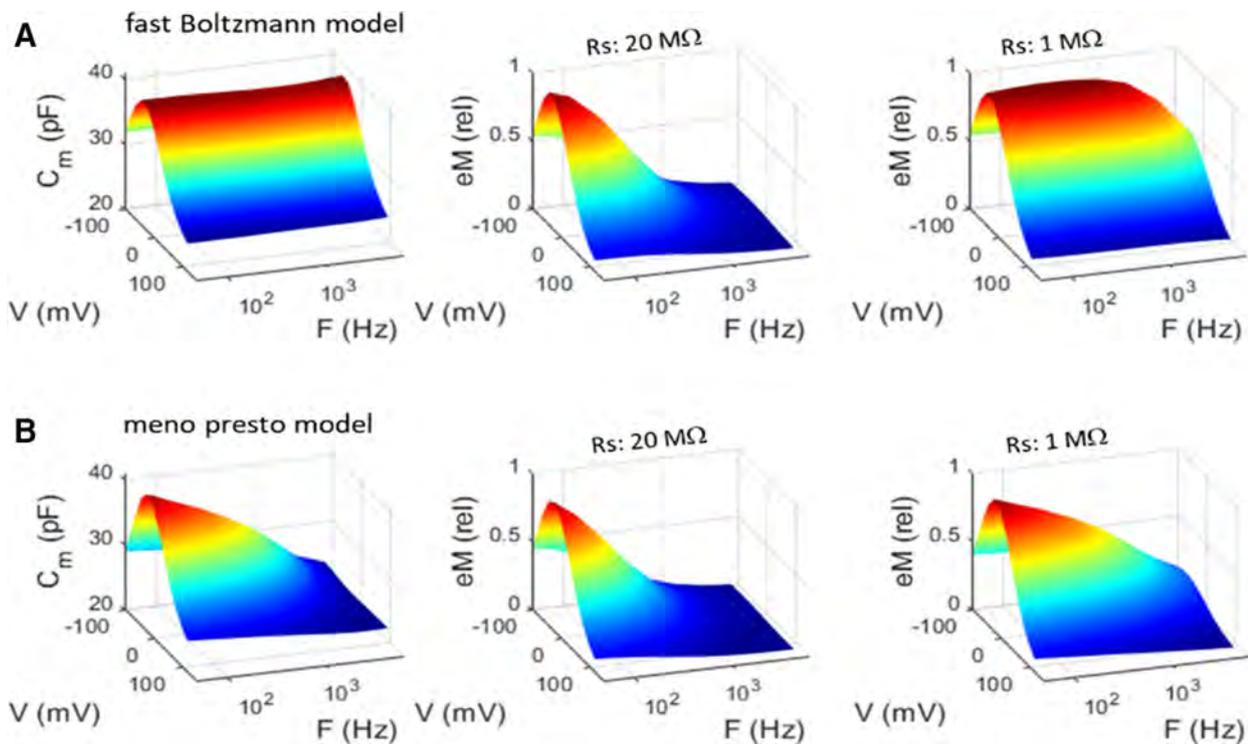

Figure 4. Models show that kinetics underlying NLC frequency response restrain frequency response of eM (Q_p). **A**, NLC of a two-state Boltzmann model is frequency independent. However, eM (Q_p ; right) faithfully follows clamp time constant. **B**, NLC of *meno presto* model incorporating slow multiexponential kinetics is low-pass. Note that eM (Q_p) frequency response is also increased by reducing clamp time constant, but is limited by kinetics that define NLC response. AC stimulus was 15 mV peak at each frequency.

sponds to the occupancy of the protein in the contracted state where positive sensor charge accumulates during depolarization/cell shortening. Thus, the validity of our model and of other similar (e.g., two state) models depends on tight coupling.

In Figure 1B, average (\pm SE; $n = 6$) magnitude and phase of first, second, and third harmonics of Q_p and eM are shown. The eM and Q_p data compare favorably, indicating that eM is tightly coupled in magnitude and time (phase) to prestin charge, as expected for a piezoelectric process. Considering the phase lag between OHC V_m and eM (Santos-Sacchi and Song, 2014), our observation of tight coupling between Q_p and eM identifies the piezoelectric nature of the OHC as being one with hysteresis. Namely, there is a delay between voltage drive and charge motion, but no delay between charge motion and OHC motion. We previously observed V_m – eM hysteresis in OHC electromechanical behavior (Santos-Sacchi et al., 1998, 2001).

Recently, NLC has been shown to present low-pass frequency-dependent behavior that we attributed to a slow, multiexponential kinetic process within prestin state transitions (Santos-Sacchi and Song, 2016). How does the frequency response of OHC NLC relate to eM ? To answer this question, we measured eM , NLC, and Q_p simultaneously across stimulation frequency. Figure 2A,B presents an example of an OHC whose eM was measured with video analysis at 25,000 fps during multifrequency voltage stimulation. In Figure 2C–E, average responses ($n = 5$) are depicted for NLC, eM , and Q_p , respectively. NLC shows low-pass behavior as we reported on previously (Santos-Sacchi and Song, 2016), but Q_p and eM show even lower pass behaviors. The latter two measures are remarkably similar, in line with our Q_p/eM data of Figure 1. The underlying mechanism for the differences between NLC and eM/Q_p is explored in the next couple of figures, where the influence of the whole-cell voltage-clamp time constant is considered. In Figure 3, an example of clamp τ effects on eM is

shown. As clamp speed is increased via amplifier R_s compensation circuitry, the frequency response of eM is similarly increased; $eM \tau_{vh}$ approaches this cell's NLC τ_{vh} , determined from a single exponential fit (Fig. 3C, blue asterisk), where prestin's kinetics are limiting. We had previously shown this effect for both AC and step eM responses (Santos-Sacchi, 1992), and this result derives from the voltage-dependent nature of eM (Ashmore, 1987; Santos-Sacchi and Dilger, 1988; Iwasa and Kachar, 1989).

Whereas eM (and Q_p ; see below) measures mirror clamp speed, NLC frequency-dependent behavior is independent of clamp speed. NLC estimates derive from the solution of the cell's admittance (Santos-Sacchi et al., 1998; Santos-Sacchi, 2004), essentially providing the ratio dQ_p/dV_m . Thus, in the face of V_m roll-off due to clamp time constant, the ratio of changes in V_m -driven Q_p and the driving force V_m remains unaffected by clamp τ , and therefore reports simply on the limiting kinetics of prestin transitions. This is confirmed through modeling (Fig. 4). Here clamp τ is altered by changes in R_s (clamp $\tau \approx R_s * C_m$). In Figure 4A, a model of an OHC possessing an NLC with frequency-independent Boltzmann characteristics shows an unencumbered increase in eM (i.e., Q_p) frequency response as R_s is lowered. However, the OHC possessing a multistate kinetic (*meno presto*) model of NLC (Santos-Sacchi and Song, 2016; Fig. 4B) shows that the frequency response of eM is governed by the kinetics revealed by NLC. That is, NLC specifies limits to the frequency behavior of eM or Q_p .

Figure 5 shows average ($n = 21$) guinea pig OHC NLC frequency dependence, and corresponding Q_p measures. For the NLC Lorentzian fit, we use the geometric mean of the dual stimulating frequencies, as we have done previously (Santos-Sacchi and Song, 2016). Only AC NLC was estimated with dual sine, but neither eM nor Q_p , so that eM and Q_p data correspond to the

primary frequencies directly. To estimate peak NLC at DC (33.5 pF, plotted leftmost on *x*-axis), measures were derived from voltage step-induced transients (Huang and Santos-Sacchi, 1993), namely, during changes in command holding potential. The mean (SE) Boltzmann characteristics of NLC at the lowest primary frequency of 48.8 Hz (geometric mean, 69.1 Hz) are NLC_{pk} : 32.03 (0.76) pF; V_h : -52.8 (4.1) mV; *z*: 0.86 (.016); and Q_{max} : 3.875 (0.17) pC. C_{lin} for this group of cells was 22.57 (0.46) pF. For comparison, our standard estimates of NLC at 390.6 Hz (geometric mean, 552.4 Hz) gives V_h : -53.3; *z*: 0.86; and Q_{max} : 3.24 pC. Note here that Q_{max} is larger at the lower frequency. At 97 Hz (near that of the NLC geometric mean of 69.1 Hz), Q_p fits provide V_h : -56.3 (2.6) mV; *z*: 0.836 (0.021); and Q_p : 127.9 (6.8) fC. AC voltage stimulation was 5 mV.

Normalized NLC (Fig. 5A) is characterized by two distinct kinetic components, one slow component ($\tau_1 = 1.12$ ms) and one fast component ($\tau_2 = 32.6 \mu s$). The latter component's amplitude is only a couple of decibels down from the former. Thus, the limiting frequency response of eM, dictated by the NLC frequency response, will derive from the second, faster component. The speed of Q_p (determined from single Lorentzian fits above 100 Hz stimulation), in agreement with eM measures, is dictated by whole-cell clamp speed (Fig. 5C,E). Here, we increased clamp speed (reduced clamp τ) to the point just before amplifier oscillation and correlated with Q_p speed, in an effort to predict prestin's cutoff τ at V_h . A linear extrapolation to zero clamp time constant (which works reasonably well for two-state kinetic models of differing kinetics; Fig. 5B) provides a limiting τ of 49 μs , compared with the fast NLC component τ of 32.6 μs . Notably, the apparent speed of Q_p increases when interrogated at voltages offset from V_h . At an offset of 30 mV from V_h , τ_{Qp} reduces to 13.3 μs , in a tradeoff between gain and bandwidth.

Figure 6 explores this gain–bandwidth trade-off in our eM data. We replot (Fig. 6A) the average data and Boltzmann fits from Figure 2, and construct eM–frequency plots at different offset voltages from V_h (Fig. 6B). The frequency responses further away from V_h are flatter and have faster time constants. These were single Lorentzian fits, and clearly even the fastest time constant (198 μs) is constrained by a slow whole-cell clamp τ .

To obtain faster clamp time constants, we recorded from mouse OHCs, where the reduced magnitude of both linear and nonlinear capacitances will enhance the speed of voltage delivery under whole-cell conditions (clamp τ down to ~15 μs). In Figure 7, we show kinetic behavior similar to that of guinea pig OHCs, with Q_p frequency response being clamp-speed dependent. Linear extrapolation provides a limiting τ_{Qp} of 27 μs .

Clearly, despite reductions in clamp time constant, the frequency responses of eM and Q_p are limited in whole-cell mode, to a limiting rate being, at best, approximate. Thus, to avoid whole-cell clamp τ effects, we measured Q_p frequency response in membrane patches, where speed of voltage delivery is unquestionably

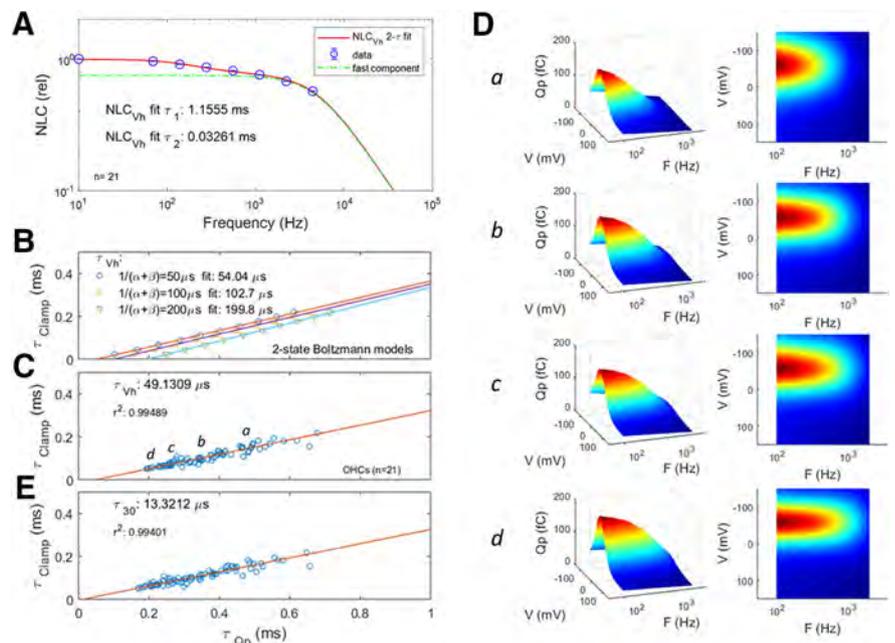

Figure 5. NLC has two frequency components whose kinetics limits Q_p frequency response. Average responses from 21 cells. **A**, Magnitude–frequency plot of average NLC at V_h . A dual-Lorentzian fit reveals slow and fast components (A_1 : 0.2453; τ_1 : 1.12 ms; A_2 : 0.7469; τ_2 : 32.6 μs). NLC is plotted relative to values at lowest frequency, which is NLC determined from step-induced (DC) transients (Huang and Santos-Sacchi, 1993) during changes in command holding potential. Error bars indicate SE. Dotted green line is plot of faster component. **B**, Relationship between clamp τ and $Q_p \tau$ for three two-state models of differing rate constants, illustrating that regressions to zero clamp τ can identify each model's characteristic time constant. **C**, Similarly, regressions on OHC Q_p provide a limiting time constant approaching the fast τ component of NLC. **D**, **a–d**, Five cell-binned averages computed and plotted, illustrating the enhanced frequency response as clamp τ decreases (**a**: $153.0 \pm 1.75 \mu s$; **b**: $100.9 \pm 1.2 \mu s$; **c**: $70.9 \pm 1.4 \mu s$; **d**: $55.7 \pm 1.9 \mu s$. Q_p Lorentzian fits data and model are from 100 to 3200 Hz. **E**, Plot of Q_p at an offset voltage of 30 mV from V_h , showing that τ_{Qp} decreases at voltages away from V_h (with gain–bandwidth tradeoffs). Five millivolt peak AC stimulation. See text for Boltzmann mean (SE).

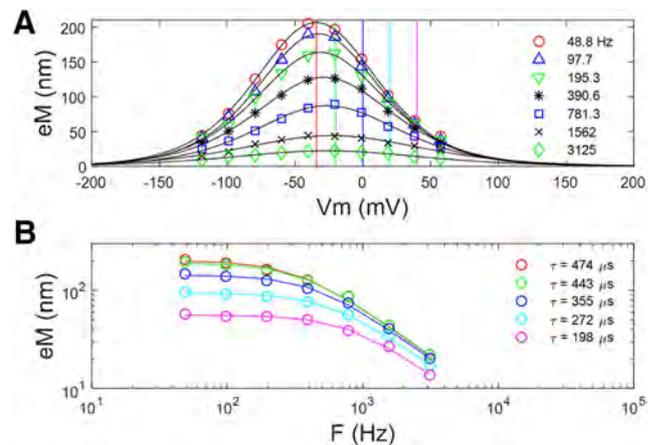

Figure 6. Similar to Q_p results, eM τ decreases at voltages offset from V_h . **A**, eM and Boltzmann fits from cells depicted in Figure 2 at the various recorded frequencies. **B**, Frequency plots derived from data at vertical lines in **A**. The further away from V_h , the faster is the frequency response, with a trade-off between gain and bandwidth.

fast. Figure 8 shows average responses ($n = 10$) of Q_p from on-cell patch recordings before establishment of whole-cell configuration. Patches (Fig. 8A,B) show frequency responses that are slower than whole-cell responses. This likely arises from physical constraints on patch membrane movements, as previously suggested by Gale and Ashmore (1997). That is, because eM is mirrored in Q_p , since each are tightly coupled, our measures of patch Q_p will show evidence of physical constraints in patch move-

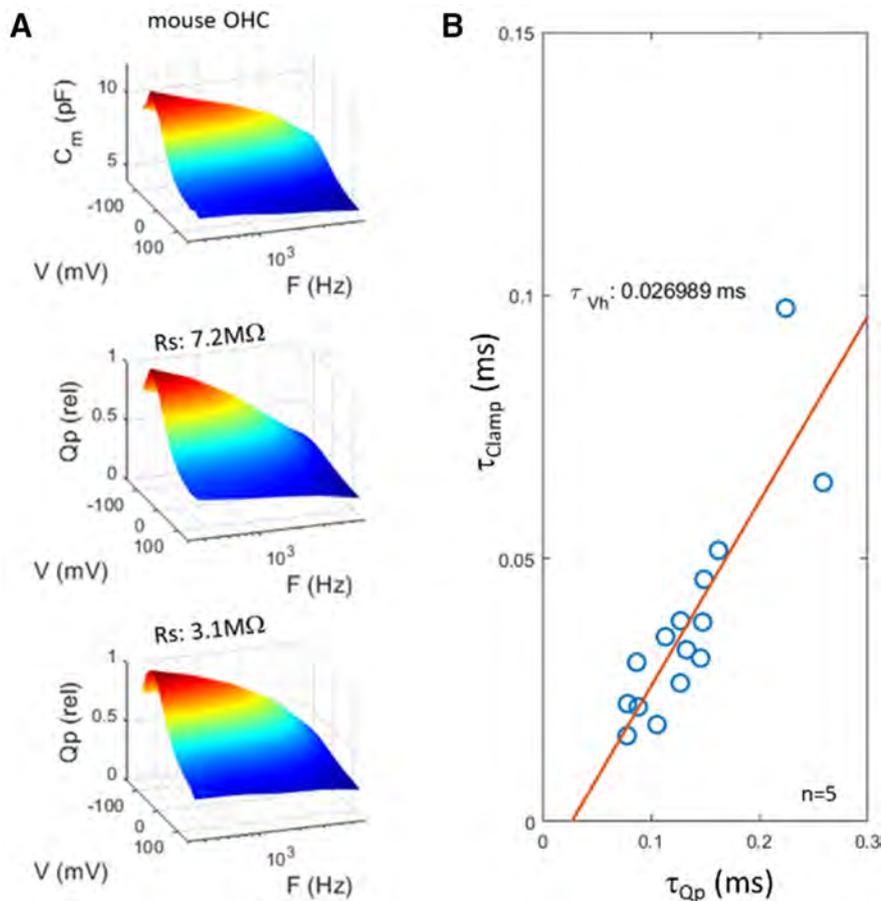

Figure 7. Mouse OHC recordings have reduced clamp time constants, but show low-pass frequency-response behavior similar to guinea pig OHCs. **A, B**, NLC is low pass at V_h (**A**) and clamp τ influences Q_p frequency response (**B**). Extrapolation estimate of τ_{Op} is 27 μ s. Five millivolt peak AC stimulation.

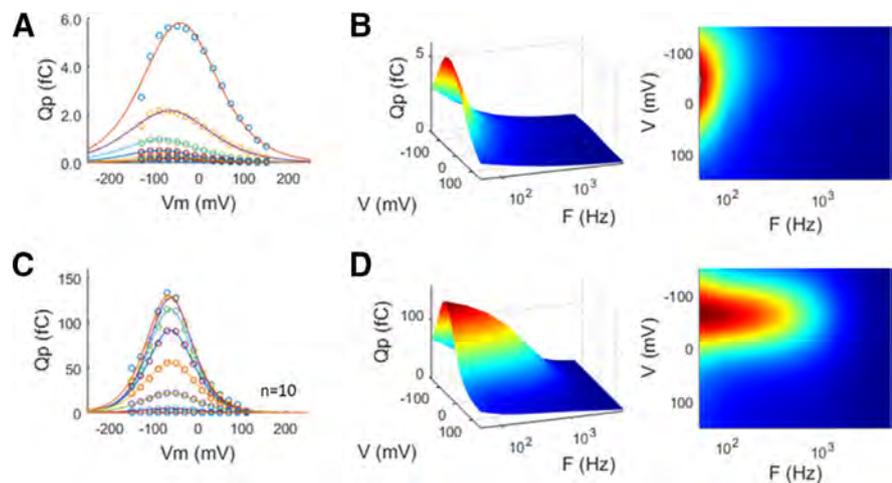

Figure 8. Average Q_p frequency response for on-cell patches compared with subsequent whole-cell measures. **A**, On-cell Q_p with Boltzmann fits to data from individual frequencies. **B**, Frequency response in patches is low pass. **C, D**, Following patch rupture, Q_p increases (**C**) and frequency response extends (**D**). These data possibly signify that patch movements are constrained compared with whole-cell conditions, as previously suggested (Gale and Ashmore, 1997). Five millivolt peak AC stimulation. Patch responses were averaged 32 times.

ments. Indeed, Adachi and Iwasa (1999) have shown that NLC can be blocked by physical constraints on the membrane. On the other hand, following whole-cell establishment (Fig. 8C,D), conformational changes in prestin are freely expressible, and an increase in bandwidth is found.

Finally, we directly studied eM frequency response using the microchamber technique, which theoretically has enormous wideband voltage delivery (Dallos and Evans, 1995; Frank et al., 1999) and, similar to whole-cell configuration, allows for unencumbered conformational changes in prestin.

It is well known that the relaxation time course of measured currents induced by voltage perturbation in whole-cell voltage clamp mirrors the time course (frequency response) of the voltage imposed across the cell membrane (Sigworth, 1995). We discussed some electrical characteristics of the microchamber in Materials and Methods. In Figure 9C–E, we additionally emphasize that the frequency response of the currents measured in the microchamber configuration also characterizes the frequency response of the voltages delivered to the membranes inside and outside the chamber. In this figure, we show results from a Matlab Simscape model of the microchamber using our stimulus protocol (see Fig. 11, model parameters in legend). The time constants of current in Figure 9C (fitted black lines; $\tau_{ta} = 19.5 \mu$ s; $\tau_{tb} = 16.2 \mu$ s) are the same for membrane voltage inside (Fig. 9D; $\tau_{ta} = 19.4 \mu$ s; $\tau_{tb} = 15.9 \mu$ s) and outside (Fig. 9E; $\tau_{ta} = 19.5 \mu$ s; $\tau_{tb} = 16.5 \mu$ s) the microchamber. A Lorentzian function $A = 1/[1 + (2\pi f\tau)^2]^{1/2}$ is used to generate a normalized magnitude frequency response that can be used to correct the frequency roll-off of voltage-dependent processes driven by the clamp, which we do below for our microchamber eM data. It is important to have frequency response estimates coincident with protocol stimulation, as drifts in the resistive components of the microchamber can have dramatic effects on the speed of voltage excitation (see Fig. 11).

Figure 10 shows microchamber measures of OHC eM at DC and across frequencies. Maximum DC eM gain (peak of the Boltzmann fit derivative) is 16.8 nm/mV in excellent agreement with earlier reports (Ashmore, 1987; Santos-Sacchi, 1989; Fig. 10A). The z parameter of the microchamber eM Boltzmann fit (0.83) also compares favorably to that of NLC (0.86) and Q_p (0.84), detailed above (Fig. 5). Based on our microchamber clamp τ (Fig. 10B), eM data were corrected for a cutoff frequency of 6.17–6.64 kHz. The microchamber approach reveals a second exponential component (τ_2) of eM that was unseen in the whole-cell data because of clamp τ limitations. Fitted sums of two Lorentzians were made at two microchamber offset voltages. At zero microchamber offset, A_1 : 1.63 nm/mV; A_2 : 3.45 nm/mV; τ_1 : 0.68 ms; τ_2 : 18.19 μ s. At -68 mV microchamber

At zero microchamber offset, A_1 : 1.63 nm/mV; A_2 : 3.45 nm/mV; τ_1 : 0.68 ms; τ_2 : 18.19 μ s. At -68 mV microchamber

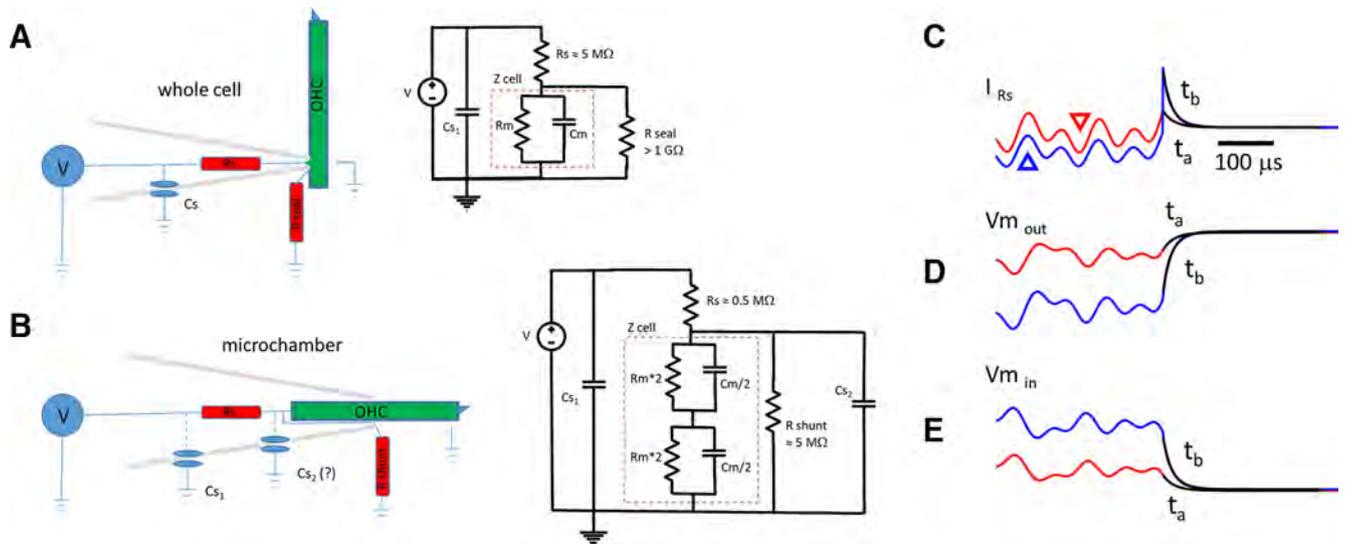

Figure 9. Electrical configuration of whole-cell and microchamber voltage clamp. **A**, Whole-cell clamp speed is limited by $\tau \approx R_s * C_m$. Stray capacitance (amplifier, pipette holder, and pipette) is typically modeled in a position that does not interfere with voltage-clamp speed, but can influence measured high-frequency currents if not compensated. **B**, The microchamber partitions the cell partway within the orifice of the macropipette. Stray C_{s1} is as with whole-cell mode. The frequency response of voltage clamp also depends on R_s and C_m , since stray C_{s2} , if it contributes at all, is dominated by C_m . The configuration in the figure is for a cell midway in the microchamber, membrane C_m equally divided. At high frequencies, the input capacitance will be the series combination of $C_m/2$ and $C_m/2$, giving a value of $C_m/4$. Thus, $\tau \approx R_s * C_m/4$ provides a faster clamp than whole cell, but the configuration suffers from lack of DC voltage-clamp control across the membranes. With partitioning of the cell more or less within the chamber, the series combination of the nonequal partitioned cell C_m will provide an input C_m less than the smaller of the two partitioned capacitances, regardless of its location inside or outside the microchamber. Thus, clamp τ for both inserted and extruded membranes will have the same U-shaped speed function, being slowest at the half-inserted condition, as depicted. **C**, Displayed are two current traces (t_a and t_b) generated by a Matlab Simscape microchamber model using a voltage protocol similar to our DC off-set AC voltage protocol (Fig. 10B, inset). The red trace (also marked with a downward red triangle) is at zero offset, and the blue trace (also marked with an upward blue triangle) is at an offset of -65 mV. Black lines are single exponential fits. Under voltage clamp, the time course of capacitive currents mirrors the time course of the voltage delivered to the cell membrane, as shown in **D** and **E**. See text for more details.

offset, near V_h , A_1 : 11.52 nm/mV; A_2 : 4.32 nm/mV; τ_1 : 3.45 ms; τ_2 : 25.26 μ s. Both slow and fast exponential component magnitudes and time constants were influenced by offsets from V_h , in a similar fashion to whole-cell data (Fig. 7). This indicates that the kinetics of the second component takes on increasingly greater dominance as excitation moves away from V_h , and that prestin follows the kinetic rules governing voltage-dependent proteins.

Discussion

NLC reflects the restricted movement of sensor charge (or gating charge) in response to transmembrane voltage perturbations, and is a characteristic of membrane-bound, voltage-dependent proteins, such as ion channels and some transporter family members, including prestin. The time constant of charge movement in voltage-dependent proteins is typically within the 100–1000 μ s range. For example, Lu et al. (1995), using very wideband capacitance measures, have shown that the GAT1 cotransporter and the cardiac Na, K pump present capacitance frequency responses over an order of magnitude slower than that produced by voltage-induced translocations of the small hydrophobic ion dipicrylamine across the membrane field: a rate of 9500 s^{-1} ($\tau = 105$ μ s, $f_c = 1.5$ kHz). Similar time constant estimates of ion channel gating currents are also within this range, and differences in kinetics among voltage-sensitive proteins likely arise from molecular variation within the protein (even within a single residue), leading to alterations in energy barriers between conformational states (Lacroix and Bezanilla, 2012). In the case of prestin, displacement currents represent charge movements that drive conformational changes in the protein, and effect voltage-dependent mechanical responses in OHCs, so-called electromotility. Since the initial identification and characterization of NLC/gating cur-

rents in OHCs (Ashmore, 1989, 1990; Santos-Sacchi, 1990, 1991), it has been viewed as a frequency-independent, fast two-state Boltzmann process. In fact, the frequency extent of NLC and eM has been documented out to progressively higher limits over the years (Ashmore, 1987; Santos-Sacchi, 1990, 1992; Dallos and Evans, 1995; Frank et al., 1999). Indeed, electrically evoked eM presents well above the auditory frequency requirements of species that have been studied (Frank et al., 1999; Grosh et al., 2004). In the present study, we provide evidence that counters the prevailing concept of ultrafast, voltage-driven eM.

By analyzing simultaneous and synchronous measures of eM, NLC, and sensor charge (Q_p) at voltage-stimulating frequencies from DC to 12.5 kHz, we show that within this bandwidth NLC displays a low-pass nature that reveals the limiting kinetics acting on eM and Q_p . Both eM and NLC display slow and fast components, the eM components near V_h [$\tau_1 = 3.45$ ms (33.8 Hz); $\tau_2 = 25.26$ μ s (6.25 kHz)] being similar to our current estimate of NLC cutoff frequency at V_h [$\tau_1 = 1.16$ ms (137.2 Hz); $\tau_2 = 32.6$ μ s (4.88 kHz)] at room temperature. At zero microchamber offset, eM time constants are faster [$\tau_1 = 0.68$ ms (234 Hz); $\tau_2 = 18.2$ μ s (8.74 kHz)]. Earlier, Gale and Ashmore (1997) found a time constant of 16 μ s (9.94 kHz) for NLC. Corrections for *in vivo* temperatures could extend the bandwidth. Indeed, we have found significant effects of temperature on NLC (Santos-Sacchi and Huang, 1998; Meltzer and Santos-Sacchi, 2001; Santos-Sacchi et al., 2009; Okunade and Santos-Sacchi, 2013), giving approximately a Q_{10} of 2. A previous Q_{10} estimate was 1.33 (Ashmore and Holley, 1988). Assuming a Q_{10} of 2, Gale and Ashmore's f_c for NLC is 22.8 kHz. Our fastest eM response would indicate an f_c of 20 kHz at 37°C. Thus, even correcting voltage-dependent NLC kinetics to body temperature would not match the widest eM

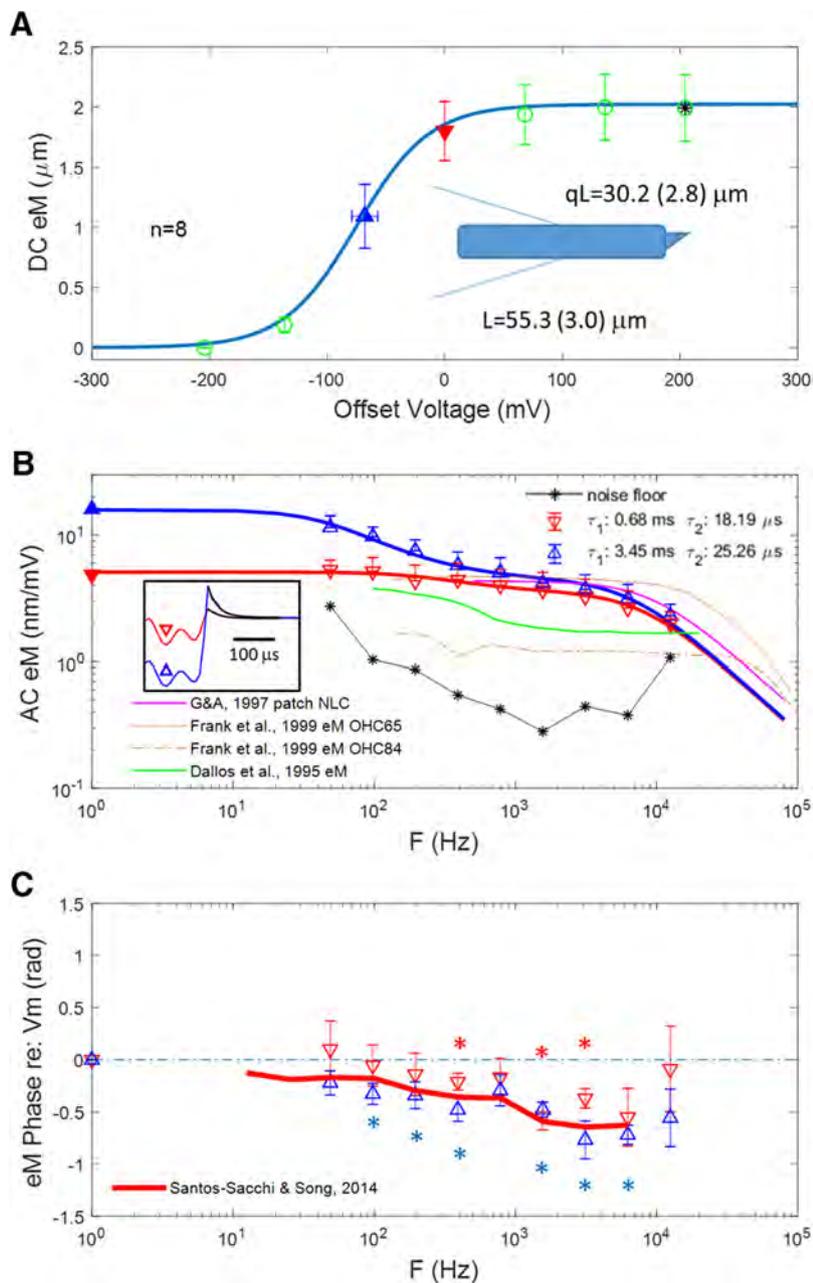

Figure 10. eM evoked with the microChamber wide-band stimulus delivery system and video captured at 50,000 fps. No frame averaging. Two components are evident, whose frequency response is dependent on offset from V_h . **A**, DC eM magnitude versus offset voltage. Cells were partitioned near midway along cell length (schematic), with average length (L) being $55.3 \pm 3.0 \mu\text{m}$, and the average portion outside the chamber (qL) being $30.2 \pm 2.8 \mu\text{m}$. The Boltzmann fit provides a z parameter of 0.83, in good agreement with our estimates from NLC and Q_p . Our eM gain of 16.8 nm/mV is typical of reported whole-cell responses. In the absence of a voltage offset, stimulation is substantially removed from V_h , the location of maximal gain. **B**, Magnitude–frequency plot of average eM from two regions of the DC plot (denoted by solid triangles). DC average gains derived from **A** are replotted on left gain (nm/mV) axis. The boxed inset shows the current relaxations after return to zero voltage (red and blue), fit with a single exponential (black lines), and used to correct for voltage frequency roll-off. Clamp τ at zero offset: $25.8 \mu\text{s}$; near V_h : $23.96 \mu\text{s}$. Colors and symbols correspond to offsets and match those of the model of Figure 9C–E. See text for more details. Responses obtained from an offset close to V_h (upward blue triangles) show a large low-pass component, whereas responses without an offset (downward red triangles) show a reduced low-pass component. Each has faster components away from V_h . Thin, black asterisk line is noise floor estimated from $+200 \text{ mV}$ offset in **A**, where AC responses are saturated. For comparison, magenta lines depict patch NLC from Gale and Ashmore. Brown lines show microchamber eM gain functions for two cells from Frank et al. Green line from Dallos et al. shows microchamber eM gain derived from their reported excitation voltage of $\pm 0.6 \text{ mV}$. Clearly, these eM data were collected at offset from V_h . See text for discussion. **C**, eM phase shows differences depending on voltage offset that may be due to differing eM gain. While a clear frequency-dependent lag relative to voltage occurs near V_h , it is less clear for responses away from V_h . Statistical significance ($p < 0.05$) from zero is indicated by correspondingly colored asterisks. The red line depicts the eM phase found by us previously under whole-cell conditions (Santos-Sacchi and Song, 2014). AC voltage stimulation at each frequency was $\sim 14 \text{ mV}$ (see Materials and Methods).

bandwidth estimate (80 kHz or $2 \mu\text{s}$ τ_c , being given by $1/2\pi\tau$) of Frank et al. (1999) found at room temperature.

Our observation of low-pass electro-mechanical behavior within our investigated bandwidth is clearly related to offset position along the eM– V_m Boltzmann relation where measures were made (Fig. 10). Frequency response measures arising from voltage perturbations away from V_h provide enhanced V_m following fidelity, i.e., a faster and flatter frequency response. It is well known that two-state, voltage-dependent transition kinetics between conformations is slowest at V_h (where the peak energy barrier resides), and speeds up on either side of V_h (Hodgkin and Huxley, 1952; Hille, 1992; Destexhe and Huguenard, 2000). The replotted eM gain data of Frank et al. and Dallos et al. (Fig. 10) clearly show that their measures were taken at significant offsets from V_h , where we also find flatter frequency responses. This likely explains the missing slower component in their data. However, what about the high-frequency limit derived from our eM/NLC and Gale and Ashmore's NLC measures? Why would the Frank et al. eM response extend beyond the limits indicated by NLC kinetics? That is, why is there an apparent uncoupling between prestin charge movement and OHC motility, which we have demonstrated should exist (Figs. 1, 2)? Possible explanations for these kinetic disparities between charge movement and eM may be due to experimental differences among studies.

In voltage-clamp experiments, including the microchamber method, corrections for voltage delivery roll-off must be made since the fidelity of voltage clamp across frequencies suffers from the effects of electrode resistance and membrane capacitance. Accounting for these effects is simply a matter of correcting for the time course of relaxation of measured capacitive currents, as we did. This is a valid and standard approach. Only in the unattainable absence of electrode resistance would no correction be necessary. In Frank et al. (1999), voltage corrections for microchamber frequency response were based on assumed stray capacitance influences, which they explicitly identified, in the absence of compensation circuitry, as limiting their microchamber voltage delivery. However, the microchamber voltage clamp behaves exactly as that of the whole-cell voltage clamp where the bulk of stray capacitance (amplifier, pipette holder, and pipette) does not diminish clamp speed. Indeed, in simulations of models shown in Figure 9, stray capacitance C_s has no

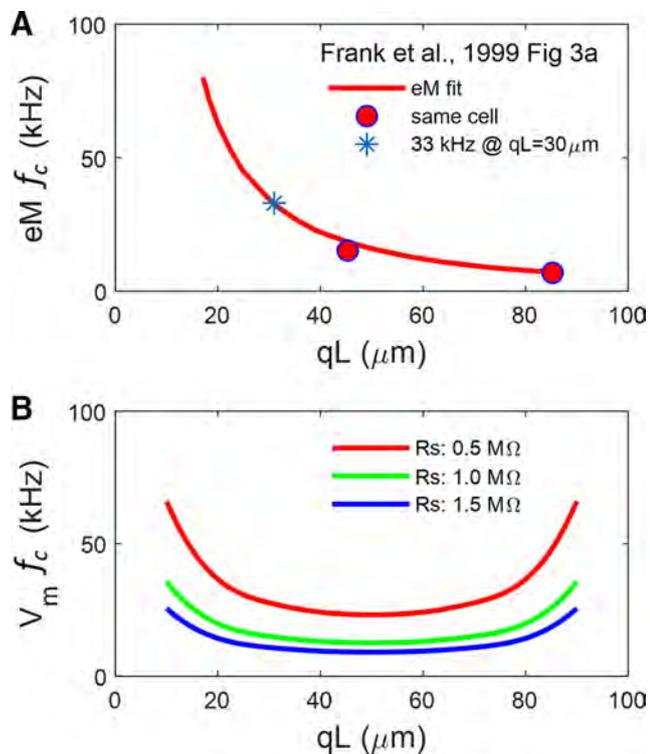

Figure 11. Apparent disparity between microchamber voltage and eM. **A**, Fit of eM f_c for 57 cells from Frank et al. Figure 3A, and response of same cell with differing cell extrusion, qL . Asterisk denotes f_c at a qL similar to our present average. **B**, V_m cutoffs for a cell model possessing NLC (capacitor with 2-state Boltzmann characteristics), indicating marked dependence of f_c on R_s . Cell parameters are C_{lin} : 22 pF; R_m : 300 M Ω ; R_s : 0.5 (red), 1.0 (green), or 1.5 (blue) M Ω ; R_{sh} : 5 M Ω ; NLC parameters are z : 0.85; Q_{max} : 3.8 pC; V_h : 0 mV. f_c is a U-shaped function of qL .

effect on clamp frequency response, and Cs_2 , which might arise at the extreme tip of the pipette, would be extremely small with negligible influence on clamp speed. Thus, correction for an assumed effect of voltage roll-off due to stray capacitance could likely have resulted in voltage overcorrections. On the other hand, we agree with Frank et al. that mechanical responses may be impeded by physical constraints, and this is potentially borne out by our very low pass Q_p behavior in patches, compared with subsequent whole-cell measures (Fig. 8). Indeed, Gale and Ashmore found a time constant for patch movements $\sim 84 \mu\text{s}$, compared with 16 μs for NLC. So, we might surmise for our measures, that the fast time constant of eM, even in whole-cell mode, could have been physically constrained. It is noteworthy that Frank et al. found a wide range of cutoffs depending on OHC qL , and that for our average qL of 30 μm , their roll-off was at 33 kHz, still substantially faster than our measure at 8.74 kHz.

This possibility of eM physical constraints is highlighted by Frank et al.'s Figure 3A, where eM f_c continuously increases as qL decreases, showing an apparent length-dependent cutoff (Fig. 11A). In Figure 11B, we show that this behavior is not expected for an ultrafast process that relies upon and can faithfully follow voltage excitation within the microchamber (see Fig. 9B, legend). That is, the efficacy of AC voltage delivery (f_c) in the microchamber should follow a U-shaped function of cell extrusion, with $qL = 0.5$ providing the slowest voltage-dependent frequency response. That is, the f_c of microchamber voltage delivery is symmetrical on either side of $qL = 0.5$, since the reduced capacitance of the smaller pole, regardless of whether it is the included or excluded pole, will present to the voltage clamp a series combination of the partitioned capacitances. The observation that for

$qL > 0.5$ mechanical f_c does not follow voltage f_c indicates that the response is not strictly voltage-dependent or that the movement of that excluded pole is mechanically impeded. Interestingly, Frank et al. required an additional overdamped resonance to fit their ultrafast eM data, which they attribute to an inertial contribution ($\sim 6\%$ of the cell's mass).

The relation between resting membrane potential and NLC V_h will determine where along the eM gain function the OHC works. Receptor potentials driving eM at a location away from V_h will provide reduced gain, but enhanced frequency response. Which characteristic is more important for cochlear amplification is difficult to assess; however, it is known that mouse mutants showing one-third of prestin expression and Q_p hear normally at low and middle frequencies (Yamashita et al., 2012), indicating that full gain may not be required. Currently, we do not know V_h *in vivo*. Even the value of resting potential of the OHC *in vivo* is contested (Dallos et al., 1982; Russell and Sellick, 1983; Johnson et al., 2011). To complicate matters, there is a plethora of biophysical forces that can alter V_h , including intracellular Cl^- level, membrane tension, and even membrane potential itself (Iwasa, 1993; Gale and Ashmore, 1994; Kakehata and Santos-Sacchi, 1995; Santos-Sacchi et al., 1998, 2017; Oliver et al., 2001; Rybalchenko and Santos-Sacchi, 2003, 2008). We hypothesize that feedback mechanisms that influence these biophysical forces, and efferent feedback (Brown et al., 1983) that alters resting membrane potential, contribute to a mechanism where eM gain–bandwidth trade-offs influence the effectiveness of cochlear amplification, similar to the tuning performed on operational amplifiers.

A note should be made about the implications of isolated OHC studies to the cell's role *in vivo*. Currently, it is impossible to monitor, across acoustic frequencies, the length changes in individual OHCs within the organ of Corti. However, tremendous strides have been made using optical coherence tomography to visualize movements within the intact living organ. Thus, unexpected observations of low-frequency mechanical behavior of supporting cells in the cochlear apex (Gao et al., 2014), and intriguing observations of motions at the OHC–Deiters cell interface deep within the organ (Cooper and van der Heijden, 2017) are changing the way we view OHC mechanical influences in the cochlea that underlie cochlear amplification. However, until more precise measures evolve, single-cell studies, which are required to determine intrinsic capabilities of the OHC that may influence cochlear mechanics, remain important for cochlear modelers.

In summary, we find that OHC eM and associated electrical correlates (NLC, Q_p) are low pass in nature, presenting behavior that is not very different from other voltage-dependent proteins, including characteristic changes in kinetics with voltage. We establish that eM and sensor charge are coupled in magnitude and time (phase), and confirm, with the microchamber technique, that driving voltage and eM phase differs, as we have shown under whole-cell voltage clamp (Santos-Sacchi and Song, 2014). eM phase lags voltage, similar to a piezoelectric with hysteresis. We speculate that the identification by some ultrafast eM *in vivo* (Grosh et al., 2004) simply reflects the effects of eM at very low gain levels, which are sufficient to influence structures within the cochlear partition. In other words, cochlear amplification does not require the full magnitude of eM observed at very low frequencies. Finally, it should be noted that intriguing indications exist that within the organ of Corti, mechanical loads on the OHC could alter the cell's frequency response (Iwasa, 2017).

Protein- and Lipid-Reactive Agents Alter Outer Hair Cell Lateral Membrane Motor Charge Movement

Received: 4 May 2004/Revised: 7 July 2004

Abstract. Outer hair cells from the mammalian cochlea are mechanically active cells that rely on charged voltage sensors within their lateral plasma membrane to gate the integral membrane motor protein, prestin, into one of two area states. Here we use protein and lipid reactive reagents to probe the influence of these bilayer components on motor-induced nonlinear membrane capacitance. Of the protein-reactive reagents tested, cross-linking and sulfhydryl reagents were most effective in altering steady state and time-varying motor activity. Of the lipid-altering agents, chloroform and HePC were most effective. Chloroform, in particular, drastically modified the susceptibility of the motor to prior voltage (initial conditions). Our data suggest that outer hair cell motor activity derives substantially from interactions with its lipid environment.

Key words: Motility — Gating charge — Membrane capacitance — Protein — Lipid

Introduction

Mechanical activity of the outer hair cell (OHC) underlies the enhanced sensitivity and frequency-resolving power of the mammalian cochlea (Dallos, 1992). The molecular motors that drive this activity harness electrical energy in a manner similar to other integral membrane proteins that generate gating currents upon voltage-induced conformational change (Armstrong & Bezanilla, 1974; Hilgemann, Nicoll & Philipson, 1991; Alkon, Etcheberrigaray, & Rojas, 1993; Bezanilla, 2002), namely, a motor-related displacement current or equivalently, a nonlinear capacitance (NLC) has been identified within

the OHC's lateral membrane, which reflects conformational fluctuations of the motor (Ashmore, 1990; Santos-Sacchi, 1991; Huang & Santos-Sacchi, 1993; Wu & Santos-Sacchi 1998). Recently, Dallos and colleagues have identified the OHC motor protein as prestin, a member of the SLC26 transporter family (Zheng et al., 2000). Thus far, when expressed in non-auditory cells, this integral membrane protein displays all the known biophysical characteristics of the OHC lateral membrane motor (Zheng et al., 2000; Ludwig et al., 2001; Meltzer & Santos-Sacchi, 2001; Santos-Sacchi et al., 2001; Santos-Sacchi & Navarrate, 2002).

Integral membrane proteins, such as ionic channels and transporters, are influenced by their lipid bilayer environment (Goulian et al., 1998). Predictably, then, both protein-and lipid-reactive reagents would be capable of modulating prestin's function. We report here on the modulation of OHC NLC, including the effects of prior voltage on OHC NLC (Santos-Sacchi, Kakehata & Takahashi, 1998), by such agents and find that OHC motor protein functional characteristics likely arise from interactions with the lipid environment. Preliminary accounts of some portions of this work have been presented in abstract form (Santos-Sacchi & Wu, 1998).

Materials and Methods

CELL PREPARATION

Guinea pigs were anesthetized with halothane and killed by cervical dislocation. OHCs and supporting cells were isolated enzymatically with dispase I (0.5mg/ml for 10 min followed by gentle trituration through a polyethylene pipette) in a modified Leibovitz medium that contained (in mM): NaCl 142, KCl 5.37, MgCl₂ 1.47, HEPES 5, CaCl₂ 2 and dextrose 5; 300 mOsm, pH7.2. The cells were then transferred to a 700- μ l perfusion chamber. Most experiments were conducted at room temperature (~23°C). Temperature for a subset of experiments was set by a Peltier device. A

Nikon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical recording.

VOLTAGE CLAMP

Single OHCs were studied under whole-cell voltage-clamp conditions using an Axon 200A amplifier at a holding potential of -80mV . Initial resistances of patch pipettes were 2–3 M Ω , corresponding to tip sizes of 1–2 μm . Residual series resistance ranged from 3 to 7 M Ω . All data collection and analysis were performed with a Windows-based program, jClamp (SciSoft, CT). Ionic blocking solutions were used to remove voltage-dependent ionic conductances so that capacitive currents could be analyzed in isolation (Santos-Sacchi, 1991; Huang & Santos-Sacchi, 1993). The patch-pipette solution contained (in mM): CsCl 140, MgCl₂ 2, EGTA 10, HEPES 5, with pH 7.2 and osmolarity 300 mOsm (adjusted with dextrose). The external ionic blocking solution contained (in mM): BaCl₂ 10, CoCl₂ 2, MgCl₂ 1.47, NaCl 100, CaCl₂ 2, HEPES 5, with pH 7.2 and osmolarity 300 mOsm (adjusted with dextrose). Whole-chamber perfusion was continuous. Protein- and lipid-reactive reagents were perfused via a Y-tube directly onto the cell under study for short periods of time (1.5–10 min).

REAGENTS

Several protein-reactive reagents were tested, including glutaraldehyde (0.3%), N-ethylmaleimide (NEM; 2 mM), p-chloromercuriphenylsulfonate (pCMPS; 2 mM), dithiothreitol (DTT; 2 mM) and diamide (2–5 mM). Glutaraldehyde is a dialdehyde fixative that works by crosslinking peptide chains; NEM, pCMPS and diamide are sulfhydryl reagents that react with cysteine groups; DTT is a reducing agent that breaks disulfide bonds [(Stirling, 1975); see also Lundblad (1995) and references therein]. Lipid-reactive reagents included saturated chloroform, hexadecylphosphocholine (HePC; 2–10 mM), filipin (0.75 mg/ml), phospholipase A2 (PLA2; 1 ng/ml), and triton (0.01%). Triton is a commonly used laboratory detergent. Chloroform is a commonly used lipid solvent. Filipin binds to cholesterol in membranes (Stetson & Wade, 1983). PLA2 cleaves fatty acyl chains from phospholipids (Danthi, Enyeart & Enyeart, 2003). HePC is a lysophospholipid analogue that can intercalate within plasma membrane (Rakotomanga, Loiseau & Saint-Pierre-Chazalet, 2004). The effects of these agents on the membrane likely ranges from altering its viscosity to changing its curvature and thickness, with subsequent effects on integral proteins.

CAPACITANCE MEASUREMENTS

Continuous high-resolution capacitance measures were acquired through admittance (Y) analysis at time resolutions of 5.12 or 2.56 ms, utilizing a two-sine-wave voltage-stimulus protocol (Santos-Sacchi et al., 1998). The stimulus consisted of the sum of two voltage sine waves (390.625 and 781.25 Hz), each at a magnitude (V) of 10 mV peak. This AC stimulus was superimposed on voltage-ramp or step stimuli. Capacitance-voltage functions were fit to the first derivative of a two-state Boltzmann function relating nonlinear charge to membrane voltage (dQ/dV ; (Santos-Sacchi, 1991; Huang & Santos-Sacchi, 1993))

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}}$$

Where

$$b = \exp\left(\frac{-ze(V - V_{\text{pkcm}})}{kT}\right)$$

Q_{\max} is the maximum nonlinear charge moved, V_{pkcm} is voltage at peak capacitance or equivalently, at half-maximal nonlinear charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. All results are reported as mean \pm SE. Gating currents were measured with the P/-5 technique at a subtraction holding potential of +50 mV (Armstrong & Bezanilla, 1977).

Pipette pressure was monitored via a T-connector to a pressure monitor (WPI, Sarasota, FL), and modified when required with a syringe connected to the Teflon tubing attached to the patch-pipette holder (Kakehata & Santos-Sacchi, 1995). The cylindrical shape of OHCs was maintained with slight positive pressure during data collection.

There are two potential, non-specific problems that must be considered when treating cell membranes with reactive agents. The membrane resistance (leakage) and/or the linear capacitance (e.g., membrane thickness) might be altered. With our dual-sine measurement technique, however, capacitance measures are resistant to membrane resistance changes. Also, linear as well as nonlinear capacitance are simultaneously measured. Changes in linear capacitance will simply shift the baseline of the NLC function, and should not interfere with the Boltzmann fit. Other than correcting steady-state voltages for series-resistance errors, which we do, we cannot correct for space-clamp changes. Nevertheless, estimates of delayed electrotonic spread in the OHC, about 70 μm for a cell of 70 μm (Ashmore 1986), indicate that our measures, which use frequencies below 800 Hz, should be reliable. Additionally, since the voltage-dependent conductances in the OHC are located in the basal pole of the cell (Santos-Sacchi, Huang & Wu 1997), the voltage drop along the lateral membrane where the motors are should be close to isopotential.

Results

PROTEIN-REACTIVE REAGENTS

OHCs present a voltage-dependent C_m that arises from restricted charge movement within the lateral plasma membrane and this electrical measure of motor activity is modifiable by protein-reactive reagents (Fig. 1A, B). Low concentrations of the cross-linking fixative, glutaraldehyde (0.3%), caused a reduction in charge movement that probably indicates an abridged conformational change of the motor protein. Simultaneously, in all tested cells ($n = 5$) V_{pkcm} shifted in the hyperpolarizing direction. The effects were cumulative over the perfusion period (10 min in this case), indicating progressive inactivation of motors. In the control condition, prior to glutaraldehyde treatment, dc steps in voltage resulted in an immediate change in OHC C_m (Fig. 1C, top trace), followed by an exponential decay that obtains from a voltage- and time-dependent shift in the voltage operating range (i.e., V_{pkcm}) of motor charge movement. This phenomenon is referred to hereafter as an amplifactory shift, since at a fixed voltage it represents a time-dependent recruitment of motors into the same conformational state evoked by the eliciting voltage step (Santos-Sacchi et al., 1998). Glutaraldehyde treatment prevented this time-dependent change

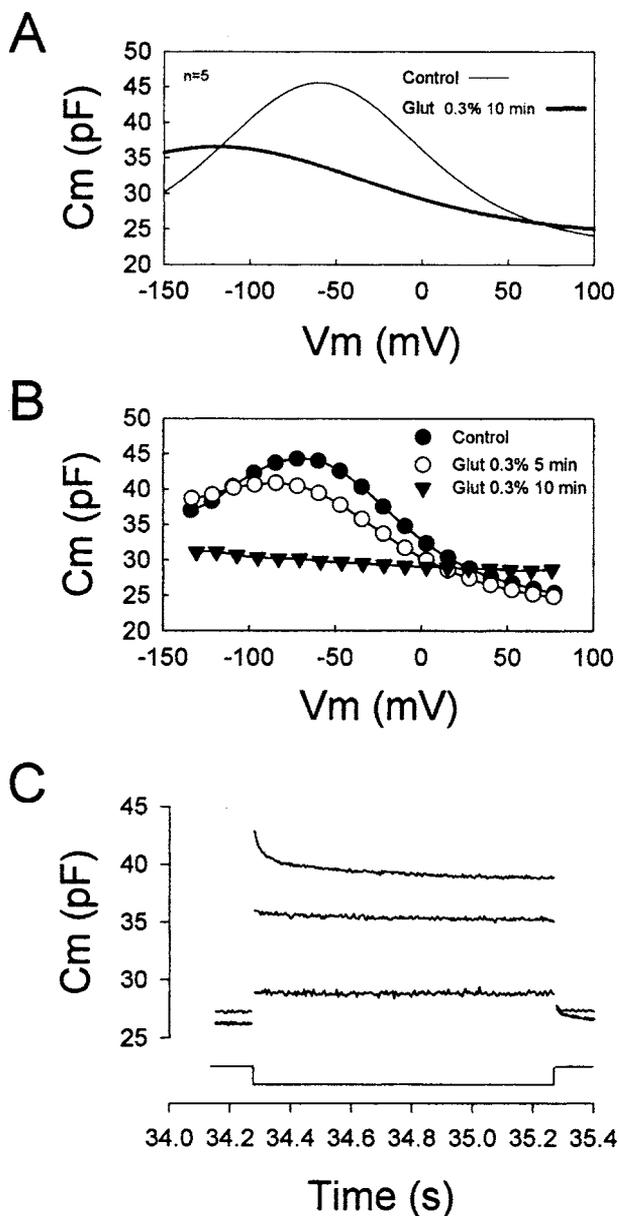

Fig. 1. Effect of low concentration (0.3%) of glutaraldehyde on OHC nonlinear capacitance. (A) C - V functions were obtained in five OHCs before and after 4.5 ± 1.1 min exposure to 0.3% glutaraldehyde. Fits with Eq. 1 were made and the estimated parameters were averaged. The resultant average fits (before and after treatment) are plotted. Control: Q_{\max} , 3.60 ± 0.13 pC; V_{pkcm} , -59.6 ± 6.8 mV; z , 0.67 ± 0.06 ; C_{lin} , 22.6 ± 0.68 ; glutaraldehyde: Q_{\max} , 3.1 ± 0.56 pC; V_{pkcm} , -119 ± 12.4 mV; z , 0.43 ± 0.04 ; C_{lin} , 23.7 ± 1.42 . (B) Nonlinear capacitance of an individual OHC is shown over time (0, 5, 10 min) following glutaraldehyde treatment. Note progressive shift in voltage dependence and decrease in capacitance. (C) Voltage step from a holding potential of +50 mV to -100 mV induces an instantaneous jump in capacitance followed by an exponential decrease in capacitance (top trace, control). Following glutaraldehyde treatment, this decay is abolished (middle trace, 5 min; bottom trace, 10 min). Same cell as in (B).

in capacitance (Fig. 1C, bottom traces), even at post-treatment times where substantial charge movement or NLC was evidenced.

Other protein-reactive agents altered OHC NLC to varying extents. Average results are presented for N-ethylmaleimide (NEM; 2 mM; $n = 4$), *p*-chloromercuriphenylsulfonate (pCMPS; 2 mM; $n = 7$), dithiothreitol (DTT; 2 mM; $n = 7$) and diamide (2–5 mM; $n = 7$) (Fig. 2; see fit statistics in legend). Though the average NEM results showed little effect on V_{pkcm} , actually, of the four cells tested, two showed shifts to the left (-12.1 ± 2.9 mV), while the other two shifted to the right (20.9 ± 3.5 mV). Similarly, DTT caused a positive shift in 3 of 7 cells (10.7 ± 4.2 mV), while the remaining cells showed a negative shift (-11.1 ± 2.8 mV). pCMPS, like glutaraldehyde, was effective in substantially reducing nonlinear capacitance, but on average shifted V_{pkcm} in the positive direction. In 5 of 7 cells, pCMPS caused V_{pkcm} to shift in the positive direction (25 ± 4.5 mV); the 2 remaining cells showed a negative shift (-10.1 ± 1.4 mV). However, Fig. 3 illustrates, in the same OHC, that while nonlinear capacitance was reduced by pCMPS, the amplificatory shift in V_{pkcm} remained essentially intact. This result is the same for DTT effects on the amplificatory shift, where comparing the C_m traces relative to pre- and post-treatment steady-state V_{pkcm} indicates similar relaxation phenomena (see Fig. 6 as well).

LIPID-REACTIVE REAGENTS

Chloroform moderately reduced NLC and shifted V_{pkcm} to the left in all cells tested ($n = 6$) (Fig. 4A). The effects on the amplificatory shift, however, were profound (Fig. 4B). Compared to controls, the magnitude and time course of the voltage step-induced change in C_m were markedly decreased. Gating currents were only slightly affected by chloroform treatment, other than showing the expected effects of a shift in V_{pkcm} (V_h), namely, changes in the magnitude of charge movement at a given voltage (Fig. 4C). Additionally, a slight reduction (~ 20 – 30%) in gating time constants was found. The effects of hexadecylphosphocholine (HePC; 2–10 mM, $n = 10$), filipin (0.75 mg/ml, $n = 3$), phospholipase A2 (PLA2; 1 ng/ml, $n = 4$), and triton (0.01%, $n = 2$) are illustrated in Fig. 5. Triton concentrations above 0.01 caused rapid and severe cell damage with loss of recordings. Only HePC significantly affected NLC, shifting V_{pkcm} in all cells tested to the right and decreasing peak capacitance slightly. Slight effects of HePC on the amplificatory shift were found, but in this case, it appears that the effects arose, as it did from DTT and pCMPS (see above), from the shift in steady-state V_{pkcm} , since realigning the traces relative to V_{pkcm} results in corresponding traces whose characteristics

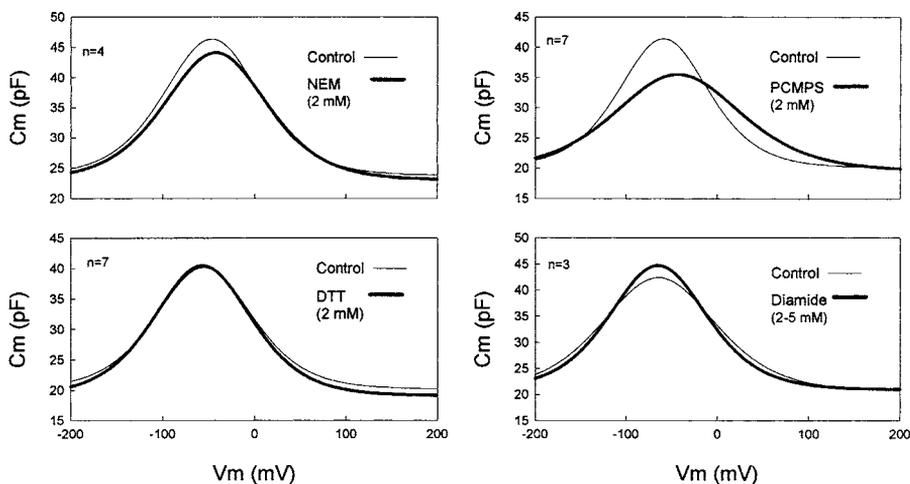

Fig. 2. Average OHC capacitance functions before and following treatments with NEM, pCMPS, DTT, and diamide. Data analyzed and presented as in Fig. 1A. pCMPS showed the greatest average effect. *NEM Control*: Q_{\max} , 3.13 ± 0.59 pC; V_{pkcm} , -46.9 ± 11.5 mV; z , 0.74 ± 0.05 ; C_{lin} , 23.8 ± 1.6 . *NEM* (3.12 ± 1.0 minutes): Q_{\max} , 3.1 ± 0.3 pC; V_{pkcm} , -42.2 ± 6.1 mV; z , 0.69 ± 0.03 ; C_{lin} , 23.0 ± 0.8 . *DTT Control*: Q_{\max} , 2.82 ± 0.06 pC; V_{pkcm} , -55.2 ± 4.3 mV; z , 0.73 ± 0.02 ; C_{lin} , 20.2 ± 0.35 ; *DTT* (2.85 ± 0.3 minutes): Q_{\max} , 3.03 ± 0.43 pC; V_{pkcm} , -56.9 ± 2.2

mV; z , 0.73 ± 0.02 ; C_{lin} , 19.13 ± 0.5 . *pCMPS Control*: Q_{\max} , 2.81 ± 0.18 pC; V_{pkcm} , -59.0 ± 6.8 mV; z , 0.77 ± 0.03 ; C_{lin} , 20.1 ± 0.66 ; *pCMPS* (3.05 ± 0.44 minutes): Q_{\max} , 2.95 ± 0.25 pC; V_{pkcm} , -43.4 ± 8.5 mV; z , 0.55 ± 0.02 ; C_{lin} , 19.6 ± 1.23 . *Diamide Control*: Q_{\max} , 3.64 ± 0.09 pC; V_{pkcm} , -64.4 ± 6.4 mV; z , 0.61 ± 0.03 ; C_{lin} , 20.6 ± 0.02 ; *Diamide* (5.43 ± 0.23 minutes): Q_{\max} , 3.38 ± 1.58 pC; V_{pkcm} , -64.9 ± 4.6 mV; z , 0.72 ± 0.02 ; C_{lin} , 21.0 ± 0.6 .

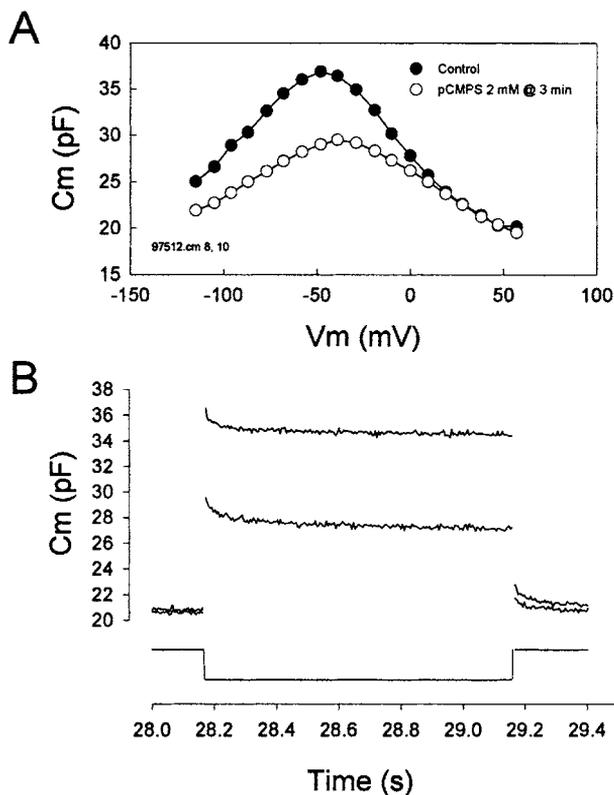

Fig. 3. Nonlinear capacitance of a single OHC before and after treatment with 2 mM pCMPS. (A) Following treatment, NLC is markedly reduced and right-shifted. (B) Voltage step from +50 to -100 mV induces an instantaneous jump in capacitance followed by an exponential decrease in capacitance. Little difference in the traces is observed except for the absolute offset magnitude.

are similar (Fig. 6; compare similarity in traces correspondingly labeled 1, 2, and 3).

TEMPERATURE AND OSMOTIC SWELLING

Finally, we looked at the effects of temperature and membrane tension (osmotic cell swelling) on OHC capacitance. As we found previously, V_{pkcm} shifted to negative potentials and the magnitude of capacitance decreased with cooling (Santos-Sacchi & Huang, 1998). Interestingly, cooling also caused a decreased amplificatory shift (Fig. 7). On the other hand, membrane tension produced little effect on the amplificatory shift, despite showing the characteristic shift of V_{pkcm} to positive potentials (Kakehata & Santos-Sacchi, 1995) (Fig. 8).

Discussion

The OHC motor is an integral membrane protein that can be viewed as fluctuating between conformational states under the control of membrane voltage and chloride concentration (Santos-Sacchi & Dilger, 1988; Oliver et al., 2001; Rybalchenko & Santos-Sacchi, 2003). One model that can accurately account for mechanical and electrical activity of the OHC posits that the motor occupies two area states, contracted and expanded (Santos-Sacchi, 1993; Iwasa, 1994; Santos-Sacchi & Navarrete, 2002). Measures of NLC provide estimates of motor-state probability, and have been used to characterize the effects of a

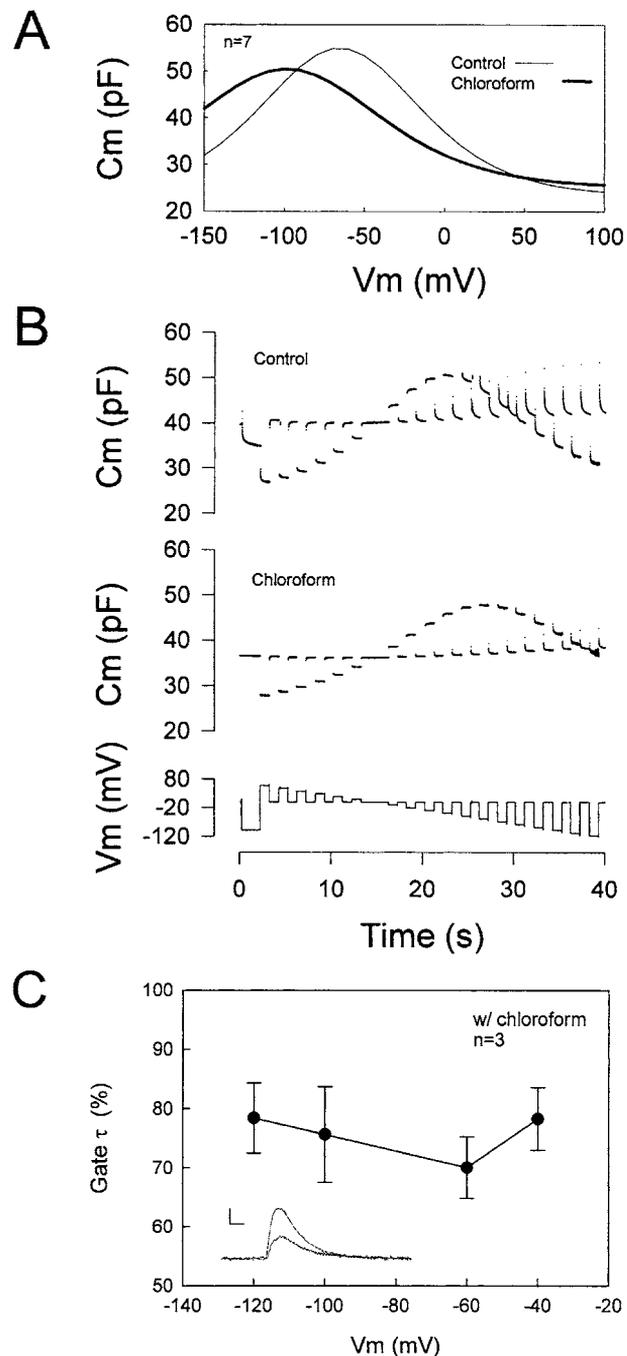

Fig. 4. Effect of chloroform on OHC nonlinear capacitance. **(A)** $C-V$ functions were obtained in seven OHCs before and after exposure to a saturated chloroform solution. Fits with Eq. 1 were made and the estimated parameters were averaged. The resultant average fits (before and after treatment) are plotted. *Control:* Q_{\max} , 4.21 ± 0.26 pC; V_{pkcm} , -65.4 ± 4.4 mV; z , 0.77 ± 0.09 ; C_{lin} , 23.3 ± 0.74 ; *Chloroform* (5.58 \pm 0.39 minutes): Q_{\max} , 4.0 ± 0.21 pC; V_{pkcm} , -98.5 ± 7.1 mV; z , 0.66 ± 0.02 ; C_{lin} , 25.0 ± 0.8 . **(B)** Nonlinear capacitance of an individual OHC is shown during steps to a range of voltages (*lower panel*). Note large capacitance relaxations in control (*upper panel*) condition, and markedly attenuated response at all voltages in chloroform-treated condition (*middle panel*). **(C)** Average gating current time course (single exponential fits to the decaying current component) is slightly speeded up ($\sim 80\%$ of control tau) after chloroform treatment. *Inset:* gating current traces from a single OHC obtained by P/-5 technique. Step from -120 to -80 mV. Larger trace is before treatment, but differences in magnitude largely result from the shift in V_h . Scale: 0.53 nA, 0.2 ms.

time- and voltage-dependent (Santos-Sacchi et al., 1998). That is, membrane voltage change, while instantaneously altering the probability of the motors' occupying either the² contracted or expanded state, also influences future motor-state probability. Since a given polarity of voltage stimulation recruits additional motors into the same conformational state evoked by that eliciting voltage step, this dynamic shift in V_{pkcm} can be viewed as an amplificatory shift (Santos-Sacchi et al., 1998). This amplificatory event is an intrinsic characteristic of prestin, since this susceptibility to initial voltage is observed in non-auditory cells expressing prestin (Santos-Sacchi et al., 2001).

Our new data indicate that membrane-reactive agents can alter OHC electro-mechanical activity. Specifically, both lipid- and protein-altering drugs are capable of influencing the energy profile of the motor protein, prestin, as evidenced by shifts in the voltage at half-maximal charge movement (V_{pkcm}). Additionally, some of these agents have significant effects on the exponential amplificatory shift of V_{pkcm} .

EFFECTS OF PROTEIN-REACTIVE REAGENTS ON THE MOTOR

Low concentrations of glutaraldehyde blocked nonlinear charge movement presumably by interfering with conformational changes normally evoked by voltage. Yet, during the development of its effects, in the face of substantial nonlinear charge movement, the time-dependent change in capacitance during steady-state voltage step, namely the amplificatory shift, was abolished. This may indicate that the mechanism or molecular structure responsible for the amplificatory shift differs from the one underlying voltage sensing. Since we previously modeled the amplificatory shift as resulting from interactions

variety of biophysical forces on the motor including membrane tension and temperature (Iwasa, 1993; Gale & Ashmore, 1994; Santos-Sacchi & Huang, 1998; Santos-Sacchi & Navarrete, 2002). These forces are capable of shifting steady-state V_{pkcm} , the voltage where the population of motors is equally distributed between the two area states. Additionally, sensitivity to initial or prior voltage conditions manifests itself as a dynamic shift in the gating charge-voltage relation ($Q-V$; or correspondingly, the capacitance-voltage relation, $C-V$) along the voltage axis, which is

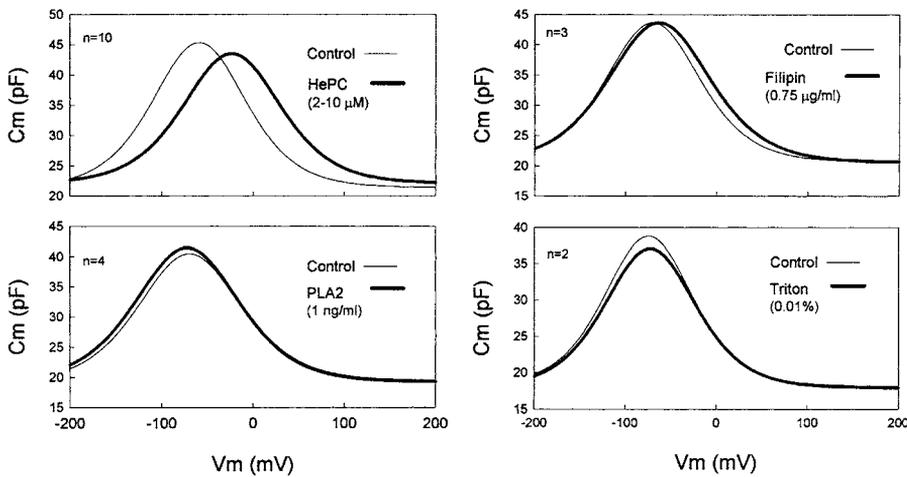

Fig. 5. Average OHC capacitance functions before and following treatments with HePC, Filipin, PLA2 and Triton. Data analyzed and presented as in Fig. 1A. HePC showed the greatest average effect. *HePC Control*: Q_{\max} , 3.26 ± 0.24 pC; V_{pkcm} , -59.2 ± 4.4 mV; z , 0.76 ± 0.01 ; C_{lin} , 21.4 ± 1.6 ; *HePC* (4.89 \pm 0.8 minutes): Q_{\max} , 3.0 ± 0.1 pC; V_{pkcm} , -23.6 ± 9.3 mV; z , 0.72 ± 0.03 ; C_{lin} , 22.0 ± 0.9 . *PLA2 Control*: Q_{\max} , 3.19 ± 0.22 pC; V_{pkcm} , -69.8 ± 8.6 mV; z , 0.69 ± 0.04 ; C_{lin} , 19.0 ± 0.7 ; *PLA2* (10.5 \pm 3.2

minutes): Q_{\max} , 3.36 ± 0.22 pC; V_{pkcm} , 72.2 ± 7.7 mV; z , 0.68 ± 0.02 ; C_{lin} , 19.2 ± 0.7 . *Filipin Control*: Q_{\max} , 3.18 ± 0.47 pC; V_{pkcm} , -69.9 ± 3.4 mV; z , 0.75 ± 0.03 ; C_{lin} , 20.6 ± 1.7 ; *Filipin* (3.0 \pm 0.3 minutes): Q_{\max} , 3.45 ± 0.3 pC; V_{pkcm} , -63.0 ± 12.7 mV; z , 0.69 ± 0.06 ; C_{lin} , 20.6 ± 2.2 . *Triton Control*: Q_{\max} , 2.69 ± 0.33 pC; V_{pkcm} , -74.2 ± 14.6 mV; z , 0.79 ± 0.13 ; C_{lin} , 18.1 ± 1.6 ; *Triton* (5.0 \pm 1.0 minutes): Q_{\max} , 2.56 ± 0.63 pC; V_{pkcm} , -72.3 ± 22 mV; z , 0.77 ± 0.08 ; C_{lin} , 17.9 ± 0.6 .

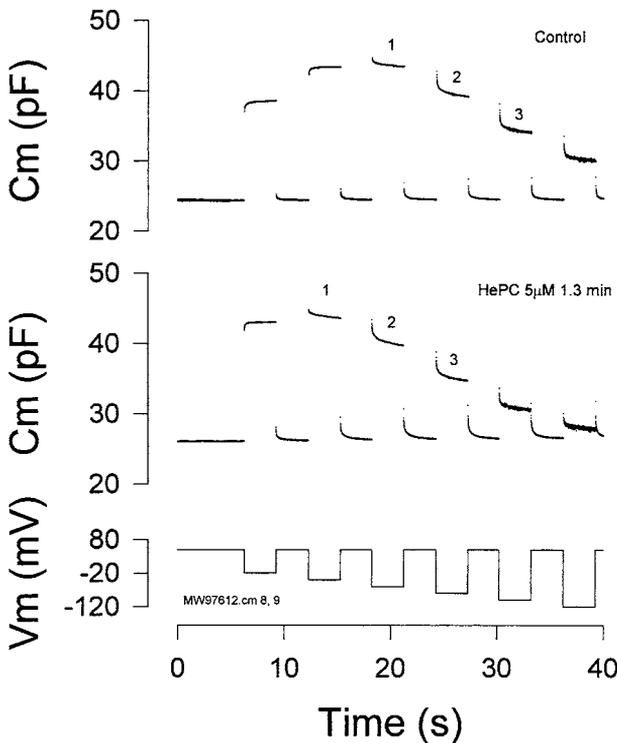

Fig. 6. Nonlinear capacitance of a single OHC during steps to a range of voltages before (*upper panel*) and after (*lower panel*) treatment with HePC. Following treatment, NLC is reduced and shifted in the depolarizing direction. Note large capacitance relaxations in control (*upper panel*) condition, which at any particular step voltage is modified by HePC. However, the similarity of relaxations at voltage step magnitudes relative to V_{pkcm} , i.e., comparing, for example, corresponding traces 1, 2 and 3 in each panel, indicates that changes in relaxations may have resulted from the shift in V_{pkcm} .

among motors via motor-induced tension (Santos-Sacchi et al., 1998), it may be that glutaraldehyde can interfere with motor-generated tension within the bilayer.

Kalinec and Kachar (1993) studied the effects of sulfhydryl reagents on voltage-dependent OHC mechanical activity. Our complementary data on the lateral membrane's voltage-sensor mechanism confirm and extend their findings. Thus, they showed that pCMPS significantly reduced the percentage of mechanically active OHCs after 60 minutes incubation, but neither NEM nor diamide were significantly effective (Kalinec & Kachar, 1993). Similarly, we found that the sulfhydryl reagent pCMPS had the most potent effect on NLC, decreasing peak capacitance and shifting V_{pkcm} to depolarized levels. Whereas, in our hands, the effects of pCMPS were fairly rapid in onset, clearly occurring within 2–3 minutes of direct cell perfusion, Kalinec and Kachar (1993) found that significant effects on motor activity required greater than 20 minutes incubation. It is likely that their population measures, based on percent of motile cells, were not as sensitive as our single-cell gating-charge measures in determining the time course of effects. Consequently, our data may indicate that affected cysteine residues may reside at exposed sites within prestin. Based on current topology models (Zheng et al., 2001; Oliver et al., 2001; Adler et al., 2003; Navaratnam et al., 2004), three cysteine residues are predicted to lie external to the bilayer. In most models, only residue C415 resides extracellularly (Oliver et al., 2001; Zheng et al., 2001; Adler et al., 2003). However, the 10 transmembrane domain topology model of Navaratnam et al. (2004), predicts

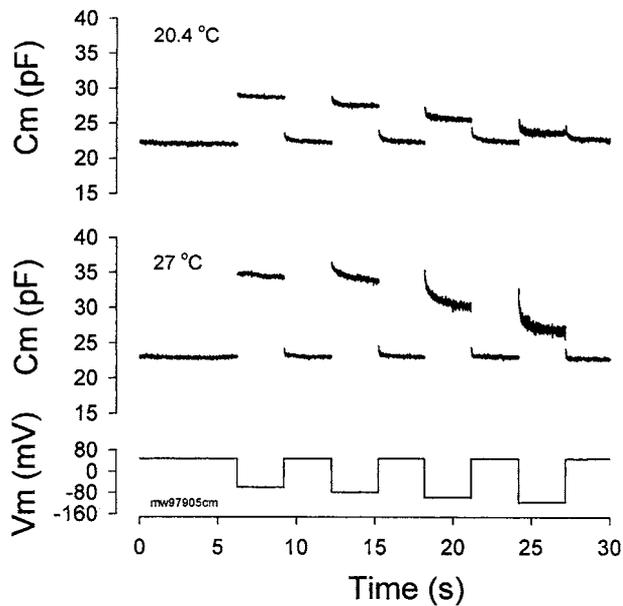

Fig. 7. Nonlinear capacitance of a single OHC during steps to a range of voltages at two different temperatures (*upper panel*: 20.4°C and *lower panel*: 27°C). Upon cooling, NLC is reduced but, in this case, there is little change in V_{pkcm} . However, C_m relaxations are markedly attenuated.

that C124, and not C415, resides extracellularly. Thus it may be that pCMPS works mainly on only one extracellularly exposed cysteine residue in prestin. Nevertheless, supplementing any effects on these putative extracellularly exposed residues, it may be that pCMPS quickly enters the OHC, possibly via large aqueous channels in the lateral membrane (Morimoto et al., 2002; Rybalchenko & Santos-Sacchi, 2003), thereby working on intracellular cysteine residues. In all models, the two other cysteine residues are found within the N and C termini, which reside within the intracellular aqueous phase (C52, C679), and though their co-location may indicate that these residues could interact, the absence of a significant effect of the membrane-permeable monothiol stabilizing agent, DTT, on NLC indicates that such potential interactions are not required for normal function.

Diamide has a dramatic effect on OHC mechanical characteristics (Adachi & Iwasa, 1997). We found little effect on NLC with our short perfusions. However, since the effects of diamide on the OHC cytoskeleton (spectrin, in particular) may require prolonged incubations, we tested an additional 5 OHCs at incubation times of 1–1.5 h at 5 mM; neither overall charge movement nor amplificatory shift was significantly affected, indicating that the diamide-sensitive subsurface cytoskeleton has little impact on intrinsic motor activity, though it can have effects on whole-cell mechanical performance (Adachi & Iwasa, 1997). Similarly, it had been previously reported that

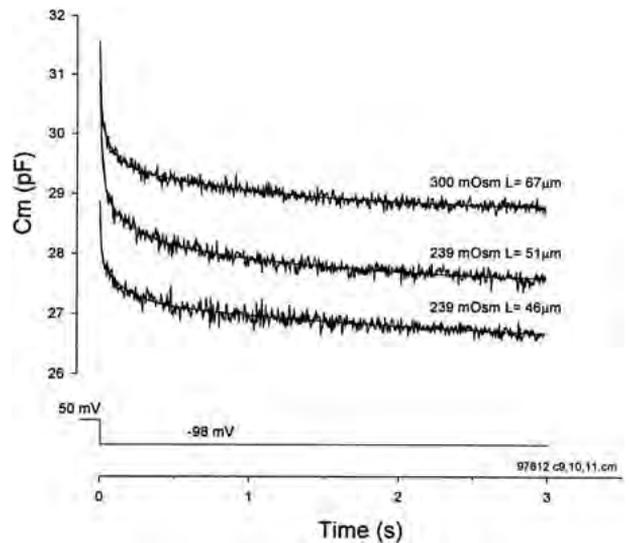

Fig. 8. Capacitance relaxations in a single OHC in response to a step voltage at increasing turgor levels. A switch from 300 mOsm to 239 mOsm caused a slow cell swelling, evidenced as cell shortening (length changed from 67 to 46 μm over a 5 min interval). Despite the increasing turgor pressure and marked shift of V_{pkcm} to hyperpolarizing levels (evidenced here as a reduction in baseline C_m magnitude) the C_m relaxation remains relatively unaltered.

digestion of the OHC cytoskeleton by intracellular enzymes did not adversely affect NLC (Huang & Santos-Sacchi, 1994; Santos-Sacchi et al., 1998) or mechanical activity (Kalinec et al., 1992).

EFFECTS OF LIPID-REACTIVE REAGENTS ON THE MOTOR

Prestin is a protein predicted by topology mapping programs to reside substantially within the lipid bilayer (Zheng et al., 2001). Consequently, it is not surprising that we find significant effects of drugs that are known to modify the lipid bilayer. Notably, chloroform has marked effects on OHC charge movement, reducing peak capacitance and shifting the motor's operating range in the negative direction; its major effect, however, was on the amplificatory shift, reducing its magnitude while increasing its speed. This was observed across a wide voltage range, and cannot be accounted for by a simple steady-state shift in V_{pkcm} . OHC gating-current speed was little affected by chloroform, and this substantially derives from the limiting effect of the whole-cell-clamp time constant (Santos-Sacchi & Huang 1998).

The effects of chloroform on other integral membrane proteins have been studied. Chloroform reduces the magnitude of Na channel gating currents but does not affect their kinetics or their operating voltage (Fernandez, Bezanilla & Taylor, 1982). On the other hand, the kinetics of Shaker K channels were speeded up, though the operating voltage remained stable (Correa, 1998). In both cases ionic

currents were blocked. Interestingly, chloroform has been found to enhance K currents through two-pore-domain K channels (Patel et al., 1999). The effects on these ion channels and other integral membrane proteins have been suggested to arise from direct actions on the proteins themselves (Franks & Lieb, 1994). However, despite this possibility it is clear that chloroform does have substantial effects on the lipid bilayer since, for example, Fernandez et al. (1982) also showed by measuring displacement currents that the hydrophobic anion, dipicrylamine, more rapidly traverses the bilayer in the presence of chloroform. Thus, although it cannot be ruled out that the OHC motor is directly affected by chloroform, the lipid-altering capabilities of this agent, especially at the saturating concentrations used in this and the previously noted studies (Correa, 1998; Fernandez et al., 1982), indicate a likely lipid-based mechanism of action.

The only other lipid-reactive agent tested that significantly affected NLC was HePC, though the absence of major effects from some of the other treatments may have been due in part to the short exposure times that we employed. HePC is a phospholipid analog that can insert into lipid monolayers and interact with cholesterol (Rakotomanga et al., 2004). Although the operating range of the OHC motor is susceptible to HePC, the amplificatory shift was minimally affected, showing behavior that apparently resulted indirectly from the steady-state shift in V_{pkcm} . It should be noted, however, that regardless of the underlying reason for alterations in the amplificatory shift, such a change at a fixed resting potential can be physiologically important. Thus, it may be possible that lipids can modulate the time course of OHC mechanical activity, just as they are able to modulate the time course of ionic currents (Oliver et al., 2004). It should also be stressed that a simple steady-state shift in V_{pkcm} does not necessarily result in changes to the amplificatory shift. For example, membrane tension produces marked changes in steady-state V_{pkcm} but has little effect on the amplificatory shift at a fixed voltage.

TEMPERATURE EFFECTS ON THE MOTOR

We have previously shown that OHC NLC is highly temperature sensitive, shifting steady-state V_{pkcm} to the left and reducing peak capacitance as temperature is decreased (Santos-Sacchi & Huang, 1998; Meltzer & Santos-Sacchi, 2001). However, we were unable to evaluate any changes in the speed of gating currents because the clamp time constant, even at 50 μ s, under whole-cell mode was limiting. Effects of temperature on the amplificatory shift are clearly observed and a decrease in temperature markedly reduces the shift. Since temperature is known to affect both membrane

proteins and lipids, it is possible that effects on motor activity may be dual.

MECHANISMS OF ACTION ON V_{pkcm}

The amplificatory shift has been modeled to result from interactions among motors via induced membrane tension (Santos-Sacchi et al., 1998). Whether the shift derives from motor interactions directly or via intervening lipid is an important issue, which can impact on OHC function. Thus, we have recently shown that functional motor microdomains may exist within the OHC, where local biophysical forces foster independent, local motor activity (Santos-Sacchi et al., 2001). The efficiency of coupling such forces, e.g., membrane tension, among motors could depend heavily upon the physical types of interactions responsible for motor coupling. For example, interactions via bilayer lipids may limit the distance over which motors could interact, whereas direct protein interactions could provide longer-range interactions. While our data may indicate that both lipid and protein moieties can influence the amplificatory shift, the high density of motor protein expression within the lateral membrane, estimated to be near 8000/ μ m² (Huang & Santos-Sacchi 1993; Gale and Ashmore 1997), may significantly promote direct motor-motor interactions. In this regard, it would be interesting to test the effect of motor expression density on the amplificatory shift. Expression density is known to influence integral membrane protein function; for example, the fraction of non-inactivating CLC-0 channels is directly related to expression level (Pusch, Ludewig & Jentsch, 1997).

Regarding the steady-state shifts in V_{pkcm} , these modulations can not be due to changes in membrane viscosity, since forward and backward transition rates between protein conformations should be affected equally by changes in viscosity (Lee, 1991). Thus, based on a two-state model, temperature, chloroform and other lipid-modifying agents known to shift V_{pkcm} must instead alter the relative energy level of each motor state. Perhaps these manipulations act via perturbation of membrane tension or membrane bending, resulting in changes in conformational stability. Each of these phenomena has been implicated in motor activity (Iwasa, 1993; Gale & Ashmore 1994; Kakehata & Santos-Sacchi, 1995; Raphael, Popel & Brownell, 2000; Lue, Zhao & Brownell, 2001; Morimoto et al., 2002; Spector & Jean 2004). However, while viscosity is not likely to be involved in steady-state shifts, the rate of amplificatory shift induced by voltage steps might be expected to be affected. We suggest that chloroform may be working to reduce membrane viscosity, thereby speeding up the amplificatory shift.

Finally, we note that while prestin is considered to be essential for motor activity (Zheng et al., 2000;

Liberman et al., 2002), and the manipulations that we have made here may, in fact, alter prestin or its interactions with the lipid bilayer, it is not certain whether homo- or heteromeric configurations comprise the intact OHC motor (Santos-Sacchi, 2003). Thus, our manipulations may actually be working on players besides prestin. Indeed, we must remain cognizant that unexpected effects of the tested agents on mechanisms other than those we have highlighted may come into play, for example, altered anion binding. We are currently working on these issues (Navaratnam et al., 2004).

Excitation of fluorescent dyes inactivates the outer hair cell integral membrane motor protein prestin and betrays its lateral mobility

Received: 18 November 2002 / Accepted: 6 March 2003 / Published online: 29 May 2003

Abstract The outer hair cell motor protein, prestin, which resides exclusively in the cell's lateral membrane, underlies the mammal's exquisite sense of hearing. Here we show that photoexposure of the commonly used dyes Lucifer yellow, 6-carboxy-fluorescein, and 4-{2-[6-(dioctylamino)-2-naphthalenyl]ethenyl}-1-(3-sulfo-propyl)-pyridinium (di-8-ANEPPS), that are in contact with the cell's lateral membrane can photo-inactivate the motor irreversibly, as evidenced by reduction in prestin's gating charge displacement or non-linear capacitance. Furthermore, utilizing restricted fiber optic illumination of the lateral membrane, we show that whole-cell, non-linear capacitance is depleted beyond that expected for an immobile population in the exposed area. These data indicate that lateral diffusion of prestin occurs within the cell's lateral plasma membrane.

Introduction

The molecular motors of the outer hair cell (OHC) drive a somatic mechanical response that underlies the enhanced sensitivity and frequency resolving power of the mammalian cochlea [2, 5, 12, 23]. Electrical measures indicate that these motors reside within the lateral plasma membrane of the OHC, and probably resemble other integral membrane proteins that are capable of generating

gating currents upon voltage-induced conformational changes [3, 10, 11, 22]. In fact, Dallos and coworkers have cloned the gene for a protein, prestin, that, when expressed in non-auditory cells, presents electrical and mechanical signatures that match those of the OHC lateral membrane motor [25, 31]. Prestin is expressed in exactly that location, namely, the lateral plasma membrane [4], predicted by the electrophysiological evidence [10].

Integral membrane proteins are capable of diffusing through the plasma membrane [7]. To study the constraints that maintain prestin's residence in the lateral membrane, we have mapped recently the extent of prestin along the OHC lateral membrane using discrete mechanical stimulation [27], and evaluated the effect of cytoskeletal destruction on motor diffusion to areas normally devoid of motor molecules, namely, the basal region of the cylindrical cell. Surprisingly, the motors did not migrate to the basal region, indicating some type of integral membrane barrier. Here we use a technique to photo-inactivate motors while monitoring their gating charge movement so that their ability to diffuse within the lateral membrane can be assessed. We provide evidence that prestin, in intact OHCs, is capable of diffusing within the lateral plasma membrane.

Materials and methods

Guinea pigs were euthanized with halothane. OHCs and supporting cells were isolated enzymatically with dispase I (0.5 mg/ml for 10 min followed by gentle trituration through a polyethylene pipette) in a modified Leibovitz medium containing (in mM): NaCl 142, KCl 5.37, MgCl₂ 1.47, HEPES 5, CaCl₂ 2 and dextrose 5; 300 mOsm, pH7.2. The cells were then transferred to a 700- μ l perfusion chamber. All experiments were conducted at room temperature (~23 °C). A Nikon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical recording. All experiments were video-taped.

Single OHCs were studied under whole-cell voltage-clamp conditions using a patch clamp amplifier (200A, Axon Instruments, Union City, Calif., USA) at a holding potential of -80 mV. Initial resistances of patch pipettes were 2–3 M Ω , corresponding to tip sizes of 1–2 μ m. Residual series resistance was 3–7 M Ω . Data were collected and analyzed using a Windows-based program (jClamp,

H.-B. Zhao, Div. of Otolaryngology, Dept. of Surgery,
University of Kentucky Medical Center,
Lexington, KY 40536, USA

SciSoft, New Haven, Conn., USA). Ionic blocking solutions were used to remove voltage-dependent ionic conductances so that capacitive currents could be analyzed in isolation [10, 22]. The patch pipette solution contained (in mM): CsCl 140, MgCl₂ 2, EGTA 10, HEPES 5, with pH 7.2 and osmolarity 300 mOsm (adjusted with dextrose). The extracellular ionic blocking solution contained (in mM): 100 NaCl, 20 TEA, 20 CsCl, 1.25 CoCl₂, 1.48 MgCl₂, 10 HEPES, pH 7.2 and osmolarity 300 mOsm (adjusted with dextrose). Whole chamber perfusion was continuous.

OHC capacitance was monitored using transient analysis [10]. Additionally, continuous, high-resolution capacitance measurements were acquired through admittance analysis at time resolutions of 5.12 or 2.56 ms utilizing a two-sine wave voltage stimulus protocol fully described elsewhere [24]. The stimulus consisted of the sum of two voltage sine waves (390.625 and 781.25 Hz), each at a magnitude of 10 mV peak. In some cases, this AC stimulus was superimposed on voltage ramp or step stimuli. Capacitance-voltage (*C-V*) functions were fit to the first derivative of a two-state Boltzmann function relating non-linear charge to membrane voltage (dQ/dV ; [10, 22]):

$$C_m = Q_{max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin}$$

where

$$b = \exp\left[\frac{-ze(V - V_{pkCm})}{kT}\right]$$

and Q_{max} is the maximum nonlinear charge moved, V_{pkCm} the voltage at peak capacitance or, equivalently, at half-maximal non-linear charge transfer, V_m is the membrane potential, z valence, C_{lin} linear membrane capacitance, e electron charge, k Boltzmann's constant, and T absolute temperature.

Patch pipettes were filled with either Lucifer Yellow (5%) or 6-carboxyfluorescein (5%) to load OHCs with the dye. The lipophilic dye 4-[2-[6-(dioctylamino)-2-naphthalenyl]ethenyl]-1-(3-sulfo-propyl)-pyridinium (di-8-ANEPPS) was delivered to the OHC plasma membrane as previously described [14, 15]. Briefly, cells were incubated with 1% dye in extracellular solution for 15 min prior to washing and recording. For whole-cell exposure, the dyes were excited with blue light (450–490 nm filter; Nikon 100-W high-pressure mercury lamp). For discrete excitation, a pulled quartz fiber optic (tip size ~2 μm) was fed directly from a Zeiss 75-W high-pressure mercury lamp, without filters. Whole cells were exposed by opening/closing the microscope light barrier manually. Fiber optic exposures were controlled via a computer-driven shutter.

Results

Prestin can be photo-inactivated

OHC membrane capacitance derives from two components: that associated with lateral membrane sensor/motor charge movement, and that proportional to membrane surface area. Figure 1 illustrates through measurements of capacitance that prestin can be irreversibly photo-inactivated. Figure 1a shows the exponential decrease in motor-associated capacitance following whole-cell photoexposure of a cell perfused intracellularly with 5% Lucifer Yellow via the patch pipette. The time constant for inactivation was 14.2 s (mean 26.4 ± 10.2 s, $n=6$). To accomplish this inactivation, the photosensitive dye must be in contact with the cell's plasma membrane (Fig. 1b). In the absence of dye, photoexposure of OHCs did not reduce whole-cell capacitance; following perfusion of the

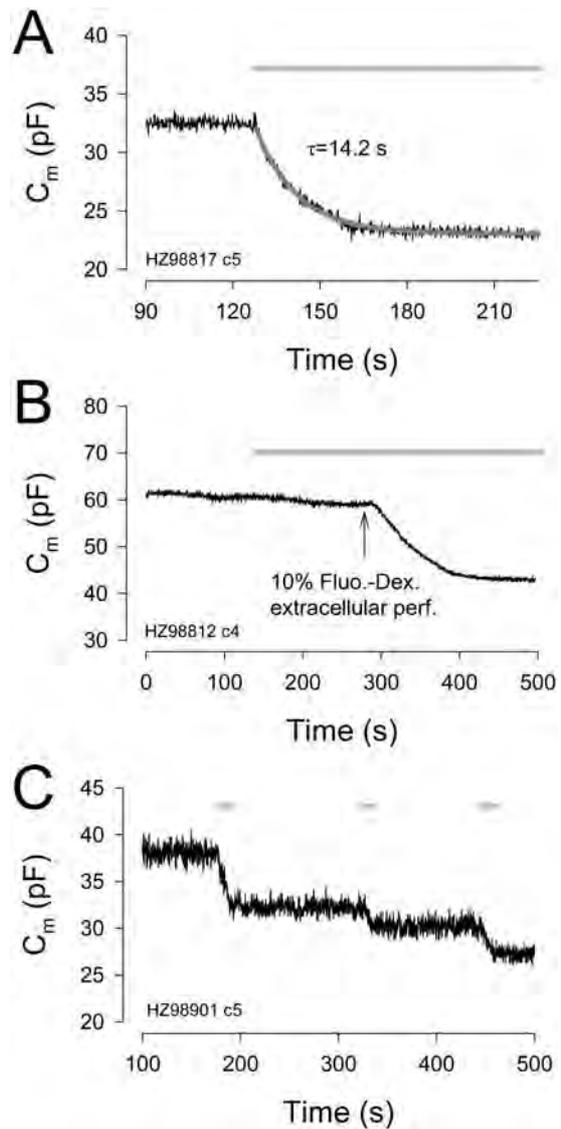

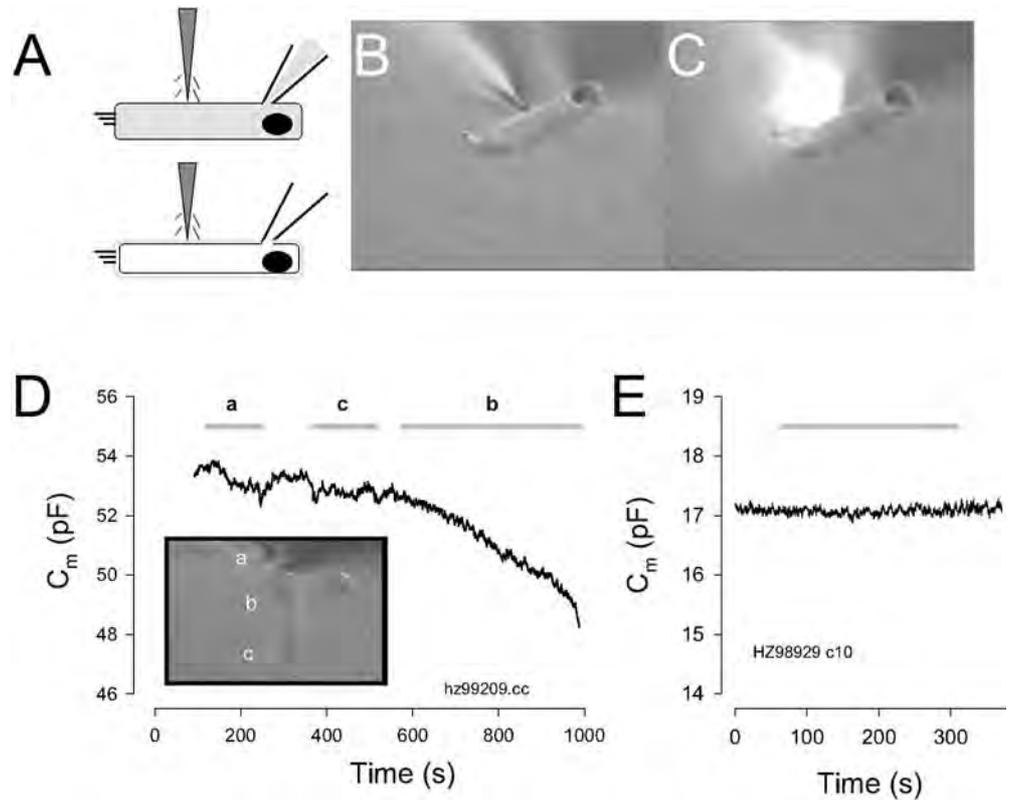

Fig. 1A–C Outer hair cell (OHC) motors can be irreversibly photo-inactivated. **A** OHC with intracellular Lucifer Yellow. Light was turned on for the period indicated by the *gray bar*. Note exponential decay of non-linear component of membrane capacitance (C_m , ordinate). Fit (*solid line*) indicates a time constant of 14.2 s. **B** Non-linear capacitance (NLC) was resistant to photoexposure in the absence of sensitizing dye. After the addition of the membrane impermeant dye fluorescein-dextran, NLC exponentially decreased. **C** OHC with 6-carboxyfluorescein intracellular. NLC decreased only during photoexposure (*bars*)

cells with extracellular solutions containing fluorescent dye the motors became susceptible. The inactivation of lateral membrane motors was rapid and only occurred during the duration of the light exposure. This is shown in Fig. 1c where the light was switched on for only short periods; between exposures the reduced capacitance remained stable.

Fig. 2A–E Restricted exposure with fiber optic light probe. **A** Cells were whole-cell patch clamped and the fiber placed adjacent to the plasma membrane of cells with either intracellular dye (*top figure*, Lucifer Yellow) or intra-membrane [*bottom figure*, 4-{2-[6-(dioctylamino)-2-naphthalenyl]ethenyl}-1-(3-sulfo-propyl)-pyridinium (di-8-ANEPPS) dye, see Methods]. **B**, **C** Digitally captured image of an OHC before and during exposure to the lateral membrane. **D** An OHC treated with di-8-ANEPPS was exposed at the basal (*a*), middle (*b*) and apical (*c*) regions of the cell. Only the lateral region exposure produced marked capacitance decreases. **E** A Deiters' cell treated with di-8-ANEPPS showed no reduction of linear capacitance during exposure

Photoexposure of restricted regions of the OHC

By delivering light through a tapered fiber optic light guide (tip size: $\sim 2 \mu\text{m}$; rough estimate of diffusive exposure: $80 \mu\text{m}^2$), photo-exposure can be directed to selected regions of the OHC (Fig. 2). In Fig. 2d, exposure of the basal and apical region of the OHC produced little decrease in capacitance, whereas exposure of the lateral membrane caused a substantial drop in capacitance. This is expected, since the motors are restricted to the lateral membrane [4, 10]. In Deiters' cells, which lack prestin, membrane capacitance remained stable during photo exposure (Fig. 2e).

We used this restricted fiber optic exposure to evaluate the possibility of motor diffusion in the lateral membrane. Figure 3 illustrates that repeated or continuous restricted exposure of the OHC lateral membrane to the light source produced accumulating capacitance decreases not expected for an immobilized, finite population of motors. Repeated fiber optic exposure to fixed portions of the OHC sensitized with either intracellular 6-carboxy fluorescein (Fig. 3a), or with the membrane-soluble dye di-8-ANEPPS (Fig. 3b), resulted in an apparent linear (i.e. non-exponential) decrease in capacitance during exposure, and stabilization in the absence of exposure. The slope of the capacitance decrease with restricted exposures ($12.3 \pm 1.8 \text{ fF/s}$; $n=6$) was substantially less than the initial slope ($312 \pm 33 \text{ fF/s}$; $n=6$) following whole-cell exposure, though the ultimate magnitude of decrease could be quite large (Fig. 3c). We interpret these

observations to result from the continuous movement of functional motors into the small region of photoexposure. That is, the rate of inactivation is limited by diffusion rate of the motor into the restricted region of exposure. Figure 4 shows whole-cell C - V functions for an OHC in which the lateral membrane was exposed for 8 min via fiber optic. In addition to a reduction in total charge moved (Q_{max}), indicating the removal of functional motors from the whole cell population, z and V_{pkCm} were altered.

Discussion

A number of studies have shown that integral membrane proteins are modified either directly by light at particular wavelengths [8, 9, 17] or by sensitizers following light activation [1, 17, 28]. Our data indicate that the OHC motor protein prestin can be rapidly photo-inactivated. Whole-cell C - V functions result from the combined characteristics of the photo-inactivated population of motors and the remaining normal populations of motors, and confirm the destruction of motors since Q_{max} was reduced. Motors are not directly susceptible to the light sources that we used but to some product that is released following the excitation of commonly used fluorescent dyes near or within the membrane. We have shown previously that gap junctions and K^+ channels within supporting Hensen's cells can be similarly photo-inactivated [20, 21]. It should be stressed that the decrease in

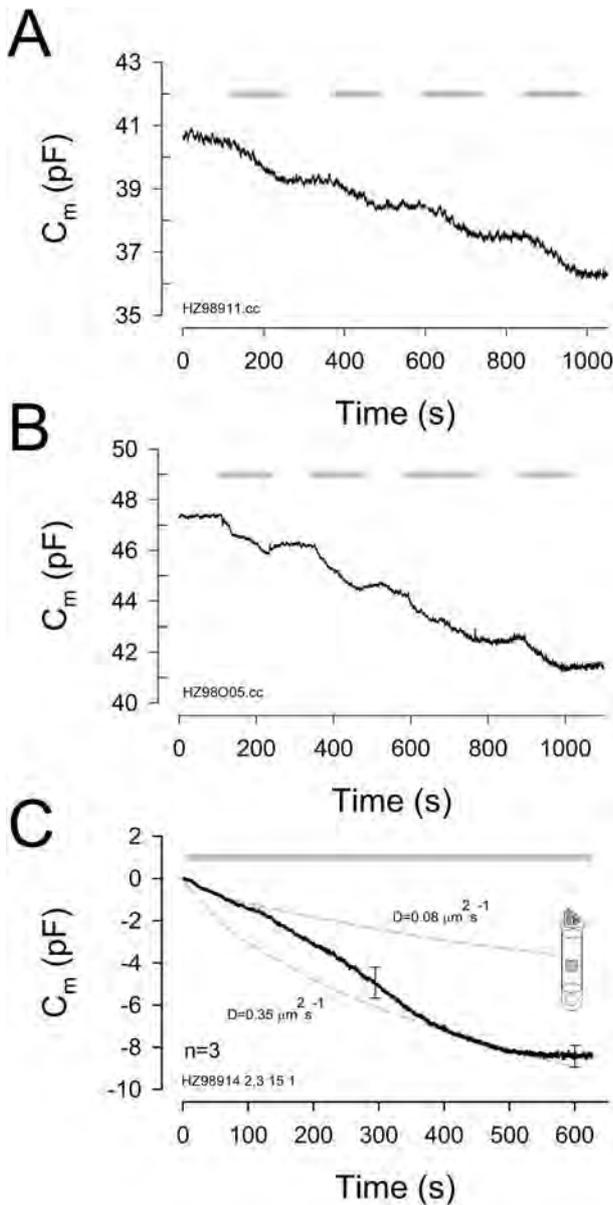

Fig. 3A–C Repeated or continuous exposure of restricted regions of the lateral membrane. **A** OHC filled with Lucifer Yellow showed accumulating decreases in NLC during repeated exposures. The slope of decrease appears linear. **B** OHC treated with di-8-ANEPPS showed similar behavior during exposures. **C** Continuous exposure of restricted region (gray area in OHC schematic) produced an initial linear segment of NLC decrease followed by a decaying rate. The trace is the mean \pm SEM of three OHC responses. The dotted lines indicate the result of model simulations with the indicated diffusion coefficients (see Discussion for details)

capacitance or conductance is not likely to be due to diffusion of reactive species far from areas of exposure, since inactivation stops immediately after the light is turned off. This is expected since photo-sensitizers probably act after binding to the membrane, and the estimated lifetime and diffusion of the evolved reactive species, e.g., singlet oxygen, are of the order of a few microseconds, and a hundred nanometers, respectively

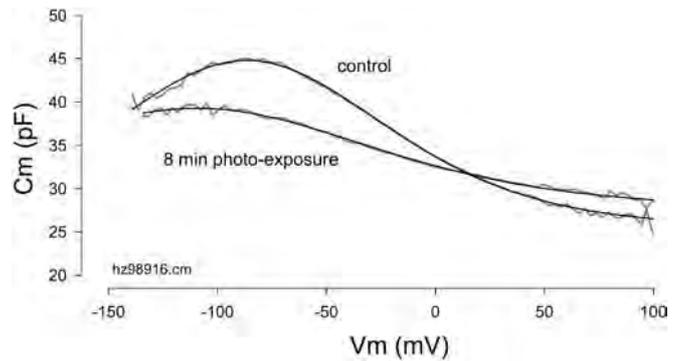

Fig. 4 Functions relating C_m to membrane potential (V_m) before and after an 8-min fiber optic exposure of an OHC treated with di-8-ANEPPS. Fitted parameters: control (V_{pkC_m} , z , Q_{max} , C_{lin} , respectively): -86.5 , 0.59 , 3.36 , 25.5 , exposed: -109.4 , 0.47 , 2.55 , 27.7

(see [19] for discussion and references). Thus, the fiber optic exposures that we made probably resulted in highly restricted lesions. Since motors can be inactivated by hydrophilic dyes (Lucifer yellow, 6-carboxyfluorescein, fluorescein-dextran) delivered to the membrane via intracellular or extracellular routes, and by the lipophilic dye (di-8-ANEPPS), susceptible targets are possibly present at intracellular, extracellular and intramembrane domains. The amino acids histidine, methionine, tryptophan and cysteine are most sensitive to reactive oxygen species [13], and these residues are found in all three domains of prestin [32] (J. Zheng, personal communication).

The inactivation of sensitized lateral membrane motors by light may be viewed as a simple irreversible reaction:

For whole cell exposure, where M_+^* is the sensitized active motor pool, M_- is the inactivated motor pool, and k_{kill} is the inactivation rate constant, the time course of inactivation is a simple exponential, with a time constant of $1/k_{kill}$. For our whole-cell data the rate constant was 0.0384 s^{-1} . If we consider that in this case the non-linear capacitance (NLC) decrease arises from destruction of all motors in the cell (~ 10 million for a low-frequency OHC [10]), we can derive an estimate of motor inactivation rate, namely, about 384,000/s. This high sensitivity to inactivation is mirrored by the inner ear's sensitivity to a variety of insults, including agents that generate reactive oxygen species [6, 16].

The description of the inactivation process in a partially exposed cell is more complicated, as the sensitized active motor pool may be supplied by the unexposed active motor pool, M_+ .

The rate constants k and $k-1$ will influence the time course of motor inactivation, and actually represent more complex diffusion processes. Thus, the forward rate constant k may be influenced by motor density, motor interactions with other integral membrane proteins and sub-membranous cytoskeleton, and diffusion distances from the irradiated area. The backward rate $k-1$ will also reflect similar influences, but additionally may suffer from the untoward effects of photo-irradiation, for example, molecular cross-linking.

Peters et al. [18] have performed a conceptually similar study to ours using continuous fluorescence recovery after photobleaching (FRAP) of the dye 3,3'-diiodoacetylcarboxyanine perchlorate (DiO) within a restricted membrane region. They pointed out that in the case where the diffusion time constant ($\tau_d = \text{irradiated radius}^2/D$; where D is the diffusion coefficient) is very much greater than the photo-inactivation time constant ($\tau_k = 1/k_{\text{kill}}$), the time course of fluorescence decay (or in our case capacitance decay) would follow the exponential time course characteristic of photo-inactivation alone. This behavior essentially accounts for the characteristic time of capacitance decrease that we observe under whole-cell photo irradiation. However, in the case where the photo-inactivation process is very much faster than the delivery of motors to the irradiated area, the time course of capacitance decrease would be dominated by the factors that govern the diffusion process. With fiber optic illumination, the time course of capacitance decrease was not a simple exponential (Fig. 3c), as we might have expected for an immobile population of motors, and as we observed with whole-cell irradiation; instead, there was a prolonged linear-like segment followed by an exponentially decaying termination. Furthermore, the magnitude of NLC decrease is far greater than that expected for the estimated exposed area. We conclude from these data that there is, in fact, lateral diffusion of motors into the irradiated area, and that the photo-inactivation process is faster than that of diffusion. This contrasts with observations on Na^+ channels in skeletal muscle that were photo-inactivated under a loose patch pipette; currents did not return for more than 60 min, indicating a diffusion coefficient of less than $0.0001 \mu\text{m}^2/\text{s}$ [26, 29].

The diffusion coefficient of untethered proteins within lipid bilayers typically ranges around $0.01 \mu\text{m}^2/\text{s}$ [7]. That of lipid molecules within the membrane is larger, ranging around $1.0 \mu\text{m}^2/\text{s}$. The diffusion of the lipid permeable dye di-8-ANEPPS within the OHC lateral membrane is within that range, but interestingly, it is voltage dependent to some extent [14, 15]. This may relate to the voltage dependence of the major protein, prestin, located in that membrane. Another lipid soluble dye, SP-DiIC18, is relatively immobile, but can redistribute within the membrane in a voltage dependent manner and probably depends on prestin activity [30]. In light of these data, it may be possible that the diffusion of prestin itself may depend on the protein's voltage-dependent area state. In the present study, we held the OHCs at a constant

membrane voltage, but it will be interesting to evaluate the effects of various holding potentials in future studies.

Given our data, the diffusion coefficient of prestin may be roughly estimated by considering that the problem is basically one of modeling a molecular sink. As a first approximation, we consider an uncapped cylindrical bilayer possessing the surface area (source) of the lateral membrane of a $65\text{-}\mu\text{m}$ -long OHC, $1,288 \mu\text{m}^2$, within which reside motors at a density of $7,500/\mu\text{m}^2$ (equated to a NLC of $0.01 \text{ pF}/\mu\text{m}^2$) [10]. The motors are considered freely diffusible, but exit the system upon entering a central region (sink) of $\sim 1/20$ ($81 \mu\text{m}^2$) the full surface area. The question is what diffusion coefficient must the molecules possess to produce a decrease in numbers at a rate of $10,000/\text{s}$ ($\sim 10 \text{ fF}/\text{s}$ in the OHC), as we estimate during fiber optic irradiation of the OHC? The problem was modeled in Berkeley Madonna using $1\text{-}\mu\text{m}$ square cells, with a square sink ($9 \mu\text{m}$ edge) in the middle of the OHC (Fig. 3c inset). The dotted lines in Fig. 3c show the time course of reductions in NLC for two diffusion coefficients that bracket the averaged data. A D of $0.08 \mu\text{m}^2/\text{s}$ can account for the initial segment of the data; however, the subsequent segments require larger coefficients. The divergence from a simple and fixed course of diffusion indicates that something more complicated is occurring, perhaps cross-linking of proteins or lipid peroxidation. We must also be aware that the diffusion of the dyes (which themselves may be rendered ineffective in the exposed area) may also influence our measures. We suggest that the earlier segments of the data, where membrane damage may be less, may better represent the diffusion characteristics of prestin and indicate that prestin is untethered. The ability to diffuse may be important for the redistribution of motors after insertion into the plasma membrane during normal motor turnover. Additionally, the absence of tethering may indicate that the proteins freely rotate within the plane of the membrane, and are unlikely to acquire any anisotropic characteristics owing to diffusional constraints.

In sum, we have shown that the OHC membrane motor is susceptible to photo-inactivation, and that this sensitivity can be exploited to reveal the protein's ability to diffuse within the lateral membrane. With the recent molecular identification of the motor [25, 31] we can expect more detailed examinations of the protein's activities in the lateral membrane.

PART IV: ANIMAL RESEARCH IN PERIPHERAL AUDITORY PHYSIOLOGY

Joseph Santos-Sacchi

BACKGROUND

Cataloging the microanatomy of the auditory end organ provided an important start for understanding the physiology of the peripheral auditory system. These anatomical studies, conducted on a variety of species, began in earnest following the development of the compound light microscope in the 1700s. The detail in some of the original work of such pioneers as Alfonso Corti is remarkable (see Hawkins¹ and references within), but alas the microscopic structures were necessarily altered by the decay following extirpation and dissection. As we shall see, this decay had a major impact on our understanding of cochlear physiology as well. Whereas the development of fixatives proved a boon for anatomists, physiologists would not benefit directly but would belatedly profit from histologists' appreciation of the need to preserve the natural state.

The cochlea, we now know, is a remarkable electromechanical device. Prior to the discovery of animal electricity and means to measure it, only the mechanical components of cochlea function could be investigated. Thus, the microscopic structures in the inner ear were used to deduce the mechanical foundation of cochlea function; for example, Helmholtz postulated his resonance theory based on the changing length (hence mechanical properties) of radial basilar membrane fibers. Clearly, in mammals, the basilar membrane with its varying dimensions and stiffness would be a prime candidate for the basis of hearing. Indeed, von Bekesy's studies² confirmed the importance of the basilar membrane's mechanical qualities by demonstrating tuned traveling waves evoked by basilar membrane disturbances. von Bekesy used a variety of animal models, mainly the human temporal bone, but also mouse to elephant, to assess the sharpness of tuning in the cochlea, and while the data he obtained contributed immensely to our understanding of cochlea mechanics and won him the Nobel prize in 1961, unforeseen factors worked to stymie an understanding of the true sensitivity and tuning of the mammalian cochlea. These factors were the same that stymied early anatomists, namely the difficult-to-avoid decay of normal cellular structure and function after death. These problems, though acknowledged by von Bekesy, were argued away, so that for many years auditory aficionados were led to believe that his data were gold. In fact, there were serious problems with his experiments, which when ultimately realized and solved would help elucidate the roles of the two types of hair cells, the inner and outer hair cells, that the early anatomists identified with the aid of improved fixation techniques. To improve on the work of von Bekesy, models other than the human would be required.

WHY DO WE STUDY ANIMAL MODELS?

There are two main reasons for the study of peripheral auditory physiology, namely, the quest to understand and cure auditory dysfunction, and simply to understand how our and other animals'

ears work. Clearly, study based on the former rationale would benefit from direct investigations on humans. Unfortunately, though, immense difficulties are associated with human experimentation on the auditory periphery. These problems include limited number of specimens, inability to control for pathological effects, and the inevitable problem of tissue destruction caused by delays in the access to the cochlea (caused by dissection difficulties due to the dense temporal bone and delays in acquisition following death). Thus, for many reasons and regardless of the clinical vs. scientific rationales, animal models are best for studies on cochlear physiology. The major hurdle in rationalizing a particular animal model is its validity and generality. As far as providing insight to the human condition, most investigators believe that a range of small mammals, including cat, chinchilla, guinea pig, rat, and mouse, are appropriate. Of course, one or another species may prove better for particular experimental questions. In general, however, these small animals are particularly well suited since very nice access to the cochlea structures can be had. This enhanced accessibility (and heightened concern for better physiological status) has led directly to enhancements of the findings of von Bekesy.

BASILAR MEMBRANE TUNING

The data on basilar membrane movement that von Bekesy obtained indicated that the response of the basilar membrane was linear, i.e., the magnitude of the displacement response grew linearly with the stimulus level. By extrapolating down to threshold levels, it was argued that basilar membrane movements at the threshold of hearing were a fraction of an atom's width. Tuning of the basilar membrane was also observed to be not as good as psychophysical measures, and von Bekesy sought reasons beyond the basilar membrane to explain how we hear so well. With the aid of animal models, these notions would dramatically change.

Using the squirrel monkey, Rhode and colleagues^{3,4} first noticed that in some animals a nonlinear growth in basilar membrane motions occurred as stimulation levels were changed. Importantly, this compressive nonlinearity of the basilar membrane response was vulnerable to the animal's status. Only when extreme care was used to maintain a healthy preparation did the response remain nonlinear, otherwise it resembled the data of von Bekesy. We know now that tuning on the basilar membrane is far sharper than the data of von Bekesy showed, indicating that his human temporal bone preparation and his animal preparations were working in a passive, damaged mode. Of course, the new Mossbauer measurement tool that Rhode and colleagues used helped to record at lower stimulus levels than von Bekesy could using stroboscopic illumination. Today, it is clear that the sharp tuning found in the eighth nerve has its direct counterpart in basilar membrane motion.⁵ This turnaround in the description of basilar membrane tuning highlights the caveat that while animal models have the potential to provide valid data, care must be exercised in order to attain validity.

THE COCHLEA IS ELECTRIC

In the 1700s, electricians (as serious students of electricity were then called) often relied on themselves or acquaintances to serve as subjects. Indeed, Volta perceived a deafening blast as a result of self-inflicted aural electrocution.⁶ Despite this early indication, it would be nearly two centuries after the controversial discovery of animal electricity that the electrical nature of audition would be confirmed. The discovery had to wait for the invention of the vacuum tube and oscilloscope, but once in hand Wever and Bray⁷ demonstrated the "cochlear microphonic," an electrical response of the hair cells (which they mistakenly took as eighth nerve firings) measured from electrodes placed on a decerebrate cat's eighth nerve. The response mimicked the acoustic stimulus, and they confirmed this finding in a number of animal species, including turtles and insects.

The study of the electrical activity of the cochlea took off, and small mammals were perfect models since their cochleae were easily exposed for electrode implantations. Extracellular (from scala media and the perilymphatic scalae) electrical recordings were made of the resting (e.g., endolymphatic potential) and sound-evoked potentials (cochlea microphonic, summing potential, and even action potentials; see Dallos⁸), but eventually these were usurped by intracellular recording directly from hair cells^{9,10} after the high impedance electrode was devised. The clear correspondence of electrical activity within the auditory periphery with hearing capabilities would place this measure above that of histopathologic determination of auditory insult and recovery.

ANIMAL MODELS OF CLINICAL IMPORTANCE

The anatomical identification and characterization of cochlear dysfunction is time-consuming. The classic histological work on otopathology (see Schuknecht¹¹), while quite informative, could not be used with high efficiency, simply because the animal or human temporal bone had to be removed and processed after death. The use of electrical measures to determine auditory sensitivity, especially those that were noninvasive (e.g., auditory brainstem response [ABR], compound action potential [CAP]) permitted ongoing and quantitative studies on the effects of noise exposure, ototoxic drug exposure, and hazardous chemicals (e.g., see Henderson and coworkers¹²). As a direct result of animal experimentation, we would no longer have to experience devastation such as that caused by the first uses of the ototoxic antibiotic dihydrostreptomycin.¹³ Nevertheless, while animal models have immensely contributed towards our understanding of pathologies that afflict humans, we must remain cognizant of species-specific differences.

One of the hottest areas of current research is that of hair cell regeneration (see Warchol¹⁴). Mammalian hair cells do not regenerate following destruction, as do those of some lower vertebrates. Thus, unlike some tissues that can be interrogated via cell culture, mammalian inner ears must be harvested for each new experiment. Perhaps some day, if the key that controls hair cell production is found, hair cell cultures may reduce the need for animal sacrifice.

In the heyday of electron microscopy, transport of electron-dense markers into various compartments of the inner ear was studied. These studies included, for example, movements of molecules out of the vasculature and into cochlea scalae, thus identifying the blood-labyrinthine barriers¹⁵⁻¹⁷ and movements of molecules across the round window membrane into the scala tympani.¹⁸ The latter experiments contributed to the scientific basis for the currently popular clinical approach of intratympanic drug delivery, notably used to deliver gentamycin for control of intolerable vertigo. This type of approach heralds a new era where the otologist will successfully treat previously inaccessible structures of the inner ear and will ultimately do so with the new tools of molecular biology.

FROM MOLECULES TO EAR

Some very important advances in auditory physiology have been made in recent years using the techniques of molecular biology. Two of them are especially dear to my heart, namely, the determination that mutations of the connexon 26 gene result in nonsyndromic deafness¹⁹ and the identification of the protein responsible for the mechanical activity of the outer hair cell.²⁰

Connexons are proteins that form gap junction channels between adjacent cells, in the ear's case, allowing ionic and metabolic communication between supporting cells.²¹ These channels were proposed to aid in the removal of harmful extracellular potassium away from active hair cells,²² and this is a likely reason for the mutation's devastation of hearing.

The mammalian outer hair cell has long been known to dance wildly in response to electrical stimulation;²³⁻²⁵ this mechanical activity is believed to promote the sharp tuning and nonlinearity

that Rhode and colleagues found in the basilar membrane. Finally, after nearly two decades, the motor responsible for the outer hair cell (OHC) boogie was molecularly identified as the protein prestin.²⁰ The story is a continuing one that is full of twists,²⁶ but most recently a knockout of the prestin gene in the mouse seriously interfered with normal auditory function,²⁷ and a mutation of the gene was shown to cause deafness in humans.²⁸ In the end, it will likely be the mouse model that holds the key to our interests in the ear, as this small prolific rodent is a perfect molecular biology laboratory. But let us not forget the guinea pig, which is a classic model in auditory research; indeed, this animal has just helped show that gene transfection (of Math1 transcription factor) into the intact cochlea can induce new hair cell growth.²⁹ Imagine, the future otologist growing some new hair cells for us hard-of-hearing baby boomers — thanks to animal research.

Dye coupling in the organ of Corti

Joseph Santos-Sacchi

Laboratory of Otolaryngology, New Jersey Medical School, Newark, USA

Summary. Dye-coupling in an in vitro preparation of the supporting cells of the guinea-pig organ of Corti was evaluated by use of the fluorescent dyes, Lucifer Yellow, fluorescein and 6 carboxyfluorescein. Despite the presence of good electrical coupling in Hensen cells (coupling ratios >0.6) the spread of Lucifer yellow was inconsistent. Hensen cells are very susceptible to photoinactivation, i.e., cell injury upon illumination of intracellular dye; and this in conjunction with Lucifer Yellow's charge and K^+ -induced precipitability may account for its variability of spread. Fluorescein and 6 carboxyfluorescein, on the other hand, spread more readily and to a greater extent than Lucifer Yellow, often spreading to cell types other than those of Hensen. Dye spread is rapid, occurring within a few minutes. These results suggest that molecules of metabolic importance also may be shared by the supporting cells of the organ of Corti.

Key words: Organ of Corti – Supporting cells – Dye coupling – Gap junctions – Photoinactivation – Guinea pig

The supporting cells of the mammalian organ of Corti are joined together by gap junctions (Jahnke 1975; Gulley and Reese 1976; Iurato et al. 1976). In a previous study, electrical coupling among these cells was shown to be present, although it was thought to be poor (Santos-Sacchi and Dallos 1983). At that time, dye spreading studies with the fluorescent dye Lucifer Yellow did not reveal dye-coupling in the supporting cells, except on very rare occasions. In recent studies on electrical coupling of Hensen cells with more precise electrophysiological techniques, coupling has been shown to be very good in vitro (Santos-Sacchi 1984, 1985). This result prompted a reinvestigation of dye coupling in the supporting cells of the mammalian inner ear.

Methods

Guinea pigs were anesthetized with pentobarbital and killed by decapitation. The cochleas were quickly removed, and

the apical and third turn was microdissected in one piece after removing the spiral ligament and stria vascularis. The preparation was transferred to a perfusion chamber. Alternately, the whole temporal bone was placed in a perfusion chamber on a Zeiss ACM microscope, and the bony capsule around the two most apical turns chipped away. The stria vascularis and spiral ligament were removed. Both chambers were maintained near $37^\circ C$ with Peltier devices (Bailey Instruments, N.J.). Medium 199 (with Hanka salts [1.26 mM $CaCl_2$, 1.7 μM $Fe(NO_3)_3$, 5.36 mM KCl , 0.44 mM KH_2PO_4 , 0.81 mM $MgSO_4$, 137 mM $NaCl$, 4.16 mM $NaHCO_3$, 0.33 mM Na_2HPO_4]; pH 7.2–7.4, GIBCO, NY) was perfused at a rate of 0.8 to 1.5 ml/min. Electrodes were pulled on a Narishige puller.

Coupling measurements were made with high input impedance devices (WPI KS-700, Dagan 8100-1) capable of constant current injection. Coupling was assessed by injecting negative current pulses of varying magnitudes into one cell and noting the voltage drop in the same and an adjacent cell. Under visual control, Hensen cells were impaled with electrodes. Double-barreled electrodes or theta glass electrodes were used to separately inject current (I1) and record voltage drops (V1) in one cell, while a neighboring cell was impaled with a single-barreled voltage recording electrode (V2).

Coupling responses and membrane potentials were recorded on a Gould strip chart recorder. Individual coupling responses were digitally stored within a Data 6000 waveform analyzer (Data Precision, MA) and saved to floppy disk. Coupling ratio is defined as the voltage drop in cell 2 divided by the voltage drop in cell 1 in response to current injection in cell 1 (V_2/V_1) (Bennett 1966).

Dye injections were made iontophoretically into individual supporting cells through single barreled electrodes. One to five percent solutions of Lucifer Yellow CH (Sigma), 6 carboxy fluorescein (Calbiochem) and fluorescein (sodium salt, Sigma) in H_2O were used. Epifluorescence observations were made with Zeiss filters (G436, FT510, LP520), with a 50 watt high pressure mercury illumination system. A Zeiss F10/0.25 objective lens was used. Photographs were taken with Polaroid type 667 black and white film. Dye spread was also evaluated under reduced epi-illumination with neutral density filters. For these studies video analyses were made with an ISIT video camera (Dage-MTI) and high resolution monitor (Ikagami). Photographs of video images were made with a Kodak Instagaphic CRT camera.

Results

Electrical coupling among the supporting cells is good; adjacent cells usually have coupling ratios around 0.6, under favorable culture conditions (Fig. 1 a). Despite the fact that Hensen cells are well coupled electrically, spread of the injected dye Lucifer Yellow occurs inconsistently. Observations have been made in which dye spread did not occur with Lucifer Yellow, although simultaneous measurements indicated the existence of electrical coupling between the injected Hensen cell and adjacent cells.

It was noted that frequently cell membrane potentials drop upon injection of Lucifer Yellow. In fact, the Hensen cells are very susceptible to photoinactivation. Photoinactivation (Miller and Selverston 1979; Cohan et al. 1983) denotes the selective killing of cells or parts of cells by irradiating intracellularly injected dyes. Apparently, during absorption of light, heat is generated which deleteriously affects cells, causing drops in membrane potential and electrical

activity. Membrane potentials of supporting cells are normally very stable; however, blue light irradiation causes an immediate and coincident drop in membrane potential of dye filled cells (Fig. 1 c). Membrane potential declines when the light is turned on and stabilizes when the light is turned off. Usually, spread of Lucifer Yellow did not occur during simultaneous epifluorescent observation. However, sometimes dye spread was observable when cells were injected prior to fluorescence observation (Fig. 1 b). Spread of Lucifer Yellow, when it occurs, is typically rapid (within one to a few min) and is limited to no more than several neighboring cells. In addition to reducing membrane potentials, blue light exposure causes coupling responses to decrease in coupled Hensen cells (Fig. 2).

Unlike Lucifer Yellow, fluorescein spreads more consistently to neighboring cells (Fig. 3 a-c), and is often observed during epi-illumination, although photoinactivation can occur with this dye. As with Lucifer Yellow, the spread of dye is almost immediate. However, a greater number

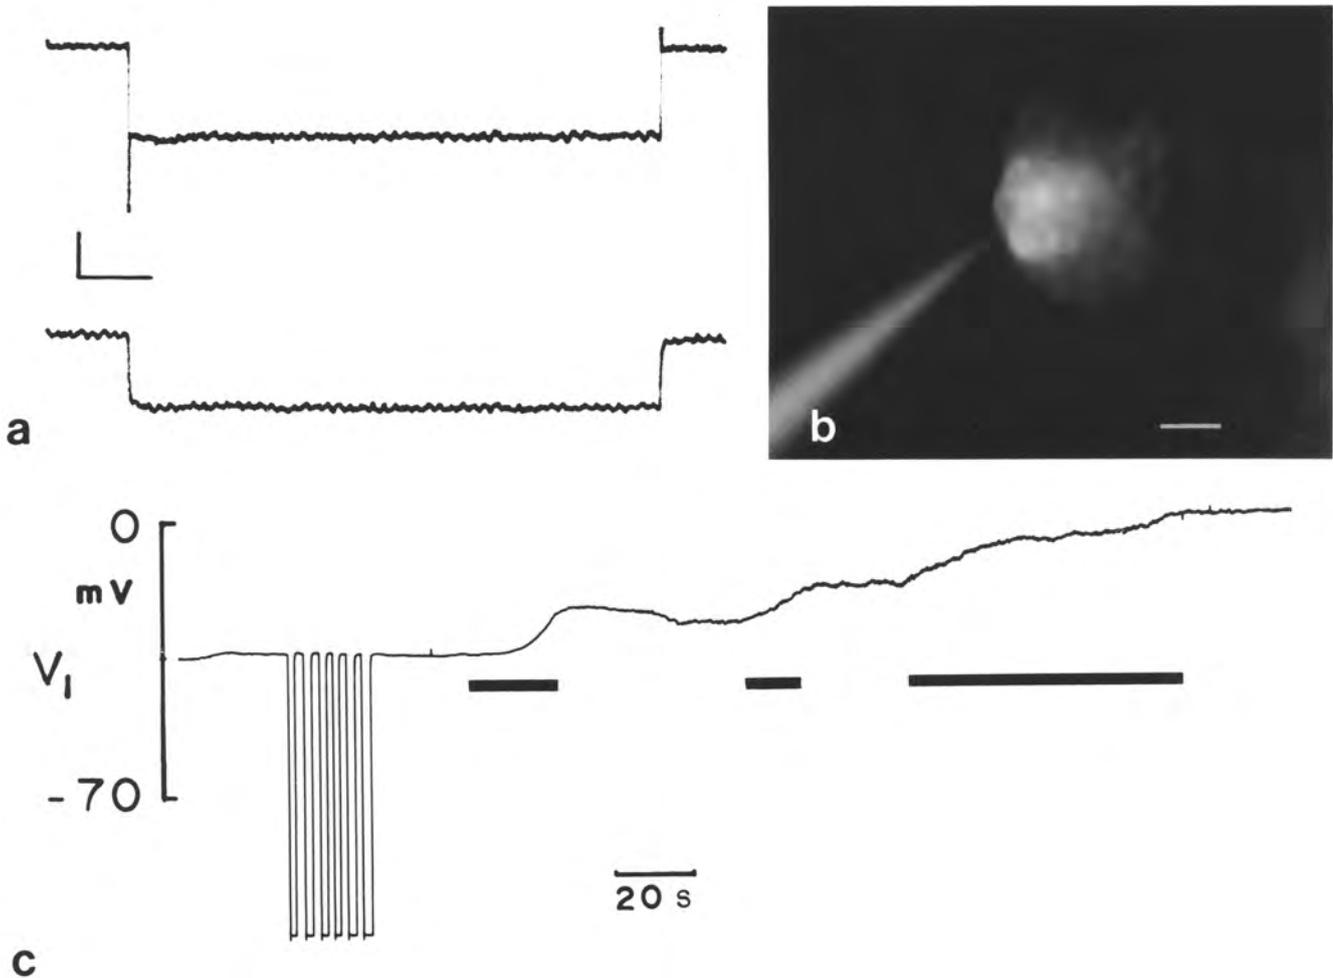

Fig. 1. **a** Two adjacent Hensen cells impaled under visual observation with 3M KCl glass electrodes. In one cell current pulses (-10 nA) were injected down one barrel of a theta glass pipet and the voltage drop was measured with the other barrel. Coupling responses were measured in the other cell with a single barreled electrode. One event was digitally stored and displayed. Calculated coupling ratio 0.8. Vertical scale: 4 mV. Horizontal scale: 0.2 sec. **b** Hensen cell injected with Lucifer Yellow without epi-illumination 45 sec prior to fluorescence observation as indicated in the trace from this cell (Fig. 1c). Dye spread had occurred. Scale: 15 μ m. **c** Hensen cell impaled with single barreled electrode containing Lucifer Yellow. A stable membrane potential was recorded for a few min whereupon dye was injected into cell with negative current pulses (-1 nA; negative deflections). Membrane potential remained stable after dye injection until blue light illumination was turned on (first black bar). Consequently cell depolarized but stabilized after light was turned off. Photoinactivation process continued upon reinstatement of epi-illumination (second black bar). Finally, light source was left on until total depolarization had occurred (third black bar)

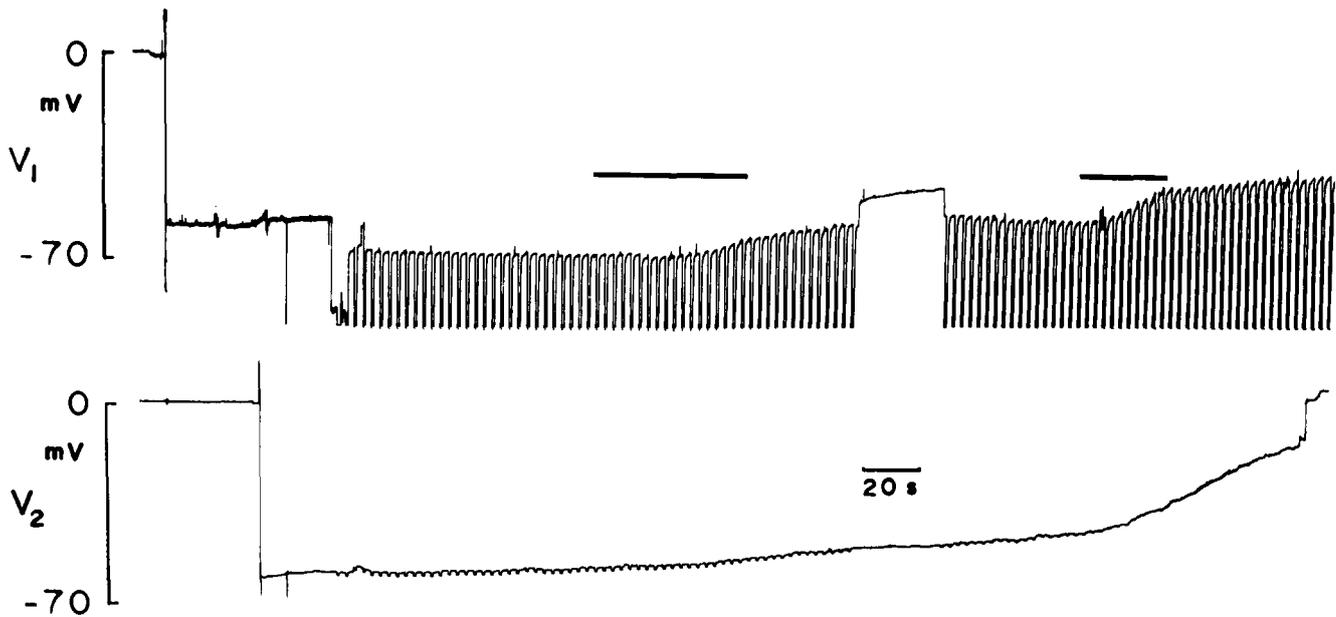

Fig. 2. Neighboring Hensen cells impaled with single barreled electrodes, one containing KCl, the other Lucifer Yellow. Current pulses (-5 nA) injected into Lucifer electrode and coupling responses measured in the other cell. Voltage drop across Lucifer electrode unbalanceable and thus off scale; however, since input resistance of Hensen cells is about 0.4 megaohms initial calculated coupling ratio is 0.7. Dye spread occurred in this example. Upon illumination of cells with blue light (*first black bar*), membrane potentials begin to fall. Subsequently, coupling response in other cell decreases. Further exposure to blue light depolarizes cells further (*second black bar*)

of cells are usually stained, and supporting cells other than Hensen cells are involved. These other cells include Deiters cells and possibly outer pillar cells. Fluorescein is somewhat membrane permeable; yet, the spread does not appear to be due to non-junctional membrane passage from one cell to another because 1) several attempts to observe dye passage through plasma membranes by directly iontophoresing fluorescein onto the external aspect of Hensen cell membranes failed to reveal cytoplasmic uptake; 2) extended soaking (up to 20 min) of Hensen cells with external solutions of fluorescein revealed much poorer staining of Hensen cell cytoplasm after washout than that of cells previously stained by intracellular spread of the dye; 3) on a few occasions fluorescein injection did not result in spread of the dye to adjacent cells, probably indicating that these cells were uncoupled; and 4) extracellular spaces between stained Hensen cells showed less fluorescence than intracellular spaces.

The dye 6 carboxyfluorescein, which is less membrane permeant than fluorescein, shows similar dye spread patterns and also spreads more consistently than Lucifer Yellow. Nevertheless, there were cases where the dye did not spread. The kinetics of dye movement were interesting for 6 carboxyfluorescein and fluorescein. Often, during the first min or two following injection of dye into a particular cell, spread was absent or was limited to closely neighboring cells. Subsequently, a sudden and rapid movement of the dye into a more extensive group of cells occurred. This is demonstrated in Fig. 3d-e, which illustrates the time course of dye spread for an injection of 6 carboxyfluorescein into a Hensen cell. After one min, spread of dye is barely detectable in the two immediately adjacent cells. At 1.5 min, the dye has begun to spread rapidly and by 3 min has spread to a large portion of the organ of Corti, including areas occupied by supporting cells other than those of Hensen, i.e., Deiters and pillar cells.

Discussion

Lucifer Yellow is a highly fluorescent molecule which has been used to demonstrate dye coupling in many cell systems (Stewart 1981; Kaneko and Stewart 1984). Presumably, electrically coupled cells permit the spread of dye through gap junctions. Yet, there is a growing number of observations of electrically coupled cells which do not demonstrate dye coupling or demonstrate dye coupling inconsistently by use of Lucifer Yellow (Takato and Goldring 1979; Audesirk et al. 1982; Kater and Hadley 1982).

In our previous study of dye coupling in the *in vitro* organ of Corti, fluorescence observations were made during injections of Lucifer Yellow and spread of the dye was observed only occasionally (Santos-Sacchi and Dallos 1983). Possibly the cells were killed by photoirradiation during observations. It would appear that Lucifer Yellow does not spread as easily to coupled cells as does fluorescein and 6 carboxyfluorescein. Perhaps the difference in molecular weights (LY 457, F 330) is responsible for this disparity. Yet, Flagg-Newton et al. (1979) have shown that the molecular cut-off for mammalian junctional spread is around 1000 Daltons. Furthermore, molecular models of the two dyes do not reveal sufficient size differences to account for dye spread differences, so that other factors, e.g., charge and precipitability, may be influential (D.C. Spray, personal communication). Lucifer Yellow readily precipitates as the potassium salt, and thus may do so intracellularly. Fluorescein is somewhat membrane permeable, and care must be taken in dye spread studies to exclude possible spread across non-junctional membranes. Several facts suggest that dye spread is through junctions, most notably the speed of dye spread and the observation that some fluorescein injections did not result in spread. 6 carboxyfluorescein spreads as well and because of its charge it is likely that the route of passage is through the aqueous channels of gap junctions.

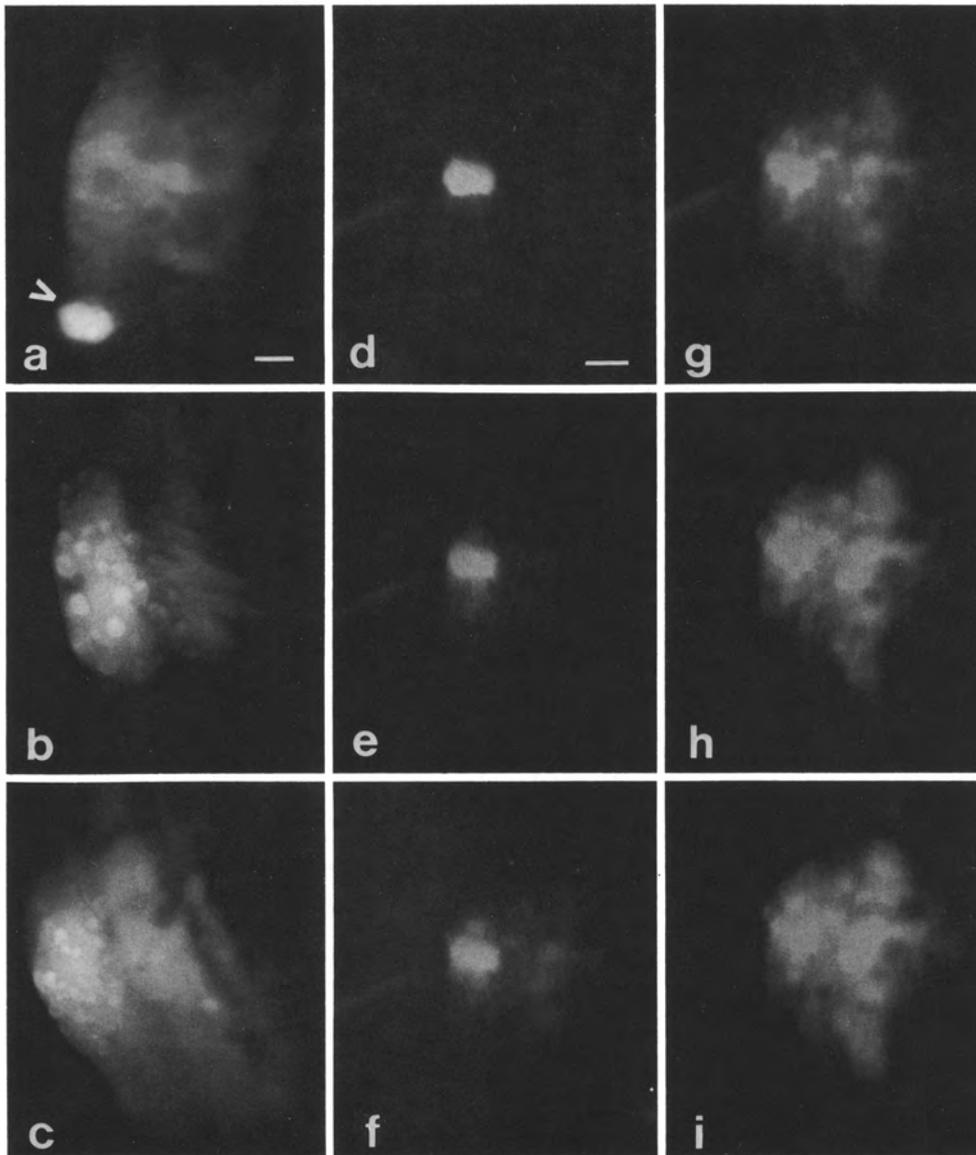

Fig. 3. **a** Organ of Corti spirals around bony modiolus through which eighth nerve courses. Hensen cells are most distal to modiolus which is located to right in all photographs. *Arrow* depicts Hensen cell injected with Lucifer Yellow. No dye spread occurred. Subsequently, fluorescein was injected about four cells away, and dye did spread to adjacent Hensen cells as well as other supporting cells closer to modiolus. Scale: 15 μm . **b** Fluorescein injected into single Hensen cell, spread of dye occurred rapidly to adjacent Hensen cells and to presumed processes of Deiters cells. Bright spherical structures in Hensen cells are lipid droplets. Scale: same as in **Fig. 3a**. **c** Fluorescein observed to spread from Hensen cells to other supporting cell types of organ of Corti. All injections depicted thus far made during epi-illumination. Scale: same as in **Fig. 3a**. **d-i** Series of photographs depicting time course of spread of 6 carboxyfluorescein through supporting cells. Epi-illumination present during whole process; however, neutral density filters were used to reduce intensity. Spread of dye video taped with low light level Dage MTI camera and individual photographs taken of monitor screen. **d** 1 min after start of injection. Barely detectable spread in immediately adjacent Hensen cells. Scale: 15 μm for this and subsequent photographs. **e** 1 min 30 sec. Dye now seen clearly in spirally adjacent Hensen cells and in cells nearer modiolus. **f** 1 min 40 sec. Cell staining more clearly seen near modiolus, **g** 2 min. Spread of dye continues spirally. **h** 2 min 30 sec. Intensity of dye in adjacent cells approaching that of injected cell. **i** 3 min. Dye more uniformly distributed in group of supporting cells of different types.

It is clear that the presence of electrical or ionic coupling cannot necessarily indicate that dye coupling exists. This has been directly demonstrated by Kettenmann and Orkand (1983), who showed that in electrically and dye coupled cells, dye coupling can be abolished without uncoupling ionic communication between the cells. It is probably true, however, that dye coupling indicates the presence of electrical coupling. Thus the observation that fluorescent dyes spread from Hensen cells to other supporting cells, includ-

ing Deiter and pillar cells, indicates that electrical communication occurs among supporting cells of different types. This may have important consequences for the organ of Corti.

The supporting cells of the organ of Corti provide structural support for the sensory hair cells. Other roles that they may play are speculative at present, yet the presence of electrical and dye coupling between them may provide clues. For example, metabolic cooperation between the sup-

porting cells may be required for normal cochlear function under conditions of high sound stimulation. Perhaps metabolites diffuse intracellularly through the supporting cells from areas of high metabolic activity, e.g., from the lateral wall of the cochlear duct. In addition, the supporting syncytium may provide a K⁺ sink as is thought to occur in astrocytes of the CNS (Somjen 1979). Potassium levels may be kept low in those areas of the organ (e.g., spaces of Nuel) where its presence would interfere with electrical activity. This may be specially important considering the recently identified outer hair cell contracture associated with potassium induced hair cell depolarization (Brownell et al. 1985; Zenner et al. 1985). Finally, the possibility exists that supporting cells may influence cochlear mechanics. The fact that Hensen cells are dye coupled and can be photoinactivated (killed) may permit an evaluation of the role supporting cells play in cochlear mechanics. That is, selective destruction of dye-injected supporting cells by photoirradiation may alter electrical responses to sound.

metal is sad but understandable: hearing has always been the Cinderella of the senses. Helen Keller thought its absence was more painful and isolating than blindness, yet most people say they'd rather lose hearing than sight. Such second-class status has had a predictable effect on research funding (low), the number of scientists attracted to the field (few), and the rate of progress (slow). As recently as the early 1980s auditory researchers were still laying the foundations for the microscopic and biochemical basis of hearing while their counterparts in vision research were, so to speak, putting up the drywall. As for the numbers, sniffed one biophysicist, "Go to the vision meetings and it's like the Super Bowl or something." He estimates that serious auditory researchers might, worldwide, number 200.

RATHER THAN PASSIVELY VIBRATING IN SYNC WITH THE MEMBRANE, THE HAIR CELLS WERE BOUNCING LIKE MANIC KIDS ON A TRAMPOLINE.

But Cinderella had her moments in the limelight, and it looks as though the Cinderella sense is about to do the same. Technological advances in laboratory techniques, coupled with an aging population—and perhaps a few influential government boomers who put in some hours listening to “Stairway to Heaven” at top volume—portend a bright future for the field. There is already a whisper of a hint, in fact, that scientists may someday be able to restore some of the hearing receptors my young friend was so casually sacrificing.

Those hearing receptors are called hair cells, specialized sensory cells that are among the most remarkable structures in the body. Only 32,000 strong (compared with, say, the eyes’ 300 million light-sensitive cells), under constant siege from age, drugs, and a world that includes snowmobiles and jet planes as well as Megadeth, they are all that stand between us and silence. Like princesses turning straw into gold, the inner hair cells transform the mechanical forces of sound into the electrical impulses of hearing.

The neurological phenomenon called hearing begins when the ear collects wave-like air-pressure disturbances—sound—produced by any physical force: a vibrating A string, a tree falling in the forest. The outer ear, which includes the fleshy pinna and the auditory canal, picks up and funnels these waves toward the tympanic membrane, or eardrum. The eardrum vibrates and jiggles the three articulated bones of the middle ear; in turn, the last of these three bones, the stapes (or “stirrup”), flexes the membrane of a small oval “window” in the fluid-filled, coiled cochlea.

Evolution has been called the great tinkerer, assembling new structures from bits and pieces of old ones, and the ear is certainly one of its most protracted projects. Natural selection has been remodeling and redecorating the ear for hundreds of millions of years, as the latest model of vertebrate moved from the ocean to the shore to dry land. Yet the hair cells at its core have hardly been touched; their structure is virtually identical in the hearing and balance systems of all animals with backbones. As it happens, this is a very good thing, since the

cochlea has made mammalian hair cells nearly impossible to study.

The cochlea is one of those structures, like black holes or the Hoover Dam, that tend to provoke awe in observers. “It’s a jewel box of an organ, isn’t it?” sighed one smitten researcher, interrupting himself in midequation. Said another, “It’s such an incredible structure! When I finish a session on the microscope, I feel disoriented, like I’ve been cave diving.” The cochlea is indeed amazing: a pea-size, spiral-shaped bony fortress buried in the thickest part of the skull, containing a mechanism of mind-boggling complexity. But like most fortresses, it imprisons as much as it protects. There’s no way to get to the hair cells when an organism is alive, since all the works are barricaded in bone, and the inner ear stops functioning seconds after death. And until recently it was impossible to keep hair cells alive outside the body.

Ironically, though the security system fashioned for the inner ear has discouraged invasions by armies of researchers, it hasn’t worked particularly well at preserving its inhabitants: we begin losing hair cells as soon as we’re born. They simply wear out from use, particularly the cells that process high-frequency sounds. Over time, exposure to loud noise makes them stiffen. No one understands the sequence of cellular events causing the stiffness, but it is known that when hair cells hold this rigid pose too long they just keel over and die.

So it goes: a firecracker too close to the ear here, a jackhammer outside the window there, perhaps even a couple of football seasons in the high-school marching band alongside the tuba and we damage a few or a hundred. By middle age the attrition has become an avalanche: studies have shown that at 65, the average male has lost more than 40 percent of his hair-cell birthright. And, in a phenomenon that might on a bad day strike you as evidence of a malign force in the universe, our hair cells are not able to regrow. Reptiles and amphibians, who have very modest hearing abilities and

nonsocial life-styles, replenish their store of hair cells throughout life. We mammals, on the other hand, with our high-fidelity ears, are organisms that depend on hearing to survive both physically and—in the case of humans and other primates—emotionally. Yet we’re the group stuck with a relatively paltry and nonrenewable allotment.

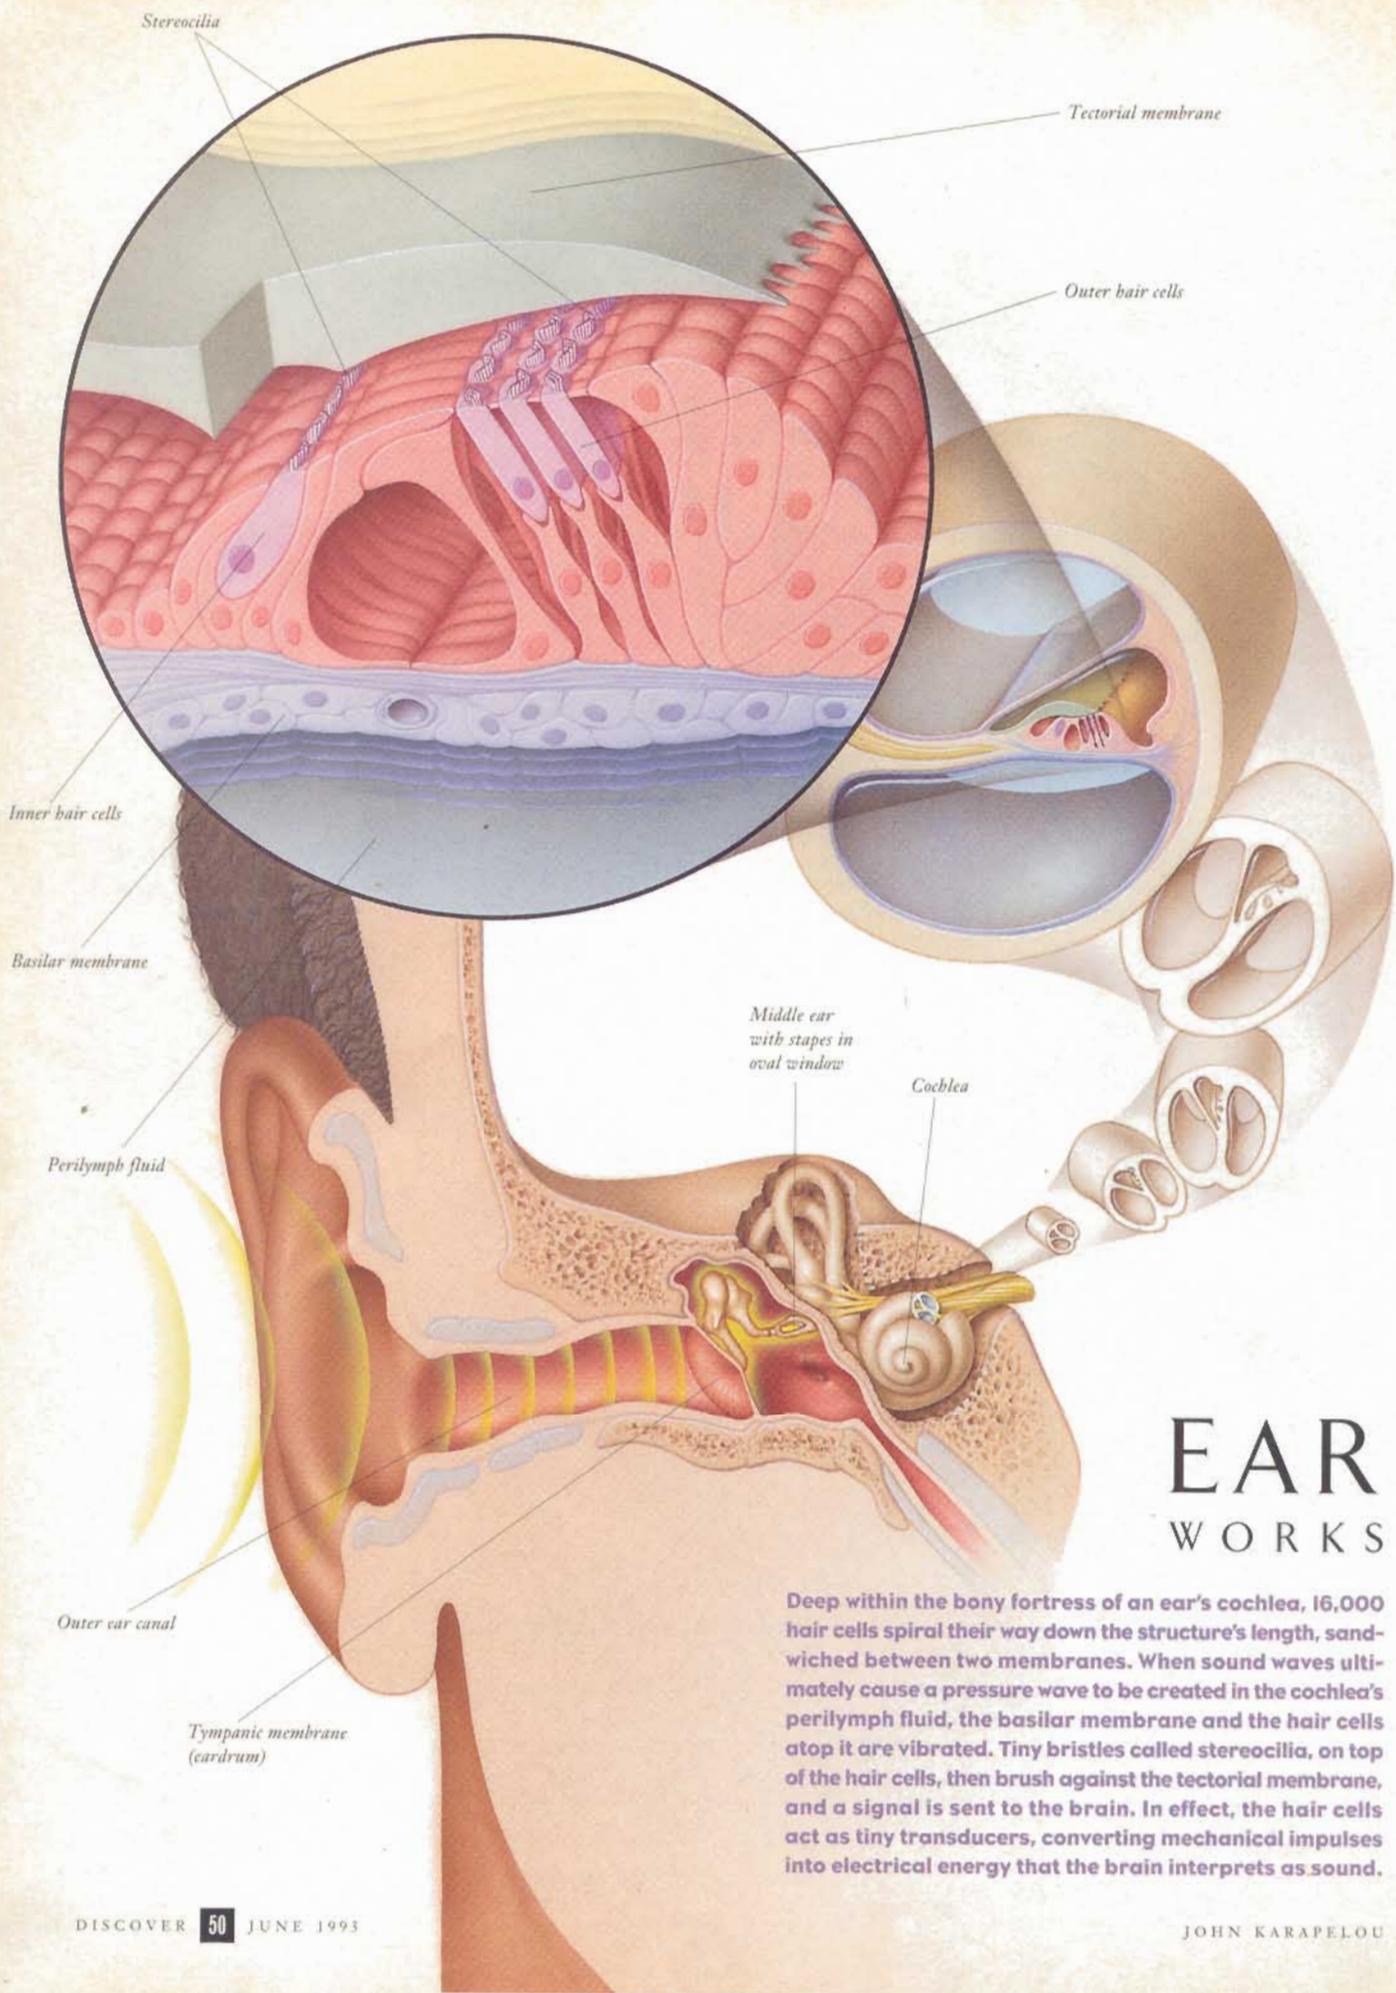

WITHIN THE cochlea, the architecture of the hair cells is supremely functional. The 16,000 cells are arranged in four parallel rows, one inner and three outer rows (relative to their distance from the cochlea’s central pole); they are sandwiched between two membranes, the basilar below and the tectorial above. Together these two membranes form a partition that spirals down the length of the cochlea. When the stapes pushes on the cochlea’s oval window, it sends a wave of pressure through the perilymph, a fluid in the inner ear, which begins a chain of events: the wave sets the basilar membrane vibrating, which vibrates the hair cells, which cause a set of bristles atop the hair cells to brush against the tectorial membrane. There are about 100 of these bristles, or stereocilia, on each human hair cell, and they are arranged in rows according to their height, as if posing for a class photo. When inactive, they lean together in a bundle in the shape of a cone. But when they are active, their movement against the tectorial membrane ultimately results in a signal being sent along the auditory

NEUROSCIENTIST Jim Hudspeth holds a model of a human hair cell's stereocilia. His question: How do the stereocilia move, and what happens when you move them?

nerve. Thus the hair cells as a whole act as tiny transducers, converting the mechanical impulses they pick up from the cochlear fluid into the electrical energy that the brain interprets as sound.

There’s an undeniably Rube Goldbergian aspect to this chain of events, and elucidating the final mechanical link in the

EAR WORKS

Deep within the bony fortress of an ear's cochlea, 16,000 hair cells spiral their way down the structure's length, sandwiched between two membranes. When sound waves ultimately cause a pressure wave to be created in the cochlea's perilymph fluid, the basilar membrane and the hair cells atop it are vibrated. Tiny bristles called stereocilia, on top of the hair cells, then brush against the tectorial membrane, and a signal is sent to the brain. In effect, the hair cells act as tiny transducers, converting mechanical impulses into electrical energy that the brain interprets as sound.

chain (the place where, if the ear were one of Goldberg's fanciful contraptions for, say, making doughnuts, the dough would hit the fat) has occupied neuroscientist Jim Hudspeth for most of his career. Hudspeth, who is now director of the Center for Basic Neuroscience Research at the University of Texas Southwestern Medical Center, recalls his initial aim: "What I saw as important was getting from a macroscopic system—the whole cochlea—to a microscopic and cellular system." That involved ignoring some tantalizing questions; it forced him, he says, to "throw away the complicated and interesting mechanics and hydrodynamics of the ear." He also resigned himself to ignoring "the complicated and interesting stuff" that happens on the way to the brain. "I just wanted to deal with one step on an intimate basis." That step was the mechanical input to the hair cells.

THE QUESTION he and his group of researchers set out to answer was, How do a hair cell's stereocilia move, and what happens when you move them? In the late 1970s, using a frog as their experimental animal, they found that prodding a stereociliary bundle with an extremely fine quartz fiber—which, given the mere millionths-of-an-inch size of the stereocilia, became known as "the telephone pole approach"—sent a current through the cells. (This current produces the chemical that excites the nerve going to the brain.) They discovered two surprising things: the direction of this nudge was critical, and the magnitude of the nudge needed to get the stereocilia to respond was infinitesimal.

Hudspeth found that only a push from front or back produced the current; side-to-side nudging did nothing, for reasons that didn't become clear to the researchers until later. Furthermore, Hudspeth calculated that if the cells were deflected by an amount of prodding equivalent to that produced by a sound at the threshold of hearing, the cilia would move the hair bundle about three-thousandths of a degree. (Just for scale, several atoms in a row add up to a full degree.) In essence, then, the whole jury-rigged mechanism—ear drum to middle-ear bones, middle-ear bones to oval window, oval window to pressure wave in the perilymph, pressure wave in the perilymph to basilar membrane vibration—is distilled to this: a

movement measured in fractions of atomic diameters. Observes Hudspeth, "It's as if the Eiffel Tower were to move a thumb's breadth."

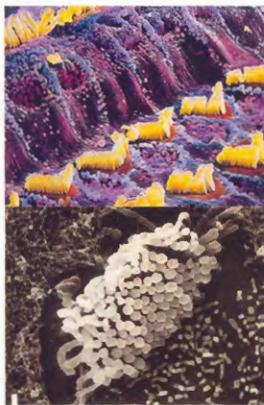

At the time Hudspeth was doing his first work, biologists understood the basic mechanism of cell signaling: a stimulus caused tiny pores—ion channels—to open in the cell membrane, and the movement of charged particles from outside to inside the cell registered as a tiny current change. Vision, for example, had been established as a process in which light hitting the eye's photoreceptors caused chemical reactions that opened ion channels and excited nerve fibers.

Hudspeth and his group assumed, then, that ion channels must be opening and closing in the hair cells when they prodded the stereocilia. What troubled them was how these relatively sluggish biochemical events could occur in the ear, which is built for speed. You can, after all, trick the eye into believing it has seen movement at 30 images a second, a phenomenon the first animators understood intuitively. But that speed is glacial to the ear: 30 cycles per second (or 30 hertz) is so low in frequency we can barely hear it. A young human ear can, however, process the highest overtone on a violin, a frequency of 20,000 vibrations a second. And our ears can discern the delay when a sound is presented to one ear six to ten millionths of a second after it's presented to the other. A biochemical cascade takes thousandths of a second—three orders of magnitude slower—and couldn't possibly do the trick.

To get around the time problem, Hudspeth's group hypothesized that there might be some kind of mechanical gate to the ion channels in the ear, a device that could open them as briskly—near instantaneously, actually—as the ear's acuity demanded. Such a device, if it existed, would be unique to the auditory system, but it would at least have the virtue of fitting the ear's design specs.

There were, Hudspeth makes clear, theoretical reasons and indirect evidence for a mechanical gate. All the same, he says, "it was kind of miraculous" when the structures began to appear in scanning electron micrographs. They were first recognized for what they were by a British lab, which, recalls Hudspeth, "was slightly embarrassing. We'd seen some of them ourselves, but we didn't know what to make of them." The strandlike structures, dubbed tip links, joined each stereocilium to its tallest neighbor, rather like wires connecting a regiment of telephone poles running over a mountain.

The front-to-back route of the tip links was the reason a side-to-side prodding of the stereocilia did not produce a current. Hudspeth likens the links to pieces of elastic tied to the handle of a door that's kept shut by one of those "noisemaking door-closers at the top of it. That's the intrinsic elasticity of the transduction channel; it keeps the door closed unless you do

TOP: Highly magnified and colorized scanning electron micrograph of human stereocilia (yellow). Above: Regenerating hair cells from the cochlea of a chick, just five days after it was exposed to an ototoxic drug.

something about it. If you pull on the elastic—that's deflection of the hair bundle—that tension is communicated to the door. As the hair bundle moves, you're literally pulling the channels ajar." When the door closes, silence reigns.

The micron-size gadgetry sported by the hair-cell bristles is only part of the unfolding story of how the ear hears. What goes on inside the cell bodies—particularly the bodies of the three outer rows of hair cells—is equally intriguing.

Auditory physiologist Joseph Santos-Sacchi of the Yale University School of Medicine is one of those intrigued. He shares with many of his colleagues an almost paternal affection for the outer hair cells and their antics: "This is a fun system to work with," he says. To show how hair cells move and to illustrate just how much fun it is, he made a videotape of a hair cell

THE AUDITORY SYSTEM IS ELABORATE, SENSITIVE BEFORE ITS OWNERS DO, PARTICULARLY IF THE

bopping along to rap star Hammer's "Can't Touch This."

The outer hair cells that captivate Santos-Sacchi are a mammalian refinement of the more primitive hair cells found in lower animals. Though the outer hair cells are differentiated from the inner hair cells by their position in the cochlea, much more than geography marks their distinction—the real difference lies in the realm of neuroanatomy.

A nerve is a one-way street: it goes either toward the brain or away from it. Most of the nerves between the inner hair cells and the brain go from the outside in, just as you might expect; after all, our ears are supposed to get information about external events to our brains. Oddly, though, most of the nerves between the outer hair cells and the brain go the other way, from brain to ear. What could the brain be telling the outer hair cells?

In the early 1980s the outer hair cell story got stranger still. Researchers found that the outer hair cells were not only wired oddly, they behaved oddly. Rather than passively vibrating in sync with the basilar membrane, which is more or less what the inner hair cells do, they were bouncing up and down like manic kids on a trampoline. Indeed, they stretched

and contracted at a speed that was orders of magnitude greater than any other cell in the body could muster.

This unexpected display of personality by the outer hair cells—called fast motility—is now one of the hottest areas of auditory research. (Santos-Sacchi has graphed the number of publications since 1985 on a time axis and says that the resulting curve can be described as "exponential, going to infinity.") Whatever its research trajectory, fast motility is hot because it poses two intriguing questions: How are the outer cells doing this? And why?

"Why" may turn out to be the easier question to answer. It's beginning to look as though one reason the outer hair cells boogie is to accelerate the motion of the basilar membrane.

The 3.2-centimeter-long membrane (about 1.25 inches) spiraling inside the cochlea is essentially an acoustical decoder. It processes the tangled mass of auditory frequencies that make up a sound like speech, sorting them into individual frequency bands. For example, in response to high-frequency sounds, the basilar membrane will vibrate more strongly at the base of the cochlea's spiral than it will at its apex. Conversely,

low-frequency sounds vibrate the membrane more strongly at the apex than at the base. (Like a tiny helical keyboard upended on its highest note, the basilar membrane processes about one-third of an octave per millimeter.)

But—and here's the mystery—the basilar membrane vibrates at frequencies a hundred times faster than any movement it could conceivably pick up merely by riding the sound wave that travels through the perilymph fluid in the inner ear. Might the outer hair cells be dancing in order to modify the movement of the basilar membrane? Might the connections between brain and outer hair cells be there so the brain can tell the hair cells how fast to dance?

Santos-Sacchi frames the problem thus: "Can outer hair cell motility function in the living animal as we all hope it might? That is, can the cells wiggle and modify the mechanics of the inner ear" at the high frequencies at which the ear works? There are reasons to think they can; after all, they must be moving for a reason. And drugs that were used experimentally to knock out the hair cells definitely altered the mechanics of the basilar membrane.

That's the why; the how of fast motility may be a little trickier to answer. In the

A LITTLE NIGHT MUSIC

EACH NIGHT, under cover of darkness, a life-and-death struggle is played out.

Night is when the bats take wing—after their avian competitors have returned to their nests, and after the nocturnal insects, their prey, have begun to show themselves. Bats glide through the night, emitting ultrasonic clicks and cries that bounce off the insects (as well as off branches and houses and trees) and return to tell the bats where to swoop down for their dinner (or where to turn left to avoid bumping into a mighty oak). But the bats are not the only ones listening to the echoes in the night. Many insects have developed the ability to eavesdrop on the sonar signals, to give themselves a fighting chance to evade their onrushing enemy.

Researchers have known since the late 1950s that some insects can hear ultrasound. That was discovered by physiologist Kenneth Roeder of Tufts University and entomologist Asher Treat of the City University of New York when they put elec-

trodes on the auditory nerves of moths and played sounds at different frequencies; only at ultrasound levels did the auditory nerves fire. Later experiments, in which some moths with ears and some without were thrown into a chamber with bats, showed that moths without the ability to hear ultrasound were captured almost 100 percent of the time while ultrasound-hearing moths had a 90 percent chance of getting away.

Obviously, for moths, ultrasound detection is a good thing.

It's good for lots of other insects too. The ability to hear ultrasound has since been uncovered in green lacewings, tiger beetles, praying mantises, katydids, crickets, and locusts. With the moths, these keen-eared insects represent five different insect orders: the Lepidoptera, Neuroptera, Coleoptera, Dictyoptera, and Orthoptera. "We really expect this to be a pattern," says Ron Hoy, a Cornell neuroethologist who has been studying the different ways

TIVE. AND INGENIOUS. BUT IT BREAKS DOWN THEY'RE PARTIAL TO NOISY ENVIRONMENTS.

laboratory, hair cells can't be coaxed to move any faster than a few thousand cycles a second, not nearly the frequencies that must be attained in living animals. Santos-Sacchi suspects his laboratory apparatus may be preventing the cells from really cutting loose, wigglywise. He thinks the limiting factor is the electrical resistance of the electrode he's using to deliver stimulus to the cell: "It's as if I were trying to measure how fast a car could actually go, but my broken ankle prevented me from pushing down on the accelerator."

However, another problem is not so easily explained away. At the base of the basilar membrane, where high-frequency sounds are decoded, hair cells don't seem to have the juice to alter the basilar membrane vibration. What researchers are left with, then, is two remarkable phenomena—the highly tuned basilar membrane and the rapidly moving cells—and no obvious bridge to connect them. "There is something missing here," Santos-Sacchi admits. "Things don't quite jibe yet." But he's sure the connection is there. "Think about it," he asks rhetorically. "Would evolution go to all this trouble for nothing?"

Of course, the average heavy-metal fan could argue that evolution didn't go to quite enough trouble. The auditory

system is elaborate, sensitive, and ingenious, but it does break down before its owners do, particularly if they're partial to noisy environments. Yet even this flaw may eventually yield to research.

IN THE MID-1980s researchers made a remarkable discovery about birds that may have important implications for us. Everyone had assumed that our feathered friends, who have relatively acute hearing, were in the same boat as mammals vis-à-vis hair cells: when you abuse 'em you lose 'em. But in 1985 both Doug Cotanche, then at the University of South Carolina, and Ed Rubel, at the University of Washington, found that in young chicks hair cells could regrow.

In Rubel's case, it was a classic story of scientific serendipity. His lab was using the chicks as their experimental animal to study the ototoxic properties of a class of antibiotics—that is, they wanted to see to what degree the drugs damaged hearing organs. "Raul Cruz, the medical resident running the study, found that the number of damaged hair cells was greatest just after we administered the drug," recalls

Rubel. But when a little time had passed, there seemed to be more and more healthy cells. "He brought me the results and I, like anybody who has completely bought into the dogma of his field, said, 'Raul, you must have counted the hair cells wrong. Go back and do it again.'"

Well, as anyone familiar with Hollywood movies or checkout-stand science fiction could have told Rubel, the counting was fine but the dogma was wrong. There really *were* more hair cells because new ones were growing. Meanwhile, in South Carolina, Cotanche and his colleagues were seeing what looked like embryonic hair cells on the noise-damaged cochleas of adult birds, leading them also to suspect that the hearing organ might be repairing itself. A collective "Aha!" ensued, followed by experiments designed to isolate hair cell regeneration. These have confirmed that hair cells in birds do grow back.

And the new hair cells work. The researchers have trained starlings to peck at a key in response to a given tone by rewarding the maneuver with a food pellet. Immediately after they're dosed with ototoxic drugs, trained birds will fail the tone test, but they gradually regain the skill as hair cells regrow.

animals hear for some 20 years. "I would not be surprised if many insects that fly at night can hear ultrasound."

Indeed, Hoy thinks he has just uncovered the sixth order of ultrasound-hearing insects: the Diptera, or flies. He and his colleagues were studying a type of parasitic fly that flits through the night listening for the chirping of crickets and then lays its larvae on them. But when the researchers analyzed the fly's hearing ability, they found that not only could it pick up the cricket's song, it could pick up ultrasound as well. "Since they fly around at night," Hoy speculates, "they probably have a bat problem. And while we haven't proved that that's what their ultrasonic hearing is for, it sure is circumstantial evidence."

That many insects have developed ultrasonic hearing is in itself an intriguing finding—in fact, for moths, green lacewings, tiger beetles, and most species of praying mantis, ultrasound is all they can hear. But researchers are now focusing their attention on the organs they developed to do it. "They all have a common structural plan," Hoy explains. "If you're going to hear bats, you need certain things. You need a sensory organ contained within an air-filled chamber, where one wall of the chamber is a tympanic membrane that, when set into vibration, is going to set the whole organ into vibra-

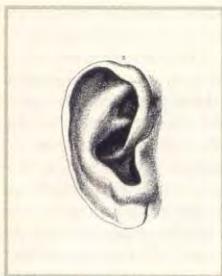

tion. And you need receptor cells to pick up those vibrations."

Interestingly, this complex solution to the bat problem, he notes, was arrived at not once but a number of times. "Insects have ears all over the place," Hoy says. "Some stick them on their waist, some on their abdomen, some on their thorax. And what that says is there was independent evolution of the ear. In other words, not all insect ears, not even all moth ears, came from one ancestral source. Independently, in each group, there's been pressure to evolve ears."

So which came first, the bat or the insect ear? Hoy says it depends on which insect you're talking about. For the moths, probably the bats came first; for crickets and grasshoppers, it was the ears. "Insects like crickets have wings that look as if they were capable of producing sounds way before bats came on the scene. And you don't sing unless somebody's around to hear. So when bats came along, the crickets just extended their hearing range."

But he admits it's all just a matter of opinion. "It would be nice if there were a fossil record to tell us. Unfortunately, though, insect ears are very small and probably don't fossilize very well. And not an awful lot of fossil hunters give a damn about insect ears, so they don't look very hard." —Lori Oliwenstein

PINNA TO THE FORE

FORGET THE EARDRUM and those three weird-shaped bones; forget the cochlea with its showy hair cells and fancy frequency sorting. Focus instead on the most visible part of our ear, the pinna—that long-ignored fleshy appendage that hugs closely (or not so closely) to the side of our head. With a few flicks of his quill pen, Darwin shrugged off the pinna in *The Descent of Man*, citing a study of a sailor who'd had one pinna cut off in a scuffle but could still hear just as well with that ear. "Darwin noted that our pinnae are small and we can't move them about as many animals can," explains psychologist Robert Butler of the University of Chicago. "He

argued that our pinnae may have had a function earlier on in our evolutionary history, but that now they're vestiges. That thinking simply carried the day."

Not that the pinna's been *totally* ignored over the years; flip through the right medical text and you'll see plenty of squirm-inducing pictures of deformed ears labeled "cup ear," "lop ear," and so on. And each swirl and swivel of the pinna has its distinguished Latin title: Rufus of Ephesus, first-century Roman anatomist, named them all one rainy day, so we have *concha*, *meatus*, *antitragus*, *scaphoid fossa*, and more. But none of this descriptive stuff answers the central, burning question: Why do we have an outer ear at all? The answer, thanks to scientists like Butler, a pinna veteran of 25 years' standing, is now known: we need the pinna to locate precisely the origin of a sound.

A few pioneering experiments led the way to our deeper pinna knowledge. In the 1950s, for example, when glass tubes were stuck into people's ear canals so that sound bypassed the pinna entirely, researchers found that the subjects couldn't tell whether sounds were coming from front or behind—until, that is, a fake ear was added to the end of the tube. Other experiments have since shown that the pinna provides not only front-back clues but clues to the horizontal and vertical position of a sound's source as well. The horizontal contribution of the pinna isn't crucial as long as we can hear through both ears—since a sound coming from the right, for example, will reach the right ear before the left ear and will also be louder in the right ear. Combined, these time and intensity differences give us enough horizontal information to make do. But with a pair of pinnae we do a better job.

For height information, however, the pinna stands alone. "Think about a sound to your right, maybe at 45 degrees and a little above eye level," says Butler. "Make it a complex sound, like that of snapping fingers—one that's a whole mix of frequencies. If you record from a microphone in your ear canal"—that is, from somewhere past the pinna—"you'll discover that a certain frequency band is amplified. Snap your fingers from another position and a *different* frequency band gets amplified. Well, that's what the pinna does; it somehow amplifies different frequencies depending on where the sound is coming from."

It's not magic, says Butler, just physics. Sound travels through the air as waves of air compression—the higher the frequency, the closer the waves are to each other. When those waves hit the pinna, they pile up on each other like ocean waves against a rock, interacting in complicated ways that diminish some of the frequencies while amplifying others. Since the contours of the ear determine which sounds are amplified and which diminished, and since the contours encountered depend on the angle at which the waves hit the ear, it's reasonable to suppose that noises from one place will be tweaked differently from those from another.

The mysterious next step is how our brains change "enrichment at 6,000 hertz" into "Oh, it came from in front of me," and "a tad more than 8,000 hertz" into "Gee, it came from above." "The sound has to be complex so you can compare frequencies," says Butler. "If the sound is pure, then we're unable to localize that pure tone. When the frequency's high, we'll point up. If it's low, we'll point below—no matter where that sound is coming from." —Rosie Mestel

Furthermore, the birds' ears *sound* as if they're up and running. Although no one yet understands why, it turns out that a click or other soft tone made in a functioning ear will echo microseconds later. If the hair cells are damaged, the echo is absent. These "otoacoustic emissions" are the best tool yet for diagnosing deafness in infants, which is what Susan Norton, a researcher-clinician who works with Rubel, usually does. Recently, however, she has been using the emissions to track the recovery of hearing in Rubel's avian subjects. Norton finds no emission right after the hair cells are damaged; with time, as the hair cells regenerate, the emissions return, first to high-intensity sounds and then to low.

The big question, of course, is what this work means for human hearing. "Very little work has been done on mammals," Rubel cautions. His group has looked at the cochleas of gerbils and seen a small increase in cell growth, although they saw no new hair cells developing. Other labs have found small rates of hair-cell regeneration, but only in the segment of the inner ear that controls equilibrium. In March, Andrew Forge of University College in London and Jeffrey Corwin and his colleagues at the University of Virginia School of Medicine announced that they had observed hair-cell regeneration in guinea pigs. The Virginia researchers also found, in culture, signs of human hair-cell regeneration by using human tissue taken from the area of the cochlea (called the utricle) responsible for balance. Even though these are balance hair cells, the researchers are excited about the implications this raises for regenerating hearing hair cells.

But first things first: the current task is to isolate the molecule that stimulates hair-cell proliferation in birds. (Or, if a molecule inhibits proliferation in mammals, to find that.) Several labs are now working on the problem, aided by biotech companies eager to be part of research that might, over the long haul, produce a drug useful to some of the 28 million Americans with hearing loss.

Rubel is expansive about the possibilities: "We're at an absolutely wonderful time in the history of biology to have discovered this," he says happily. "We are learning so much, and we have so many powerful techniques we couldn't imagine when we were in grad school." It's early yet, he takes pains to point out. "You've got to remember, this whole field of hair-cell regeneration is only four years old. But we're doing great! And in my opinion," he adds, "when you talk about actually restoring hearing, hair-cell regeneration is the only game in town." □

RESEARCH ARTICLE

Outer hair cell electromotility is low-pass filtered relative to the molecular conformational changes that produce nonlinear capacitance

 Joseph Santos-Sacchi^{1,2,3} , Kuni H. Iwasa⁴ , and Winston Tan¹ 

The outer hair cell (OHC) of the organ of Corti underlies a process that enhances hearing, termed cochlear amplification. The cell possesses a unique voltage-sensing protein, prestin, that changes conformation to cause cell length changes, a process termed electromotility (eM). The prestin voltage sensor generates a capacitance that is both voltage- and frequency-dependent, peaking at a characteristic membrane voltage (V_h), which can be greater than the linear capacitance of the OHC. Accordingly, the OHC membrane time constant depends upon resting potential and the frequency of AC stimulation. The confounding influence of this multifarious time constant on eM frequency response has never been addressed. After correcting for this influence on the whole-cell voltage clamp time constant, we find that both guinea pig and mouse OHC eM is low pass, substantially attenuating in magnitude within the frequency bandwidth of human speech. The frequency response is slowest at V_h , with a cut-off, approximated by single Lorentzian fits within that bandwidth, near 1.5 kHz for the guinea pig OHC and near 4.3 kHz for the mouse OHC, each increasing in a U-shaped manner as holding voltage deviates from V_h . Nonlinear capacitance (NLC) measurements follow this pattern, with cut-offs about double that for eM. Macro-patch experiments on OHC lateral membranes, where voltage delivery has high fidelity, confirms low pass roll-off for NLC. The U-shaped voltage dependence of the eM roll-off frequency is consistent with prestin's voltage-dependent transition rates. Modeling indicates that the disparity in frequency cut-offs between eM and NLC may be attributed to viscoelastic coupling between prestin's molecular conformations and nanoscale movements of the cell, possibly via the cytoskeleton, indicating that eM is limited by the OHC's internal environment, as well as the external environment. Our data suggest that the influence of OHC eM on cochlear amplification at higher frequencies needs reassessment.

Introduction

Outer hair cell (OHC) electromotility (eM) underlies cochlear amplification in mammals, where in its absence, hearing deficits amount to 40–60 dB (Dallos et al., 2008; Ashmore et al., 2010). The molecular basis of OHC eM is the membrane-bound protein prestin (SLC26a5), an anion transporter family member that has evolved to work as a voltage-dependent motor protein in these cells (Zheng et al., 2000). The protein's voltage-sensor activity presents as a voltage-dependent (or nonlinear) capacitance (NLC), obeying Boltzmann statistics (Ashmore, 1990; Santos-Sacchi, 1991), and whose peak magnitude corresponds to the voltage (V_h) where sensor charge is equally displaced to either side of the membrane. Voltage-dependent conformational change in prestin is believed to form the basis of precise phase differences between OHC activity and basilar membrane motion

that leads to amplification, indicative of local cycle-by-cycle feedback (Dallos et al., 2008). Recent measurements of OHC extracellular voltage and basilar membrane motion have observed the predicted amplifying phase differences (Dong and Olson, 2013). However, other recent measurements did not find appropriate phase or timing differences in the motions within the organ of Corti, and have challenged the standard view of amplification (Ren et al., 2016; He et al., 2018). Additionally, it is commonly accepted that unconstrained (load-free) OHC eM magnitude is invariant across stimulating frequency, having been measured out beyond 70 kHz (Frank et al., 1999); the flat frequency response is another important element in cycle-by-cycle feedback theory. However, these data were obtained at voltage offsets far removed from V_h , which has questionable

physiological significance. Based on our measures (Santos-Sacchi and Tan, 2018), we estimate that their depolarized offset from V_h would have been ~ 65 mV. Indeed, by exploring at an offset potential near V_h , we recently demonstrated that eM measured with the microchamber displays significant low-pass behavior (Santos-Sacchi and Tan, 2018). Here we further explore the low-pass nature of eM under whole-cell voltage clamp out to 6.25 kHz in the guinea pig and mouse with ramped changes in holding potential that provide shorter, more stationary-in-time measures compared with our previous experiments. Furthermore, whole-cell voltage clamp provides far better voltage control than the microchamber, but patch electrode series resistance effects must be considered. Following precise corrections for NLC-induced, voltage- and frequency-dependent voltage roll-off under whole-cell voltage clamp, never previously done, we find that eM and NLC show similarities in their nonlinear voltage and frequency dependence, both frequency cut-offs being U-shaped functions of holding voltage, with minima near V_h . Macro-patch experiments on the OHC lateral membrane, which provide robust voltage control, confirm our low-pass whole-cell measures of NLC within the speech frequency range. We further find that the frequency cut-offs of eM and NLC are disparate. Modeling suggests that both internal (e.g., cytoskeletal interactions, membrane lipid interactions) and external (e.g., viscous environment of the cell) loads are influential in effecting this disparity.

Materials and methods

Whole-cell recordings were made from single isolated OHCs from the apical two turns of organ of Corti of guinea pigs. An inverted Nikon Eclipse TI-2000 microscope with a 40 \times lens was used to observe cells during voltage clamp. Experiments were performed at room temperature. Blocking solutions were used to remove ionic currents, limiting confounding effects on NLC determination and voltage delivery under voltage clamp (Santos-Sacchi, 1991; Santos-Sacchi and Song, 2016). Extracellular solution was (in mM): NaCl 100, TEA-Cl 20, CsCl 20, CoCl₂ 2, MgCl₂ 1, CaCl₂ 1, and HEPES 10. Intracellular solution was (in mM): CsCl 140, MgCl₂ 2, HEPES 10, and EGTA 10. All chemicals were purchased from Sigma-Aldrich.

An Axon 200B amplifier was used for whole-cell recording with jClamp software (<http://www.scisoftco.com>). An Axon Digidata 1440 was used for digitizing. AC (frequency) analysis of membrane currents (I_m) and eM were made by stimulating cells with a voltage ramp from 100 to -110 mV (nominal), superimposed with summed AC voltages at harmonically related frequencies of 195.3, 390.6, 781.3, 1,562.5, 3,125, and 6,250 Hz, with a 10- μ s sample clock. Currents were filtered at 10 kHz with a four-pole Bessel filter. Corrections for series resistance were made during analysis. Capacitance was measured using dual-sine analysis at harmonic frequencies (Santos-Sacchi et al., 1998; Santos-Sacchi, 2004). Briefly, real and imaginary components of membrane current at harmonic frequencies were determined by Fast Fourier Transform (FFT) in jClamp, corrected for the roll-off of recording system admittance (Gillis, 1995) and stray capacitance (Santos-Sacchi, 2018). Series resistance (R_s),

membrane resistance (R_m), and membrane capacitance (C_m) were extracted using the dual-sine, three-parameter solution of the standard patch clamp model (Santos-Sacchi et al., 1998; Santos-Sacchi, 2004), based on the original single sine solution (Pusch and Neher, 1988). To extract Boltzmann parameters, capacitance-voltage data were fit to the first derivative of a two-state Boltzmann function.

$$C_m = NLC + C_{lin} = Q_{max} \frac{ze}{k_B T} \frac{b}{(1+b)^2} + C_{lin}, \quad (1)$$

where

$$b = \exp\left(-ze \frac{V_m - V_h}{k_B T}\right).$$

Q_{max} is the maximum nonlinear charge moved, V_h is voltage at peak capacitance or equivalently, at half-maximum charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k_B is Boltzmann's constant, and T is absolute temperature.

As noted above, whole-cell NLC determination was made following stray capacitance removal (Santos-Sacchi et al., 1998; Santos-Sacchi and Song, 2016; Santos-Sacchi, 2018; Santos-Sacchi and Tan, 2018). Patch pipettes were coated with M-coat (Micro Measurements) to reduce stray capacitance. Remaining stray capacitance was removed by amplifier compensation circuitry before establishing whole-cell configuration, and if necessary, additional compensation was applied under whole-cell voltage-clamp conditions (Schnee et al., 2011a,b) and/or through a software algorithm within jClamp software to ensure expected frequency-independent linear capacitance (Santos-Sacchi and Song, 2016; Santos-Sacchi, 2018). The latter approach simply performs single tau capacitance compensation mathematically on collected data, analogous to the electronic compensation with the amplifier. R_s was determined from voltage step-induced whole-cell currents before AC measures, the derivation provided in the appendix of (Huang and Santos-Sacchi, 1993). $R_m(v)$ across ramp voltage was determined from R_s -corrected ramp voltage and generated ramp currents with AC components removed, $\Delta V_m / (\Delta I_{R_s})$.

Simultaneous and synchronous eM measures were made with fast video recording. A Phantom 110 or 310 camera (Vision Research) was used for video measures at a frame rate of 25 kHz. Magnification was set to provide 176 or 106 nm/pixel. A method was developed to track the apical image of the OHC, providing subpixel resolution of movements (see Fig. 1). Video frames were filtered with a Gaussian Blur filter (<http://www.gimp.org>) before measurement. The patch electrode provided a fixed point near the basal end of the cell. Since movements were measured at the apical pole of the cell and the cell was held physically at the point of electrode insertion, estimates of full whole-cell movements were obtained from the ratio of apical/basal partitioning at the point of electrode insertion as in microchamber experiments (Frank et al., 1999; Santos-Sacchi and Tan, 2018). Resultant movements were analyzed by FFT in MATLAB. The colors in surface plots were generated in the MATLAB plotting routine *surf* with shading set to <interp>. This procedure allows contours to be readily observable. Although eM was measured at all

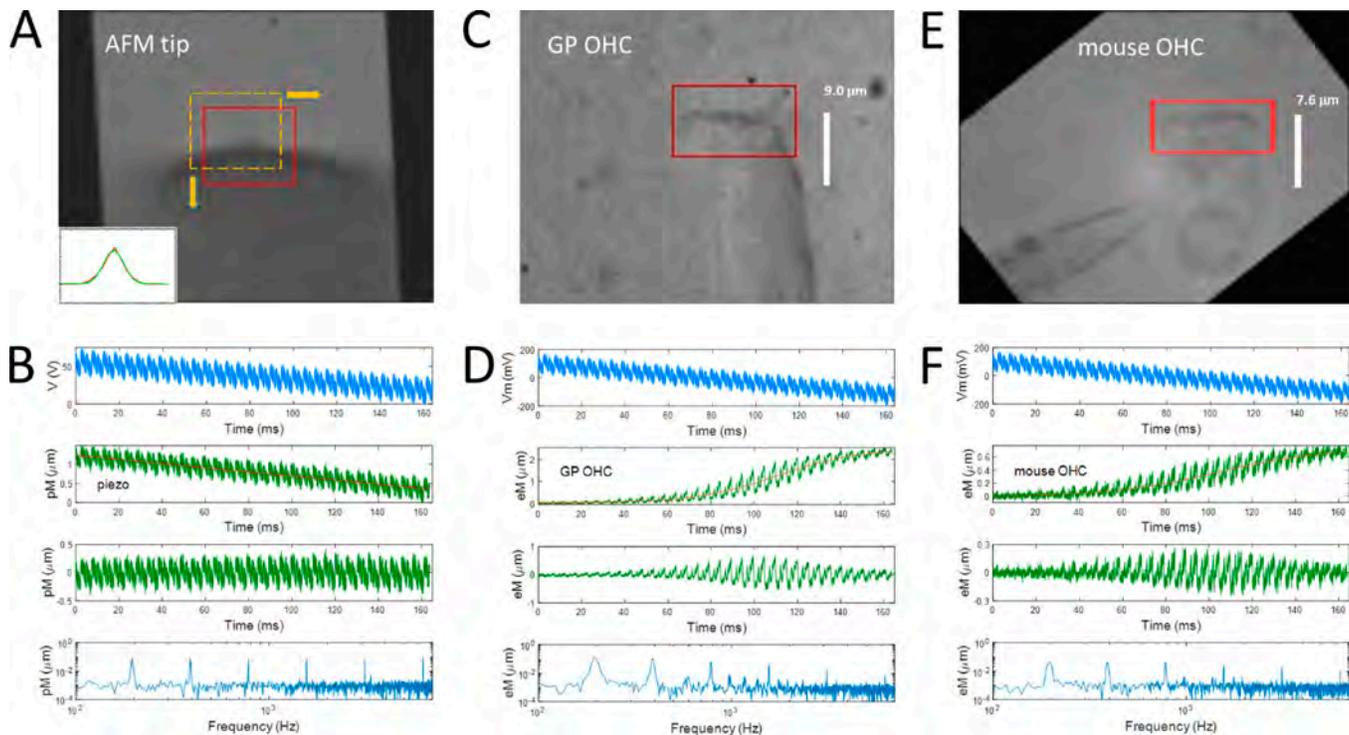

Figure 1. **Motion measures from fast video using a shape tracking algorithm implemented in the program jClamp.** (A) Frame of an AFM probe tip with a fiducial red box delimiting a region of the image to track. For each frame in the video stream, the image was sampled at single pixel offsets of ± 10 pixels in both the vertical and horizontal dimensions (yellow dotted box) relative to the fiducial image. Rotation of the image was possible to maximize displacements to a single dimension. A pixel comparison was made (subtraction of sampled image pixels from fiducial pixels and summed). The resulting distribution along the x and y axis was fit with a Gaussian function to obtain subpixel image movements. (B) Panel 1 shows the voltage command to the piezo stack. Panel 2 shows the piezo movements (pM) induced by the voltage command. The red line is a linear fit used to detrend the data (Panel 3), before FFT of the whole duration response (Panel 4). The magnitude plot shows high fidelity in capturing tip movements across frequency. (C) The apical portion of a guinea pig OHC under whole-cell voltage clamp was similarly tracked. (D) Panel 1 shows voltage clamp command. Panel 2 shows OHC eM. The red line is a sigmoidal fit used to detrend the data (Panel 3), before FFT of the whole duration response (Panel 4). (E and F) Similar results for a mouse OHC. Unlike the piezo response, eM falls precipitously across frequency. The frequency response arises from τ_{clamp} and the intrinsic low-pass nature of eM. The removal of τ_{clamp} contribution is easily accomplished (see Results). GP, guinea pig.

six AC frequencies, only five estimates of NLC were possible using the dual-sine approach. To obtain τ_{clamp} estimates at 6.25 kHz, the magnitude of NLC at 3.125 kHz was used, factored by 0.748, in line with the slope of its decrease across frequency.

Models were implemented in MATLAB Simulink and Simscape, as detailed previously (Song and Santos-Sacchi, 2013; Santos-Sacchi and Song, 2014b). Model R_s and R_m were from the averages of guinea pig and mouse OHC parameters obtained (see below). R_s -corrected V_m vs. eM data were fit with the first derivative of a two-state Boltzmann function (Santos-Sacchi, 1991). We processed biophysical data as either group-averaged (whole-cell currents and eM averaged before analysis) or individual cell analysis followed by averaging, thus providing statistics (mean \pm SEM).

Under voltage clamp, the voltage delivered across the cell membrane depends on the electrode R_s . In the absence of R_s , the command voltage is delivered faithfully to the cell membrane in magnitude and time (phase). Otherwise, the voltage delivered to the membrane will suffer from voltage drops across R_s , depending on the magnitude and time (phase) of evoked currents. In any analysis of voltage-dependent cellular processes, such as eM (Santos-Sacchi and Dilger, 1988; Iwasa and Kachar, 1989), it

is important to accurately assess membrane voltage. Actual membrane potential under voltage clamp can be exactly determined by subtraction of the voltage drop across R_s , i.e., $I_{R_s} * R_s$, with I_{R_s} being the sum of resistive and capacitive components of the cell membrane current. For sinusoidal stimulation across the voltage ramp, the AC command voltage V_c and evoked currents I_{R_s} are evaluated as complex values at each excitation frequency and ramp offset voltage, $(A + jB)$, where A and B are the real and imaginary components, obtained by FFT, thereby supplying $V_c(f, v)$ and $I_{R_s}(f, v)$. Our goal is to accurately determine the frequency response of eM, given a nonzero series resistance that imposes its own influence on the frequency response of voltage-driven eM data. The method essentially seeks to identify the true excitation voltage, $V_m(f, v)$, i.e., the drive for eM, supplied to the plasma membrane.

Before we present an analysis of averaged eM data, we illustrate the approaches available for R_s correction in a MATLAB Simulink model. In the model, we are able to directly measure imposed membrane voltage so we can compare results from these approaches to actual values. The generated charge in the model is taken as the equivalent of eM, since we have shown that OHC eM and prestin charge movement are

directly coupled (Santos-Sacchi and Tan, 2018). The model we use to confirm our voltage corrections has been fully described before (Santos-Sacchi and Song, 2014a), and includes a slow, stretched exponential intermediary transition between chloride binding transitions and voltage-dependent charge transitions, the latter corresponding to eM. Modifications of the model were made to correspond to the biophysical data. Chloride was 140 mM. For the model, the number of prestin particles was set to 25.92e6, and $z = 0.92$ for the guinea pig, and correspondingly 5.62e6, and 1 for the mouse. The forward (α) and backward (β) voltage-dependent transition rate constants for the electromechanical component of the model were 1.2947e6 and 1.1558e4, respectively. Both forward (α_m) and backward (β_m) parallel intermediary transition rate constants (which are equal to each other, but separately labeled to distinguish direction—incidentally, the equivalence is the basis of detailed balance in the model) were defined as

$$\alpha_m, \beta_m = A \cdot \exp(b \cdot m), \text{ for } m = 0.. 26, \quad (2)$$

where $b = -0.4663$ and $A = 3.0398e4$ for the guinea pig data comparisons, or $A = 15.199$ for the mouse data comparisons to account for the difference in NLC and eM frequency response of the species that we find. Units for rate constants and A are in s^{-1} ; b is unitless.

For the model, there are three ways to correct the frequency response of eM magnitude for the confounding effects of R_s -induced membrane voltage roll-off.

Method 1

The complex ratio of AC command voltage (located at differing ramp voltage offsets [v]) to the directly measured membrane voltage within the model at each excitation frequency can be used to correct eM magnitude frequency response, eM being both a function of frequency and holding voltage (Santos-Sacchi and Tan, 2018), namely, eM (f, v), akin to NLC (f, v) (Santos-Sacchi and Song, 2016). Parallel bars indicate absolute values:

$$V_m(f, v) = V_m(f, v)_{\text{model}} \quad (3)$$

$$|eM(f, v)_{\text{actual}}| = \left| eM(f, v)_{\text{measured}} \cdot \frac{V_c(f, v)}{V_m(f, v)} \right| \quad (4)$$

Method 2

The complex ratio of command voltage to calculated $V_m(f, v)$, namely, $I_{R_s}(f, v) \cdot R_s$, can be used for correction.

$$V_m(f, v) = V_c(f, v) - I_{R_s}(f, v) \cdot R_s \quad (5)$$

$$|eM(f, v)_{\text{actual}}| = \left| eM(f, v)_{\text{measured}} \cdot \frac{V_c(f, v)}{V_m(f, v)} \right| \quad (6)$$

Method 3

Finally, the multifarious clamp time constant, $\tau_{\text{clamp}}(f, v)$, determined at each excitation frequency and ramp voltage offset, can be used to correct, via a Lorentzian function ($A=1/[1+(2\pi f\tau)^2]^{1/2}$), the magnitude of eM, scaled to DC (steady state) levels $[1 - R_s/R_m(f_0, v)]$, $f_0 = 0 \approx$ ramp frequency.

$$\tau_{\text{clamp}}(f, v) = [C_{\text{lin}} + \text{NLC}(f, v)] \cdot R_{\parallel}(f_0, v), \quad (7)$$

where

$$R_{\parallel}(f_0, v) = \frac{R_s \cdot R_m(f_0, v)}{R_s + R_m(f_0, v)} \quad (8)$$

$$V_m(f, v) = V_c(f, v) \cdot \frac{[1 - \frac{R_s}{R_m(f_0, v)}]}{[1 + (2\pi f \cdot \tau_{\text{clamp}}(f, v))^2]^{1/2}} \quad (9)$$

$$|eM(f, v)_{\text{actual}}| = \left| eM(f, v)_{\text{measured}} \cdot \frac{V_c(f, v)}{V_m(f, v)} \right| \quad (9)$$

For the model, Fig. S1 (guinea pig parameters) and Fig. S2 (mouse parameters) show that each method of R_s correction gives the same results, revealing the intrinsic low pass eM response of the meno presto model that derives from its stretched-exponential intermediary transition kinetics (Song and Santos-Sacchi, 2013; Santos-Sacchi and Tan, 2018).

Because R_s was measured before running the ramp protocols, there is always a possibility that it changed during recording. The possibility of slight changes in R_s is well established in the literature. Fortunately, the currents generated simultaneously with eM must also report on R_s . Thus, we plot frequency cut-offs of eM based on Methods 2 and 3, each showing overlap (see Fig. 6), and indicating that our estimates of R_s are indeed accurate, with only minor corrections of the initial estimates ($0.95\text{--}1.05 \times$ initial estimates).

For the on-cell macro-patch approach, we used pipette inner diameters of $3.31 \pm 0.24 \mu\text{m}$ (electrode resistance in bath $1.49 \pm 0.04 \text{ M}\Omega$, $n = 10$), with M-coat applied within $\sim 20 \mu\text{m}$ of the tip. Extracellular solution was in the pipette. To establish Gohm seals ($2.7 \pm 0.24 \text{ G}\Omega$, $n = 10$) we supplemented extracellular solution with $5\text{--}7.5 \mu\text{M Gd}^{+3}$; we have shown previously that these low concentrations help to form seals without affecting NLC (Santos-Sacchi and Song, 2016). Ramps with superimposed sinusoids were used, as above. Subtraction of currents at very depolarized potentials, where predominantly linear membrane capacitance and stray capacitance contribute, provided prestin-associated nonlinear currents (see Fig. 7). Subsequently, these nonlinear capacitive currents were used for dual-sine capacitance estimation.

Data points from previous publications were extracted from plots using the application Grabit (written by Jiro Doke) in MATLAB.

Online supplemental material

Figs. S1 and S2 depict model data of the meno presto model for guinea pig and mouse. Each illustrates that voltage corrections used on the collected cell data are accurate and appropriate.

Results

Fig. 1 depicts the method used to measure eM. Movement of a piezo-driven AFM tip (0.2 N/m) confirmed the fidelity of the measuring technique out to 6,250 Hz (Fig. 1 B, panel 4). To obtain accurate FFT results, the ramp-induced movement was detrended by subtracting a linear fit for the AFM tip measures or a sigmoidal fit for the guinea pig or mouse OHC eM measures (Fig. 1, B panel 3; D, panel 3; and F, panel 3). Subsequent analyses followed this detrending approach. In Fig. 1, D and F, panel 4, an

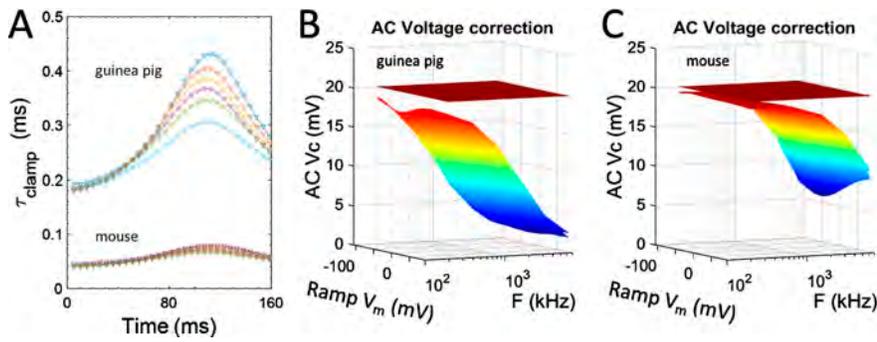

Figure 2. Voltage roll-off corrections. (A) Guinea pig and mouse OHC NLC is voltage-dependent and, as such, will influence the voltage clamp time constant, which is commonly calculated for whole-cell voltage clamp as $\tau_{\text{clamp}} = R_s * C_m$, or in our case, $\tau_{\text{clamp}} = R_s * (C_{\text{lin}} + \text{NLC})$ (precisely, $R_{ij} * [C_{\text{lin}} + \text{NLC}]$; see Materials and methods). The time constant is multifarious, and depends on holding voltage and frequency of stimulation. The voltage (or voltage-dependent eM) correction for the clamp time constant must be done at each stimulating frequency and holding voltage. (B and C) Complex whole-cell currents or calculated multifarious clamp time

constants were used to predict the roll-off in AC command voltage that actually excites the membrane (multicolored surface plots; see equations in Materials and methods). Each approach gives equivalent results. Note that because of the small size of mouse OHCs, τ_{clamp} is faster than the guinea pig OHCs, and introduces better voltage delivery. Nevertheless, each must be corrected (brown flat surface plot, equivalent to command voltage) to ensure removal of voltage roll-off issues when analyzing eM data. F, frequency.

FFT of the whole ramped eM response was made, and shows that unlike the piezo-driven response (Fig. 1 B, panel 4), the magnitude of both guinea pig and mouse OHC eM falls precipitously with frequency. This roll-off arises from both the voltage-filtering effects of R_s and the kinetics of prestin and/or mechanical impediments to cell movements. In the following analysis, we restrict FFT inspection to defined integral segments (see the red and blue highlighted example regions in Fig. S1, Fig. S2, Fig. 3, and Fig. 4) of the eM ramp response to assess voltage dependence of the frequency response. Furthermore, we detail methods (see Materials and methods) to remove the effects of series resistance interference, thus revealing true eM frequency response as a function of true membrane voltage.

For the OHC under voltage clamp, we do not have direct access to the membrane voltage as in the model (see Materials and methods), so only two methods for eM correction are available—that using estimates of R_s and NLC to gauge τ_{clamp} , and that using direct measures of whole-cell currents. In Fig. 2, complex whole-cell currents or calculated multifarious clamp time constants were used to predict the roll-off in AC command voltage (see equations in Materials and methods). Corrections will precisely account for the frequency-dependent roll-off in AC voltages and subsequently, the same corrections are applied to voltage-dependent eM measures.

We analyzed eight guinea pig OHCs. eM was commensurate with previously reported average eM gains of 15–19 nm/mV (Ashmore, 1987; Santos-Sacchi, 1989). Average (\pm SEM) Boltzmann parameters of NLC at the lowest frequency of 195 Hz are Q_{max} : 3.18 ± 0.06 pC, V_h : -46.1 ± 1.1 mV, z : 0.92 ± 0.02 , and C_{lin} : 22.58 ± 0.51 pF. R_s was 9.1 ± 0.8 M Ω . R_m at zero holding potential was 401 ± 75 M Ω . Average eM gain evoked by the ramp protocol (Fig. 3 B) was 22.8 ± 2.8 nm/mV. Maximum eM was 2.54 ± 0.32 μ m; equivalent z was 0.94 ± 0.02 . Fig. 3, E–G, surface and two-dimensional (2-D) plots, show average guinea pig OHC eM before and after correcting for R_s -induced voltage errors.

We also analyzed four mouse OHCs. Average (\pm SEM) Boltzmann parameters of NLC at the lowest frequency of 195 Hz are Q_{max} : 0.74 ± 0.02 pC, V_h : -47.2 ± 3.3 mV, z : 0.82 ± 0.01 , and C_{lin} : 7.60 ± 0.13 pF. R_s was 5.7 ± 0.1 M Ω . R_m at zero holding potential was 239 ± 53 M Ω . Average eM gain evoked by the ramp protocol

(Fig. 4 B) was 7.0 ± 0.6 nm/mV. Maximum eM was 1.06 ± 0.08 μ m; equivalent z was 0.70 ± 0.03 . Fig. 4, E–G, surface and 2-D plots, show average mouse OHC eM before and after correcting for R_s -induced voltage errors.

Fig. 3, E–G, and Fig. 4, E–G, illustrate that using either of the two possible correction approaches (Method 2 and Method 3) produces essentially the same results (in line with modeling in the figures in the Online supplemental material) and confirming the low pass nature of both guinea pig and mouse eM. Notably, the equivalence of the two methods also confirms the validity of the dual sine approach to measure high frequency capacitance, whose multifarious influence on clamp time constant must be considered in order to properly evaluate eM frequency response under voltage clamp.

In Fig. 5, A and B, we plot, at all interrogated frequencies, the voltage dependence of group-averaged eM gain and NLC for mouse and guinea pig OHCs. Guinea pig responses are lower pass than mouse responses. We additionally analyzed OHC response data individually, followed by averaging. Fig. 5, C and D, show mean and SEM of eM at V_h , and Boltzmann parameters of fits based on single cell analysis at frequencies spanning 195 to 3,125 Hz (mouse eM was additionally measured at 6,250 Hz). It is clear that the guinea pig eM frequency response is lower pass than the mouse response (quantification is shown in Fig. 6). It is noteworthy that guinea pig OHCs show a disparity between eM and NLC V_h that is not found in the mouse. Such disparity has been observed previously for guinea pig OHCs (Song and Santos-Sacchi, 2013; Duret et al., 2017), and we previously found that the disparity is diminished with increased turgor pressure for the guinea pig. For our mouse OHCs, we note that the cells appear substantially turgid (see Fig. 1 E), so this may be the reason for the absence in disparity in the mouse.

Fig. 6 shows eM and NLC cut-off frequencies (F_c) for guinea pig and mouse. To approximate differences in frequency responses between NLC and eM for the mouse and guinea pig, we apply single Lorentzian fits to group-averaged eM and NLC within a restricted bandwidth (195–3,125 Hz) at each incremental holding potential of the ramped AC response. The cut-off frequencies display U-shaped dependencies on holding potential, AC voltage stimulation at V_h providing the slowest response.

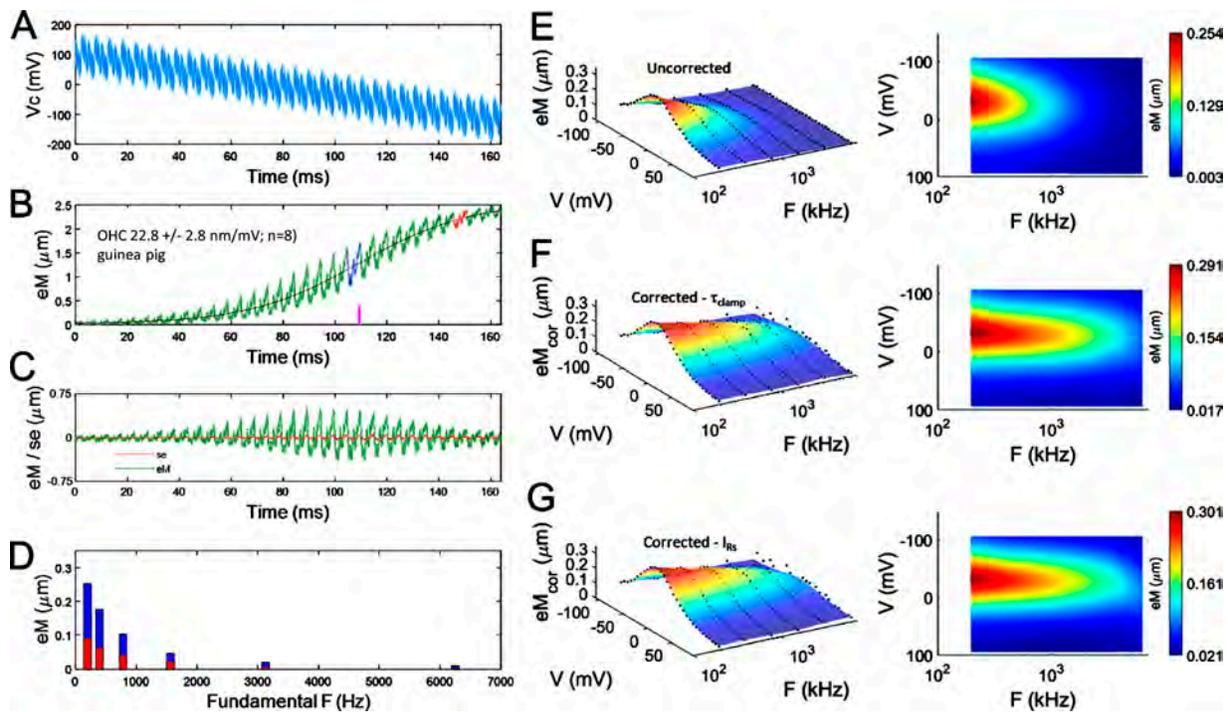

Figure 3. **Group-averaged guinea pig OHC eM frequency response corrected by two methods.** Data presented in A–E are pre-correction, and in F and G are after correction. (A) The hyperpolarizing ramp voltage stimulus (100 to –120 mV) with superimposed sum of 20 mV AC harmonic frequencies (195.3–6,250 Hz). A pedestal of 100 mV (81.32 ms) preceded the ramp. (B) Raw averaged eM. Two selected integral regions are highlighted. Blue is near V_h (magenta bar beneath shows position of V_h). Red highlights a hyperpolarized region. (C) The eM data detrended (green) and the standard error (red). (D) Magnitude responses at the six interrogated frequencies of the two highlighted regions (colors correspond to those in B). Data were detrended as in C before FFT. The surface plots on the right provide a full analysis across ramp voltage at all integral regions of the eM data. (E) Uncorrected eM; the 2-D voltage frequency plots permit clearer visualization of the frequency responses. Black dots are data points. (F) eM adjusted with Method 3 based on corrections to multifarious τ_{clamp} (see Materials and methods). (G) eM adjusted with Method 2 based on membrane current corrections, namely, $V_m = V_c - I_{R_s} * R_{ij}$. Note tight correspondence between the two approaches. These data indicate that OHC eM is low pass in nature. eM_{cor} , corrected eM.

eM corrections based on Methods 2 and 3 are overlapped, indicating accurate estimates of R_s . Individually analyzed cell averages (filled symbols with SEM, using Method 2) show good agreement with the group-averaged data. The F_c at V_h for guinea pig OHC eM is 1.47 ± 0.065 kHz, and that for mouse OHC eM is 4.26 ± 0.74 kHz. NLC measures follow this pattern, with cut-offs faster than that for eM. The F_c at V_h for guinea pig OHC NLC is 2.47 ± 0.091 kHz, and that for mouse OHC NLC is 6.83 ± 0.46 kHz.

To assess the frequency response of NLC under near ideal voltage clamp, we employed macro-patches of the guinea pig OHC lateral membrane. NLC measures were made using the ramp protocol, as above. Our video analysis setup was insufficient to measure patch movements induced by our ramped 20 mV AC stimuli. However, as with voltage-corrected whole-cell measures, patch NLC shows low-pass behavior (Fig. 7). At the lowest frequency of 195 Hz, fitted Boltzmann parameters of NLC are Q_{max} : 38.6 ± 6.1 fC, V_h : -38.1 ± 4.4 mV, and z : 0.67 ± 0.03 . No correction for resting potential was made for on-cell patch V_h . z is lower than whole-cell measures. For comparison, Gale and Ashmore (1997b), using a lock-in amplifier to measure NLC with 1 kHz sinusoids, found z to be 0.65 (slope factor $\beta = 0.04$). Given our z and a hemispherical patch surface area (diameter equal to 3.5–4 μm), we calculate 3,851–5,030/ μm^2 elementary prestin motor units, in line with previous estimates.

Fig. 8 compares peak NLC from on-cell macro-patches with scaled values of whole-cell eM, NLC, and data from Gale and Ashmore (1997a). For frequency roll-off comparison, values were scaled to coincide with our macro-patch NLC values at 390.6 Hz. The roll-off of whole-cell eM and that of the patch movements measured by Gale and Ashmore are similar. The measures of peak NLC of whole-cell, macro-patch, and Gale and Ashmore’s patch NLC (points within our recording bandwidth are shown) are similar. The cut-off frequencies obtained with Lorentzian fits (either whole-cell or macro-patch data) show that eM and NLC frequency responses differ, with eM being slower, as noted above. We emphasize that the single Lorentzian fits here do not describe the full frequency response of NLC, but only that within our recording bandwidth. These measures are intended to make comparisons with our eM measures within the same recorded bandwidth. Thus, we conclude that the degree of coupling between prestin conformational changes (i.e., NLC) and eM must underlie differences between their frequency responses.

Finally, we observe that fits of the square root of eM provide cut-offs comparable to those for NLC for both mouse and guinea pig OHCs. The F_c at V_h for guinea pig OHC $eM^{1/2}$ is 2.77 ± 0.11 kHz, and that for mouse OHC $eM^{1/2}$ is 7.69 ± 0.81 kHz. t test comparisons to the cut-offs of NLC (2.47 ± 0.091 and 6.83 ± 0.46 ,

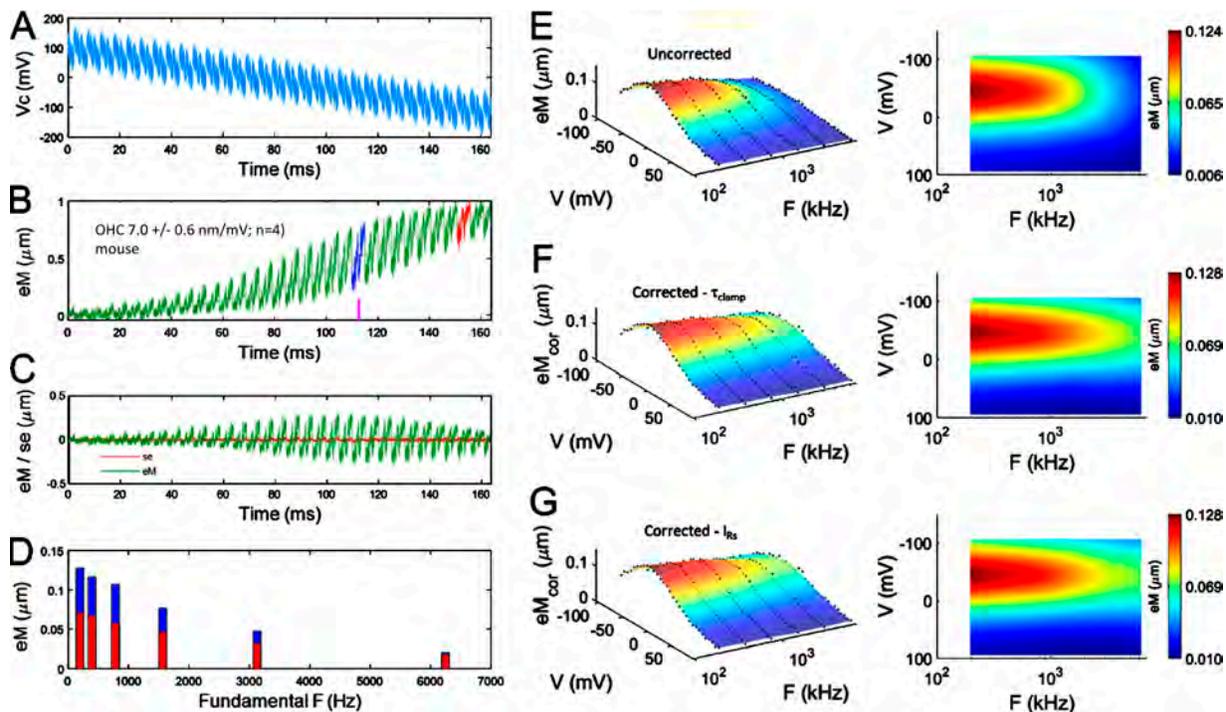

Figure 4. **Group-averaged mouse OHC eM frequency response corrected by two methods.** The caption of Fig. 3 directly applies to this figure. Note that the frequency extent of eM for the mouse is wider band than the guinea pig, before and after voltage corrections.

respectively) show no statistically significant differences ($P = 0.1092$ and $P = 0.4948$, respectively). Below we consider the basis of such disparity.

Discussion

Prestin works by sensing voltage with consequent alterations in its conformational state, leading to contractions and elongations of the cylindrical cell that provides enhancement of auditory threshold (Ashmore, 2008; Santos-Sacchi et al., 2017). Because of the large restricted prestin-generated charge movements evoked by voltage (Ashmore, 1990; Santos-Sacchi, 1991), a substantial alteration in membrane capacitance ensues, paradoxically altering the very voltage that the sensor senses. This is even expected to occur during normal acoustic stimulation, where the receptor potential will suffer from a multifarious membrane resistor-capacitor (RC) filter. For example, the receptor potential cut-off frequencies estimated using linear capacitance alone (Johnson et al., 2011) would be greatly reduced at V_h , where NLC can be as great as linear capacitance. In our study under voltage clamp, series resistance and membrane capacitance conspire to limit the imposition of voltage across the membrane, interfering in both time and magnitude. To evaluate effects of membrane potential across frequency, it is required to alleviate this interference. Here we have compensated for the multifarious time constants induced by R_s and NLC(v, f) in order to reveal the true voltage-induced frequency response of both guinea pig and mouse OHC eM across an array of holding potentials. Before proceeding, we review the literature on measures of eM frequency response.

eM bandwidth studies

A review of OHC eM bandwidth studies has been published recently (Santos-Sacchi, 2019). Here we briefly review those studies with the aid of Table 1. Over the years, better techniques that have extended voltage delivery capabilities have provided increasingly higher estimates for eM cut-off frequencies. Of course, R_s of the patch pipette or the microchamber pipette, in combination with OHC capacitance, ultimately controls frequency delivery bandwidth under voltage clamp. Typically, the time course of the clamp can be garnered from exponential decays of current induced by voltage steps, but AC currents can also be used as we have done in our present work. Prior to Frank et al. (1999), eM cut-offs were typically below 10 kHz. Interestingly, Gale and Ashmore (1997a) measured both patch NLC and membrane movements, and found a NLC cut-off near 10 kHz, but a patch movement cut-off significantly lower (see Fig. 8). The reduced cut-off was attributed to mechanical impediments to patch movements, despite the expected coupling between charge movement and mechanical response. The introduction of the partitioning microchamber by Dallos and Evans essentially reduced membrane capacitance by delivering the voltage stimulus across the reduced series combination of the partitioned cell membrane capacitance (Dallos and Evans, 1995). Given membrane time constants that are equal for each partition, each will experience a flat delivery of a command voltage across the cell. However, the command voltage frequency response itself will be attenuated by the $R_s * C_{in}$ filter, C_{in} being the input capacitance resulting from the series combination of partitioned capacitances (see microchamber

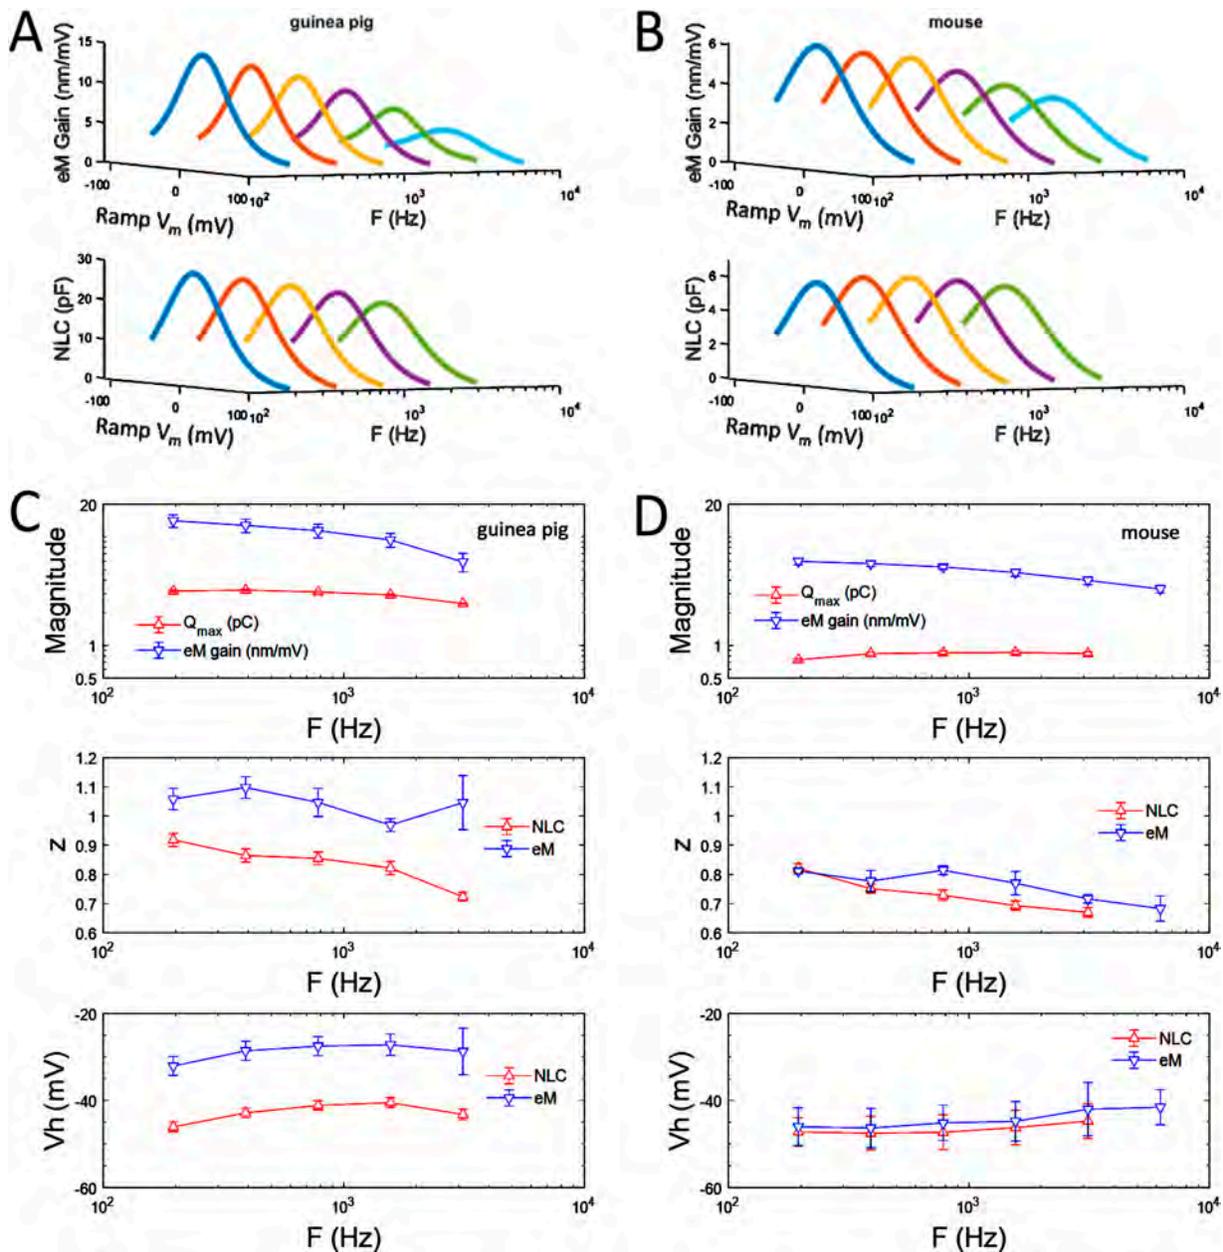

Figure 5. **Comparison of AC measured group-averaged guinea pig (A) and mouse (B) OHC NLC and associated eM frequency response as a function of holding voltage at each of the interrogated frequencies.** Neither mouse OHC NLC nor eM frequency response is as low pass as that of guinea pig OHC. These data were derived from cell averages of raw eM and membrane currents, as in Figs. 3 and 4. (C and D) Mean and SEM of eM at V_h and Boltzmann parameters of fits based on single-cell analysis. Note disparity of eM and NLC V_h and z for guinea pig as previously observed (Song and Santos-Sacchi, 2013). Mouse OHC eM and NLC V_h , on the other hand, are comparable.

schematic in Fig. 9 of Santos-Sacchi and Tan, 2018). Thus, Dallos and Evans, even though they did not monitor membrane currents to determine actual voltage roll-off, did estimate, given published OHC characteristics, the voltage delivery cut-off to be ~30 kHz in their experiments. This cut-off, as noted above, depended on their microchamber R_s and the input membrane capacitance. Of note for the studies by both Dallos and Evans and Frank et al., their zero microchamber offsets interrogated eM at holding membrane potentials far removed from V_h ; this is apparent from the small

eM gains reported compared with established eM gains between 15–19 nm/mV. Santos-Sacchi and Tan (2018) measured eM frequency response at two microchamber offsets, one near V_h and the other well offset from V_h (we estimate ~65 mV away). By measuring clamp tau from exponential decays at those two offsets, they found that eM is lower pass at V_h . Unfortunately, none of the previous studies have actually accounted for the voltage- and frequency-dependent roll-off of voltage delivery to the OHC, and without that correction, the true voltage-dependent eM frequency response remained unclear.

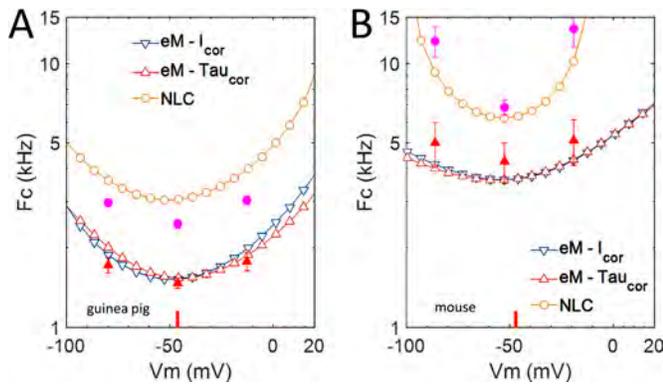

Figure 6. **Frequency cut-offs (F_c) for NLC and eM.** (A and B) Single Lorentzian fits of NLC and associated eM data in Fig. 5, A and B. The plots show that the F_c of NLC and eM increases as ramp voltage deviates from V_h . The open symbols are from fits to averaged data. The cut-off frequency for each is a U shaped function of holding voltage, with NLC measures showing frequency cut-offs faster than that for eM. Using either of the two eM correction methods gives equivalent results (see Materials and methods section). The filled symbols with SEM are obtained from individually analyzed OHC data. The F_c at V_h for guinea pig OHC eM is 1.47 ± 0.065 kHz, and that for mouse OHC eM is 4.26 ± 0.74 kHz. The F_c at V_h for guinea pig OHC NLC is 2.47 ± 0.091 kHz, and that for mouse OHC NLC is 6.83 ± 0.46 kHz. The red bar on the voltage axis indicates NLC V_h .

Similarities and differences between voltage-sensor movement (NLC) and eM

The electromechanical results we report on now explore the component of eM within 0.195–6.3 kHz, corresponding to human speech frequencies, and are made under whole-cell voltage clamp where, unlike the microchamber, precise DC and AC voltage delivery to the membrane is possible and predictable. Thus, we find with whole-cell recording, following voltage corrections due to the multifarious clamp time constant, that prestin’s eM and NLC frequency response, in both mouse and guinea pig, exhibits low-pass electromechanical behavior within our measurement bandwidth. The frequency response is slowest at V_h , with a cut-off, approximated by single Lorentzian fits within that bandwidth, near 1.5 kHz for the guinea pig OHC and near 4.3 kHz for the mouse OHC, each increasing in a U-shaped manner away from V_h . NLC measures follow this U-shaped pattern.

By using macro-patch measurements, where voltage control is near ideal, we find that NLC frequency response is similar in roll-off to corresponding whole-cell measures within the speech frequency bandwidth, indicating our whole-cell voltage corrections were effective. Nevertheless, eM frequency cut-offs differ from those of NLC, which are faster. In OHC patches, Gale and Ashmore found that patch movement F_c was only 0.19 times that of NLC F_c (using the ratio of their reported corresponding tau values of 16 and 83.5 μ s for NLC and movements, respectively), which they attributed to interactions of prestin with cytoskeletal elements and viscous damping (Gale and Ashmore 1997a). That is, factors that influence prestin electromechanical behavior are present within the on-cell patch, i.e., intrinsic to the local environment of prestin within the membrane. Indeed, we have found physical and functional interactions of MAP1S, a small actin-binding protein, with prestin (Bai et al., 2010). However,

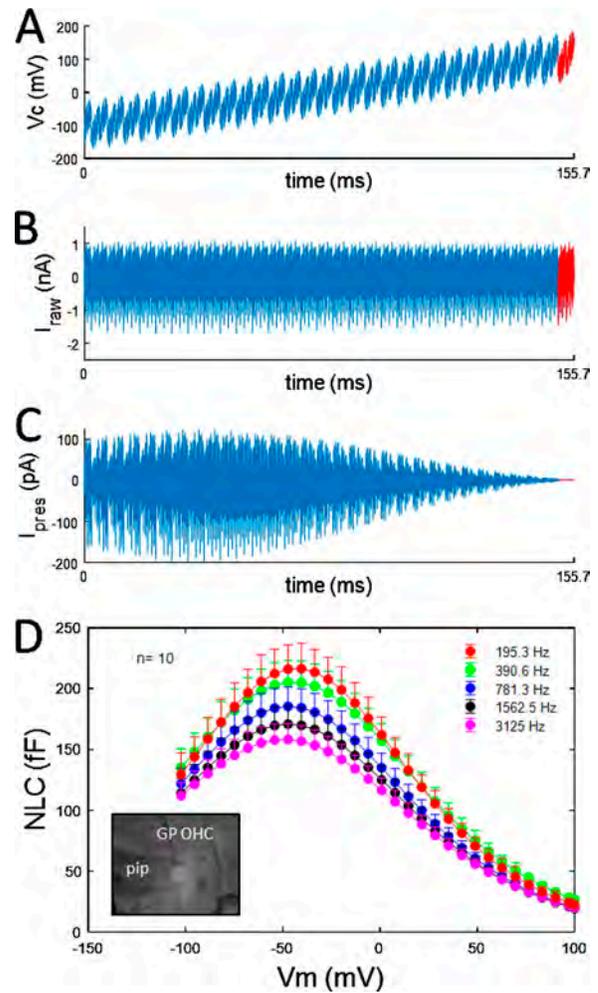

Figure 7. **Macro patches were made on the GP OHC lateral membrane to verify low pass behavior found in whole-cell measures of NLC.** (A) Command voltage; red highlighted regions used for stray and linear current subtractions; see Materials and methods). (B) Group-averaged currents recorded from on-cell macro-patches. Currents with AC components removed were used for detrending AC responses before highlighted region subtraction and FFT. (C) Resulting prestin-associated nonlinear currents. (D) Patches were individually analyzed to obtain NLC derived from nonlinear currents. Inset shows a patched OHC lateral membrane. Diameter of the OHC is 10 μ m. Mean \pm SEM. Pip, patch pipette; I_{raw} , raw current; fF, femtofarads; I_{pres} , prestin currents.

such influential effects on eM might be expected to work on both eM and NLC, since charge movement and mechanics are coupled (Dong and Iwasa, 2004; Santos-Sacchi and Tan, 2018). Consequently, the discrepancy between eM and NLC frequency response that is observed must point to variability of coupling charge movement to eM. Of course, uncoupling is clearly observable by deflating the OHC, which preserves NLC while abolishing whole-cell eM (Santos-Sacchi, 1991). Thus, we suggest that a variable coupling between whole-cell mechanics and prestin activity limits OHC influences on cochlear amplification at high frequencies. To this point, Vavakou et al., 2019 have recently observed limited, low-pass estimates of OHC eM frequency response using optical coherence microscopy vibrometry in the high-frequency region of the living gerbil.

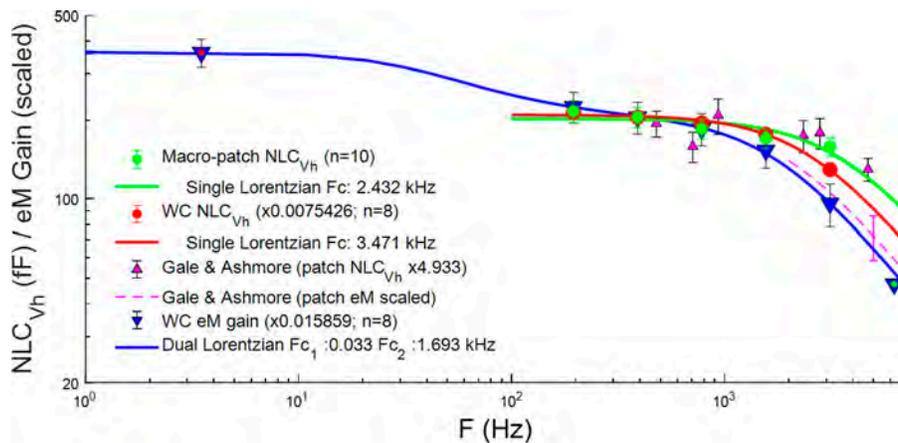

Figure 8. **Comparison of macro-patch peak NLC frequency response with whole-cell responses and published data (eM and NLC).** Data are scaled to macro-patch NLC at 390.6 Hz to compare frequency roll-off. Whole-cell NLC and macro-patch NLC both show low pass behavior. A single Lorentzian fit of the macro-patch (green) and whole-cell (red) NLC, indicates low pass behavior for each that is faster than whole-cell eM cut-off. For comparison, the roll-off of patch movement measures of Gale and Ashmore (1997a; purple dashed line being the equivalent Lorentzian of their movement tau and the purple SEM error bar depicting the equivalent mean \pm SEM response at 5 kHz; scaled in magnitude to over lie our eM roll-off) are plotted, and roll-off appears similar to that of our whole-cell eM. Gale and Ashmore’s patch NLC data (their points

within our measurement bandwidth) are comparable to our macro-patch measures. The downward blue triangle with a red dot is derived from the ramp eM gain (Fig. 3 B), and that with the light blue dot is from group-averaged responses (Fig. 5 A). Overall, the figure shows the discrepancy between eM and NLC roll-off, with NLC presenting a higher frequency cut-off. Mean \pm SEM. WC, whole cell.

What factors may influence OHC eM frequency response?

Within our interrogation bandwidth, NLC and eM are low pass. Since we accurately corrected for voltage delivery roll-off, the differential eM roll-off must result from other factors intrinsic and/or extrinsic to the cell. Two features require exploration not previously considered. One is the mechanism for voltage dependence of the cut-off frequency, F_c (Fig. 6). The other is a discrepancy in F_c for NLC and eM. The values of F_c for NLC are higher than those of eM. That is, eM appears to be low-pass filtered.

There are two factors that contribute to the frequency dependence that we measure. One is due to the intrinsic transition rates between prestin’s conformational states (Iwasa, 1997). Another factor, which is extrinsic to the motile element itself, is due to mechanical loads imposed on both the cell and the motile element. In the absence of mass, the characteristic frequency is determined by viscoelastic relaxation.

Mechanical factors could lead to a voltage dependence of F_c if the axial stiffness of the cell is itself voltage dependent, because the characteristic frequency of viscoelastic relaxation is determined by k/η , where k is the axial stiffness and η the drag coefficient. Indeed, it has been reported that the axial stiffness significantly decreases on deep depolarization (He and Dallos, 1999, 2000). Such a reduction in stiffness leads to a lower viscoelastic frequency as holding voltage is moved away from V_h , and is inconsistent with our observations. On the other hand, an alteration of axial stiffness has been theoretically predicted as an analogue of “gating compliance,” in which conformational transitions contribute to length changes of the cell (Iwasa, 2000). The predicted voltage dependence of the compliance, the inverse of stiffness, is bell-shaped, similar to NLC and qualitatively similar to our observed F_c values. Nevertheless, this effect is much too small to account for our observations. Actually, the magnitude of the “gating compliance” is quantitatively consistent with a report that voltage dependence of axial OHC stiffness is absent (Hallworth, 2007). Indeed, a previous treatment of a viscoelastic process involving the OHC does not lead to voltage dependence of the viscoelastic frequency for a

voltage driven stimulus, while it does for a force stimulus (Iwasa, 2016).

A stochastic transition model, even the simplest two-state model, inherently predicts voltage dependence because the characteristic frequency is expressed as a sum of transition rates in opposite directions from the distribution’s midpoint (Iwasa, 1997). In one direction, the rates increase exponentially with larger depolarizations, and in the other direction with larger hyperpolarizations, similar to the F_c values in Fig. 6.

Disparate frequency dependence for NLC and eM is a new observation, and there is no previous theoretical prediction or explanation. This is because it has been assumed that the cell undergoes the same mode of motion as the motile element. For a model in which eM is the low-pass filtered output of the motile element, it is possible to obtain different values of F_c for NLC and eM.

To capture the essential features of the observed high-frequency behavior of NLC and that of eM, we examined various mechanical loads assuming two conformations for the motile element (see Appendix). Virtually all kinetic models of prestin thus far reported, including the meno presto model (Santos-Sacchi and Song, 2014a), use this two-state formalism for eM and NLC generation.

We found that our experimentally observed eM and NLC frequency dependence can be explained by assuming that the motile element, which undergoes stochastic transitions, drives a mechanical system with two modes of motion. More specifically, cell displacement is the low-pass filtered output of the motile element displacement (see Appendix). The schematic configuration of the mechanical model is shown in Fig. 9. The model is constructed based on likely mechanical interactions within and external to the OHC. Thus, we view the elements k_2 , η_2 , and k_1 as representing the local environment, consisting of the lateral plasma membrane and cytoskeletal structures, surrounding the motile element (P). The elements k_0 and η_0 represent parts of the cell distant from the given motile element, primarily involved in energy dissipation due to the drag against the external medium. The existence of the elastic element k_0 may indicate

Table 1. History table of OHC eM frequency measurements

Publication	Method to evoke and measure load-free eM	Frequency response cut-off	Voltage delivery and/or eM measurement limitations	Notes
(Kachar et al., 1986)	Transcellular AC current; standard video	No estimate of roll-off; 1–30 Hz frame rates.	$R_m * C_m$ time constant; limited to 60 frames/s	
(Ashmore, 1987)	Whole-cell voltage clamp; photodiode	Dual Lorentzian cut-offs at 67 and 664 Hz	Voltage clamp $R_s * C_m$ time constant	
(Santos-Sacchi, 1992)	Whole-cell voltage clamp; photodiode	Single Lorentzian cut-off at 1 kHz	Voltage clamp $R_s * C_m$ time constant	
(Reuter et al., 1992)	Transcellular AC current stimulation in organ explants; stroboscopic video	40 dB down at 15 kHz	Membrane $R_m * C_m$ time constant	
(Dallos and Evans, 1995)	Microchamber cell partitioning, AC voltage from low-impedance waveform generator; photodiode	No estimate of roll-off, as shape of frequency response is a function of apical to basal impedances; eM detection above 10 kHz; zero microchamber V offset	$R_s * C_{in}$ (input capacitance of partitioned cell) for command voltage; ratio of partitioned impedance modifies roll-off shape	Low frequency eM gain: ~5 nm/mV indicative of offset away from V_h ; no estimation of V delivery roll-off based on generated currents
(Gale and Ashmore 1997b)	On-cell and excised membrane patch under voltage clamp	Patch movements (\approx eM) measured with step voltages; 10 kHz cut-off for patch NLC; 0.19 \times lower cut-off for movements	Near ideal voltage clamp	First indication that eM and NLC frequency response may differ
(Frank et al., 1999)	Microchamber cell partitioning; voltage clamp; laser Doppler vibrometer	Variable cut-off; for 30 μ m cell extrusion 33 kHz; smaller extrusions > 70 kHz; zero microchamber V offset	$R_s * C_{in}$ for command voltage; ratio of partitioned impedance modifies roll-off shape	Low frequency eM gain: ~5 nm/mV indicative of offset away from V_h ; voltage corrections based on $R_s * C_{in}$ (stray membrane capacitance)
(Kitani et al., 2011)	Transcellular AC current; video analysis at 18 kHz	Responses measured up to 4 kHz	$R_m * C_m$ time constant	Time dependent changes in eM magnitude may be attributed to mechanisms other than prestin
(Santos-Sacchi and Tan, 2018)	Microchamber cell partitioning; voltage clamp; video analysis at 50 KHz frame rate	At microchamber V offset to V_h , dual Lorentzian cut-offs of 33 Hz and 6.3 kHz; at zero microchamber V offset, dual Lorentzian cut-offs of 234 Hz and 8.7 kHz	$R_s * C_{in}$ for command voltage; ratio of partitioned impedance modifies roll-off shape	Low frequency eM gain (at V_h): 16.8 nm/mV; voltage corrections based on exponential current decays during V stimulation at two microchamber offsets; eM measures made under whole cell voltage clamp were not corrected for delivery roll-off

that the drag is not concentrated at a single location, but it is distributed along the cellular axis.

Small mechanical displacements, x and y , elicited by small sinusoidal voltages with frequency f applied on the motile element, can be expressed as (see derivation in Appendix),

$$x(f) = \frac{k_{12} \gamma(f)}{k_{02} + k_{12} + i f / f_1}, \quad (10a)$$

$$\gamma(f) = \frac{\beta \bar{P}_{\pm} a q N}{1 + f / f_g} \cdot \frac{\nu}{k_{12}^2 (k_{01} + k_{12} + i f / f_1) - (k_{12} + i f / f_2)}, \quad (10b)$$

where f_g is the gating frequency, $k_{02} = k_0/k_2$, $k_{12} = k_1/k_2$, $2\pi f_0 = \eta_0/k_2$, and $2\pi f_2 = \eta_0/k_2$. Here, $i = \sqrt{-1}$. The voltage dependence of the magnitude of these quantities is determined by \bar{P}_{\pm} , which is proportional to NLC at low frequencies (see Appendix). Notice here that NLC is associated with x , and eM with γ . Eq. 10a indeed shows that x is a low-pass filtered output of γ .

Importantly, the model captures two features of our experimental observations. One is the voltage dependence of F_c due to

gating frequency f_g . The other is that the roll-off of eM takes place at lower frequency than that of NLC.

Fig. 10 shows model fits of experimentally determined eM and NLC frequency responses at three holding potentials, passing through V_h . The parameter values obtained by simultaneous data fit at each holding voltage appear reasonable. However, standard errors are large, mainly due to the dependency between the substantial number of parameters. Such an example is shown in Fig. 10 A, which shows plots using two sets of parameter values, where the stiffness ratios of one set are larger than the other by about fivefold. For this reason, it is unlikely that the present analysis can provide definitive information regarding the axial stiffness of OHCs. Nevertheless, Fig. 10 indicates that the gating frequency f_g obtained at each holding voltage is consistent with the stochastic model with the lowest value, namely near V_h (at -45.8 mV). That is, the values of f_g distinctly characterize the plots at each holding voltage, while the values for the remaining parameters remain essentially the same.

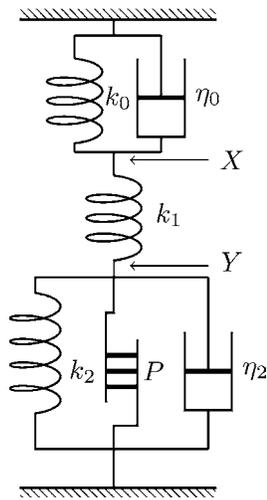

Figure 9. **Schematic diagram of mechanical load on the motile element.** Mechanical load consists of three elastic elements k_0 , k_1 , and k_2 , and two dashpots η_0 and η_2 . X represents the displacement of the cell, and Y indicates the displacement of the motile element, labeled as P.

Summary

The relationship between OHC resting potential and NLC V_h will govern the frequency response of eM. We previously proposed that a mismatch between resting potential and NLC V_h could enhance the frequency response of eM through a gain-bandwidth adjustment (Santos-Sacchi and Tan, 2018). Our new data are in line with this proposal and provide a detailed description of the OHC’s electromechanical cut-off frequency across voltage in both guinea pig and mouse OHCs. This cut-off frequency is U-shaped about V_h , and increases as holding voltage deviates from V_h . Importantly, the eM voltage dependence is mirrored by that of NLC, though frequency cut-offs differ. The cut-off disparity likely results from the influences of internal and external loads upon the motile mechanism. In this regard, we should comment on the observed differences in F_c values for mouse and guinea pig. Do differences in intrinsic prestin

kinetics exist between mouse and guinea pig, as the viscoelastic model might suggest? While preliminary, we have macro-patch measures out to 20 kHz that indicate similar prestin kinetics in the two species. That is, we explored the frequency response of NLC in patches from mouse and guinea pig OHC lateral membranes, each showing low-pass, stretched exponential behavior with roll-offs at half magnitude near 10–12 kHz at room temperature (unpublished data). In this light, we expect that the structural differences between the two species’ cells (e.g., length, diameter) may have provided differing loads on prestin with consequential differences in eM and NLC, given that the piezoelectric nature of prestin will be affected by load. In sum, all of our observations indicate that the influence of OHC activity on cochlear amplification is more complicated than has been envisioned.

Finally, we note that the kinetics of prestin are readily monitored through shifts in V_h , a reflection of the ratio of forward to backward transition rates. These kinetics, a determining factor in eM frequency response, depend on a host of other factors, including intracellular chloride, membrane tension and thickness, and temperature (Iwasa, 1993; Gale and Ashmore, 1994; Meltzer and Santos-Sacchi, 2001; Oliver et al., 2001; Santos-Sacchi et al., 2001; Izumi et al., 2011; Santos-Sacchi and Song, 2016). Indeed, alterations in prestin kinetics have been found in mutations in prestin (Homma et al., 2013). We suspect that eM frequency response is not a static feature in vivo.

Appendix

Rate equations for membrane molecules with mechanoelectric coupling: Introduction

There are two kinds of theories for describing the frequency dependence of cells with motile elements based on mechano-electric coupling. One of them is based on kinetic equations with intrinsic transition rates, which have been used to describe conformational changes of proteins, such as ion transporters (Kolb and Läuger, 1978), ignoring the effect of mechanical load imposed on those cells (Iwasa, 1997).

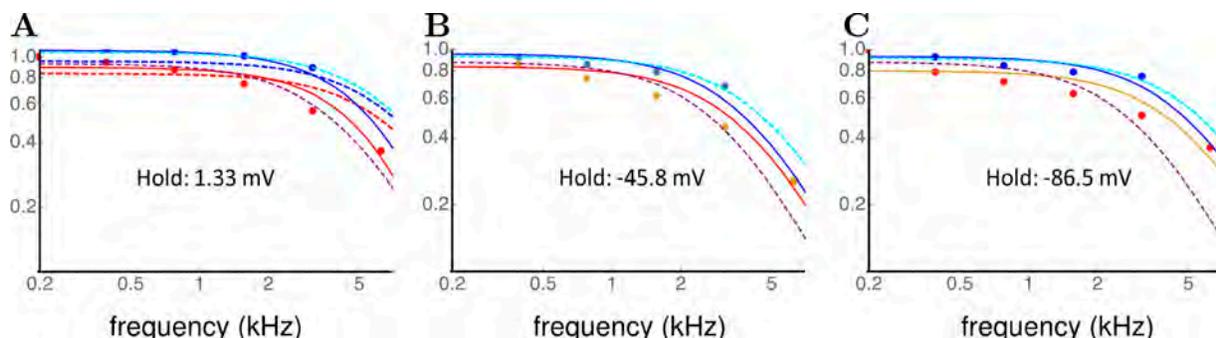

Figure 10. **Frequency dependence of NLC and eM.** Comparison with model predictions. Blue data points represent NLC and red data points eM. Solid lines indicate simultaneous fit for NLC and eM with the model at each holding potential. The color coding is the same as for the data points. Dashed lines in cyan and purple represent Lorentzian fit, respectively, for NLC and eM data. **(A)** Holding potential 1.33 mV; fit parameters are $f_g = 7.86$ kHz, $f_1 = 23.4$ kHz, $f_2 = 69.9$ kHz, $k_0/k_2 = 0.58$, and $k_1/k_2 = 0.26$. **(B)** Holding potential -45.8 mV, $f_g = 3.97$ kHz, $f_1 = 29.5$ kHz, $f_2 = 80.6$ kHz, $k_0/k_2 = 3.82$, and $k_1/k_2 = 1.31$. **(C)** Holding potential -86.5 mV, $f_g = 5.14$ kHz, $f_1 = 38.1$ kHz, $f_2 = 74.3$ kHz, $k_0/k_2 = 4.37$, and $k_1/k_2 = 1.60$. At 1.33 mV (in A), the best fit stiffness ratios are different from at other voltages. To examine the effect of difference in the stiffness ratios, additional dashed lines are drawn in blue and red, respectively, for NLC and eM, where the parameter values for B are used, except for the gating frequency f_g , which is set at 7.86 kHz.

Another kind of treatment assumes that intrinsic conformational transitions are infinitely fast. Conformational transitions are determined by the equation of motion for these cells, on which mechanical load is imposed (Iwasa, 2016). The resulting frequency responses of these cells are characterized by mechanical factors, such as the resonance frequency and the frequency for viscoelastic relaxation.

The present treatment introduces the dependence on mechanical load into the conformational transition rates, enabling description of the general case, where the intrinsic transition rates are finite. Two previous theories are recovered as special cases. In addition, we examine how mechanical complexity of the system can give rise to discrepancy in the frequency dependence of nonlinear capacitance NLC and that of motile response. For simplicity, we assume that the motile molecule has two discrete conformational states. The terms “motile molecules” and “motile element” are used interchangeably.

Motile element with two states

Consider a membrane molecule with two discrete conformational states, C_0 and C_1 , and let the transition rates k_+ and k_- between them be schematically expressed as

Let P_1 be the probability that the molecule is in state C_1 . Then, the probability P_1 can be expressed by the transition rates

$$\frac{P_1}{1 - P_1} = \frac{k_+}{k_-} = \exp[-\beta q(V - V_0)], \quad (A1)$$

where q is the charge transferred across the membrane during conformational changes, V the membrane potential, V_0 a constant, and $\beta = 1/k_B T$ with the Boltzmann constant and T the temperature.

If q is positive, the energy level of the state C_1 is higher, reducing P_1 as the membrane potential V rises. For prestin in outer hair cells, which shorten on depolarization, if we choose C_1 as the shortened state, the unit length change a on conformational change is negative, and then we have $q < 0$. Notice that the quantity a does not appear in Eq. A1.

The transition rates that satisfy Eq. A1 can be given by

$$k_+ = \exp[-\alpha\beta q(V - V_0)], \quad (A2)$$

$$k_- = \exp[(1 - \alpha)\beta q(V - V_0)], \quad (A3)$$

where α is an arbitrary constant.

The time dependence of P_1 can be expressed by the rate equation

$$\frac{d}{dt}P_1 = k_+ - (k_+ + k_-)P_1. \quad (A4)$$

Now we introduce sinusoidal voltage changes of small amplitude v on top of constant voltage \bar{V} , i.e., $V = \bar{V} + v \exp[i\omega t]$, where ω is the angular frequency and $i = \sqrt{-1}$. Then the transition rates are time-dependent due to the voltage dependence Eq. A1. They satisfy

$$\frac{k_+}{k_-} = \frac{\bar{k}_+}{\bar{k}_-} (1 - \beta q v \exp[i\omega t]). \quad (A5)$$

Notice \bar{k}_+ and \bar{k}_- are time independent, and we assume that v is small so that $\beta q v \ll 1$. A set of k_+ and k_- that satisfies Eq. A5 can be expressed

$$k_+ = \bar{k}_+ (1 - \alpha\beta q v \exp[i\omega t]), \quad (A6)$$

$$k_- = \bar{k}_- \{1 - (1 - \alpha)\beta q v \exp[i\omega t]\}. \quad (A7)$$

If we express $P_1 = \bar{P}_1 + p_1 \exp[i\omega t]$, we have respectively for the 0th and first order terms (Iwasa, 1997)

$$\bar{P}_1 = \frac{\bar{k}_+}{\bar{k}_+ + \bar{k}_-}, \quad (A8)$$

$$p_1 = -\frac{\bar{k}_+ \bar{k}_-}{\bar{k}_+ + \bar{k}_-} \cdot \frac{\beta q v}{i\omega + \bar{k}_+ + \bar{k}_-}. \quad (A9)$$

Notice that p_1 does not depend on the factor α .

Eq. A9 leads to voltage-driven mechanical displacement $ap_1 \exp[i\omega t]$ with

$$ap_1 = -\bar{P}_1 \cdot \frac{\beta a q v}{1 + i\omega/\omega_g}, \quad (A10)$$

where $\bar{P}_\pm = \bar{P}_1(1 - \bar{P}_1)$. The amplitude $|x|$ of the motile response is given by

$$|x|^2 = \frac{(\beta a q \bar{P}_\pm)^2}{1 + (\omega/\omega_g)^2} \cdot v^2. \quad (A11)$$

Charge displacement is expressed by qp_1 and the contribution to complex admittance $Y(\omega)$ is given by $(q/v)(d/dt)p_1 \exp[i\omega t]$ (Iwasa, 1997). The contribution to the membrane capacitance is $C_{nl}(\omega) = \text{Im}[Y(\omega)]/\omega$ and therefore

$$C_{nl}(\omega) = \frac{\beta q^2 \bar{P}_1(1 - \bar{P}_1)}{1 + (\omega/\omega_g)^2}. \quad (A12)$$

This contribution to the membrane capacitance is commonly referred to as NLC because it shows marked voltage dependence. Notice also that the above derivation evaluates the contribution of a single unit of motile element. For a cell that contains N motile units, both $|x|$ and C_{nl} need to be multiplied by N .

The roll-off frequency ω_g due to gating is expressed by $\omega_g = \bar{k}_+ + \bar{k}_-$, which is voltage dependent. Using Eqs. A2 and A3, we obtain

$$\omega_g = \exp[-\alpha\beta q(\bar{V} - V_0)] + \exp[(1 - \alpha)\beta q(\bar{V} - V_0)]. \quad (A13)$$

This means that $1/\omega_g$ rises at both ends of the membrane potential because α can take any value between 0 and 1. That means ω_r can be asymmetric unless $\alpha = 1/2$.

In the special case of $\alpha = 1/2$, $k_+ = 1/k_-$. If we define $b(V) = \exp[-\beta q(\bar{V} - V_0)/2]$, then

$$1/\omega_g = 1/[b(V) + 1/b(V)], \quad (A14)$$

which resembles the bell-shaped voltage dependence of nonlinear capacitance at low frequencies ($\omega \rightarrow 0$).

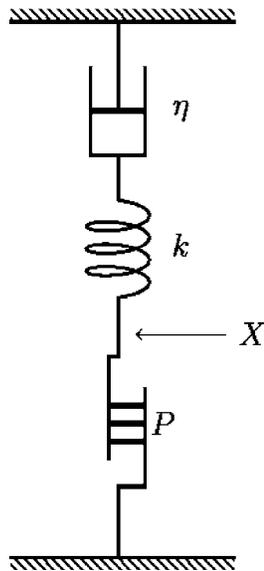

Figure A1. **Schematic representation of a cell with viscous drag.** The stiffness of the cell is k , and drag coefficient is η . The motile element is labeled P . The mechanical displacement of the cell is represented by X .

Mechanoelastic coupling

For motile membrane proteins based on mechanoelectric coupling, charge transfer is affected by mechanical factors. Here, we assume the cell is cylindrical as in the case of cochlear outer hair cells and approximate it as a one-dimensional object (Fig. A1).

Supposing charge transfer q is associated with a change a in the length of the cell, Eq. A1 should be replaced by

$$\frac{P_1}{1 - P_1} = \frac{k_+}{k_-} = \exp[-\beta[q(V - V_0) + aF]], \tag{A15}$$

where F is the axial force on the cell. The revised transition rates k_+ and k_- also depend on the mechanical factor

$$K_+ = \exp\left[-\alpha \frac{\beta}{2}[q(V - V_0) + aF]\right], \tag{A16}$$

$$k_- = \exp\left[(1 - \alpha) \frac{\beta}{2}[q(V - V_0) + aF]\right]. \tag{A17}$$

For the rest of the present paper, the dependence on the value of the parameter α does not appear except for ω_g .

With a shorthand notation $\bar{P}_\pm (= \bar{P}_1(1 - \bar{P}_1))$, the change of the conformational probability p_1 can be driven either by changes in the voltage as well force:

$$p_1 = -\beta \bar{P}_\pm \frac{qv + af}{1 + i\omega/\omega_g}. \tag{A18}$$

If the motile element is driven by voltage changes, p_1 is proportional to v and mechanical displacement is given by ap_1 .

Effect of viscous drag

Movement is driven by a deviation from Boltzmann distribution. When voltage changes with amplitude v imposed, p_1 as expressed by Eq. A18 is the goal of the drive. Since this force is countered by viscous drag (with drag coefficient η), the equation of motion in the frequency domain can be expressed by

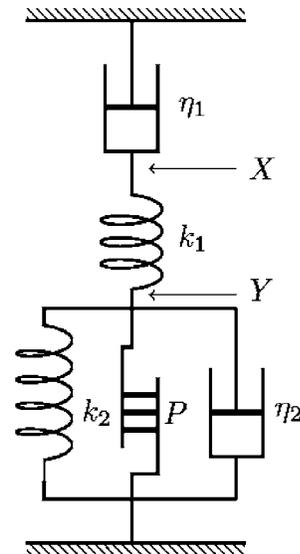

Figure A2. **Schematic representation of a cell with complex mechanical relaxation.** The local relaxation process associated with the motile element P is characterized by a spring with stiffness k_2 and a dashpot with drag coefficient η_2 . The local displacement is expressed by Y . The global relaxation process is characterized by a spring k_1 and a dashpot with drag coefficient η_1 . The cellular displacement is expressed by X .

$$i\eta\omega ap = ka(p_1 - p). \tag{A19}$$

Notice here that the equilibrium transition rates here depend not only on \bar{V} but also on \bar{F} because the motile element based on piezoelectricity is sensitive to mechanical force as well as the membrane potential.

Eq. A19 leads to

$$(1 + i\omega/\omega_\eta)p = -\frac{\beta \bar{P}_\pm}{1 + i\omega/\omega_g} \cdot qv, \tag{A20}$$

similar to the previous treatment for the special case without inertial loading (Iwasa, 2016). Here, the viscoelastic relaxation frequency is defined by $\omega_\eta = k/\eta$. It is essentially an equation for viscoelastic relaxation, adding a low pass filter to the motile mechanism. It is consistent with previous expressions in both extremes, i.e., $\omega_g \rightarrow \infty$ and $\omega_\eta \rightarrow \infty$.

The voltage dependence of NLC and that of motile response are identical. In the following, we show that mechanical load with complex relaxation can lead to discrepancy in their frequency dependences.

Complex mechanical relaxation

Let X represent the point that links a spring k_1 with a dashpot η_1 . Let Y represent the point that joins the spring k_1 with the rest, which includes a spring k_2 , a dashpot η_2 , and a driver (Fig. A2). The equations of motion of this system driven by force F generated at the location P can be expressed

$$\eta_1 \frac{dX}{dt} = -k_1(X - Y), \tag{A21}$$

$$F + k_2Y + \eta_2 \frac{dY}{dt} = k_1(X - Y). \tag{A22}$$

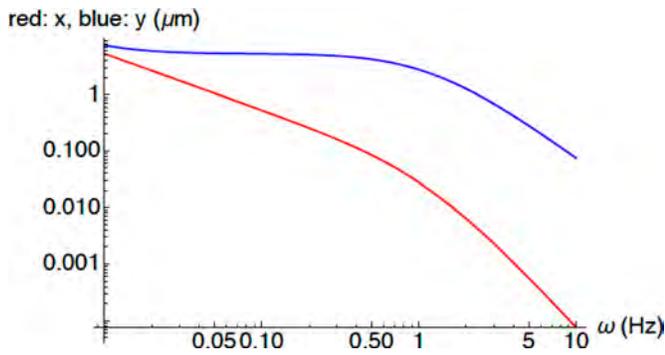

Figure A3. An example of the frequency dependence of x (red) and y (blue). Parameter values: $\omega_g = 2$, $\omega_1 = 0.01$, $\omega_2 = 5.12$, and $\frac{k_1}{k_2} = 0.16$.

If the force generator operates at a frequency ω with small amplitude on top of its steady value \bar{F} , $F = \bar{F} + f \exp[i\omega t]$. By letting the small amplitude components of X and Y with frequency ω be represented by x and y , Eqs. A21 and A22 turn into

$$i\omega\eta_1 x = -k_1(x - y), \tag{A23}$$

$$f + (k_2 + i\omega\eta_2)y = k_1(x - y). \tag{A24}$$

Eq. A23 can be rewritten as

$$x = \frac{y}{1 + i\omega/\omega_1}, \tag{A25}$$

which indicates that the quantity x is obtained by low-pass filtering Y with roll-off frequency of $\omega_1 (= k_1/\eta_1)$.

By introducing a characteristic frequency, $\omega_2 (= (k_1 + k_2)/\eta_2)$, Eq. A24 can be transformed into

$$f + (k_1 + k_2)[1 + i\omega/\omega_2]y = k_1x. \tag{A26}$$

Elimination of x from Eq. A26 with the aid of Eq. A25 leads to

$$y = f/G_1(\omega), \tag{A27}$$

$$G_1(\omega) = \frac{k_1}{1 + i\omega/\omega_1} - (k_1 + k_2)(1 + i\omega/\omega_2). \tag{A28}$$

An approach analogous to those in the previous sections lead to an equation

$$G_1(\omega)ap = ak_2(p - p). \tag{A29}$$

Since we have $y = ap$, this equation leads to

$$[G_1(\omega) + k_2]y = \frac{\beta\bar{P}_\pm k_2 a q v}{1 + i\omega/\omega_g}. \tag{A30}$$

Eqs. A25 and A30 show that the relationship between y and v has three adjustable parameters, ω_1 , ω_2 , and $k_r (= k_1/k_2)$. For an example of the frequency dependence of y , see Fig. A3.

The frequency dependence of NLC is the same as that of y . Motile response x is obtained by low-pass filtering y . The roll-off frequency of y is voltage-dependent due to the voltage dependence of ω_g .

With the connectivity of Fig. A2, it is difficult to make high frequency roll off of both quantities as similar as the experimental data. For y to roll off at relatively high frequency, ω_1 has to be small and ω_2 has to be large because G_1

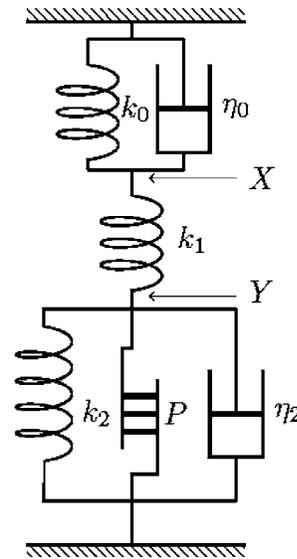

Figure A4. Schematic diagram of a cell with an alternative complex mechanical relaxation. The top dashpot η_1 in Fig. A2 is replaced by a combination of a dashpot η_0 and an elastic element k_0 .

must be small as required by Eq. A30. This requirement makes x roll off at a frequency much lower than y does (Fig. A3).

Modified complex mechanical relaxation

The model described above predicts a difference between x and y much larger than the experimentally observed frequency dependence. Let us add a spring across the upper dashpot (Fig. A4).

The set of equations that describe this configuration are

$$\left(\eta_0 \frac{d}{dt} + k_0\right)X = k_1(Y - X), \tag{A31}$$

$$F + \left(\eta_2 \frac{d}{dt} + k_2\right)Y = -k_1(Y - X). \tag{A32}$$

If force F is driven at angular frequency ω with amplitude f , the equation is transformed into

$$(i\omega\eta_0 + k_0)x = k_1(y - x), \tag{A33}$$

$$f + (i\omega\eta_2 + k_2)y = -k_1(y - x), \tag{A34}$$

where variables in the lower case x and y are the complex amplitude of frequency ω .

Eqs. A33 and A34 can be rewritten as

$$x = \frac{k_1}{k_0 + k_1 + i\omega\eta_0} \cdot y, \tag{A35}$$

$$f = k_1x - (k_1 + k_2 + i\omega\eta_2)y. \tag{A36}$$

In the manner similar to Eqs. A27 and A28 in the previous case, these equations can be expressed as

$$y = f/G_2(\omega), \tag{A37}$$

$$G_2(\omega) = \frac{k_1}{k_0 + k_1 + i\omega\eta_0} - (k_1 + k_2 + i\omega\eta_2), \tag{A38}$$

which corresponds to $G_1(\omega)$ in the previous case.

Since force generation is associated with spring k_2 in the manner similar to the previous case, we obtain

$$[G_2(\omega) + k_2]y = \frac{\beta a q k_2 \bar{P}_\pm}{1 + i\omega/\omega_g} \cdot v, \quad (\text{A39})$$

and x is obtained with Eq. A35.

If the cell contains N motile units, a should be replaced by aN . For numerical analysis, the number of parameters can be reduced by introducing the ratios $k_{02} (= k_0/k_2)$, $k_{12} (= k_1/k_2)$, $\omega_0 (= k_2/\eta_0)$, and $\omega_2 (= k_2/\eta_2)$ and x and y are expressed by

$$x = \frac{k_{12}}{k_{02} + k_{12} + i\omega/\omega_0} \cdot y, \quad (\text{A40})$$

$$y = \frac{\beta a q N \bar{P}_\pm}{1 + i\omega/\omega_g} \cdot \frac{1}{k_{12}^2 / (k_{01} + k_{12} + i\omega/\omega_0) - (k_{12} + i\omega/\omega_2)} \cdot v. \quad (\text{A41})$$

The corresponding equations (Eq. 10) in the main text are expressed with linear frequency f instead of angular frequency ω . Because these equations depend only on frequency ratios, no extra factor appears.

Acknowledgments

Supplemental material

Santos-Sacchi et al., <https://doi.org/10.1085/jgp.201812280>

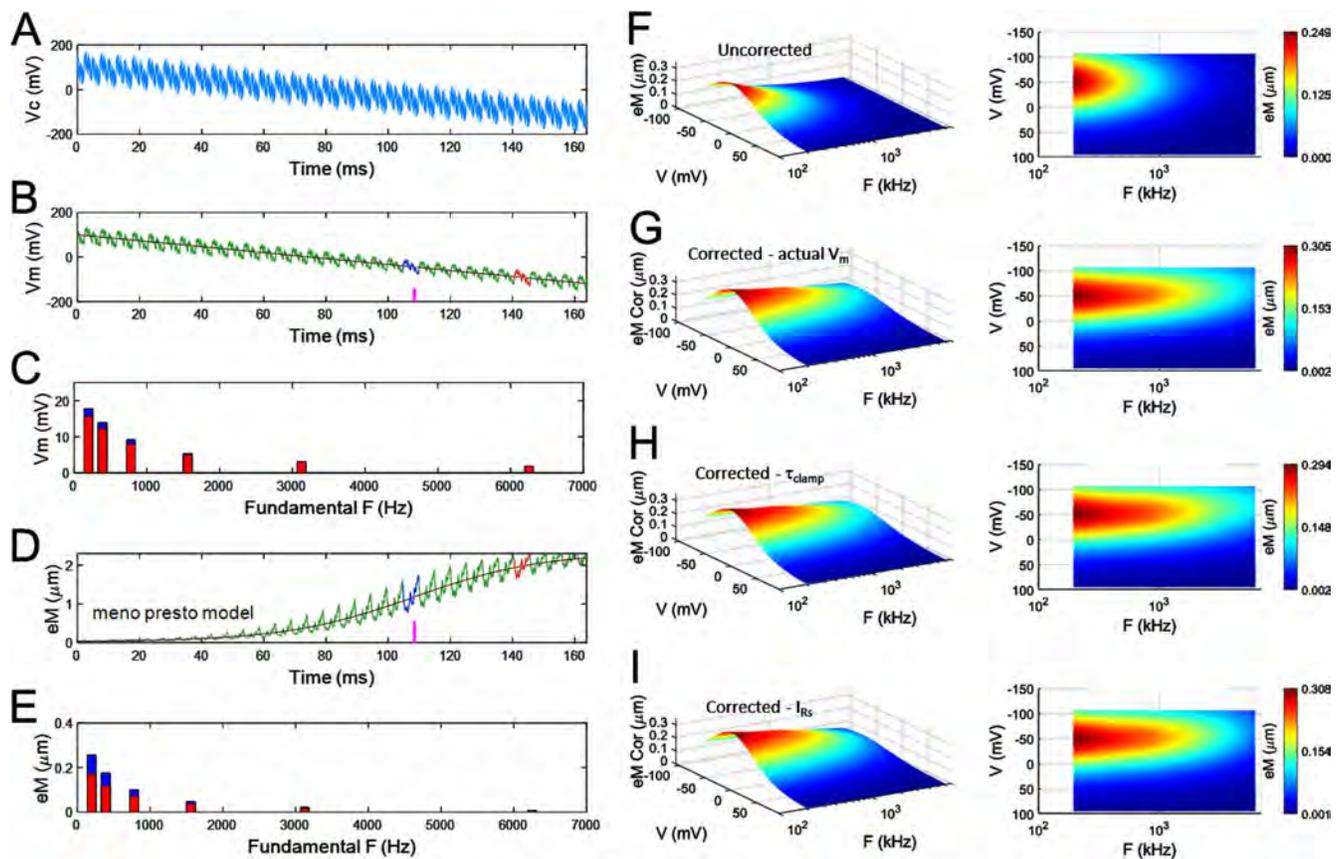

Figure S1. **Meno presto model (based on guinea pig [Fig. 3] and mouse [Fig. 4] averaged experimental parameters) of OHC under voltage clamp illustrating three methods for eM correction.** (A) The hyperpolarizing ramp voltage stimulus (100 to -120 mV) with superimposed sum of 20 mV AC harmonically related frequencies (195.3–6,250 Hz). A pedestal of 100 mV (81.32 ms) preceded the ramp. (B) Membrane voltage. Two selected integral regions are highlighted. Blue is near V_h (magenta bar beneath shows position of V_h). Red highlights a hyperpolarized region. In C, these regions were analyzed by FFT and magnitude results shown. (D) Raw eM (scaled charge from model) also depicting selected regions to analyze. (E) Magnitude responses at the six interrogated frequencies. Data were detrended as in Fig. 1 before FFT. The surface plots on the right provide a full analysis across ramp voltage at all integral regions of the eM model data. The adjacent 2-D plots present the frequency response that can more easily be compared among plots. eM- V_m data at each frequency were fit with the first derivative of a two-state Boltzmann before plotting. (F) Uncorrected eM. (G) Corrected eM using Method 1 based on actual V_m measures within MATLAB model. (H) eM adjusted with Method 3 based on corrections to multifarious τ_{clamp} (see Materials and methods). (I) eM adjusted with Method 2 based on membrane current corrections, namely, $V_m = V_c - I_{rs} * R_{ij}$. Each method provides comparable results. Note also that the frequency response of eM resulting from the guinea pig kinetic parameters is more low pass than those of the mouse (corresponding to the different imposed stretched intermediary rates), and the frequency responses are similar to the experimental data.

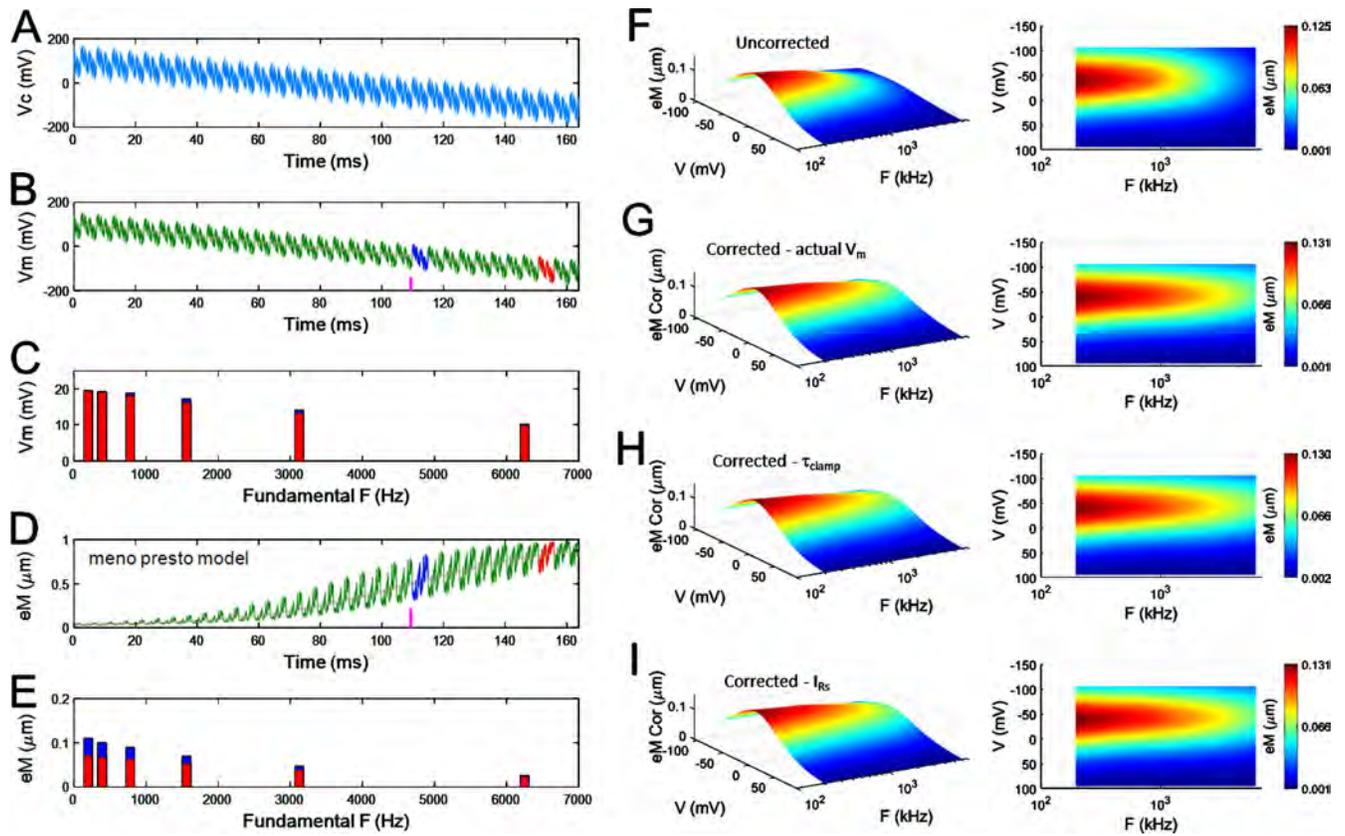

Figure S2. Meno presto model (based on guinea pig [Fig. 3] and mouse [Fig. 4] averaged experimental parameters) of OHC under voltage clamp illustrating three methods for eM correction. See legend of Fig. S1.

Complex nonlinear capacitance in outer hair cell macro-patches: effects of membrane tension

Joseph Santos-Sacchi^{1,2,3*} & Winston Tan¹

Outer hair cell (OHC) nonlinear capacitance (NLC) represents voltage sensor charge movements of prestin (SLC26a5), the protein responsible for OHC electromotility. Previous measures of NLC frequency response have employed methods which did not assess the influence of dielectric loss (sensor charge movements out of phase with voltage) that may occur, and such loss conceivably may influence prestin's frequency dependent activity. Here we evaluate prestin's complex capacitance out to 30 kHz and find that prestin's frequency response determined using this approach coincides with all previous estimates. We also show that membrane tension has no effect on prestin's frequency response, despite substantial shifts in its voltage operating range, indicating that prestin transition rate alterations do not account for the shifts. The magnitude roll-off of prestin activity across frequency surpasses the reductions of NLC caused by salicylate treatments that are known to abolish cochlear amplification. Such roll-off likely limits the effectiveness of prestin in contributing to cochlear amplification at the very high acoustic frequencies processed by some mammals.

Prestin (SLC26a5) underlies outer hair cell (OHC) mechanical activity¹, whereby voltage-dependent conformational transitions couple into length changes of the cell (electromotility; eM)^{2–4}. Sensor charge movements associated with these conformational changes are measurable as an electrical correlate of eM, i.e., nonlinear capacitance (NLC)^{5–7}, which is maximal at V_h , the voltage where prestin charge is distributed equally across the OHC membrane and where eM gain is greatest.

The study of OHC NLC by admittance techniques in whole cell voltage clamp is compromised by contributions from stray capacitance, membrane conductances, and electrode series resistance (R_s), the latter altering over time due to plugging of the patch pipette tip with intracellular constituents. Because of this, it is virtually impossible to measure complex membrane capacitance in whole cell mode. We avoid these issues by measuring membrane admittance from macro-patches of the OHC lateral membrane. The lateral membrane of the cylindrical OHC is dominantly populated by prestin (>8000 functional units/ $\mu\text{m}^{2,8-10}$), whereas voltage-dependent membrane conductances are housed in the basal pole membrane¹¹. Consequently, macro-patch admittance, following removal of stray capacitance by subtraction of admittance at very depolarized levels where NLC is absent¹², can be used to study complex sensor-charge movements arising from voltage-induced conformational changes in prestin.

Here, we evaluate patch admittance to provide estimates of complex capacitance representing charge movements both in phase and 90° out of phase with AC voltage excitation. We compare such data to previously obtained measures of OHC NLC frequency response^{13,14}, and additionally report on the effects of membrane tension^{15–17} on the frequency response of complex NLC. Will an assessment of NLC based on measures of complex NLC alter our current view, as suggested¹⁸, and can turgor pressure, normally present in the OHC¹⁹, with its effect on membrane tension be influential? Our observations indicate that the bulk of sensor charge movement is in phase with voltage, while the resistive component (dielectric loss) is relatively small. Furthermore, membrane tension, though altering prestin's operating voltage point, has no effect on its frequency response. Thus, magnitude estimates of complex NLC are comparable to those measured with other methods^{13,14}, being unusually low pass in nature (non-Lorentzian) and indicating that the absolute movement of prestin charge that drives electromotility (eM)^{20,21} is unlikely to extend with high fidelity to the very high acoustic frequencies (60–160 kHz) detected by some mammals.

Methods

All experimental protocols were approved by the Yale Animal Care and Use Committee, and were in accordance with relevant guidelines and regulations. Methods, including details of our voltage chirp stimulus protocol, are detailed in¹³. Briefly, extracellular solution was (in mM): NaCl 100, TEA-Cl 20, CsCl 20, CoCl₂ 2, MgCl₂ 1, CaCl₂ 1, Hepes 10, pH 7.2. Experiments were performed at room temperature. Extracellular solution was in the patch pipette. On-cell macro-patches on the guinea pig OHC lateral membrane were made near the middle of the cylindrical cell, since prestin density/activity is uniform within the lateral membrane^{8,22}. We have previously shown that capacitance frequency response in the OHC patch remains the same after excision of the patch, indicating that on-cell recording is applicable for our purposes¹³. Borosilicate pipettes of inner tip diameters between 3–4 μm were used, with M-coat applied within about 20 μm of the tip to minimize pipette capacitance. In order to establish gigohm seals we supplemented extracellular solution with 5 μM Gd³⁺; we have shown previously that these low concentrations help to form seals without affecting NLC^{13,23}. In 2 on-cell patches, we have omitted Gd³⁺ in the pipette solution and NLC frequency response is not significantly different than in its presence. An Axon 200B amplifier was used with jClamp software (www.scisoftco.com). An Axon Digidata 1440 was used for digitizing at 10 μs (Nyquist frequency of 50 kHz), with a 4-pole Bessel filter of 10 kHz. Membrane admittance was determined using a series of voltage chirps (4096 points each, resolution 24.4 Hz) superimposed onto holding potentials ranging from –160 to 160 mV, in 40 mV increments. 100 ms after each step to a new holding potential, 26 contiguous chirp-induced current responses at each holding potential were time-averaged. Real and imaginary components of the membrane admittance at all chirp frequencies were determined by FFT in jClamp, and corrected for the roll-off of recording system admittance^{13,24}. This correction controls for all attenuation and phase characteristics of the system, including the filter, as we have shown previously¹³, providing valid estimates of capacitance beyond the filter cut-off. Our dual-sine methodology permitted us to measure capacitance with high fidelity out to 20 kHz across holding potentials¹³. Here using single sine analysis we extend that to 30 kHz.

Our patch pipette inner tip diameters (see Results) were used to estimate the linear capacitance of membrane patches. We estimate a linear membrane patch capacitance of 187.8 ± 15.4 fF (n = 25). This was determined by estimating membrane patch hemispheric surface area using the standard value of 1 μF/cm²²⁵. In our presentation below, we provide absolute estimates of NLC, and specific estimates of NLC by dividing patch admittance with linear capacitance for each patch, thereby accounting for different patch size. Patch experiment data were accepted for inclusion if maximum NLC within our recording bandwidth was >150 fF. Complex values were first averaged for all average-based analyses. Plot traces are smoothed with a 6 point (150 Hz bandwidth) running average in Matlab.

In order to extract Boltzmann parameters, capacitance-voltage data were fit to the first derivative of a two-state Boltzmann function.

$$C_m = NLC + C_{sa} + C_{lin} = Q_{max} \frac{ze}{k_B T} \frac{b}{(1+b)^2} + C_{sa} + C_{lin} \quad (m1)$$

where

$$b = \exp\left(-ze \frac{V_m - V_h}{k_B T}\right), \quad C_{sa} = \frac{\Delta C_{sa}}{(1+b^{-1})}$$

Q_{max} is the maximum nonlinear charge moved, V_h is voltage at peak capacitance or equivalently, at half-maximum charge transfer, V_m is R_s -corrected membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k_B is Boltzmann's constant, and T is absolute temperature. C_{sa} is a component of capacitance that characterizes sigmoidal changes in specific membrane capacitance^{12,26}. Functional prestin density in the membrane is based on quantity of sensor charge.

$$Q_{max} = \left[\frac{4 \cdot k_B \cdot T}{z \cdot e} \right] \cdot NLC_{Vh} \quad (m2)$$

$$Prestin \text{ density} = \frac{Q_{max}}{\text{patch surface area}} \quad (m3)$$

A power fit of NLC across frequency (f) was performed^{13,27}.

$$NLC(f) = NLC_0 + a * f^b \quad (m4)$$

where NLC_0 is the zero frequency component, and a and b control the frequency response.

Results

In our present study, we successfully recorded from 25 macro-patches on the OHC lateral membrane, where membrane breakdown did not occur; breakdown might be expected beyond our voltage protocol voltages²⁸. Our pipette inner tip diameter was 3.45 ± 0.15 μm. R_s of pipettes (under slight positive pressure) in bath prior to patching, determined by step voltages, was 1.34 ± 0.04 MΩ. However, this may not reflect series resistance following patch configuration. We therefore calculated R_s given a typical resistivity for pipette solutions of 100 ohm-cm²⁹, and our pipette taper angle of 0.2 rad; we calculate an R_s of about 920 kΩ. Since the patch membrane extends into the pipette where pipette diameter is larger, we further estimate a reduction of R_s to 735 kΩ. The difference in NLC frequency response provided between measured and calculated R_s were minimal, showing

a -2.2 dB reduction in NLC at 30 kHz for the directly measured values. Below we utilize the calculated value response.

The lateral membrane of the OHC is virtually devoid of voltage-dependent conductances¹¹, and we additionally use channel blockers to insure this. Our seal resistance, determined by linear fit of step induced currents within a linear region of the I-V between -40 and $+40$ mV, was 5.39 ± 0.65 G Ω .

Consequently, the macro-patch membrane, unlike the membrane in whole cell conditions, may be considered an isolated capacitor under voltage clamp, and thus amenable to determination of complex capacitance. In the following analysis of complex capacitance, we follow the methodology of Fernandez *et al.*³⁰, applied to each patch individually, based on its characteristics. The OHC patch capacitance presents as a parallel combination of linear (C_{lin}) and prestin-generated (NLC) capacitance. Conceivably, prestin's voltage-sensor may work as an imperfect, lossy capacitor that possesses both resistive (due to dielectric loss) and capacitive components (e.g., modelled as a combination of capacitor and resistor); that imperfection may influence estimates of NLC¹⁸. In addition to biophysical capacitance, system-generated stray capacitance (C_{stray}) will contribute to our measures. C_{stray} , though voltage-independent, may also possess resistive and capacitive components, its admittance being $Y_{stray}^*(\omega)$. Under voltage clamp, an AC voltage across the patch membrane (V_m) induces an AC current (I_m), where the admittance ($Y_m = I_m/V_m$) is a complex function of angular frequency, $\omega = 2\pi f$ and $i = \sqrt{-1}$

$$Y_m(\omega) = G_m(\omega) + iB_m(\omega) \quad (1)$$

with G_m representing membrane conductance, B_m representing membrane susceptance. Before continuing, we remove the effects of series resistance (R_s) by subtracting it from the real component of membrane impedance $Z_m(\omega)(1/Y_m(\omega))$, and then converting back to admittance³⁰. $Y_m(\omega)$ can be described in more detail,

$$Y_m(\omega) = G_m(\omega) + G_{leak} + Y_{stray}^*(\omega) + i\omega C_m(\omega) \quad (2)$$

where $C_m(\omega) = C_{lin} + \text{NLC}$.

G_{leak} represents a DC leakage conductance. C_{lin} is taken as frequency independent and via small signal analysis we seek to determine the frequency dependence of NLC, after removing $Y_{stray}^*(\omega)$. To our benefit, admittance at $+160$ mV lacks NLC¹²

$$Y_m^{160}(\omega) = G_m(\omega) + G_{leak} + Y_{stray}^*(\omega) + i\omega C_{lin} \quad (3)$$

Thus, subtraction of membrane admittance at $+160$ mV from those corresponding measures at all other holding potentials provides a differential admittance, $Y_m^*(\omega)$, devoid of stray capacitance effects.

$$Y_m^*(\omega) = Y_m(\omega) - Y_m^{160}(\omega) = G_m^*(\omega) + iB_m^*(\omega) \quad (4)$$

Actually, after subtraction, there remains a small differential residual nonlinear, voltage-dependent DC leakage conductance (G_{leak}), which we remove from $G_m^*(\omega)$ by subtraction of the real part of $Y_m^*(\omega)$ at zero frequency. We determine this value to subtract by extrapolating to zero frequency with a linear fit of $\text{Re}(Y_m^*(\omega))$ between 24.41 and 463.86 Hz at each of the stepped holding potentials. This is akin to removing leakage conductance determined by prior DC step estimates, but has the further advantage of being determined during the actual chirp stimulation period.

Complex membrane capacitance, a function of angular frequency, is defined as (see Fernandez *et al.*³⁰)

$$C_m^*(\omega) = \frac{Y_m^*(\omega)}{i\omega} = \frac{B_m^*(\omega)}{\omega} - i \frac{G_m^*(\omega)}{\omega} = C_m^*(\omega) - i C_m^{*''}(\omega) \quad (5)$$

In Fig. 1A, we plot the average capacitive (real, $C_m^*(\omega)$) and apparent conductance (imaginary, $C_m^{*''}(\omega)$) components of the complex capacitance for holding potentials of 40, 0, -40 and -80 mV. The values are voltage dependent. While the capacitive component is large and frequency dependent, the conductance component is smaller and less frequency dependent, differing from a larger component predicted from diffusion-based charge translocation¹⁸.

The absolute magnitude of the complex capacitance can be used to glean an estimate of membrane capacitance ($C_m^1(\omega)$),

$$C_m^1(\omega) = |C_m^*(\omega)| \quad (6)$$

In Fig. 1B, the absolute magnitude, $|C_m^*(\omega)|$, of the complex capacitance is plotted. The lower panel plots the phase angle. The magnitude rolls off continuously across frequency at each holding potential. In Fig. 1C, the data are plotted as a specific complex capacitance, i.e., per linear capacitance of the patches. As found in whole cell recordings, peak NLC can be larger than linear capacitance^{5,6}.

It is also possible to estimate capacitance of the macro-patch membrane by a "phase tracking" approach. That is, the phase angle of the complex admittance $Y_m^*(\omega)$ can be rotated to minimize its real component ($G_m^*(\omega)$), providing a new value (Y_m^{**}), whose imaginary component reflects the capacitive component (susceptance) of the admittance in the absence of conductance interference. Another estimate of membrane capacitance, $C_m^2(\omega)$, can then be obtained.

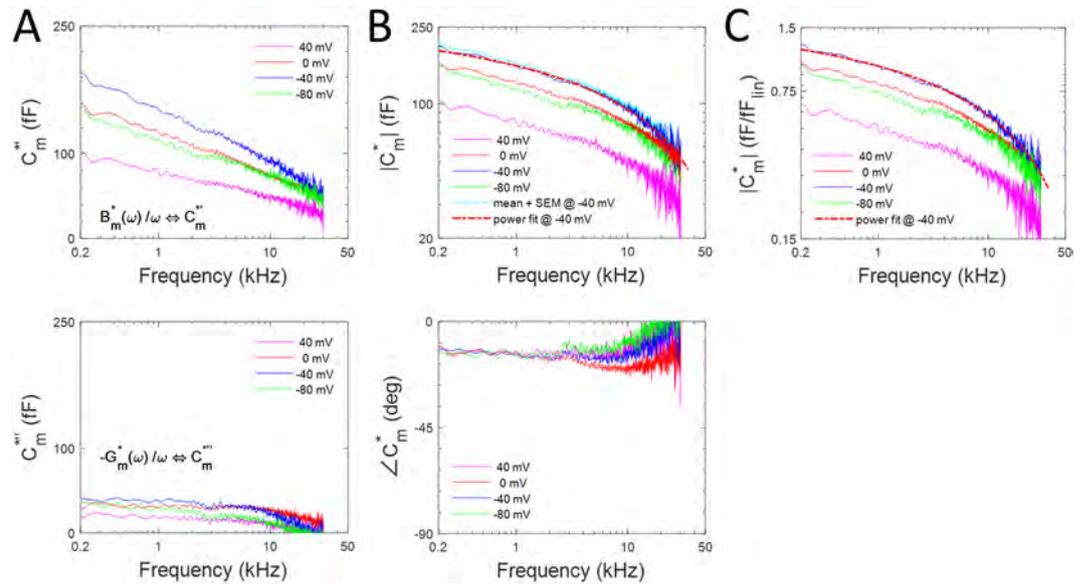

Figure 1. Complex capacitance of OHC lateral membrane macro-patches. (A) Top panel shows the mean real components of complex capacitance at selected holding potentials; bottom panel shows corresponding imaginary parts. (B) Top panel plots mean magnitudes of complex capacitance at different holding potentials. A power function fit of the magnitude at the -40 mV holding potential is shown by the dotted line (red) overlying the mean (dark blue line). The light blue line is the mean + SEM at that same holding potential data. Fit parameters: NLC_0 : 279.17 fF, a: -34.35 , b: 0.18. Bottom panel show the phase of complex capacitance. (C) Plot of the means of complex capacitance magnitude per estimated linear patch capacitance (see Methods). Fit parameters: NLC_0 : 1.71 fF, a: -0.19 , b: 0.19. Note low-pass behavior of magnitude functions.

$$\angle(Y_m^*(\omega)) = \text{atan}\left(\frac{B_m^*(\omega)}{G_m^*(\omega)}\right) \quad (7)$$

$$Y_m^{**} = Y_m^*(\omega) \cdot e^{-i\left(\angle(Y_m^*(\omega)) - \frac{\pi}{2}\right)} \quad (8)$$

$$C_m^2(\omega) = \frac{\text{Im}(Y_m^{**})}{\omega} \quad (9)$$

This approach is similar to traditional real time capacitance phase tracking under voltage clamp³¹, where the capacitive component at the angle of $\delta Y/\delta C_m$ ³² is obtained by adjusting the lock-in recording angle until the conductance component is minimized and the capacitive component is maximized. In that approach, calibration with a known capacitance provides membrane capacitance estimates at the measurement frequency. This approach to measure OHC patch NLC was used by Gale and Ashmore¹⁴.

In Fig. 2A, we plot the two estimates of OHC NLC [$C_m^1(\omega)$, and $C_m^2(\omega)$], corresponding to methods utilizing the complex capacitance magnitude, and the phase tracking approach, respectively – both at -40 mV holding potential (near V_h). The measures overlap, indicating that Eqs. 6 and 9 return the same result. In Fig. 2B, the voltage dependence of the complex capacitance magnitude at selected frequencies, presents a bell-shaped function typical of OHC NLC^{5,6}, whose peak precipitously decreases with frequency, but whose voltage at peak (V_h) remains similar across frequency. These data are fit (Eq. m1) to extract the Boltzmann parameters given in the legend. Prestin density based on fits to capacitance at 1 kHz is $1133/\mu\text{m}^2$, similar to previous estimates at a similar frequency^{8–10}.

Having arrived at practical approaches to estimate OHC patch NLC, we now look at the influence of membrane tension. Several studies under whole cell voltage clamp have found that as membrane tension is increased, NLC V_h shifts in the depolarizing direction, and decreases in peak magnitude^{15–17}. However, utilizing lock-in estimates of lateral membrane patch capacitance instead of the whole cell technique, Gale and Ashmore⁹ found no evidence for a reduction in peak capacitance despite shifts in the depolarizing direction.

In Fig. 3, we explore the effects of membrane tension on the magnitude, $|C_m^*(\omega)|$, of complex NLC across frequency, as it is a robust measure of NLC, equivalent to that obtained with the phase tracking approach. Results at 0, -4 , -8 and -10 mm Hg (i.e., 0, 0.53, 1.06 and 1.33 kPa) pipette pressure are shown in Fig. 3A–D, left panels. Membrane tension shifts V_h , as indicated by the rearrangement of the capacitance magnitude traces as negative pressure alters. For example, in left panel A, the trace at -80 mV (green) is above the trace at 0 mV (red), whereas in left panel D, the positions are reversed. In the right panels, plots of C-V functions of complex capacitance magnitude at the four different pipette pressures are shown (mean \pm SEM, $n = 8$). The depolarizing shift in V_h is

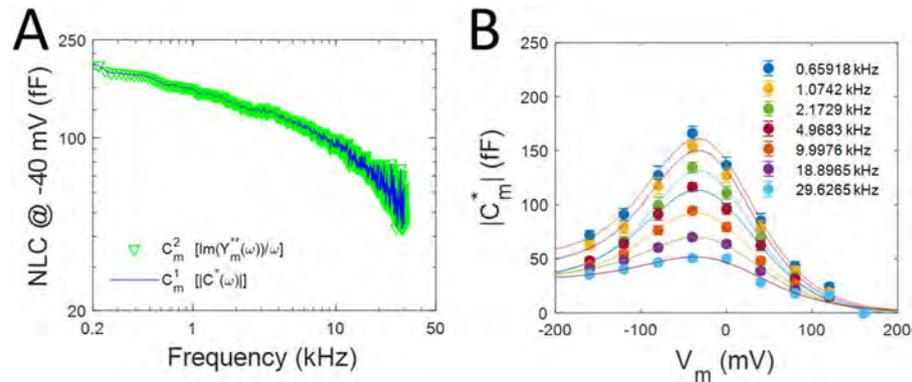

Figure 2. Comparison of two estimates of NLC frequency response at -40 mV holding potential. (A) Each estimate provides equivalent results. (B) C-V plot of complex capacitance magnitude of OHC lateral membrane macro-patches at selected frequencies (mean \pm SEM). Data are fit (Eq. m1) to extract Boltzmann parameters (see Methods). -40 mV is close to V_h . From lowest to highest frequency fit values are (peak NLC, V_h , z): 133.60, 127.61, 115.42, 98.81, 76.81, 52.60, 34.35 fF; -25.2 , -25.3 , -26.0 , -26.4 , -26.9 , -20.6 , -16.4 mV; 0.61, 0.62, 0.62, 0.57, 0.59, 0.56, 0.54. Prior to averaging patch responses ($n = 25$), capacitance values from each patch were obtained by averaging over a bandwidth of about 200 Hz about the listed frequency value.

readily apparent as negative pressure increases (red bars). There is little change in peak capacitance, however. ΔC_{sa} is mainly unaffected by tension.

For comparison of frequency dependence as a function of membrane tension, Fig. 4A replots the peak magnitude traces (-40 mV) from Fig. 3 at the different pipette pressures. The frequency response of complex capacitance magnitude is unaffected by membrane tension, indicated by the overlap of traces. The sensitivity of patch V_h shift to tension was 24.1 mV/kPa based on our fits (Fig. 4B).

We previously measured OHC NLC in macro-patches using a dual-sinusoidal methodology¹³. In Fig. 5, we replot selected NLC_{v_h} data points from that study (yellow circles) alongside NLC_{v_h} data (green circles) from Gale and Ashmore¹⁴. We also plot whole cell data on NLC_{v_h} (rat, mouse and guinea pig) from previous studies that used either the phase-tracking approach or 2-sine methodology. These scaled whole cell data interrogated a frequency bandwidth extending to 5 kHz, and closely follow the attenuation of patch NLC within that bandwidth. The Gale and Ashmore data (green circles, SEM, and fit from their Fig. 3B; in green) are also scaled ($\times 3.5$) to overlie our data. Their measures were made with a lock-in amplifier using a 100 fF calibration at each frequency. Scaling to our data was necessary because our average patch size/capacitance was greater than theirs. As is evident, our previous data intersects their data points, indicating an acceptable correspondence. Finally, extraction of NLC_{v_h} from our new measures (red circles) of patch absolute complex capacitance (from Fig. 3, scaled $\times 1.05$) corresponds well to our previous observations and theirs. We emphasize that the absolute magnitude of complex capacitance ($C_m^1(\omega)$) is equivalent to our phase tracking approach ($C_m^2(\omega)$) to estimate capacitance (Fig. 2), each corresponding to the estimates provided by the traditional phase tracking method³³ employed by Gale and Ashmore¹⁴. In the discussion, despite their assertions, we detail how Gale and Ashmore's data points above their 60 kHz amplifier cut-off are actually valid data points depicting NLC_{v_h}. Capitalizing on the validity of their high frequency data, we combine all three patch data sets in the plot to arrive at a unified power function fit ($r^2 = 0.97$) of NLC_{v_h} across frequency (solid magenta line), which shows precipitous roll-off of sensor charge movement relative to voltage drive. Fitted parameters are NLC₀: 185.2 fF, a : -7.22 , and b : 0.28. At 77 kHz, NLC_{v_h} is 40 dB down from NLC₀. Furthermore, since each method takes into account the dielectric loss in prestin, we conclude that this dielectric loss does not significantly account for the low-pass nature of prestin charge movement. To further substantiate this claim, we make another estimate of membrane capacitance, $C_m^3(\omega)$, one that does not take into account dielectric loss, but is appropriate for a loss-less capacitor.

$$C_m^3(\omega) = \frac{\text{Im}(Y_m^*(\omega))}{\omega} = \frac{B_m^*(\omega)}{\omega} \quad (10)$$

Figure 6 shows the results for our three estimates of prestin capacitance [$C_m^1(\omega)$, $C_m^2(\omega)$ and $C_m^3(\omega)$], all reasonably overlying each other, and exhibiting low-pass behavior. Thus, all results available to date show an unusually low-pass behavior of prestin voltage-sensor performance, with little influence of dielectric loss.

Discussion

We previously evaluated OHC macro-patch NLC frequency dependence utilizing a dual-sine methodology that worked on extracted prestin displacement currents¹³. That approach did not allow separation of real and imaginary components of NLC. Here we provide an analysis of OHC NLC in membrane macro-patches utilizing single sine methods that have been used to characterize gating charge movements in other voltage-dependent proteins³⁰, where real (capacitive) and imaginary ("resistive", representing dielectric loss) components of sensor charge are separated. We explored these alternative approaches in order to determine whether new estimates of NLC frequency response incorporating the influence of dielectric loss would substantially alter our previous estimates,

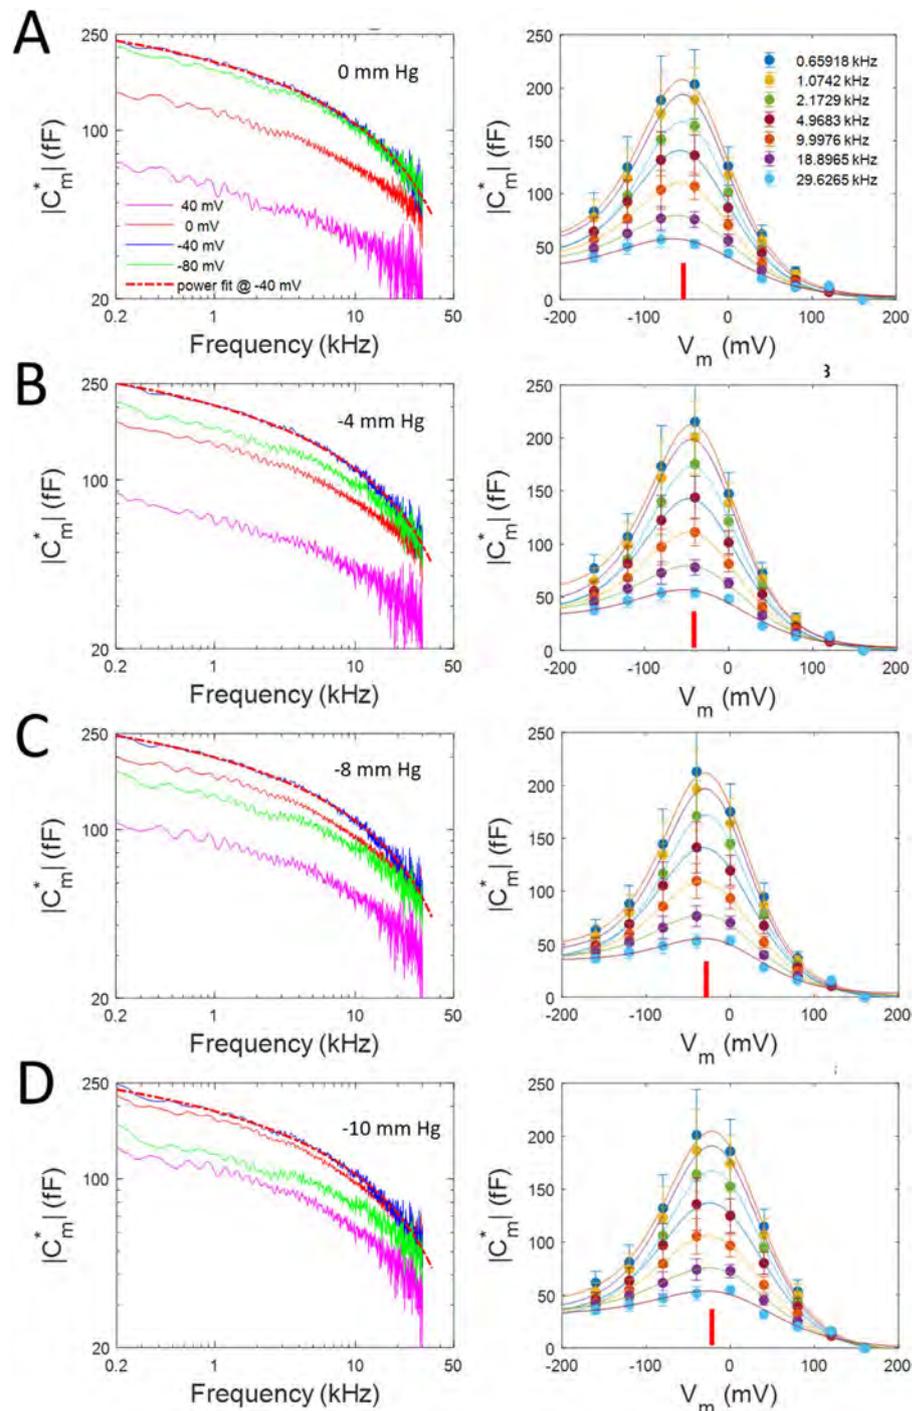

Figure 3. Effect of membrane tension on magnitude of complex capacitance voltage and frequency dependence. Panels (A–D) depict results at 0, –4, –8 and –10 mm Hg pipette pressure. The effect of membrane tension is to shift V_h , as indicated by the change in voltage at maximal capacitance as negative pressure increases, without appreciably altering frequency response (dotted lines are fits to a power function). On the right, C–V plots of complex capacitance magnitude at the four different pipette pressures are shown. Red bars indicate voltage at peak capacitance. The depolarizing shift in V_h is readily apparent as pressure increases. Peak magnitudes do not appreciably alter. ΔC_{ss} is tension and frequency independent. Mean \pm SEM ($n=8$). From lowest to highest frequency fit values from Eq. m1 are (peak NLC, V_h , z): Panel A, 179.15, 166.45, 146.43, 120.30, 88.90, 62.62, 41.51 fF; –49.4, –49.0, –49.0, –50.9, –49.0, –48.2, –51.2 mV; 0.70, 0.71, 0.71, 0.66, 0.70, 0.58, 0.53; Panel B, 182.80, 175.62, 153.91, 124.40, 91.56, 60.38, 39.08 fF; –38.5, –40.0, –39.4, –40.7, –39.4, –36.4, 35.8 mV; 0.74, 0.72, 0.72, 0.67, 0.66, 0.60, 0.57. Panel C, 187.73, 175.16, 155.35, 124.08, 90.68, 57.97, 34.77 fF; –25.9, –25.7, –25.7, –26.2, –26.0, –20.6, –14.5 mV; 0.73, 0.73, 0.72, 0.67, 0.66, 0.62, 0.65. Panel D, 185.03, 175.67, 156.00, 124.51, 91.22, 58.39, 36.32, fF; –17.2, –17.7, –18.0, –18.1, –8.8, –12.3, –8.0 mV; 0.67, 0.66, 0.66, 0.61, 0.60, 0.58, 0.55.

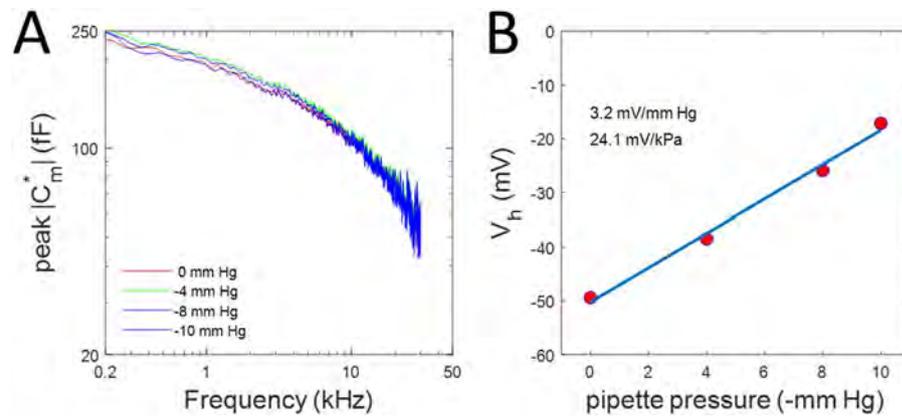

Figure 4. Effects of membrane tension on NLC frequency response and operating voltage. **(A)** Comparison of NLC frequency response at -40 mV at four pipette pressures. Roll-off is equivalent as indicated by overlap of traces. **(B)** V_h of NLC at the lowest frequency in Fig. 3 is plotted versus pipette pressure. A linear fit (blue line) indicates a sensitivity of 24.1 mV/kPa.

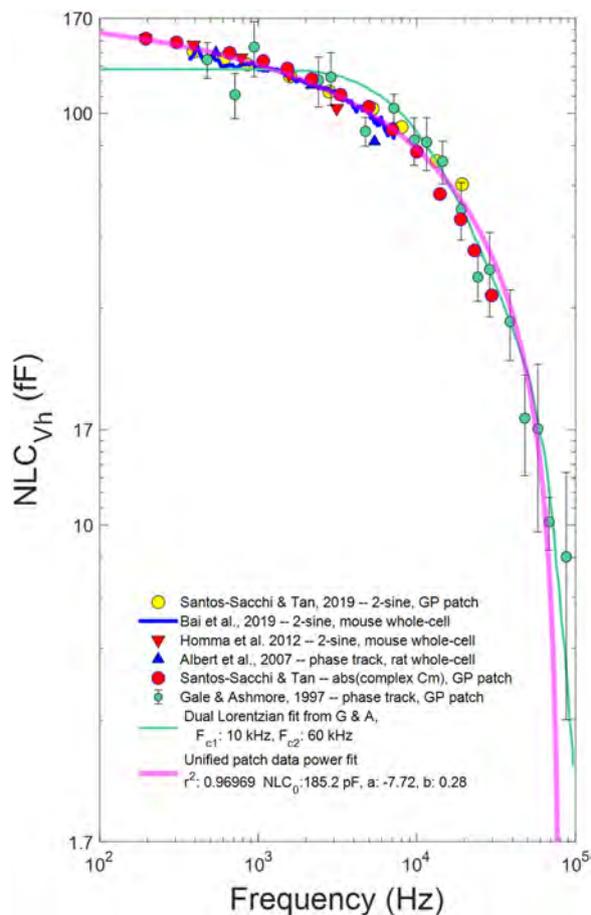

Figure 5. Replot of some whole-cell NLC data^{27,45,46}, and NLC patch data from Santos-Sacchi and Tan¹³ with those of Gale and Ashmore¹⁴. Using a dual-sine capacitance estimation algorithm, NLC of OHC patches (yellow circles) overlie the data of Gale and Ashmore, collected with a traditional phase tracking approach using a lock-in amplifier (data: green circles; their fit green solid line). Whole cell data, both 2-sine and phase-tracking, show a similar frequency response within their interrogation bandwidth. Finally, NLC_{Vh} (red symbols) obtained from Eq. m1 fits of our complex capacitance data (obtained as in Fig. 2B) are also commensurate with previous observations, giving a unified power fit for the patch data (magenta line; see Discussion) with parameters NLC_0 : 185.2 fF, a : -7.22 , b : 0.28.

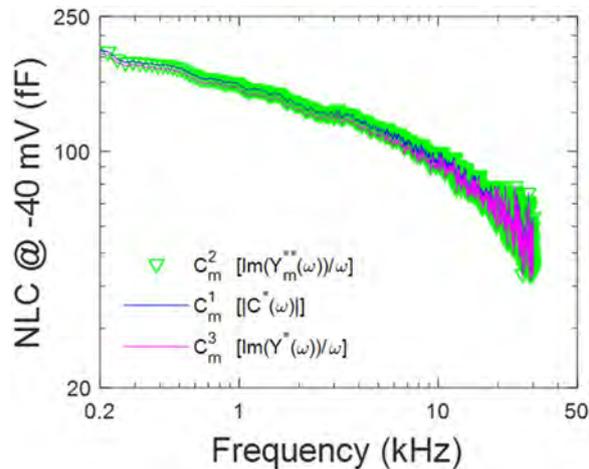

Figure 6. Three estimates of the frequency response of NLC at -40 mV holding potential. Estimates from raw admittance data (pink line) reasonably compare with the other estimates despite the fact that the real component is not taken into account.

as was predicted through modelling¹⁸. This is not the case, however. Thus, the bulk of prestin charge movement appears to move in phase with voltage, and the small dielectric loss that we find does not significantly influence measures of OHC NLC frequency response.

It was previously noted that low frequency determined OHC NLC (C-V) measures are unable to identify whether prestin charge movement is multistate/diffusional in nature^{8,34}. However, wide-band frequency interrogation of prestin NLC may provide clues. In this regard, the large bell-shaped (across frequency) resistive component of complex capacitance, which is associated with DPA^- voltage-driven translocation through bulk membrane lipid³⁵, and which Sun *et al.*¹⁸ predicted for prestin modelled as a simple diffusion process of charge translocation is not found here. The resistive component we measure is relatively small and flat across frequency (Fig. 1A, lower panel). This is likely because prestin charge movement is not a diffusional process, but instead similar to gating charge movement in other membrane proteins. Thus, Fernandez *et al.*³⁶ found that whereas chloroform, which alters membrane viscosity, can influence the speed of DPA^- charge translocation within the membrane, Na channel voltage-sensor charge translocation speed is not affected. Similarly, sensor charge in prestin is likely constrained to charged protein residues that move during protein conformational change³⁷. Indeed, Sun *et al.*'s model included membrane diffusion of chloride ions as voltage sensors in prestin. However, chloride anions do not solely function as extrinsic voltage sensors for prestin, nor do they move through bulk lipid; instead they likely influence prestin kinetics^{13,38,39} (also see our comment #1 on Walter *et al.* eLife 8, 2019 - <https://elifesciences.org/articles/46986>)⁴⁰.

Prestin's voltage operating range, whose midpoint is at V_h , is very sensitive to membrane tension¹⁵. Here, we measured the effect of membrane tension on prestin performance by changing patch pipette pressure to study its influence on NLC frequency response. The average sensitivity of patch V_h shift to tension was 24.1 mV/kPa, which corresponds well to our previous measures¹⁷ in whole cell mode of 21.6 mV/kPa. Adachi *et al.*⁴¹ found similar sensitivity in whole cell mode (27.5 mV/kPa). Gale and Ashmore⁹, in their patches, found a somewhat smaller sensitivity of 11.1 mV/kPa. In prestin transfected cells, values of near 4 mV/kPa were found^{42,43}. One mechanism whereby shifts in V_h might occur would be due to changes in the ratio of transition rates between its conformational states. Naturally, if this were occurring then changes in NLC frequency response might arise. We found no change in NLC magnitude, similar to results of Gale and Ashmore⁹, or frequency response during alterations in membrane tension, and conclude that tension is not altering transition rates. Indeed, we previously found that membrane tension in whole cell mode did not significantly alter the phase or frequency response of electromotility⁴⁴. This is in contrast to salicylate which likely alters transition rates since NLC frequency response is affected¹³.

Lastly, we revisited the seminal patch data of Gale and Ashmore¹⁴, along with those whole-cell NLC measures of others^{27,45,46}, and recast our current and previous patch data¹³ with those prior results on OHC NLC. The small variability within our current and previous patch NLC data set allowed us to identify a power dependence of frequency, whereas Gale and Ashmore originally applied a Lorentzian fit. Their interpretation of NLC frequency response requires re-examination. They asserted that their capacitance measures made above their amplifier's 60 kHz cut-off frequency were inaccurate, being unduly reduced by this cut-off. However, the amplifier's transfer function effect on the phase tracking approach^{24,31,33} is inconsequential, since the lock-in phase is adjusted to maximize the imaginary (capacitive) component and minimize the real (resistive) component of the recorded signal. That is, the phase shift due to the amplifier was eliminated, and amplifier attenuation was corrected by their 100 pF calibration. Thus, their small-signal capacitance measurement was truly that of the patch membrane (and possibly non-voltage dependent stray capacitance), but when fitted by a Boltzmann derivative across voltage, provided valid, *not invalid*, estimates of voltage-dependent OHC NLC *above the amplifier cut-off*. Consequently, their fit to OHC NLC data at V_h , which included the amplifier roll-off component, actually provided a dual-Lorentzian evaluation of OHC NLC, and their conclusion that only the lower frequency Lorentzian component of the fit

fully characterized the behavior of OHC NLC (10 kHz cut-off) was misplaced. Furthermore, their interpretation suggested that OHC NLC roll-off is 6 dB/octave, when, in fact, roll-off is more than double that at high frequencies and is actually frequency dependent. Finally, the proposed inaccuracies in their high frequency estimates provided leeway to dismiss low-pass NLC indications of electromechanical behavior in favor of eM measures that were flat beyond 80 kHz⁴⁷, the latter driving our concept of OHC eM's wideband influence on cochlear amplification over the last couple of decades. In addition to all of our frequency evaluations of OHC NLC, past^{13,20,23,48,49} and present, recent eM measures, *in vitro* and *in vivo*, have challenged that concept^{20,44,48,50}.

In summary, Fig. 5 shows that a power function fit to all patch data to-date reasonably describes the roll-off in NLC_{V_h} . This unifying observation highlights an inability of voltage to sufficiently drive prestin electromechanical activity at very high frequencies (60–160 kHz), where CA (cochlear amplification) is known or expected to exist. The additional low pass influence of external loads on the whole cell eM frequency response and the frequency-dependent RC membrane time constant that we characterized recently⁴⁸, also lessens the effectiveness of voltage-dependent eM in influencing organ of Corti motion at very high frequencies. This point is further emphasized by experiments showing that perilymphatic perfusion of 5 mM salicylate or its congener is devastating to CA^{51,52}. Considering the 1.6 mM $K_{1/2}$ of salicylate action, the effect of the perilymphatic treatment is not a full block of NLC, but rather about 75% (12 dB) reduction⁵³. Thus, the reduction in NLC resulting from its power frequency dependence (12 dB down at 25 kHz, 20 dB down at 53 kHz, and 40 dB down at 77 kHz; Fig. 5) likely has biological impact across the full auditory frequency spectrum of mammals, and indicates a continuously diminishing influence of voltage alone to drive prestin electromechanical activity and CA via a cycle-by-cycle means. As a caveat, it may be possible that at any given frequency the measured NLC/eM amplitude is sufficient to drive CA, as we implied previously^{20,54}, and that a reduction in CA that might occur with salicylate could be working on the existent magnitude at that particular frequency.

Two additional issues need to be addressed. They are temperature dependence, and species dependence of NLC frequency response. It is likely that temperature dependence of NLC frequency response is not so great (Q_{10} of 1.33), as Gale and Ashmore (1997) have directly attested to in membrane patches. We had previously argued that because V_h is highly temperature sensitive^{55,56}, the kinetics of prestin should be, as well – we estimated a Q_{10} of 2 based on modelling of V_h shifts observed in IR temperature jump experiments⁵⁷. But, since we now find that membrane tension does not influence prestin kinetics, in spite of shifts in V_h , it is possible that temperature-induced shifts, likewise, work not through kinetics, but by some other means. Given that one-half magnitude NLC is at 7 kHz (from the power fit, Fig. 5), a Q_{10} of 1.33 would increase the cut-off to only about 10 kHz. Concerning species specificity, the data so far do not support such differences, since rat, mouse and guinea pig show similar frequency responses (see Fig. 5). Whether genetic variations in prestin that have been observed in mammals that capitalize on very high frequency detection^{58,59} could change this view remains possible, and we need to test these species. Currently, however, how CA is driven by OHCs in the basal high frequency turn of mammals that enjoy perception of sound above 60 kHz is an enigma.

RAPID COMMUNICATION

Potentialiation of the cGMP-Induced Guinea Pig Acrosome Reaction by Zinc

JOSEPH SANTOS-SACCHI, MILDRED GORDON, AND WILLIAM L. WILLIAMS
School for Biomedical Education, The City College, New York, NY 10031 (J.S.-S., M.G.), and Population Council, Center for Biomedical Research, Rockefeller University, New York, NY 10021 (W.L.W.)

ABSTRACT The addition of 8 bromo cGMP (10 mM) immediately (~2 min) upon suspension of Guinea pig sperm in glucose-free BWW medium induces a significant number of acrosome reactions within minutes. The simultaneous addition of micromolar concentrations of $ZnCl_2$ (25–1000 μM) potentiates the cGMP effects. Mid-micromolar concentrations were able to dramatically increase the percentage of acrosome reactions by a factor of 6.5 over 8 bromo cGMP alone. The induction of acrosome reactions was dependent upon external Ca^{++} , and it is suggested that in this species Zn^{++} functions by affecting cyclic nucleotide metabolism and/or Ca^{++} flux.

Considerable attention has been focused upon the role of Zn^{++} in sperm metabolism. For example, it has been shown that removal of bound Zn^{++} from human sperm increases both oxygen uptake and motility (Huacuja et al., '73), whereas incubation of sperm with Zn^{++} reduces motility (Holland et al., '76). Johnsen and Eliasson ('78) have demonstrated that a reduction of membrane-associated Zn^{++} promotes membrane destabilization in human sperm, as indicated by an increased susceptibility to lipid peroxidation. Results such as these have led some workers to speculate that spermatozoal Zn^{++} depletion may be involved in the capacitation process (Johnsen and Eliasson, '76, '78) and, indeed, some evidence exists in support of this. Aonuma et al. ('78) have shown that mouse sperm preincubated with zinc (250 μM) are unable to fertilize eggs, and by experimental manipulation they related the zinc effects to an inhibition of capacitation. Williams and Lenz ('79) showed that zinc salts were effective vaginal contraceptives in the rabbit. Meizel and Lui ('76) determined that incubation of hamster sperm with zinc (250 μM) as well as synthetic trypsin inhibitors, (Lui and Meizel, '79) dramatically inhibited the acrosome reaction (AR). Thus, zinc may well influence the critical events necessary for egg penetration.

Recently, Santos-Sacchi and Gordon ('80) have demonstrated that the Guinea pig sperm acrosome reaction can be induced by exoge-

nous cyclic guanosine monophosphate (cGMP) analogues, and they suggested that a rise in the cGMP/cAMP ratio is the critical effector of the AR. Because Zn^{++} has been shown to inhibit adenylate cyclase in human sperm (Haesungcharern and Chulavatnatol, '78), it seemed worthwhile to study the effects of zinc upon the cGMP-induced Guinea pig acrosome reaction.

MATERIALS AND METHODS

Guinea pig cauda epididymal spermatozoa were extruded into 0.9% NaCl in H_2O , disaggregated by pipetting, and washed two times by centrifugation (1,000 g, 4 min each). Spermatozoa were then suspended in glucose-free BWW medium (NaCl 94.59 mM, KCl 4.7 mM, $CaCl_2$ 1.71 mM, KH_2PO_4 1.19 mM, $MgSO_4$ 1.19 mM, $NaHCO_3$ 25.07 mM, pyruvate 0.25 mM, lactate 21.58 mM, and bovine serum albumin 1 gm/L) at a final concentration of 2×10^7 spermatozoa/ml and were incubated at 37°C in capped tubes under an air atmosphere. Calcium-free medium was also employed. Media were prepared immediately prior to use.

Address reprint requests to Mildred Gordon, School for Biomedical Education, the City College, 138th St. and Convent Ave., New York, NY 10031.

After October 1, 1980, William L. Williams will be at the following address: Reproduction Research Labs, Dept. of Biochemistry, University of Georgia, Athens, GA. 30602.

The initial pH was adjusted to 7.55 and throughout experiments remained less than 8.20.

Immediately (~2 min) after suspension of sperm in glucose-free BWW, various combinations of the following agents were added to sperm samples: 8 bromo cGMP, 8 bromo cAMP, 8 bromo GMP and ZnCl₂ (Table 1). The bromo analogues were chosen because they proved to be more efficacious than dibutyryl cyclic nucleotides (Santos-Sacchi and Gordon, '80). After 20 min incubation with these agents, acrosome reactions were assessed by hemocytometer. At least five chambers (0.5 mm³ each) were counted for each condition. Care was taken to count all cells through the 0.1 mm counting chamber depth. Standard errors of the mean averaged less than 15%. Results are reported as percentage of acrosome reactions in the total motile sperm population (%AR^{tot} = [conc. of AR spermatozoa/conc. of total spermatozoa - conc. of immotile spermatozoa] × 100) (Santos-Sacchi and Gordon, '80). The onset of the AR and activated motility were qualitatively evaluated over time by light and differential interference microscopy. Spermatozoa were processed for electron microscopy (Gordon, '73) and examined with a Philips 300EM at 80kV.

RESULTS

Table 1 presents the percentages of acrosome reactions induced by various agents. Whereas 8 bromo cGMP alone was able to induce a significant number of acrosome reactions, the simultaneous addition of micromolar concentrations of Zn⁺⁺ enhanced its effect, and this effect was concentration-dependent. The highest potentiating effects of Zn⁺⁺ were observed at mid-micromolar concentrations, where a 6.5-fold increase in the percent of acrosome reactions was obtained over 8 bromo cGMP alone. The presence of Ca⁺⁺ was nec-

essary for the induction of acrosome reactions. Zinc ions alone (250 μM) or in combination with 8 bromo cAMP or 8 bromo GMP were essentially an ineffective inducer of the acrosome reaction. In addition, zinc ions (250 μM) added at 0 time had no effect upon the percent of acrosome reactions present after 5 hr incubation in glucose-free BWW (Zn⁺⁺: 5.94 ± 0.91% vs. no Zn⁺⁺: 5.92 ± 0.61%).

Upon the addition of 8 bromo cGMP alone or in combination with Zn⁺⁺, sperm become extremely active within minutes. By 5-10 min activated, acrosome-reacted sperm were observed, and by 15-25 min a maximum was reached. Acrosome-reacted sperm remained motile for at least 2 hr, after which increasing numbers became immotile. Differential interference and electron microscopy indicate that the induced reactions are physiological, as previously determined for the cGMP-induced AR (Santos-Sacchi and Gordon, '80).

DISCUSSION

Cyclic GMP analogues are able to induce acrosome reactions in Guinea pig sperm, and this ability was found to be dependent upon the time of addition after initial suspension in media (Santos-Sacchi and Gordon, '80). That is, a dramatic increase in the ability of 8 bromo or dibutyryl cGMP (10 mM) to induce acrosome reactions was observed over a 1 hr period (0 hr: < 1% vs. 1 hr: ≥ 13%). This increased ability was correlated with a decrease in sperm cyclic AMP levels during 1-hr incubation. The present finding that Zn⁺⁺ in micromolar concentrations can potentiate the action of cGMP analogues may be explained by its ability to inhibit adenylate cyclase (Haesungcharern and Chulavatnatol, '78). Thus, the addition of Zn⁺⁺ may further increase the cGMP/cAMP ratio, thereby promoting Ca⁺⁺ influx and the acrosome reaction. Spermatozoa will not acrosome-react in cal-

TABLE 1. %AR^{tot} score induced by addition of agents immediately after suspension of sperm in glucose-free BWW

cium-free media (Yanagimachi and Usui, '74) nor in calcium-free media containing micromolar concentrations of Zn^{++} and 8 bromo cGMP. Furthermore, the addition of Zn^{++} alone had no effect upon acrosome reaction induction. These data suggest that while Zn^{++} cannot substitute for Ca^{++} , it is possible that optimal concentrations of Zn^{++} affect intracellular Ca^{++} availability and distribution, perhaps by promoting release of bound Ca^{++} , thereby potentiating the effect of a cGMP-induced Ca^{++} influx.

Data from several sources indicate that Zn^{++} profoundly affects sperm function. For example, vaginal inserts of several zinc salts result in the reduction or absence of fertilized ova in mated does (Williams and Lenz, '79). Interestingly, *in vitro* experiments with hamster sperm gave results that are opposite from those with the Guinea pig. Whereas Zn^{++} (250 μ M) in the present study was unable to inhibit acrosome reactions in Guinea pig sperm, it has been reported to inhibit hamster sperm acrosome reactions (Meizel and Lui, '76). Furthermore, it was recently reported that TLCK (a synthetic trypsin inhibitor) actually increased the number of acrosome reactions in Guinea pig sperm as compared to controls (Vitug et al., '79), while the same compound was found to inhibit hamster acrosome reactions (Meizel and Lui, '76; Lui and Meizel, '79). We have observed a potentiation of cGMP-induced Guinea pig acrosome reactions by TLCK (unpublished results). Species differences may be the underlying reason for such disparities.

Mapping the Distribution of Outer Hair Cell Voltage-Dependent Conductances by Electrical Amputation

J. Santos-Sacchi, G.-J. Huang, and M. Wu

Sections of Otolaryngology and Neurobiology, Yale University School of Medicine, New Haven, Connecticut 06510 USA

ABSTRACT The mammalian outer hair cell (OHC) functions not only as sensory receptor, but also as mechanical effector; this unique union is believed to enhance our ability to discriminate among acoustic frequencies, especially in the kilohertz range. An electrical technique designed to isolate restricted portions of the plasma membrane was used to map the distribution of voltage-dependent conductances along the cylindrical extent of the cell. We show that three voltage-dependent currents, outward K, $I_{K,n}$, and I_{Ca} are localized to the basal, synaptic pole of the OHC. Previously we showed that the lateral membrane of the OHC harbors a dense population of voltage sensor-motor elements responsible for OHC motility. This segregation of membrane molecules may have important implications for auditory function. The distribution of OHC conductances will influence the cable properties of the cell, thereby potentially controlling the voltage magnitudes experienced by the motility voltage sensors in the lateral membrane, and thus the output of the “cochlear amplifier.”

INTRODUCTION

The outer hair cell (OHC) plays a pivotal role in mammalian auditory perception (see Dallos, 1992). In addition to being one of the two sensory type cells in the organ of Corti, the OHC is capable of voltage-dependent mechanical responses that appear to provide feedback into the basilar membrane, thereby enhancing the passive mechanical vibration of the cochlear partition (Brownell et al., 1985; Ashmore, 1987; Santos-Sacchi and Dilger, 1988; Ruggero, 1992). Electrophysiological and ultrastructural evidence indicates that membrane-bound voltage sensor-motor elements control OHC length (Santos-Sacchi, 1990, 1991, 1992; Ashmore, 1990, 1992; Kalinec et al., 1992; Forge, 1991; Iwasa, 1993). These molecular motors reside predominantly within the lateral plasma membrane of the OHC (Dallos et al., 1991; Huang and Santos-Sacchi, 1993, 1994).

The voltage-dependent nature of OHC motility necessarily indicates that factors which influence the voltages generated in the cell are capable of having an impact on the cell's role in hearing. Although the driving force for OHC motility is the voltage generated by the gating of transduction channels in the stereocilia of the apical membrane (Evans and Dallos, 1993), ultimately, receptor potentials may be modulated by ionic conductances located in the basolateral membrane. A variety of ionic channel types is found in the basolateral membrane (see Ashmore, 1994), including voltage-dependent K and Ca channels (Santos-Sacchi and Dilger, 1988; Ashmore and Meech, 1986; Nakagawa et al., 1991; Housley and Ashmore, 1992). We focus here on the distribution of these voltage-dependent conductances in the cylindrical OHC, because the arrange-

ment of such conductances within the membrane will affect the cell's cable properties and the corresponding driving force imposed on the distributed system of OHC molecular motors. We demonstrate through an electrical isolation technique that voltage-dependent ionic conductances are restricted to the basal pole of the OHC. These results augment our concept of the highly partitioned nature of the OHC membrane, i.e., that mechano-electrical transduction (sensory) resides within the apical membrane, electromechanical transduction (motor) resides within the lateral membrane, and voltage-gated channels (and synaptic machinery) reside within the basal membrane.

Preliminary presentations of these data have been made (Santos-Sacchi, 1995; Santos-Sacchi and Huang, 1996).

METHODS

Guinea pigs were overdosed with pentobarbital. The temporal bones were removed and OHCs were isolated from the cochleas by gentle pipetting of the isolated top two turns of the organ of Corti in Ca-free medium with collagenase (0.3 mg/ml). The cell-enriched supernatant was then transferred to a 700- μ l perfusion chamber, and the cells were permitted to settle onto the coverglass bottom. All experiments were performed at room temperature ($\sim 23^\circ\text{C}$). A Nikon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical recording. Cell lengths ranged from $\sim 60\ \mu\text{m}$ to $80\ \mu\text{m}$.

We have developed a technique for electrically amputating portions of the OHC so that characteristics of restricted areas of the plasma membrane can be analyzed in isolation (Huang and Santos-Sacchi, 1993). The technique involves a double voltage-clamp protocol with two independent clamp amplifiers. Utilizing the partitioning microchamber of Evans et al. (1991) in combination with whole-cell voltage clamp, we are able to electrically amputate that portion of the OHC housed within the chamber (see Fig. 1 A). That is, when identical voltage clamp stimuli are simultaneously delivered to the microchamber and the cell interior, only that portion of the membrane outside the chamber is excited. The efficiency of this amputation technique is dependent upon the seal (shunt resistance) that the microchamber makes with the OHC, and we have determined that a seal of $>5\text{--}10\ \text{M}\Omega$ is sufficient and obtainable (Huang and Santos-Sacchi, 1993). By grounding the microchamber interior, the cell is put equivalently and simply under the whole-cell voltage-clamp condition. Incremental amputations were made by moving the cell into or out of the chamber with

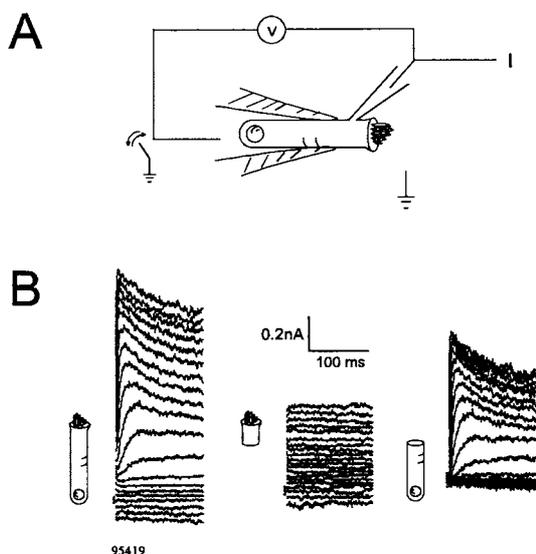

FIGURE 1 (A) Schematic of an outer hair cell, two-thirds of which is inserted into a microchamber and whole-cell voltage-clamped via a patch pipette. The microchamber and perfusion dish contain extracellular solution (see Methods). Identical voltage protocols are delivered to both microchamber and patch pipette to electrically isolate properties of the extruded portion of the cell. Grounding the microchamber (or clamping to zero) provides whole-cell measures. Membrane current is measured via the patch pipette. (B) OHC is held at -80 mV and nominally stepped from -120 to $+90$ mV in 10 -mV increments. Series resistance corrected traces depict currents from -110 to $+80$ mV in 10 -mV increments. Residual series resistance: 5.6 M Ω . OHC figures indicate the portion of the cell from which associated currents arise. (Left) Whole-cell condition. (Middle) Currents obtained by amputating the basal two-thirds of the cell, that is, deriving from the apical one-third of the OHC. (Right) Subtraction of currents resulting in those attributable to the basal two-thirds of the cell. Note that time- and voltage-dependent outward K currents are restricted to this region of the cell.

slight suction or pressure, while simultaneously moving the whole-cell patch pipette via a motorized manipulator. Fortunately, the membrane is somewhat giving, so that sometimes seals are maintained during the motion. Because the microchamber orifice diameter was smaller than initial OHC diameter and during the course of recording under whole-cell mode OHCs typically swell somewhat (cells were monitored with video), we are confident that shunt resistances remained adequate. Transmembrane currents were measured via the patch pipette. Patch pipette series resistance was estimated after the establishment of whole-cell configuration from the transient current response induced by a 10 -mV step (Huang and Santos-Sacchi, 1993).

To study voltage-dependent K currents, the cells were bathed in a modified Leibovitz medium containing (in mM): NaCl 142.2, KCl 5.37, CaCl₂ 2, MgCl₂ 1.48, HEPES 5, with 300 mOsm osmolarity (adjusted with dextrose) and pH 7.2. The intracellular solution was (in mM): KCl 140, EGTA 10, MgCl₂ 2, and HEPES 5, with 300 mOsm and pH 7.2. The K currents were studied at holding potentials of either -80 mV or -60 mV. The latter holding potential was used to observe $I_{K,n}$, a K current that is active at rest but deactivates at hyperpolarized potentials (Housley and Ashmore, 1992). To study the inward Ca conductance, Ba was used as the charge carrier. After the formation of whole-cell configuration in normal bath solution, barium solution (in mM: BaCl₂ 100, MgCl₂ 2, tetraethylammonium 35, 4-amino pyridine 5, CsCl 5, HEPES 10) was perfused. Intracellular solution was (in mM): CsCl 140, EGTA 10, MgCl₂ 2, HEPES 5. Osmolarity and pH were adjusted as above. Typically, OHCs were stepped from the holding potential in nominal increments of 10 mV to a range of potentials. For the identification of inward Ca currents, leakage subtraction was performed with the $P/4$ technique.

Although averaging and subtraction of ionic currents are routinely performed to evaluate the effects of a variety of treatments, problems may arise because of residual series resistance. Essentially, current traces may not have been obtained at constant voltage. Because the OHC has a relatively low resting membrane resistance and large voltage-dependent conductances, this problem may be intensified. To overcome this problem and allow averaging and subtraction of current traces, point-by-point I - V curves were constructed, and each nominal voltage was corrected by subtracting the voltage drop across the series resistance. Currents at fixed voltage increments were then obtained through interpolation, so that generated current traces represented true currents at 10 -mV increments. Because only interpolation was used, the complete range of corrected trace voltages was sometimes less than the nominal voltage range. Valid manipulations of current traces were then feasible. It should be noted that these corrections did not alter the experimental conclusions, because analyses without series resistance correction produced qualitatively similar results. Data collection was performed with either pClamp (Axon Instruments, CA) or a Windows-based voltage-clamp program, jClamp, both utilizing an Axon AD1200 A/D board. Analyses were performed with the software program MATLAB (Mathworks, MA) or jClamp.

RESULTS

The OHC possess a prominent voltage-dependent outward K current (Fig. 1 B, left; Ashmore and Meech, 1986; Santos-Sacchi and Dilger, 1988; Santos-Sacchi, 1989). Fig. 1 B (middle) illustrates the effects of electrically amputating the basal two-thirds of the OHC plasma membrane on the currents measured through the patch pipette; the remaining currents are attributable to the apical third of the cell. Note that activation of time- and voltage-dependent K conductances is absent. An essentially linear response is observed. The right panel demonstrates, by subtracting the apical currents from the whole-cell currents, the response of the basal two-thirds of the cell. It is clear that K currents are restricted to this area, and that little leakage current is present.

It is possible, although not at all easy, to progressively amputate smaller and smaller portions of an OHC body so that a more precise distribution of the K conductances can be obtained. Fig. 2 A illustrates average results ($n = 3$) from such successful single-cell amputations, where, in each case, four successive amputations were accomplished. The left panel depicts the whole-cell current before each partitioning condition. Slight changes in what appears to be leakage conductance are probably produced by the inescapable trauma of cell manipulation. Nevertheless, these relatively small effects are essentially eliminated by the resultant current subtractions that follow. The middle panel shows the currents generated by the apical portions of the cells as the amputation is restricted to more basal regions. Note that voltage-dependent conductances are progressively uncovered as the amputation is lessened. The right panel reveals, through subtraction as in Fig. 1, the decrease in K current magnitude as measures are restricted to smaller and smaller regions of the basal pole. In Fig. 2 B, the I - V plot obtained from the right panel emphasizes that reductions in K current are not observed until amputation falls below the supranuclear region; this, of course, indicates that the voltage-dependent K conductance of the OHC resides below the

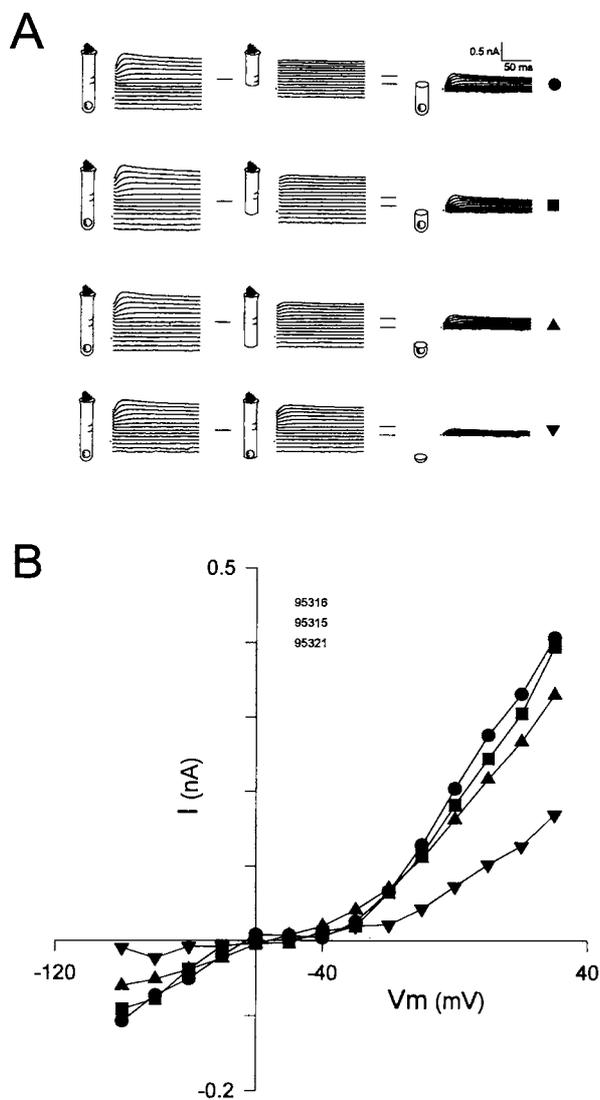

FIGURE 2 (A) Series resistance corrected and averaged current traces from three cells, each of which was successfully amputated at four positions. Each OHC was held at -80 mV and nominally stepped from -120 to $+90$ mV in 10 -mV increments. Corrected traces depict currents from -100 to $+30$ mV in 10 -mV increments. Average residual series resistance: 8.38 M Ω . OHC figures indicate portion of cell from which associated currents arise. (Left) Whole-cell condition obtained before amputation. (Middle) Apically restricted currents obtained by amputating four incrementally larger portions of the OHC's base. (Right) Subtraction of currents resulting in those attributable to the basal portions of the cell. (B) Peak current versus step potential obtained from the traces in A, right panel.

supranuclear region. Fig. 3 summarizes the results of electrical amputation by further subtracting the current traces to provide discrete localization of K currents along the basal extent of the cell. A total of 13 additional cells, where at least two incremental amputations were made, provided similar results.

Another prominent OHC K current that is active near rest and is believed to govern the cell's resting potential (Housley and Ashmore, 1992) is that of $I_{K,n}$. The current is characterized by a nearly instantaneous onset upon step

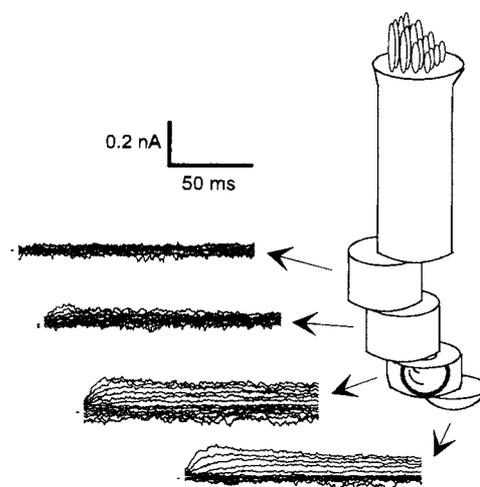

FIGURE 3 Localization of outward K currents along the basal extent of the OHC. Currents from the illustrated sections of the OHC were obtained by subtraction of currents in Fig. 2 A, right panel. From apical to basal, the currents correspond to (symbols in Fig. 2 A): circle-square, square-upward triangle, upward triangle-downward triangle, and simply downward triangle. The bulk of K conductances are restricted to the basal, nuclear region of the OHC.

hyperpolarizations from somewhat positive holding potentials (> -60 mV). The current deactivates upon hyperpolarization with a fairly long time constant that is variable among cells. Thus, while $I_{K,n}$ contributed to those currents studied above at the holding potential of -80 mV it was considerably deactivated. Fig. 4 exemplifies the effect of electrical amputation on OHCs whose $I_{K,n}$ is robust, because for these experiments holding potential was -60 mV. In this case, amputation was made slightly above the nucleus, and it is clear that the principal location of $I_{K,n}$ is within the basally amputated region, corresponding to the location of outward K currents. Six additional cells, with varying extents of $I_{K,n}$, were successfully amputated at the same level and provided similar results.

The OHC possesses a small, noninactivating Ca conductance that is revealed by leakage subtraction (Fig. 5) (Santos-Sacchi and Dilger, 1988; Nakagawa et al., 1991). Fig. 5 presents the averaged results ($n = 4$) of amputation experiments designed to localize Ca conductances. In these experiments, amputation of the basal pole of the cell successfully and reversibly removed the inward Ba currents, indicating that the Ca conductance colocalizes with K conductances.

DISCUSSION

Hair cells, like other nonsensory epithelial cells, are polarized morphologically and functionally. The apical and basolateral membranes of hair cells are specialized for mechanoreception and synaptic transmission, respectively (Hudspeth, 1989). Stereocilia, which are modified microvilli, are confined to the hair cell's apical region, where they serve to gate mechanically sensitive ion channels.

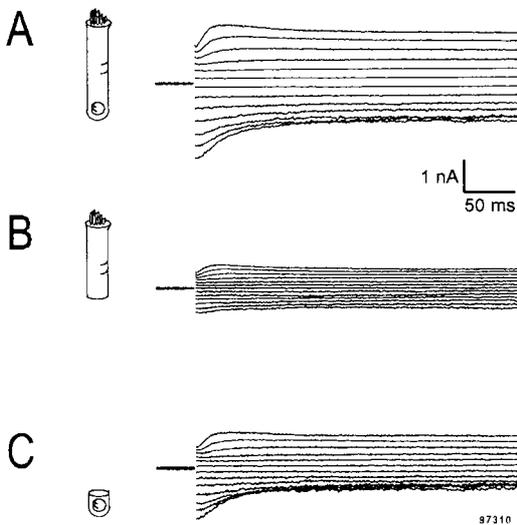

FIGURE 4 OHC held at -60 mV and nominally stepped from -140 to $+10$ mV in 10 -mV increments. Series resistance-corrected traces depict currents from -125 to $+5$ mV in 10 -mV increments. Residual series resistance: 6.5 M Ω . OHC figures indicate portion of cell from which associated currents arise. (A) $I_{K,n}$ is observed upon hyperpolarization with an instantaneous onset and slow deactivation. Outward K currents are also observed upon depolarization. (B) Amputation of the basal, nuclear pole of the OHC results in a nearly complete removal of $I_{K,n}$ and outward K currents. (C) Subtraction of apical currents (B) from whole cell currents (A) reveals those currents attributable to the basal, nuclear pole of the OHC. It is clear that $I_{K,n}$ resides in the same location as the outward K currents.

Gating of these channels generates receptor potentials and ultimately leads to calcium-dependent neurotransmitter release onto eighth nerve afferents. Furthermore, the outer hair cell's lateral membrane serves an electromechanical function. OHCs generate voltage-dependent mechanical responses, the frequency limit (> 20 kHz) of which is currently imposed by measurement techniques (Santos-Sacchi, 1992; Dallos and Evans, 1995). Membrane-bound sensor-motor elements responsible for this unique motility have been localized to the central extent of the OHC's cylindrical soma, namely between apical cuticular plate and basal, nuclear region (Dallos et al., 1991; Huang and Santos-Sacchi, 1993). Gating current studies indicate that the density of molecular motors within the OHC lateral membrane is $\sim 7500/\mu\text{m}^2$ (Huang and Santos-Sacchi, 1993); this is in line with morphological evidence showing similar densities of 10 -nm intramembranous particles, the putative molecular motors (Forge, 1991). It is clear that the lateral membrane of the OHC, unlike that of other types of hair cells, is uniquely specialized.

It is demonstrated here that the voltage-dependent K and Ca conductances of the OHC are not distributed within the plasmalemma along the entire length of the cell, but instead are restricted to the basal, synaptic pole. The cellular mechanisms that direct and maintain the segregation of molecular motors to the lateral membrane and ionic channels to the basal membrane possibly involve the extensive cortical cytoskeleton found in OHCs (Holley and Ashmore, 1988).

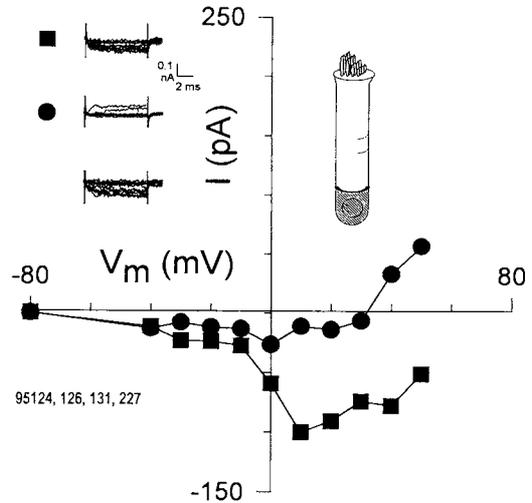

FIGURE 5 Localization of voltage-dependent Ca conductance. Average results from four cells. OHCs were held at -80 mV and stepped nominally from -40 to $+40$ mV in 10 -mV increments. Leakage subtraction was performed with the $P/4$ protocol to reveal inward Ba currents. Because the currents were so small, no correction for residual series resistance was made. Average residual series resistance: 8.25 M Ω . The I - V plot was obtained from the top two averaged sets of traces in the upper left; data points were averages of the final 4 ms of the current traces. Squares indicate currents obtained before amputation, and circles indicate currents obtained after amputation of the basal, nuclear pole, as indicated in the figure of the OHC. The bottom set of traces was obtained after return to whole-cell conditions. These data indicate that the OHC Ca conductance resides in the same region as the voltage-dependent K conductances.

Disruption of the cytoskeleton might promote intermixing of the molecules, which could be identified electrophysiologically. It is important to note that the K conductances were not amputated, because of a simultaneous removal of a required Ca influx. Although a component of the outward K current may be Ca-dependent, the bulk of this current is not (Santos-Sacchi, 1989). Recently this independence from Ca was confirmed and, in addition, it was shown that $I_{K,n}$ is little affected by the removal of extracellular calcium (Mammano and Ashmore, 1996; Nenov et al., 1997). Thus, electrical amputation of the K as well as Ca currents in this study is due almost exclusively to direct removal of the voltage stimulus to the channels' voltage sensors.

After the identification of a noninactivating L-type Ca current in OHCs (Santos-Sacchi and Dilger, 1988; Santos-Sacchi, 1989), other detailed examinations, including a localization study, of the conductance were made (Nakagawa et al., 1991, 1992). Focal Ca channel blocker application demonstrated that Ca current blockade occurred primarily during application to the basal pole of the OHC. This is in line with the results of the present experiments. Similar $I_{K,n}$ localization studies by these investigators, using focal application of the blocker Ba, indicated that $I_{K,n}$ is distributed along the length of the OHC (Nakagawa et al., 1994). Our data, however, present a more restricted localization of $I_{K,n}$ at the basal pole of the OHC. Focal application ("puffer") studies may sometimes suffer from diffusion of drugs away

from sites of presumed application. Earlier studies in lower-vertebrate hair cells, using unequivocal localization methods, demonstrated that Ca-activated K and Ca conductances are colocalized to synaptic sites along the full extent of the basolateral membrane of these cells (Issa and Hudspeth, 1994; Roberts et al., 1990). In addition to a role in synaptic function, the clustering of these conductances may be required for the electrical tuning found in these nonmammalian hair cells. Electrical resonance is not found in mammalian auditory hair cells, and in the case of the OHC it has been suggested that the Ca-independence of the outward K current might preclude such oscillatory behavior (Santos-Sacchi, 1989). Also unlike lower vertebrate hair cells, OHC synaptic sites are restricted to the basal, nuclear region of the plasma membrane—the same region where voltage-dependent K and Ca conductances reside. Thus it is conceivable that the K and Ca conductances of the OHC, as in lower-vertebrate hair cells, are associated with afferent and/or efferent synaptic sites. Whereas it is clear that efferent synaptic functionality is robust based on a host of indirect physiological studies (e.g., Brown et al., 1983), the functionality of the meager afferent supply to the OHC, which most likely has never been recorded from, remains questionable (Lieberman, 1982; Robertson, 1985). The contribution of K and Ca conductances to synaptic activity of the OHC must await direct studies of this issue.

Many characteristics of OHCs are correlated with cell length. Although we did not study the effects of cell length on conductance distribution, it is likely that the basic compartmentalization of the OHC remains the same, regardless of length. Indeed, regardless of length, it is clear, for example, that mechanically gated transduction channels are restricted to the cell apex, synapses are restricted to the basal pole, and subsurface cisternae line the lateral membrane. One of the characteristics that does depend on cell length is the occurrence of $I_{K,n}$ (Housley and Ashmore, 1992), with the whole-cell conductance being greater in shorter cells. All of our cells were between $\sim 60 \mu\text{m}$ and $80 \mu\text{m}$, but the occurrence of $I_{K,n}$ in cells of this length range is not clearly dependent on cell length. In 83 cells studied, 43 were found to have observable $I_{K,n}$ (length: $68.26 \pm 1.2 \mu\text{m}$ [mean \pm SE]; zero current potential [after pipette-cell solution equilibration]: $-57.5 \pm 1.4 \text{ mV}$). The remaining cells lacked observable $I_{K,n}$ (length: $64.1 \pm 0.8 \mu\text{m}$; zero current potential: $-39.8 \pm 1.5 \text{ mV}$). Thus, in this length range there appears to be little dependence of $I_{K,n}$ on cell length. Note, however, that this is not in disagreement with the data of Housley and Ashmore (1992), where clear dependence of OHC conductance on length is not obvious in this restricted range of length.

Given the conductance localization pattern in the OHC, it is possible to draw some conclusions about ionic channel density. The length, unlike the constant width ($10 \mu\text{m}$), of OHCs is inversely related to its characteristic frequency, ranging in the guinea pig from $\sim 80 \mu\text{m}$ ($\sim 200 \text{ Hz}$) to $20 \mu\text{m}$ ($\sim 40,000 \text{ Hz}$). Whereas the surface area of the lateral membrane is directly related to the cell's length, the surface

area of the basal, synaptic pole remains roughly constant. As noted above, the K current density of OHCs has been shown to increase as cell length decreases (Housley and Ashmore, 1992). Clearly, then, K channel density must increase, not as a consequence of reduced surface area, but as a consequence of an increased channel population. Interestingly, we have recently shown that motility gating current density and intramembranous particle density in the lateral membrane increase as length decreases (Kakehata et al., 1997). The higher density of these molecules (channels and molecular motors) in high-frequency OHCs probably corresponds to the enhanced frequency tuning afforded by these cells in the high-frequency region of the cochlea.

Finally, the voltage-dependent ionic channel distribution determined here necessarily limits the conductances' influence on local voltage drops across the lateral membrane, where the motility voltage sensors reside. The OHC lateral wall (subsurface cisternae, cortical cytoskeleton, and plasma membrane) is a complex structure with electrical properties that are equally complex (Pollice and Brownell, 1993; Kruger et al., 1997). Nevertheless, the absence of current shunting in the lateral membrane may ensure that voltages generated there (viz., the driving force for the "cochlea amplifier") will be largely unaffected by remote conductance changes in the basal pole of the cell.

We thank Margaret Mazzucco for technical help.

Abstract

Whole cell voltage clamp and freeze fracture were used to study the electrophysiological and ultrastructural correlates of the outer hair cell (OHC) lateral membrane molecular motors. We find that specific voltage-dependent capacitance, which derives from motility-related charge movement, increases as cell length decreases. This increasing non-linear charge density predicts a corresponding increase in sensor-motor density. However, while OHC lateral membrane particle density increases, a quantitative correspondence is absent. Thus, the presumed equivalence of particle and motor is questionable. The data more importantly indicate that whereas the voltage driving OHC motility, i.e. the receptor potential, may decrease with frequency due to the OHC's low-pass membrane filter, the electrical energy ($Q \times V$) supplied to the lateral membrane will tend to remain stable. This conservation of energy delivery is likely crucial for the function of the cochlear amplifier at high frequencies. © 1998 Elsevier Science Ireland Ltd. All rights reserved

The outer hair cell (OHC) lateral membrane possesses voltage-dependent molecular motors that work at acoustic frequencies to enhance basilar membrane motion [10]. The motors are believed to be proteins represented by ultrastructurally observable intramembranous particles [5,13], which based on electrophysiological determinations of associated voltage-sensor charge movement, possess about 1 equivalent electron charge for each 10 nm particle [1,10,17]. The voltage-dependent nature of OHC motility is predicted to limit the cochlear amplifier's effectiveness at high acoustic frequencies, where the cell's receptor potential is attenuated by the RC properties of the plasma membrane; receptor potentials at threshold levels may provide insufficient drive to evoke enhancement of basilar membrane motion [16,18]. In fact, however, it is the high frequency region that appears to benefit most from the activity of OHCs [14]. In an attempt to reconcile this dilemma, we have analyzed the

voltage-dependent capacitance of OHCs isolated from different best-frequency locations along the cochlea spiral. A variety of evidence indicates that the OHC's robust non-linear charge movement is inextricably related to the cell's mechanical activity [6,11,20].

OHCs were freshly isolated from the organ of Corti of the guinea-pig cochlea, and were whole-cell voltage clamped at room temperature using an Axon 200B (see [9] for details). Recordings were made within 3 min after whole cell establishment to limit any confounding effects of gradual turgor pressure change [12]. Membrane capacitance was evaluated at different potentials by transient analysis of currents induced by a voltage stair step stimulus (–150–100 mV, 10 mV steps), and the capacitance function was fit to the first derivative of a two state Boltzmann function relating non-linear charge to membrane voltage (dQ/dV [9]),

$$c_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + c_{\text{lin}} \quad b = \exp\left(\frac{-ze(V - V_{pkCm})}{kT}\right)$$

Q_{\max} is maximum nonlinear charge, V_{pkCm} is voltage at peak

capacitance or equivalently, at half maximal non-linear charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. C_{lin} was estimated from the fit to the above capacitance (C_m) equation, and indicates the membrane's intrinsic linear capacitance. Cell length (L) was measured in 20 cells before whole-cell configuration was obtained. The fitted linear function, $L = 2.9 \times C_{lin} - 0.24$ ($r^2 = 0.89$), was used to obtain length from C_{lin} in all cells ($n = 245$; cochleae > 100). Data collection and analysis was performed with a Windows-based patch clamp program jClamp (<http://www.med.yale.edu/surgery/otolar/santos/jclamp.html>).

For ultrastructural studies, guinea pigs ($n = 15$) were deeply anesthetized, and the cochleae fixed by intra-labyrinthine perfusion of 2.5% glutaraldehyde in 0.1 M sodium cacodylate buffer (pH 7.4). Following dissection, the cochleae were kept in the same fixative overnight at 4°C. Specimens were infiltrated with 30% glycerol for 1–4 h, and frozen in liquid nitrogen slush (-210°C). Fracturing was carried out at 10^{-7} Torr, at -130°C , and rotary shadowing

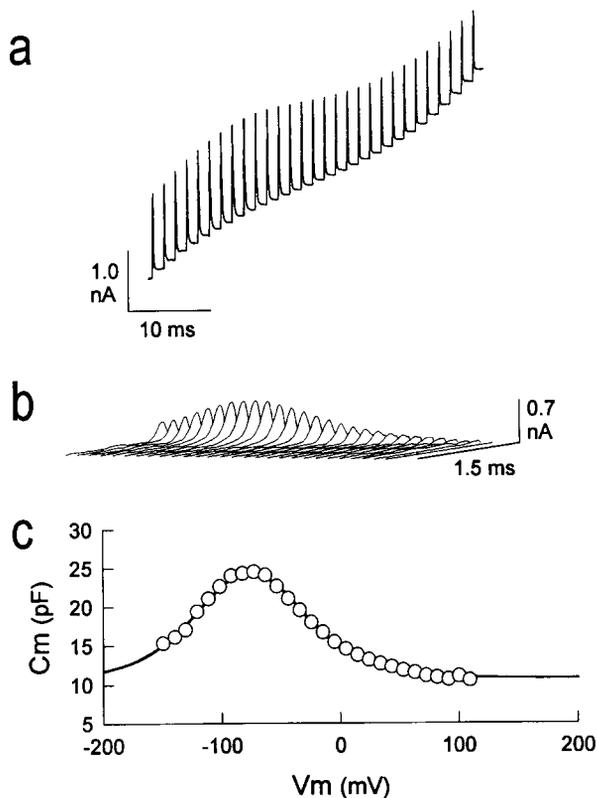

Fig. 1. Non-linear capacitance of an OHC isolated from the basal, high frequency region of the cochlea. (a) Capacitive currents induced by a stair step voltage protocol. (b) Gating currents extracted by subtracting the linear capacitive current obtained at the largest depolarization. (c) Capacitance of the cell (oc), comprised of a bell shaped voltage dependent capacitance riding atop a linear capacitance. The solid line is a fit (see text) indicating V_{pkC_m} , -76 mV; Q_{max} , 1.7 pC; C_{lin} , 10.8 pF; z , 0.83 . Length is 30.3 μm . Electrode series resistance was 3.7 M Ω .

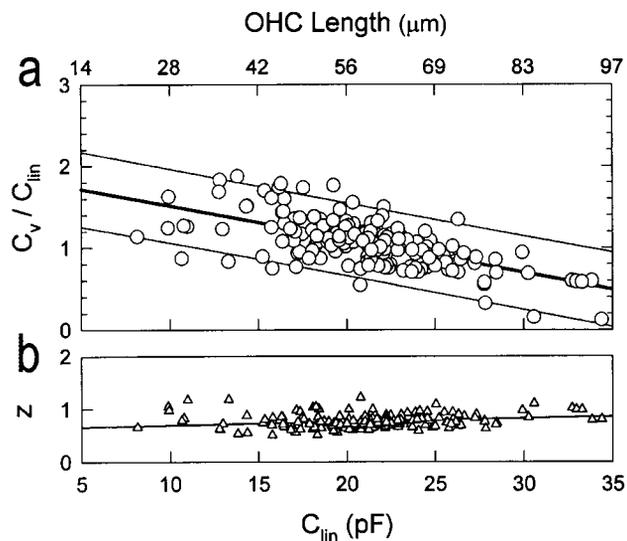

Fig. 2. (a) The ratio of maximum voltage dependent capacitance (C_v) to linear capacitance (C_{lin}) increases as OHC length (or equivalently, C_{lin}) decreases. Total capacitance was determined directly from capacitive currents. C_v is the peak capacitance minus C_{lin} , the latter being determined from Boltzmann fits to the data. (b) The valence z changes little with cell length or C_{lin} . The slight decrease in z may indicate a decreased charge for the voltage sensor and/or a decrease in the electrical distance displaced within the plane of the lateral membrane.

with platinum and carbon backing were made with a vacuum evaporator JEOL JFD-7000. Replicas were examined with a JEOL 1010 or JEOL JEM-100S transmission electron microscope at 100 kV. The protoplasmic fracture face of the OHC lateral membrane was examined at final photographic magnifications of 120 000. Images were divided into 2 cm^2 samples, and the total number of particles was used to obtain densities.

OHC length is inversely related to best frequency; as best frequency decreases from about 40 kHz to 100 Hz in the guinea pig, cell length increases from about 20 to 90 μm . Short, high frequency, OHCs possess a non-linear capacitance whose peak value can be greater than the cell's linear capacitance (Fig. 1). This is markedly different from cells residing in the low frequency region where the magnitude of non-linear capacitance is typically equivalent to or less than the cell's linear capacitance [1,17]. Moreover, as OHC length decreases (indicated by decreasing linear capacitance, C_{lin}), the relative magnitude of maximum voltage dependent capacitance (C_v) increases, as indicated by the ratio of the two (Fig. 2). Boltzmann fits show that the valence, z , changes little with cell length indicating that the parameter responsible for the relative increase in capacitance is the maximum charge, Q_{max} ($Q_{max} = 4kT/ze \times C_v$). The specific non-linear charge (Q_{sp}), based on whole cell surface area, changes with a slope of -413 $\text{e}^-/\mu\text{m}^2$ per pF of linear capacitance (Fig. 3a). This change, however, is an underestimate and does not reflect the highly compartmentalized nature of the OHC plasma membrane. While mechano-electrical transduction channels are restricted to

the OHC apical membrane [15], and voltage-dependent ionic channels are restricted to the basal membrane [19], mechanical responses and associated non-linear capacitance are restricted to the central extent of the cell, the lateral membrane [2,9,13]. Accordingly, a constant 6.2 pF (from [9]) of linear capacitance or correspondingly, 620 μm^2 , representing the constant apical and basal membrane should be excluded from calculations of Q_{sp} . When only the sensor-motor area is considered, the change in Q_{sp} as a function of cell length is striking, showing an increasing non-linear growth as cell length decreases (Fig. 3b). Q_{sp} 's up to 46 000 $e^-/\mu\text{m}^2$ are observed.

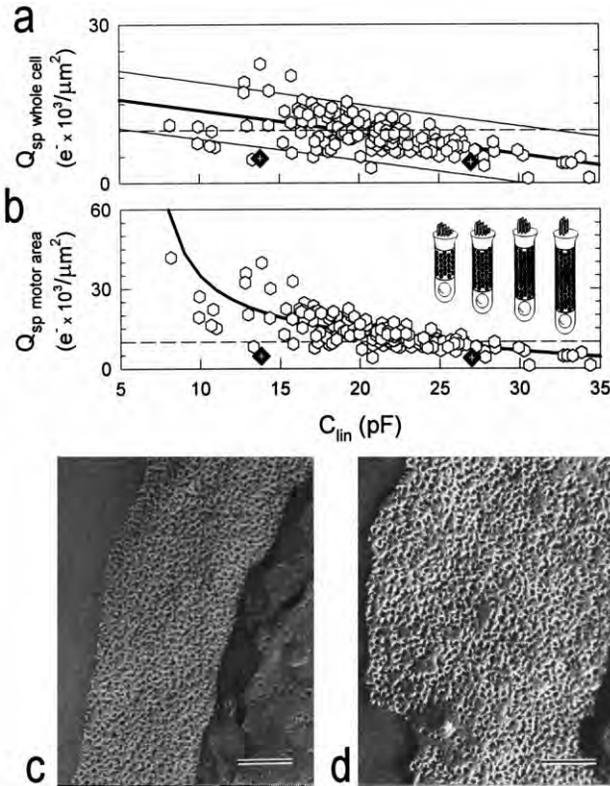

Fig. 3. (a) Non-linear charge density determined from whole cell surface area. Surface area was determined from the equivalence of linear capacitance and membrane surface area ($0.01\text{pF} = 1 \mu\text{m}^2$; [9]). Charge density increases as cell length or C_{lin} decreases. The slope, indicated by the solid line fit is $-413/pF$, and the thin parallel lines are 95% prediction limits. The two diamonds indicate the particle densities within the OHC lateral plasma membrane at two disparate frequencies. For values see text. The dashed line is the theoretical maximum density of particles based on 10 nm diameter. (b) Charge density obtained after correction of whole cell surface area for area devoid of sensor-motors. A constant $620 \mu\text{m}^2$ was subtracted from whole cell surface area. The solid line is simply the linear fit as above similarly corrected. The OHC schematics illustrate the relative change in sensor-motor containing lateral membrane area as cell length decreases. Other symbols as in (b). (c) Freeze-fracture replica showing the protoplasmic fracture face of the lateral plasma membrane of an OHC from a high frequency region of the cochlea. Densely packed intramembranous particles are characteristically found. Scale bar, 100 nm. (d) Same view obtained from cell in a low frequency region of the cochlea. Density is less than in (c). Scale bar, 100 nm.

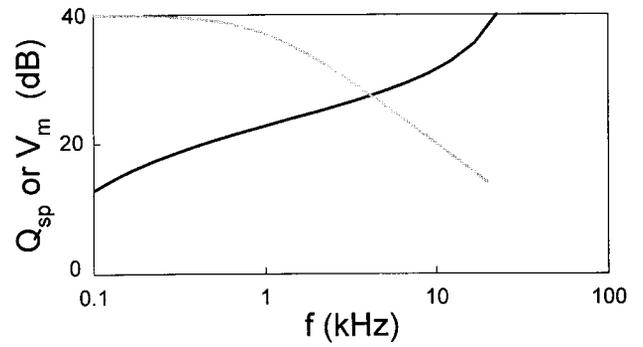

Fig. 4. Relationship between roll-off of receptor potential of a hypothetical OHC and increase of non-linear charge density as a function of frequency. The receptor potential falls at 20 dB per decade above about 1 kHz (gray line), whereas the charge density increases by a similar amount over frequency (black line obtained from b). OHC data were converted to frequency based on the map of Dannhof et al. [4].

A two state Boltzmann model has been successfully employed by several groups to characterize the OHC sensor-motor [1,10,17]. If this model is appropriate for the analysis of OHC charge movement, then the Boltzmann characteristics indicate that the density of independent sensor-motors should increase in correspondence with the specific charge density. A frequency-associated increase in the density of membrane protein is not unusual for the OHC. One K channel current, IK_n , is known to increase as characteristic frequency increases [8], and since this current is limited to the fixed area of the cell's basal pole, channel density must increase [19] (see [7] for an alternative explanation). Using freeze fracture, we measured the density of the putative ultrastructural correlate of the sensor-motor in the lateral membrane from areas of disparate characteristic frequencies (Fig. 3c,d). In a low frequency region (~ 200 Hz) where cell length averaged $76.3 \pm 2.2 \mu\text{m}$, particle density was $4033 (\pm 90; 35 \text{ samples})/\mu\text{m}^2$. In a high frequency region (~ 4 kHz) where cell length averaged $38.8 \pm 0.4 \mu\text{m}$, particle density was $4745 (\pm 155; 38 \text{ samples})/\mu\text{m}^2$. While the densities are significantly different (t -test, $P < .001$), they do not correspond to the densities predicted by Q_{sp} . Indeed, even the theoretical maximum density of 10 nm intramembranous particles, namely about $10\,000/\mu\text{m}^2$, does not approach electrophysiological estimates. Two possibilities may account for the disparity. First, the particles may not represent the sensor-motor molecules. Second, the two-state Boltzmann model inappropriately characterizes the sensor-motor as an independent entity possessing close to one electron charge. However, even if each intramembranous particle possessed more than one charge, the measured growth in particle density still requires that particle (voltage sensor) charge not remain fixed along the cochlea spiral. While a variably charged voltage sensor may not be unrealizable, the simplest explanation is the first.

Finally, the charge density data may help to explain how the OHC is able to overcome the effects of its membrane filter. In vivo measures of OHC receptor potentials show

that above about 1 kHz, AC voltages decrease at a rate 6 dB/octave [3,15]. Thus, the driving force for OHC motility is attenuated at high frequencies. However, our data indicate that, across frequency, motility-related charge increases to nearly the same extent as the decrease in receptor potential magnitude (Fig. 4). Thus, the electrical energy ($Q \times V$) delivered to the OHC lateral plasma membrane remains stable across frequency. It is likely that this frequency-independent energy delivery sustains the wide-band nature of the cochlear amplifier.

(Received 24 November 1997; accepted after revision 11 March 1998)

1. Isolated outer hair cells (OHCs) from the guinea-pig were whole-cell voltage clamped to study the influence of initial voltage on the voltage dependence of motility-related gating current or, equivalently, on the voltage dependence of membrane capacitance.
2. Prepulse delivery caused changes in the magnitude of motility-related gating currents, which are due predominantly to shifts in the voltage at peak capacitance (V_{pkC_m}). Depolarization shifts V_{pkC_m} in the hyperpolarizing direction, and hyperpolarization does the opposite. The mean shift between -120 and $+40$ mV prepulse states with long-term holding potentials (> 2 min) at -80 mV was 14.67 ± 0.95 mV ($n = 10$; mean \pm s.e.m.).
3. The effect of initial membrane potential is sigmoidal, with a voltage dependence of 23 mV per e-fold change in V_{pkC_m} , and maximum slope within the physiological range of OHC resting potentials. This indicates that the cell is poised to respond maximally to changes in resting potential.
4. The kinetics of prepulse effects are slow compared with motility-related gating current kinetics. High-resolution measurement of membrane capacitance (C_m) using two voltage sinusoids indicates that shifts in V_{pkC_m} induce C_m changes with time courses fitted by two exponentials (τ_0 , 0.070 ± 0.003 s; τ_1 , 1.28 ± 0.07 s; A_0 , 1.54 ± 0.13 pF; A_1 , 1.51 ± 0.13 pF; means \pm s.e.m.; $n = 22$; step from $+50$ to -80 mV). Recovery of prepulse effects exhibits a similar time course.
5. Prepulse effects are resistant to intracellular enzymatic digestion, to fast intracellular calcium buffers, and to intracellular pressure. Through modelling, we indicate how the effect may be explained by an intrinsic voltage-induced tension generated by the molecular motors residing in the lateral membrane.

The outer hair cell (OHC) is one of two receptor cell types within the organ of Corti, and plays a critical role in mammalian hearing. The OHC sharpens the passive mechanical vibration of the cochlear partition through a mechanical feedback mechanism (Ruggero, 1992). The basis of this high-frequency feedback mechanism is believed to be the unique voltage-dependent mechanical activity of the cell (Brownell, Bader, Bertrand & de Ribaupierre, 1985; Ashmore, 1987; Santos-Sacchi & Dilger, 1988). This electro-mechanical transduction is mirrored by an electrical signature, a voltage-dependent capacitance or, correspondingly, a gating charge movement (Ashmore, 1989; Santos-Sacchi, 1990, 1991), which may indicate that membrane-bound voltage sensor-motor elements control OHC length (Santos-Sacchi, 1990, 1991, 1993; Ashmore, 1992; Iwasa, 1993). Indeed, estimates of the OHC membrane-bound charge density responsible for the non-linear capacitance ($7500 e^- \mu m^{-2}$; Huang & Santos-Sacchi, 1993) coincide fairly well with estimates of the density of OHC intramembranous particles, the putative

sensor-motor elements, observed with electronmicroscopy ($6000 \mu m^{-2}$; Forge, 1991). One currently held hypothesis is that these membrane motors control OHC length via membrane areal changes induced by voltage-dependent, two-state conformational changes (Santos-Sacchi, 1993; Iwasa, 1994).

The voltage-dependent mechanical response may be dynamically modulated by a variety of physiologically important factors that can modify the mechanical gain of the cell. One of the most effective means of influencing the motility function is by exerting tension on the plasma membrane (Iwasa, 1993). Reducing membrane tension effectively increases the mechanical gain at the normal resting potential, by shifting the most sensitive region of the motility function along the voltage axis towards the resting potential value (Kakehata & Santos-Sacchi, 1995). Ligand-gated ion channels which can alter the resting membrane potential (Ashmore & Ohmori, 1990; Housley & Ashmore, 1993) may also influence the mechanical gain of the cell by moving the cell operating point, i.e. resting

potential, closer or further away from the most sensitive region of the motility function. Thus, either shifts in resting potential or shifts in the voltage dependence of OHC motility can alter the gain of the cochlear amplifier. We report here that these two mechanisms are not independent. That is, a change in resting potential affects the voltage dependence of OHC capacitance and motility. Furthermore, through modelling, we indicate that the effect can be explained by motor-driven tension on viscoelastic elements within the lateral plasma membrane.

METHODS

OHCs were freshly isolated from the organ of Corti of the guinea-pig cochlea following anaesthetic overdose (halothane inhalant; Halocarbon Labs, NJ, USA) and decapitation (Kakehata & Santos-Sacchi, 1995). The cells were whole-cell voltage clamped at -80 mV (unless otherwise noted) using an Axon 200B amplifier with patch pipettes having initial resistances of 2–3 M Ω , corresponding to tip sizes of 1–2 μ m. No series resistance compensation was performed. Residual series resistance (R_s) ranged from 3–7 M Ω . Ionic blocking solutions were used to remove voltage-dependent ionic conductances so that capacitive currents could be analysed in isolation (Santos-Sacchi, 1991; Huang & Santos-Sacchi, 1993). The patch pipette solution contained (mM): 140 CsCl, 2 MgCl₂, 10 EGTA and 10 Hepes, pH 7.2 and 300 mosmol l⁻¹ (adjusted with dextrose). The external solution contained (mM): 100 NaCl, 20 TEA, 20 CsCl, 2 CoCl₂, 1.52 MgCl₂, 10 Hepes and 5 dextrose, pH 7.2, 300 mosmol l⁻¹. In some experiments, modifications to the standard solutions were made: pipette solution, replacement of 10 mM EGTA with 10 or 20 mM BAPTA, or inclusion of pronase or trypsin (500 μ g ml⁻¹); extracellular solution, inclusion of neomycin (1 mM), or sodium salicylate (5 mM). Drugs were obtained from Sigma, and were selectively applied to individual cells by local perfusion, during simultaneous whole-chamber perfusion with control solution. Experiments were performed at room temperature (21–23 °C).

Three methods were used to analyse OHC motility-related gating charge movement and the corresponding non-linear membrane capacitance. Gating currents were extracted with the $P/-5$ leakage subtraction procedure (Bezanilla & Armstrong, 1977) using a subtraction holding potential of +60 mV. This procedure permits isolation of non-linear capacitive currents by subtracting out the intrinsic linear membrane capacitive currents obtained at a potential where non-linear currents do not contribute significantly. Fits of charge movement were made with a two-state Boltzmann function.

Detailed evaluation of membrane capacitance was made at different potentials by transient analysis of currents induced by a voltage stair-step stimulus (10 mV stair steps from a holding potential of -150 mV to $+40$ mV). The full stair-step duration was variable and depended upon the time constant of the clamp amplifier; the duration of each individual step was automatically adjusted to 15 times the clamp time constant determined immediately before presentation of the stair-step protocol. This was done to ensure a steady-state current response at each progressive step. Since our clamp time constant was typically less than 0.15 ms, each step was about 2.25 ms in duration. Given twenty, 10 mV incrementing steps in the stair-step, the total duration of the protocol was about 45 ms. The time between prepulse and stair-step was 10 ms and was spent at the prior long-term (> 2 min) holding potential, which was either 0 mV (Fig. 2) or -80 mV (Fig. 3). Thus, a full capacitance function can be obtained within 45 ms with this technique. The

capacitance function was fitted to the first derivative of a two-state Boltzmann function relating non-linear charge to membrane voltage (dQ/dV ; Santos-Sacchi, 1991; Huang & Santos-Sacchi, 1993),

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}}, \quad (1a)$$

where

$$b = \exp\left(\frac{-ze(V - V_{\text{pk}C_m})}{kT}\right), \quad (1b)$$

Q_{\max} is the maximum non-linear charge moved, $V_{\text{pk}C_m}$ is voltage at peak capacitance or, equivalently, at half-maximal non-linear charge transfer, V_m is membrane potential, z is valency, C_{lin} is linear membrane capacitance, e is electron charge, k is the Boltzmann constant, and T is absolute temperature.

Continuous high-resolution capacitance measures were acquired through admittance (Y) analysis at time resolutions of 5.12 or 2.56 ms, utilizing a two-sine wave voltage-stimulus protocol. The stimulus consisted of the sum of two voltage sine waves (390.625 and 781.25 Hz), each at a magnitude (V) of 10 mV peak. Two (one) full cycles of the low-frequency signal and four (two) full cycles of the high-frequency signal (512 (256) points at 10 μ s sampling rate) were continuously delivered every 5.12 (2.56) ms, and the real and imaginary components of the current responses were obtained through Fast Fourier Transform every 5.12 (2.56) ms. The analysis, which was performed in real time and saved to disk, is model dependent; the OHC clamp was modelled as a pipette resistance (R_p) in series with a parallel combination of membrane resistance (R_m) and capacitance (C_m) (Santos-Sacchi, 1993). Given an independent measure of input resistance of such a model and the real and imaginary components of the current response to single sinusoidal stimulation, Pusch & Neher (1988) provide solutions for C_m , R_s and R_m :

$$R_s = (A - b)/(A^2 + B^2 - Ab), \quad (2)$$

$$R_m = (1/b)[(A - b)^2 + B^2]/(A^2 + B^2 - Ab), \quad (3)$$

$$C_m = [1/(\omega B)][(A^2 + B^2 - Ab)^2]/[(A - b)^2 + B^2], \quad (4)$$

where,

$$b = 1/(R_s + R_m) = 1/R_{\text{in}},$$

$$Y = I/V,$$

$$A = \text{Re}(Y),$$

$$B = \text{Im}(Y),$$

$$\omega = 2\pi f,$$

and Re is real, Im is imaginary, and f is frequency. Since R_s remains the same at each of the two stimulating frequencies, the input resistance, R_{in} , can be obtained without an independent measure, as is required by the Pusch & Neher technique.

In some experiments, OHCs were collapsed and re-inflated by pipette pressure. Pipette pressure was modified with a syringe connected to the Teflon tubing attached to the patch pipette holder, and was monitored via a T-connector to a pressure monitor (WPI, FL, USA). Voltages were corrected for the effects of residual series resistance. All experiments were video taped. Data collection and analysis were performed with an in-house developed Windows-based whole-cell voltage clamp program, jClamp (www.med.yale.edu/surgery/otolar/santos/jclamp.html), utilizing a Digidata 1200 board (Axon Instruments). Fits were made with the Levenberg–Marquardt least-squares algorithm. Data are presented as means \pm standard error of the mean.

RESULTS

The OHC generates gating-like currents when the membrane potential is stepped away from the holding potential (Fig. 1). The decay time constant of the current is very fast (in this example, $\sim 110 \mu\text{s}$ for the current at voltage offset), and essentially follows the speed of the voltage-clamp stimulus (Santos-Sacchi, 1992; however, see Gale & Ashmore, 1997). Charge movement induced by a step from 0 to -60 mV was increased by prepulsing the OHC to negative voltages. Prepulse effects were clearly evident for durations greater than 30 ms and appeared to plateau at values greater than 1 s (Fig. 1C). A single-exponential fit to the charge increase induced by -120 mV prepulses at increasing durations (Fig. 1C, inset) gave a time constant of 200 ms.

Figures 2A and B indicate that voltage prepulse can cause a shift in the voltage dependence of the charge movement or, correspondingly, the capacitance of the cell. In this example, a 1 s prepulse to $+40 \text{ mV}$ produced a voltage at peak capacitance ($V_{\text{pk}C_m}$) or voltage at half-maximal charge movement (V_h) of -76.5 and -83.4 mV , respectively. A 1 s prepulse to -120 mV shifted the values to -56.8 and -56.7 mV . The differences in the magnitude of the fitted shift may have arisen from the inherent difference in prepulse delivery for each data collection protocol. In the case of stair-step analysis, a single prepulse preceded the entire stair-step stimulus, while in the $P/-5$ procedure, a prepulse preceded each step potential. The shift of these functions along the voltage axis was opposite to that of the prepulse direction. Furthermore, the shift in the voltage dependence of OHC capacitance (viz. $\delta V_{\text{pk}C_m}$) was non-linearly related to initial voltage. Figure 2C shows that the relation was sigmoidal and, significantly, the greatest sensitivity to prepulse was within the physiological voltage range. OHCs normally have resting potentials near -70 mV

(Dallos, Santos-Sacchi & Flock, 1982). The maximum mean shift due to a 1 s prepulse was 14.8 mV , with a voltage slope factor of 22.2 mV , and a mid-point voltage of -54.4 mV ($n = 4$).

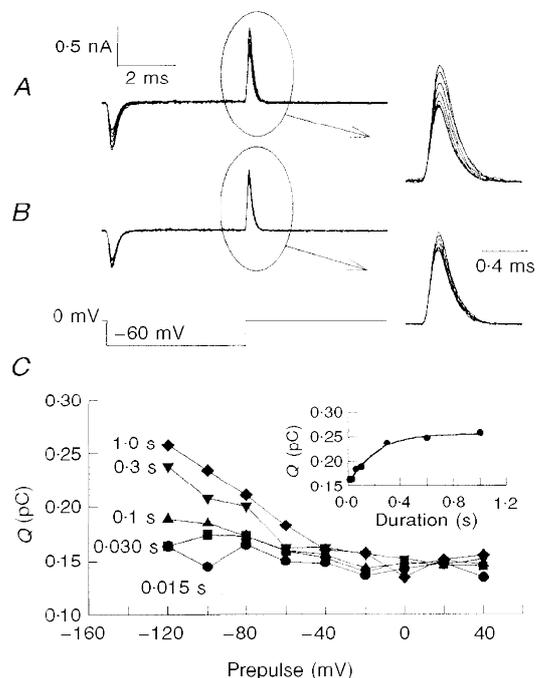

The effects of prepulse were reversible on the same time scale as onset. Figure 2D depicts the mean ($n = 22$) recovery from a 1 s prepulse to 50 mV . After a 1 s recovery at -150 mV , $V_{\text{pk}C_m}$ has nearly recovered to steady state from the prepulse-induced shift. A single-exponential fit to $V_{\text{pk}C_m}$ (Fig. 2D, inset) gave a time constant of 330 ms. Under these conditions, the mean $V_{\text{pk}C_m}$ shift was about 10 mV .

The data of Figs 1 and 2 were obtained with the cells held at a long-term holding potential of 0 mV , because whole-cell recording stability was better at this potential; in order to demonstrate the physiological relevance of the observed prepulse phenomenon, additional experiments were conducted at long-term holding potentials of -80 mV prior to the evaluation of prepulse effects. Figure 3 illustrates that the phenomenon remains qualitatively and quantitatively the same under such conditions. The mean shift between -120 mV and $+40 \text{ mV}$ prepulse states with long-term holding potentials ($> 2 \text{ min}$) at -80 mV was $14.67 \pm 0.95 \text{ mV}$ ($n = 10$).

The time course of prepulse effects is slow compared with the gating current time constants. In order to confirm the stair-step and P/N kinetic data, we utilized another technique to garner high-resolution information on the time course of prepulse effects. Since the shift in $V_{\text{pk}C_m}$ will necessarily cause the capacitance measured at a fixed potential to change, the time course of the capacitance change can be used to study prepulse effect kinetics. This is illustrated in Fig. 4, where OHC capacitance was monitored as the cell was stepped from a holding potential of $+50 \text{ mV}$

Figure 1. Motility-related charge movement is affected by initial voltage conditions

At a fixed membrane potential, an increase in charge is induced by a negative prepulse. The charge increase is due to the shift in the voltage dependence of charge movement, and the response is time dependent. An OHC was stepped to -60 mV from a holding potential of 0 mV . The command which generated each current trace was preceded by a prepulse of either 1 s (A) or 60 ms (B), with a magnitude ranging from -120 to $+40 \text{ mV}$ (20 mV increments). Leakage subtraction ($P/-5$; subtraction hold, 60 mV) revealed gating-like currents associated with OHC motility. As the length of prepulse increased, charge increased. C, under these conditions, prepulse effects were clearly present at potentials more negative than -50 mV and at durations greater than 30 ms. Inset shows time course of charge increase induced by prepulse to -120 mV . Fit indicates a single-exponential time constant of 0.2 s .

to -89 mV for 4 s. At the onset, C_m was about 39.8 pF, but decreased during the maintained voltage step to about 35.5 pF (Fig. 4B). The time course of this decrease was composed of fast and slow components, which was well fitted by a double exponential (t_0 , 0.058 s; t_1 , 1.34 s; A_0 , 2.2 pF; A_1 , 1.48 pF). (It might be expected that the time course would deviate somewhat from a true double exponential, even if the underlying mechanism followed a double-exponential time course, since the change in C_m is not linear, but follows the bell-shaped capacitance function.) The change in C_m was accounted for by a shift in V_{pkC_m} of about $+25$ mV. This was determined from responses to 25 ms voltage ramps delivered during the course of a maintained voltage step (Fig. 4A; arrows indicate ramp presentations). V_{pkC_m} , determined by fits of the resultant capacitance functions, corresponded in time to the relaxation in membrane capacitance (Fig. 4B). All cells studied with this high-resolution C_m measurement technique showed a double-exponential time course (τ_0 , 0.070 ± 0.003 s; τ_1 , 1.28 ± 0.07 s; A_0 , 1.54 ± 0.13 pF; A_1 , 1.51 ± 0.13 pF; $n = 22$; nominal step from $+50$ to -80 mV). In order to show that the time course of C_m change is not due to recovery from membrane breakdown at very depolarized potentials, we measured more physiological membrane potential pertur-

bations. Voltage steps from -80 to -40 mV, where membrane stability is unquestionable, produced changes in C_m with similar time courses. Figure 4C presents such an example.

The apparent difference in the time course observed with standard transient analysis techniques used in Figs 2 and 3 and the admittance measuring technique is explained by the higher time resolution and measurement density afforded by the latter method. A single-exponential fit to double-exponential data obtained with the admittance method also generates time constants in the tenths of seconds range when the extent is limited to 1 s, and few data points are sampled. It should also be noted that the duration of the stair-step protocol, typically around 50 ms, is close to τ_0 , and, as such, some V_{pkC_m} shift may have accumulated during that ramped measurement.

The actual direction and magnitude of C_m change during a shift in V_{pkC_m} depended on the initial holding potential and the step potential *vis-à-vis* the initial V_{pkC_m} . This is illustrated in Fig. 5A where the OHC membrane potential was stepped through V_{pkC_m} in 10 mV increments. Steps in potential induced essentially instantaneous jumps in C_m followed by slower changes. Small voltage steps from the initial holding level produced small time-dependent changes

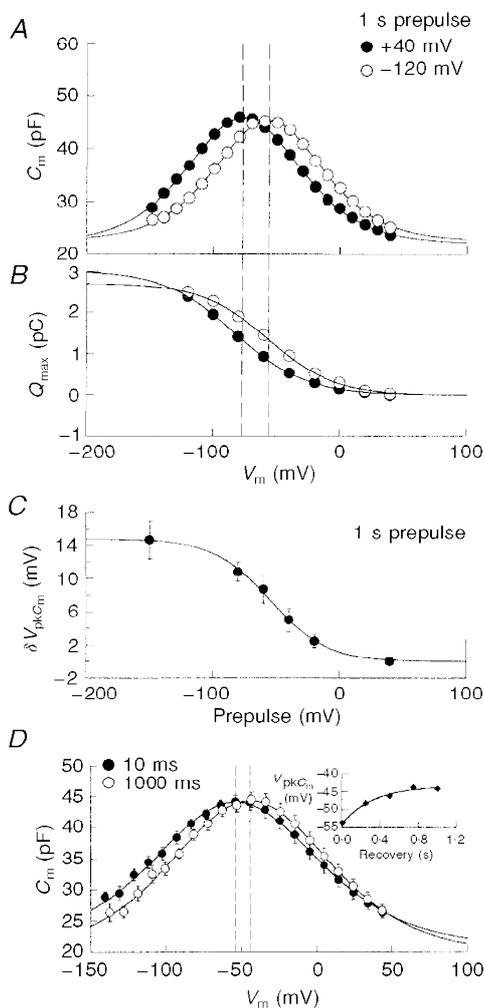

Figure 2. Voltage prepulse causes a shift in the voltage dependence of charge movement and non-linear capacitance

Long-term holding potential was 0 mV. Voltage-dependent capacitance was evaluated with the stair-step technique (A), and corresponding gating charge movement was evaluated with the $P/5$ technique at a subtraction holding potential of $+60$ mV (B). With either technique, voltage dependence was evidenced by a shift in the positive direction for negative prepulses (1 s duration). The shift is about 20 mV for a 40 mV prepulse (V_{pkC_m} is indicated by the dashed lines). Continuous line fit in A for -120 mV prepulse: V_{pkC_m} , -56.8 mV; z , 0.9 ; Q_{max} , 2.6 pC; C_{lin} , 22.5 pF; peak C_m ($C_{m,pk}$), 45.4 pF. For $+40$ mV prepulse: V_{pkC_m} , -76.5 mV; z , 0.86 ; Q_{max} , 2.86 pC; C_{lin} , 22.0 pF; $C_{m,pk}$, 45.9 pF. Continuous line fit in B for -120 mV prepulse: V_h , -56.7 mV; z , 0.96 ; Q_{max} , 2.7 pC. For $+40$ mV prepulse: V_h , -83.4 mV; z , 0.90 ; Q_{max} , 3.0 pC. C, the shift in voltage dependence is sigmoidal. The plot illustrates for 4 cells the mean (\pm s.e.m.) shift in the voltage at peak capacitance, obtained with the stair-step technique. The sigmoidal continuous line fit ($\delta V_{pkC_m} = a/[1 + \exp((V_{prepulse} - V_h)/b)]$) indicates a maximum mean shift, a , of 14.8 mV, a slope factor, b , of 22.2 mV, and a mid-point voltage, V_h , of -54.4 mV. Data are normalized to $+40$ mV response. D, recovery from prepulse effects has a similar time course to onset. Mean (\pm s.e.m.) from 22 cells. V_{pkC_m} was evaluated with the stair-step protocol from a holding potential of -150 mV. A 1 s prepulse to 50 mV preceded recovery durations of 10, 250, 500, 750 and 1000 ms at -150 mV. Only the 10 ms and 1000 ms recovery functions are shown. Inset shows time course of V_{pkC_m} recovery. Fit indicates a single-exponential time constant of 0.33 s. Recovery from prepulse appears nearly complete at 1 s. Continuous line fit for 10 ms recovery: V_{pkC_m} , -53.7 mV; z , 0.7 ; Q_{max} , 3.39 ; C_{lin} , 20.9 pF. Continuous line fit for 1000 ms recovery: V_{pkC_m} , -44.2 mV; z , 0.73 ; Q_{max} , 3.45 pC; C_{lin} , 19.8 pF. Parallel dashed lines indicate the V_{pkC_m} of each function.

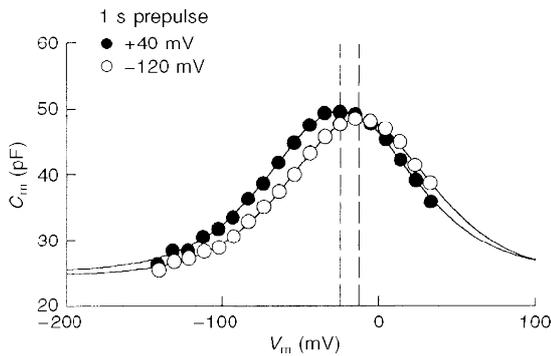

Figure 3. Prepulse-induced shifts occur at physiological holding potentials

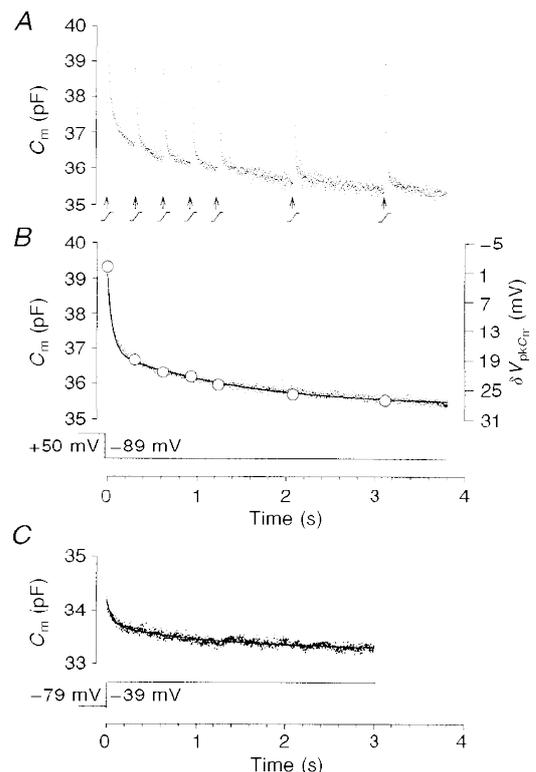

Prepulse-induced shift of capacitance function after an OHC was held at a long-term holding potential of -79 mV. As with depolarized long-term holding potentials, prepulses from physiological holding potentials caused a shift in the positive direction for negative prepulses (1 s duration). The shift in this case is 11.8 mV for a 40 mV prepulse. Continuous line fit for -120 mV prepulse: V_{pkC_m} , -12.5 mV; z , 0.84 ; Q_{max} , 2.9 pC; C_{lin} , 24.7 pF; $C_{m,pk}$, 48.5 pF. For $+40$ mV prepulse: V_{pkC_m} , -24.3 mV; z , 0.84 ; Q_{max} , 3.0 pC; C_{lin} , 25.2 pF, $C_{m,pk}$, 49.8 pF.

in C_m because the magnitude of V_{pkC_m} shift was small. Progressively larger voltage steps produced larger V_{pkC_m} shifts and, thus, larger changes in C_m at each fixed step potential. The direction of capacitance change was increasing for voltage steps positive to V_{pkC_m} , and decreasing for voltage steps negative to V_{pkC_m} . Also note for this protocol that C_m at the holding potential accumulated somewhat over time because full C_m relaxation was not reached during the interstep recovery period. Figure 5B shows the effect of voltage-step duration on the non-linear capacitance function. Determination of C_m at zero time (5 ms; the initial data point measured during a voltage step is contaminated by the transient response) or after 1 s provided differing functions, with the 1 s determination showing a relative compression of the function in the depolarizing direction; indeed, C_m overlap occurred at very depolarized levels. This is expected since the magnitude of prepulse effect is a function of step potential.

There are several possible mechanisms which may account for the observed prepulse effects, including intracellular pressure change. OHC voltage-dependent motility occurs under a constant cell volume constraint (Santos-Sacchi, 1993; Dallos, Hallworth & Evans, 1993). Thus, during whole-cell voltage stimulation, intracellular pressure may change, despite continuity with pipette volume. Since modification of intracellular pressure is known to shift V_{pkC_m} via tension applied to the plasma membrane (Iwasa, 1993; Gale & Ashmore, 1994; Kakehata & Santos-Sacchi, 1995), it is of interest to determine whether prepulse effects are simply related to a motility-induced intracellular pressure change. Figure 6A illustrates that when OHCs ($n=6$) were collapsed with negative pipette pressure, causing a limiting negative shift in V_{pkC_m} (Kakehata & Santos-Sacchi, 1995), prepulse effects were still observed. Collapsed OHCs cannot generate an intracellular pressure change (nor the consequent pressure-induced membrane tension) since the usual voltage-

Figure 4. The time course of prepulse effects has a fast and a slow component

A, an OHC was stepped to -89 mV from a holding potential of $+50$ mV, and the C_m at the new step potential was monitored every 2.5 ms using the admittance technique (see Methods). At the time points indicated, voltage ramps (25 ms in duration) were delivered in order to determine V_{pkC_m} from the voltage-capacitance function. In B, the step stimulus was delivered without ramps, and the continuous line (which is difficult to see, since it is obscured by the many data points) is a double-exponential fit to the resultant capacitance data (t_0 , 0.058 s; t_1 , 1.34 s; A_0 , 2.2 pF; A_1 , 1.48 pF). The close correspondence of the overlying open symbols, which denote the change in V_{pkC_m} relative to the first ramp measurement (i.e. δV_{pkC_m}), indicates that the shift of the OHC capacitance function along the voltage axis accounts for the relaxation of capacitance during step potentials. C, a voltage step from a long-term holding potential (> 2 min) of -79 mV to -39 mV, induces a change in C_m over a similar time course to that in 4B. The fitted line (t_0 , 0.067 s; t_1 , 1.18 s; A_0 , 0.46 pF; A_1 , 0.44 pF) is obscured by the data points.

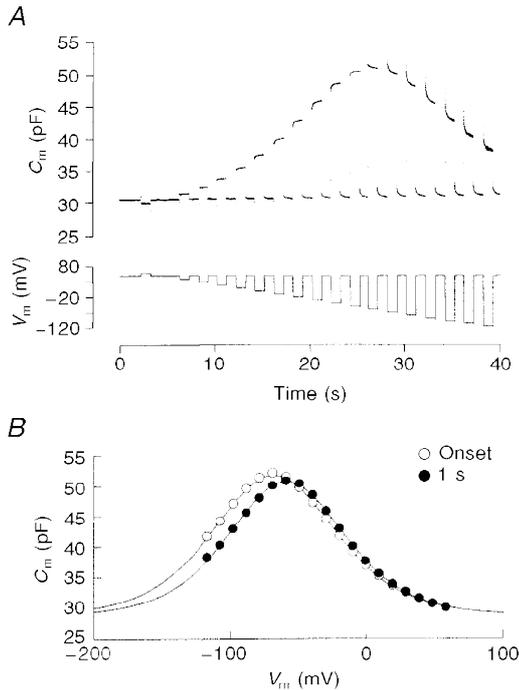

Figure 5. The direction and magnitude of C_m change depends on initial holding potential and step potential relative to V_{pkC_m}

A, an OHC was stepped (-10 mV increments) from a holding potential of $+48$ mV through V_{pkC_m} . Step durations were 1 s, with equal recovery intervals at the holding potential. A total of 40 s of data were collected at 5 ms resolution. The top panel shows C_m measured with the admittance technique. The bottom panel shows the DC voltage stimulus, corrected for residual series resistance. Note that steps to voltages more depolarized than V_{pkC_m} induce C_m changes which increase over time, while steps to potentials more hyperpolarized than V_{pkC_m} induce C_m changes which decrease over time. The magnitude of C_m change corresponds to step size. *B*, the C_m functions derived from the measurements at onset (5 ms point; the initial data point measured by Fast Fourier Transform during a voltage step is invalid since it is contaminated by the transient response – these aberrant points are visible at the transitions between voltage steps) or 1000 ms are plotted, along with fitted functions. The plots indicate differences in the instantaneous and steady-state C_m functions; notably a shift and compression in the steady-state function in the depolarizing direction. Continuous line fits for onset: Q_{max} , 2.81 pC; z , 0.85; C_{lim} , 28.7 pF; V_{pkC_m} , -68 mV. For steady-state: Q_{max} , 2.54 pC; z , 0.9; C_{lim} , 28.7 pF; V_{pkC_m} , -58.7 mV.

dependent whole-cell mechanical response (but not gating current) is abolished. Prepulse-induced voltage shifts merely superimposed upon the negative pressure-induced steady-state voltage shift. These data suggest that voltage-induced motility induces little or no intracellular pressure changes, in line with modelling efforts (Tolomeo & Steele, 1995).

Other possible prepulse mechanisms might involve intracellular Ca^{2+} increases, and cytoskeletal–motor interactions. These can be excluded since we have found no alterations of prepulse effects upon using the fast Ca^{2+} chelator BAPTA (10 mM ($n = 4$) or 20 mM ($n = 4$)) intracellularly, or after intracellular digestion with pronase ($n = 5$) or trypsin

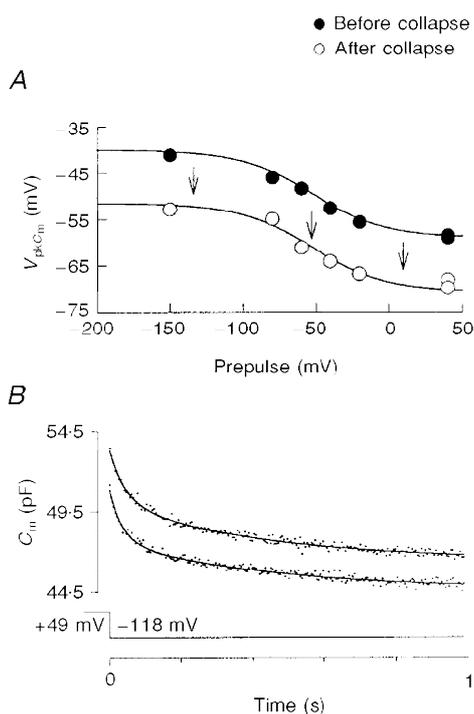

Figure 6. The mechanism responsible for prepulse effects appears intrinsic to the lateral membrane

A, intracellular pressure does not alter prepulse effects. Before (●) and after (○) collapse of OHC by reduction of intracellular pressure via patch pipette. Note the parallel negative shift in V_{pkC_m} with negative pressure. Prepulse at each potential was 1 s in duration. The sigmoidal lines were generated with the electro-mechanical model described in the Discussion. Parameter values are the same as set out in the Discussion, except that for the continuous line corresponding to data before collapse: μ_1 , 4 mN m $^{-1}$; η_1 , 0.24 mN s m $^{-1}$; μ_2 , 4 mN m $^{-1}$; and η_2 , 4.8 mN s m $^{-1}$. The continuous line corresponding to data after cell collapse was generated with the same parameters except that a constant of 1 kTorr was subtracted from the mechanical energy, E_m , to account for the resultant decrease in membrane tension (see Discussion for model details). *B*, C_m measurements made before (zero time after whole-cell configuration, bottom trace) and after (10 min after whole-cell configuration, top trace) intracellular pronase treatment (500 μ g ml $^{-1}$, delivered via the patch pipette). After 10 min, the cell had lost its cylindrical shape and formed a sphere. The cell was held at $+49$ mV and stepped to -118 mV for 1 s. In each case the onset C_m relaxed with a double-exponential time course. The difference in absolute magnitude (DC) is due to a steady-state shift in V_{pkC_m} , from -90.7 to -97.6 mV, possibly induced by osmotic effects or a release in tension on the membrane after cytoskeletal disruption. Such shifts during intracellular enzymatic treatments have been noted previously (Huang & Santos-Sacchi, 1994). The relaxations are quite similar, indicating that the treatment had little effect on the molecular structures responsible for voltage-induced V_{pkC_m} shift. The continuous lines indicate the sum of two exponentials – zero time: τ_0 , 0.034 s; τ_1 , 0.447 s; 10 min: τ_0 , 0.042 s; τ_1 , 0.417 s.

($n = 4$; 500 mg ml^{-1}). Intracellular proteolytic treatment has been shown to abolish normal OHC cyto-architecture by disrupting the cortical cytoskeleton and subsurface cisternae (Huang & Santos-Sacchi, 1994). An example of the negligible effect of intracellular pronase treatment on voltage-dependent $V_{\text{pk}C_m}$ shift is provided in Fig. 6B. Another indication that the $V_{\text{pk}C_m}$ shift was unrelated to intracellular structures is the poor correlation between the fitted C_m exponential parameters and precise estimates of cell length, viz. linear capacitance (r^2 of τ_0 vs. C_{lin} , 0.23; r^2 of τ_1 vs. C_{lin} , 0.15; r^2 of A_0 vs. C_{lin} , 0.004; r^2 of A_1 vs. C_{lin} , 0.033; $n = 22$; step from +50 mV to -80 mV). It should be noted that the pronase and trypsin experiments also exclude a host of biochemical processes which would rely on enzymes susceptible to proteolytic destruction, for example protein kinases. Other treatments which did not interfere with prepulse effects were salicylate (sub-maximal dose, 5 mM; $n = 5$), and neomycin (1 mM; $n = 3$).

DISCUSSION

The OHC possesses a voltage-dependent capacitance or gating charge movement with a $V_{\text{pk}C_m}$ or mid-point voltage, V_h , that is variable (Santos-Sacchi, Huang & Kakehata, 1994). The present data indicate that one of the factors contributing to this variability is a dependence on initial voltage conditions. More importantly, since motility-related gating charge characteristics are known to mirror characteristics of the mechanical activity of the OHC (Ashmore, 1989, 1992; Santos-Sacchi, 1991, 1992; Kakehata & Santos-Sacchi, 1995), the present experiments demonstrate a link between the two factors, membrane potential and $V_{\text{pk}C_m}$, that control the gain of OHC motility.

Some superficial characteristics of prepulse effects on OHC motility-related gating currents are reminiscent of the Cole-Moore effect on K^+ channel gating currents (Cole & Moore, 1960; Stefani, Toro, Perozo & Bezanilla, 1994); however, no shift in voltage dependence is associated with the Cole-Moore effect. On the other hand, a shift in voltage dependence is responsible for depolarization-induced fast (complete within 50 ms) and slow (occurring over seconds to minutes) inactivation of Na^+ channel gating (Bezanilla, Taylor & Fernandez, 1982). Inactivation of Na^+ channels is characterized by charge immobilization (Armstrong & Bezanilla, 1977; Bezanilla & Armstrong, 1977). We had previously noted an absence of OHC charge immobilization on very short time scales (within a window of 26 ms; Fig. 9 in Santos-Sacchi, 1991), where Na^+ channel gating charge immobilization is clearly observed. Given the present results, this is understandable since in the OHC the fast prepulse effect has a mean time constant of 70 ms; additionally, since the voltage dependence of OHC charge movement is significantly less steep than Na^+ channel gating charge movement, a given shift in voltage dependencies will present a smaller charge immobilization for the OHC. In preliminary experiments, an extended observation window

permits the observation of charge immobilization in the OHC, with a time course similar to the capacitance data. To a limited extent, then, Na^+ channel gating behaviour is comparable to that of the OHC lateral membrane motor. Simple kinetic schemes to account for prepulse effects on the Na^+ channel were discussed by Bezanilla *et al.* (1982), and may possibly apply to the OHC. These abstract schemes do not, however, provide insight into the physical correlates of prepulse effects in the OHC.

The present data suggest that voltage prepulse appears to work directly on the lateral membrane and/or the embedded molecular motors, and not via extrinsic tension delivered by intracellular pressure or delivered by some other means, e.g. Ca^{2+} -dependent cytoskeletal interactions or enzyme-based second messengers. While an extrinsic source of tension can probably be ruled out, an intrinsic source of tension can be envisioned. In this regard, it is notable that the magnitude of voltage prepulse effects presents characteristics similar to those of OHC motility itself. Namely, the sigmoidal voltage dependence is similar between the two. It is, therefore, conceivable that the activity (conformational changes) of the molecular motors themselves produces a force within the lateral membrane which dynamically modifies $V_{\text{pk}C_m}$. Thus, while the electrical energy supplied by the membrane potential will drive lateral molecular motors into a preferred state, leading to an overall change in membrane area, the force induced by this strain within the viscoelastic membrane will influence the state of adjacent motors, but will decay over time. In order to account for the kinetics of $V_{\text{pk}C_m}$ shift, the induced membrane tension must dissipate following the time course observed in the OHC C_m measurements (Figs 4 and 5). Iwasa (1994) evaluated the effects of an externally applied tension on the OHC membrane by redefining eqn (1) to include an additional energy term (E_m) in the description of OHC C_m :

$$b = \exp\left(\frac{-ze(V - V_{\text{pk}C_m}) + E_m}{kT}\right), \quad (5)$$

where E_m , the mechanical energy per motor unit, was calculated from the product of a , the unit areal change in the lateral membrane motor, and T_m , the mean membrane tension in the axial and circumferential directions, determined from the law of Laplace. From Iwasa (Fig. 4, 1993) and Kakehata & Santos-Sacchi (Fig. 4, 1995), it is known that 1 kPa intracellular pressure induces an OHC longitudinal strain ($\Delta L/L$) of 0.07. Such a longitudinal strain corresponds to a shift in $V_{\text{pk}C_m}$ of 22.5 mV (Kakehata & Santos-Sacchi, 1995), and can be accounted for by an induced membrane mechanical energy of $1.2 kT$ according to eqns (1a) and (5).

We model E_m as being additionally voltage and time dependent. The voltage-dependent characteristics match those of OHC motility, and the time-dependent characteristics accord with the time constants of OHC C_m measurements. Depolarization, which drives the motors into

a compact state, induces tension in the membrane. The electro-mechanical model is implemented as follows.

The patch-clamped OHC is modelled electrically as an electrode resistance (R_s) in series with a parallel combination of a membrane resistance (R_m), linear capacitance (C_{lin}) and voltage-dependent capacitance (C_v) as defined above (see Santos-Sacchi, 1993, for details). The electrical model parameters are: R_s , 5 M Ω ; R_m , 100 M Ω ; C_{lin} , 29 pF; Q_{max} , 2.3 pC; V_{pkC_m} , -50 mV; and z , 1. Voltage-dependent OHC contraction, δL , is described by a two-state Boltzmann function (Santos-Sacchi, 1991):

$$\delta L = \frac{\delta L_{max}}{1 + \exp\left(\frac{-ze(V - V_{pkC_m}) + E_m}{kT}\right)}, \quad (6)$$

now including the additional mechanical energy term E_m , which is derived from the deformation-induced membrane force (F).

$$E_m = F_m \times \delta d_m, \quad (7)$$

$$F_m = F/N_{cir}, \quad (8)$$

where F_m is the force per motor unit, determined by dividing whole-cell membrane force (F) by N_{cir} , the number of parallel motors along the circumferential dimension of the OHC. δd_m is the diameter change of the lateral membrane motor.

The OHC lateral membrane is modelled as a parallel combination of Maxwell (series combination of spring and dash-pot) elements (standard 4-parameter Maxwell model; Tschoegl, 1989) (inset in Fig. 7A). The equations describing the mechanical model are:

$$\frac{dx}{dt} = \frac{\dot{F}_1}{\mu_1} + \frac{F_1}{\eta_1} = \frac{\dot{F}_2}{\mu_2} + \frac{F_2}{\eta_2}, \quad (9)$$

$$F = F_1 + F_2, \quad (10)$$

where the dot, e.g. in \dot{F}_1 , indicates differentiation with respect to time, μ_1 and μ_2 are the spring stiffness coefficients, and η_1 and η_2 are the dash-pot coefficients of viscosity.

The force induced by step deformation is a decaying double-exponential function of time:

$$F = x[\mu_1 \exp(-t/\tau_1) + \mu_2 \exp(-t/\tau_2)], \quad (11)$$

where:

$$\tau_1 = \eta_1/\mu_1,$$

$$\tau_2 = \eta_2/\mu_2,$$

$$x = 0, t \leq 0,$$

$$x = 1, t > 0,$$

and the deformation of the model, x , is obtained from the motility function $\delta L(V)$. Maximum contraction, δL_{max} , is set at 3 μm (Santos-Sacchi & Dilger, 1988). The parameter values of the mechanical elements are chosen to produce

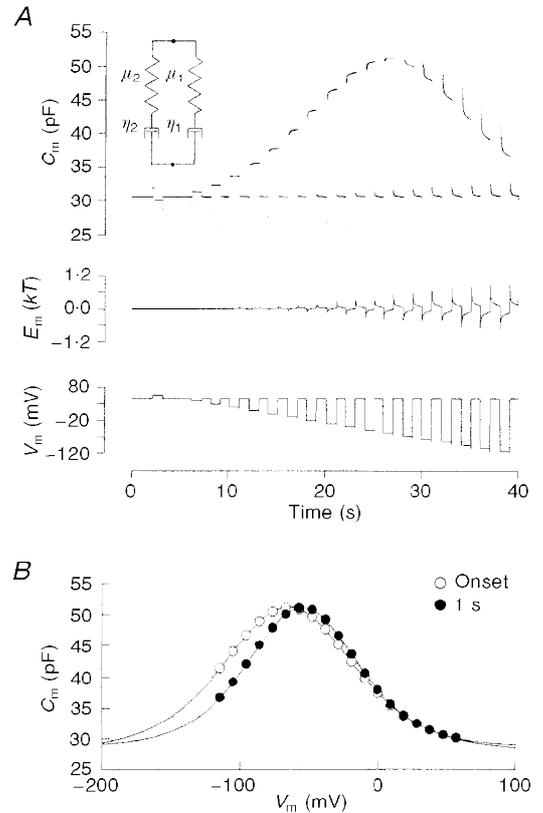

maximal instantaneous voltage-dependent mechanical energy (E_m) of 1.2 kT , and to provide a double-exponential time course for the relaxation of that energy which matches the time course empirically determined in Fig. 5. The mechanical parameter values which satisfy these conditions are: μ_1 , 5.8 mN m $^{-1}$; η_1 , 0.35 mN s m $^{-1}$; μ_2 , 4.2 mN m $^{-1}$; and η_2 , 5 mN s m $^{-1}$. δd_m is set to 0.5 nm and N_{cir} is 3000 (Santos-Sacchi, 1993). Notably, our model is of the plasma membrane, since contributions by intracellular structures have been dismissed. In this regard, our model differs from classical treatments of the red cell membrane (e.g. Chien, Sinu, Skalak, Usami & Tozeren, 1978) and a recent treatment of OHC viscoelastic behaviour (see below; Ehrenstein & Iwasa, 1996), since, in those analyses, cytoskeletal element contributions were not ruled out. The model was evaluated with the software package Simulink (Mathworks, MA, USA) or hard-coded in C. Maximum force (F) generated with the model is about 30 nN. This compares favourably with the force determined from whole-cell stiffness measurements (10 mN m $^{-1}$ \times 3 μm = 30 nN; Hallworth, 1996; Iwasa & Adachi, 1997), or voltage-dependent force estimates (0.1 nN mV $^{-1}$ \times 200 mV = 20 nN; Hallworth, 1996; Iwasa & Adachi, 1997). The stiffness coefficients for the membrane spring components are also in good agreement with the OHC membrane stiffness estimate (1 mN m $^{-1}$) of Tolomeo, Steele & Holley (1996); the values are greater than red blood cell plasma membrane stiffness (10 $\mu\text{N m}^{-1}$; Skalak, Tozeren, Zarda & Chein, 1973).

Figure 7 illustrates the results obtained from the model when it is stimulated with the same voltage protocol used in Fig. 5. The voltage-dependent mechanical energy which develops is shown in the middle panel of Fig. 7A, and at large voltage steps approaches instantaneous values of 1 kT , followed by relaxations towards zero. The model was also used to account for the data in Fig. 6A, indicating its usefulness in describing prepulse effects. The similarity between the capacitance of the model and OHC indicates that tension developed by the voltage-driven molecular motors residing within the lateral membrane can account for the biophysical data.

Because of the correspondence between OHC capacitance and motility, the length of the OHC is expected to mirror the intrinsic tension-dependent changes in C_m . However, the physiological significance of the link between membrane potential and the voltage dependence of OHC capacitance and motility is dependent on the magnitude and time course of the phenomenon. The magnitude of V_{pkC_m} shift is maximal in the physiological voltage range, showing a voltage dependence of about 22 mV per e-fold change in V_{pkC_m} . A step in membrane potential will produce not only a very rapid change in cell length, but, in addition, a slow length change as V_{pkC_m} shifts. Given the model parameters used above, the ratio of slow length change to rapid length change following a voltage step from the resting potential of -70 mV is a bell-shaped function of step voltage, with a maximum of about 0.2 at a voltage near the resting

Figure 7. Model results incorporating a voltage-induced mechanical energy within the plasma membrane

A, the top panel shows the whole-cell capacitance induced by the voltage stimulus in the bottom panel. Same voltage protocol as used in Fig. 5. The middle panel shows the generated mechanical energy, E_m . Model C_m results are quite similar to the OHC C_m data of Fig. 5. Inset, viscoelastic model of membrane, consisting of a parallel combination of two Maxwell elements (series combination of spring and dash-pot). The symbols μ_1 and μ_2 indicate the spring stiffness coefficients, and the symbols η_1 and η_2 indicate the dash-pot coefficients of viscosity. B, onset (5 ms) and steady-state (1 s) C_m function as in Fig. 5B. Continuous line fits for onset: Q_{max} , 2.94 pC; z , 0.81; C_{lin} , 28.1 pF; V_{pkC_m} , -65.1 mV. For steady state: Q_{max} , 2.42 pC; z , 0.95; C_{lin} , 28.7 pF; V_{pkC_m} , -54.8 mV.

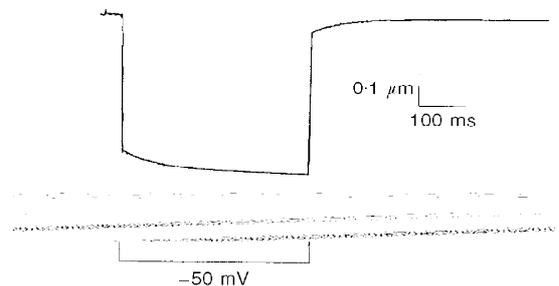

potential. An example of the mechanical response of the model is shown in Fig. 8. This is a significant component of the length change, and such a slow length change is observable in records of OHC mechanical responses obtained under whole-cell voltage clamp (Ashmore, 1987; Santos-Sacchi, 1990, 1992).

The physical basis of the time course of V_{pkC_m} shift observed here probably derives from viscoelastic elements within the motor itself and/or within the lipid bilayer. Alterations in the mechanical properties of these structures may, therefore, control the time course of the phenomenon. Nevertheless, the double-exponential time course indicates that the mechanism may only be significant at frequencies below about 3 Hz. Even correcting for temperature effects (e.g. Q_{10} for OHC gating charge kinetics is 1.5; Santos-Sacchi, 1990) will not significantly increase the frequency response. However, such slow effects may be utilized by the OHC medial efferent

system. The effects of the medial efferent system on the peripheral auditory system encompass the time scales reported here (Sridhar, Liberman, Brown & Sewell, 1995). It is also to be expected that pathological states which cause membrane potential alterations in the OHC, e.g. acoustic overexposure (Cody & Russell, 1985), may evoke V_{pkC_m} shifts with attendant changes in the gain of OHC motility. Since, normally, V_{pkC_m} is more depolarized than the OHC resting membrane potential (Dallos *et al.* 1982; Santos-Sacchi, 1991; Ashmore, 1992; Kakehata & Santos-Sacchi, 1995), a depolarizing shift in resting potential augmented by a hyperpolarizing shift in the motility function should increase mechanical gain, but reduce motor-generated non-linearities; namely, DC and harmonic mechanical components (Santos-Sacchi, 1993). In the peripheral auditory system, where non-linearities are the hallmark of normal activity, such interference with motility-based non-linearities may be significant.

Figure 8. Predicted mechanical responses of the OHC to voltage steps

Model results indicating the slow DC component attributable to motor-induced membrane tension. Step voltage from -70 mV to -50 mV.

Interestingly, Ehrenstein & Iwasa (1996) have observed external, osmotically induced viscoelastic behaviour in the intact OHC with a single time constant of about 40 s. Within this time scale, tension induced by steady-state membrane strain relaxes exponentially. This very slow time course may suggest that the underlying mechanical elements responsible for their observed viscoelastic behaviour are distinct from those responsible for the V_{pkC_m} shifts observed here. However, it should be noted that the apparent viscosity of a medium may depend upon rate, duration and magnitude of deformation (see Hochmuth, 1993). For example, Chien *et al.* (1978) found that an increase in duration of erythrocyte deformation from 2 to 20 s, caused an increase in the time constant of recovery from about 110 to 260 ms. In this regard, the fast rate and small magnitude of deformation induced by membrane voltage markedly differ from those of the osmotic treatments of Ehrenstein & Iwasa (1996).

Finally, it is noted that the V_{pkC_m} shift which is induced by voltage-dependent motor activity underlies the existence of both an instantaneous and a steady-state electro-mechanical transduction function, as exemplified through capacitance measurements (Fig. 5). This is somewhat analogous to the instantaneous and steady-state stereociliar mechano-electrical transducer functions which derive from displacement-induced adaptation (Shepherd & Corey, 1994). In each case, a time-dependent relaxation in a tension produced by the appropriate physiological stimulus on a membrane component (stereociliar channel or OHC motor) will effectively result in a repositioning of the cell operating point along the corresponding transduction function.

Fast Electromechanical Amplification in the Lateral Membrane of the Outer Hair Cell

Joseph Santos-Sacchi,* Enrique Navarrete, and Lei Song

Departments of Surgery (Otolaryngology), Cellular and Molecular Physiology, and Neurobiology, Yale University School of Medicine, New Haven, Connecticut 06510

ABSTRACT Outer hair cells provide amplification within the mammalian cochlea to enhance audition. The mechanism is believed to reside within the lateral membrane of the cell that houses an expansive array of molecular motors, identified as prestin, which drives somatic electromotility. By measuring nonlinear capacitance, the electrical signature of electromotility, at kilohertz rates we have uncovered new details of the early molecular events that arise from voltage perturbations of prestin. We show that dynamic changes in motor state probability occur within the kilohertz range, and signify an amplificatory event. Additionally, we show a lack of effect of CI driving force, an absence of cell length effect (indicating that the kinetics does not vary across auditory frequency), and the first demonstration of the time dependence of tension induced amplificatory shifts. The process we have identified, where the stimulus-response function shifts in time along the stimulus axis in a multi-exponential manner, bears similarities to those components of adaptation found in the OHC stereociliar transducer identified recently. As with the forward transducer, the speed of the reverse transducer amplificatory event consequently impacts on high frequency peripheral auditory processing.

INTRODUCTION

The hallmark of mammalian cochlear amplification is a mechanical nonlinearity that is thought to arise from the mechanical activity of outer hair cells (OHC). There are two key nonlinear electro-mechanical systems in OHCs, the stereocilia forward transduction apparatus and lateral membrane reverse transduction apparatus. Each is considered a potential powerhouse for cochlear amplification. These systems transduce acoustically derived electrical energy back into mechanical energy that must finally feedback into the organ of Corti to provide an enhanced drive to the inner hair cells (IHC), which predominately control eighth-nerve afferent activity.

The favored mechanism for fast stereocilia feedback corresponds to events underlying a Ca-dependent adaptation of the hair cell's receptor current (1,2). Owing to tension dependence of the stereocilia channel, insight into channel open/closed state probability derives from inspection of the cell's nonlinear receptor current-bundle displacement (I-X) or conductance-displacement (G-X) relationship, which quantifies the activity of the channels' tension sensors. Positive tension increases the probability that the channels will reside in the open state. During a step bundle displacement, fast adaptation apparently results from the influx and binding of Ca ions to a component of the unidentified transduction channel, somehow closing the channel. At the channel population level, the process is observed as a shift of the channels' Boltzmann distribution along the stimulus axis in the same direction (polarity) as the stimulus (bundle displacement).

Thus, the process of opening transduction channels tends to close those same channels in a time-dependent manner, and the process has been shown recently to operate at the submillisecond timescale (kHz range) in OHCs (3). The resultant, channel-induced bundle movements may provide feedback into the auditory end organ.

The OHC lateral membrane motor, recently identified as prestin (4), is voltage dependent, and has been known for some time to work effectively in the kilohertz range (5,6). One popular model posits that the integral lateral membrane motors fluctuate in area between two states, contracted and expanded, just as bundle channels fluctuate between closed and open states (7,8). Owing to the motor's voltage dependence, insight into motor state probability derives from inspection of the cell's nonlinear charge-voltage (Q-V) or capacitance-voltage (C-V) relationship, which quantifies the activity of the motors' voltage sensors (9,10). Depolarization favors the contracted state. Prestin presents a behavior somewhat akin to, but notably different from the bundle adaptation process. That is, during a step voltage stimulus there is a shift in the motors' Boltzmann distribution along the stimulus axis, but unlike bundle adaptation, the shift is of opposite polarity (11). A negative voltage step will shift the distribution in the positive direction, and visa versa. This necessarily leads to an amplification of the mechanical response, because, for example, the shift caused by a hyperpolarizing voltage stimulus results in an accompanying, time-dependent augmentation in the number of motors in the expanded state at the new voltage (see Fig. 2). Thus, the voltage-dependent process that causes motors to expand tends to recruit more motors into the expanded state, whereas the process that contracts motors tends to recruit additional motors into the contracted state. Whereas the OHC motor can be driven between states at

frequencies in excess of 80 kHz (6), the fastest component of the amplificatory shift was shown previously to be ~ 70 ms (11), a timescale well below the kilohertz requirements for an influence on cochlear amplification. We show that just as previous measures of bundle adaptation kinetics were and still may be compromised by the technical problems inherent in studying acoustic rate events (3), our previous measures of amplificatory kinetics were underestimated. We now find components of the amplificatory shift that operate at submillisecond timescales, establishing the significance of this phenomenon in high frequency auditory processing. Additionally, we investigate the influence of Cl^- anions, a recently identified key player in OHC motor activity (12,13), and membrane tension on this amplificatory mechanism.

METHODS

Guinea pigs were decapitated after anesthetic overdose with halothane. Outer hair cells were freshly isolated from the guinea pig cochlea using Dispase (1 mg/ml) followed by trituration, and were whole-cell voltage clamped at room temperature using an Axon 200B amplifier. Membrane voltages were corrected for the effects of residual series resistance, which ranged from 3–5 M Ω . Ionic blocking solutions were used to remove voltage-dependent ionic conductances so that capacitive currents could be analyzed in isolation (10). Extracellular solution included: 100 mM NaCl, 20 mM TEA, 20 mM CsCl, 2 mM CoCl_2 , 1.48 mM MgCl_2 , 2 mM CaCl_2 , 10 mM HEPES, and 5 mM dextrose, adjusted to pH 7.2 with NaOH, and

adjusted to 300 mOsm with dextrose. Pipette solution included: 140 mM CsCl, 10 mM EGTA, 2 mM MgCl_2 , and 10 mM HEPES, adjusted to pH 7.2 with CsOH, and adjusted to 300 mOsm with dextrose (used in Figs. 1 and 3–5). In some cases, TEA, CsCl, CoCl_2 , CaCl_2 , and MgCl_2 were omitted (Figs. 6–8). Gluconate was used to replace chloride (Fig. 6). In some experiments, the extracellular solution was used in patch electrodes. In a few experiments, 50 μM GdCl_3 was included in the extracellular solution to decrease residual currents. At this concentration, gadolinium has an insignificant effect on OHC capacitance (14).

To deliver rapid changes in membrane tension, we used a pressure clamp system from ALA Instruments (Westbury, NY). Pipette tip diameters were increased in size for these experiments (~ 1 M Ω).

Outer hair cell capacitance was measured with a continuous high-resolution two-sine voltage stimulus protocol (20 mV peak at both f_1 and f_2 ; $f_2 = 2 \times f_1$; f_1 ranging up to 3906.3 Hz), and subsequent FFT based admittance analysis (11,15). These small, high frequency sinusoids were superimposed on voltage steps and sinusoids that spanned up to ± 200 mV.

Outer hair cell C-V plots were fitted with the function $C_m = C_{\text{lin}} + C_v$, where C_{lin} is the voltage-independent (linear surface area component) capacitance of the lipid bilayer, and $C_v = dQ_{\text{nonl}}/dV$ is the voltage-dependent component of C_m originating from prestin voltage-sensor activity. The first derivative with respect to V_m of a two-state Boltzmann function $Q = Q_{\text{max}}/(1 + \exp(-ze(V_m - V_{\text{pk}C_m})/k_B T))$ was used to fit the C-V data (10). Q_{max} is total charge moved. The measured apparent valence of prestin voltage-sensor (z) is defined as $z = q \times d$, where d is a normalized perpendicular projection of distance traveled by the voltage sensor charge (q) within the plasma membrane field. $V_{\text{pk}C_m}$ is the membrane potential (V_m) at which prestin molecules are distributed equally between expanded and contracted states. It corresponds to the peak of the C_v function.

All data collection and most analyses were carried out with an in-house developed Windows based whole-cell voltage clamp program, jClamp

(www.scisoftco.com), using a Digidata (Axon, CA) 1320 board. MATLAB (The MathWorks, Natick, MA) or SigmaPlot was used for fitting the C_m data.

RESULTS

Voltage steps from a holding potential of +50 mV (Fig. 1 C), a potential chosen because it is in a near-linear region of the OHC Q-V function, induce changes in whole cell current and capacitance (Fig. 1, A and B). The change in steady state current is a monotonic function of voltage (in this case, residual unblocked currents largely representing the activity of G_{metL} (13) (Fig. 1 E), whereas capacitance is a bell-shaped function of voltage (Fig. 1 D). Membrane current noise increases with hyperpolarization level due to activation of membrane conductances, reaching a maximum at the most hyperpolarized level of -150 mV. On the other hand, membrane capacitance noise peaks near the voltage at peak capacitance (V_{pkcm}). This likely results from the cresting chatter of prestin transitions between compact and expanded states at that voltage, because for a molecule that fluctuates between two states, variance of activity will be maximal when state probability is 0.5. Both channel current noise and gating shot noise analyses have been used to garner single channel characteristics (16–18). For the OHC, NLC noise, which is analogous to shot noise, should peak when motor state probability is half, i.e., where NLC is maximal. As far as other possible contributors to the generation of OHC capacitive noise, because the mechanical compliance of the lateral membrane (analogous to behavior hair bundle compliance (19)) is maximal at the midpoint voltage (V_{pkcm}) of the Boltzmann (20), the membrane embedded motors might be more susceptible to mechanical and/or thermal noise influences. It has been shown that motors are quite sensitive to mechanical and thermal perturbations (21–24).

Time-dependent changes in the magnitude of C_m (ΔC_m) at a fixed step occur because the C-V function shifts along the voltage axis as a result of changes from initial voltage conditions (Fig. 1 A). Fig. 2 illustrates a mechanistic account of the observation, and is discussed later. As a methodological control, Dieters' cells, supporting cells from the organ of Corti, were tested. No time-dependent changes in capacitance are observed during step changes in voltage (data not shown).

In our original work on this time-dependent phenomenon, double exponential fits to ΔC_m were made (11)

$$\Delta C_m = C_m(t) = C_0 e^{-t/\tau_0} + C_1 e^{-t/\tau_1} + C_{off}, \quad (1)$$

where C_0 and C_1 are the magnitudes of each of the components of the exponential time courses τ_0 and τ_1 , respectively. C_{off} is an offset, the cell's linear capacitance, required for fitting purposes. An example is shown in Fig. 3 A, using a C_m sampling rate (f1) of 195 Hz, used previously. However, Fig. 3, B and C, shows that the double exponential is not as accurate as the stretched exponential fitting function (25),

$$\Delta C_m = C_m(t) = C_0 \cdot e^{[-(t/\tau)^{1/h}]} + C_{off}, \quad (2)$$

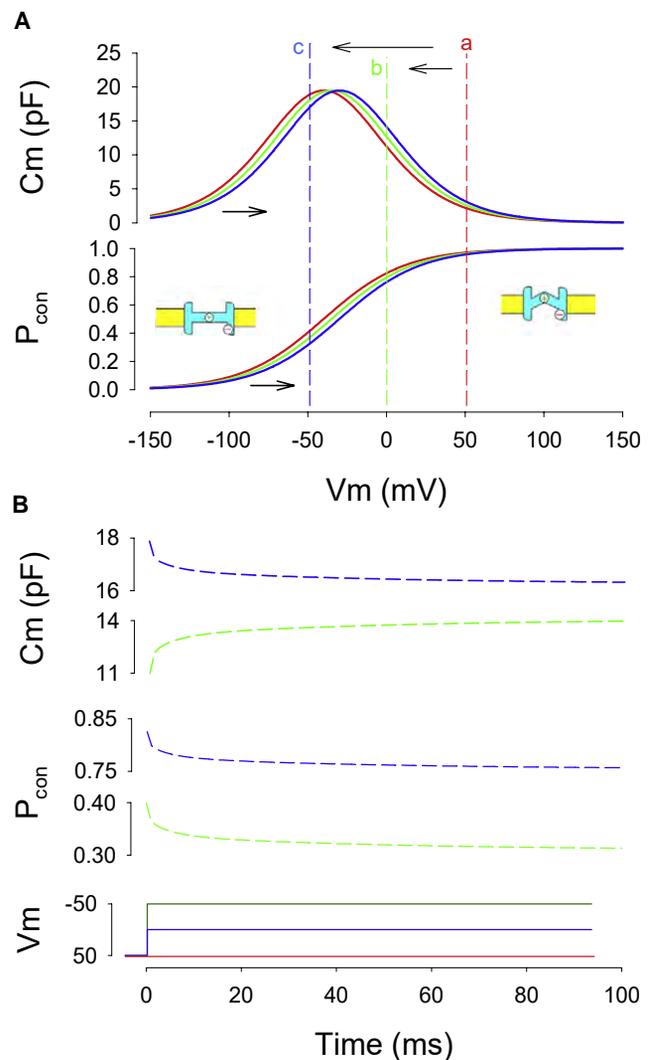

FIGURE 2 NLC shifts report on the conformational state probability of the OHC motor protein. (A) Model NLC and corresponding probability of the motor being in the compact state (P_{con}) versus membrane voltage. Cartoons depict motor in expanded state with anion bound and with positive gating charge on cytoplasmic side, and in contracted state with gating charge displaced toward the extracellular side of the membrane. (B) Corresponding time-dependent changes in state probability and NLC (green traces) during voltage steps from +50 mV to 0 mV ($a \rightarrow b$) or from +50 mV to -50 mV ($a \rightarrow c$; blue traces). Note polarities of relaxations.

where meanings are as above, and h is an indicator of non-homogeneity in the time course of change, the value of 1 reducing to a single exponential distribution. Residuals of the double exponential fit, especially at early times, are larger than those of the stretched exponential fit. The stretched exponential approach has been used to characterize complex relaxations in proteins where the discrete assumptions of single or multi-exponential processes may not hold (26). It can be useful when component rates of a phenomenon are not stationary in time, or when a phenomenon could present multiple components if looked at over a wider timescale. For example, because the apparent viscosity of a medium may

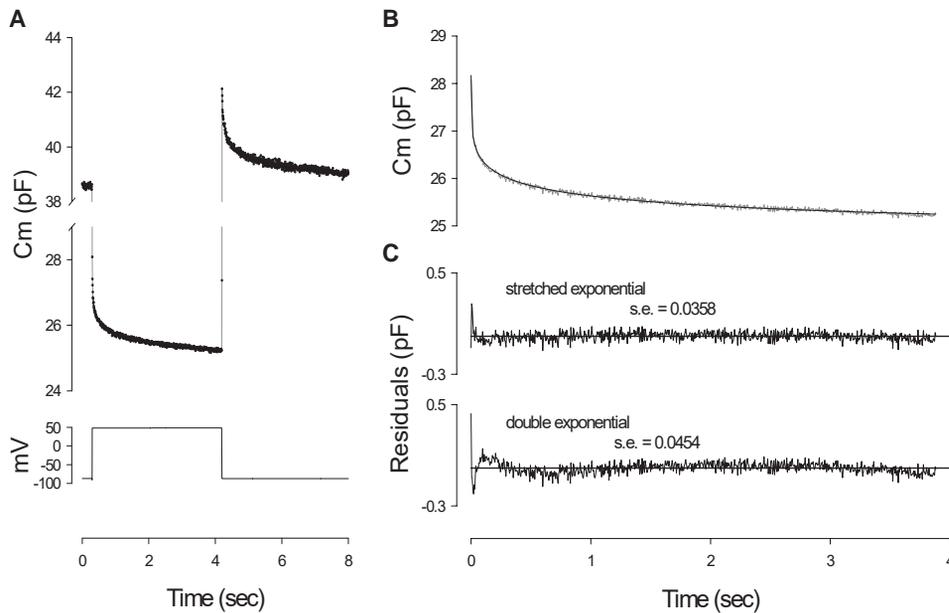

FIGURE 3 Long duration voltage pulse stimulation shows multi-exponential components in the OHC C_m relaxation. (A) C_m response induced by 4 s voltage step from -87 mV to $+53$ mV. (B) C_m trace during pulse fitted with a stretched exponential. Note excellent fit with residuals (C) being greater for the double exponential fit.

depend on rate, duration and magnitude of deformation, such stimulus dependence could be better assessed by a more dynamic fit. Although this type of fitting procedure may be especially important when an extended time course of ΔC_m is inspected, if we focus our attention on short initial time segments during a step in voltage, a double exponential proves adequate to show the fast kinetics of ΔC_m (Fig. 4). To resolve faster components of ΔC_m , sampling frequency was extended to 1.9–3.9 kHz, and step durations were restricted below 100 ms. By increasing sampling frequency from 0.196 to 1.95–3.9 kHz, a significant enhancement in the resolution of early events is obtained, simply because sampling begins at 256 or 512 μ s, rather than 5.12 ms after the onset of the voltage step. Because typically the first few points are discarded because of the transient current response contamination of the FFT, most of our older data (11) were obtained after an initial delay of >10 ms, having clearly biased the analysis toward slower components of ΔC_m . Fig. 4 A illustrates this enhancement in resolution over our previous measurements (11). Fig. 4 B shows the ΔC_m response to a 20-ms step voltage where fits to either a stretched exponential or a double exponential were made and the residuals plotted. Each seems adequate (SE = 0.0326 vs. 0.0337 pF, respectively). The stretched fit gives a time constant of 1.2 ms and h value of 2.2. The first component of the double exponential is well below 1 ms, and the second is an order of magnitude larger (τ_0 : 0.57 ± 0.142 ; τ_1 : 6.38 ± 1.22 ms; A_0 : 1.61 ± 0.3 , A_1 : 1.7 ± 0.41 pF, $n = 6$). These data indicate that early components of the amplificatory shift work in the kilohertz range.

The time course of ΔC_m , and consequently, the shift in V_{pkcm} , is dependent on voltage step magnitude (Fig. 5). Because the clamp time constant (τ_{clamp}) will depend on the step potential when recording from OHCS, as it depends on the sum of linear- and voltage-dependent capacitance, C_m

($\tau_{clamp} = Rs \times Rm / (Rs + Rm) \times C_m$), the time course of capacitance shift was determined at the termination of the voltage step when the holding voltage was reestablished (tail capacitance; Fig. 5 A, inset). The greater the voltage change the faster was the amplificatory shift. This voltage dependence could be due to a variety of voltage-dependent phenomenon in the OHC that may affect prestin, including membrane tension, membrane stiffness (as it can influence tension effects), or transmembrane chloride movements.

Chloride is a major player in prestin activity (12,13,27), and has been shown to permeate the OHC lateral plasma membrane under the control of membrane voltage and tension (13). Because chloride can shift the voltage dependence of NLC (13,28), it is conceivable that chloride influx during step changes in membrane potential could shift V_{pkcm} in a time-dependent manner. However, inspection of currents and capacitance simultaneously evoked by voltage steps (Fig. 1) indicates no correspondence of the two in time. Instead, it is possible that the time course of accumulation or removal of subplasmalemmal intracellular chloride may be the important factor. To evaluate this possibility, we varied the chemical driving force for Cl by changing the concentration of extracellular Cl^- (1, 10, or 140 mM), while using either normal pipettes with 10 mM intracellular Cl^- or perforated patch pipettes to maintain normal low intracellular Cl^- concentrations of ~ 10 mM (27). These manipulations produced neither significant changes in the magnitude nor the time course of the amplificatory shift (Fig. 6). These data indicate that Cl^- in and of itself does not contribute to the timing of the amplificatory process, leaving the possibility that mechanical events, e.g., membrane tension, within the OHC membrane might influence the generation of the shift. We had previously modeled the shift as resulting from relaxations of motor induced membrane tension (11).

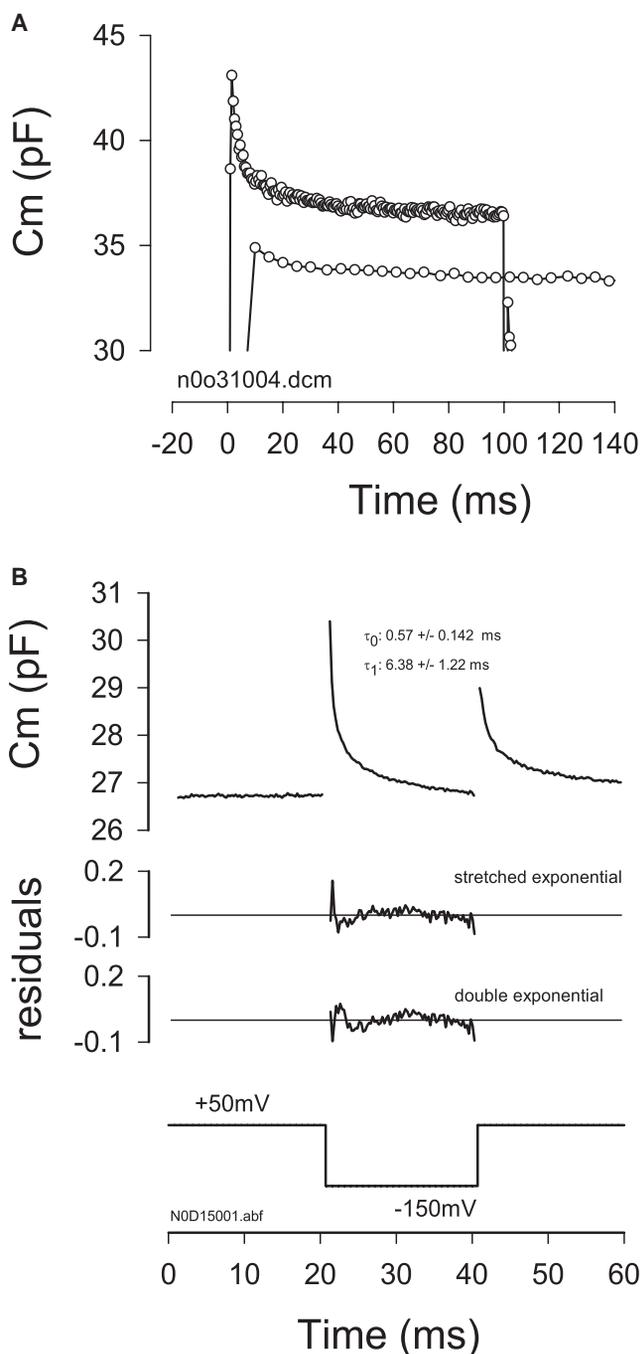

FIGURE 4 Early components of the amplificatory shift are shown with a faster C_m sampling rate. (A) C_m relaxations measured in the same cell in response to a voltage step from +50 mV to -150 mV. Top trace was sampled at 1.96 kHz and bottom trace (shifted down for visibility) was sampled at 196 Hz. Early components are evident with fast sampling. (B) Example of C_m relaxation (averaged traces, $n = 9$) in response to 20 ms voltage step from +50 to -150 mV at a C_m sampling frequency of 3.9 kHz. In this case a double exponential fit and stretched fit provide equally good fits as indicated by residuals. For six cells, τ_0 : 0.57 ± 0.142 τ_1 : 6.38 ± 1.22 ms; A_0 : 1.61 ± 0.3 , A_1 : 1.7 ± 0.41 pF.

The voltage-induced deformations of the lateral membrane must be influenced by the mechanical properties of the cell; for example, the stiffness of the OHC varies with cell length

(30) and whole cell stiffness (that is additionally voltage dependent (31)) might feedback into the active mechanics of the lateral membrane. To see if cell stiffness can influence the shift, we tested whether cell length correlates with the time course of the shift. Fig. 7 shows that cell length does not influence the time course of the amplificatory shift.

Finally, we tested whether rapid changes in membrane tension, which are expected to produce rapid changes in motor state probability (21,22,24), can mimic or interact with the voltage induced amplificatory shift. Fig. 8 shows that rapid changes in membrane tension at a fixed voltage shifts V_{pkcm} in a time-dependent manner, mimicking to some extent the C_m relaxations induced by step voltage changes. The examples shown are two of the best cells obtained in over 30 cells studied. An example of the OHC strain associated with a pressure step (black solid trace) is depicted in Fig. 8 A, and shows that the major strain occurs at the onset of the pressure delivery to the cell. In Fig. 8 B, before step changes in pipette pressure, a voltage ramp (denoted by the numeral 1) was delivered to measure V_{pkcm} . Subsequently, a step in pressure was delivered and after 2 s another voltage ramp (2) was delivered to gauge the shift in V_{pkcm} . Finally, a voltage step from 0 to -50 mV was delivered to observe the voltage-induced C_m relaxation at the stepped pressure. The protocol was repeated after a minute wait for recovery. In this manner, pressure steps up to 2 kPa were delivered. The lowest pressure step depicted (Fig. 8 B, black line) produced no response because cellular material in the pipette tip obstructed flow. With increasing pressures it can be seen that the pipette unplugged at decreasingly shorter times after onset of the pressure step (red, green, dark green, blue, and purple). The last pressure pulse (purple) caused the cell to burst at ~1.75 s after onset. The shift in V_{pkcm} and changes in z are plotted in Fig. 8, C and D. The reduction in z may correspond to the restricted movements of charge that Adachi and Iwasa (33) found on extreme inflation of the trypsinized OHCs. In general, the effects of rapid pressure changes correspond to analogous step changes in voltage; however, the time course of the shifts (compare relaxations due to pressure alone versus the additional voltage step (3)) is slower for pressure changes. One caveat is that intracellular pressure may not be as constant as membrane voltage because OHC strain changes slightly during the constant pipette pressure pulse.

DISCUSSION

By measuring OHC nonlinear membrane capacitance at sub-millisecond resolutions, we have examined the early time course of the dynamic response of the OHC motor to preconditioning membrane voltages and tensions. We show for the first time that this time course is multi-exponential, with the earliest detectable components residing in the kilohertz range, thereby establishing the phenomenon's potential significance in peripheral auditory processing of the mammal. These effects actually extend well into the low frequency range, as well; indeed, altering steady state resting potentials can stably

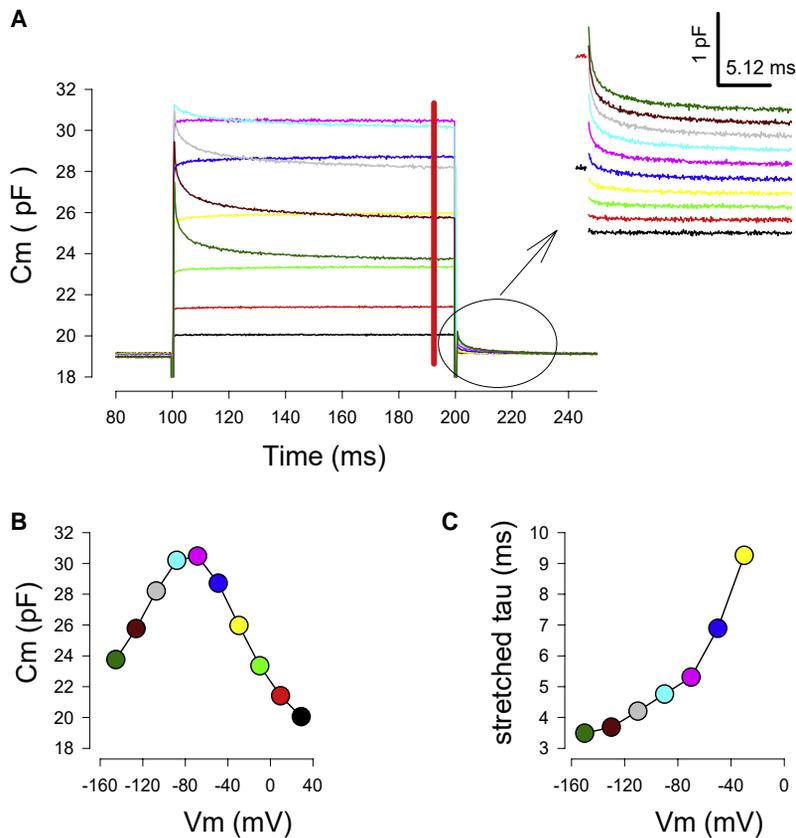

FIGURE 5 Voltage dependence of amplificatory shift. (A) Averaged C_m traces ($n = 9$) in response to voltage steps from +50 mV to -150 mV as in Fig. 1. The red bar indicates the region used to plot the C-V curve (B). Tail capacitance (inset) was used to measure voltage dependent time constants (C).

set the operating point of electromotility to different points along the voltage axis.

Our data, although measuring whole cell capacitance, actually provide insight into the initial condition-dependent conformational states of the motor protein, prestin. As such, the correspondence between voltage-induced ΔC_m and motor state probability can be extracted from the data of Fig. 1, as schematized in Fig. 2. Thus, for voltage steps to potentials positive to V_{pkcm} (Fig. 2 A, $a \rightarrow b$), the magnitude of C_m increases during the step duration, because the rising side of the C-V function moves to the right and the shift eventually halts at a point where capacitance is now larger at the step potential. For steps to potentials negative to V_{pkcm} (Fig. 2 A, $a \rightarrow c$), the magnitude of C_m decreases during the step duration, because the falling side of the C-V function moves to the right and the shift halts at a point where capacitance is now lower at the step potential. Although capacitance may increase or decrease (Fig. 2 B), both correspond to a unidirectional change in motor state probability, as a conversion of capacitance to gating charge would show. Consequently, depolarizing voltages, in addition to causing a near instantaneous redistribution of motors to the compact state, will foster a supplemental recruitment of additional motors into that state, leading to an amplification of the initial response. The same amplification effect holds for hyperpolarizing voltages, where recruitment of motors will be into the expanded state. To reiterate, when OHC holding potential is stepped to a negative potential and maintained there, there will be a shift

in the motor state probability function in the opposite direction to positive potentials. The initial voltage step to a negative potential will immediately cause a set of motors to move to the expanded state. When the motor state probability function moves to positive potentials, at the fixed holding potential more motors will enter the expanded state because the new probability at the fixed holding potential dictates it. From this, it is easy to predict the distortion in the mechanical response that will arise, distortion being the hallmark of mammalian cochlear amplification (34).

It should be emphasized that the amplificatory shift that occurs in the Boltzmann function does not predict a high pass response. In contrast, it is a process that rapidly follows the instantaneous change in motor state probability initiated by a step voltage, and continues over the stretched exponential time course we have described, reaching maximum at steady state. Thus, it is a low pass response where motors are recruited into the same state initially evoked by the onset of the voltage stimulus. We previously modeled the expected response (11), which we and others have observed in OHC mechanical responses. The multi-exponential amplificatory response dictates that the phenomenon will have impact in the acoustic frequency range. To be sure, the most important frequency range for humans is that of the speech frequencies (500–2000 Hz).

Although anions play a major role in NLC generation, our results indicate that modifying the driving force for chloride movement across the OHC lateral membrane through G_{metL}

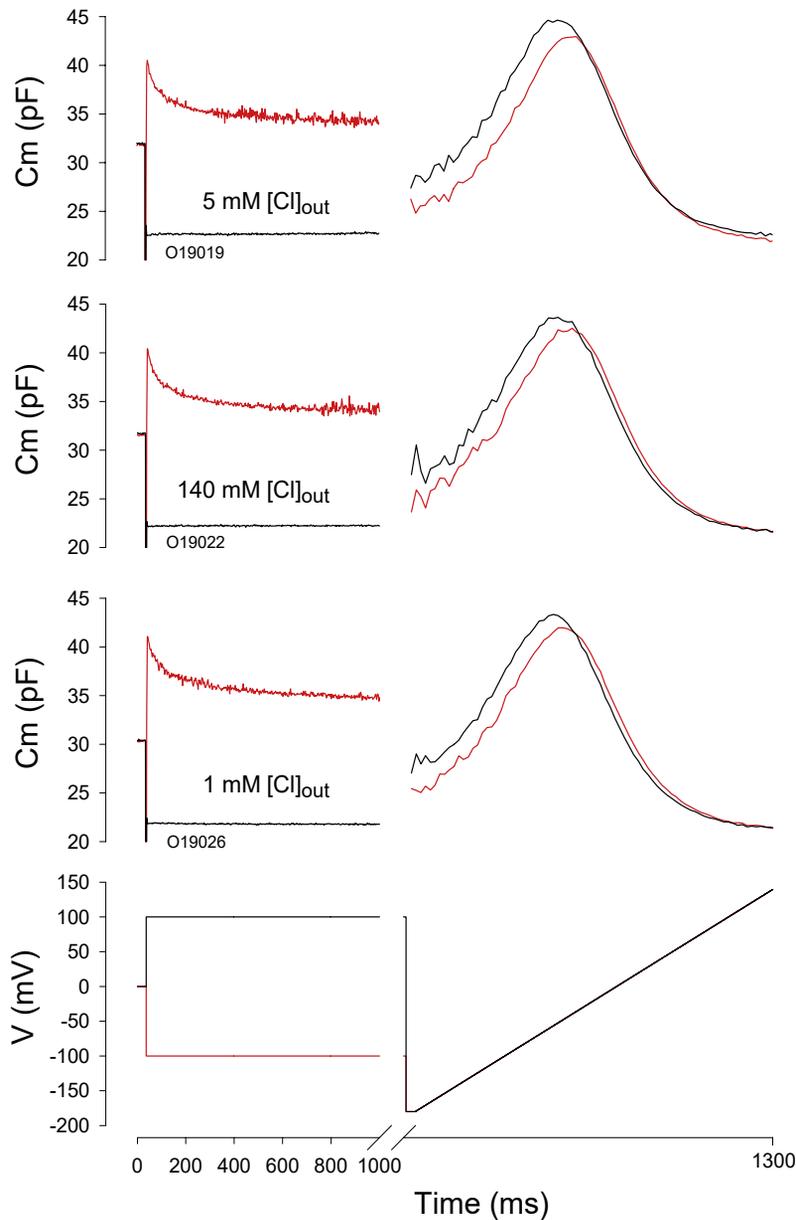

FIGURE 6 Time course and magnitude of amplificatory shift is not dependent on Cl^- driving force. Results from a typical cell clamped with a perforated gramicidin patch to maintain intracellular Cl^- levels. Extracellular Cl^- was altered to 5 mM (top, C_m traces), 140 mM (middle, C_m traces) and 1 mM (bottom, C_m traces). Voltage protocol is shown at bottom. After step jumps to either 100 or -100 mV from 0 mV, a ramp was voltage delivered to gauge the shift of V_{pkcm} . Shifts were -47.8 to -40.9 , -50 to -41.5 , and -54 to -46 for 5, 140, and 1 mM Cl^- , respectively.

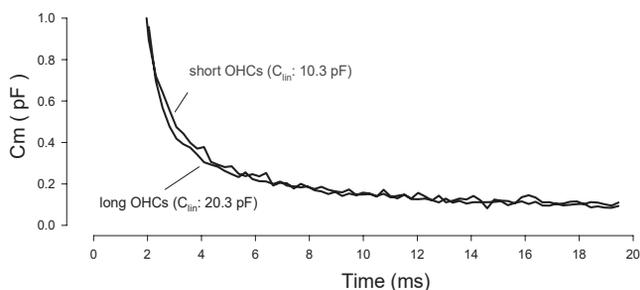

FIGURE 7 Whole cell characteristics do not influence time course of the amplificatory shift. Double exponential fits were made. Short OHC labeled trace is averaged C_m response (return to $+50$ mV from -150 mV) from four short cells ($C_{\text{lin}}: 10.3 \pm 0.69$ pF; $\tau_0: 0.76$; $\tau_1: 4.09$ ms). Long OHC labeled trace is average from five long cells ($C_{\text{lin}}: 20.27 \pm 0.88$; $\tau_0: 0.76$; $\tau_1: 3.98$ ms). Time courses are essentially equal.

(13) does not modify the extent or time course of the amplificatory shift. This is in marked contrast with the effects of altering the driving force for Ca^{2+} on stereociliar adaptation (3). Reducing the entry of Ca^{2+} through the stereociliar channels can remove the tension-induced shift in the forward transducer function along the stimulus axis. Thus, parallels between the two mechanisms (apical stereociliar and lateral prestin motor) are not tight. It should be noted that although driving force for chloride did not significantly affect the amplificatory shift of the motor, the interactions of anions with the motor may still play a role. In this regard, we have found recently that the state probability of prestin influences anion binding affinity (L. Song and J. Santos-Sacchi, unpublished), and that even if concentrations remain the same at the intracellular binding sites of prestin, changes in

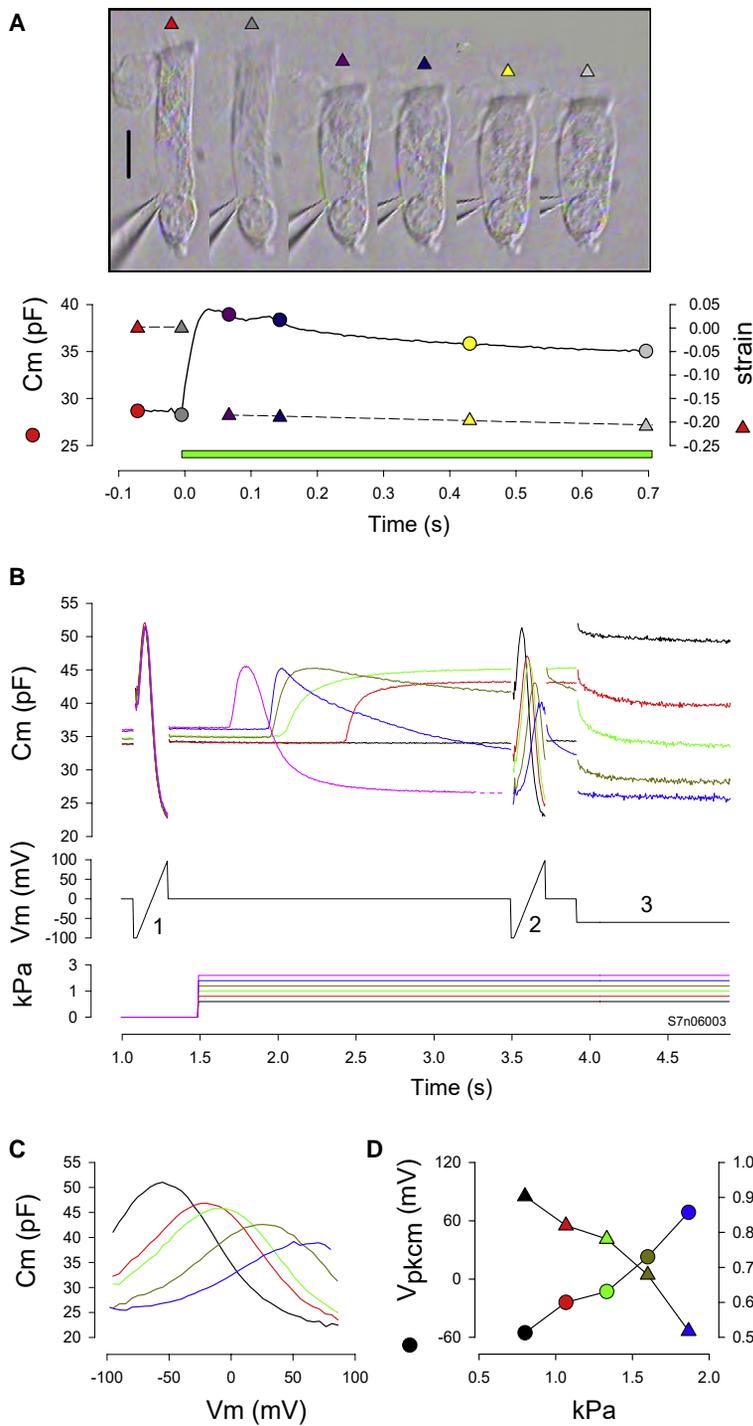

FIGURE 8 Rapid turgor pressure changes induce membrane tension with accompanying relaxations in C_m . (A) Photos of an OHC at different time points during a 1.8 kPa pressure step. C_m relaxation and longitudinal strain ($(L - \delta L)/L$) are plotted beneath. Green bar indicates pressure delivery to the cell. Note the majority of strain occurs before C_m relaxation begins. (B) Another cell. Color coded C_m traces induced by combinations of voltage ramps (1 and 2), voltage steps (3) and pressure steps. Single exponential fits of the C_m relaxations due to 1.4 (dark green), 1.6 (blue), and 1.8 (purple) kPa steps were 1.01, 0.88, and 0.16 s, respectively. (C) C-V plots obtained 2 s after onset of pipette pressure steps. Voltage was corrected for R_s effects that ranged from 1.7–4.5 $M\Omega$ during the pressure changes. (D) Boltzmann parameters V_{pkcm} and z as a function of pressure.

binding site affinity, as can occur with allosteric modulation, could alter energy profiles, resulting in V_{pkcm} shifts. We are exploring such possibilities currently.

Since the initial observations of Iwasa (21), membrane tension effects on the OHC motor have provided important information on surprisingly efficient piezoelectric activity of this protein (35). Because membrane tension can shift V_{pkcm} and, indeed, in extreme applications, restrict conformational activity (33), we had modeled the voltage-induced

amplificatory shift as resulting from motor induced tension (11). In this study we attempted to directly test this by applying rapid changes in membrane tension and seeking C_m relaxations that mimic those induced by voltage steps. Although there are indications of C_m relaxations after rapid tension changes, the time courses of voltage-induced and tension-induced C_m relaxations differ, tension effects being slower. It is possible that during our attempts to alter membrane tension through global changes in OHC structure

we may have been restricted by the viscoelastic properties of the whole cell. For example, Ehrenstein and Iwasa (36) found that mechanical relaxations in the OHC have a time constant on the order of 40 s. However, because the fastest C_m relaxation time constants that we found with pressure steps were ~ 2 orders of magnitude faster than their measured time course, our pressure clamp driver seems to have been quite successful in overcoming this mechanical impediment. We suggest that tension induced by the molecular motors themselves can better bypass this viscoelastic constraint, thereby providing more rapid tensions to evoke fast amplification shifts. Thus, we still view motor-derived membrane tension, possibly through alterations of anion binding affinity, to underlie voltage-induced amplification shifts. Nevertheless, as we have shown previously, the membrane environment of prestin can have profound effects on the magnitude and time course of the amplification shift (37).

In summary, we show remarkably fast changes in the Boltzmann distribution of prestin motor states induced by initial voltage conditions. The shifts along the voltage axis represent amplification supplementation to the voltage-induced mechanical response of the cell, and it is expected that this phenomenon will impact on high frequency peripheral auditory processing.

On the temperature and tension dependence of the outer hair cell lateral membrane conductance G_{metL} and its relation to prestin

Received: 19 December 2005 / Accepted: 20 December 2005 / Published online: 7 March 2006
© Springer-Verlag 2006

Abstract Recently, we identified an outer hair cell (OHC) lateral membrane conductance, G_{metL} , that colocalizes with prestin and passes Cl^- , thereby influencing prestin's (SLC26A5) electromechanical activity. In this study, we report on a comparison of the temperature and tension dependence of G_{metL} and prestin. Though we find significant temperature and tension dependence of each, substantial differences exist which indicate their independent identity. The following data support this conclusion: (1) The voltage dependence of G_{metL} does not follow that of prestin's nonlinear capacitance (NLC) function when the latter is shifted by either temperature or membrane tension; (2) Unlike native OHCs whose NLC can be modulated by influx of extracellular Cl^- , prestin-transfected Chinese hamster ovary (CHO) cells do not show this phenomenon; (3) Stretch-sensitive, single channel currents are not evidenced after prestin transfection in CHO cells; and (4) There is no correlation between prestin expression level (gauged via NLC) and transmembrane current through G_{metL} . Thus, G_{metL} must result from the activity of another molecular species within the lateral membrane of the OHC. A clue to its identity is the conductance's nonlinear temperature dependence in contrast to prestin and other

OHC conductances' linear dependence. Whereas K^+ conductances in OHCs present a uniform Q_{10} close to 1.2, G_{metL} shows a bimodal Q_{10} , with a Q_{10} of 1.5 below 34°C and a Q_{10} of greater than 4 and above. The dissociation of SLC26A5 (prestina) and G_{metL} theoretically provides for a modifiable anionic feedback to prestin via the degree of spatial separation between these interacting partners within the OHC lateral membrane.

Introduction

The outer hair cell (OHC) lateral membrane motor, prestin or SLC26A5 [15, 27, 31], is thought to underlie the mammalian cochlear amplifier [14], and intracellular chloride is known to influence its activity [19, 21, 29]. This motor activity, measured either as a length change of the OHC or as an associated nonlinear capacitance (NLC), has been modeled successfully as a two-state Boltzmann process, with depolarization driving the motor into the compact state [10, 22, 23]. Recently, we discovered a stretch/voltage sensitive conductance (G_{metL}) that nonselectively passes small cations and anions through the OHC lateral membrane [21]. Furthermore, the intracellular accumulation of chloride via this conductance strongly influences prestin activity, increasing the probability of prestin being in the compact state. We found no indication of a conductance similar to G_{metL} in isolated neighboring Deiters' cells, which lack prestin.

G_{metL} shares some properties of prestin, namely, its restricted location within the lateral membrane, tension dependence, and modulation by Cl^- channel blockers [21]. In this regard, it is well established that some transporter family members actually underlie ionic conductances, including, for example, cystic fibrosis transmembrane conductance (CFTR) [8], the sodium/bicarbonate cotransporter, NBCn1 [4], and the glial glutamate transporter EAAT2 [20]. In fact, recently, another SLC26 family member, SLC26A7, has been shown to function as a chloride channel that is regulated by pH [13]. It is interesting to note, whereas SLC26A7 chloride currents are

blocked by DIDS, that G_{metL} is actually enhanced by DIDS [21], similar to the Na current associated with NBCn1 expression [4]. It is conceivable that G_{metL} could result from either the expression of prestin itself or through other proteins within the lateral membrane. In this study, we analyze the temperature and tension dependence of G_{metL} and prestin, thereby allowing us to determine whether prestin activity results in or influences Cl^- movements through membranes expressing this protein. Our data indicate that the molecular identity of G_{metL} is distinct from prestin, providing insight into their feedback capabilities.

Materials and methods

General

Guinea pigs were killed with halothane inhalation overdose in accordance with an approved protocol from Yale University's Animal Use and Care Committee. OHCs were freshly isolated from the adult guinea pig organ of Corti by sequential enzymatic (dispase 0.5 mg/mL) and mechanical treatment in Ca-free medium. Currents and capacitance from voltage-clamped cells were recorded at room temperature or at other temperatures (set by a Peltier device controlling the perfusion chamber) using an Axon 200A or 200B amplifier, Digidata 1321A or NI PCI-6052E board (Axon Inst., CA, USA; National Inst., USA), and the software program jClamp (Scisoft, CT, USA). To limit interfering K^+ conductances, the base intra- and extracellular solution was NaCl or TrisCl 140–150, CaSO_4 2.5, MgSO_4 1.2, HEPES 10, pH 7.2, 300 mOsm. Chloride substitutions were made with malate. For K^+ current studies, intracellular solutions were made with KCl. Solutions were delivered to individual cells by Y tube during continuous whole bath perfusion of base extracel-

lular solution. Series resistance effects were corrected offline. Currents were monitored at the fixed holding potential stated in the figure legends. Evaluations of gerbil prestin were made in Chinese hamster ovary (CHO) cells. Transient cotransfection was achieved as described previously [16], with cotransfection of GFP. Data are presented as mean \pm SE.

Nonlinear capacitance

Nonlinear membrane capacitance was evaluated using a continuous high-resolution (2.56 ms sampling), two-sine voltage stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz), with subsequent fast Fourier transform-based admittance analysis as fully described in Santos-Sacchi et al. [24, 26]. These high-frequency sinusoids were superimposed on voltage ramps. To avoid capacitive current contamination (influenced by the cell's voltage-dependent capacitance) of I_{metL} , we used ramps of 1 s duration. Peak nonlinear capacitance was determined by subtracting linear capacitance. $C-V$ data were fit with the first derivative of a two-state Boltzmann function and a constant representing the linear capacitance [22],

$$C_m = Q_{\text{max}} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}} \quad (1)$$

$$b = \exp\left(\frac{-ze(V_m - V_{\text{pkcm}})}{kT}\right)$$

where Q_{max} is the maximum nonlinear charge moved, V_{pkcm} is voltage at peak capacitance or half maximal nonlinear charge transfer, V_m is membrane potential, C_{lin} is linear capacitance, z is apparent valence, e is electron charge, k is Boltzmann's constant, and T is absolute

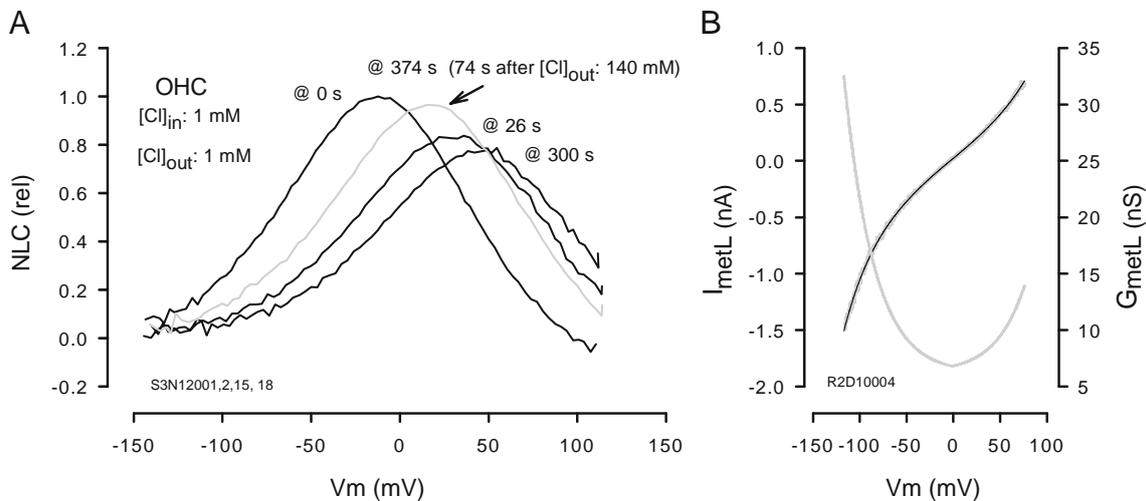

Fig. 1 Chloride enters the OHC through a lateral membrane conductance. **a** After obtaining whole-cell condition with 1 mM intra/extracellular Cl^- (Na-based) solutions, OHC NLC shifts rightward and decreases. NLC reaches steady state at about 2/3 of initial NLC beyond 1 min washout. Subsequently, a switch to 140 mM extracellular Cl^- restores NLC (grey trace), indicating Cl^- influx through G_{metL} . **b** Ionic current of an OHC with 150 mM Cl^- (Tris-based) intra/extracellular solution evoked by a 1 sec voltage ramp. The sigmoidal current is fitted with Eq. 2 (solid line; $V_h: -0.71$ mV) and the slope conductance (grey, V-shaped line) derived from the fit

temperature. A phenomenological equation was devised to fit the sigmoidal V_m dependence of I_{metL} , providing estimates of the midpoint voltage (V_h) of its operating voltage range, which were then compared with the midpoint voltage, V_{pkcm} , of the simultaneously recorded NLC.

$$I = A * dV * \exp(|dV|/b) + off \quad (2)$$

where A is current amplitude, $dV=V_m-V_h$, b is a slope factor, and off is an offset.

Single channel recoding

Prestin-transfected CHO cells and controls were tested for the occurrence of stretch-activated single channel currents. Forty control CHO cells and 55 CHO cells transfected with normal prestin-yellow fluorescent protein were recorded by cell-attach configuration. Some of them were also recorded by inside-out configuration. Patches were made over fluorescent hot spots. Bath solution (mM): 140 NaCl, 2 MgSO₄, 2 CaSO₄, 10 HEPES; pipette solution (mM): 140 NaCl, 2 MgSO₄, 2 CaSO₄, 10 EGTA, 10 HEPES pH 7.2, 300 mOsm.

Results

NLC capacitance in the OHC is a shallow function of voltage (Fig. 1). The magnitude- and voltage-operating range is highly dependent on intracellular chloride levels but is also dependent in the native OHC on extracellular chloride which passes through a lateral membrane conductance. Figure 1a shows that, in the presence of low extracellular chloride (1 mM), washout of intracellular chloride with low chloride containing patch pipette solutions shifts NLC to depolarizing levels and decreases its peak magnitude. After reaching steady state, the introduction of normal extracellular chloride levels (140 mM)

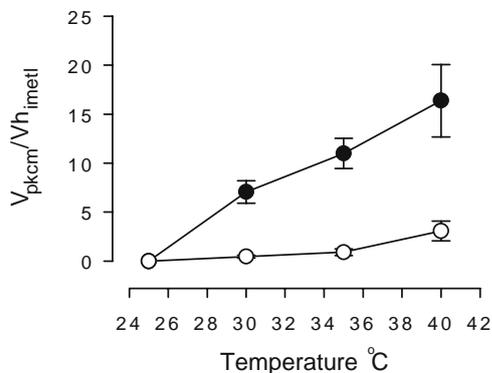

Fig. 2 After obtaining stable whole-cell conditions with 150 mM Cl⁻ (Tris-based) intra/extracellular solutions, bath temperature was altered. V_{pkcm} of the NLC (filled circles) shifted rightward (depolarizing) with increases in temperature; however V_h of I_{metL} (open circles) did not follow, indicating independence of the two simultaneous measures. Plotted is mean±SE, $n=4$

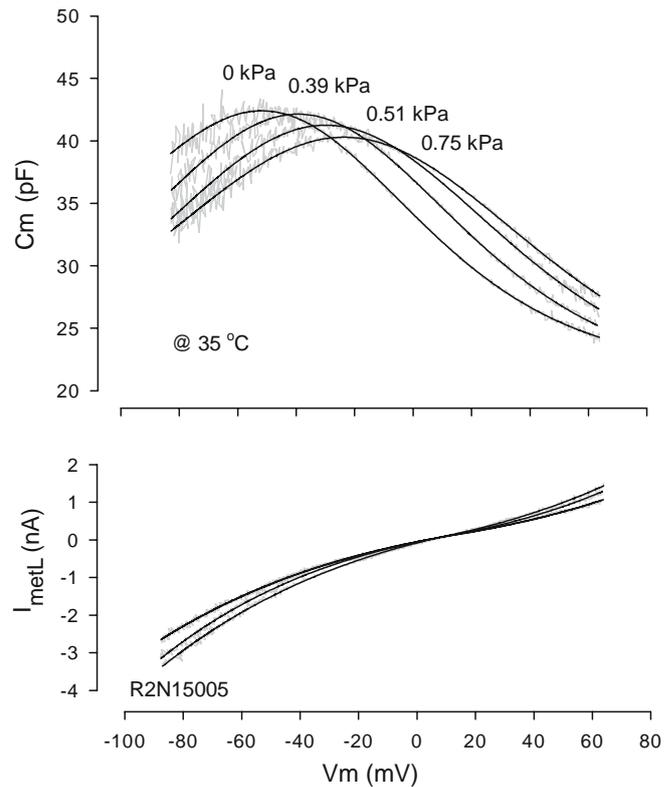

Fig. 3 After obtaining stable whole-cell conditions with 150 mM Cl⁻ (Tris-based) intra/extracellular solutions, tension was applied to the OHC membrane by pipette pressure. NLC shifts rightward and decreases with increasing turgor pressure. Note that I_{metL} increases with increasing membrane tension, but its voltage dependence remains unaltered. V_{pkcm} (mV) vs V_h (mV) with increasing pressure: -49.2/13.9; -39.0/14.2; -30.6/10.4; -23.0/11.3. Indeed, the initial turgor pressure change from 0 to 0.39 kPa produced a NLC shift, but no significant change in current, indicating the independence of the two simultaneous measures. Temperature was 35°C

restores NLC. This restoration is a consequence of a gradient-driven, lateral membrane chloride current, I_{metL} , that has a V-shaped conductance, G_{metL} , and has been shown to be charge nonselective [21]. Fitting the slope conductance of the G_{metL} defines a midvoltage (V_h), where conductance is minimal, and establishes an operating voltage range which can be compared to that of NLC measured in the same cell. To determine whether the underlying molecular structure, prestin, which is responsible for NLC generation, also fosters G_{metL} , we simultaneously compared V_h and V_{pkcm} , under conditions where V_{pkcm} is known to change.

First, we altered bath temperature (from 25 to 40°C), which has been shown to shift V_{pkcm} in the depolarizing direction [17, 25]. Figure 2 shows that whereas the operating voltage range of prestin is altered by temperature, shifting about 1 mV/°C, that of G_{metL} is little affected. Second, we changed intracellular turgor pressure to alter tension on the OHC membrane. As expected, increasing turgor pressure shifted V_{pkcm} to depolarizing levels [6, 9, 11, 27] (Fig. 3); however, the voltage-operating range of G_{metL} is unaffected. These observations were confirmed in more than five OHCs. Finally, we directly tested whether

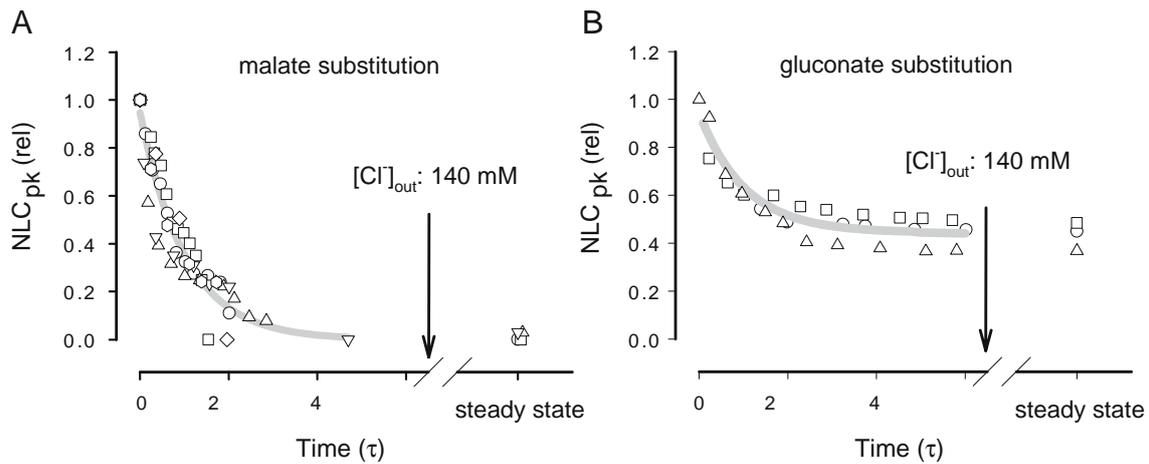

Fig. 4 a, b After obtaining whole cell in prestin-transfected cells with 1 mM intra/extracellular Cl^- (Na-based) solutions, NLC shifts rightward and decreases to barely perceptible levels when malate is the substitute anion. Using gluconate as substitute, reduction is only about 30%, similar to what we find in OHCs [21, 30]. Unlike in OHCs, a subsequent switch to 140 mM extracellular Cl^- does not restore NLC, indicating lack of Cl^- influx. Symbols denote individual cells whose washout effects were corrected for washout rate and plotted against the exponential washout time. The mean (\pm SE) value of τ was 49.18 ± 7.57 s (malate); $\tau = 35.56 \pm 10.00$ s (gluconate)

prestin transfection in nonauditory cells results in the generation of a chloride conductance in addition to NLC. We previously showed that prestin targets the plasma membrane and generates NLC in CHO cells [18]. Now, we find that, as with OHCs in the presence of low extracellular chloride (1 mM), washout of intracellular chloride with low chloride containing patch pipette solutions shifts NLC to depolarizing levels and decreases its peak magnitude (Fig. 4). However, unlike native OHCs, the introduction of normal extracellular chloride levels (140 mM) fails to restore NLC. The degree of reduction in NLC during

washout of chloride is dependent on the substitute anion. For malate, NLC decreases nearly fully (Fig. 4a); however, with gluconate as substitute, about 30% NLC remains (Fig. 4b), similar to what we find in OHCs [21, 29]. For either substitute anion, however, the subsequent reintroduction of high extracellular chloride does not increase NLC. Similar experiments carried out with gramicidin patches to eliminate pipette washout of chloride near the inner aspect of prestin gave the same results (Fig. 5a). On the other hand, when we increased intracellular chloride via the patch pipette after gramicidin patch rupture or when we

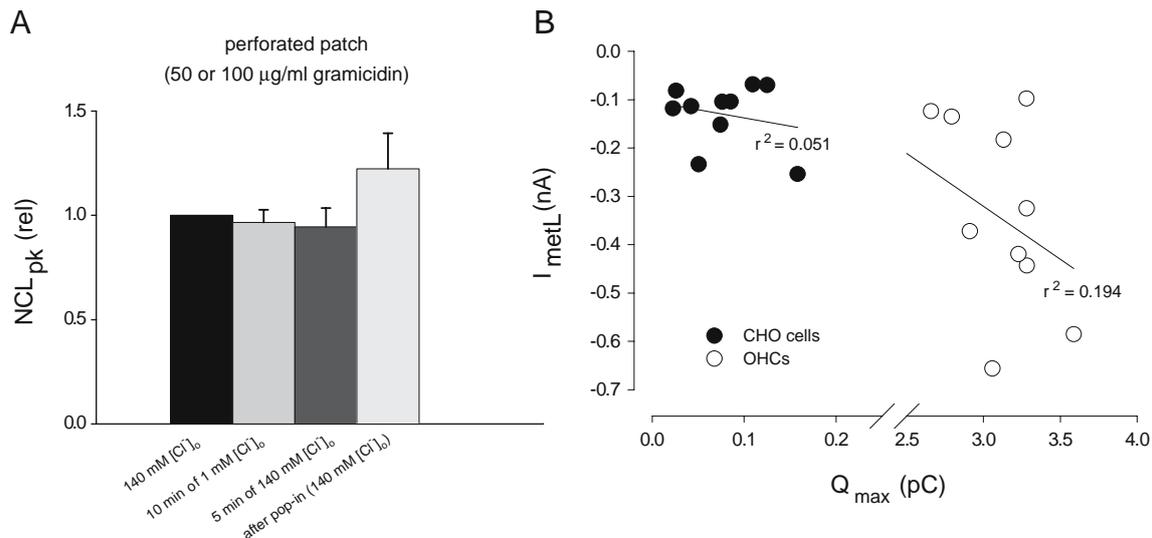

Fig. 5 a Lack of chloride influx in prestin-transfected CHO cells under perforated patch conditions. Prestin-transfected CHO cells were patched with gramicidin pipettes to limit the pipette washout of chloride so that transmembrane chloride flux could be unambiguously determined. In the presence of 140 mM extracellular chloride, relative NLC was determined after series resistance allowed whole-cell measurements. Subsequently, extracellular chloride was altered to see if NLC could be modulated by influx or outflux of chloride. Reductions and reperfusion of chloride had no effect, but NLC was augmented when true whole-cell configuration was established after patch rupture, indicating that chloride did not enter through the membrane. $n=6$ cells. **b** Comparison of G_{metL} and prestin activities shows no correlation in either prestin-transfected CHO cells or OHCs, as might have been expected if the expression level of prestin influenced I_{metL} activity. Symbols denote separate cells

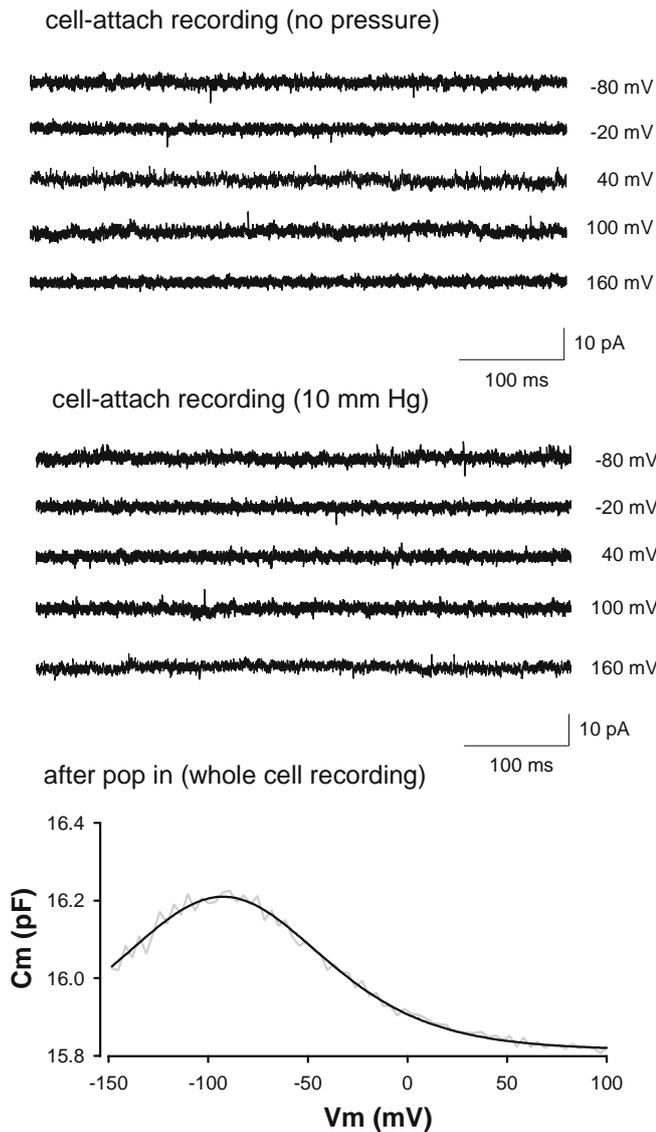

Fig. 7 I_{metL} is bimodally temperature sensitive, showing high sensitivity above 34°C , and typical diffusional sensitivity below that. K^+ current magnitude in OHCs is not temperature sensitive. OHC I_{metL} at -70 mV, circles; OHC I_{K^+} $+30$ mV, triangles. Plotted is mean \pm SE, $n=3-5$. Series resistance correction was performed on a point by point basis ($V_{\text{m}} = V_{\text{command}} - I \cdot R_{\text{s}}$). The progressive limited range of voltages as a function of current magnitude results in the “tilted” appearance of the I - V curves

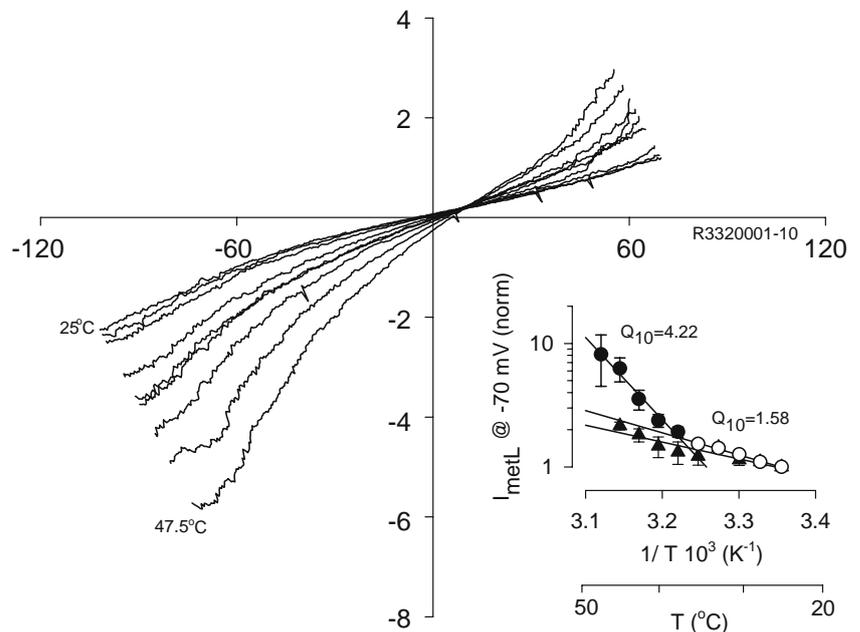

Fig. 6 On cell patch recording of prestin-transfected CHO cells to determine single channel currents [before (*top panel*) and after (*middle panel*) stretch to patch]. In the prestin-transfected cell, shown stretch did not elicit single channel currents (*top and middle panels*). The *bottom panel* NLC was confirmed after patch rupture. Forty cells of control CHO cells and 55 transfected cells of prestin-YFP fusions were recorded by cell-attach configuration. Some of them were also recorded by inside-out configuration. No stretch-sensitive activity was found from the prestin group. In both groups, some non-stretch-activated endogenous currents were recorded. They were activated only at hyperpolarization potentials, i.e., around rest potential (-80 to -60 mV). The numbers are 7 out of 40 from control CHO cells and 5 out of 55 from prestin cells

reintroduced chloride via whole-cell pipette backfill after intracellular washout, NLC increased or recovered, respectively. We also compared prestin activity (Q_{max}) to G_{metL} activity (I_{metL} at -70 mV in symmetrical 140 Cl solutions) to see if there was a correlation between the two (Fig. 5b). In either CHO cells or OHCs, the activities were uncorrelated. In addition, we searched for stretch-dependent, single channel activity that might have arisen following prestin expression in CHO cells and found none (Fig. 6). Taken together, our data show that prestin is not responsible for the chloride conductance, G_{metL} , found in OHCs.

Finally, though we found no change in the voltage-operating range of G_{metL} with temperature (Fig. 2), I_{metL} magnitudes at -70 mV were bimodally temperature sensitive. Figure 7 shows that below about 34°C , the Q_{10} value was 1.58 (open circles, inset), but above that temperature, Q_{10} was 4.22 (closed circles). In comparison, in the absence of ionic-blocking solutions, K^+ currents at $+30$ mV (steady holding level) in OHCs (triangles) show Q_{10} s of less than 1.3.

Discussion

G_{metL} is partially blocked by a few stretch-channel blockers, including gadolinium, tamoxifen, and quinine but is resistant to a host of other channel and transporter blockers [21]. Although the molecular identity of G_{metL} remains unknown, it is clear that G_{metL} and prestin share some characteristics, including restriction to the lateral membrane and sensitivity to chloride channel blockers (e.g., niflumic acid). One possibility is that G_{metL} arises from prestin itself, just as SLC26A7 underlies a chloride conductance [13]. Here, because we hypothesized that G_{metL} could arise from the conformational activity of prestin, we surmised that modulating prestin's voltage dependence with temperature and pressure would necessarily affect G_{metL} 's voltage dependence if the foregoing premise were true. To test whether prestin produces the OHC conductance or whether prestin somehow gates this conductance (possibly via a prestin-induced mechanical activation), we monitored characteristics of G_{metL} while modulating NLC with established techniques, including manipulations of turgor pressure and temperature, to see if each is similarly affected. In addition, we determined whether transfection of prestin into nonauditory cells induces a chloride conductance. The absence of a correspondence between the voltage-operating range of NLC and of G_{metL} in OHCs and an absence of significant Cl^- flux in prestin-transfected cells lead us to conclude that each is independent. This conclusion is further established by the absence of a correlation between Q_{max} and I_{metL} magnitudes in CHO cells and OHCs, and the absence of induced, stretch-dependent single channel activity in prestin-transfected CHO cells.

Another indication of the distinct nature of the two lateral membrane components is the temperature effects we observe on each. Though each is temperature sensitive, a clear breakpoint in sensitivity is evidenced for G_{metL} , where the conductance markedly changes its behavior as a characteristic temperature is crossed; NLC, on the other hand, is monotonically responsive to temperature, and this additionally indicates that possible phase transitions within the lateral membrane do not occur. That is, temperature has its effects on the protein structures underlying NLC and G_{metL} , not the membrane environment. This is not to say that temperature cannot affect prestin via the lipid bilayer, as we have shown that lipid reactive agents and, indeed, temperature can alter the kinetics of voltage- (prepulse) induced shifts in the motor's Boltzmann function along the voltage axis [28].

It is of interest that the temperature dependence of G_{metL} points to a molecular structure whose conformation is switched at a threshold temperature. Again, the absence of such a threshold phenomenon in the K^+ currents of OHCs argues against a nonspecific influence on the membrane. This type of behavior is reminiscent of some temperature sensitive transient receptor potential (TRP) channels [7], where Q_{10} above threshold temperatures, ranging from 30 to 50°C, can switch to greater than 10. It is also interesting that TRP channels can be mechanically sensitive, as is

G_{metL} . Nevertheless, TRP channels are cation selective, and we have previously tested the TRP channel blocker, ruthenium red, without effect [21]. It is interesting that GLUT5 is known to be associated with prestin within the lateral membrane [1]; however, in our preliminary tests, cotransfection of GLUT5 and prestin into CHO cells did not generate chloride fluxes. It may be that I_{metL} may arise from other components within the lateral membrane, including other SLC26 family members whose residence has not yet been determined in the OHC. CFTR has also been found to interact with prestin in OHCs [30], though we have not found electrophysiologic evidence for this or other chloride channels in the OHC [21].

Currently, there are two mechanisms that may contribute to cochlear amplification in mammals. One mechanism involves stereociliary bundle mechanics, driven by ionic flux of Ca^{++} through the, as yet, molecularly unidentified {however, see [5] for a review} stereociliary mechano-electrical transducer (MET) conductance [3, 12]. The other mechanism involves prestin-based electromotility of OHCs [2, 14, 31], which, being anion dependent [19], can be modulated by ionic flux of chloride through the, as yet, molecularly unidentified lateral membrane conductance, the G_{metL} [21, 30]. Our observations indicate that for the latter mechanism, interaction between ion and motor function arises from distinct molecular contributors, namely, prestin and G_{metL} , whereas in the former case, the MET conductance works on itself. This difference between feedback mechanisms may be important in understanding capabilities of each mechanism towards amplification. For example, whereas the molecular colocalization of the stereociliary bundle's feedback mechanism constrains timing of interactions between Ca^{++} and the channel, the distinct identities of prestin and G_{metL} could permit variable interaction delays simply by varying the distances between each within the lateral membrane. It is well known that setting appropriate feedback delays is crucial in nonlinear system performance, and, thus, having a potential means to adjust feedback delays may be viewed as particularly advantageous.

(Received 14 December 2000; accepted after revision 25 January 2001)

1. Under whole-cell voltage clamp, the effects of initial voltage conditions and membrane tension on gating charge and voltage-dependent capacitance were studied in human embryonic kidney cells (TSA201 cell line) transiently transfected with the gene encoding the gerbil protein prestin. Conformational changes in this membrane-bound protein probably provide the molecular basis of the outer hair cell (OHC) voltage-driven mechanical activity, which spans the audio spectrum.
2. Boltzmann characteristics of the charge movement in transfected cells were similar to those reported for OHCs ($Q_{\max} = 0.99 \pm 0.16$ pC, $z = 0.88 \pm 0.02$; $n = 5$, means \pm S.E.M.). Unlike that of the adult OHC, the voltage at peak capacitance (V_{pkcm}) was very negative (-74.7 ± 3.8 mV). Linear capacitance in transfected cells was 43.7 ± 13.8 pF and membrane resistance was 458 ± 123 M Ω .
3. Voltage steps from the holding potential preceding the measurement of capacitance–voltage functions caused a time- and voltage-dependent shift in V_{pkcm} . For a prepulse to -150 mV, from a holding potential of 0 mV, V_{pkcm} shifted 6.4 mV, and was fitted by a single exponential time constant of 45 ms. A higher resolution analysis of this time course was made by measuring the change in capacitance during a fixed voltage step and indicated a double exponential shift ($\tau_0 = 51.6$ ms, $\tau_1 = 8.5$ s) similar to that of the native gerbil OHC.
4. Membrane tension, delivered by increasing pipette pressure, caused a positive shift in V_{pkcm} . A maximal shift of 7.5 mV was obtained with 2 kPa of pressure. The effect was reversible.
5. Our results show that the sensitivity of prestin to initial voltage and membrane tension, though present, is less than that observed in adult OHCs. It remains possible that some other interacting molecular species within the lateral plasma membrane of the native OHC amplifies the effect of tension and prior voltage on prestin's activity.

In mammals, two classes of hair cell evolved to meet the requirements of high frequency acoustic reception. The inner hair cell, which is innervated by the majority of eighth-nerve afferents (Spendlin, 1986), is the primary sensory receptor. The outer hair cell (OHC), while capable of generating acoustically evoked receptor potentials (Dallos *et al.* 1982), additionally functions as a mechanical effector that is thought to provide feedback to the basilar membrane to enhance auditory sensitivity and frequency resolving power (Brownell *et al.* 1985; Ashmore, 1987; Dallos, 1992).

The OHC is clearly unique. It alone is capable of voltage-induced mechanical responses ranging up to at least 100 kHz (Frank *et al.* 1999). The lateral membrane of this cylindrical cell houses the molecular machinery responsible for this

response (Dallos *et al.* 1991; Kalinec *et al.* 1992; Huang & Santos-Sacchi, 1993). Recently the gene for a candidate motor protein, prestin, has been cloned (Zheng *et al.* 2000), and this protein is restricted to the lateral membrane of OHCs (Belyantseva *et al.* 2000). Prestin, in addition to enabling voltage-induced mechanical activity in transfected non-auditory cells, was shown to display some of the electrical characteristics of the native OHC sensor/motor, namely gating charge movement or non-linear capacitance that exhibits shallow voltage dependence (Zheng *et al.* 2000).

In this study we explored further the characteristics of prestin's voltage sensor, and found that similar to the native OHC motor, prestin's charge *vs.* voltage (Q – V) function possesses memory (Santos-Sacchi *et al.* 1998) and is

mechanically sensitive (Iwasa, 1993; Gale & Ashmore, 1994; Kakehata & Santos-Sacchi, 1995). That is, the motor molecule's behaviour is influenced by prior voltage conditions and membrane tension.

METHODS

The electrical characteristics of prestin and the native OHC sensor/motor were evaluated under the same conditions. Transient transfection of human embryonic kidney (TSA201) cells with gerbil prestin was performed as previously described (Zheng *et al.* 2000). Co-expression of green fluorescent protein provided visual identification of transfected cells. OHCs were freshly isolated from the cochleae of gerbils, which were killed by decapitation following anaesthetic overdose (100 mg kg⁻¹ Nembutal, i.p.). This method follows the guidelines established by Northwestern and Yale University's Animal Care and Use Committees. Cells were whole-cell voltage clamped with an Axopatch 200B amplifier (Axon

Instruments, CA, USA) at a holding potential of 0 mV. The patch pipette solution contained (mM): 140 CsCl, 2 MgCl₂, 10 EGTA, 10 Hepes; pH 7.2. The external solution contained (mM): 120 NaCl, 20 TEA-Cl, 2 CoCl₂, 2 MgCl₂, 10 Hepes, 5 glucose; pH 7.2. Osmolarity was adjusted to 300 mosmol l⁻¹ with glucose. Current responses were filtered at 5 kHz. Corrections were made for the effects of residual series resistance, which averaged less than 10 MΩ. All data collection and most analyses were performed with a Windows-based whole-cell voltage-clamp program, jClamp (SciSoft, CT, USA), utilizing a National Instruments PCI-6052E 16-bit interface. Matlab (Natick, MA, USA) was used for some analyses. Fits were made with the Levenberg-Marquardt algorithm. Recordings from TSA201 cells that evidenced electrical coupling to adjacent cells were excluded from data analysis. Coupling was assessed with input capacitance measures (Santos-Sacchi, 1991a).

Whole-cell membrane capacitance was measured with two techniques, transient and AC. The former entailed the delivery of a stair-step voltage ranging from -160 to 120 mV, in 14 mV

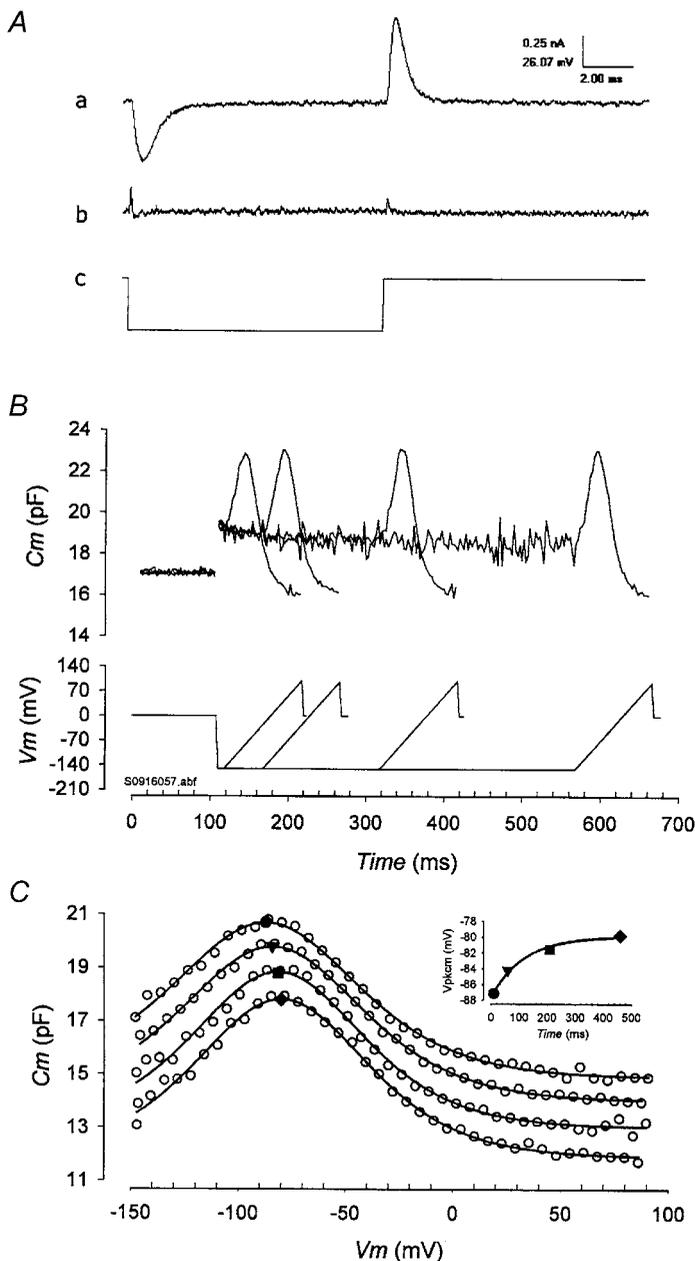

Figure 1. Prestin's charge movement is sensitive to initial voltage

A, gating current (*a*) in a prestin-transfected TSA201 cell induced by a voltage step (*c*) to -100 mV from a holding potential of 0 mV. Non-transfected cells did not produce gating currents (*b*). *P/-4* protocol was used with a subtraction holding potential of +50 mV. *B*, whole-cell C_m determined with dual sinusoidal technique (top panel). The bottom panel shows the voltage protocol. Sinusoids have been removed for visual clarity. Data were obtained from 4 episodes; voltage was stepped to -150 mV with incrementing durations from a holding potential of 0 mV. Five-second intervals at the holding potential were allowed for recovery between episodes. *C*, capacitance data from *B* are plotted vs. ramp voltage. Traces are shifted downward (1 pF decrements) for visual clarity. Fits indicate a shift in V_{pkcm} denoted by ● (V_{pkcm} , Q_{max} , z and C_{in} were, respectively: -87.15 mV, 0.89 pC, 0.66 and 14.7 pF), ▼ (-84.2 mV, 0.91 pC, 0.64 and 15.0 pF), ■ (-81.5 mV, 0.97 pC, 0.61 and 15.0 pF) and ◆ (-79.8 mV, 0.96 pC, 0.63 and 14.9 pF). The same symbols are used in the inset plot to show the time course of the shift. A single exponential fit gave $\tau = 116$ ms.

increments. Transient currents were integrated to obtain cell capacitance (C_m) measurements as previously described (Huang & Santos-Sacchi, 1993). The second technique utilized a continuous high-resolution (2.56 ms sampling) two-sine voltage stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz), with subsequent fast Fourier transform (FFT)-based admittance analysis (Santos-Sacchi *et al.* 1998). These high-frequency sinusoids were superimposed on voltage ramp, step or sinusoidal stimuli. Capacitance data were fitted to the first derivative of a two-state Boltzmann function (Santos-Sacchi, 1991*b*):

$$C_m = Q_{\max} \left(\frac{zeb}{kT(1+b)} \right) + C_{\text{lin}}, \quad (1)$$

$$b = \exp \left(\frac{-ze(V_m - V_{\text{pkcm}})}{kT} \right),$$

where Q_{\max} is the maximum non-linear charge moved, V_{pkcm} is voltage at peak capacitance or half-maximal non-linear charge transfer, V_m is membrane potential, C_{lin} is linear capacitance, z is valency, e is electron charge, k is Boltzmann's constant and T is absolute temperature. Gating currents were obtained as described previously (Santos-Sacchi, 1991*b*). V_{pkcm} was tracked in real time with 2 mV resolution by monitoring the reversal of gating current polarity as fully described previously (Kakehata & Santos-Sacchi, 1995). Pipette pressure was monitored with a solid-state device (WPI, FL, USA) (Kakehata & Santos-Sacchi, 1995).

RESULTS

With ionic currents blocked, transfected TSA201 cells evidenced non-linear gating currents with characteristics similar to those obtained from native OHC lateral membrane sensor/motors (Fig. 1*Aa*). Control cells that were not transfected did not generate such currents (Fig. 1*Ab*). This result confirms the findings of Zheng *et al.* (2000). Transient analysis of the membrane capacitance arising from these gating currents provided estimates of the voltage-dependent Boltzmann characteristics of the charges. In five cells, we obtained values similar to those reported for OHCs, namely $Q_{\max} = 0.99 \pm 0.16$ pC and $z = 0.88 \pm 0.02$ (means \pm S.E.M.). Unlike that of the OHC, however, the voltage at peak capacitance (V_{pkcm}) was very negative (-74.7 ± 3.8 mV) at the outset of whole-cell voltage clamp. Guinea-pig OHCs had their peak non-linear capacitance at -21.5 mV (Kakehata & Santos-Sacchi, 1995). Linear capacitance in transfected cells was 43.7 ± 13.8 pF and membrane resistance was 458 ± 123 M Ω .

Voltage steps from the holding potential preceding the measurement of capacitance *vs.* voltage (C - V) functions caused a time- and voltage-dependent shift in V_{pkcm} . Figure 1*B* illustrates an example utilizing the admittance-based measurement technique. From a holding potential of 0 mV, the cell was stepped to -150 mV for 10, 60, 210 or 460 ms, after which the cell was ramped to 100 mV to obtain the C - V function. The negative prepulse caused a shift in the capacitance function in the depolarizing direction; as prepulse length increased, the magnitude of the shift increased, with a 7.3 mV shift being obtained after 460 ms. The inset in Fig. 1*C* presents the time course of the shift and shows a

single exponential fit with a time constant of 116 ms. Figure 2 presents the average results obtained from such prepulse experiments; a single exponential fit to the averaged data points provided a time constant of 45 ms. In comparison, similar data obtained from native OHCs could be fitted with a time constant of about 200 ms (Santos-Sacchi *et al.* 1998). Additionally, whereas prepulse-induced, steady-state shifts of 14 mV are found in native OHCs (Santos-Sacchi *et al.* 1998), the average shift was 6.4 mV in transfected cells (Fig. 2).

We refined our estimates of the time course of the V_{pkcm} shift by measuring cell capacitance during constant voltage steps. Since a change in voltage induces a shift in the bell-shaped capacitance function along the voltage axis, at any fixed voltage the magnitude of the capacitance will change over time, and will reflect the time course of the shift in V_{pkcm} (Santos-Sacchi *et al.* 1998). Figure 3 illustrates this phenomenon for a transfected cell and a gerbil OHC. During the voltage step, the capacitance magnitudes changed with a double exponential time course. For the transfected cell τ_0 was 51.6 ms and τ_1 was 8.5 s, whereas for the OHC τ_0 was 69.2 ms and τ_1 was 2.79 s. It should be noted that the duration of the step was short relative to the second time constant values. Good fits by eye were obtained by fixing both second time constants at 1.2 s, the second time constant value obtained from OHCs when longer step durations were delivered (Santos-Sacchi *et al.* 1998).

Finally, we evaluated the effects of membrane tension on V_{pkcm} . Membrane tension, applied via pipette or osmotic pressure, is known to shift V_{pkcm} in OHCs (Iwasa, 1993; Gale & Ashmore, 1994; Kakehata & Santos-Sacchi, 1995). Figure 4 shows that changes in pipette pressure can reversibly shift V_{pkcm} in transfected cells. For example, a pipette pressure of 2 kPa resulted in a shift of about 7.5 mV. With pressures larger than 2 kPa cells were blown off the pipette or seals were lost. Changes in the

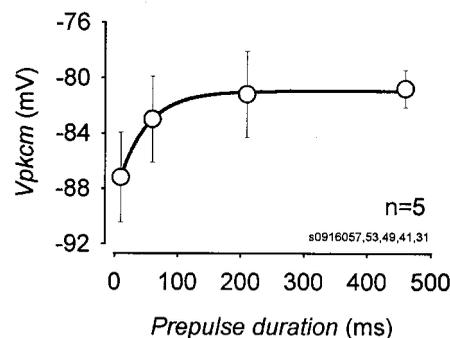

Figure 2. Average V_{pkcm} *vs.* prepulse duration

Data were obtained from experimental protocols as in Fig. 1. Plotted are the means \pm S.E.M. for five transfected cells. The single exponential fit gave $\tau = 45$ ms.

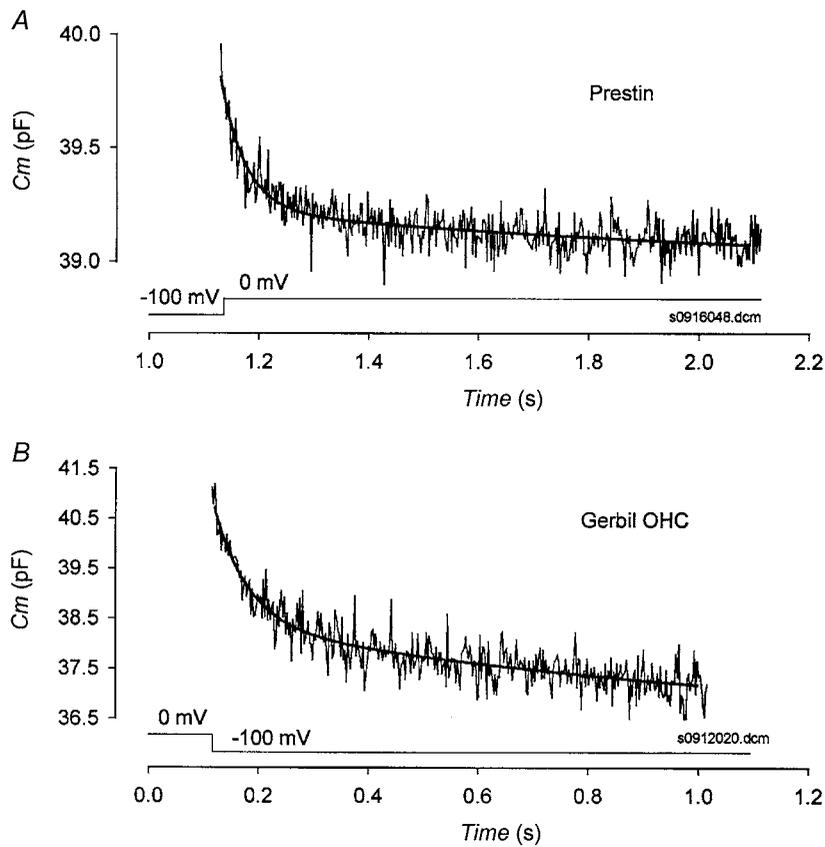

Figure 3. Time course of capacitance change following voltage step

A, transfected cell capacitance decreased with $\tau_0 = 51.6$ ms and $\tau_1 = 8.5$ s indicative of the time-dependent shift in V_{pkcm} . *B*, OHC capacitance decreased with $\tau_0 = 69.2$ ms and $\tau_1 = 2.79$ s. These results are predicted by a visco-elastic model of motor interactions (Santos-Sacchi *et al.* 1998).

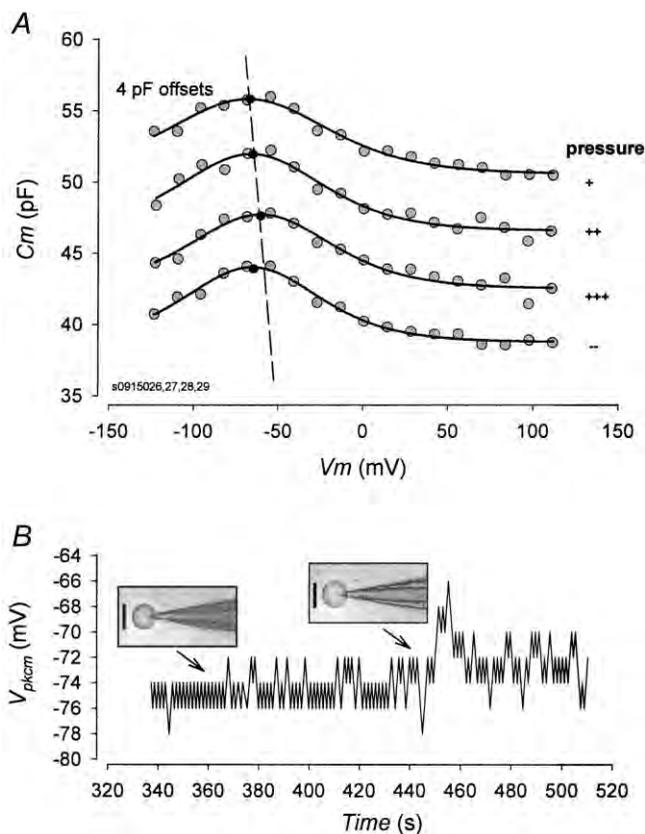

Figure 4. Effects of membrane tension on V_{pkcm}

A, $C-V$ functions were obtained with transient analysis under conditions where pipette pressure was modified. Capacitance functions are offset by -4 pF for visual clarity. ●, fitted V_{pkcm} . A straight line is drawn through the top three values, indicating the depolarizing shift in V_{pkcm} that accompanied pipette pressure increases. Pipette pressure was less than 0 kPa ($-$), ~ 0.6 kPa ($+$), ~ 1.3 kPa ($++$) and ~ 2 kPa ($+++$). When pressure was made negative, V_{pkcm} shifted back in the hyperpolarizing direction. Fits (from top trace to bottom trace) for V_{pkcm} , Q_{max} , z and C_{lin} were, respectively: -68.0 mV, 0.81 pC, 0.66 and 50.6 pF; -66.2 mV, 0.91 pC, 0.60 and 50.6 pF; -60.5 mV, 0.91 pC, 0.58 and 50.5 pF; -65.4 mV, 0.96 pC, 0.55 and 50.8 pF. *B*, V_{pkcm} was tracked during changes in pipette pressure. Photographs of patch-clamped transfected cells correspond to points (arrows) before and after a pressure increase that changed cell diameter by 8%. A slight depolarizing shift in V_{pkcm} was observed during the pressure increase.

dimensions of the cells confirmed that pipette pressure was delivered to the cells (Fig. 4B). The magnitude of the response was small compared to that of OHCs where shifts as large as 50 mV are found (Takehata & Santos-Sacchi, 1995).

DISCUSSION

Non-linearity is the hallmark of the mammalian auditory system's active process whereby near-threshold responses are selectively enhanced. In fact, a variety of non-linear phenomena exist within single OHCs that identify candidate mechanisms likely to underlie the 'cochlear amplifier'. These include non-linearities intrinsic to the mechanics of the cell soma, as well as those of the stereociliary bundle. Within the soma several non-linear, voltage-dependent processes have been studied, including electromotility (Brownell *et al.* 1985; Ashmore, 1987; Santos-Sacchi & Dilger, 1988), stiffness (He & Dallos, 1999) and membrane lipid mobility (Oghalai *et al.* 2000). Recently, we showed that the very same stimulus, i.e. lateral membrane voltage, that evokes OHC somatic mechanical activity influences its form (Santos-Sacchi *et al.* 1998). We successfully modelled the effect as a visco-elastic interaction among lateral membrane motor molecules, where motor-induced membrane tension shifted the cell's C - V function. One of the consequences of this interaction is similar to that occurring within the stereociliary bundle, namely that a shift in the operating point of the transducer function over time provides for differing instantaneous and steady-state responsiveness. Consequently, in the case of the OHC soma, we observe hysteresis in the C - V or Q - V function, the magnitude of which may be frequency dependent (J. Santos-Sacchi & E. Navarrete, unpublished observation). Even at the system level, susceptibility of the motor to membrane tension underlies the generation of non-linearities resulting from mechanical interactions among OHCs within the organ of Corti (Zhao & Santos-Sacchi, 1999). Our present observation that prestin displays the same complex electrical characteristics, and attendant non-linearities, as those of the native OHC motor confirms the identity of this protein. Since prestin presents these qualities in the absence of its normal cellular environment, our work also raises questions about the molecular requirements for full functional activity.

There are several features that differentiate OHCs from other hair cells. Most notably, the OHC possesses an extensive composite lateral wall, consisting of the mechanically active lateral plasma membrane, the cortical cytoskeleton and the subsurface cisternae (Flock *et al.* 1986; Holley *et al.* 1992; Pollice & Brownell, 1993). Structural distinctions such as these probably underscore a functional requirement for unique protein constituents, and indeed, besides prestin, other proteins specific to the OHC are known to exist (Sakaguchi *et al.* 1998; Zheng *et al.* 2000). While it is possible that novel auxiliary protein

subunits act in conjunction with prestin to modify its behaviour, as occurs for ionic channels (Walker & De Waard, 1998), our present results indicate that other unique proteins present in the normal OHC are not required for the generation of voltage-induced or tension-induced shifts in V_{pkem} . We had previous indications of this autonomy, since we demonstrated that neither of the effects was abolished in OHCs by destruction of intracellular constituents with trypsin or pronase (Takehata & Santos-Sacchi, 1995; Santos-Sacchi *et al.* 1998).

Notwithstanding the many electrical properties of the lateral membrane motor that appear intrinsic to prestin, auxiliary subunit contributions cannot be ruled out. In this regard, we found that V_{pkem} values in transfected cells are very negative relative to those found in adult OHCs (-74.7 vs. -21.5 mV; Takehata & Santos-Sacchi, 1995). Two physiological mechanisms that are capable of shifting V_{pkem} are membrane tension (Iwasa, 1993; Gale & Ashmore, 1994; Takehata & Santos-Sacchi, 1995) and phosphorylation (Frolenkov *et al.* 2000). While the voltage dependencies that we found may simply result from differences in resting membrane tension between transfected cells and OHCs, or from differences in the degree of phosphorylation, it is also possible that auxiliary subunits can contribute. Indeed, the voltage-dependent Ca^{2+} channel β subunit is known to shift the voltage dependence of the channel's activation (De Waard *et al.* 1994). Interestingly, during the development of rat OHCs, V_{pkem} shifts from hyperpolarized levels to more depolarized levels as found in adult guinea-pig OHCs over the course of a few days (Oliver & Fakler, 1999). Although Oliver & Fakler (1999) argued in favour of phosphorylation over subunit interaction, the issue remains open. Finally, we note that the magnitude of the effects that we observed in the present study is not as great as that seen in native OHCs (Takehata & Santos-Sacchi, 1995; Santos-Sacchi *et al.* 1998). Thus, while the intrinsic properties of a single protein, prestin, may form the basis of mammalian auditory system responsiveness, it remains possible that some other interacting molecular species within the lateral plasma membrane amplifies the effect of tension and prior voltage on prestin's activity. One such candidate protein is the sugar transporter GLUT-5, which localizes to the OHC lateral membrane and may influence the OHC motor (Géléoc *et al.* 1999; Belyantseva *et al.* 2000). GLUT-5 is not expressed in TSA201 cells (J. Zheng, unpublished data). Notwithstanding this scenario, it should be noted that another possibility, not yet examined, is that intrinsic constituents of the TSA201 cell's plasma membrane could influence the activity of an expressed foreign protein. Nevertheless, it is certainly clear that with the identification of prestin and other novel OHC proteins, the issue of molecular interactions within the OHC's mechanically active lateral plasma membrane can be directly assessed.

Chloride ions have been hypothesized to interact with the membrane outer hair cell (OHC) motor protein, prestin on its intracellular domain to confer voltage sensitivity (Oliver et al., 2001). Thus, we hypothesized previously that transmembrane chloride movements via the lateral membrane conductance of the cell, G_{metL} , could serve to underlie cochlear amplification in the mammal. Here, we report on experimental manipulations of chloride-dependent OHC motor activity *in vitro* and *in vivo*. *In vitro*, we focused on the signature electrical characteristic of the motor, the nonlinear capacitance of the cell. Using the well known ototoxicant, salicylate, which competes with the putative anion binding or interaction site of prestin to assess level-dependent interactions of chloride with prestin, we determined that the resting level of chloride in OHCs is near or below 10 mM, whereas perilymphatic levels are known to be ~140 mM. With this observation, we sought to determine the effects of perilymphatic chloride level manipulations of basilar membrane amplification in the living guinea pig. By either direct basolateral perfusion of the OHC with altered chloride content perilymphatic solutions or by the use of tributyltin, a chloride ionophore, we found alterations in OHC electromechanical activity and cochlear amplification, which are fully reversible. Because these anionic manipulations do not impact on the cation selective stereociliary process or the endolymphatic potential, our data lend additional support to the argument that prestin activity dominates the process of mammalian cochlear amplification.

Key words: chloride; hearing; outer hair cell; capacitance; basilar membrane; cochlea

Introduction

Hallowell Davis coined the term “cochlear amplifier” to signify a boost in hearing capabilities near threshold that is provided by the uniquely mammalian outer hair cell (OHC) (Davis, 1983). The subsequent discovery of electrically evoked OHC mechanical activity provided a very attractive substrate for amplification (Brownell et al., 1985). Nevertheless, processes thought to be characteristic of mammalian cochlear amplification (e.g., spontaneous otoacoustic emissions) have been observed in lower vertebrates lacking OHCs (Manley et al., 2001); such observations have fueled the debate over whether the source of amplification in the mammal is the prestin-containing lateral membrane of the OHC or the stereociliary transduction apparatus, each of which can potentially provide feedback into the basilar membrane through accessory structures (Santos-Sacchi, 2003). This debate may frame an evolutionary battle between an anionic based mechanism and a cationic based mechanism, the calcium ion underpinning stereocilia-based feedback (Fettiplace et al., 2001; Chan and Hudspeth, 2005) and the chloride ion underpinning

prestin-based feedback (Oliver et al., 2001; Rybalchenko and Santos-Sacchi, 2003).

The manner whereby stereocilia may provide force feedback during auditory stimulation relies on the intracellular action of calcium ions on either myosin molecules or the transduction channel itself, possibly ankyrin-repeat transient receptor potential cation channel, subfamily A, member 1; both of these actions influence apical bundle mechanics (Yamoah and Gillespie, 1996; Gillespie and Corey, 1997; Fettiplace and Ricci, 2003; Corey et al., 2004). In contrast, the lateral membrane motor, prestin (Zheng et al., 2000), is highly sensitive to intracellular anions (Oliver et al., 2001; Rybalchenko and Santos-Sacchi, 2003; Song et al., 2005), in particular, chloride, which has been shown to pass through a lateral membrane conductance, G_{metL} , in a voltage- and tension-dependent manner (Rybalchenko and Santos-Sacchi, 2003). Both ions respectively alter the steady state energy profile of their corresponding transduction mechanism; calcium shifts the stereociliar channel open probability along the mechanical deflection axis (Kennedy et al., 2003), and chloride shifts the area state probability of prestin along the voltage axis (Rybalchenko and Santos-Sacchi, 2003). These ionic effects contribute to force generation in each system, because, as the data imply, conformational changes in the molecules accompany ion binding.

There have been several reports that have focused on the assignment of amplificatory substrate in the mammal. Notably, a prestin knock-out has provided direct evidence that this unusual motor protein (Zheng et al., 2000) is required for OHC electro-

mechanical activity and cochlear amplification (Liberman et al., 2002). In contrast, studies on isolated mammalian cochleas, which may retain some residual characteristics of cochlear amplification, point to potential contributions from stereociliary mechanics (Fettiplace et al., 2001; Kennedy et al., 2003; Chan and Hudspeth, 2005).

We report here that modulating chloride activity *in vitro* and *in vivo*, with cochlear amplifier intact, either directly by basolateral perfusion of the OHC with altered chloride content solutions or by the use of tributyltin (TBT), a chloride ionophore (Tosteson and Wieth, 1979; Wieth and Tosteson, 1979; Song et al., 2005), alters OHC electromechanical activity and cochlear amplification in a reversible manner. Because these anionic manipulations do not impact on the cation-selective stereociliary process or the endolymphatic potential, our data lend additional support to the argument that prestin activity dominates the process of mammalian cochlear amplification.

Materials and Methods

In vitro

The methods for single hair cell recordings were the same as those described in detail previously (Song et al., 2005). Hartley albino guinea pigs were killed with halothane. Temporal bones were excised, and the top three turns of the cochleae were dissected with enzyme treatment (0.5 mg/ml Dispase I; 10–12 min). Individual outer hair cells were isolated by gentle trituration. Isolated single outer hair cells were then studied under whole-cell voltage clamp and were held at 0 mV to eliminate the electrical drive for Cl across the lateral membrane; therefore, Cl concentration changes were studied in isolation. A custom made Y-tube perfusion system was used to deliver experimental solutions to isolated OHCs. Perforated patch solutions contained 25 mg/ml gramicidin in 0.25% DMSO (Akaike, 1996).

Nonlinear capacitance (NLC) was measured using a continuous high-resolution (2.56 ms sampling) two-sine stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz) superimposed onto a voltage ramp from –150 to +140 mV (Santos-Sacchi et al., 1998b; Santos-Sacchi, 2004). Capacitance data were fit to the first derivative of a two-state Boltzmann function (Santos-Sacchi, 1991) as follows:

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}},$$

where

$$b = \exp\left(\frac{-ze(V_m - V_{\text{pkcm}})}{kT}\right),$$

where Q_{\max} is the maximum nonlinear charge moved, V_{pkcm} (also commonly called V_h) is voltage at peak capacitance or equivalently at half-maximum charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. NLC was calculated by subtracting linear capacitance (C_{lin}) from peak amplitude ($C_{m,\text{pk}}$).

The base extracellular solution contained the following (in mM): 140 NaCl, 2 CaSO₄, 1.2 MgSO₄, and 10 HEPES. Cl concentration was adjusted from 1 to 140 mM by substituting Cl with gluconate. Final solutions were adjusted to ~300 mOsm with D-glucose and adjusted to pH ~7.2–7.3 with NaOH. Pipette solutions (same as extracellular solution except with the addition of 10 mM EGTA) contained Cl ranging from 1 to 140 mM. This composition permitted us to reduce ionic currents (mainly K currents), which we and others routinely block to measure precisely NLC or gating charge movements (Santos-Sacchi, 1991; Song et al., 2005). The extracellular perfusion solution (1–140 mM Cl) also contained graded concentrations of salicylate (1 μM to 10 mM), with or without the addition of 1 μM TBT. For the gramicidin patch experiments, although we attempted to record cells as soon after the animals were killed as possible, we were limited by time required for dissection and cell

isolation and by the time after seal formation to achieve good whole cell conditions, namely achieving a series resistance of <20 MΩ.

In vivo

Animals and surgery. Pigmented guinea pigs weighing 250–350 g were used in this experiment. After anesthesia, the left bulla was opened via a lateral and ventral approach, and the middle ear muscle tendons were sectioned. A hole (~0.3 × 0.4 mm) in the scala tympani of the cochlea was made for measuring the basilar membrane (BM) velocity.

Basilar membrane velocity measurements. The BM velocity at the site corresponding to the frequency near 17 kHz [the characteristic frequency (CF)] was measured from a gold-coated reflective glass bead (10–30 μm in diameter) on the BM using a laser interferometer (Polytec OFV 1102 Laser Vibrometer; Polytec, Waldbronn, Germany). The BM velocity response was evoked by pure tones (2–24 kHz) delivered through a speaker coupled to the ear canal. The output of the interferometer consists of a voltage proportional to the velocity of the targeted bead. The voltage was measured with a lock-in amplifier and recorded by reading the magnitude and phase by computer query via the serial line output from the lock-in amplifier. The vibration of stapes was measured at the end of each experiment and used to compute the gain of BM motion.

Perilymphatic perfusion. For the perilymphatic perfusion, an inlet hole (diameter, ~90 μm) was made in the scala tympani of the basal turn of the cochlea close to the round window niche, and the hole for BM measurement served as fluid outlet. A polyethylene tube with a fine tip (diameter, ~80 μm) was inserted into the inlet hole, and the other end of this tube was connected to a three-way perfusion system that allowed solution replacement. Perfusion was accomplished using a precision syringe pump. Tributyltin (50 μM), salicylate (1–10 mM), or combinations of the two agents in artificial perilymph (PL) were infused into the scala tympani at the rate of 2 μl/min with the duration of 10–20 min. Similar results were found with 10 μM TBT, but higher concentrations ensured better access across the BM into the spaces of Nuel. The normal artificial perilymph composition is as follows (in mM): 132 NaCl, 3.5 KCl, 25 NaHCO₃, 1.3 CaCl₂, 1.14 MgCl₂ · 6H₂O, 0.51 NaH₂PO₄ · H₂O, 5.0 Tris, 3.3 glucose, and 2.1 urea. For chloride reductions, gluconate substitutions were made. During our treatments, we measured low-frequency cochlear microphonics (CM), a procedure commonly accepted to gauge the OHC stereociliar transducer function (Patuzzi and Moleirinho, 1998) and endolymphatic potential (EP) to evaluate potential effects on supporting cell K recycling, which might be expected to compromise the EP (Wangemann et al., 2004).

Results

Determination of the resting chloride gradient across the OHC membrane

Our first goal was to characterize resting intracellular levels of chloride in OHCs, using the effects of salicylate on NLC as a quantitative measurement tool. The elucidation of the chloride gradient across the OHC basolateral membrane is important in understanding our subsequent *in vivo* manipulations of perilymphatic chloride levels. Peak OHC NLC is reduced in the presence of salicylate (Fig. 1a). The flattening of NLC (and increase at voltages away from the voltage at peak capacitance [V_{pkcm}]) at high salicylate doses occurs because the voltage sensitivity is depressed across a wider voltage range, an observation completely in line with previous work (Tunstall et al., 1995; Kakehata and Santos-Sacchi, 1996; Santos-Sacchi and Navarrete, 2002). Because salicylate competes for the binding site of chloride on prestin (Oliver et al., 2001), increasing the intracellular concentration of chloride should counter the effects of salicylate. Indeed, the addition of TBT to the extracellular solution induces an influx of chloride down its chemical gradient and a restoration of NLC. We have shown previously that TBT only enhances the flux of chloride when there is a chemical gradient of the anion across the OHC plasma membrane. Consequently, we found that the effects of salicylate cannot be countered by TBT when intracellular and

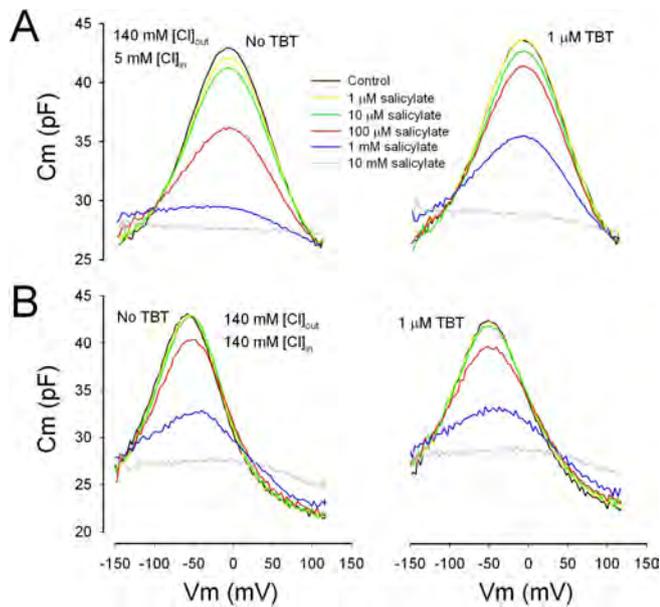

Figure 1. TBT rescues the reduction of salicylate block in NLC under whole-cell voltage clamp. Only in the presence of a chloride gradient can TBT counter this reduction. **A, B**, Effects of graded concentrations of salicylate in the presence of a chloride chemical gradient (**A**) and in the absence of a gradient (**B**). Note also the shifts in operating voltages (V_{pkcm}) that accompany changes in intracellular chloride, an increase shifting NLC to hyperpolarizing voltages. Such shifts directly alter the gain of OHC electromotility at the normal resting potential of the cell (Takehata and Santos-Sacchi, 1996).

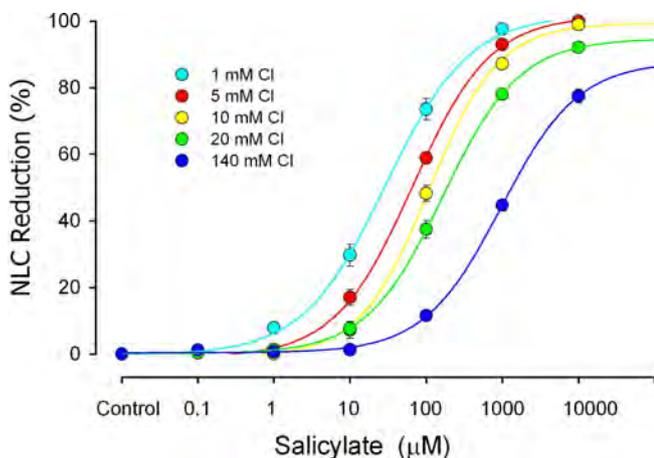

Figure 2. Average dose–response curves (mean \pm SE; $n = 4–5$) for extracellularly applied salicylate block of NLC. Each curve was collected at a different intracellular concentration of chloride. Chloride was unequivocally controlled by matching intracellular and extracellular levels, as we have done previously (Song et al., 2005). Note the leftward shift as intracellular chloride is reduced, indicating a more effective action of salicylate on the motor. Logistic fits provided the following slope and IC_{50Sal} values (1, 5, 10, 20, and 140 mM chloride, respectively): 0.79, 29.5 μ M; 0.83, 77.9 μ M; 0.81, 124.0 μ M; 0.86, 165 μ M; 0.86, 964 μ M. There is no significant difference between slopes at any concentration.

extracellular chloride levels are equal (Fig. 1*b*). From these data, it is clear that the degree of NLC reduction by salicylate is greatly dependent on intracellular Cl level. When we reduce the concentration of Cl on the cytoplasmic aspect of the integral membrane motor protein, the ability of salicylate to reduce remaining NLC increases (Fig. 1*a,b*, compare left panels). To quantify this observation, we constructed average dose–response functions for a range of salicylate and chloride concentrations (Fig. 2). Although salicylate has its effects on the intracellular aspect of the motor

(Takehata and Santos-Sacchi, 1996; Oliver et al., 2001), for these experiments, we needed to unequivocally control intracellular Cl by setting both intracellular and extracellular Cl concentration to the same level under whole-cell voltage clamp; this is an essential approach that we used previously, because the lateral membrane conductance, G_{metL} , efficiently passes Cl ions (Rybalchenko and Santos-Sacchi, 2003; Song et al., 2005). Voltage-dependent NLC was quantified by subtracting linear capacitance from peak capacitance, which directly correlates with estimates of maximum motor charge movement ($Q_{max} = 4kT/ze \times NLC$) (Santos-Sacchi et al., 1998a), determined from fits to the first derivative of a two-state Boltzmann function (see Materials and Methods). IC_{50Sal} for extracellular salicylate action on the motor ranges from 29 μ M for the 1 mM intracellular Cl condition to 964 μ M for the 140 mM Cl condition. From these data, and assuming a salicylate dissociation constant, K_{dSal} of 23.8 mM (Oliver et al., 2001), we can extract an average chloride dissociation constant, $K_{dCl} = [Cl]/(IC_{50Sal}/K_{dSal} - 1)$, of 3.4 ± 0.6 mM (mean \pm SD, from the five tested chloride concentrations), which compares favorably to previous direct estimates of the K_{dCl} of ~ 6 mM of the motor (Oliver et al., 2001; Song et al., 2005). Although this small difference is likely insignificant, the agreement is actually much better considering that our IC_{50Sal} values are based on extracellular concentrations of salicylate, and we previously demonstrated that intracellular levels will be slightly lower than extracellular levels (Takehata and Santos-Sacchi, 1996). With our data serving as a calibration standard, we were able to glean an estimate of the intracellular chloride activity of OHCs, a quantity of which the determination is essential in assessing the significance of the role of this anion in cochlear amplification *in vivo*. Thus, by using the gramicidin patch variant of the whole-cell voltage clamp, we measured the effect of salicylate without perturbing intracellular chloride levels (because gramicidin is impermeant to Cl) in the presence of normal, *in vivo*-like extracellular chloride concentrations, namely 140 mM. Under these conditions, the effectiveness of salicylate on OHCs, which were patched quickly after isolation from the cochlea to abate chloride loading, was similar to that under the 10 mM intracellular Cl condition (Fig. 3*A*), indicating that intracellular chloride rests near 10 mM. OHCs maintained in culture for longer times showed higher chloride levels, and this accumulation of intracellular chloride was accompanied by cell swelling (Fig. 3*B*). The similarity between our estimate of OHC intracellular chloride (~ 10 mM) and the K_{dCl} of OHC (~ 6 mM) (Oliver et al., 2001; Song et al., 2005) and the opposing interactions between salicylate and intracellular chloride levels set predictable outcomes from comparable manipulations *in vivo*, if cochlear amplification arises predominantly from OHC lateral membrane motor activity.

In vivo effects of chloride manipulations

To test for anionic modulation of cochlear amplification, we directly measured BM motion using a laser interferometer in living guinea pigs, the cochleas of which were surgically exposed. Perfusion of artificial PL (see Materials and Methods for compositions) in the scala tympani was accomplished via a local two-port system in the basal turn and permitted basolateral perfusions of OHCs without altering the ionic milieu of endolymph that bathed the apically located stereocilia (Fig. 4*A*). BM motion is sharply tuned to a characteristic frequency determined by place along the cochlea spiral, in our preparation corresponding to $\sim 16–17$ kHz. The tip of the tuning curve is highly vulnerable, and generally any manipulation of the cochlear fluids or homeostatic environment results in a decrease in cochlear amplification.

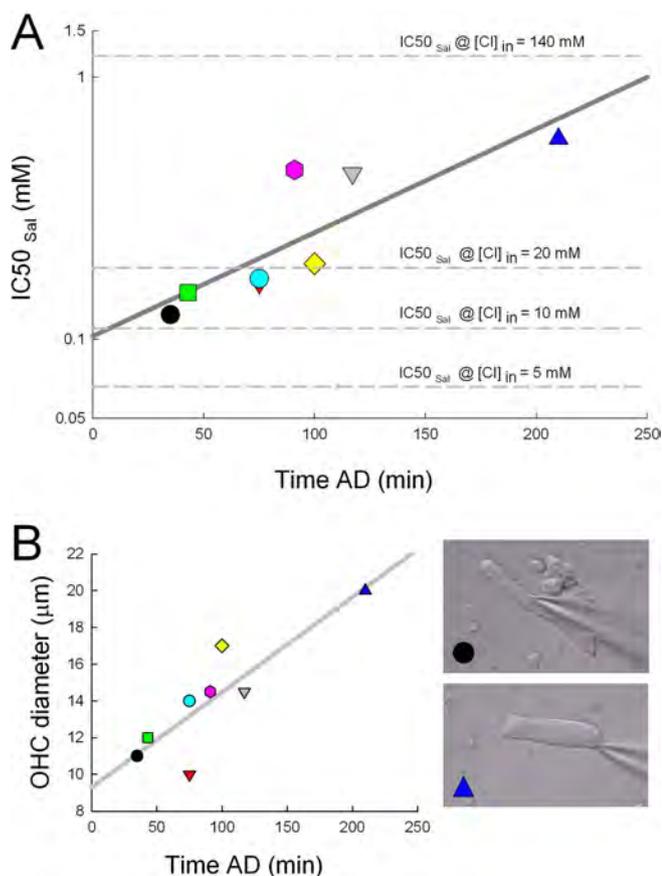

Figure 3. Estimates of OHC intracellular chloride levels using the gramicidin patch method. **A**, IC_{50sal} was determined in the presence of 140 mM extracellular chloride to mimic the *in vivo* condition. It should be stressed that IC_{50sal} measures only evaluate the interactions between intracellular salicylate and chloride on the motor and are not directly influenced by extracellular chloride levels; thus, the IC_{50sal} values determined above in Figure 2A serve as valid calibrations to estimate intracellular chloride levels regardless of extracellular chloride levels. The plot shows that as the length of time after an animal's death (AD) increased, intracellular chloride increased. For the cases in which quick measurements were made, IC_{50sal} was close to that of the value obtained with 10 mM intracellular chloride, indicating that OHC chloride levels are near or possibly <10 mM for cells under *in vivo*-like conditions. **B**, OHC diameter is a sensitive indicator of cell swelling and shows an increase as time AD increased, corresponding with the simultaneous estimates of intracellular chloride above. OHC images show one cell recorded at 30 min and another at 210 min, the latter showing pronounced swelling. The chloride loading after death probably indicates that our measures provide overestimates of intracellular chloride levels. Each symbol in the plots denotes an analysis from an individual cell from different animals ($n = 8$).

Interestingly, to date, no manipulation has been found [other than positive DC electric current (Parthasarathi et al., 2003)] to improve cochlear amplification once compromised. Figure 4B shows BM responses in a sensitive cochlea, where surgical preparation caused minimal loss in sensitivity (<10 dB), as gauged by preoperation and postoperation auditory compound action potential (CAP) measures. After switching perfusion from normal PL to a PL containing TBT (50 μ M), a reduction in BM motion was observed (Fig. 4B). An even larger reduction was brought on by a switch to salicylate containing PL (5 mM) and was reversed by washout. Interestingly, in a cochlea where the preparatory manipulations produced a large decrease in CAP sensitivity (>20 dB), the action of TBT was to augment acoustically evoked BM vibration (Fig. 4C). Peak amplitude (at best frequency) of the BM mechanical tuning (evoked by 40 dB sound pressure level acousti) with artificial perilymph and TBT perfusion into the

scala tympani showed an enhancement of 4.42 ± 1.16 dB (mean \pm SD; $n = 5$; paired t test, $p < 0.001$). In linear terms, this is a >50% increase in response (1.66 ± 0.22). This highly unusual and repeatable finding may indicate that intracellular chloride is normally poised at a level that is optimal, and that changes in intracellular chloride activity can have either positive or negative effects on BM tuning, depending on initial condition of the preparation (i.e., perhaps preparative procedures altered Cl levels and our perfusions re-established preinsult conditions). Again, in this animal, salicylate caused a decrease in BM motion, but the combination of salicylate and TBT resulted in an effect less detrimental than salicylate alone, reminiscent of the rescuing effect of TBT on the block by salicylate of NLC *in vitro*. Finally, we directly tested the effects of low-chloride PL (5 mM; substitution with gluconate) on BM motion. A profound loss of cochlear amplification was found (loss of sharp tip region and shift of CF to lower frequencies), which was fully reversible after reperfusion with normal PL (Fig. 4D). The addition of TBT to the normal perfusion again augmented BM motion above initial conditions. However, TBT was unable to counter the loss induced by low-chloride perfusions, because very little gradient in chloride existed across the OHC plasma membrane. CM at sub-CF frequencies (0.5 kHz), which report on stereociliary forward transduction in OHCs (Patuzzi and Moleirinho, 1998), were unchanged or slightly increased by low chloride or salicylate perfusions, as expected from previous work (Desmedt and Robertson, 1975; Fitzgerald et al., 1993). This implies that our treatments do not affect stereociliary processes, including the transducer Ca sensitivity. Additionally, we measured the EP in three animals under low-chloride conditions and found it to be unaffected (<3 mV variations). Together, the *in vitro* and *in vivo* data indicate the powerful role played by chloride in cochlea amplification and highlight the importance of the prestin-containing lateral membrane and its conductance, G_{metL} .

Discussion

The problem of assignment of cochlear amplification to the apical or lateral membrane of the OHC may reduce to a test of the effects of modulating chloride levels around the basolateral region of the OHCs, a manipulation that should not interfere with the cationic workings of the proposed stereociliary mechanism. Indeed, this general approach has been used to assess the contribution of calcium ion effects on the role of stereocilia in amplification, in which modulation of endolymphatic ionic makeup was performed while maintaining perilymphatic makeup (Chan and Hudspeth, 2005). We approached this issue by directly measuring cochlear amplification on the BM *in vivo*, along with complimentary measures of isolated OHC activity under whole-cell voltage clamp. Thus, *in vitro*, we measured the electromechanical activity of isolated OHCs by gauging the motor-generated NLC of the cell under whole-cell voltage clamp (Santos-Sacchi, 1991), and *in vivo* we measured BM vibratory velocity directly (Nuttall et al., 1991). Interactions among three manipulations of the lateral membrane motor were made using the following: (1) salicylate, a well known ototoxicant that works directly on the motor (Tunstall et al., 1995; Kakehata and Santos-Sacchi, 1996) via its interaction with the chloride binding site of the motor (Oliver et al., 2001); (2) TBT, an ionophore that promotes OHC Cl flux down its chemical gradient (Song et al., 2005); and (3) extracellular chloride levels, which will influence intracellular chloride activity via G_{metL} (Rybalchenko and Santos-Sacchi, 2003; Song et al., 2005). We found that in intact OHCs, intracellular chloride rests at level well below that of extracellular chloride, being ~ 10 mM or

less intracellularly. Manipulations of extracellular chloride, the effects of which arose from the chemical gradient of chloride across the OHC membrane, had pronounced effects on motor charge movement *in vitro* and markedly and reversibly affected cochlear amplification on the basilar membrane.

Our data provide clear evidence that the gain of cochlear amplification is tied directly to the gain of OHC motor activity, the electrical correlates of which are the amount of motor charge moved and the voltage range over which the motors operate, both of which are influenced by intracellular chloride and salicylate (Tunstall et al., 1995; Kakehata and Santos-Sacchi, 1996; Oliver et al., 2001; Rybalchenko and Santos-Sacchi, 2003; Song et al., 2005). Effects on stereociliar transduction and EP were absent, lending support to a direct effect on the OHC lateral membrane motor protein, prestin. Interestingly, although salicylate was found to affect emissions in the Tokay gecko (Stewart and Hudspeth, 2000), the hair cells of which lack prestin, there is no direct action of salicylate on the stereociliar mechano-electrical transducer (MET) channels (Kimitsuki et al., 1994). Although a variety of physiological factors affect the gain of OHC motor activity, including membrane tension (Iwasa, 1993; Gale and Ashmore, 1994; Kakehata and Santos-Sacchi, 1995), temperature (Santos-Sacchi and Huang, 1998), and phosphorylation (Huang and Santos-Sacchi, 1993; Szonyi et al., 1999; Frolenkov et al., 2000; Deak et al., 2005), the recruitment of a ubiquitous anion to drive our exquisite sense of hearing bares an underlying simplicity in design for such a complicated endorgan.

How might chloride work on cochlear amplification?

Clearly, it has been shown that chloride ions have a powerful effect on prestin activity via an intracellular binding or interaction site (Oliver et al., 2001; Rybalchenko and Santos-Sacchi, 2003; Song et al., 2005). The effect may not simply apply to chloride interactions but also to interactions with other anions, for example, sulfate. Interestingly, whereas sulfate was initially found by Oliver et al. (2001) to be ineffective in influencing prestin activity, namely an inability to support NLC, we and others have since found that sulfate can support NLC in intact OHCs while shifting V_h to very depolarized potentials (Rybalchenko and Santos-Sacchi, 2003; Ashmore, 2005; Fettiplace, 2005). Nevertheless, the physiological abundance of chloride indicates that it may be the major player in OHC function.

It is conceivable, however, that manipulating perilymphatic chloride could have effects within the cochlear aside from the OHC lateral membrane. For example, chloride transport is thought to play a role in K recycling within the inner ear (Wangemann et al., 2004). Our observation that the endolymphatic potential is unperturbed during our manipulations rules out such a possibility, because K recycling interference would compromise

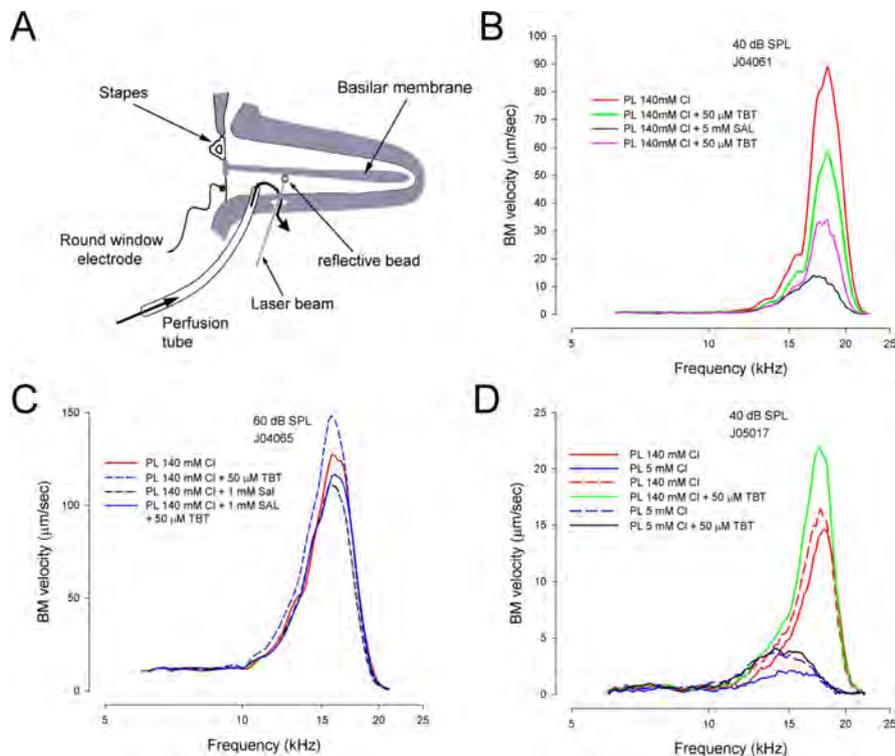

Figure 4. *A*, Schematic of *in vivo* preparation. See Materials and Methods for details. *B*, BM responses to acoustic stimulation during perfusion with artificial PL. The temporal order of listed perfusions is from top to bottom. This was a sensitive cochlea where CAP thresholds were little affected by surgery (<10 dB). In this case, a switch from normal PL to TBT-containing solution causes a decrease in BM motion. Salicylate produces a more pronounced reduction, and recovery follows reperfusion with TBT PL. *C*, This example shows a preparation that was less sensitive; thresholds deteriorated at >20 dB. TBT perfusion, in this case, augmented BM vibration and antagonized the detuning effects of salicylate. *D*, Perfusion of low chloride PL caused a profound loss of cochlear amplification, which was completely reversible. Again, in this animal, TBT increased BM vibration in the presence of normal chloride levels but was ineffective in the presence of low chloride levels, in which a chloride gradient across the OHC membrane would be small or absent. The small difference in the effects of low Cl treatment between the first perfusion and the fourth perfusion may stem from previous TBT treatment or the time between data collections. For visual clarity, sound pressure is plotted on a linear scale; frequency is plotted logarithmically.

the EP. Additionally, it is well known that OHC turgor can be modulated by extracellular chloride manipulations (Cecola and Bobbin, 1992; Song et al., 2005), and that electromotility can be modulated by changes in membrane tension (Iwasa, 1993; Gale and Ashmore, 1994; Kakehata and Santos-Sacchi, 1995). Indeed, we hypothesized that cochlear amplification could be controlled by turgor pressure changes in OHCs (Kakehata and Santos-Sacchi, 1995). Thus, it may be that turgor pressure changes accompanied by chloride flux contributes to our *in vivo* measures (*in vitro* we control turgor pressure and show chloride effects directly). We note, however, that in the absence of a chloride conductance and gradient, such effects on turgor pressure would not arise, because it is the flux of chloride that instigates water movement into and out of the OHC. Interestingly, manipulations of perilymphatic osmolarity *in vivo* have been found to modulate otoacoustic emissions, and the auditory compound action potential (Choi and Spector, 2005). Thus, it may be that two mechanisms known to modulate the OHC lateral membrane may contribute to the chloride effects we observed, although the effects we observe are larger than those observed with osmolarity manipulations.

The lateral membrane as forward and reverse transducer

The apparent voltage-dependent nature of OHC electromotility necessarily encumbers the effectiveness of the presumed stimulus

(receptor potentials) in driving high-frequency mechanical activity. This conundrum derives from the low-pass resistor-capacitor (RC) filter effect of the plasma membrane of the cell (Santos-Sacchi, 1989, 1992; Housley and Ashmore, 1992), estimated to be between 50 and 800 Hz. Consequently, receptor potentials generated by stereociliary transduction elements will be reduced at high acoustic frequency, resulting in diminished feedback into the basilar membrane. Although several proposals have been advanced to understand how the OHC may deal with this difficulty (Santos-Sacchi et al., 1998a; Kakehata and Santos-Sacchi, 1995; Dallos and Evans, 1995; Spector et al., 2003), the issue remains unresolved.

We presented previously a hypothesis that the OHC lateral membrane, with its mechanically active conductance, G_{metL} , may have usurped the role of stereocilia by fluxing anions, rather than cations, during acoustic stimulation (Rybalchenko and Santos-Sacchi, 2003; Santos-Sacchi, 2003). Notably, acoustically driven motions of the organ of Corti have been shown to deform the OHC soma (Fridberger and De Monvel, 2003), potentially gating G_{metL} at acoustic rates. Furthermore, tuned mechanical responses of the isolated OHC induced by water-jet driven mechanical stimulation of the lateral membrane can be blocked by polylysine (Brundin et al., 1989; Brundin and Russell, 1994), a chemical that partially blocks G_{metL} (Rybalchenko and Santos-Sacchi, 2003). Such a cellular adaptation of forward transduction may offer a means to overcome the RC filter problem. Basically, the anion driven conformational state dependence of prestin would be unencumbered by the low-pass filtering effects of the OHC membrane but would only depend on the kinetics of anion current flow and submembranous accumulation and clearing. We have shown mechanical gating of G_{metL} in the kilohertz range (Rybalchenko and Santos-Sacchi, 2003), but additional work on this hypothesis is required.

Although our data provide support for an evolutionary switch from cation to anion control, it was shown recently that manipulations of Ca-dependent stereociliar mechanics altered a remaining nonlinearity present in an *in vitro* explant of the mammalian cochlea, suggesting that bundle mechanics could partly contribute to mammalian cochlear amplification (Chan and Hudspeth, 2005). Thus, it appears that the evolution of the OHC and its mechanically active lateral membrane may have occurred to supplement an already primitive amplificatory system, which, for the mammal, begged an extra boost.

Furosemide alters nonlinear capacitance in isolated outer hair cells

Joseph Santos-Sacchi *, Min Wu, Seiji Kakehata

Received 19 December 2000; accepted 14 February 2001

Abstract

The outer hair cell (OHC) from the organ of Corti plays a crucial role in hearing through its unique voltage-dependent mechanical responses. Furosemide, one of the loop diuretics, disrupts normal cochlear function. Here we report on direct effects of furosemide on OHC motility-related, voltage-dependent capacitance using the whole-cell patch-clamp technique. Extracellularly applied furosemide reversibly shifted the voltage at peak capacitance (V_{pkC_m}) to positive levels. The shift, whose maximum approached 90 mV, evidenced a Hill coefficient of 1.5 and $K_{1/2}$ of 10 mM. Changes in the magnitude of nonlinear capacitance were not fully reversible. While it is clear that the overwhelming effect of furosemide on hearing results via its effects on the endolymphatic potential, the present results indicate that furosemide directly alters OHC motility and may, in part, contribute to sensory dysfunction. © 2001 Published by Elsevier Science B.V.

Key words: Outer hair cell; Motility; Nonlinear capacitance; Basilar membrane tuning

1. Introduction

The outer hair cell (OHC) from the organ of Corti is believed to provide feedback into the basilar membrane through its unique voltage-dependent mechanical responses (Ashmore, 1987; Brownell et al., 1985; Santos-Sacchi and Dilger, 1988). The feedback sharpens the passive mechanical vibration of the cochlear partition. The OHC has a nonlinear gating charge movement or, equivalently, a voltage-dependent capacitance which presents characteristics similar to those of OHC motility, indicating that membrane-bound voltage sensor-motor elements control OHC length (Ashmore, 1990; Dallos et al., 1993; Santos-Sacchi, 1991, 1993).

Furosemide, one of the loop diuretics, is ototoxic. Systemic or intracochlear administration of furosemide induces changes in receptor potentials (Forge and Brown, 1982), auditory -nerve responses (Evans and Klinke, 1982) and basilar-membrane vibration (Ruggero and Rich, 1991). Furosemide is thought to exert its effects on these stimulus-related responses via inter-

ference with stria vascularis function (Brown and McElwee, 1972; Kusakari et al., 1978; Wangemann, 1995), namely, through a reduction of the positive endolymphatic potential (EP). Ruggero and Rich (1991) suggested that a decrease in basilar membrane vibration at near-characteristic frequencies (CF) results from an indirect action of furosemide on OHCs via a reduction of receptor potentials, the presumed driving force for OHC motility. They concluded that the sensitivity and frequency selectivity of basilar membrane responses are due to the mechanical activity of OHCs. In order to examine whether furosemide may interfere with OHC motility more directly, we studied the effects of furosemide on OHC motility-related nonlinear capacitance using the whole-cell patch-clamp technique.

2. Methods

OHCs were freshly isolated from the organ of Corti of the guinea-pig cochlea, following death by anesthetic overdose with Nembutal. The procedures were in accordance with Yale University's Animal Use And Care Committee guidelines. OHCs were whole-cell voltage clamped using patch pipets with initial resistances of

2–3 M Ω . Series resistance ranged from 3 to 5 M Ω . The patch-pipette solution contained (in mM): 140 CsCl, 2 MgCl₂, 10 EGTA and 10 HEPES, with pH 7.2 and 300 mOsm. Ionic blocking solutions were used to remove voltage-dependent ionic conductances so that capacitive currents could be analyzed in isolation. The external solution contained (in mM): 100 NaCl, 20 TEA, 20 CsCl, 2 CoCl₂, 1.52 MgCl₂, 10 HEPES and 5 dextrose, pH 7.2, 300 mOsm. Furosemide was tested in concentrations ranging from 0.5 to 30 mM, with NaCl adjusted to maintain osmolarity. Drugs were applied via cell-chamber perfusion, or in some cases via Y tube. Voltages were corrected for the effects of residual series resistance.

Whole-cell membrane capacitance was measured with two techniques, transient and AC. The former entailed the delivery of a stair-step voltage stimulus. Transient currents were integrated to obtain cell capacitance (C_m) measures as previously described (Huang and Santos-Sacchi, 1993). The latter technique utilized a continuous high-resolution (2.56 ms sampling) two-sine voltage stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz), with subsequent fast Fourier transform-based admittance analysis (Santos-Sacchi et al., 1998). These high-frequency sinusoids were superimposed on voltage-ramp stimuli. Capacitance data were fit to the first derivative of a two-state Boltzmann function (Santos-Sacchi, 1991),

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}} \quad (1)$$

$$b = \exp \frac{-ze(V_m - V_{\text{pk}C_m})}{kT}$$

where Q_{\max} is the maximum nonlinear charge moved, $V_{\text{pk}C_m}$ is voltage at peak capacitance or half-maximal nonlinear charge transfer, V_m is membrane potential, C_{lin} is linear capacitance, z is valence, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. $V_{\text{pk}C_m}$ was tracked in real time with 2 mV resolution by monitoring the reversal of gating current polarity as fully described elsewhere (Kakehata and Santos-Sacchi, 1995).

3. Results

The inset of Fig. 1 illustrates the effect of furosemide on $V_{\text{pk}C_m}$ of an isolated OHC utilizing the $V_{\text{pk}C_m}$ tracking procedure. The drug (20 mM) shifted $V_{\text{pk}C_m}$ from a resting value of -65 mV to about $+20$ mV; washout reversed the effect. In order to prevent interference by potential turgor pressure changes (Kakehata and Santos-Sacchi, 1995), the cylindrical cell was collapsed with

negative pipette pressure from the outset of recording. The dose response curve for the shift in $V_{\text{pk}C_m}$ (Fig. 1) indicates a Hill coefficient of 1.5, K_m of 10.06 mM, and maximum shift of 86.9 mV. Significant shifts were seen at low concentrations, i.e. at 1 mM, the average shift was 5.96 ± 1.43 mV ($n = 18$; mean \pm S.E.M.).

Furosemide also reduced the magnitude of nonlinear capacitance in a graded manner (Fig. 2, inset). For the cell depicted in Fig. 2, $C_{m,\text{pk}}$ decreased from 36.2 pF to 35.6, 34.0, 32.3 and 30.9 pF at 0.7, 4, 15 and 20 mM, respectively. The corresponding positive shifts in $V_{\text{pk}C_m}$ were 12, 20.9, 62.4 and 75.6 mV. However, the effects of furosemide on the magnitude and voltage dependence of OHC capacitance were not necessarily correlated. Upon washout, whereas $V_{\text{pk}C_m}$ typically returned to near-initial conditions, nonlinear capacitance usually remained depressed. Since OHC capacitance and mechanical functions coincide (Kakehata and Santos-Sacchi, 1995; Wu and Santos-Sacchi, 1998), this depression corresponds to a change in the form of the OHC electromechanical function.

4. Discussion

A correspondence between OHC nonlinear capacitance and motility indicates that the lateral membrane motor and sensor are tightly coupled or one entity (Santos-Sacchi, 1991; Kakehata and Santos-Sacchi, 1995); the motor is likely the recently identified protein prestin (Zheng et al., 2000; Santos-Sacchi et al., 2001). We demonstrate here that furosemide directly alters the OHC's peak capacitance and $V_{\text{pk}C_m}$, demonstrating that the drug directly affects the mechanical activity of the OHC. The magnitude of its effect is one of the largest of any drug measured to date. Interestingly, the peak capacitance does not recover with the same time course as $V_{\text{pk}C_m}$, indicating that the voltage sensitivity of the mechanical response is more sensitive to furosemide than is its operating point along the voltage axis. It should be noted that the Boltzmann model parameters that describe the nonlinear capacitance are not necessarily linked, and it is not unusual to independently affect one but not another. For example, $V_{\text{pk}C_m}$ could shift simply due to a change in membrane surface potential, while all other parameters remain constant.

The mechanism whereby furosemide affects the OHC motor is not clear. Furosemide, which is a known inhibitor of chloride transport (see Wangemann, 1995), is also reported to block Cl channels, such as γ -aminobutyric acid A (Nicoll, 1978; Pearce, 1993) and Ca²⁺-dependent Cl channels (Evans et al., 1986). Despite the existence of a potentially susceptible Cl channel in the lateral membrane (Gitter et al., 1986; Ohnishi et al., 1993), we have ruled out consequent effects on turgor

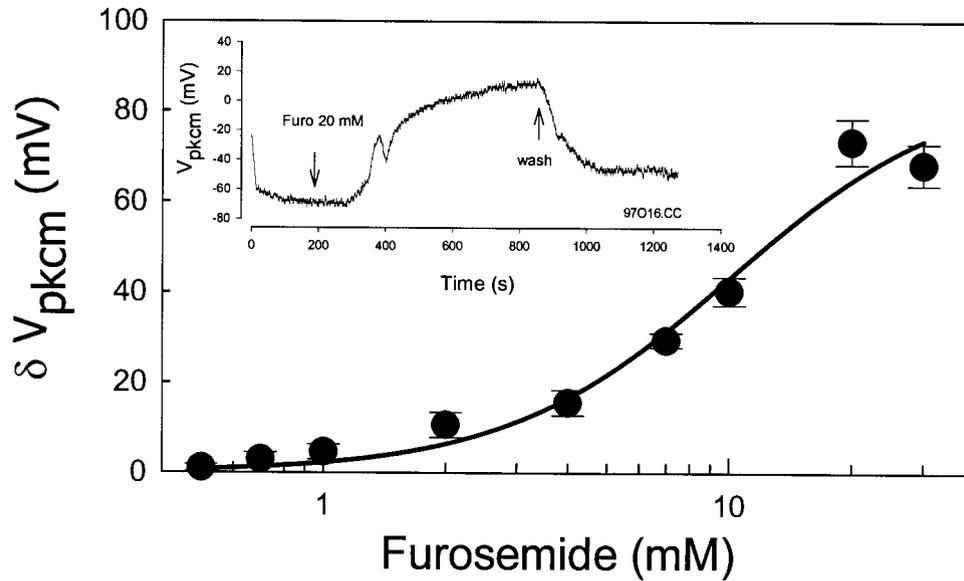

Fig. 1. Effect of furosemide on V_{pkcm} . Inset: V_{pkcm} as a function of time after whole-cell voltage-clamp configuration was obtained with the tracking technique. Furosemide (20 mM) was applied by bath. The delay in response is due to time required for bath solution exchange. Cell was collapsed from the outset of recording. Note reversible shift in V_{pkcm} . The main figure shows three parameter Hill fit giving a Hill coefficient of 1.5, K_m of 10.06 mM, and maximum shift of 86.9 mV. Data points are mean \pm S.E.M., with observation number ranging from 3 to 10.

pressure by collapsing the OHCs. It may be significant that furosemide can also block sulfate transport (Wolpaw and Martin, 1986) and that the recently identified OHC motor protein, prestin, is homologous to sulfate transporters (Zheng et al., 2000).

The predominant ototoxic effects of furosemide on cochlear function are believed to result from a drop

in the EP (Evans and Klinke, 1982; Sewell, 1984; Wangemann, 1995). However, while Ruggero and Rich (1991) conclude that furosemide-induced decreases in basilar membrane vibration at near-CF are via an indirect action of furosemide on OHCs, there is some evidence that furosemide treatments can affect OHCs directly (Comis et al., 1990; Forge and Brown, 1982).

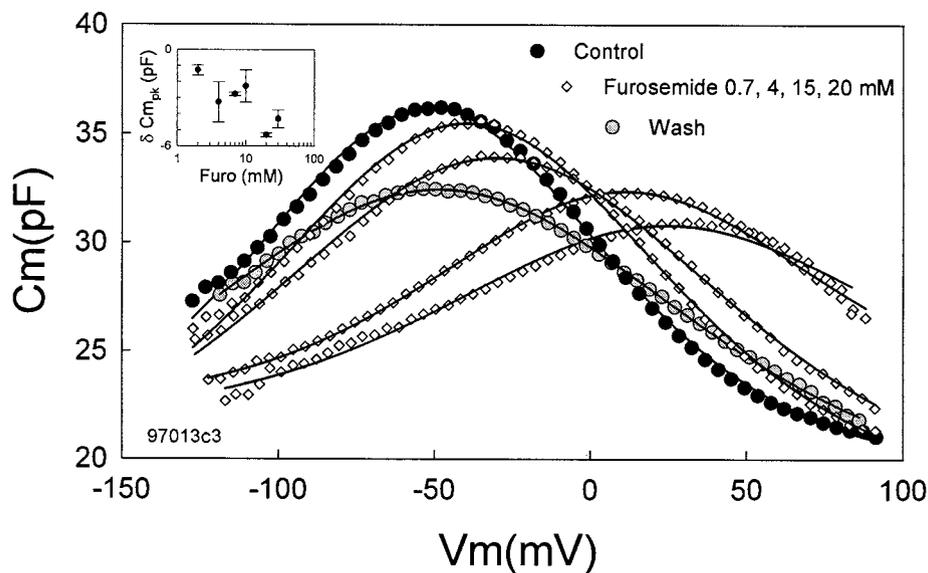

Fig. 2. Effect of furosemide on OHC $C-V$ function. Inset: Change in peak capacitance as a function of furosemide concentration (mean \pm S.E.M.). The main plot shows, for an individual OHC, the effects of 0.7, 4, 15, and 20 mM furosemide (diamonds, successively decreasing peaks) on the cell's $C-V$ function. Control (filled circle) and wash conditions (gray circle) are shown as well. Fits (solid lines) are to Eq. 1. Fitted parameters: control (V_{pkcm} , z , Q_{max} , C_{lin} , respectively): -51.51 , 0.67 , 2.57 , 19.35), 0.7 mM (-39.47 , 0.60 , 2.95 , 18.19), 4 mM (-30.11 , 0.52 , 3.06 , 18.13), 15 mM (11.36 , 0.61 , 1.69 , 22.19), 20 mM (24.67 , 0.53 , 1.76 , 21.51) and wash (-48.44 , 0.48 , 3.03 , 18.09).

Indeed, it has recently been demonstrated that otoacoustic emissions, which are thought to reflect OHC mechanical activity, are capable of recovering from the effects of furosemide treatment prior to the recovery of the EP (Mills et al., 1993). These data indicate that EP alterations may not solely underlie furosemide's effects on cochlear function.

Ostensibly, the strongest argument that intravenous furosemide works solely on the stria vascularis, without direct effects on OHC function, is the rapidity of its adverse effects on eighth-nerve function; perilymphatic perfusion apparently requires longer times and high concentrations, and Evans and Klinke (1982) and Sewell (1984) are frequently quoted in support of this argument. However, Evans and Klinke report only data from one experimental attempt at perilymphatic perfusion, and Sewell cites his unpublished observations. It is invariable that during surgical preparation for perilymphatic perfusion cochlear function is depressed by 20 dB or greater (Sewell, personal communication). Thus, during perilymphatic perfusion of furosemide, if the effects were smaller than 20 dB they would not have been observed. Since we show that the effect of furosemide is immediate on isolated OHCs, we would expect a rapid effect via perilymphatic perfusion of the mid-micromolar concentrations instilled by Evans and Klinke. We conclude that effects were masked by a compromised cochlear.

It is expected that either a shift in the OHC membrane potential or the voltage dependence of the cell's mechanical response may modify the OHC's feedback into the basilar membrane, since the gain of the OHC mechanical response will be modified (Takehata and Santos-Sacchi, 1996). Small changes in feedback can have pronounced effects. For example, the major efferent neurotransmitter, acetylcholine, maximally hyperpolarizes the OHC membrane potential a few millivolts (Housley and Ashmore, 1991). Such an effect may underlie the observation by Dolan et al. (1997) that stimulation of the OHC efferent system is capable of modifying basilar membrane mechanics *in vivo*. How effective might furosemide be in altering OHC activity in the living animal, given its large K_m of 10 mM? Mid-micromolar concentrations of furosemide can shift V_{pkC_m} by about 1 mV. By comparison, salicylate, another ototoxic agent which has measurable consequences at perilymphatic concentrations of 400 μ M (Jastreboff et al., 1986), shifts V_{pkC_m} less than the same concentration of furosemide (Takehata and Santos-Sacchi, 1995). Following intravenous administrations of ototoxic furosemide levels, perilymphatic concentrations are cleared more slowly than in serum, but reach only low micromolar concentrations ($\sim 15 \mu$ M) (Rybak et al., 1979). Interestingly, immature animals accumulate higher perilymphatic levels (Mills et al., 1997).

While the effects of such low furosemide concentrations on cochlear function in the absence of EP effects has yet to be determined, it can be reasonably concluded that a compromised EP, as occurs with intravascular administration, will have a predominant effect on cochlear function.

Abstract

The input capacitance of cell pairs or small groups can be used to gauge the degree of electrical coupling via gap junctions (Santos-Sacchi, 1991). In order to estimate junctional sensitivity to intracellular Ca^{+2} and H^+ concentration, the input capacitance of supporting cell syncytia of the organ of Corti was measured with the whole cell voltage clamp technique, while directly modifying the cation concentrations via the patch pipette. Typically, a pH below 6.5 was capable of uncoupling Hensen cells. On the other hand, pCa levels as low as 3 were ineffective.

Keywords: Gap junctions; Organ of Corti; Supporting cell; Homeostasis; Ionic concentration

1. Introduction

The supporting cells of the organ of Corti not only serve to physically support the hair cells, but probably to maintain the homeostasis of the organ. It is significant, therefore, that the supporting cells are joined together by gap junctions (Jahnke, 1975; Gulley and Reese, 1976; Iurato et al., 1976), and are consequently electrically and metabolically coupled (Santos-Sacchi and Dallos, 1983; Santos-Sacchi, 1986). In our previous work, we demonstrated that uncoupling was induced reversibly by treatments which lead to a rise in $[Ca^{+2}]_i$ or $[H^+]_i$, either by direct intracellular iontophoresis of these ions or in the case of H^+ , by perfusion of the cells with CO_2 saturated media (Santos-Sacchi, 1984, 1985, 1991). During those experiments the degree of intracellular ionic concentration changes was unknown. The present work was carried out in order to estimate the relative uncoupling abilities of these two ions, by intracellular perfusion with known cation concentrations. We report that supporting cell coupling is more sensitive to alterations of $[H^+]_i$.

A preliminary account of this work has been presented previously (Sato and Santos-Sacchi, 1991).

2. Methods

Albino guinea pigs were decapitated under halothane anesthesia. The cochleas were removed, the top two turns separated, and placed in calcium free Leibovitz salt solution containing 1 mg/ml trypsin. The tissue was agitated gently in a modified test tube shaker for about 15 min, where upon isolated cells were harvested and allowed to settle onto the coverslip bottom of a 750 μ l perfusion chamber. The cells were continuously perfused with an ionic blocking solution containing (in mM) 100 NaCl, 20 TEA, 20 CsCl, 2 $CoCl_2$, 1.52 $MgCl_2$, 10 HEPES and 5 dextrose, pH 7.2, 300 mOsm. Patch electrodes contained (in mM) 140 CsCl, 10 HEPES, 10 EGTA, and 2 $MgCl_2$, with the pH ranging from 4.03 to 8.14, adjusted using CsOH. Alternatively, at a fixed pH of 7.2, pCa was altered between 2.3 and 8. EGTA buffering was used only for levels of Ca at and below 1 μ M (Imai and Takeda, 1967). Calcium levels in bulk solution were verified using a Ca-sensitive electrode (Orion Research). Initial resistances of the patch electrodes ranged from 3–4 $M\Omega$. The ionic blocking solution was used to reduce the

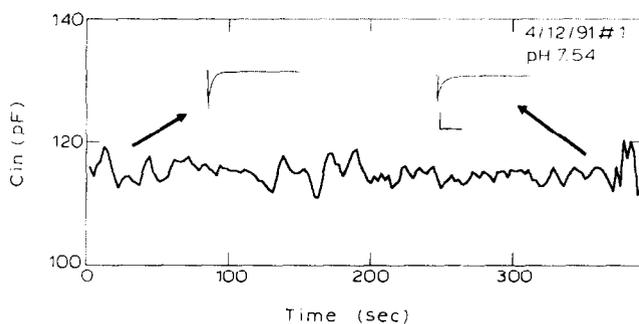

Fig. 1. Group of four cells, one cell of which was whole cell recorded. Pipette pH was 7.54. The input capacitance is stable during the 6.5 min recording, indicating that no uncoupling had occurred. Insets: Capacitive current traces due to -10 mV steps collected at beginning and end of recording session. Changes in trace shape is indicative of changes in cell parameters. Scale: 1.4 nA/4 ms.

voltage dependent ionic conductances so that capacitive currents were recorded in isolation. Blockers of plasmalemma voltage dependent ionic channels do not interfere with junctional communication (Fig. 1; Santos-Sacchi, 1991).

Pairs or small groups of isolated Hensen cells were easily identified under Hoffmann optics and one cell of the pair or group was whole cell voltage clamped. The measurement of input capacitance is a sensitive indicator of cell coupling because by definition the input capacitance will correspond to the amount of electrically contiguous membrane. Changes in input capacitance can therefore indicate the degree of cell coupling (Santos-Sacchi, 1991). However, because the other whole cell parameters (i.e., R_s and R_m) can change as well during alterations in coupling, it is necessary to estimate the input capacitance corrected for these changes. For a single cell the proper method of measuring membrane capacitance can be obtained by modelling the cell-clamp as an electrode resistance (access resistance, R_s) in series with a parallel combination of a membrane resistance (R_m), and a membrane capacitance (C_m). Solving for membrane capacitance (Santos-Sacchi, 1993),

$$C_m = \frac{(R_m + R_s)^2 Q}{R_m^2 V_c} = \frac{(R_{tot})^2 Q}{R_m^2 V_c} \quad (1)$$

The charge (Q) is obtained by integration of the decaying current transient induced by the command voltage step (V_c : 10–20 mV), at a holding potential of -80 mV. R_{tot} is equal to the sum of membrane and electrode resistances, and is obtained from the steady state current response. R_s is estimated from the current decay time constant (Santos-Sacchi, 1993). To a first approximation, for pairs or small groups of cells, R_{in} and C_{in} replaced R_m and C_m , respectively. The capacitance determination is actually only exact when either the cells are highly coupled (if voltage drops are equal in coupled cells) or uncoupled. Nevertheless, the

intermediate capacitance values during uncoupling are useful inasmuch as they reflect changes in cell-to-cell interaction, i.e., in the electrical contiguity between the membranes of adjacent cells. Cell uncoupling was judged to occur if input capacitance values approached single cell levels (25 ± 9 pF; Santos-Sacchi, 1991), within recording periods of 6 min. Syncytia with an initial R_{in} less than 70 M Ω were abandoned. Electronic series resistance compensation was not performed in order to gauge pipette plugging.

The care and use of the animals in this study were approved by the Yale Animal Care and Use Committee under NIH grant DC00273.

3. Results

Whole cell recordings were made 30 min to 2 h after tissue isolation, sufficient time for residual halothane, a potent uncoupler, to be washed away. The input capacitance of a syncytium of supporting cells depends upon the number of coupled cells. In Fig. 1, a group of four Hensen cells, one cell of which was whole-cell recorded, possesses an input capacitance of about 120 pF. This is roughly four times the value of single cells (Santos-Sacchi, 1991). In this case, the pipette solution pH was 7.54, and the Ca concentration was less than 10 nM. The input capacitance is stable during the 6.5 min recording period, indicating that the recorded cell remains coupled to adjacent cells. When pH is lowered below 6.5, an increase in the probability of uncoupling occurs (Figs. 2 and 3). Note in Fig. 2 that the input capacitance begins to decrease during uncoupling before the input resistance changes. This indicates that capacitance measures are more sensitive than DC resistance measures in evaluating junctional conductance changes. Between pH 7 and 8, only one cell uncoupled ($N = 7$), possibly due to injury during recording. Between pH 5 and 7, five cells uncoupled ($N = 13$), and between pH 4 and 5, 6 cells uncoupled ($N = 12$).

Unlike H^+ effects, Ca^{+2} induced uncoupling was observed in only one out of two cases at pCa 2.27 (Fig. 4). At lower concentrations ($N = 18$; pCa 3–8) no uncoupling was observed throughout the recording period, which typically lasted for greater than 6 min. Pooling all data for cells into two groups where pH was either above or below 7, we obtained 2 uncouplings / 26 observations, and 11 uncouplings / 25 observations, respectively. There were significantly fewer uncoupled cells in the high pH condition ($\chi^2 = 6.2$; $P = 0.01$).

4. Discussion

The classic experiments of Loewenstein (e.g., Loewenstein et al., 1967) implicated Ca^{+2} as a control-

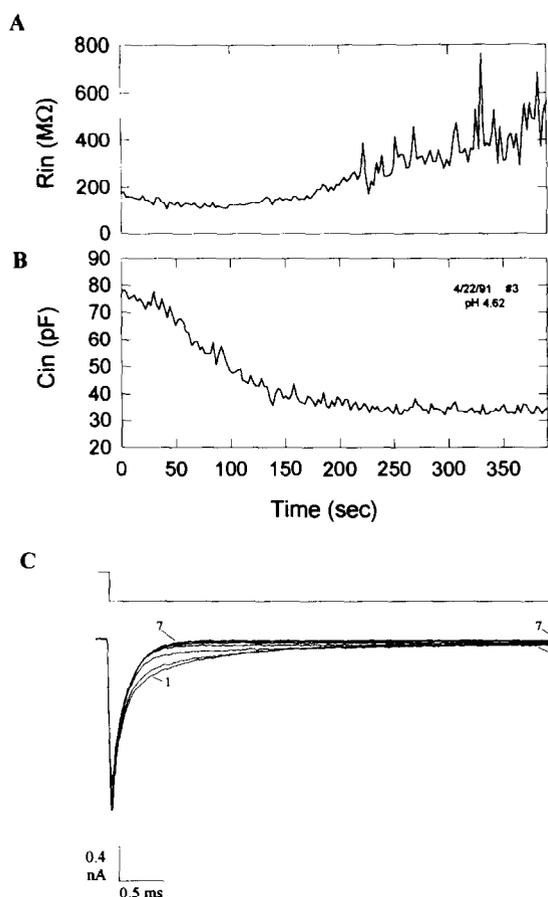

Fig. 2. Two cells with patch pipette at pH 4.62. (A): Input resistance increases as cells uncouple. Note that R_{in} begins to rise following changes in C_{in} . (B): Input capacitance begins to decrease almost immediately after establishment of whole cell configuration. It eventually approaches single cell values as the recorded cell's junctional conductance decreases. (C): Capacitive transients recorded at 50 s intervals (1–7). Note the decrease of steady state values over time indicative of increasing input resistance; the reduction of the charge (area under curves) over time corresponds to the decrease in C_{in} .

ling factor in gap junctional communication. Subsequently, pH was implicated as well (Turin and Warner, 1977). Considerable controversy still exists concerning

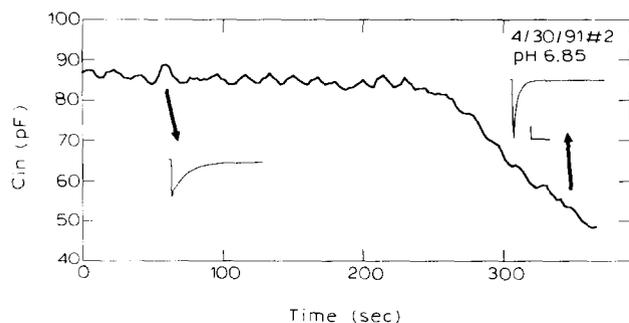

Fig. 3. Two or three cells. Patch pipette pH was 6.85. Cell uncoupling occurred only after prolonged recording. Insets: Capacitive current traces due to -10 mV steps collected at beginning and end of recording. Changes in trace shape is indicative of changes in series resistance, as well as R_{in} and C_{in} . Scale: 0.4 nA/ 0.8 ms.

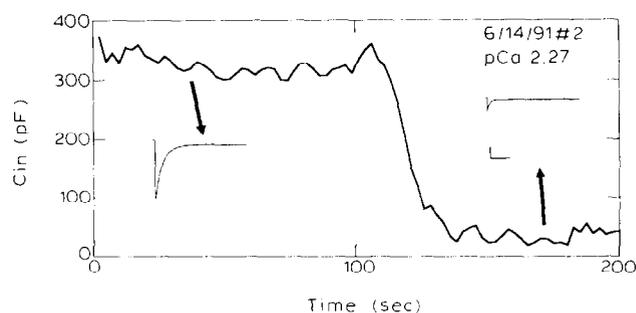

Fig. 4. Large group of cells, one cell of which was whole cell recorded. Pipette pH was 7.2 and pCa was 2.27. The input capacitance drops after one hundred seconds, indicating that uncoupling had occurred due to this high level of Ca^{+2} . the sensitivity of gap junctional communication to intracellular Ca^{+2} and H^{+} levels. For example, Spray et al. (1981) found in fish blastomeres that uncoupling due to pH alterations occurred near physiological levels whereas calcium effects were observed only in the millimolar range. Indeed, Ca^{+2} has been shown to permeate both hepatocyte and smooth muscle cell gap junctions (Saez et al., 1989; Christ et al., 1993). On the other hand, others have found that Ca^{+2} can uncouple cells at concentrations approaching physiological levels, viz., in the low to sub-micromolar range (Neyton and Trautmann, 1986; Noma and Tsuboi, 1987; Perachia, 1990). The intracellular regulation of Ca^{+2} and H^{+} are coupled, so that it is important to have control of each ion during experimental manipulations. In the present study, direct perfusion of small Hensen cells with buffered solutions provided a convenient means to study the differential effects of these ions on supporting cell junctional conductance.

It is demonstrated here that an individual Hensen cell is more likely to uncouple from its neighbors during alterations of pH near physiological levels than during alterations of calcium near physiological levels. Indeed, only when calcium levels were clearly pathologic, did uncoupling occur. It should be noted that the ability to maintain the cell's intracellular H^{+} and Ca^{+2} concentrations at that of the electrode's solution depends upon the efficacy of the intracellular perfusion, and intracellular buffering capacity. The latter is an especially important factor at sites proximal to gap junctions which may be distal to the perfusion site. In this regard, it is important to note that Hensen cells are relatively small, with single cell capacitance values of about 25–30 pF (Santos-Sacchi, 1991). Intracellular concentration variability may also occur due to pipette plugging. One difference noted between the two experimental protocols was a greater series resistance for high Ca^{+2} containing pipettes. In the Ca^{+2} modification experiments the average series resistance was 29

$M\Omega$ as compared to $17 M\Omega$ for the H^+ modification experiments. Typically, as the concentration of either ion was increased, the series resistance increased. Nevertheless, there are indications that the experimental differences between H^+ and Ca^{+2} sensitivities are real, and not related to perfusion problems. That is, in a group of cells ($N = 5$) near pH 6, where the probability of uncoupling is great, the series resistance was $21.6 M\Omega$. At a comparable concentration of calcium, (pCa 6 [$N = 5$]), where the probability of uncoupling is negligible, the series resistance was $10.1 M\Omega$. Thus, in cases of similar perfusion efficiencies, intercellular communication in the supporting cells appears more sensitive to the effects of H^+ than Ca^{+2} . Nevertheless, other means of raising intracellular Ca^{+2} levels should be explored.

The supporting cells of the organ of Corti are extensively coupled to one another via gap junctions (Iurato et al., 1976; Jahnke, 1975). It is probable that such coupling is important for sinking of K^+ released during hair cell and neural activity, even in relative quiet. Indeed, it has been shown that Henson cells 'share' ionic channels among each other via gap junctions; in particular, an inward rectifier is active near normal resting potentials (Santos-Sacchi, 1991). The sensitivity of the inner ear to metabolic insult is high and it is likely that resulting H^+ imbalances contribute to this insult by uncoupling supporting cells.

SUMMARY

Sensory hair cell ribbon synapses respond to graded stimulation in a linear, indefatigable manner, requiring that vesicle trafficking to synapses be rapid and nonrate-limiting. Real-time monitoring of vesicle fusion identified two release components. The first was saturable with both release rate and magnitude varying linearly with Ca^{2+} , however the magnitude was too small to account for sustained afferent firing rates. A second superlinear release component required recruitment, in a Ca^{2+} -dependent manner, of vesicles not in the immediate vicinity of the synapse. The superlinear component had a constant rate with its onset varying with Ca^{2+} load. High-speed Ca^{2+} imaging revealed a nonlinear increase in internal Ca^{2+} correlating with the superlinear capacitance change, implicating release of stored Ca^{2+} in driving vesicle recruitment. These data, supported by a mass action model, suggest sustained release at hair cell afferent fiber synapse is dictated by Ca^{2+} -dependent vesicle recruitment from a reserve pool.

INTRODUCTION

The hair cell afferent fiber synapse maintains a high level of tonic vesicle release and responds to graded input with linear changes in release across a wide range of stimulus frequencies (Furukawa et al., 1978). Information regarding frequency, intensity, and phase of stimulation are transferred across this synapse with high fidelity (Rose et al., 1967, 1971) and mechanisms by which this occurs are the focus of much work (Eisen et al., 2004; Meyer et al., 2009; Neef et al., 2007; Nouvian et al., 2006; Parsons et al., 1994; Schnee et al., 2005). Hair cells have a presynaptic dense body (DB) or synaptic ribbon, as do other sensory cells requiring graded and tonic release (Lagnado, 2003; Parsons and Sterling, 2003; Schnee et al., 2005; von Gersdorff and Matthews, 1997). The functional significance of the DB is unclear but synapses

with DBs have common features including linear release with increasing Ca^{2+} load, high release rates, and limited fatigue. At conventional synapses, vesicle populations are classified based on location and release kinetics, with a readily releasable pool (RRP) of vesicles near the membrane, a more distal recycling pool that communicates with the RRP, and a larger reserve pool whose role varies with synapse type (Rizzoli and Betz, 2005). Physiological investigations with either capacitance measurements or optical techniques find that pools do not strictly adhere to these distributions and that the ability to move between pools varies with synapse type (Rizzoli and Betz, 2004, 2005).

At ribbon synapses, vesicle pools have been classified by position relative to the ribbon and plasma membrane (Nouvian et al., 2006). The locations of vesicles around the ribbons have been correlated with capacitance measurements that identify pools based on release kinetics and saturation (Gomis et al., 1999; Gray and Pease, 1971; Mennerick and Matthews, 1996; Moser and Beutner, 2000; Schnee et al., 2005). Data establishing a direct link between vesicle location and release pools are limited. Furthermore, vesicle populations are often more difficult to observe in auditory hair cells because saturation is less evident and rapid vesicle trafficking appears to create overlap between pools (Schnee et al., 2005).

The role of the DB in regulating synaptic transmission remains unclear. In hair cells lacking DBs because of knockout of the anchoring protein bassoon, sustained exocytosis is maintained but synchronous vesicle release is lost (Khimich et al., 2005). DBs may tether vesicles, clustering them near presynaptic membranes, a hypothesis supported by morphological data (Lenzi et al., 1999; Wittig and Parsons, 2008). The DB may also control release rates, acting as a conveyor belt to rapidly bring vesicles to release sites (Parsons and Sterling, 2003). Causal data to support any specific role is limited (Nouvian et al., 2006).

How vesicles reach synaptic regions is also contentious. In the visual system, vesicles may freely diffuse within the cytosol until affixing to DBs (Holt et al., 2004; LoGiudice and Matthews, 2009). Brownian motion can provide enough DB-vesicle encounters to maintain vesicle availability during long release paradigms (Beaumont et al., 2005). Data from hair cells suggest vesicles are present in a gradient; density is highest near the synapse and lower

away from the synapse (Lenzi et al., 1999; Schnee et al., 2005), intimating a more structured system. Calcium dependence of vesicle trafficking has also been suggested (Spassova et al., 2004).

In this study, we assess synaptic vesicle trafficking and fusion at the hair cell afferent synapse in real time. Our approach has allowed us to separate release into a linear component that does not require recruitment of vesicles and a superlinear component dependent upon vesicle trafficking. We are able to clearly identify pools of depletable vesicles that correspond in size to those vesicles near the DB. Data presented here implicate strong interactions between the RRP and the recycling pool, which together account for the observed linear release component and also demonstrate an ability to rapidly recruit from the reserve pool. Vesicle trafficking is calcium dependent and release of stored calcium may be critical for recruitment of vesicles to the release site from the distant reserve pool.

RESULTS

Ca²⁺ Dependence of Trafficking

At retinal ribbon synapses, paired-pulse experiments identified an RRP that could be depleted (Coggins and Zenisek, 2009). For experiments with turtle auditory hair cells, we designed a protocol to elicit a capacitance change roughly equivalent to release of all vesicles associated with the DB (300 ms pulse to -20 mV, based on previous estimates of vesicle distribution, Schnee et al., 2005) and the interval between pulses was varied from 1 s to 10 ms (Figure 1A). Surprisingly, we did not observe depletion or reduction of release during the second pulse at any interpulse duration (Figure 1B). Rather, as the interpulse interval was reduced, capacitance increased (Figure 1). The increase in release from the second pulse approached that equivalent to a single 600 ms pulse (data not shown). These data suggest that vesicles can be rapidly recruited to release sites faster than they are depleted. To test whether a depletable pool could be observed by altering stimulus duration, we held the interpulse interval at 30 ms and varied stimulus duration between 10 and 300 ms (Figure 1C). Depletion was never observed and again, as stimulus duration was increased, the second response was greater than the first, indicative of rapid vesicle recruitment. Assuming capacitance reflects synaptic vesicle fusion, a change of 400 fF equates to 8000 vesicles (assuming 50 aF per vesicle) or 186 vesicles per synapse (see Figure 4 for synapse counts), more vesicles than previously identified to be near the synapse (Schnee et al., 2005), indicating that rapid vesicle recruitment is required.

To identify discrete pools, it might be necessary to reduce calcium entry as a potential means of slowing release and possibly vesicle trafficking. Additionally, pool populations might be masked by priming of synapses such that the second stimulation might not provide similar information to the initial one. This can be a significant issue when multiple stimulations are required to assess release across a broad time frame. Additionally, both intra- and intercellular variability may make it more difficult to identify discrete vesicle pools.

Two-Sine Measurements

To address these concerns and more directly investigate vesicle trafficking, we developed a method for continually monitoring

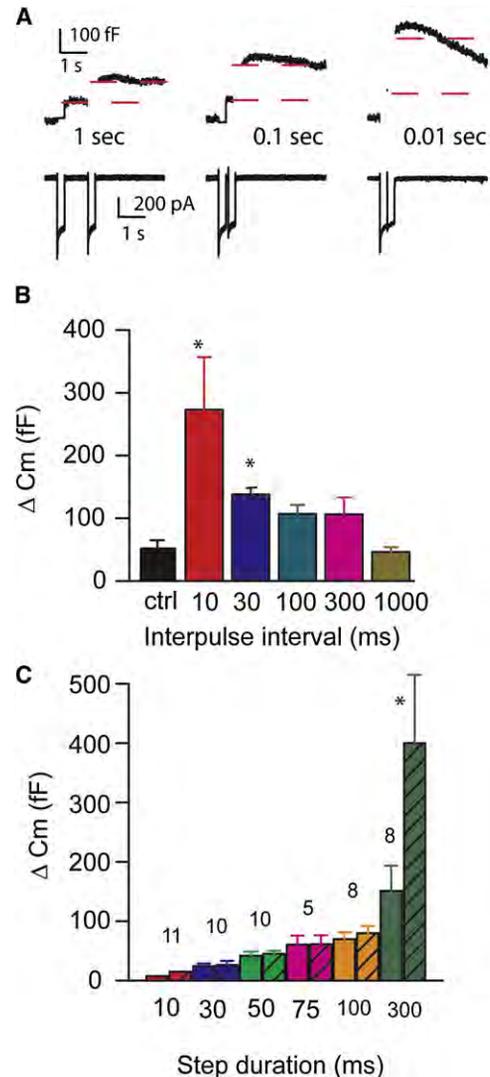

Figure 1. Paired-Pulse Paradigms Suggest Vesicle Trafficking Is Fast, Limiting the Ability to Identify Discrete Pools

(A) Paired pulses of 300 ms duration with interpulse intervals from 1000 to 10 ms, with capacitance shown above and I_{Ca} below. Red lines indicate instantaneous capacitance values, revealing a lack of depletion regardless of interpulse interval (IPI) with short duration IPIs unmasking a facilitatory effect. (B) Summary of data from protocol shown in (A) demonstrating that release from the second stimulus was greater than that observed from the first ($n = 4$). The bar graph represents change in capacitance for the second pulse with IPI given below, ctrl is the average capacitance change for the first stimulus. (C) Summary of release data where the IPI was constant at 30 ms and the stimulus duration varied from 10 to 300 ms. Cross-hatched bars indicate second pulse response, while open bars indicate initial response; n is given above each pair. Asterisks indicate statistical significance at the $p < 0.05$ level.

cell capacitance that simultaneously tracks capacitance and conductance changes. This two-sine technique requires accurate compensation of electrode capacitance and calibration of the recording system (for detailed description of technique see Santos-Sacchi, 2004 and Supplemental Information, Figures S1–S3). With this approach, we could resolve all components of release from a single cell with a single pulse. Importantly,

continuous monitoring of capacitance allowed the use of protocols eliciting submaximal I_{Ca} , thereby slowing Ca^{2+} influx, with the goal of creating separation between individual components of trafficking and release.

Figure 2 provides an example of a cell probed with a depolarization eliciting either 75% or 35% of the maximal Ca^{2+} current. As predicted, strong depolarization compressed release components so that saturable pools were difficult to observe (Figures 2B and 2C, left panel). Surprisingly though, the rate of release increased during the stimulation (Figure 2). We commonly observed a slight delay in release after the stimulus onset that varied with intensity and repetition making it difficult to quantify (Figure 2C). Probably this delay relates to strong calcium clearance mechanisms at the synapse and results from nonphysiological stimulus protocols where cells are held at very hyperpolarized potentials (see Figure 5). Slowing Ca^{2+} entry separated release into at least two clearly identifiable components, an initial shallow component that showed depletion followed by a large, rapid, superlinear component (Figure 2B). These results are in contrast to those from photoreceptors where the initial release was fast, followed by longer but slower release components (Innocenti and Heidelberger, 2008). With slower Ca^{2+} accumulation, the depletable pool size increased from 24 vesicles/synapse to 60 vesicles/synapse (based on 50 aF/vesicle and synapse numbers presented in Figure 4). Therefore, slowing Ca^{2+} entry unmasked a saturable pool of vesicles whose pool size varied with Ca^{2+} load. Depending on stimulus intensity this additional pool could be recruited into the depletable first component (Figure 2D).

Plotting the Ca^{2+} load against capacitance changes corroborated the superlinear nature of the second release component (Figure 2E). Interestingly, the dramatic difference in Ca^{2+} load required to elicit the secondary larger capacitance change depended on the rate of Ca^{2+} entry. Depolarizations closer to the peak elicited the superlinear component with less than 200 pC of Ca^{2+} entry as compared to 600 pC when Ca^{2+} entry was slowed. This may reflect the presence of strong Ca^{2+} clearance mechanisms at the synapse that were overwhelmed with rapid Ca^{2+} entry. Fitting the data in Figure 2E with a Hill equation by using previously determined maximal release values (Schnee et al., 2005) yielded a Hill coefficient of 3.6 ± 0.4 for the high-frequency cells ($n = 14$). The coefficient was not dependent upon level of depolarization as the shift in the capacitance versus Ca^{2+} load with depolarization was parallel (Figure 2E). This value is similar to that obtained when photolysis of caged calcium was used to stimulate release and to that observed in mouse IHCs (Beurg et al., 2010; Beutner et al., 2001). Interestingly, this value is predominated by the superlinear component of release that is at least in part a reflection of vesicle trafficking and not only of release.

The nonlinearity in release differs from previous measurements (Schnee et al., 2005). However, a limitation to those experiments was the use of the single-sine method, which provided no direct kinetic information; rather, kinetics were inferred from responses measured after the pulse by combining responses from multiple cells and/or multiple pulses to individual cells. A comparison of data collected by using the two-sine wave technique to that previously obtained by using the single-sine

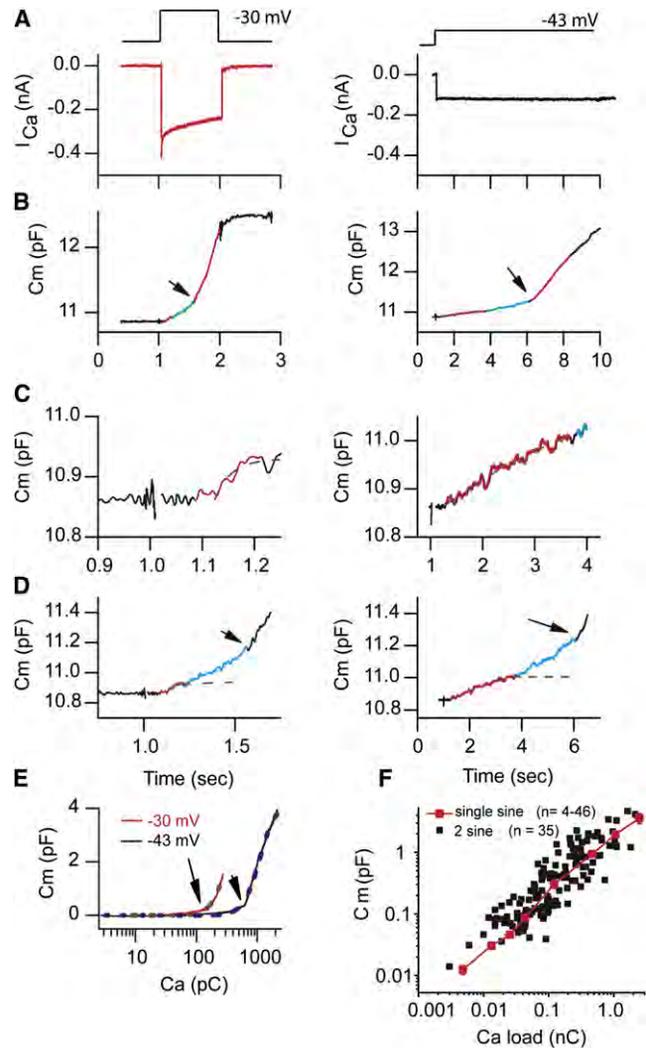

Figure 2. Two Ca^{2+} -Dependent Components of Vesicle Release Were Observed during Hair Cell Depolarization

(A) I_{Ca} elicited in response to membrane depolarization from -85 mV to -30 mV (75% peak, left) or -43 mV (35% of peak, right). (B) Capacitance change elicited in response to I_{Ca} in (A); arrow indicates superlinear onset. Colors show regions where rates are different. (C) Expansion of the axis of (B). Red identifies a saturable pool of vesicles that differs in amplitude between stimulus protocols. Blue indicates an intermediary component that also is saturable depending on Ca^{2+} load and purple represents the superlinear component. (D) Expansion of plots in (B) to illustrate the intermediate component of release where depletion has ended but superlinear response has not started. The dashed line is the exponential fit showing depletion. (E) Capacitance against Ca load (integral of current in A), demonstrating both linear and nonlinear (indicated by arrow) responses. Dashed lines are fit to Hill equation: $Cm = Cm_{(max)} \times x^n / (k^n + x^n)$ where n is Hill coefficient ($r^2 = 0.99$, see text for details). (F) Plot of capacitance change after stimulation from high-frequency (1 mM EGTA internal) cells included in this study for varying intensities and durations of depolarization as compared to previous data obtained with single-sine wave method (Schnee et al., 2005).

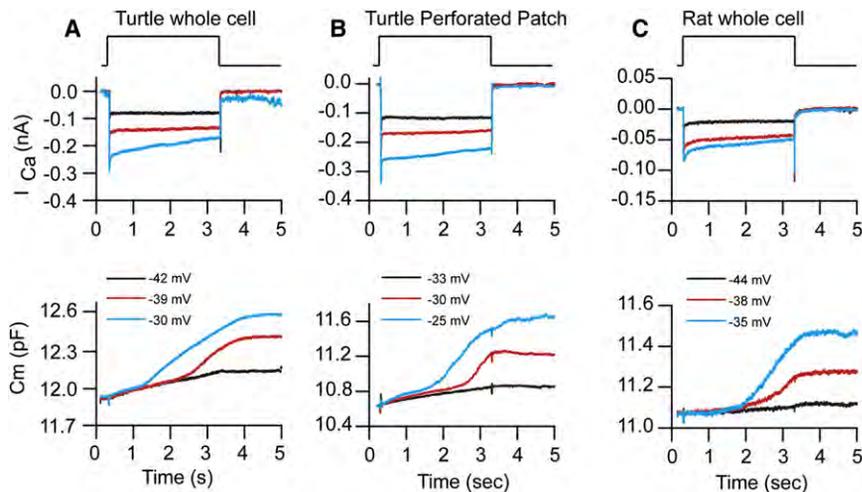

Figure 3. Superlinear Release Is Observed in Whole-Cell and Perforated-Patch Recordings and across Species

(A) The I_{Ca} (above) and capacitance response (below) are presented for a turtle cell recorded in whole-cell mode (1mM EGTA as buffer). A saturating response as well as two superlinear responses are presented in response to different levels of depolarization.

(B) A perforated patch-recording ($n = 4$) presented in a similar manner to (A).

(C) A whole-cell recording from a rat inner hair cell ($n = 16$) with 1 mM EGTA as the buffer. Similar responses were observed from all conditions.

technique confirmed that variability between and within cells may have masked the superlinear behavior of individual cells (Figure 2F). These data point out the limitations of using a technique that requires multiple sampling to intuit kinetic information as compared to direct measurements of kinetics.

To determine whether the superlinear release component was an artifact of whole-cell recording, we performed perforated-patch experiments to maintain endogenous buffering. We observed two release components in both perforated-patch recordings and whole-cell recordings by using 1 mM EGTA (Figure 3), indicating that the observed release properties are not due to the whole-cell recording technique. To ensure that the superlinear release component is not unique to turtle, we recorded from rat and mouse inner hair cells (ages postnatal day P7–P15) and observed two components of release in these preparations (Figure 3C). Previous work in chick auditory hair cells also documented two release components (Eisen et al., 2004), suggesting multiple release components may be a ubiquitous feature of vesicle release in hair cells.

Comparisons between Hair Cells of Different Frequency Locations

Quantitative comparison of release properties between frequency positions requires knowing the number of synapses present. Whole-mount papillae were double labeled with Ctbp2+PSD-95 or Ribeye+PSD-95 antibodies to count the number of functional ribbon synapses at the same tonotopic positions used in the electrophysiological analysis ($n = 6$). Examples from a high-frequency position are shown in Figures 4A–4F. Ribbon synapses were localized in hair cell basolateral regions (Figures 4D and 4E), were scarce above the nucleus and were typically present in series, probably corresponding to the finger-like projections of the afferent fiber (Figures 4D and 4F, inset). No synapses were included that did not positively label adjacent pre- and postsynaptic markers (Figure 4F, inset). PSD-95 puncta that did not have a corresponding Ribeye component accounted for less than 5% of the observed puncta. Frequency histograms are plotted to show the distribution of synapses for both frequency positions (Figure 4G). The low-frequency distribution

was best fit with a normal distribution having a center value of 19.5 ± 0.4 synapses/cell and a full-width at half-maximum value of 9 ($r^2 = 0.92$; $n = 38$

cells). The high-frequency distribution was best fit by the sum of two Gaussians with center peaks of 46 ± 1 and 75 ± 4 , and full-width at half-maximum values of 21 and 9, respectively ($r^2 = 0.92$; $n = 90$ cells). Previous morphological work suggested that at higher frequencies some hair cells are dually innervated (Sneary, 1988). Hypothesizing that dual innervations might account for the bimodal distribution in synapse number and further correlate with I_{Ca} , we plotted the frequency distribution of peak I_{Ca} (Figure 4H), revealing a bimodal distribution. The second population of cells with larger I_{Ca} ($\sim 3\%$ of the total) and those with larger synapse number ($\sim 5\%$ of the total) may represent dual innervations and skew the absolute mean values (Sneary, 1988). Therefore, we used the major peak value in all analyses, rather than the mean of the total population, to ensure similar cell populations were compared between high- and low-frequency cells. I_{Ca} (peak of fit) increased from 313 pA to 586 pA between frequency locations; similarly, synapse number increased from 20 to 46 from low to high frequency such that the Ca^{2+} load per synapse was 16 pA/synapse for low frequency compared to 13 pA/synapse for high frequency. Calcium channels are considered clustered at release sites based on previous measurements in turtle (Tucker and Fettiplace, 1995) and frog (Roberts et al., 1990).

First Release Component: Pool Size

As discussed above, depolarizations elicited two distinct components of release, the first corresponding to a saturable pool whose release rate varied with Ca^{2+} entry and a second component in which the release rate was increased relative to the first component. Sixty-four percent of high-frequency cells and 80% of low-frequency cells had a clearly identifiable saturable vesicle pool. The smallest saturable pool observed (Figures 4K and 4L) had asymptotic capacitance measurements of 48 ± 20 fF ($n = 12$) and 90 ± 35 fF ($n = 9$) for low- and high-frequency cells, respectively. This pool size agrees reasonably well with vesicle numbers under the ribbon closest to the plasma membrane and might represent the RRP (Schnee et al., 2005; Rizzoli and Betz, 2005). The largest saturable pools identified (Figures 4K and 4L) were 145 ± 71 ($n = 11$) for low- and

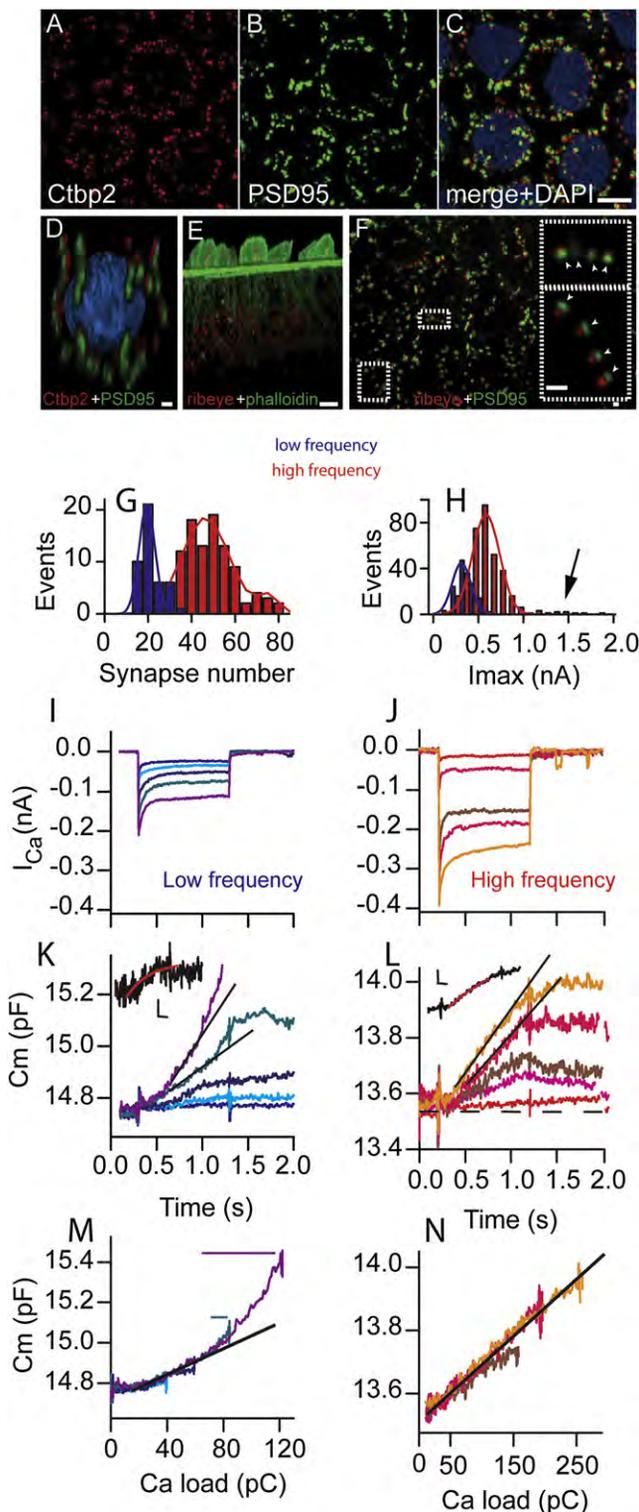

Figure 4. Low-Frequency Cells Release Faster per Synapse Than High-Frequency Cells

328 ± 187 fF ($n = 12$) for high-frequency cells. These values are not statistically different from previous morphological measurements estimating vesicles associated with the DB and the total pool may correspond to the recycling pool and the RRP (Rizzoli and Betz, 2005; Schnee et al., 2005). Movement of vesicles within this pool was dependent on the rate of Ca^{2+} entry, suggesting that trafficking of vesicles to release sites is fast and Ca^{2+} dependent and that the ability of vesicles to move between pools is enhanced at auditory ribbon synapses.

First Release Component: Release Rates

Release rates varied linearly with Ca^{2+} load (Figures 4M and 4N). To compare high- and low-frequency cells, we selected stimuli where the Ca^{2+} load was comparable when normalized to synapse number. Rates were estimated by fitting lines to the initial portions of the release plots prior to depletion. The release rate at low-frequency synapses was significantly faster (530 ± 10 vesicles/s/synapse, $n = 14$) than at high-frequency synapses (191 ± 60 vesicles/s/synapse, $n = 11$) ($p < 0.05$, see Figure S6A). We also compared the Ca^{2+} dependence between frequency positions (Figures 4M and 4N). Release varied linearly with Ca^{2+} for the initial release component but the relationship often appeared more exponential in low-frequency cells (Figure 4M), as has been described for mammalian low-frequency cells (Johnson et al., 2008). However, careful inspection reveals encroachment of the superlinear release component (Figures 4K and 4L). No superlinear component is seen in high-frequency cells at these stimulus levels (Figure 4L). The presence of this superlinear component may account for the exponential appearance, suggesting perhaps that vesicle trafficking and not intrinsic

(E) A 3D confocal reconstruction showing the presence of ribbons (Ribeye, red) in the basolateral region of hair cells. Hair bundles can be localized with phalloidin staining (green).
(F) A maximum-intensity projection by using Ribeye (red) and PSD95 (green) to colocalize synapses. Insets in F represent regions outlined to better illustrate the coupling of label. Scale bars: C and E, $5 \mu\text{m}$; D and F, $1 \mu\text{m}$. Note that the Ribeye antiserum also labels the kinocilium nonspecifically.
(G) A frequency histogram (blue being low frequency and red high frequency throughout) for the number of synapses per cell with solid lines as Gaussian fits to plots (see text for details).
(H) A plot of the frequency distribution for peak I_{Ca} , again with Gaussian fits to data as solid lines; arrow indicates small peak corresponding to high-frequency cells with twice the I_{Ca} .
(I–N) I_{Ca} (I and J) and capacitance measurements (K and L) in response to different voltage steps (-44 , -41 , -38 , -35 , -43 mV from -80 mV) for low- (blue) and in response to different voltage steps (-50 , -47 , -44 , -41 , -38 mV from -80 mV) for high-frequency (red) cells. Both high-frequency (J, L, and N) and low-frequency (I, K, and M) hair cells show linear, incremental increases in release with increased Ca^{2+} load. Expanding the smallest capacitance response from (K and L) reveals a saturating component (inset, scale bars are 200 ms and 20 fF). Black lines indicate linearity of release for larger depolarizations. (M and N) plot the data from (K and L) against the integral of the corresponding I_{Ca} illustrating the linear relationship between release and Ca^{2+} entry for the first release component. Note that the low-frequency response appears nonlinear because of encroachment of the superlinear component. Encroachment is depicted by horizontal solid lines above traces derived from the point where the capacitance response diverges from linearity (L). Solid black lines in (M and N) point out linearity of response.

differences in Ca^{2+} dependence of release may be responsible for the observed results (Figure 4M). We consistently observed that the superlinear component required less Ca^{2+} influx in low-frequency cells than high-frequency cells, which could create an apparent exponential appearance to the Ca^{2+} dependence.

Superlinear Release Components

The larger superlinear release component was observed in all cells when the Ca^{2+} load was high (Figure 5). The superlinear nature of the response is denoted by a sharp increase in release rate during constant stimulation. As in Figures 3 and 4, capacitance traces elicited by smaller I_{Ca} showed a linear response until reaching a point where release rate dramatically increased. Additional depolarization did not further increase the release rate but rather shortened the onset time of this faster component (Figure 5B). Maximal rates, obtained by fitting a linear equation to the slope of the superlinear component, were 0.9 ± 0.5 pF/s ($n = 13$) and 1.0 ± 0.8 pF/s ($n = 17$) for low- and high-frequency cells, respectively, corresponding to 20,000 vesicles/s and 18,000 vesicle/s or 900 vesicles/s/synapse and 434 vesicles/s/synapse for low- and high-frequency cells, respectively. As with the first release component, low-frequency synapses operated faster than high-frequency synapses, though release rates per cell were comparable. Plotting the change in capacitance against Ca^{2+} load (Figure 5C) shows that the inflection point where the superlinear component began was at the same Ca^{2+} load for the two responses, suggesting the temporal difference in Figure 5B was due to the difference in rate of Ca^{2+} entry. As seen in Figure 2, this onset time for the superlinear component could be varied by altering the Ca^{2+} load. Further inspection of the Ca^{2+} load driving capacitance change (Figure 5D) shows that first component release plateaus just prior to the onset of the superlinear response. Whether initial vesicle pool depletion provides a signal for rapid vesicle recruitment to the synapse remains to be explored.

Functional Relevance of Superlinear Component

The superlinear capacitance changes are paradoxical in that postsynaptic recordings have indicated that release at the hair cell afferent fiber synapse is linear (Keen and Hudspeth, 2006; Li et al., 2009). No physiological experimental data exist that correspond to the superlinear release kinetics, yet large numbers of vesicles must be released continually in order to account for afferent firing properties (Taberner and Liberman, 2005). To address this question, we voltage clamped hair cells at -45 mV, near the expected resting potential (Farris et al., 2006) and then depolarized the cells to the peak I_{Ca} . The response was compared to the conventional experimental protocol in which the cell is held at -85 mV (Figures 5E–5G). At the hair cell's resting potential, where Ca^{2+} channel open probability is nonzero (Figure 5E), the I_{Ca} in response to the depolarization was minimally reduced, yet the capacitance change was dramatically increased (Figure 5F). The capacitance response from -85 mV was small and saturating, indicating that release was depleted and the superlinear component not recruited, while the response at the resting potential was almost linear, more in line with what is expected based on afferent fiber recordings. These data suggest

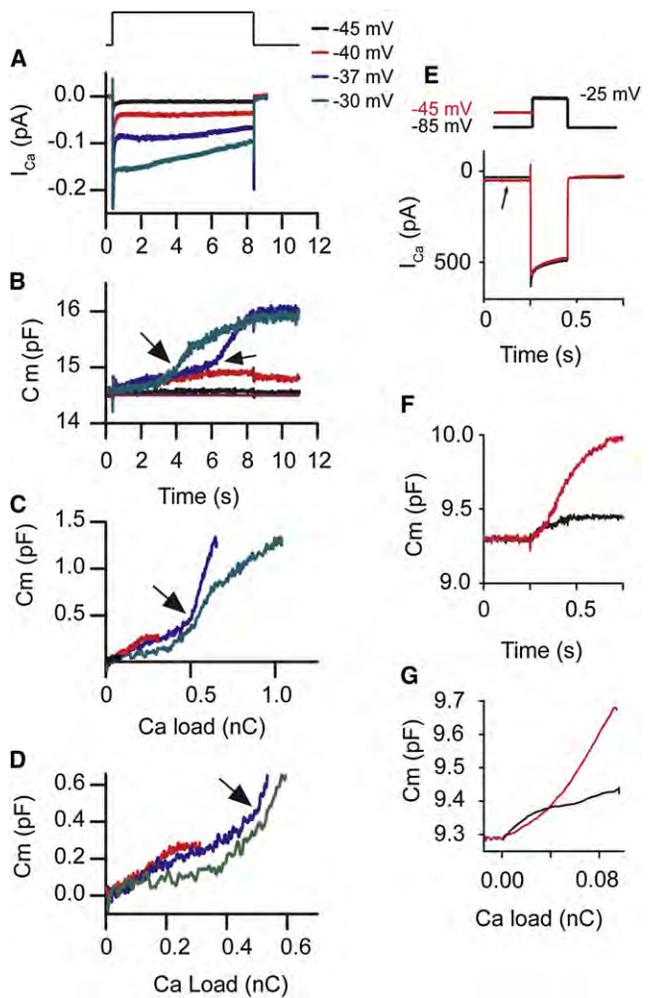

Figure 5. The Superlinear Release Component Onset Is Ca^{2+} Dependent but the Release Rate Is Not

(A) I_{Ca} in response to listed voltage steps from -85 mV. (B) The capacitance responses corresponding to I_{Ca} in (A). In each panel, arrows indicate where release becomes superlinear. (C) A plot of the Ca^{2+} load against the capacitance change; responses are color-coded as in (A) and (B). (D) An expansion of (C) to better exhibit the capacitance results versus Ca^{2+} load. (E) The upper panel shows stimulus and the lower panel presents the I_{Ca} in response to color-coded stimuli where prepulse to -45 mV (red) or -85 mV (black) were presented. that vesicle release and trafficking kinetics are strongly dependent on calcium homeostasis such that altering homeostasis by hyperpolarizing the cell results in the recruitment of an apparent superlinear process, whereas under physiological conditions release could be maintained for much longer periods of time by the merging of linear and superlinear processes. The magnitude of the release observed with the prepulse requires recruitment of vesicles to release sites (i.e., a superlinear process), suggesting that the prepulse results in the temporal merging of the two release components. Biophysically, it is possible to distinguish

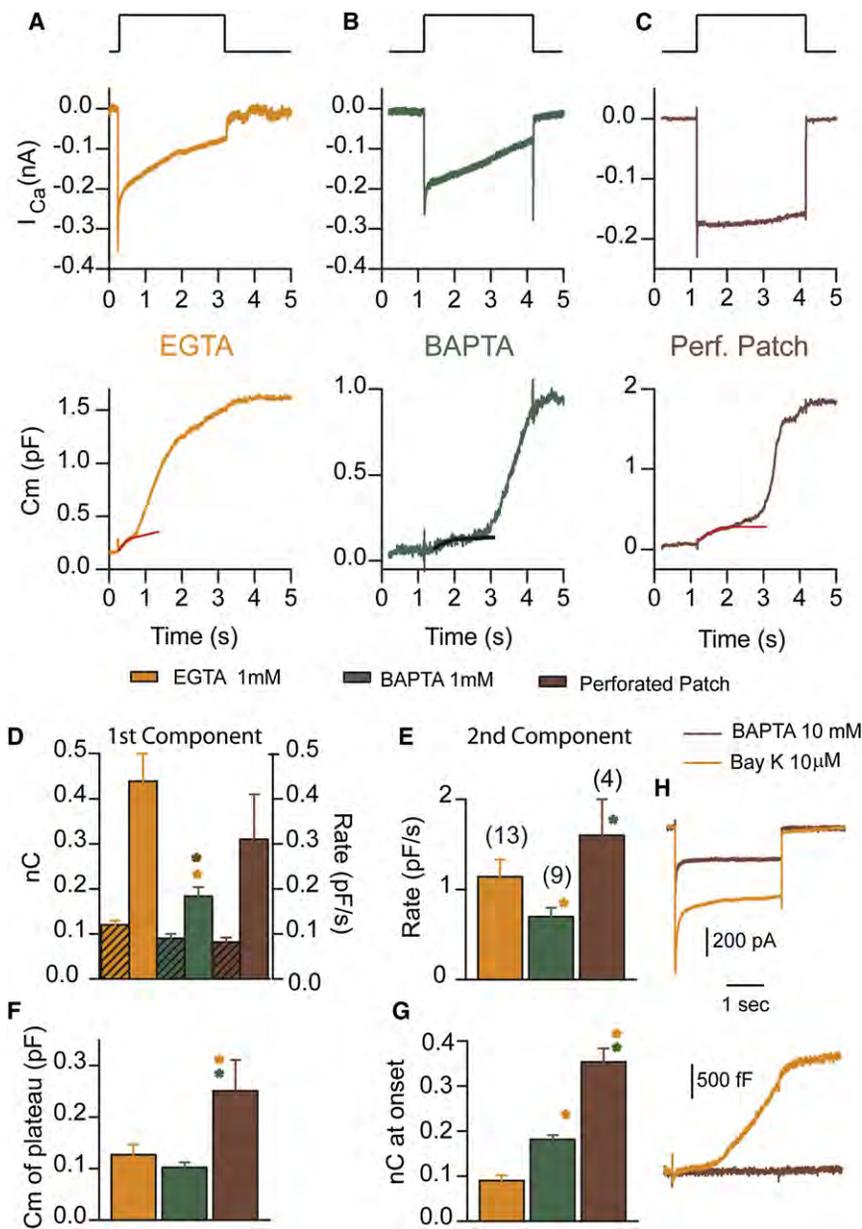

Figure 6. Fast Ca²⁺ Buffers Slow Release Rates and Onset of Release but Pool Size Does Not Change

(A–C) EGTA (tan) at 1 mM (A), BAPTA (green) at 1 mM (B), and perforated patch (purple) (C) with I_{Ca} (upper panels) and capacitance (lower panels) in response to a depolarization eliciting about 60% of the maximal I_{Ca} .

(D) A plot of the Ca²⁺ load (hatched bars) and the release rate for the first component under different internal Ca²⁺ buffering. Asterisks indicate significance at the $p < 0.05$ level against the recording condition indicated by color.

(E–G) Similarly, (E) plots the rate of the superlinear component, (F) plots the capacitance change for the depleted pool, and (G) plots the Ca²⁺ load at the onset of the superlinear response. The number of cells is given in parentheses above bars in (E).

that elicited about 60% of the maximal I_{Ca} (Figures 6A–6C). First, component rates varied with stimulus intensity so rates were compared for a similar Ca²⁺ load (Figure 6D). BAPTA significantly slowed release as compared to EGTA or perforated patch. The perforated-patch recordings suggest an endogenous buffer capacity less than 1 mM BAPTA, but more than 1 mM EGTA, similar to that suggested previously (Moser and Beutner, 2000) and consistent with a release mechanism located near the source of Ca²⁺ influx. A comparison of initial release rates against Ca²⁺ load for individual cells is presented in Figure S6B illustrating how BAPTA reduces release rates. As compared to EGTA, BAPTA also increased the duration of the plateau between the first release component and the onset of the superlinear component, represented by the Ca²⁺ load required

between release and trafficking, but physiologically, the process is created to provide rapid and continual release. The linearity obtained by incorporating the superlinear component is clearly demonstrated by plotting the Ca²⁺ load against capacitance (Figure 5G). This is not unlike arguments made previously when investigating Ca²⁺ dependence of release in hair cells by using caged Ca²⁺ (Beutner et al., 2001). These data suggest multiple sequential first-order processes could account for trafficking and release in the hair cell.

Ca²⁺ Buffering Alters the Two Release Components Differently

The effect of Ca²⁺ buffering on release properties was investigated with EGTA, BAPTA, and perforated patch at stimulations

for the onset of the superlinear release (Figure 6G). In this instance perforated-patch responses suggest endogenous buffering was stronger than either BAPTA or EGTA. This might indicate that the site of action is further removed from the Ca²⁺ source where concentration rather than kinetics is more relevant (Naraghi and Neher, 1997). In contrast, changes in the rate of the superlinear component (Figure 6E) suggest the perforated-patch response was less efficacious than EGTA or BAPTA, supporting the contention that endogenous buffer kinetics are slow. Finally, the difference in Ca²⁺ load required to initiate the superlinear component of release led to an increase in the magnitude of the first component plateau (Figure 6F), supporting the conclusion that vesicle movement to release sites was rapid and Ca²⁺ dependent. The delay between release components also

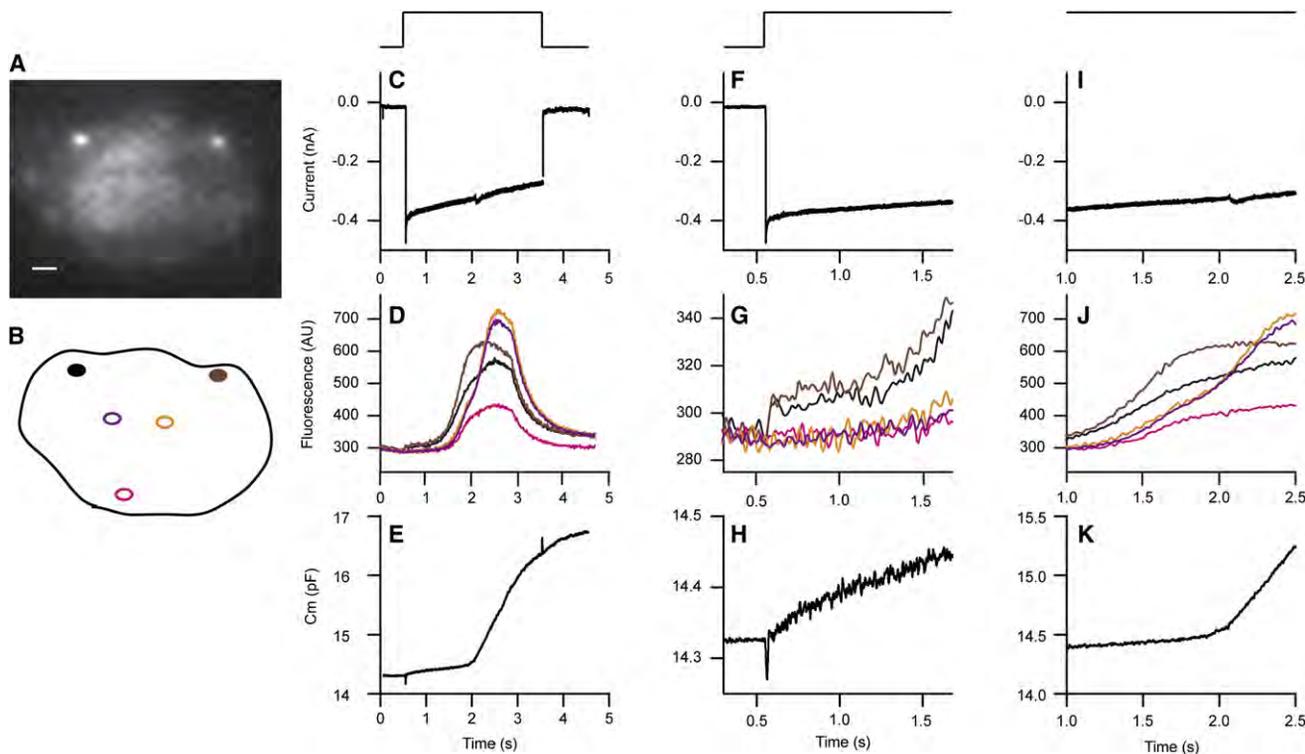

Figure 7. High-Speed Ca^{2+} Imaging Coupled with Continuous Capacitance Measurements Reveals a Nonlinear Increase in Ca^{2+} during Responses with Superlinear Release Properties

(C–E) (C) shows stimulus above which the I_{Ca} response elicits local changes in Ca^{2+} (D) as well as capacitance changes (E).

(F–H) An expansion of the plots from (C–E) in (F–H) focuses on the initial changes in Ca^{2+} current (F), local Ca^{2+} changes (G), and first component of capacitance (H). (I–K) A focus on the onset of the superlinear component again with the Ca^{2+} current (I), local Ca^{2+} signaling (J), and capacitance (K) signals.

supports this conclusion, demonstrating that despite the presence of Ca^{2+} to drive release, depletion persisted for longer periods of time when Ca^{2+} buffering was increased because trafficking was slowed.

An alternative possibility is that vesicle position at the synapse is Ca^{2+} dependent and that greater buffer efficacy leads to diffusion of vesicles away from the synapse. We tested this hypothesis by recording cells with 10 mM BAPTA internally, blocking release at all but maximal stimulus levels, and then increasing Ca^{2+} load by using Bay K (10 μM), which prolongs Ca^{2+} channel open time (Figure 6H). Capacitance changes evoked by Bay K treatment included both linear and superlinear components supporting the hypothesis that vesicle movement toward the synapse is Ca^{2+} dependent and largely unidirectional.

Calcium Imaging Demonstrates Multiple Release Components

It is possible that additional sources of Ca^{2+} , for example Ca^{2+} stores, enhance release during longer stimulations (Lelli et al., 2003). We tested this hypothesis with high-speed confocal Ca^{2+} imaging. Labeling ribbons with a rhodamine-tagged ctbp2-terminal binding peptide in the patch electrode (Zenisek et al., 2003) allowed synapses to be localized during simultaneous Ca^{2+} imaging and capacitance measurements (Figure 7A). The capacitance changes show a typical response with both

release components (Figures 7C–7E). The fluorescent signal, however, is quite complex and not simply the integral of the current, as might be predicted. Rather, the initial response (Figures 7F–7H), representing mostly first component release, shows a rapid increase at the synapse followed by a plateau, similar to that observed in mouse (Frank et al., 2009), indicative of strong Ca^{2+} clearance followed by an integrating increase in signal. Sites distal to the synapse show little change initially, consistent with the source of Ca^{2+} being at a distance, followed by a slow increase. The later signals (Figures 7I–7K), corresponding to the onset of the superlinear response, present a different picture. Ca^{2+} at the synapse shows an abrupt increase in signal, followed by a plateau and decrease in signal even in the face of constant Ca^{2+} entry (Figures 7D and 7J). Ca^{2+} signals away from the synapse show a slower integrating signal followed by a sudden increase in signal whose rate is faster and peak greater than that observed at the synaptic region (Figure 7J). The change in kinetics at these distant sites suggests a secondary source of Ca^{2+} . Similar results were obtained in five cells where the superlinear release component was observed. Smaller depolarizations revealed simple integrating responses that diminished away from the synapse while larger depolarizations yielded similar complex responses (Figure S7). Together these data suggest that Ca^{2+} dynamics are complex, clearance near the synapse is strong, and a second source of Ca^{2+} may play a role in vesicle

trafficking. Also, although the second component of release appears to be superlinear when compared to the Ca^{2+} integral, indicating more release per Ca^{2+} for the second component, when compared to the Ca^{2+} fluorescent signal the opposite is true. By using fluorescence changes at the synapse, the ratio (Cap/Fluor) of the first component divided by the second component provided an indicator of relative efficiency of release and was 1.5 ± 0.4 ($n = 3$), indicating that release was more efficient at lower values of Ca^{2+} .

DISCUSSION

Utilization of a two-sine technique for real-time tracking of vesicle fusion has allowed for more detailed investigation of presynaptic release components at the auditory hair cell-afferent fiber synapse. By using stimuli that did not elicit maximal I_{Ca} , saturable pools were clearly identified, whereas variability between and within cells made this impossible (in turtle) with the single-sine technique (Schnee et al., 2005). A superlinear release component whose onset varied with Ca^{2+} load and correlated with release of an additional source of Ca^{2+} was also revealed. The superlinear component of release is postulated to reflect the ability of hair cells to rapidly recruit vesicles from regions distant from the synapse, which may underlie the inability to deplete vesicle pools and the ability of hair cell synapses to operate at high rates for sustained periods of time.

The first component of vesicle release had a pool size consistent with vesicles within the vicinity of the DB and thus did not require significant vesicle recruitment, though movement of vesicles to release sites on the plasma membrane would be required. The release rate and amplitude of the first component varied linearly with Ca^{2+} entry. Saturable vesicle pools could be observed within this first release component. The size of the saturable pool varied both with frequency position and Ca^{2+} load and could increase significantly if Ca^{2+} entry were slowed, suggesting that additional vesicles could be recruited to release sites faster than the existing pool of vesicles could be released. This vesicle pool may be as small as the vesicle population associated with the plasma membrane and DB to as large as all the vesicles associated with the DB (Figure 8A). This first component of release is very similar to what has been described for ribbon synapses of hair cells and other sensory cells (Beutner et al., 2001; Eisen et al., 2004; Moser and Beutner, 2000; Neef et al., 2007; Neves and Lagnado, 1999; Parsons et al., 1994; Schnee et al., 2005; Thoreson et al., 2004; von Gersdorff and Matthews, 1997).

The second, superlinear component represented a much larger pool of vesicles, requiring trafficking of distant vesicles to the synapse, likely equating to the reserve pool (Figure 8A). It also behaved as if there were a threshold Ca^{2+} load required for onset that was sensitive to factors affecting homeostasis, such as Ca^{2+} buffering and the rate of Ca^{2+} entry. Ca^{2+} imaging experiments suggest a correlation with release of an internal pool of Ca^{2+} , though further studies are needed. Third, the release rate did not increase with Ca^{2+} load; rather, the onset time decreased. These results suggest the superlinear component is more a reflection of vesicle trafficking than vesicle fusion.

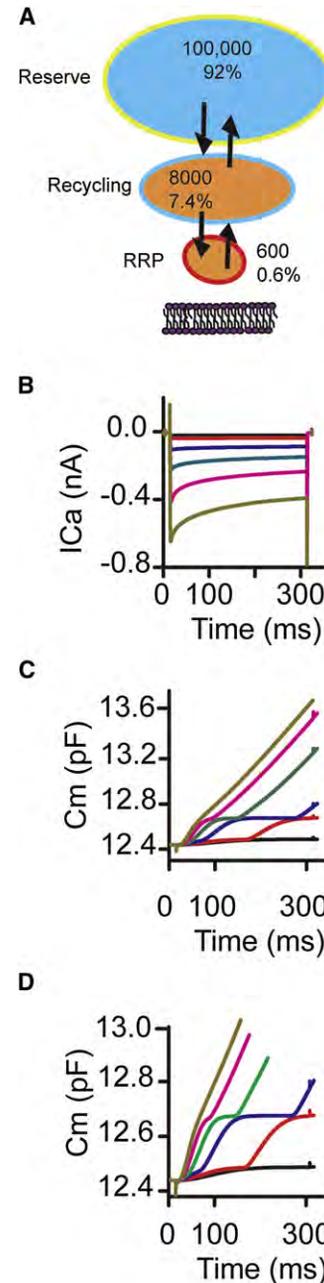

Figure 8. Mass Action Model Incorporating First-Order Ca^{2+} Dependence of Trafficking and Release Reproduces Release Data (A) A schematic representation of a model identifying vesicle pools, rate constants, and Ca^{2+} gradients. (B) A Hodgkin-Huxley model of I_{Ca} in response to increasing depolarizations from -53 in 3 mV increments. (C) Corresponding capacitance changes elicited in response to calcium currents elicited in (B). (D) An expansion of the y axis to better visualize vesicle pools.

One possible mechanism for the increased yet insensitive release rate for the superlinear component is that release sites are not maximally filled at stimulus onset, in a similar manner to the DB being only 50% occupied (Lenzi et al., 1999; Schnee

et al., 2005), but during stimulation the percentage of occupied release sites increases such that the measured release rate increases (vesicle trafficking is faster than vesicle fusion). This would explain the variability in size of depletable vesicle pool with stimulus intensity. The assumption is that the measured release rate is a reflection of the sum of filled and unfilled release sites and the machinery controlling release is operating maximally during stimulus conditions where Ca^{2+} at the release site is saturating. As more sites are filled, the measured release rate increases. When all release sites are full, the release rate will be constant, with the time to achieving this condition varying with Ca^{2+} load.

An alternative hypothesis is that additional synapses are recruited during the stimulation as the Ca^{2+} signal spreads. This seems unlikely, as synapses without Ca^{2+} channels have not been identified in mature hair cells (Frank et al., 2009; Issa and Hudspeth, 1996; Schnee et al., 2005).

Another possibility is that superlinear release does not represent synaptic vesicle fusion, but rather, endosomal fusion or fusion of vesicles at some distant site (Coggins et al., 2007; Zenisek et al., 2000). Direct tests of this possibility are lacking; however, the ability of afferent fibers to operate spontaneously at rates of more than 100 spikes/s and to sustain release in the face of stimulation at rates more than 400 spikes/s argue for the requirement of rapid vesicle replenishment (Lieberman and Brown, 1986; Taberner and Liberman, 2005). The maximal release rate reported here for mammalian inner hair cells when the superlinear component is included is about 307 vesicles/s/synapse (assuming 15 synapses and 50 aF/vesicle) (Meyer et al., 2009), probably underestimating the release required to sustain these large firing rates. Prepulse experiments further illustrate that under more physiological stimulation conditions, release is linear and sustained; neither of these properties would occur without the superlinear component summing with the first release component. Finally, previous experiments have imaged vesicle release in mammalian hair cells at rates higher than reported here for superlinear component of release and also suggested trafficking must be rapid (Griesinger et al., 2005).

Data suggest that low-frequency cells release at faster rates per synapse than high-frequency cells, though the release rate per cell was similar for both components. In turtle, largely one fiber innervates one hair cell, but with multiple synapses it may be the overall release rate that is more significant than release per synapse, in contrast to the mammalian system in which one fiber innervates one synapse. The underlying mechanisms responsible for differences in release per synapse remain to be determined. In contrast, work in mammalian systems (Johnson et al., 2008) has shown a difference in the Ca^{2+} dependence of release. In turtle there was an apparent difference in Ca^{2+} dependence associated with the ability of low-frequency cells to recruit superlinear release with less Ca^{2+} than high-frequency cells. Comparable experiments are needed to test this in mammalian hair cells.

Our data are consistent with the existence of multiple vesicle pools, with the first linear saturable release component including both the RRP and recycling vesicle pools and the superlinear release component corresponding to the reserve pool (Figure 8A). Based on release measurements, we estimated vesicle

pool sizes of 600 vesicles in the RRP (0.6%), 8000 vesicles in the recycling pool (7.4%), and 100,000 vesicles in the reserve pool (92%) (Figure 8A). These sizes are consistent with data from other synapse types (Rizzoli and Betz, 2005), the major difference being the ability of vesicles to be recruited for release from each pool. The rate and extent of Ca^{2+} entry appear to finely regulate the first two pools, while release of intracellular stored Ca^{2+} may be involved in recruitment of the reserve pool of vesicles. At other synapses recruitment of the reserve pool vesicles appears to be limited (Rizzoli and Betz, 2005).

Previous work developed a simple mass action model for vesicle release accounting for observed release properties (Schnee et al., 2005). No specific role for the DB was included and the model did not incorporate Ca^{2+} dependence of release or vesicle trafficking. Alone, this model cannot reproduce superlinear release. Modification of this simple model to include both first-order Ca^{2+} -dependent release and Ca^{2+} -dependent vesicle trafficking reproduced all of the basic release properties reported (Figures 8A–8D, see Supplemental Information for more detailed description). Simulations show both saturable linear release components and a superlinear release component of invariant rate (Figures 8B–8D). Saturating levels correspond well with anticipated pool sizes. Models that did not include Ca^{2+} dependence of vesicle trafficking could not reproduce the superlinear component of release unless higher order release functions were incorporated and even here the superlinear component did not correspond well with available vesicles (data not shown). The model varied from physiological measurements in that the separation between vesicle pools was more sharply defined, probably reflecting the artificial nature of threshold Ca^{2+} levels to recruit vesicle pools. Perhaps vesicle trafficking is uniformly Ca^{2+} dependent and the recruitment depends on the location of vesicles with respect to Ca^{2+} influx, with the Ca^{2+} gradient into the cell dictating the pool size and rate of movement more than the location or specialization of the vesicle. This possibility is consistent with data demonstrating that vesicle movements are similar between different regions of the cell (Zenisek et al., 2000), but is unusual in that it suggests vesicles are tethered in some manner, whether directly associated with the ribbon or not. It is in contrast with arguments that vesicle movement is diffusion based (Holt et al., 2004; LoGiudice and Matthews, 2009), unless diffusion can be regulated via Ca^{2+} levels, but is consistent with recent cryoelectron tomography arguing that all vesicles are tethered by the cytoskeleton (Fernández-Busnadiego et al., 2010). Perhaps the differences in release properties between ribbon synapses in the visual and auditory system, mainly being that release in hair cells is much less defatigable, have more to do with trafficking than with mechanisms of release. Hair cells are required to maintain continual and rapid release in order to maintain high spontaneous activity in the afferent fiber but this is much less of a requirement in the visual system.

Afferent fibers show a pronounced neural adaptation in which firing rates can be reduced by more than 50% during the initial phase of stimulation (Lieberman and Brown, 1986). Data presented here may provide insight into possible mechanisms by which this may happen. We suggest the initial decrease in firing represents the time when vesicles are being released faster than

replenished, so that vesicle trafficking is not maximized. That firing rates do not adapt to zero but rather to a relatively high rate indicates that trafficking (superlinear component) is rapidly accessible under physiological conditions. Similar to the response described in Figure 5, under physiological conditions the processes tend to merge but vesicle release shows a reduction in slope initially that becomes sustained. The level of neural adaptation may in part be determined by how rapidly each synapse is capable of recruiting vesicles between pools—the faster the recruitment, the less adaptation is observed. In fact, it may be argued that steady-state firing requires recruitment of vesicles such that the rate of release at any given synapse may be dictated by access to the reserve pool of vesicles. Thus it may be that spontaneous firing rates are regulated by resting calcium currents and vesicles in the RRP and recycling pool, while stimulated release is more dependent upon vesicle recruitment from the reserve pool and the ability to modulate release of stored calcium (Guth et al., 1991).

In summary, we used real-time capacitance measurements to identify saturable pools of vesicles and discovered a superlinear release component requiring recruitment of vesicles to release sites. We suggest that Ca^{2+} -dependent vesicle trafficking is responsible for this movement, which is required for hair cell synapses to maintain high rates of sustained vesicle fusion. We postulate that the superlinear release component reflects synapses operating at maximal rates of release and trafficking and that release of an as yet undefined internal pool of Ca^{2+} may be required. These characteristics of synaptic vesicle recruitment and release make hair cell ribbon synapses quite unique as compared to other synapses.

EXPERIMENTAL PROCEDURES

Tissue Preparation

The auditory papilla from red-eared sliders (*Trachemys scripta elegans*) were prepared as previously described (Schnee et al., 2005) by using methods approved by the IACUC committee at Stanford University and following standards established by NIH guidelines. Tectorial membranes were removed as previously described by using a hypertonic and hypercalcemic (10 mM Ca^{2+}) solution (Farris et al., 2006). The external recording solution contained 125 mM NaCl, 0.5 mM KCl, 2.8 mM CaCl_2 , 2.2 mM MgCl_2 , 2 mM pyruvate, 2 mM creatine, 2 mM ascorbate, 6 mM glucose, and 10 mM N-(2-hydroxyethyl) piperazine-N'-(2-ethanesulfonic acid) (HEPES) with pH adjusted to 7.6 and osmolality maintained at 275 mosm/kg. One hundred nanometers apamin was included in the external solution to block SK potassium currents (Tucker and Fettiplace, 1996). Cells were imaged with a BX51 fixed-stage upright microscope (Olympus) with bright-field optics. Conventional epifluorescence was used for the Ca^{2+} imaging.

Cochlea from rat pups (ages P7–P10) were dissected into an external solution containing 135 mM NaCl, 5.8 mM KCl, 1.3 mM CaCl_2 , 0.9 mM MgCl_2 , 0.7 mM NaH_2PO_4 , 10 mM HEPES, 5.6 mM glucose, 2 mM pyruvate, and 2 mM creatine. Both stria and spiral ganglia were peeled from the organ of Corti and the remaining epithelium was placed into a glass-bottomed recording chamber. The tectorial membrane was removed and the organ of Corti held in place with single strands of dental floss. Apamin was included at 100 nM to block small conductance calcium-activated potassium currents.

Electrophysiology

Fire-polished borosilicate patch electrodes of resistance 3–5 M Ω were used for all recordings. Unless otherwise stated, the internal solution for turtle contained 110 mM CsCl, 5 mM MgATP, 5 mM creatine phosphate, 1 mM ethylene glycol-bis (β -amino ethyl ether)-N,N,N',N'-tetraacetic acid (EGTA), 10 mM

HEPES, 2 mM ascorbate (pH 7.2). Osmolality was maintained at 255 mosm by adjusting CsCl levels; pH was 7.2. For perforated-patch recordings the internal solution contained 110 mM Cs aspartate, 15 mM CsCl, 3 mM NaATP, 3 mM MgCl_2 , 1 mM BAPTA, and 10 mM HEPES. Amphotericin dissolved in dry DMSO was used as the perforating agent. In several experiments Alexa 488 was included in the recoding pipette to verify the whole-cell mode was not obtained. For rat hair cells the internal solution contained 90 mM Cs methylsulfonate, 20 mM TEA, 1 mM EGTA, 5 mM MgATP, 5 mM creatine phosphate, 3 mM ascorbate, 3 mM MgCl_2 , and 10 mM HEPES. Stimulus protocols were applied 10 min after achieving whole-cell mode to allow equilibration of internal solution and run up of I_{Ca} (Schnee and Ricci, 2003). Hair cells were voltage clamped with a lock-in amplifier (Cairn) allowing for capacitance measurements as initially described by Neher and Marty (1982) and later used for hair cell recordings (Johnson et al., 2002; Schnee et al., 2005). A ± 40 mV sine wave at 1.5 kHz was imposed onto the membrane holding potential, blanked during depolarization that elicited I_{Ca} , and resumed so that capacitance measurements before and after stimulus were obtained. Capacitance data were amplified and filtered at 100 Hz offline. This amplifier was also used initially for validation of the two-sine wave method (see below). The multi-clamp amplifier (Axon Instruments) was also used for capacitance measurements. All data were sampled with a Daq/3000 (IOtech) driven by jClamp software (Scisoft).

Two-Sine Method

Vesicle release was determined by measuring membrane capacitance correlates of surface area change. Capacitance was measured with a dual sinusoidal, FFT-based method (Santos-Sacchi, 2004; Santos-Sacchi et al., 1998) relying on component solutions of a simple model of the patched cell (electrode resistance, R_s , in series with a parallel combination of membrane capacitance, C_m , and membrane resistance, R_m ; see Figure 1 in Santos-Sacchi, 2004). In this RC analysis method, two voltage frequencies, f_1 and f_2 (twice the f_1 frequency) are summed and the real and imaginary components of the current response are used to determine the magnitudes of the three model components. The time resolution of the C_m measurement is the period of f_1 , which we varied from 5.12 to 0.32 ms, corresponding to 195 to 3125 Hz. Comparisons between single-sine and dual-sine-wave methods showed no differences for membrane responses to 100 ms depolarizations to -20 mV. Single-sine values of 90 ± 15 fF ($n = 12$) were obtained as compared to 110 ± 24 fF for dual-sine wave measurements from the same cell population. The same two-sine wave technique (implemented in jClamp) has been used previously, but only as a before and after measurement which gave similar results to the single-sine method (Edmonds et al., 2004; Thoreson et al., 2004). Details of methods and control data are presented in Figures S1–S3. The time between stimuli was varied based on the previous stimulus but was never less than 2 min and typically varied between 5 and 10 min to ensure appropriate time for reaching equilibrium.

Calcium Imaging

Swept-field confocal high-speed (SFC) calcium imaging was performed as previously described (Beurg et al., 2009). The SFC (Prairie Technologies, Middleton WI) was coupled to a Redshirt camera. Fluo 4ff was used as the indicator, chosen to both limit effects on release properties and serve to localize the calcium source. Images were captured at 125 fps with a 35 mm slit. A 100 \times dipping lens with an added 1.25 magnification gave a final pixel size of ~ 350 nm. Ribbons were identified by using the Ctbp2 peptide tagged with rhodamine (Zenisek et al., 2003). Data was analyzed by selecting 3 \times 3 pixel regions uniformly encompassing Ctbp2-labeled regions. Image planes were selected to help isolate individual synapses to ensure individual synapses were being investigated.

Data Analysis

Data were included based on several parameters. Leak currents needed to be less than 50 pA at -85 mV and series resistance (uncompensated) needed to be stable and below 15 M Ω . As electrode capacitance compensation is critical for the accurate use of the two-sine wave methodology, bath height and electrode filling were kept low to limit stray capacitance. Unless otherwise stated, data are presented as mean \pm standard deviation with number of samples (n)

given. Where appropriate Student's *t* tests, two-tailed, were performed to assess significance; *p* values and correlation coefficients (r^2) are listed with data.

Immunofluorescence and Quantification of Synapse Number

Isolated papillae were incubated for 1 hr at 4°C in external solution containing 4% formaldehyde and 0.1% Triton X-100. After washing four times for 10 min at room temperature in external solution containing 0.1% Triton X-100, papillae were incubated for 30 min in the same solution supplemented with 5% bovine serum albumin. Specimens were then incubated with primary antisera diluted at 1:250 to 1:500 in the same solution overnight at 4°C. Antisera included those against Ctbp2 (rabbit polyclonal, #1869), Ribeye (rabbit polyclonal, #1846), and PSD-95 (mouse monoclonal, Abcam #2723, concentrated at 3.3 μg/μl with UPPA-Protein Concentrate Kit, #662120, Calbiochem). After washing five times for 10 min at room temperature, samples were incubated with FITC or TRITC-conjugated secondary antibodies (Invitrogen, Carlsbad, CA) at a dilution of 1:500. Where mentioned, FITC-conjugated phalloidin (#77415, Sigma) was added during the incubation with the secondary antibodies. After washing five times for 10 min at room temperature, specimens were mounted between two coverslips with Vectashield (H1200, Vector Laboratories, Burlingame, CA) and images were acquired with a Zeiss LSM5 Exciter confocal microscope with a 63 × 1.4 NA oil-immersion objective or with a spinning disc confocal by using 100 × 1.4 NA oil-immersion lens. Background noise and contrast enhancement were adjusted with Volocity software (Improvision). Confocal Z-stacks taken with 0.1 μm steps were analyzed by using Volocity software. Ribeye- and PSD95-positive fluorescent objects with 25%–100% intensity were identified on independent channels. Intersecting objects were subsequently selected as potential synaptic ribbons (Figure S5A) and manually confirmed by using the point tool of Volocity (Figure S5B). When two synaptic ribbons were in close proximity, objects were analyzed in the XZ-YZ planes (Figures S5C and S5D) and line intensity profiles were performed (Figure S5E) to identify individual synaptic terminals. The number of peaks, typically one, identified the number of synapses (see Movie S1 and Figure S5).

SUPPLEMENTAL INFORMATION

Supplemental Information includes six figures, Supplemental Experimental Procedures, one table, and one movie and can be found with this article online at doi:10.1016/j.neuron.2011.01.031.

ACKNOWLEDGMENTS

We thank Drs. Revathy Uthaiiah and Jim Hudspeth for providing the Ctbp2 and Ribeye antibodies. The Ctbp2 peptide tagged with rhodamine was generously provided by David Zenisek at Yale University. We thank Medha Pathak, Alan Cheng, the reviewers, and the editorial board for their help with this manuscript. This work was funded by NIDCD grant DC009913 to A.J.R. and J.S.-S. and by core grant P30 44992. M.C.-M. was supported by a Dean's Postdoctoral Fellowship from Stanford School of Medicine and a Cajamadrid Foundation Fellowship.

Supplemental Information

Calcium-Dependent Synaptic Vesicle
Trafficking Underlies Indefatigable Release
at the Hair Cell Afferent Fiber Synapse

Michael E. Schnee, Joseph Santos-Sacchi, Manuel Castellano-Muñoz, Jee-Hyun Kong, and
Anthony J. Ricci

Supplemental Figures S1 and S2 are the control experiments for the two sine wave technology. They are essential to validate the use of the technique for investigating release kinetics and in particular for demonstrating the nonlinear release component is related to vesicle fusion. These figures are essentially the controls for Figures 2, 3, 5, and 7 in the main text.

Supplemental Figure S3 uses a mathematical model, also used in Figure 8 of the text, to corroborate both the methodology used and the underlying conclusions drawn from the data.

Movie S1 (also called Supplemental Figure S4) is the movie illustrating the methodology used to quantify the immunocytochemistry. This movie is available with the article online.

Supplemental Figure S5 also validates the immunohistochemistry methodology used for identifying ribbon synapses.

Supplemental Figure S6 provides the raw data examples of release rates measured between high and low frequency cells and also the effects of different internal calcium buffers on release rates for individual cells.

Supplemental Figure S7 provides calcium imaging data for a cell that with small stimulations did not show superlinear release and with larger stimulations did.

The additional text provides detailed description of the new two sine technology as well as of the modeling used. Figure legends for the supplemental figures are also included. The table included in the text of the supplement provides values for each parameter of the model.

Supplemental Figure S1A gives the basic result from a two sine stimulation where the cell was held at -85 mV, depolarized to -35 mV and then returned to -85 while simultaneously stimulating with the sum of two sine waves. The upper panel provides the deconvolved current elicited from the stimulus while the lower panel reveals multiple kinetically distinct capacitance components. To determine which components were driven by vesicle fusion, Ca^{2+} buffers were increased and results compared. Supplemental Figure S1B demonstrates that with 1 mM EGTA three capacitive components were observed; with 1 mM BAPTA only two components were observed and when 10 mM BAPTA was used only a fast component remained (see arrows). Capacitance measurements before and after the stimulus showed no vesicle fusion with 10 mM BAPTA for this duration stimulus, suggesting the initial fast capacitance change was not release

driven. Most likely this fast component was associated with gating charge for the Ca^{2+} channel (Kilic and Lindau, 2001) or an effect of the probative sine wave on channel activation. To differentiate between possibilities, Cd was used to block the Ca^{2+} current (I_{Ca}) but not gating (Supplemental Figures S2A and S2B). With 10 mM BAPTA in the pipette Cd blocked the initial fast component, implicating activation of I_{Ca} by the sine waves. Supplemental Figure S1C and S1D reveal that as the sine wave frequency was increased the fast capacitive component was reduced, suggesting channel kinetics could not follow higher frequency stimulation. Single sine waves of ± 60 mV, applied in voltage clamp from a holding potential of -85 mV and low pass filtered show the I_{Ca} activation (Supplemental Figures S1E and S1F). Barium was used to increase I_{Ca} without altering gating and Bay K (10 μM) was used to increase the current while slowing gating (Supplemental Figures S2C–S2E). Barium increased the current with a corresponding increase in the fast component, suggesting current and not gating was causal. Bay K increased the current while slowing kinetics, resulting in a decreased fast component. Apparently, slowing the kinetics had a similar effect to increasing the sine wave frequency (Supplemental Figure S2E). And finally, a model incorporating gating currents for the Ca^{2+} channel was used to further validate the analysis program and demonstrate that current activation and not gating was responsible for the initial fast component (Supplemental Figure S3). Together these data demonstrate the fast component is neither due to release nor gating charge movement, but rather a function of current activation by the probative sine wave. Using a 0.32 ms period for the fast sine wave removed the majority of fast component leaving only Ca^{2+} dependent capacitive changes. Remaining artifacts were digitally subtracted. All measurements in main text were done under these conditions. A model was created to test the

accuracy of the JClamp analysis software, to identify the mechanism of the fast non release dependent capacitance change and to investigate mechanisms of vesicle trafficking and release. The model was further probed to demonstrate electrode capacitance altered in a linear manner the fast artifact associated with the measurements. To this end a Hodgkin-Huxley (HH) type of model was created for the I_{Ca} , much like that previously described (Farris et al., 2006; Hudspeth and Lewis, 1988; Zidanic and Fuchs, 1995). The following equations summarize how g_{Ca} was described using a third order HH model.

$$I_{Ca} = g_{Ca} (V_m - E_{Ca}) \quad (1)$$

$$I_{Ca} = g_{Ca} m^3 (V_m - E_{Ca}) \quad (2)$$

$$dm/dt = \alpha_m(1-m) - \beta m \quad (3)$$

$$\alpha_m = \alpha_0 * \exp[-(V_m + V_0)/V_A] + K_A \quad (4)$$

$$\beta_m = \beta_0 * \exp[(V_m + V_0)/V_B] + K_B \quad (5)$$

Where I_{Ca} is calcium current, g_{Ca} maximal Ca^{2+} Conductance when all channels are open, m is the activation probability of the HH model, α_m is the voltage dependent opening rate, β_m is the voltage dependent closing rate, α_0 , K_A , β_0 , and K_B are rate constants and V_0 , V_A and V_B , and V_m are potentials, E_{Ca} is reversal potential for I_{Ca} .

Calcium induced inactivation of the current was implemented simply by scaling m as a function of calcium entry as:

$$m = m - ([Ca]_i/3.5e^{-12})^{1.4} \quad (6)$$

where $[Ca]_i$ is the integral of I_{Ca} .

Release and vesicle trafficking were modeled as described previously (Schnee et al., 2005). This simple mass action model was modified to incorporate a calcium dependence of release as well as Ca^{2+} dependent thresholds for vesicle trafficking. The equations were as follows:

$$dF/dt = K_1 * A(t) \quad (7)$$

$$K_1 = k_1 * [Ca]_i \quad (8)$$

$$dA/dt = k_2 * B(t) * (A_t - A(t))/A_t - K_1 * A(t) \quad (9)$$

$$dB/dt = k_3 * C(t) * ((B_t - B(t))/B_t - k_2 * B(t) * (A_t - A(t))/A_t) \quad (10)$$

$$dC/dt = k_4 * D(t) - k_3 * C(t) * (B_t - B(t))B_t \quad (11)$$

$$dD/dt = -k_4 * D(t) \quad (12)$$

$F(t)$ is the number of vesicles fusing with the membrane and is related to time-dependent capacitance changes by converting with 50 aF/ves. $A(t) - D(t)$ are time dependent number of vesicles in each pool while A_t and B_t are maximal number of vesicles possible in rapid and readily releasable pools. Vesicle numbers were fixed based on morphological counts (Schnee et al., 2005). Calcium-dependent thresholds were set to simulate recruitment of additional pools of vesicles.

Supplemental Table S1 identifies the values used for each model parameter.

Parameter	Value	Parameter	Value
g_{Ca}	6.7 nS	A threshold	4.2×10^{-12}
E_{Ca}	100 mV	B threshold	5.3×10^{-12}
α_0	0.97	C threshold	2.3×10^{-11}
V_0	100 mV	D threshold	3×10^{-11}
V_A	6×10^{-3} mV	K_1	300
K_A	940	K_2	150
β_0	22800	K_3	15
V_B	8×10^{-3}	K_4	3
K_B	510	A_t	1920
Ca channel number	1800	B_t	3720

With this model we were able to probe the validity of our conclusions regarding the nonrelease dependent capacitance change (Figure S3) demonstrating that current activation by the sine wave and not gating charge was responsible. Also remaining artifact was due to electrode capacitance variability. We were also able to demonstrate that JClamp analysis software reproduced expected capacitance changes as defined by the model. And finally, as demonstrated in the main text, the model was capable of reproducing most aspects of measured release.

Fast component artifact that remains at high frequencies appears to be the result of how well electrode compensation was performed and how linear the patch amplifier behaved. Ensuring a linear amplifier and maximal electrode compensations further reduces artifact. Remaining artifacts were linearly subtracted from data. Variations in sine wave amplitude did not alter capacitance responses and any remaining artifact scaled predictably as driven by electrode capacitance.

Figure S1. Two Sine Wave Method for Capacitance Measurements Reveals Multiple Kinetic Components

(A) I_{Ca} , upper, and capacitance, lower panel elicited from a depolarization to -35 mV, from a holding potential of -85 mV with sine waves of 1.56 and 0.8 kHz and amplitude of ± 20 mV superimposed. The capacitance trace reveals three components, a very fast (indicated by arrows), intermediate and slow component.

(B) Ca^{2+} buffers separate capacitance components, where the black trace denotes 1 mM EGTA internally, the red trace 1mM BAPTA, and the green trace 10 mM BAPTA.

(C) Recordings with 10 mM BAPTA where sine wave frequency was varied from a period of 5.12 to 0.32 ms, upper panel is I_{Ca} , lower panel capacitive response.

(D) Summarizes the results in (C) plotting the change in capacitance against sine wave period; the color code for sine wave period is the same for C-F (n=19).

(E) Demonstrates the sine wave stimulus was activating I_{Ca} using a sine wave of ± 60 mV from a -80 mV holding potential.

(F) Low pass filtered responses are plotted in (F) to show current activation (n=8).

Figure S2. Initial Fast Capacitive Component Is Driven by I_{Ca}

(A) Top trace is stimulus, middle trace is I_{Ca} in the absence (black) and presence (red) of Cd and lower trace are capacitance changes (n=5). 10 mM BAPTA was in the pipette to inhibit release.

(B) Plots I_{Ca} (red) and capacitance (black) in the absence (filled) and presence (open) of Cd (1 mM).

(C and D) Upper panel is stimulus, middle I_{Ca} and lower capacitance response in the absence (black) and presence (red) of Bay K (10 μ M) (C) or 5 mM Ca (red) or 5 mM Ba (blue).

(E) Summarizes data from C and D using different probative sine wave frequencies.

Figure S3. Theoretical Reconstruction of Capacitance Components Demonstrates that Fast Initial Component Is Due to Inductive I_{Ca}

(A–D) Left is capacitance and right is I_{Ca} elicited at different voltage steps, top trace represents time course of stimulus. (A) includes I_{Ca} , gating currents and release components, (B) includes I_{Ca} and gating, (C) only current and (D) only gating. Note the scale bar changes.

(E) Represents the sensitivity of the Ca^{2+} current to the sine wave frequency, similar to the data presented in Figure 2. Here a sine wave of increasing frequency is superimposed onto a voltage step to -30 mV. As the frequency increased the Ca^{2+} current decreased. Only low frequency stimulus is shown at top.

Figure S4 (also called Movie S1). Movie of Z-Stack (0.1 μm Sections) Showing psd95 (Green) and Ribeye (Red) Antibody Labeling

Individual synapses are marked for counting. This movie is available with the article online.

Figure S5. Confocal Z-Stacks Taken with 0.1 μm Steps Were Analyzed Using Volocity Software

Ribeye- (red) and PSD95- (green) positive fluorescent objects with 25-100% intensity were identified on independent channels. Intersecting objects were subsequently selected as potential synaptic ribbons (A) and manually confirmed using the *point tool* of Volocity (B). When two synaptic ribbons were in close proximity, objects were analyzed in the XZ-YZ planes (C and D) and line intensity profiles were performed (E) to ascertain the occurrence of individual synaptic terminals.

Figure S6. Release Rates per Synapse Vary between Cells of Different Characteristic Frequencies and Dependent on internal Ca^{2+} Buffering

(A) Plots release rate per synapse, either as capacitance (left axis) or as vesicles (right axis) against Ca^{2+} load per synapse per second. Data were obtained by depolarizing to elicit varying size Ca^{2+} currents, each cell is connected by lines with points reflecting different depolarizing levels.

(B) Plots release rate against Ca^{2+} load for high frequency cells using either 1 mM EGTA (open black circles) or 1 mM BAPTA (filled green squares) against Ca^{2+} load.

Figure S7. High Speed Confocal Ca^{2+} Imaging of Synaptic Zones Reveals Both Linear and Superlinear Changes in Ca^{2+}

(A) Ctbp2 labeling of DB with schematic on right indicating regions that were imaged. Two stimuli were used, one eliciting about 15% (E) of the peak Ca^{2+} current, the other 65% (B) of maximal current. Capacitance responses are given in (C,F) for the different Ca^{2+} loads, (F) eliciting only the first component while (C) eliciting both components. (G) Ca^{2+} imaging experiments reveal a signal that integrates Ca^{2+} with a faster larger response at the synapse, decreasing with distance away from the synaptic zone. (D) finds nonlinear increases in Ca^{2+} signal with rise times and peaks invariant with distance from the synapse but for the furthest distance.

Recent experiments describe a technique for tracking membrane capacitance during depolarizations where membrane conductance is varying. This is a major advance over traditional technologies that can only monitor capacitance when conductance is constant because it gives direct information regarding release kinetics from single stimulations. Presented here are additional data supporting the use of this technology with multiple conductances being active including BK-Ca-activated potassium channels, SK Ca-activated potassium conductances and also the rapidly activating sodium conductance. It goes further to illustrate the ability to monitor rapid capacitive changes. And finally, it points out the need to evaluate single step responses because of the use-dependent movement of vesicles.

Ribbon type synapses are commonly found in peripheral sensory cells such as auditory hair cells and photoreceptors, where vesicle fusion is in response to a graded receptor potential.¹ These synapses typically show little fatigue and multiple components of release.² Paired and post synaptic measurements suggest a linear input output function for these synapses, particularly at auditory hair cell afferent fiber synapses.²⁻⁴ Recent evidence suggests that the linearity in release properties arises from the sum of nonlinear processes, the linearity appearing as the processes merge temporally about the hair cell's resting potential.⁵ In that study, two components of release were identified. The first component varied directly in release rate and

magnitude with calcium influx and was saturable with a vesicle population corresponding to those near the synapse. The second 'superlinear' component had a constant rate, was indefatigable and required recruitment of vesicles from more distant pools. These new processes were revealed by the use of a dual sine technique which allows for the continuous monitoring of capacitance changes, even in the face of conductance changes.^{5,6}

Traditionally, a single sine technique has been used to monitor capacitance.⁷ In this case the imaginary component of the complex current correlates to capacitance, as long as there is no conductance change of either membrane or electrode, otherwise the imaginary component reflects both capacitance and conductance in an inseparable manner.⁷ The two sine method allows for the continual tracking of conductance and capacitance and thus the potential ability to separate each.⁶ The added complexity of monitoring capacitance during conductance change is that the sine wave may activate ion channels, with an attendant intrusive inductance that interferes with measures of capacitive current phase, leading to unacceptable errors in capacitance measures.⁵ Sufficiently higher frequency sine wave stimuli can alleviate this problem because channel kinetics will not be able to respond to the rapid cycle by cycle voltage change. **Figure 1** illustrates that the dual sine wave approach can be used to track capacitance in the presence of BK-calcium activated potassium channels, SK-calcium activated potassium channels, as well as rapidly activating and inactivating sodium channels.

Key words: ribbon synapses, hair cells, vesicle trafficking, capacitance measurements

Addendum to: Schnee ME, Santos-Sacchi J, Castellano-Muñoz M, Kong JH, Ricci AJ. Calcium-dependent synaptic vesicle trafficking underlies indefatigable release at the hair cell afferent fiber synapse. *Neuron* 2011; 70:326-38; PMID:21521617; DOI:10.1016/j.neuron.2011.01.031.

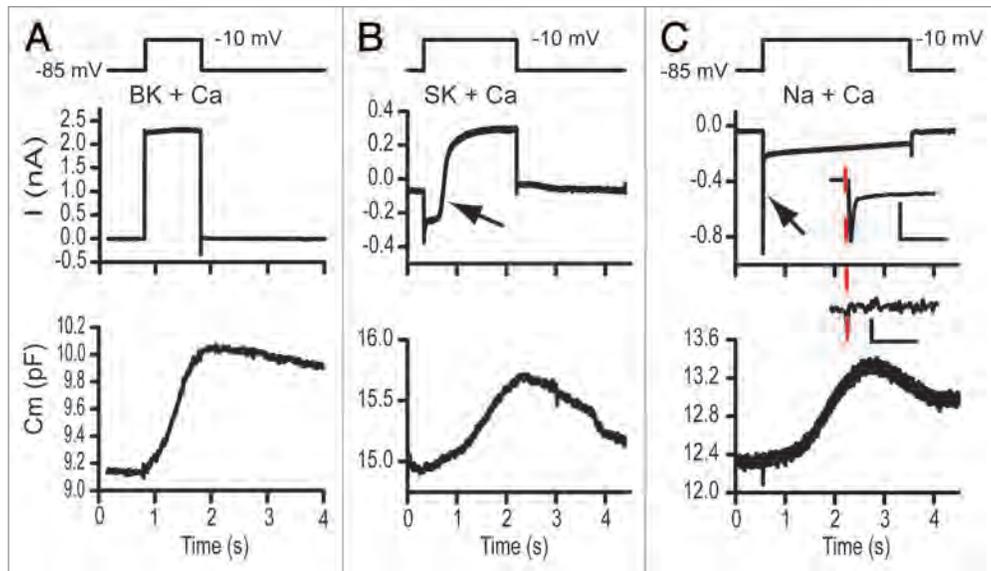

Figure 1. The dual sine wave technology allows for monitoring capacitance concomitantly with the occurrence of voltage or calcium-dependent currents. In each frame the upper panel depicts the stimulus, the middle panel the extracted currents and the lower panels the capacitance measurements. The sine waves are not shown on the stimulus but had frequencies of 6.3 and 9.4 kHz. Stimulus artifacts were digitally removed and data filtered with a Fourier filter to remove high frequency components. Both (A and B) were recordings from turtle hair cells while (C) was from an immature rat hair cell. (A) illustrates capacitance changes measured with a potassium based intracellular solution where the BK calcium activated potassium current activates rapidly in response to a depolarization to -10 mV. (B) Similar records with a cesium based intracellular solution without the presence of apamin externally. The large calcium current activated the SK calcium activated current, indicated by the arrow. SK activation had no effect on capacitance measurements (depolarization to -10 mV). (C) presents capacitance measurements from a postnatal day 8 rat inner hair cell that transiently expressed Na currents. This rapidly activating, rapidly inactivating current, indicated by arrow, also had little effect on the measured capacitance response. The inset expands in time each response with the scale bars reflecting 10 ms and 100 fF and 0.5 nA. The dashed line indicates onset time so that stimulus artifact can be separated from Na current. (A and B) were post filtered, while (C) was not in order to not lose fast components.

In each case rapidly activating L-type calcium channels ($\alpha 1D$) are driving vesicle fusion. The conductance changes do not alter the capacitance measurements.

The high frequency sine wave approach samples capacitance at higher rates than the traditional single sine method. These higher sampling rates allow monitoring of vesicle fusion kinetics at least at the macroscopic level. **Figure 2** depicts release from an auditory hair cell showing a small rapid saturable pool of release, (indicated by the arrow in A) and a larger less saturable pool of recruitable vesicles. Time expansion of (A) reveals the rapid release rise time; release begins immediately at the stimulus onset and continues until saturation. The solid red line is an exponential fit to this small first component of release.

Data using the two sine technology reveals a dynamic equilibrium between vesicles and calcium such that pool sizes are continually in flux between release and recruitment. This dynamic situation makes experiments requiring repetitive stimulation suspect because the baseline

vesicle distribution varies with each stimulation; thus, protocols requiring multiple stimulations may not produce the same response as an individual stimulus. Clearly, this is a major limitation of the single sine technique that provides only single time points for each stimulation, and requires substantial stimulus-response averaging both between and within cells to obtain a time course of release. **Figure 3** provides an example of this problem uncovered with the dual sine technique. A second repetition of the same stimulation results in faster release with an earlier onset to the second release component. Thus, the apparent calcium-dependence of release varies with each voltage pulse, most likely due to reshuffling of vesicle populations (or some biochemical change to the vesicles that makes them more easily released) as dictated by calcium homeostasis.

Data obtained with the dual sine technique provide new insight into how ribbon synapses function. These data also challenge the usefulness of single sine

techniques for understanding the effects of repetitive stimuli. Finally, the ability to measure capacitance in the face of evoked conductances likely will make the dual sine approach useful for the analysis of a variety of model systems.

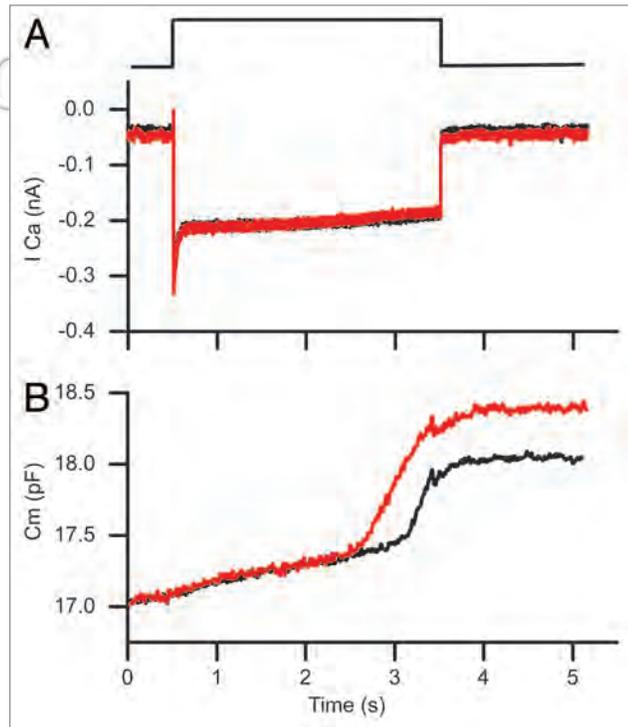

Figure 3. The dual sine technique demonstrates a major flaw with techniques that require repetitive stimulation in that responses are altered by previous stimulations. The black trace was obtained 10 min after breakthrough and is a response to a depolarization to 75% of the peak calcium current. The red trace was obtained 5 min later and shows an increased release with insignificant change in the calcium current. This likely reflects a redistribution of vesicles following the first stimulation. The red trace was offset in the y-axis in order to clearly overlay traces.

Intracellular calcium affects prestin's voltage operating point indirectly via turgor-induced membrane tension

Intracellular Calcium Affects Prestin's Voltage Operating Point Indirectly via Turgor-Induced Membrane Tension

Abstract. Recent identification of a calmodulin binding site within prestin's C-terminus indicates that calcium can significantly alter prestin's operating voltage range as gauged by the Boltzmann parameter V_h (Keller et al., J. Neuroscience, 2014). We reasoned that those experiments may have identified the molecular substrate for the protein's tension sensitivity. In an effort to understand how this may happen, we evaluated the effects of turgor pressure on such shifts produced by calcium. We find that the shifts are induced by calcium's ability to reduce turgor pressure during whole cell voltage clamp recording. Clamping turgor pressure to 1kPa, the cell's normal intracellular pressure, completely counters the calcium effect. Furthermore, following unrestrained shifts, collapsing the cells abolishes induced shifts. We conclude that calcium does not work by direct action on prestin's conformational state. The possibility remains that calcium interaction with prestin alters water movements within the cell, possibly via its anion transport function.

INTRODUCTION

Prestin is the protein responsible for OHC electromotility, and forms the molecular basis of mammalian cochlear amplification [4, 13, 23, 26]. The protein is sensitive to a variety of biophysical forces which are capable of shifting its voltage operating range (quantified by the Boltzmann fit parameter, V_h) of the protein. These include initial holding potential [21], intracellular anions [15, 18, 25], temperature [14, 20], and membrane tension [7, 10, 11]. The structural components of prestin responsible for these sensitivities are not known. Recently, Keller et al [12] have shown that structurally disordered elements in the C-terminus of prestin can serve as calmodulin binding sites, and that intracellular calcium can dramatically shift V_h of prestin in the hyperpolarizing direction during wash-in of calcium-containing patch pipette solutions following establishment of whole cell recording. Treatments with trifluoperazine (TFP), a calmodulin inhibitor, or mutations of residues within the calmodulin binding site (R571D, R572D, K573D, R576D, K577D and K580D) abolished the calcium effect. In our hands, those same mutations were shown to shift V_h in the positive direction [2], in line with manipulations that increase membrane tension. Additionally, we had previously shown that negative V_h shifts in NLC occur during wash-in due to reduction of turgor pressure (reduced membrane tension). We wondered if Keller et al. [12] had identified the mechanism of action for membrane tension effects on prestin. To determine if calcium plays this pivotal role we evaluated the effect of turgor pressure using their experimental approach.

METHODS

Isolated OHCs from guinea pigs were whole cell voltage clamped using methodology previously described in detail [22,24]. Briefly, gigohm seals were formed and then ruptured to allow pipette solution wash-in. Wash-in typically takes about 3 minutes [16]. NLC was determined using admittance analysis, with 2 voltage sinusoids at harmonic frequencies superimposed on ramps ranging from -150 to + 100 mV. Detrending of raw currents preceded FFT analysis. Capacitance data were fit to the first derivative of a two-state Boltzmann function [19],

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin} \quad b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right) \quad (1)$$

where Q_{\max} is the maximum nonlinear charge moved, V_h is voltage at peak capacitance or equivalently, at half maximum charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. In addition to determining V_h via voltage ramps

every 30 seconds, V_h was tracked in real time by monitoring the voltage at gating current reversal using the +/-P technique [1], a procedure we previously described in detail [11]. The V_h values determined by either protocol were not statistically different ($p > .05$). Video images were captured during recording to gauge cell swelling.

Solutions were the same as Keller et al. [12]. Intracellular (in mM): 150 CsCl, 2 MgCl₂, 0.1 CaCl₂ (or 10 EGTA), and 10 (or 20) HEPES; extracellular (in mM): 150 NaCl, 2 MgCl₂, 2 CoCl₂, and 10 HEPES. All solutions were adjusted to pH 7.4, and osmolarity to 340 mmol/kg with glucose. Intracellular pressure (i.e., pipette pressure) was either 0 kPa, as per Keller et al. [12], or clamped to 1 kPa. This latter pressure corresponds to normal OHC turgor pressure [17]. TFP (50 μ M), a calmodulin antagonist, was locally perfused in bath solution. Two sided t-tests were used to assess significance.

RESULTS

Figure 1A shows the time course of V_h change following rupture of the OHC patch membrane following seal formation. Initial values of V_h immediately after establishment of whole cell conditions (measured with ramp protocol; *open and filled circles*) quickly shifted to more negative values (about -60 mV, indicated at the onset of successful V_h tracking, *line plot*) regardless of the presence of Ca²⁺. Thereafter, V_h for the Ca²⁺-containing condition shifted over the course of minutes to more negative potentials, whereas in the absence of calcium, a continued depolarizing shift was observed. V_h measures from ramp protocols and tracking paradigm were equivalent (Fig. 1B, C). These changes in V_h are in line with Keller et al. [12].

Figure 2 shows averaged data similarly collected ($n=4-6$ cells), with ΓV_h relative to time after patch rupture shown for comparison. These data confirm that V_h shifts in opposite directions over time depending upon the solution used. Interestingly, we find that in the group lacking Ca²⁺, cells tended to swell during recording. This was not observed in cells recorded with Ca²⁺. Thus, in order to test for turgor pressure effects we measured another calcium group of cells in the presence of a constant 1 kPa pipette pressure. The presence of increased turgor pressure completely countered the calcium effect, showing no statistically significant difference between the V_h values obtained with and without Ca²⁺ (Fig. 2, *down triangles vs. open circles*; p 's > 0.05). Additionally, following V_h tracking for several minutes we collapsed all cells and measured the resulting V_h . No significant differences for all conditions were found compared to the initial V_h values at patch rupture time (Fig. 2, symbols above by *collapsed* label). We conclude that in our experiments turgor pressure changes governed the V_h shifts.

Our results with local perfusion of TFP as per Keller et al. [12] are variable (Fig. 3). In the 2005 MOH meeting proceedings, we published that local perfusion itself can cause rapid (within seconds) shifts in OHC V_h , presumably due to membrane tension effects. Recently, we have further investigated this phenomenon and determined that perfusion-induced shifts are absent following collapse of the OHC. This may impact on our variable results with TFP perfusion, since when cells are deflated TFP has little effect, whereas when cells are inflated there is a depolarizing shift in V_h , which is rapidly reversed upon flow cessation. In addition, we find that even perfusion of normal bath solution will cause a depolarizing shift for the intracellular Ca²⁺ solution condition. Previous studies used prolonged treatments with calmodulin inhibitors such as TFP (>30 min) prior to evaluating effects on cell shape or V_h [5, 6]. In our hands, then, the ability of TFP to work within seconds as a calmodulin inhibitor during acute perfusion is unresolved.

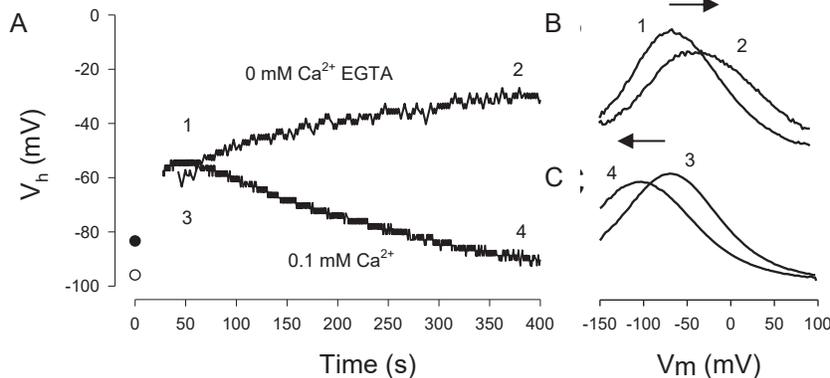

FIGURE 1. NLC V_h tracked in real time during wash-in of indicated solution. (A) Since V_h -tracking takes time to initially find V_h , we also measured NLC with ramps. Symbols indicate V_h immediately after patch rupture (*filled circle*: 0.1 mM Ca²⁺; *open circle*: no Ca²⁺). Numbers 1- 4 also indicate ramp-measured V_h at select times. C_m - V_m functions from those measures are plotted in (B) and (C) (no averaging).

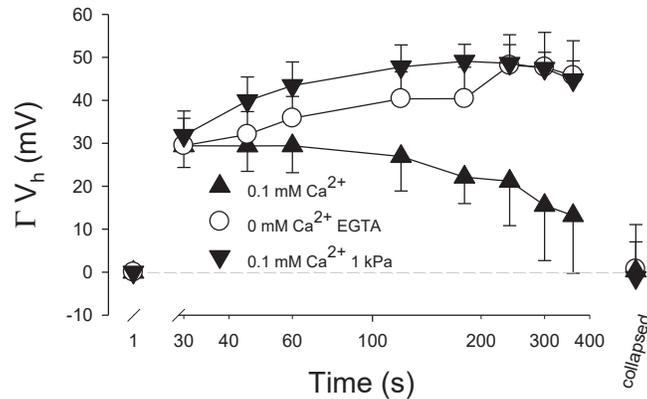

FIGURE 2. Averaged measures of V_h shift. Calcium-induced negative shifts in V_h are absent in the presence of positive intracellular turgor pressure. After recording for several minutes, cells were collapsed with negative pipette pressure, and V_h values for all conditions returned to levels observed at patch rupture.

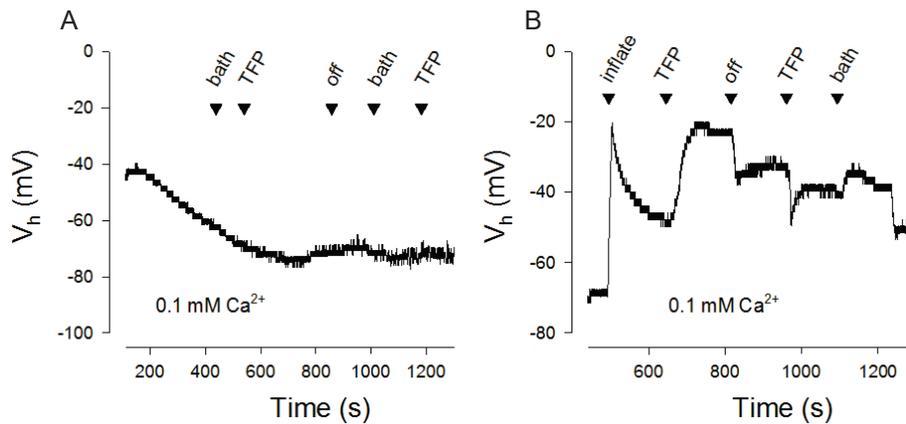

FIGURE 3. Effects of TFP perfusion on V_h shift. Calcium-induced negative shifts were obtained in OHCs and the effects of TFP perfusion and bath perfusion assessed. (A) Deflated cells show no response to perfusions. (B) In another cell, after inflation via positive pipette pressure positive shifts were observed.

DISCUSSION

Here we show that shifts of OHC V_h induced by intracellular solutions in the presence or absence of Ca^{2+} result from alterations in membrane tension caused by changes in turgor pressure. In the absence of Ca^{2+} , cells tend to swell, but in its presence cells do not swell. The OHC is highly sensitive to osmotic influences [3], likely influenced by membrane bound ion transport mechanisms. The shape is normally maintained by a cortical cytoskeleton [8], but cells may swell or collapse during whole cell recording, altering V_h due to prestin's membrane tension sensitivity [11]. Because of this we and others typically evaluate direct effects on prestin by collapsing OHCs to remove these effects.

The action of Ca^{2+} on OHC shape and NLC have been previously evaluated. Dulon et al. [5] used the Ca^{2+} ionophores ionomycin and A23187 to show that increases in intracellular Ca^{2+} induce cell volume decreases by up to 5%. This is in line with our observations. The calmodulin inhibitor TFP was able to block this effect, without altering the induced changes in intracellular Ca^{2+} . Frolenkov et al [6] also used ionophores or ACh to increase intracellular Ca^{2+} ; however, whereas turgor reductions similar to those observed by Dulon et al. [5] were observed, simultaneous measures of NLC showed virtually no changes in V_h . This may not be unusual, since depending on initial V_h , turgor pressure reductions can have a limited effect on V_h shift [11]. Both studies concluded that calcium

can work on cytoskeletal elements via a calmodulin dependent pathway. Interestingly, Frolenkov et al. [6] did determine that agents which alter phosphorylation state can shift V_h in the absence of turgor pressure changes.

How can our results be reconciled with the Ca^{2+} /calmodulin hypothesis of Keller et al. [12]? First, species differences may exist. For example, salicylate sensitivity of mouse prestin is nearly an order of magnitude greater in mouse than guinea pig [9, 22]. Second, Ca^{2+} may be working on cellular mechanisms that influence the generation of water movements, thus turgor changes, in cells. Perhaps even prestin's anion transport function is directly calmodulin dependent, controlling ion fluxes that influence membrane stress that is fed back to prestin's tension sensor. In this scenario, calmodulin inhibitors or mutations of prestin that abrogate calmodulin binding [2, 12] may disrupt the cell's ability to maintain turgor pressure, and thus provide self-control to motor function.

COMMENTS AND DISCUSSION

Paul Teal: The argument is mostly convincing.

In the discussion, Frolenkov et al. are cited as finding that increased Ca^{2+} caused turgor reductions similar to those observed by Dulon et al, but simultaneous measures of NLC showed virtually no changes in V_h . Even though there is discussion on possible reconciliation with Keller et al., there is none on reconciliation with this result which seems to be just as significant. Or have I misunderstood? Some clarification might help here.

No doubt displaying my ignorance here but when the pipette pressure in one of the experiments (as per Keller et al) is 0 kPa, how is the solution actually introduced?

Joseph Santos-Sacchi [reply to Paul Teal]: Thanks, Paul.

Positive turgor pressure introduced by pipette pressure changes V_h in the depolarizing direction and shifts will continue until the cell bursts – membranes can only withstand about 5-7% stretch. The effect of negative pressure depends on the initial turgor level. When a cell still appears cylindrical at low pressure, because the cortical cytoskeleton maintains a cylindrical state, it may be possible to reduce pressure and cause cell collapse. We previously showed that there is a limiting hyperpolarizing shift when the cell approaches collapse. Thus, during recording, a negative pressure could produce small to no changes in V_h . I assume that the membrane at that point is lax. Our simple observation in our new MOH paper is that the solutions used with 0 Ca cause increased turgor pressure (thus membrane tension) and positive shifts, which dissipate when the cell is collapsed with all solutions tested.

Pipette pressure, which could cause bulk flow of pipette fluid into the cell, is not necessary to exchange ionic solutes. Indeed, with perforated patch recording (depending on ionophore species used), ionic replacement of cell constituents with that of the pipette is possible. Clearly, pipette pressure cannot be changed during that process else the perforated patch would burst, putting the cell into standard whole cell voltage clamp mode.

Thanks, again.

Andrew Bell: Hello Lei and Joseph:

You have shown that OHCs are very sensitive to changes in osmotic pressure, a result supported by Chertoff & Brownell (your ref. 2). This seems to imply that OHCs are also capable of responding to changes in hydraulic pressure of the cochlear fluids. By extension, this raises the possibility that small changes in intracochlear pressure – due to sound pressure – could also alter the electrical potential of the cell. The implication is that OHCs might react directly to a sound stimulus (Bell 2003) and bending of the stereocilia is not the only possible effective stimulus. Do you consider such a complementary mechanism possible?

Bell, A. (2003). Are outer hair cells pressure sensors? Basis of a SAW model of the cochlear amplifier. In *Biophysics of the Cochlea from Molecules to Models* (ed. A.W. Gummer), pp.429-431.

Joseph Santos-Sacchi [reply to Andrew Bell]: Hi Andrew, thanks. Yes, I agree and we have published on this in abstract and manuscript form (Rybalchenko and Santos-Sacchi 2003 *JPhysiol*). Subsequent papers from our lab also refer to this possibility. The susceptibility to in vivo tensions stems not only from the tension sensitivity of the motor, but also to the tension sensitivity of GmelL, a lateral membrane conductance that permits chloride flux. — Joe

A Walkthrough of Nonlinear Capacitance Measurement of Outer Hair Cells

Lei Song and Joseph Santos-Sacchi

Abstract

Nonlinear capacitance (NLC) measures are often used as surrogate measures of outer hair cell (OHC) electromotility (eM), since the two are commonly thought to share many biophysical features. The measurement of NLC is simpler than direct measurements of eM and, therefore, many investigators have adopted it. A standard patch-clamp hardware configuration is sufficient for recording NLC, given the proper software interface. Thus, the approach is cost effective. We use the software jClamp since it is tailored to capacitance measurement. Here we detail steps that we use to measure NLC. The walk through includes isolation of guinea pig OHCs, building voltage commands, recording, and analysis.

Key words Nonlinear capacitance, Outer hair cells, Electromotility, Prestin, Cochlea, Inner ear

1 Introduction

The OHC lateral membrane protein prestin [1] powers electromotility [2–5], key to mammalian cochlear amplification [6]. Direct measurement of OHC motility requires a number of additional techniques (such as microchamber [7–9] or equipment (such as fast camera [10] or photodiode [7, 8, 11] which are not standard additions to the usual patch clamp [12] setup. For the investigation of prestin function in nonnative cells [13–15], although electromotility measurement is possible, a micro chamber is required to deform the cell [1] and the magnitude of motility is an order of magnitude smaller than that of the native OHC [1, 13–15]. NLC, a surrogate measure of motility, is the electrical signature of prestin activity. NLC can substitute for measures of motility, and can be carried out on a typical patch-clamp setup without additional equipment. The advantage of NLC is more evident in the assessment of prestin function in transfected cell lines which often express much less prestin, but requires relatively fast measures to acquire large number of cells for statistics [13, 14, 16].

Conventional methods for measuring cell capacitance use step-induced transient analysis (charge integration) or the use of a lock-in amplifier to interrogate phase responses to sine wave stimuli [17–19]. Using a phase detector, the phase tracking method follows the current changes attributed to capacitance changes. Limitations include having low and stable membrane conductance, and these measures are subject to influence of fast (stray) capacitance between pipette and bath solution [18, 20]. We use two-sine method where the additional set of recorded parameters from the second sine is used to solve capacitance which is more resistive to fast conductance change. Data analysis can alternatively be performed on one of the recorded sine wave currents if desired so it offers flexibility in data analysis.

Here we introduce the measurement of NLC of OHCs, a procedure that circumvents the mechanical measurement of OHCs. An example of using two types of stimuli (dual-sine and transient step perturbations atop a voltage ramp) on the same OHC is shown (Fig. 1) where a stair-step stimulus we previously used to detect OHC capacitance [9] and a two-sine stimulus are each applied to

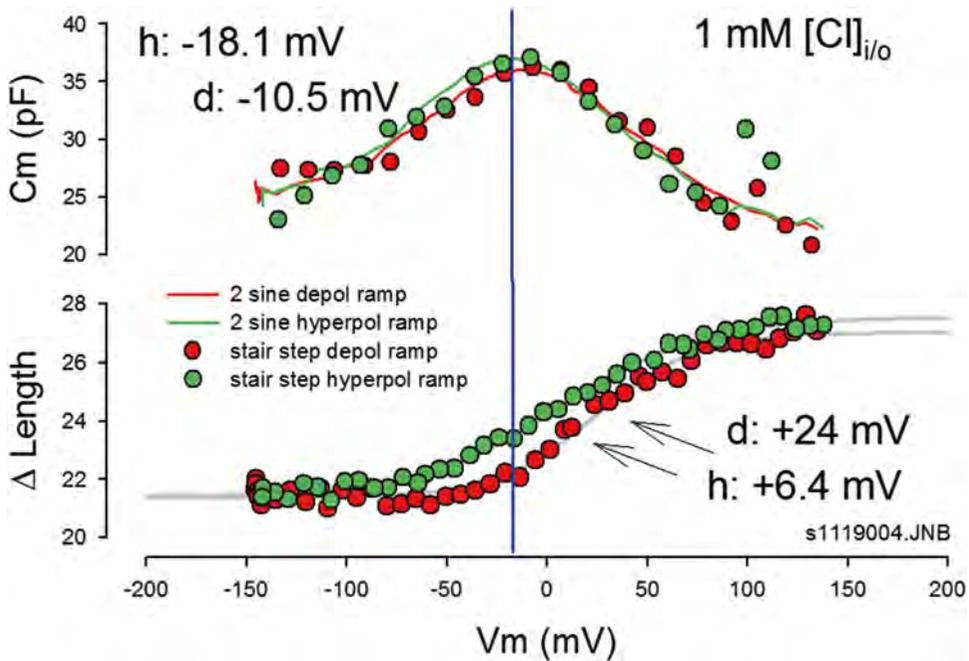

Fig. 1 Example traces of NLC collected from same OHC by using a stair step stimulus (*upper panel, circle*) and 2-sine (*upper panel, solid lines*). Stimulus of either depolarization or hyperpolarization ramp are color coded. In general the two stimulus methods generate NLC curves that are overlapping, except the curves that were generated by using 2-sine are less “noisier” than those acquired by step stimulus. *Bottom panel* shows simultaneous measurement of motility. *Blue line* is the voltage at peak capacitance for a hyperpolarized ramp. A depolarized shift of V_h in motility measurement is marked for each depolarized and hyperpolarized stimulus

the same whole-cell patched OHC. Two-sine analysis is less noisy than that acquired by stair-step stimuli (upper panel, Fig. 1), although mechanical measurement obtained by each ramp stimulus almost overlap (lower panel, Fig. 1). We focus on measuring NLC in OHCs by using the two-sine method. We routinely use the software jClamp (jClamp, www.scisoft.com) in our daily data collection so our introduction is unavoidably based on the operation of that software. However, the basic steps can be replicated by a skilled physiologist/programmer by referring to original publications [21, 22].

We introduce the basic steps for acquiring NLC so a trained electrophysiologist who is familiar with patch clamping can start the measurement with minimal modifications such as the addition of software. Major procedures include isolating OHCs, preparation of the experiment solutions, building stimulus command, and recordings. Some notes are provided to offer tips to acquire high quality data.

2 Materials

2.1 Patch-Clamp Hardware and Software

1. PC running on windows (XP, Vista, Win 7, and Win 8).
2. Pipette puller (Sutter P-2000 or similar) and soft glass thin wall pipette (WPI, Sarasota, FL).
3. Amplifier (Axon 200 series or 700 series) and headstage.
4. D/A converter: Axon 13xx, 14xx series (Molecular Devices, Sunnyvale, CA), National Instrument Austin, TX) or IO Tech (Measurement Computing Corp, Norton, MA).
5. A Windows compatible camera is optional for measuring NLC and electromotility simultaneously, but is also helpful in monitoring OHC conditions.
6. Software: jClamp (*see Note 1*).

2.2 Solutions

All solutions are made in deionized water.

1. Ionic blocking extracellular solutions (mM): Mix 92 NaCl, 20 TEACl, 20 CsCl, 1 CaCl₂, 2 CoCl₂, 1 MgCl₂, 10 HEPES, in 950 mL of H₂O. Use 1–2 M NaOH to adjust pH 7.2–7.4, then top off to 1 L. Use D-Glucose to increase osmolality of solution to ~300 mOsm (*see Note 2*). Store at 4 °C.
2. Intracellular pipette solution (mM): 136 CsCl, 2 MgCl₂, 10 HEPES, 10 EGTA, start from a smaller volume such as 180 mL. Use 1–2 M CsOH to adjust pH 7.2–7.4 as in Subheading 2.2, **step 1**. Then top off to 200 mL (you can make smaller volume based on your consumption of pipette solution). Use D-glucose to adjust osmolality to ~300 mOsm.

Be sure to keep intracellular and extracellular solution to within 2 mOsm. When making “physiological” intracellular chloride concentration, gluconate is used as an anion substitute for chloride (*see Note 3*). Store at 4 °C.

3. Filter all solutions with a 0.22 µm filter after the solution is made.
4. (Dispase I, 10 U/mL, Roche).

2.3 Equipment

1. pH meter (e.g., Corning pH meter 430 or similar).
2. Dissecting tools: Scissor (assorted sizes), hemostat, Malleus Bone Nipper, No. 3, No. 5 and fine forceps.

3 Methods

3.1 Isolating Guinea Pig Outer Hair Cells

All animal protocols should be approved by the institutional animal care and use committee according to NIH guidelines.

1. Euthanize animals with isoflurane overdose.
2. Dissect and isolate temporal bones and place in a petri dish filled with 1x PBS.
3. Refrigerate unused second cochlea at 0–4 °C for later use (up to 4 h).
4. Open bulla with a Malleus Bone Nipper, to expose cochlea and remove ossicles with No. 3 forceps.
5. Press and crack the apical part of the cochlea using blunted or No. 3 forceps. Lift the cracked bone to create an opening.
6. Carefully tuck between the bone and spiral ligament and press toward the bone (outward) using the blunted forceps tip or No. 3 forceps. Cracked bone chips will then be lifted away. Start from the opening and work down toward the base to expose the whole Organ of Corti.
7. Carefully strip off Organ of Corti (*see Note 4*).
8. Place stripped Organ of Corti in either extracellular solution or PBS with Dispase (5 U/mL).
9. Incubate for 10–12 min at room temperature, then transfer the organ of Corti strip to the recording chamber with a few drops of extracellular solution.
10. Gently triturate the Organ of Corti strip using a flame thinned pipette tip (200-µL pipette tip) mounted on a 1 cc syringe (*see Note 5*).
11. Leave the suspension solution in the recording chamber for about 15–20 min for cells to sink and stick to the glass bottom.
12. Fill the dish with extracellular solution and start recording (*see Note 6*).

3.2 Preparing for Whole-Cell Patch Clamping of Outer Hair Cells

1. Prepare a recording pipette with a resistance of 4–6 M Ω . We typically use thin-walled electrodes (TW150-4 from WPI, Sarasota, FL) (*see Note 7*).
2. Use standard whole-cell patch-clamp technique to form a G Ω seal and then rupture membrane to form a whole-cell configuration. OHC membrane tension (evidenced by changes in cell turgor) should be monitored during pipette washout. This is a crucial step to avoid artifacts since NLC is sensitive to turgor pressure-induced membrane tension [23–27] (*see Note 8*).

3.3 Recording Nonlinear Capacitance

1. Prior to building a command file, make sure the system calibration file is correct (*see Note 9*). Always use an electrical cell model to verify that the measurement system is working properly.
2. Build command file in jClamp within the command building utility. We routinely apply two-sine stimulus [21, 22] superimposed onto a voltage ramp. For construction of command, see help file in jClamp (*see Note 10*).
3. Save command file in the quick access RPD (Rapid Parameter Directory) window to allow quick activation of commands during online recording. Once activated, a command window will pop up and stimulus parameters can be modified online.
4. Use “init” button in the command utility window (or the RPD buttons) to start recording (*see Note 11*). Changes of the command are not saved automatically unless the save button is clicked. Nevertheless, each data file possesses the command protocol for reconstruction.
5. Select Cm vs. Vm in Results window. The data will be displayed as NLC curves online following each data collection. Each stimulus condition can be repeated until stabilization of NLC is reached, usually when intracellular pipette solution exchange is accomplished.

3.4 Data Analysis

1. Open Analysis window then select data file by using open folder icon to load raw data.
2. Select part(ition) 3 by clicking “Sel” for the two-sine ramp collection we typically use (Fig. 2). Only part 3 of the command (ramp) is selected and displayed.
3. Select Y axis: Cm in the drop down window and X axis: Voltage to plot NLC curve.
4. Check “Rs” for series resistance correction.
5. Check “DtR” for detrending of data prior to FFTing (optional, *see Note 12*).
6. Fit NLC curve by select fitting icon and move cursor by left clicking and holding.

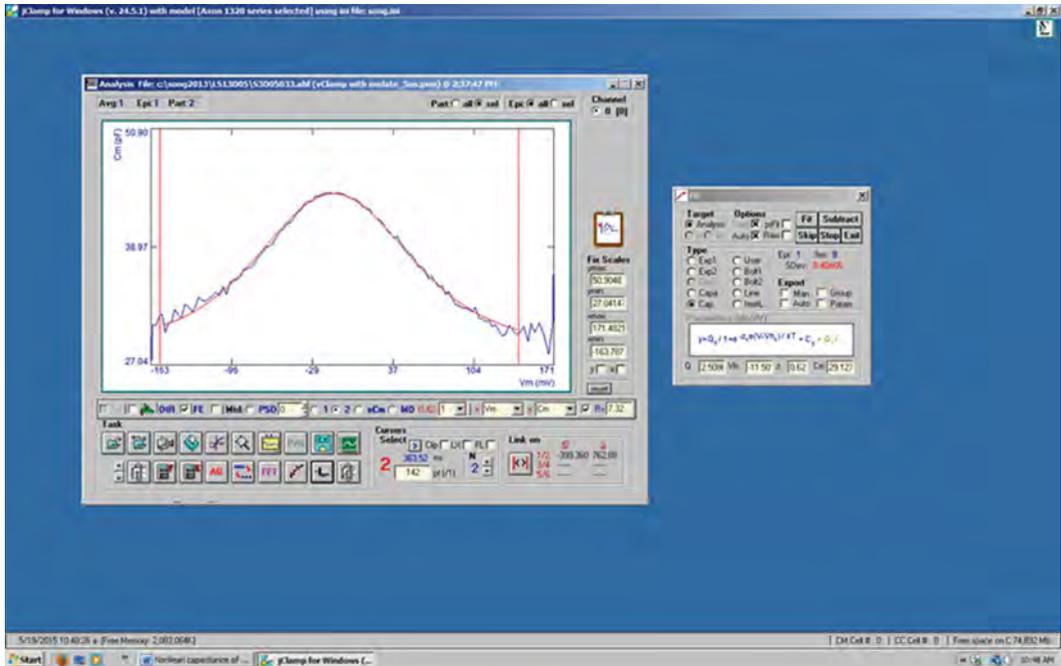

Fig. 2 Screenshot of data analysis window. Red lines/cursors highlight the voltage range fitted. Activate the cursor by clicking the fitting icon on the bottom row of buttons, 7th from the left. Then click each cursor and drag to the proper place. Before fitting, remember to check R_s so the series resistance is corrected. Right window pops up when selecting curve fitting icon. Select Cap and click “fit” button. Fitting parameters are shown in the bottom windows. You can export those fitting parameters by selecting “Param” in “Export” panel (see jClamp help files for more detailed explanations)

7. Select the range for fitting and in the pop up window, select “CAP” fit. Parameters shown in the windows are Q_{max} (total charge moved), V_h (voltage at peak capacitance), z (valence), and C_{in} (linear capacitance) (Fig. 2).
8. Export fitted parameters. Select “Param” and then click “Fit” button. Select “Auto” will include fitted curve in the export file so traces can be used in other plotting software, such as SigmaPlot.
9. Plot NLC curve in supported extremal software. Left click on the software icon and drag to the data analysis window and release. Refer to Help file in jClamp for detailed instructions (see **Note 13**).

4 Notes

1. Although other common software used for patch clamping can also measure NLC, the analyses were very often carried out in a separate program post hoc [28–31]. Our in house developed

software jClamp (distributed through Scisoft, Ridgefield, CT) is by far the easiest software to measure and analyze linear/nonlinear capacitance. The online display of NLC and a number of data analysis features offer handy functions when tracking voltage shifts of NLC. Once an investigator becomes familiar with the program, the data acquisition and analysis are routine.

2. When possible, ionic blocking solutions are used to eliminate current that may interfere with NLC measurements. When “physiological” solutions are needed for your investigation, check the current (by selecting in the analysis window “Vm vs. Im”). If a nonlinear current is present at the voltage where NLC is present, you need to take precaution when interpreting your data, because nonlinear currents can interfere with NLC assessment.
3. Intracellular chloride is the key anion that modulates prestin’s function [32]. When an experiment requires reduction of intracellular chloride, substitute anions often shift NLC curve toward different directions along the voltage axis [32–35]. Errors in fitting for parameters occur if the NLC is moved out of the stimulus voltage range [33, 34]. In general, gluconate substitution maintains NLC curves within the voltage range of the amplifier so that both ends of the curve reach a steady state. Fitting is more reliable under those conditions. When another anion substitution is required, adjust voltage range of stimulation accordingly within the limit of amplifier so that the NLC curve is clearly within the voltage range. Remember, you cannot fit a NLC curve where the peak is not clearly resident, with substantial capacitance measures on either side.
4. Use a forceps to press from under the coiled organ of Corti to break the bone from the modiolus. Start from apex then work down toward base. An alternative is to separate the organ of Corti from the apex and use fine forceps to hold the broken end, while carefully pulling along the spiral of the modiolus.
5. The 200- μ L pipette tips are flame heated in the middle of the taper then pulled to thin the wall. Then trim the base of pipette tip to fit a 1 cc syringe and cut the thinned tube so the opening is just large enough to suck in the strip of the organ of Corti. Metal needles or glass pipettes are not appropriate, as cells tend to adhere to the surface of glass and metal.
6. Fill extracellular (bath) solution gently so OHCs, which adhere to the bottom of the dish, will not float away. An alternative is to use a large opening patch pipette to move an individual OHC settled at the bottom of the dish to the recording chamber.

7. Typical pipette resistances in 140 mM Cl solution are around 4 M Ω . When the gluconate substitute is used, the resistance is raised to 5–6 M Ω in 5 mM Cl pipette solution.
8. Membrane tension: Outer hair cell membrane tension is a strong modulator of NLC [10, 24, 25, 27]. Increased membrane tension (e.g., caused by turgor pressure) can shift NLC curve over 50 mV [10, 25, 26]. Such a shift in V_h may create errors in data interpretation; we strongly recommend investigators to control turgor pressure in OHC recordings during NLC and motility measurements. Tension changes can occur due to a variety of reasons including imbalanced osmolality between intracellular and extracellular solution, higher intracellular chloride levels [36] or influx of chloride [35] or other ions, plugged pipette, and positive pressure clamped to the pipette [10, 24, 26]. Therefore, either controlling or close monitoring of membrane tension is important to obtain unbiased data. We routinely adopt two approaches to reduce artifacts derived from membrane tension changes: (1) to monitor cell turgor/length change with a video camera [36], and (2) to collapse the cell by suctioning the pipette. If turgor tension is not the focus of study, collapsing cells is the best approach to eliminate the problem. When membrane tension is part of the study or a “natural” condition is desired especially in motility measurement, collapse the cell at the end to acquire recordings as a control condition. Capturing images and making measurements of cell length change also gives helpful indications of turgor changes and is highly recommended when a video camera is available.
9. Calibration should be done prior to the experiment and needs to be repeated after some time period, or whenever the system changes—new sampling clock, different filter setting on the amplifier, change in amplifier gain, etc. If the calibration is wrong then the data are WRONG! On the headstage, remove the pipette holder. Insert a 10 M Ω resistor and connect to the ground. Run the calibration according to the menu instruction. This is a step easily ignored by investigators. Do not use wrong calibration files! File names should be saved to contain time and amplifier filter frequency and clock information so that earlier calibration files are all identifiable. Calibrations are saved with data files.
10. Building command file: A command file is built in the Command Utility interface prior to the experiment and a shortcut can be used. Move cursor to the left of screen and point to the command utility icon (6th from the top) and open the panel (shown on the right). Load command protocols by clicking folder icon in Command Utility window and select from the command file folder. If a command is used frequently,

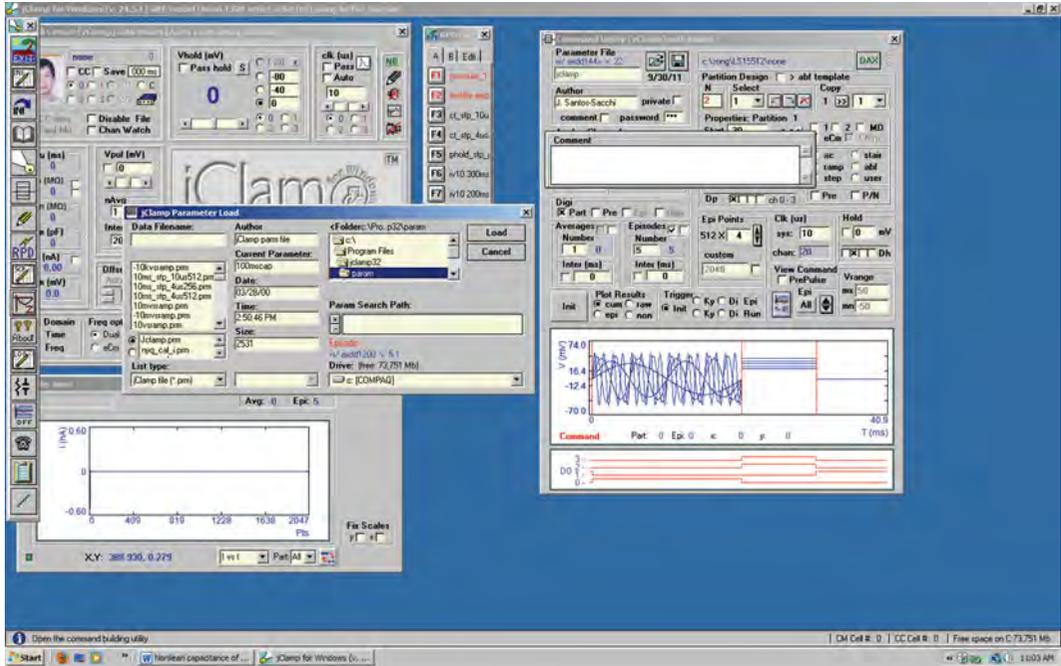

Fig. 3 Screenshot of command building window. Left column is activated by moving cursor to the left. Then select 6th icon from the list to activate command utility window. Click open folder icon to select command file to work on. Command files are saved in “Param” subfolder in jClamp folder

you may save it in the “RPD” window (Shown in small panel with quick access keys, (Fig. 3) to enable quick access. A typical dual-sine ramp command is shown below in command utility window. We use four sections to define the command. The sections 1 and 4 have matching holding potentials. Partition 2 defines the beginning of ramp voltage. Partition 3 is the ramp where the start voltage is at the end of the ramp (-200 mV in the screenshot). Command Cm window needs to be selected and typical resolution is 2.56 ms if two-sine [22, 33] is to be superimposed onto the ramp (Fig. 4).

11. Quick access key (RPD) is the fast approach to activate a saved command file frequently used. We use it only at the beginning of the recording series. Upon activation of a command, the command utility window and Result Window data display will both pop up. Change the data display to V_m vs. C_m in drop down window so the NLC is displayed online. If the command needs repeated, use “init” key to activate the command during the continuous recording of the cell. The advantage of doing so is the ability to keep all the prior NLC curves on the data display window so you can track the changes of NLC online. This is particularly useful in determining the completion of cell dialysis [35] and tracking whether the cell has reached steady

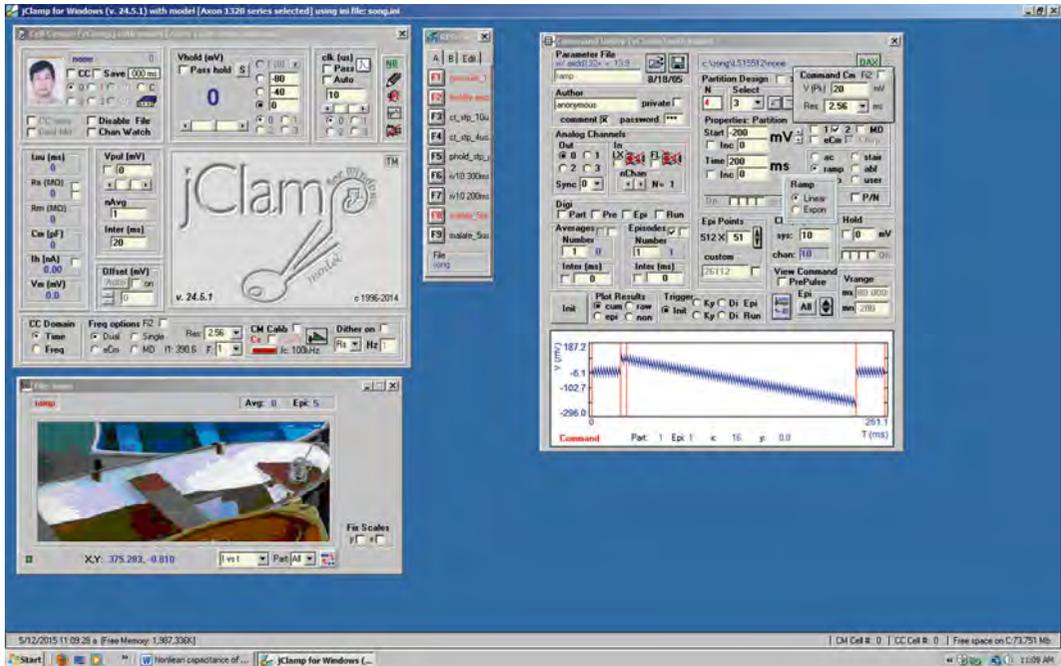

Fig. 4 Screenshot of window when building a ramp command with superimposed two-sine. First check “ramp.” Then move cursor to 2 (two-sine). “Command Cm” box will pop up when box of “2” is checked. Typical two-sine resolution is 2.56 ms and two-sine voltage is 10–20 mV (shown in the figure). Each section has to have 2-sine enabled. Start voltage of the ramp is +80 mV in partition 2 and –200 mV in partition 3. Typical ramp duration is 200–300 ms

state upon various manipulations (perfusion of extracellular solution containing drugs, change holding potential, change membrane tension, etc.). We routinely record NLC online until a few overlapping NLC traces appear before advancing to the next manipulation in the experiment. This is essential in acquiring high quality data.

12. Detrending is a method to properly prepare the data prior to FFT analysis and extraction of NLC. Detrending removes slow changes in the current response but leaves behind clear dual-sine currents, which possess the capacitance information. For example, without detrending, a fast ramp or sine wave superimposed with a two-sine stimulus will erroneously result in NLC peaks larger than slower ramp or sine stimuli. Detrending uses a small scale “piece-wise linear” approach to remove the trend generated by the underlying ramp or sinusoid stimulus. Users may choose to enable “detrending” if the underlying stimulus rate is fast and a small noise increase is not crucial.
13. jClamp can be linked to other data analysis or plotting software such as Excel, SigmaPlot, Matlab, and Origin. You need to

select in the ini file to link the software (*see* jClamp help files for detailed steps). The linked software will appear on the upper right corner in jClamp analysis window (the SigmaPlot icon in the screenshot, (Fig. 2). To export the plot, simply left click and drag the software icon to the NLC curve analysis window and release. A generic plot will automatically be generated in the selected software.

Article

An Electrical Inspection of the Subsurface Cisternae of the Outer Hair Cell

Lei Song¹ and Joseph Santos-Sacchi^{1,2,3,*}¹Surgery (Otolaryngology), ²Neurobiology, and ³Cellular and Molecular Physiology, Yale University School of Medicine, New Haven, Connecticut

ABSTRACT The cylindrical outer hair cell (OHC) of Corti's organ drives cochlear amplification by a voltage-dependent activation of the molecular motor, prestin (SLC26a5), in the cell's lateral membrane. The voltage-dependent nature of this process leads to the troublesome observation that the membrane resistor-capacitor filter could limit high-frequency acoustic activation of the motor. Based on cable theory, the unique 30 nm width compartment (the extracisternal space, ECS) formed between the cell's lateral membrane and adjacent subsurface cisternae (SSC) could further limit the influence of receptor currents on lateral membrane voltage. Here, we use dual perforated/whole-cell and loose patch clamp on isolated OHCs to sequentially record currents resulting from excitation at apical, middle, and basal loose patch sites before and after perforated patch rupture. We find that timing of currents is fast and uniform before whole-cell pipette washout, suggesting little voltage attenuation along the length of the lateral membrane. Prior treatment with salicylate, a disrupter of the SSC, confirms the influence of the SSC on current spread. Finally, a cable model of the OHC, which can match our data, indicates that the SSC poses a minimal barrier to current flow across it, thereby facilitating rapid delivery of voltage excitation to the prestin-embedded lateral membrane.

INTRODUCTION

The outer hair cell (OHC) provides a unique function for mammalian hearing, underlying a 40–60 decibel boost that enhances our ability to detect and discriminate among sounds, namely, cochlear amplification (1). The structure of the OHC is likewise unique, being cylindrical and ranging in length over tens of micrometers depending on tonotopic location along the cochlea spiral, reaching ~90 μm in the apical OHC of the guinea pig. The lateral wall of the OHC, composed of the lateral plasma membrane, cortical cytoskeleton, and subsurface cisternae (SSC), hosts a restricted subplasmalemmal compartment of 30–50 nm width, termed the extra cisternal space (ECS) (2,3). This ECS is an interesting compartment because prestin, the molecular motor that drives OHC electromotility, resides in the adjacent plasma membrane, with its C- and N-terminals and its anion-binding site projecting into the space (4–6). Prestin contributes to the lateral membrane's capacitance, not only linearly, due to its abundant occupancy increasing surface area (7,8), but nonlinearly because of the electrical signature of prestin activity, namely, nonlinear capacitance (NLC) (9,10). Previous modeling efforts have attributed special electrical characteristics to the ECS (11,12), but they did not include NLC in the lateral plasma membrane.

One recurring concern with the voltage-dependent nature of OHC electromotility is the membrane resistor-capacitor (RC) filter effect on the driving force (sound-induced recep-

tor potentials) for prestin activation. Indeed, it has been estimated that OHC mechanical responses would be 20 dB less than basilar membrane movements at high acoustic frequencies (13). Since then, a number of solutions to the RC problem have been proposed, in an attempt to confirm high frequency, cycle-by-cycle voltage drive for the cochlea amplifier. The presence of the SSC/ECS might also interfere with voltage delivery to the lateral membrane, presenting barriers to receptor current flow. In this report, we directly investigate the influence of the SSC/ECS on OHC electrical behavior. Using dual voltage clamp on isolated OHCs, we find that whole-cell recording via perforated patch records equally fast responses from electrical stimulation of the lateral membrane along its entire length via loose patch. Cable modeling indicates that the SSC barrier does not limit current spread to the ECS, thereby facilitating efficient and rapid delivery of voltage drive to the molecular motors within the lateral membrane.

MATERIALS AND METHODS

Experiment

Electrical measurements were made with modifications to the approach used by Anson and Roberts (14). Three types of electrode arrangements were used—perforated patch whole-cell recording followed by patch rupture into standard whole-cell mode, each accompanied by roving loose patch voltage stimulation. Specifically, two electrodes were patched onto isolated OHCs simultaneously: a perforated patch electrode (gramicidin, 25 or 50 $\mu\text{g}/\text{ml}$) initially served as the recording electrode (holding potential at 0 mV), and a loose patch electrode placed at three locations along the lateral membrane to deliver voltage stimulations. Subsequently, the perforated patch electrode was ruptured to make recordings under standard whole-cell mode. The perforated patch permitted replacement of

intracellular cations with those of pipette cations, notably Na to inhibit K currents in the basal membrane, thus reducing their effects on our measures of currents and NLC. We view the perforated patch condition as the least intrusive and thus the condition most indicative of normal cellular behavior.

Isolated OHCs from the organ of Corti of guinea pigs were obtained as previously described (15). Long cells (~80 μm long) from apical turns were chosen to allow reliable cable analysis. We used 5 mM chloride to mimic the intracellular chloride concentration of the normal cell that we measured previously (16). Prestin is sensitive only to intracellular chloride, and to clamp intracellular chloride to 5 mM we needed to match inside and outside chloride because the lateral membrane harbors a substantial chloride conductance (6). The bath solution contained, in mM, NaCl 5, Na gluconate 135, CaSO₄ 2, MgSO₄ 1.2, and HEPES 10. Final solutions were adjusted to 300 mOsm with D-glucose and pH 7.2–7.3 with NaOH. The whole-cell patch pipette solution was the same as the extracellular solution except with the addition of 10 mM EGTA. Loose patch electrodes contained the bath solution with resistances near 1 M Ω . Loose patch electrodes served as stimulating electrodes roving along the lateral membrane of OHCs (Fig. 1), positioned ~20, 45, and 70 μm from the base of the cell. To reduce cellular adhesion to the roving pipette, tips were treated with trichlorosilane. Experiments were performed at room temperature (22–23°C). A Nikon Eclipse E600-FN microscope with 40 \times water immersion lens was used to observe cells during the electrical measurements.

Axon 200B amplifiers were used for patch clamping, currents being sampled at 10 μs with an Axon Digidata 1322 using jClamp software (www.scisoftco.com). Voltage steps of 20 ms duration ranging from –160 to +160 mV with 20 mV steps were delivered via a loose patch electrode. Perforated patch electrodes were used to collect current data. Recorded currents were filtered with a 10 kHz 4 pole Bessel filter. Current traces were individually fit with single exponentials in jClamp. Initial electrode resistance was 4–6 M Ω . Gohm seals are reached before decrease of patch resistance due to gramicidin perforation. With pipette backfilling, time for establishing perforated patch whole-cell patch was

around 30–40 min. R_s for the perforated patch electrode was typically 15–25 M Ω , and was reduced by series resistance compensation to maintain a ~10 M Ω resistance. Similarly, after rupture of the perforated patch and establishment of whole-cell recording, R_s was maintained near 10 M Ω . It was important to keep electrode series resistance uniform among cell recordings because time constants are dependent on the series resistance. Amplifier lag controls were not manipulated but were left at minimum levels during R_s compensation. The recording protocol (perforated patch recording with apical, middle, and basal stimulation, followed by whole-cell recording and roving stimulation) was quite demanding so that many cells were lost before completing all recording conditions. Whole-cell NLC was measured with the recording electrode using a 2-sine voltage stimulus atop a voltage ramp with subsequent admittance analysis as previously described (17).

To investigate the effects of subsurface cisternae damage, OHCs were incubated in extracellular solutions that contained 10 mM salicylate for 30–40 min. This time period of exposure has been shown to cause irreversible damage to the subsurface cisternae (3), thereby minimizing contributions of the SSC/ECS to our measures. Washout of salicylate was performed before recording to alleviate its direct reversible effects on prestin's NLC (18,19).

Average responses for stimulation at basal, middle, and apical positions for a range of step voltage commands included three cells where all recording/stimulation configurations were successfully completed. Statistical tests included cells where less than the full paradigm was completed, with numbers ranging from 3 to 10 (see Fig. 4 for numbers of cells used for statistical tests). We were careful to ensure that electrophysiological conditions (especially recording clamp time constants) were similar before and after patch rupture. Results for perforated/whole-cell conditions (with standard –10 mV pulse stimulation via the recording pipette) were (mean \pm SE; $n = 3$): R_s : 10.1 \pm 0.1 M Ω vs. 10.4 \pm 0.2 M Ω ; R_m : 314 \pm 83 M Ω vs. 256 \pm 87 M Ω ; C_m 39.4 \pm 1.15 pF vs. 41.8 \pm 1.9 pF; clamp τ : 375 \pm 12 μs vs. 403 \pm 26 μs . These measures were repeated and remained stable for each roving pipette stimulation configuration. For salicylate-treated cells, perforated/whole-cell conditions were (mean \pm SE; $n=3$): R_s : 10.5 \pm 0.2 M Ω vs. 10.4 \pm 0.2 M Ω ; R_m : 267 \pm 36 M Ω vs. 262 \pm 42 M Ω ; C_m 40.1 \pm 0.2 pF vs. 40.0 \pm 0.4 pF; clamp τ : 401 \pm 9 μs vs. 395 \pm 8 μs .

Model

A lumped parameter model and a cable model of 47 sections that helped to understand the data were implemented in MATLAB's Simulink (The MathWorks, Natick, MA) using Simscape and are schematized (see Figs. 5 a and 6 a). The cable model was a standard one-dimensional model similar to that of Halter et al. (11) (see Results below). Though the length of the OHCs that we modeled was short compared to typical cell lengths used for cable analyses, we found it beneficial to analyze in this manner to compare to previous results and help in defining current paths and resistances within the OHC. An automation link between jClamp and MATLAB allowed us to stimulate the model and analyze in jClamp, similar to the biophysical experiments. Parameters were taken from the biophysical data as provided in Results. Both whole-cell and loose patch NLC were modeled as

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin},$$

$$b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right),$$

where Q_{\max} is the maximum charge moved, z is valence, C_{lin} is the linear capacitance of the cell membrane and V_h is the voltage at half-maximal charge. e , k , and T have their usual meanings.

To fit current transients to the cable model, we averaged traces across all cells. Because the absolute magnitudes of the currents differed and we were

concerned with maintaining time constant information, we first scaled all currents to unity based on peak current, and then averaged and rescaled to average magnitude. In this way, current shapes (τ) from all traces contributed equally to the averages.

RESULTS

Experiment

We investigated longitudinal charge movement within the cell by recording with perforated patch clamp while simultaneously stimulating along the length of isolated OHCs using a loose patch electrode (Fig. 1), in a manner similar to that of Anson and Roberts (14). Perforated patch recording leaves the plasma membrane unbroken but allows electrical continuity with the whole cell (20). The enlarged, circled section in Fig. 1 indicates possible current flow from the stimulating loose patch electrode into the ECS or across the SSC into the axial core of the cell. We found that loose patch stimulation at all cell positions relative to the recording electrode produced equally fast responses under the perforated recording condition. Interestingly, we only observed single exponential responses. For example, Fig. 2, A–C, shows that time constants of induced current transients were similar with basal, middle, and apical stimulation during perforated patch recording conditions, regardless of voltage stimulation magnitude. These data may indicate that charge movement within and along the ECS is rapid. However, upon perforated patch rupture with suction, and establishment of standard whole-cell recording, time constants showed differences; apical and middle stimulation showed slower responses, and interestingly took on a clear voltage dependence arising from the loose patch's NLC (Fig. 2, D–F). We take this to indicate that the SSC was somehow altered either by washout of

cell constituents or washin of gramicidin, resulting in altered characteristics of the cell's cable properties. Whole-cell NLC measured under these two conditions were similar (Fig. 2, C and F), indicating that the large increase in time constants is not due to a corresponding large increase in NLC of the whole cell. It should be noted that limiting time constants are imposed by the patch clamp (roughly, $R_s C_m$) and in absolute terms do not reflect cell capabilities. We only use these measures as a tool to understand relative timing relationships between conditions and between electrodes.

The incorporation of gramicidin into a membrane is a fairly slow process; for example, up to 45 min is required to obtain good series resistance of the perforated patch electrode before beginning our experiments. Following patch rupture, we required only ~10 min to complete the rest of the experiment, though maintaining the cell for the complete protocol was not guaranteed. Thus, little gramicidin is expected to incorporate with the plasma membrane and this is evidenced by the maintenance of fairly high membrane resistance in whole-cell mode (see Materials and Methods for values). In any case, a reduction in membrane resistance should speed up the electrical response rather than slow it down, as occurred after patch rupture. Thus, we reasoned that establishing the whole-cell condition by pipette suction caused alterations to the SSC during washout/in. To test this hypothesis, we transiently treated cells with salicylate, which has been shown to irreversibly alter SSC ultrastructure (3). The effect of prior salicylate treatment (30–45 min) was to abolish the increase in time constants that occur following patch rupture, as would be expected if the SSC/ECS were altered before patch rupture (Fig. 3, A and B). As with untreated cells, we were careful to ensure that recording conditions were similar before and after patch

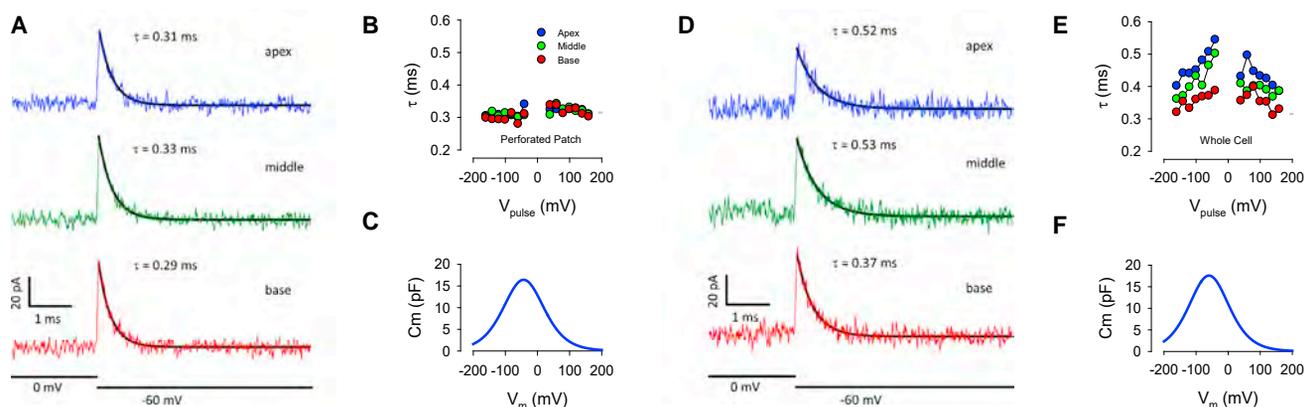

FIGURE 2 Time constants (τ) of current responses induced by step voltages of the roving loose patch electrode before (A–C) and after (D–F) rupture of recording the electrode perforated patch. (A) Traces of currents measured during apical, middle, and basal stimulation. Traces are averages (see Materials and Methods). Note that current responses have similar exponential decays. (B) Average response tau across voltage stimulation magnitude. Circles depict average responses at each voltage for 3–10 cells. (C) NLC based on average fits (see Materials and Methods). Q_{\max} , V_h , z : 2.95 pC, –59.7 mV, 0.61. (D) Traces of currents measured during apical, middle, and basal stimulation following recording electrode patch rupture into standard whole-cell mode. Traces are averages. Note that current responses now have differing exponential decays. (E) Average response tau across voltage stimulation magnitude, showing clear voltage dependence. Circles depict average responses at each voltage. (F) NLC based on average fits. Q_{\max} , V_h , z : 2.81 pC, –43.2 mV, 0.60. To see this figure in color, go online.

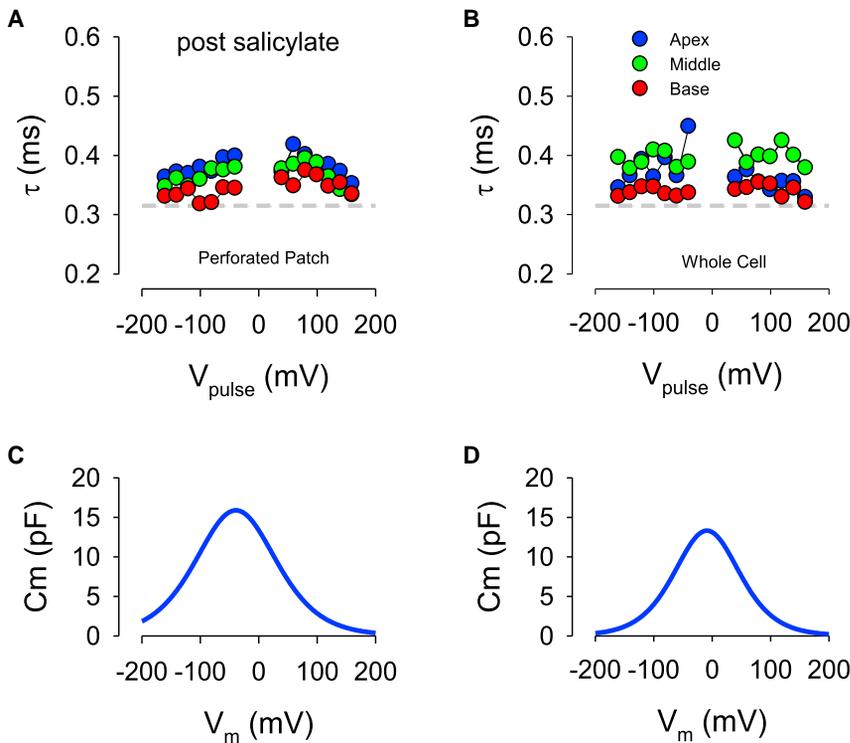

FIGURE 3 Time constants (τ) of perforated (A) and whole-cell (B) patch responses following salicylate treatment induced by step voltages of the roving loose patch electrode. Circles depict average responses at each voltage for three cells. Note similarity of time constants (τ) before and after establishment of whole-cell condition. (C) and (D) show corresponding measures of average NLC measured with whole-cell/perforated patch electrode (Q_{max} , V_h , z : 2.94/2.00 pC, $-39.0/-9.2$ mV, 0.55/0.68). To see this figure in color, go online.

rupture (see Materials and Methods). In these cells, NLC before patch rupture was slightly less than controls not treated with salicylate (compare Fig. 2, C and F with Fig. 3, C and D). After patch rupture, NLC was shifted rightward and decreased somewhat (see figure legends for fits).

Fig. 4, A and B, compare the time constants obtained at -60 mV steps and time to peak current (Tpk) at the 160 mV pulse, each at three locations, before and after

establishing whole-cell conditions for cells without salicylate treatment. Statistically significant differences are found at all stimulation locations (significance is given in plot). The observations on current time constants are to a large extent paralleled by measures of Tpk. That is, although these metrics were stable across stimulus locations for the perforated patch condition, they increased for the whole-cell condition. For example, current spread latency between

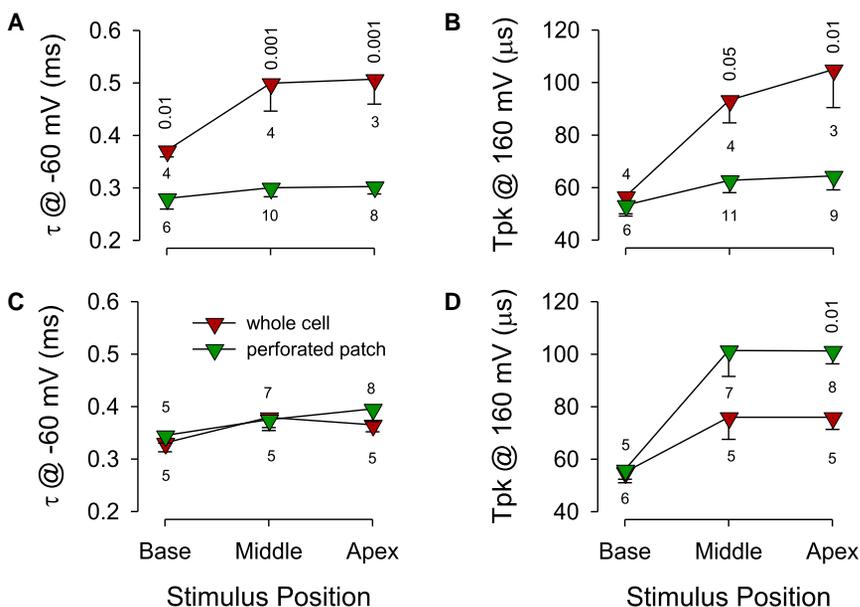

FIGURE 4 (A) Average time constants at -60 mV show little difference among roving patch locations for the perforated patch condition, but significant differences following whole-cell recording. (B) Similarly, times to peak (Tpk) current increase at apical and middle positions following patch rupture. (C) For salicylate-treated cells, time constants show no significant differences between perforated patch and whole-cell conditions. (D) Tpk shows no significant differences at basal and middle positions; however, a difference was observed at the apical position where Tpk was now shorter following patch rupture. Number of cells is noted. Statistical significance ($p < ; t$ -test), where present, between pre- and post-patch rupture is shown for each location. To see this figure in color, go online.

stimulating and recording electrodes based on Tpk between basal and apical stimulation is on the order of only $3.4 \mu\text{s}$ (53.3 ± 3.3 vs. $56.7 \pm 4.0 \mu\text{s}$; $p > 0.05$), whereas following establishment of whole-cell conditions the spread significantly slowed to $41.1 \mu\text{s}$ (105.0 ± 14.5 vs. $64.4 \pm 5.2 \mu\text{s}$; $p < 0.05$). Fig. 4 C shows that no significant differences are found in time constants for the salicylate-treated case, indicating that SSC alterations were present both before and after patch rupture. Tpk for salicylate-treated cells show no differences at basal and middle stimulation locations (Fig. 4 D), but a significant difference is found for the apical stimulation position. However, this difference, namely that Tpk is shortened following rupture, is opposite that observed without salicylate (see Fig. 4 B). This may indicate an interactive action of combined salicylate and gramicidin.

Models

Lumped parameter model

To understand our results, we constructed a lumped parameter model of the OHC, before and after establishing whole-cell configuration (Fig. 5 A). The model parameters are those actual averaged (see above) measures obtained in perforated patch mode (*condition 1*) and whole-cell mode (*condition 2*). C_p , the linear capacitance of the patch, and patch NLC were set to 0.02 of the measured whole-cell values. R_p , the patch resistance that was stimulated, was set based on Halter et al.'s value of lateral membrane conductivity, 0.001 mS/cm^2 (11). This is reasonable, because

we have previously shown that the lateral membrane is devoid of voltage-dependent conductances (21). V_h of the loose patch was set to a 20 mV more depolarized value than whole-cell or perforated patch V_h because the tension provided to the patch ($\sim 1 \text{ kPa}$) to increase loose patch shunt resistance (R_{sh}) is known to shift $V_h \sim 20 \text{ mV/kPa}$ (22). R_{sh} was set to $5.0 \text{ M}\Omega$. R_{sp} was set to $1.8 \text{ M}\Omega$, based on measures of electrode resistance before cell attachment. Stimulation was done as with the biophysical measures using jClamp and Simulink. In the perforated condition, an intervening resistance (R_{inter}) between stimulating and recording electrodes of $10 \text{ M}\Omega$ or less produced results that resembled our data (see below).

Fig. 5 B shows the time constants of evoked currents when the model was simulated with parameters obtained under perforated patch and whole-cell experimental conditions. Though tau were similar in magnitude to our data, no differences in tau are observed between the two conditions, unlike the increase in voltage-dependent tau that we observed experimentally. This means that the differences observed between model and data are not due to the experimentally observed changes in R_s , R_m , C_{lin} , and NLC between the two conditions. Could unrecognized changes in R_{sp} or R_{sh} have influenced our data? In Fig. 5, C and D, we show the effects of altering R_{sp} (1, 5, 10 $\text{M}\Omega$) and R_{sh} (1, 5, 15 $\text{M}\Omega$). No influence on tau was found. Changes in R_{sh} can, however, alter the magnitude of the current response, and thus could underlie differences between current magnitudes found in whole-cell and perforated patch recordings. Finally, we modified R_{inter} (10, 100, 300 $\text{M}\Omega$) and found an increase in voltage-dependent tau as a function

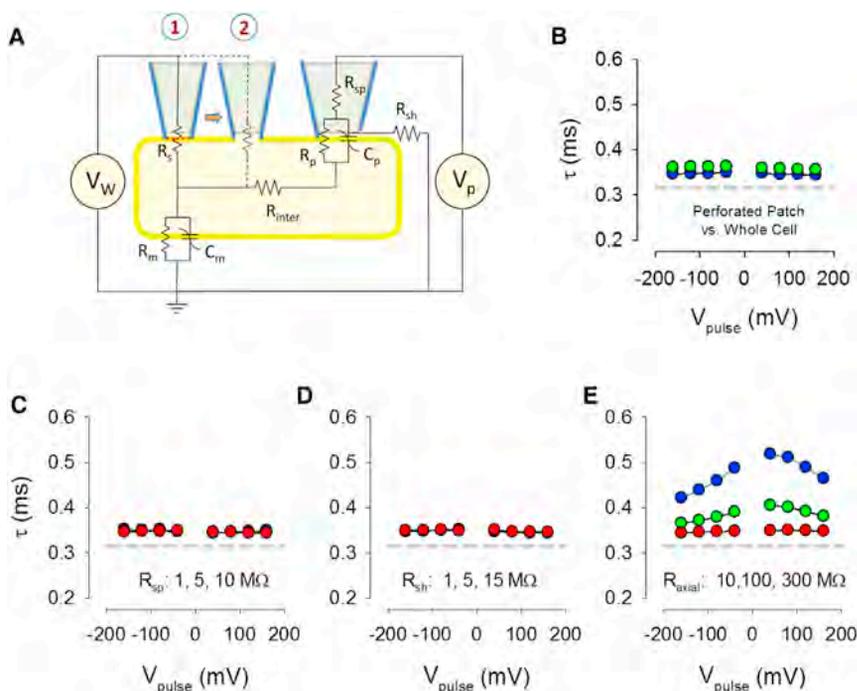

FIGURE 5 Lumped parameter model of OHC under the experimental conditions. (A) Schematic showing circuit and parameters of current measuring and voltage stimulating pipettes. Model was evaluated first under perforated patch (*condition 1*) and then under whole-cell (*condition 2*). See Materials and Methods for details. Right pipette is stimulating pipette. Parameters are taken from actual biophysical data given in Results. (B) With biophysical measures obtained under perforated patch and whole-cell condition, no differences in taus are observed. (C and D) Neither R_{sh} nor R_{sp} affects the evoked current time constants. However, interelectrode resistance has a profound effect on them, producing results similar to the biophysical data, indicating that this resistance must have changed upon entry into whole-cell mode. To see this figure in color, go online.

of increasing resistance (Fig. 5 E). A value between 100 and 300 M Ω was required to simulate our experimental observations. It should be noted that the possibility of an induced cross talk between recording and stimulating electrodes following patch rupture is ruled out, because in the salicylate-treated controls, no increase in tau is found following patch rupture.

Cable model

To hone in on the identity of the intervening resistance, R_{inter} , we assembled a 47 section cable model (Fig. 6 A) similar to the one devised by Halter et al. (11). We kept their basis values for R_L (0.001 mS/cm²), R_{ecs} , R_{ax} (70 Ω cm), and R_{sc} (0.1 mS/cm²); however, in our case we included lateral membrane NLC based on our measurements. Other values were R_s 10 M Ω , R_p 1.8 M Ω , R_{sh} 3–12 M Ω , C_m 0.8 μ F/cm², C_b 3 pF, C_a 2pF, R_{mb} 300 M Ω , and R_{ma} 10 G Ω (high because stereocilia were damaged by trituration during cell isolation). ECS width was set to 30 nm. Similar to our experimental measures, a 10 kHz 4 pole Bessel filter implementation in Simulink was used on model currents.

As noted previously, we only observe single exponential current transients in our experiments. Fig. 6 B shows that

the cable model cannot reproduce our data if we use the R_{sc} value of Halter et al. (11). The resultant pink solid lines are not simple single exponentials, and whole-cell NLC of this model (measured via the recording electrode) was substantially less than our biophysical measurements (Q_{max} : 1.35 pC vs. 2.95 pC). We must increase R_{sc} conductance by three orders of magnitude (0.15 S/cm²) to fit our perforated patch data (black solid lines), and to simultaneously obtain a value matching our normal whole-cell NLC values (Q_{max} : 2.92 pC). This indicates that the SSC are highly conductive, on the order of electroporated membranes (23). To fit the data following patch rupture (Fig. 6 C), the ECS resistivity had to be increased three orders of magnitude (70 k Ω cm); this apparent increase in resistivity could instead indicate that the ECS space had collapsed or the actual ionic strength of the space had decreased. Additionally, R_{sc} conductance was reduced, as well (0.015 S/cm²). Thus, the intervening resistance, R_{inter} , of the lumped parameter model corresponds to the R_{ecs} and R_{sc} components of the cable model. Fig. 7 shows time constants and NLC of the model using the perforated patch and whole-cell parameters obtained by trace fits. Similarity to the biophysical data is clear (compare with Fig. 2). These results

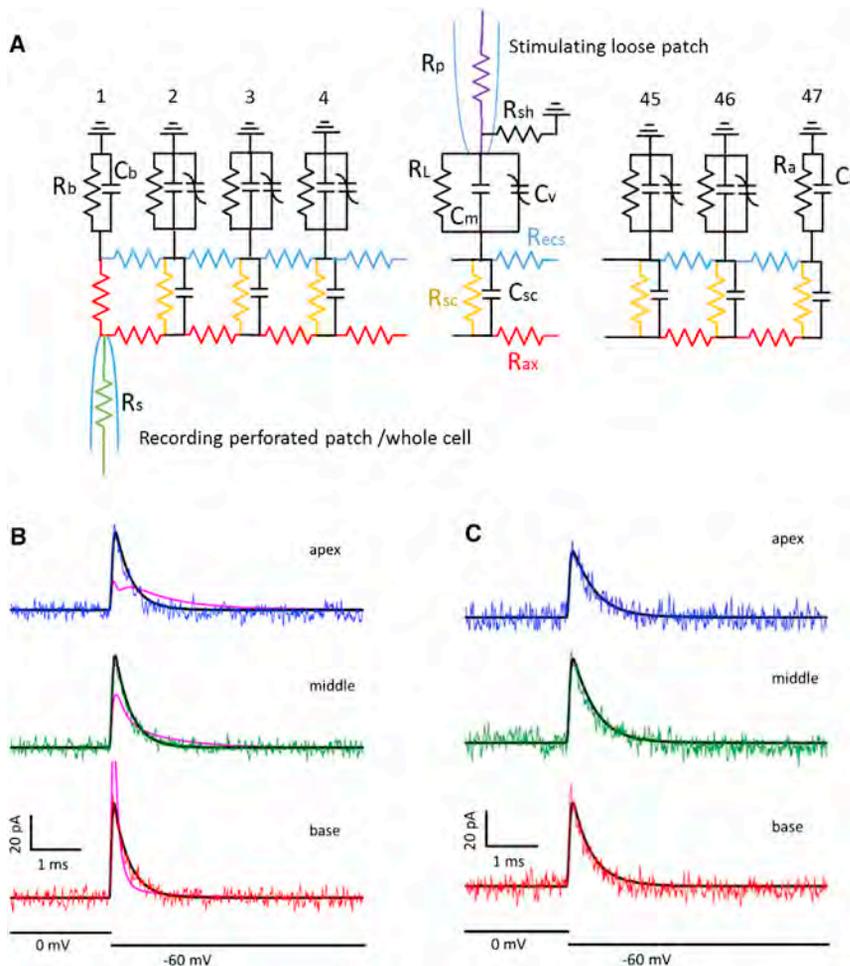

FIGURE 6 (A) Cable model with 47 sections. Roving loose patch electrode was placed at section 2, 22, and 42 to mimic basal, middle, and apical stimulations. See Model Results for parameter values. (B) R_{sc} values based on Halter et al. (11) (0.1 mS/cm²) could not fit data in perforated mode (pink traces); however, a value of 0.15 S/cm² fit the data well (black traces). (C) For the model to fit whole-cell data, R_{ecs} resistivity had to be increased to 70 k Ω cm (black traces), with R_{sc} conductivity set to 0.015 S/cm². To see this figure in color, go online.

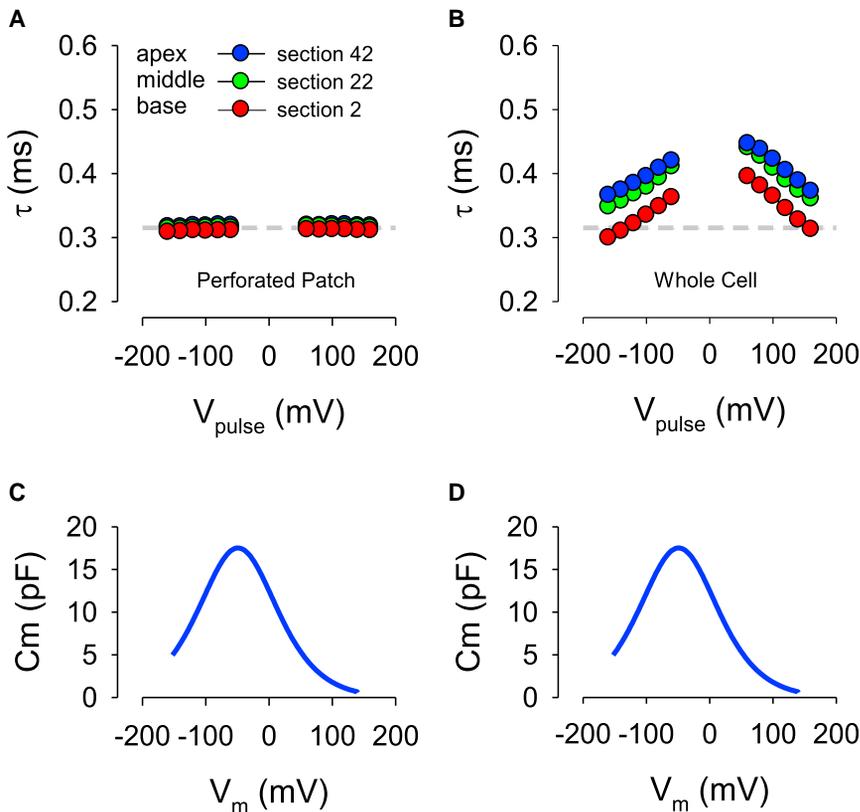

FIGURE 7 Cable model time constants (τ) of perforated (A) and whole-cell (B) patch responses induced by step voltages of the roving loose patch electrode. Note increase in time constants (τ) after change from perforated patch parameters to whole-cell parameters (see Model Results), and an apparent rise in voltage dependency similar to what is seen with the biophysical data. (C) and (D) show corresponding measures of whole-cell NLC measured with recording whole-cell electrode (Q_{max} , V_h , z : 2.78/2.94 pC, $-40.7/-56.3$ mV, 0.60/0.60). Compare to Fig. 2. To see this figure in color, go online.

indicate that under unperturbed conditions, with perforated patch recording intact, the high conductance of the SSC facilitates voltage delivery to the lateral membrane. Cable model results similar to the salicylate experiments were obtained with ECS resistivity set to $70 \text{ k}\Omega \text{ cm}$ and R_{sc} conductivity of 0.03 or 0.026 S/cm^2 for perforated patch or whole-cell condition, respectively (model data not shown).

Finally, to evaluate the influence of SSC conductance on voltage excitation of the lateral membrane, we used our cable model driven by current injection into the cell's apical axial core, mimicking receptor currents (Fig. 8). In the absence of the SSC, frequency response magnitude is maximized, but phase is significantly changing at frequencies below 1 kHz . With R_{sc} conductivity from Halter et al. (11), significant reduction of frequency response magnitude and large phase changes across the spectrum arise. By increasing R_{sc} conductivity frequency response magnitude is enhanced and phase behavior is flattened. Thus, electrical transparency of the SSC tends to facilitate voltage delivery to the lateral membrane.

DISCUSSION

The mammalian OHC functions to enhance perception at acoustic frequencies, even beyond 100 kHz in some mammals. As a result, there is no doubt that the cell can produce mechanical activity at high frequencies (24), nor is there

doubt that the OHC's stereocilia transduction apparatus operates at high frequencies (25–27). Indeed, there is little disagreement that cochlear amplification deriving from OHC electromechanics works most efficiently at high frequencies (28). Nevertheless the conundrum arising from a voltage-dependent basis of amplification continues to garner interest. The problem stems from the observed disparity between OHC resting membrane potential and the voltage where maximal mechanical activity occurs (V_h) (13,27). Should these two voltages overlap there would then be less difficulty with an RC filter. Several mechanisms have been postulated to understand why the RC filter should not interfere with prestin activity at high frequencies. Previously, we envisioned three mechanisms that might help: 1), because turgor pressure within the OHC shifts the voltage dependence of NLC and electromotility (22,29,30), we suggested that alterations in turgor pressure could align V_h and resting potential (22); 2), because prestin charge density increases in high-frequency OHCs (31,32), we reasoned that the rising electrical energy delivered to the lateral membrane could counter the reduced voltage drive; and 3), we reasoned that the flux of chloride through the stretch-activated chloride conductance, G_{metL} , in the lateral membrane could gate prestin's chloride-dependent activity independent of the membrane RC (6). Though the first two possibilities remain tenable, the latter is unlikely, because we have recently discovered that the effects of chloride on prestin are

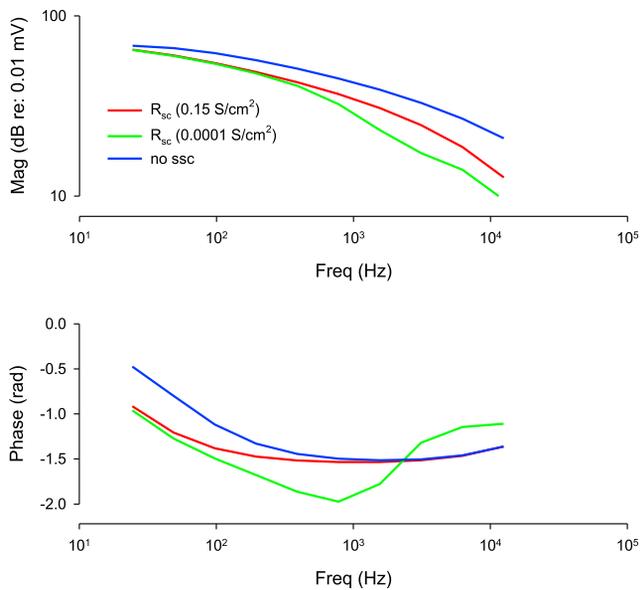

FIGURE 8 Magnitude and phase of voltage drop across section 33 lateral membrane of the cable model induced by 0.1 nA AC injection into the apical axial core. Without SSC frequency response is maximal. Reduction of R_{sc} from value based on Halter et al. (11) (0.1 mS/cm^2) tends to increase frequency response and provide a flat phase response. To see this figure in color, go online.

low-pass filtered by a slow intermediary state transition (33). Others, as well, have developed theories on overcoming the RC problem. These include 1), an intrinsic high pass augmentation of receptor potentials due to prestin's piezoelectricity (34); 2), a reduction of the RC effects by increases in membrane conductance (35); and 3), the observation that OHC resting potential may be more depolarized than the original estimates made in vivo (27,36), thus aligning resting potential and V_h (37).

Beyond the RC problem, however, ultrastructural specializations of the OHC lateral wall, namely the membranous SSC and the restricted, femtoliter space (ECS) it establishes, could provide isolation of the lateral membrane from axial receptor currents. This potentially could lead to reduced voltage drive to prestin motors embedded in the lateral membrane. Our present data directly relate to this issue.

Cable effects of the SSC

There has been a paucity of information on the electrical role of the SSC, mainly arising from modeling results of whole-cell electrical stimulation (11,38). Our experiments were aimed at electrically exploring restricted regions of the cell's lateral wall. Our data and model analyses indicate that the electrical transparency of the SSC promotes uniformly fast stimulus delivery to the lateral membrane motor, and therefore limits time-dependent, potentially nonlinear, activation of the motors. Based on average time to peak current measures between our apical and basal stimulus electrodes in the perforated patch condition

($3.5 \mu\text{s}$; see Results), for a $55 \mu\text{m}$ distance, a conduction velocity $>150 \text{ m/s}$ is obtained, and considering the high resistivity of the lateral plasma membrane, likely promotes isopotential conditions at any given acoustic frequency for the range of OHC lengths found within the cochlea spiral. This possibility was previously suggested because voltage-dependent conductances are absent along the OHC lateral membrane (21). The observation that damage to the SSC alters timing along the length of the OHC may indicate its high conductance is actively maintained. Indeed, the row of mitochondria adjacent to the SSC may play a role, because the washin of gramicidin following perforated patch rupture may uncouple mitochondrial oxidative phosphorylation (39). It is noteworthy that salicylate can also uncouple mitochondrial oxidative phosphorylation (40). We are currently evaluating the effects of other mitochondrial perturbations on SSC conductance.

Interestingly, in the model of Halter et al. (11), ECS current was found to exceed that within the cell's axial core, possibly pointing to unusual differences in resistivity between ECS and axial cytoplasm as also suggested by Fari-nelli et al. (38). Nakagawa and Brownell (12) have used the voltage-dependent dye, di-8-ANEPPS, to observe high frequency phase differences between OHC basal and lateral membrane voltages, which they attribute to the effects of a higher resistance of the axial core than ECS. Of course, this is counter intuitive based on the cross-sectional area of the ECS. Indeed, even fluorescent dye diffusion is somewhat slower in the ECS than in the axial core, though, of course, dye spread may not necessarily correlate with current spread (41). We were able to obtain single-exponential behavior of currents with our cable model if we set R_{ecs} resistivity to $0.7 \Omega \text{ cm}$, while maintaining the higher R_{ax} resistivity at $70 \Omega \text{ cm}$ and R_{sc} conductivity at 0.1 mS/cm^2 . However, typical values of cytosolic resistivity range between ~ 30 and $600 \Omega \text{ cm}$ (42), and considering the geometry of the ECS, this would mean that the ionic strength of the space would be enormous. It could be that the abundance of prestin within the lateral membrane, estimated to be up to 10 million copies based on nonlinear charge movement (43), contributes to a higher ionic strength in the ECS by virtue of its transport capabilities (44–46). Nevertheless, we consider it more reasonable to have the SSC highly conductive, possibly due to fenestrations, or vesiculations that may require work to maintain, because phospholipid bilayers tend to assume planar configurations (47). In this scenario, we might expect the performance of the OHC to be dependent on the energetics required to maintain an unusually high SSC conductivity.

Chloride dependent coupling of molecular to cellular mechanics in the outer hair cell of Corti's organ.

and Neurobiology, Yale University
School of Medicine, New Haven, Connecticut*

Abstract. Within the OHC lateral membrane, conformational changes in the motor protein prestin are driven by voltage induced displacements of intrinsic, charged moieties that can be monitored by measures of the cell's nonlinear capacitance. The cellular expression of these summed molecular events is a robust electromotility of the whole cell. We now find that the coupling of molecular to cellular mechanics is dependent on intracellular chloride levels, where normal levels (<10 mM) do not support tight coupling between the two. Thus, in vivo, electromotility is predicted to be poorly coupled to changes in OHC receptor potentials, whereas molecular conformational change is tightly coupled. We suspect that membrane mechanical characteristics driven by prestin may more significantly govern cochlea amplification than electromotility.

Keywords: chloride, capacitance, prestin, OHC

INTRODUCTION

Mammalian outer hair cell (OHC) electromotility results from voltage-dependent conformational changes of the membrane protein prestin [1], with the cell's motor charge movement or nonlinear capacitance (NLC) being considered a surrogate measure of electromotility [2,3]. A number of physiological factors shift prestin's voltage dependence, including changes in intracellular Cl and membrane holding potential (pre-pulse effect) [4,5], each presumably affecting electromotility and NLC equivalently.

We have been studying the consequences of combined chloride and pre-pulse manipulations on NLC with simultaneous measurements of electromotility. We find, as expected from our previous work, that OHCs patch clamped with pipettes containing 140 mM intracellular chloride show robust depolarizing shifts of NLC upon negative pre-pulse, with electromotility displaying a similarly coupled shift. However, lower, more physiological levels of intracellular chloride [6], induce an uncoupling of mechanical responses from NLC, evidenced as discordance between the voltage dependence of each. This discordance is also variably affected by polarity and rate of voltage stimulation. Such discordance requires a rethinking of how the OHC may influence basilar membrane mechanics and cochlear amplification, possibly pointing away from previously envisioned mechanisms of mechanical feedback.

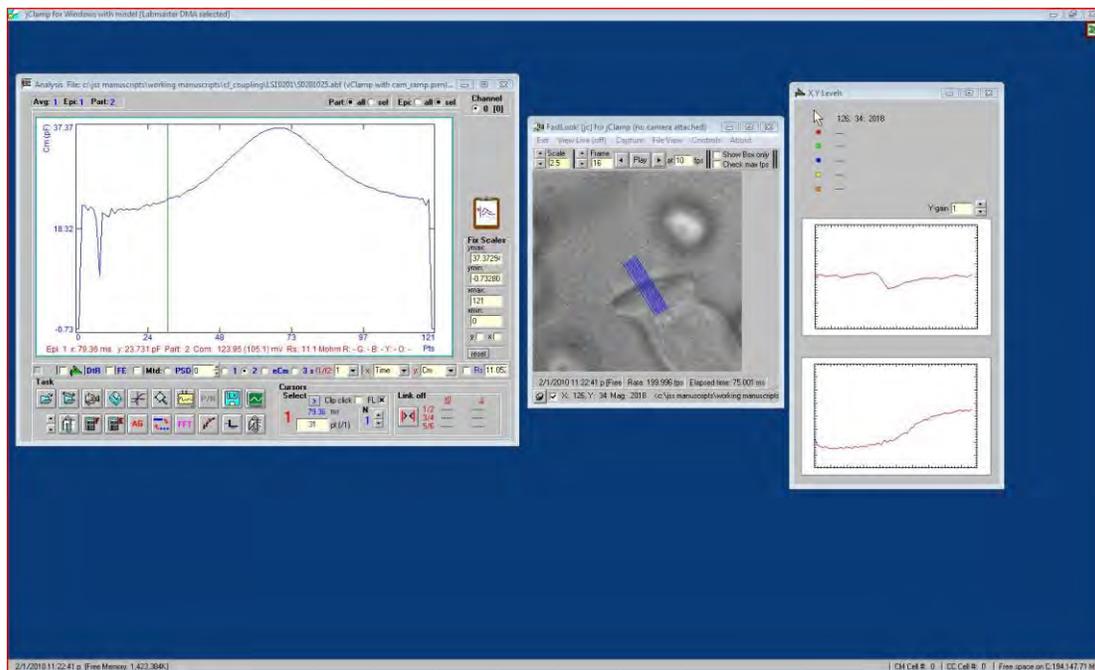

FIGURE 1. jClamp (Scisoftco.com) software was used to simultaneously measure NLC and electromotility. Capacitance measures were synchronized to video frame capture so that voltage dependence of NLC and motility could be compared. Motility functions were obtained by measuring movements of the cuticular plate edge, with the base of the OHC fixed by the patch electrode.

METHODS

OHCs were voltage clamped using an Axon 200B amplifier under jClamp (Scisoftco.com) software control. NLC and mechanical responses were measured simultaneously with depolarizing and hyperpolarizing ramps of 100 ms – 5 sec duration, effectively modulating the rate of voltage change. NLC was measured with a dual sine method [7] with a 390 Hz resolution, and mechanical responses were measured (in pixels; 15 pix/5 μm) from video images (Prosilica GE680 camera) synchronized within jClamp (Fig. 1) to the voltage stimuli. Frame rate was typically set at 200 fps. Solutions were as previously described [8]. Chloride was substituted with gluconate. No averaging was done. V_h (mid- point voltage) for motility functions was determined from midpoint of sigmoidal fits; V_h of NLC from peak capacitance.

RESULTS

Under voltage clamp, OHCs display a nonlinear capacitance that is bell shaped with its peak residing at a voltage (V_h) where motor charge movement is equally distributed on either side (Fig. 2A). Coupled to this nonlinear charge movement is a mechanical response of the whole cell that follows the charge's voltage dependence. Shifts in NLC V_h , induced by changing the long term holding potential (prepulse) of the cell,

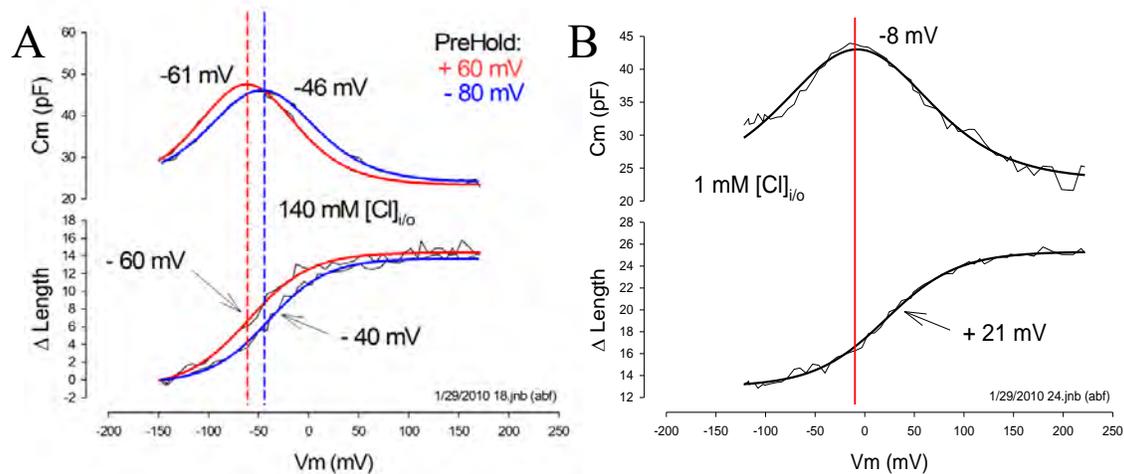

FIGURE 2. OHC NLC and electromotility share a common voltage dependence that changes when holding potential is changed. **A)** NLC and motility before and after holding resting potential for 2 minutes at indicated voltages. This effect is seen regardless of intracellular chloride concentration. **B)** However, when intracellular chloride is set low, NLC and motility voltage dependence are separated.

are accompanied by equivalent shifts in electromotility voltage dependence. This tight coupling between motor conformation and electromotility is seen when intracellular chloride is high, e.g., 140 mM, the typical intracellular level used for experimentation during the last few decades to study OHCs. More recently, normal OHC intracellular chloride levels were found to be < 10 mM [6], and given the significant influence of chloride on OHC motor charge movement [4,8,9], we evaluated the influence of chloride concentration on electromechanical coupling. Surprisingly, electromotility uncoupled from charge movement at low chloride levels (Fig. 2B and 3). We have found disparities in some cells as large as 50 mV between molecular and whole cell mechanical responses.

The disparity is not only chloride dependent, but increases as ramp rate is increased (data not shown). This increase resembles a visco-elastic like behavior. Lowering intracellular chloride changed the rate dependence of the uncoupling - low frequency effects were diminished and high frequency effects were augmented.

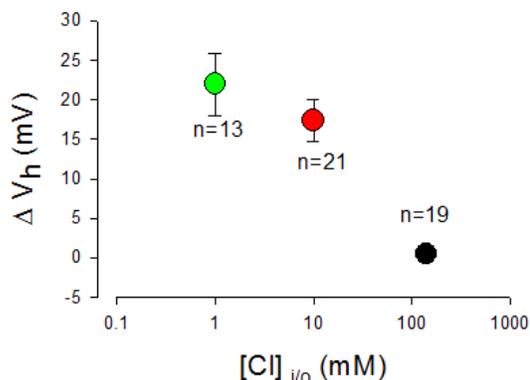

FIGURE 3. Average difference in V_h (ΔV_h) between NLC and mechanical response. No difference is observed when intracellular chloride is clamped to 140 mM. However, at lower levels an uncoupling of voltage dependence is apparent.

We also observed that coupling efficacy was stimulus polarity dependent, and was observable for voltage steps or ramps (Fig. 4). Uncoupling was larger for depolarizing excursions, suggesting work against the OHC cytoskeletal spring [10] during cell contraction. Interestingly, we find that agents which modify the cytoskeleton can

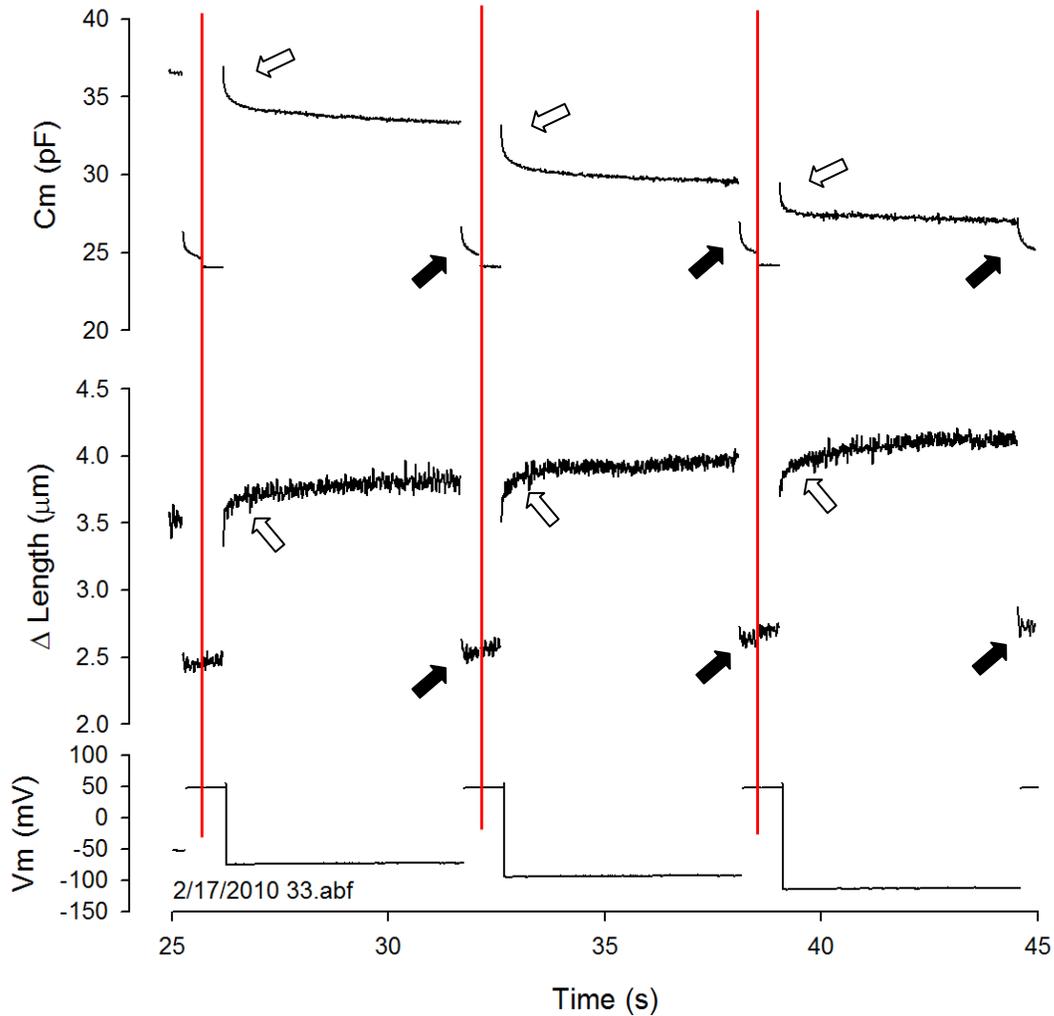

FIGURE 4. Simultaneous changes in OHC capacitance and OHC length during incrementing step changes in voltage, illustrating the polarity dependent coupling between motor charge movement and whole cell mechanical response. Red lines indicate a recovery period (1 sec) at 50 mV between voltage steps to hyperpolarized levels. Note that voltage steps in the hyperpolarizing direction induce synchronous time dependent changes in both NLC and electromotility (white arrows); however, returning depolarizing steps, though inducing similar time dependent changes (of opposite direction) in NLC, corresponding time dependent changes in electromotility are absent (black arrows). This polarity dependent coupling is observable with ramps of opposite polarity, as well (data not shown).

modulate the disparity, further suggesting that chloride influences a cytoskeletal-based coupling between prestin's conformational state and whole cell mechanics.

DISSUSSION

Coupling between the molecular conformation of prestin motors (estimated from nonlinear charge movement or NLC) and OHC whole cell mechanical response (measured directly by video) is not fixed. Depending on intracellular chloride and stimulus conditions, the voltage dependence of NLC and electromotility can vary independently. V_h of NLC is significantly influenced by initial voltage condition, and

has corresponding effects on electromotility. However, electromotility shows augmented effects attributable to degree of electromechanical coupling. Coupling is very tight with high intracellular chloride (140 mM), and at low rates of voltage perturbation. Even with normal low intracellular chloride concentrations (<10 mM, [6]), increases of voltage perturbation rate promotes growing voltage uncoupling of molecular and whole cell mechanical activity. Agents affecting the cortical cytoskeleton alter ramp rate effects, possibly by modifying lateral membrane stiffness/tension. These observations are expected to have considerable consequences *in vivo*; namely, whole cell mechanical activity of the OHC (and feedback into the basilar membrane that it is expected to provide) may not simply follow the membrane potential of the cell.

CONCLUSIONS

The uncoupling we find imposes an additional challenge for the voltage-sensitive protein prestin to drive the cochlear partition during acoustic stimulation, since the whole cell mechanical response will be variably uncoupled from voltage, depending on phase of receptor potential. On the other hand, the molecular conformation of prestin is tightly coupled, implying that membrane characteristics (e.g., changes in membrane stiffness) driven by prestin may more significantly govern “cochlea amplification” than electromotility.

Conformational State-Dependent Anion Binding in Prestin: Evidence for Allosteric Modulation

Lei Song and Joseph Santos-Sacchi*

Department of Surgery (Otolaryngology), Department of Cellular and Molecular Physiology, and Department of Neurobiology, Yale University School of Medicine, New Haven, Connecticut

ABSTRACT Outer hair cells boost auditory performance in mammals. This amplification relies on an expansive array of intramembranous molecular motors, identified as prestin, that drive somatic electromotility. By measuring nonlinear capacitance, the electrical signature of electromotility, we are able to assess prestin's conformational state and interrogate the effectiveness of anions on prestin's activity. We find that the affinity of anions depends on the state of prestin that we set with a variety of perturbations (in membrane tension, temperature, and voltage), and that movement into the expanded state reduces the affinity of prestin for anions. These data signify that anions work allosterically on prestin. Consequently, anions are released from prestin's binding site during expansion, i.e., during hyperpolarization. This is at odds with the extrinsic voltage sensor model, which suggests that prestin-bound intracellular anions are propelled deep into the membrane. Furthermore, we hypothesize that prestin's susceptibility to many biophysical forces, and notably its piezoelectric nature, may reflect anion interactions with the motor.

INTRODUCTION

Allosteric modulation of protein function is ubiquitous, denoting the control of a protein's conformational state (tensed versus relaxed) and activity by perturbation (via ligand or nonligand mechanisms) of sites distal to the protein's active site (1–4). Monod et al. (3) originally developed a concerted allosteric model to describe the effects of oxygen binding on hemoglobin, but this model has also been shown to be useful for understanding other proteins, including intramembranous proteins. For example, modeling the modulation of Maxi-K channels by voltage and Ca²⁺ has benefited from allosteric theory (5,6). One interesting consequence of allostery is the coupling of the conformational state and ligand-binding affinity, a phenomenon that forms the basis of state-dependent block of ion channels (7).

The conformational state of the outer hair cell (OHC) motor protein, prestin, is primarily driven by voltage. Changes in the conformational state of the molecule can be gleaned from the voltage dependence of its nonlinear charge movement or its equivalent bell-shaped nonlinear capacitance (NLC) (8, 9). Indeed, the voltage at peak capacitance (V_{pkcm}) or, equivalently, the half-maximal charge movement (V_h), is a sensitive indicator of the distribution of motors in the compact or expanded state, according to two-state models of OHC motor activity (10,11). However, the distribution is not fixed; rather, it depends on a host of external influences. Prolonged negative holding potentials (prepulse) (12), positive membrane tension (13–16), and increasing temperature (17,18) can each significantly shift V_{pkcm} rightward, in the depolarizing direction, in a multiexponential,

time-dependent manner (19), indicating a redistribution of compact motors into the expanded state.

Recent observations have established an important role for anions in controlling prestin and OHC function (20–24). Charge movement in prestin is modulated by Cl[−] ions with a $K_{1/2}$ of ~6 mM (21,22). We have argued that the binding of anions works allosterically to modify prestin activity (20,23–26). Here we capitalize on prestin's sensitivity to membrane tension, temperature, and voltage to show that prestin's binding affinity for the anions Cl[−] and salicylate is dependent on motor conformation, confirming an allosteric interaction.

MATERIALS AND METHODS

General preparation and procedure

Hartley albino guinea pigs were overdosed with halothane. The temporal bones were excised and the cochleae were dissected in a calcium-free (no chelator) solution and then treated with enzyme (0.5 mg/mL Dispase I, 10–12 min). Individual OHCs were isolated by gentle trituration. The suspension of cells was then transferred to a petri dish for the cells to settle.

The base extracellular solution contained (in mM) NaCl 132, CaCl₂ 2, MgCl₂ 2, and Hepes 10. The final solutions were adjusted to ~300 mOsm with D-glucose (except for the solutions used for the osmotic challenge experiment, which were adjusted to ~280 mOsm) and pH 7.2–7.3 with NaOH. The intracellular solution was the same as the extracellular solution except for the addition of 10 mM EGTA. Other Cl[−] levels were achieved by replacing Cl[−] with gluconate. Salicylate (10 mM) was added to the base extracellular solution (~300 mOsm, pH 7.2–7.3) and subsequently diluted into concentrations of 0.1, 1, 10, 100, 1000, and 10,000 μ M. Continuous local perfusion was achieved with the use of a custom-made Y-tube. Perfusion of salicylate either as a concentration series or at a single dose were performed with and without positive pressure in the patch pipette (increased tension at ~0.7 kPa). Pipette pressure was monitored via a pressure monitor (PM015R; World Precision Instruments, Sarasota, FL). Whole-cell NLC (see below) recordings were made after the pressure stabilized.

Experiments were performed at room temperature and at 32–35°C. To study the effect of temperature, bath solutions at room temperature were

exchanged with preheated bath solutions to increase the temperature around the OHC of interest. A temperature probe (model DP26-TC-AP; Omega Engineering) was placed in the bath near the recorded OHC to document the temperature rise. Recordings of NLC were made when the temperature rose $\sim 10^\circ\text{C}$. A Nikon Eclipse E600-FN microscope with a $40\times$ water immersion lens was used to observe cells during electrical measurements. Digital images were taken with a Hamamatsu image processor.

Patch-clamp and stimulus protocols

OHCs were recorded under a whole-cell, patch-clamp configuration. An Axon 200B amplifier was used for data collection. NLC was measured using a continuous high-resolution (2.56 ms sampling) two-sine stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz) superimposed on a 200 ms voltage ramp from -180 to $+200$ mV (12,27). All recordings and analyses were performed using jClamp (SciSoft, Ridgefield, CT; www.scisoftco.com). Capacitance data were fit to the first derivative of a two-state Boltzmann function (8):

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}} \text{ where}$$

$$b = \exp\left(\frac{-ze(V_m - V_{\text{pk}C_m})}{kT}\right),$$

where Q_{\max} is the maximum nonlinear charge moved; $V_{\text{pk}C_m}$ or V_h is the voltage at peak capacitance or, equivalently, at half-maximum charge transfer; V_m is the membrane potential; z is the valence; C_{lin} is the linear membrane capacitance; e is the electron charge; k is Boltzmann's constant; and T is the absolute temperature. Q_{sp} , the specific density of charge movement is defined as $Q_{\max}/(C_{\text{lin}} - 6.5 \text{ pF})$; 6.5 pF corresponds to the area in OHCs devoid of prestin NLC (28). Peak NLC was calculated by subtracting the linear capacitance (C_{lin}) from the peak amplitude (C_{mpk}). We used C_{lin} determined from the fit to each individual NLC trace. Paired t -tests were used and reported as the mean \pm SE. Dose response curves were fitted in SigmaPlot (Systat Software) using a four-parameter Hill equation. For the Cl^- dose response curve, the low-concentration end point was fixed to 25% of the maximum charge because we previously determined this asymptote using a full range of Cl concentrations (22).

RESULTS

Membrane tension alters the IC50 of salicylate on NLC

Salicylate is known to block NLC in OHCs via intracellular interactions with the motor (29,30). Recently, it was shown that salicylate competes with Cl^- for prestin's anion-binding site(s) (20,21). We assessed salicylate's relative affinity (competition with Cl^-) by noting the degree of reduction in NLC with intracellular Cl^- fixed at 10 mM, the normal resting level of chloride (20). Fig. 1, A and B, demonstrate that with a fixed extracellular salicylate perfusion of 0.1 mM, tension reduced the effectiveness of the salicylate insult (intra- and extracellular solutions both contained 10 mM Cl). The reduction of nonlinear peak capacitance was 11.22 ± 0.68 pF for collapsed cells and 7.44 ± 1.15 pF for pressurized (~ 0.7 kPa) cells ($n = 4$, $P < 0.01$, paired t -test). In percentage terms, this corresponds to reductions of 22.08% and 16.57%, respectively. Since the perfusion is done extracellularly, it is possible that the manipulation of membrane tension can change membrane properties such that salicylate entry into the cells will be different under the

two conditions. To rule out this possibility, we introduced 0.1 mM salicylate intracellularly via the patch pipette, and obtained comparable significant results. Indeed, even with equal concentrations of salicylate intra- and extracellularly, similar results were obtained. The use of an osmotic challenge (~ 280 mOsm) produced comparable results (data not shown).

Tension effects were explored in greater detail in another set of experiments to measure the IC50 of salicylate. A series of salicylate concentrations (0.1–10,000 μM) were applied to OHCs first under collapsed conditions and then, after complete washout (assessed by the return of NLC to pretreatment conditions), under pressurized conditions (~ 0.7 kPa). Fig. 1 C illustrates the shift in the dose response curve obtained for a single OHC. Data from four cells (with pipette solutions containing 10 mM Cl^-) yielded a shift of IC50 from 144.77 ± 61.33 to 550.05 ± 221.49 mM. This represents an ~ 4 -fold reduction in effectiveness, indicating an equivalent reduction in the affinity of salicylate for prestin. For cells with 140 mM Cl^- in and out, the shift for IC50s for salicylate dose response curves was from 333.89 ± 46.81 to 563.77 ± 27.99 mM ($n = 3$). The smaller shift at higher chloride levels is consistent with our previous finding that salicylate is more effective at lower chloride levels (20).

Membrane voltage prepulse and temperature alter salicylate's effect on NLC

The data obtained so far indicate that increasing membrane tension, which tends to redistribute the motors into the expanded state, reduces the affinity of salicylate for prestin's anion-binding site. If the conformation of prestin were responsible for this effect, we would expect any method we used to redistribute prestin into the expanded state to work similarly. Fig. 2 A confirms that by heating the cells, we diminished the ability of salicylate to reduce NLC. The average reductions of nonlinear peak capacitance for 1 mM salicylate treatment were 9.9 ± 1.00 pF at room temperature and 5.58 ± 0.73 pF after an $\sim 10^\circ\text{C}$ increase in bath temperature ($n = 4$, $P < 0.05$, paired t -test). Intermediate temperatures between room temperature and $+10^\circ\text{C}$ were proportionally effective. The effectiveness of salicylate insult (reduction of NLC) fell at a rate of 0.366 pF/ $^\circ\text{C}$ with increases in temperature (see Fig. S1 in the Supporting Material).

Additionally, Fig. 2 B shows that holding at negative voltages, which redistributes prestin into the expanded state, diminishes the ability of salicylate to reduce NLC. The average reduction of nonlinear peak capacitance for 1 mM salicylate treatment was 10.50 ± 0.16 pF at $\sim +55$ mV holding potential and 6.41 ± 1.05 pF at ~ -75 mV holding potential ($n = 4$, $P < 0.005$, paired t -test). Intermediate holding voltages between $+55$ and -75 mV were proportionally effective. The effectiveness of salicylate insult (reduction of NLC) fell at a rate of 0.029 pF/mV with hyperpolarization (see Fig. S1).

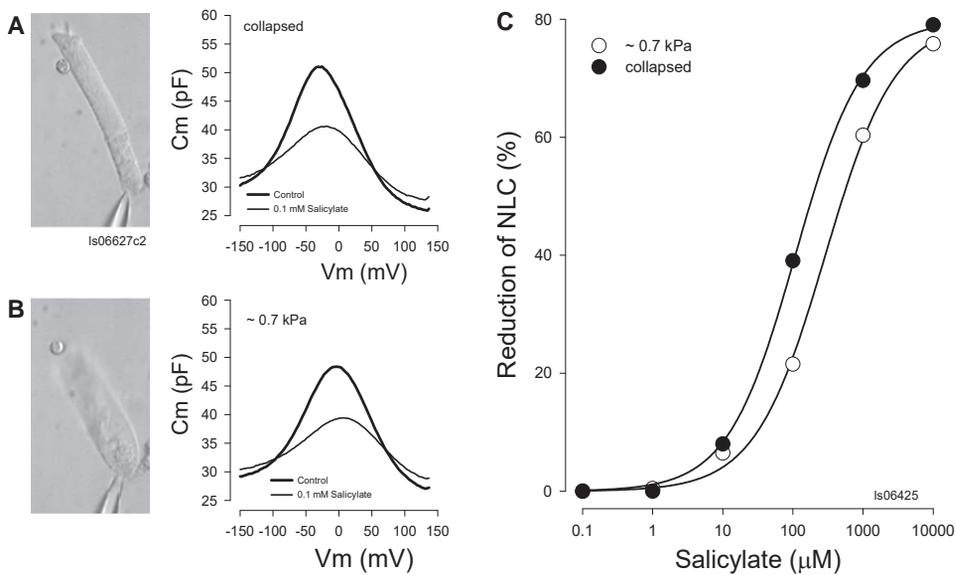

FIGURE 1 Competition between salicylate and chloride for prestin's anion-binding site is dependent on membrane tension. (A) Image of patch-clamped OHC under collapsed conditions and associated NLC traces obtained before (control) and after perfusion with 0.1 mM salicylate. Cell diameter is 10 μm . (B) Corresponding image (note the reduced length and increased diameter of cell) and NLC traces for the same cell after an increase in pipette pressure (0.7 kPa). The averaged reduction of nonlinear peak capacitance due to salicylate perfusion is 11.22 ± 0.68 for collapsed cells and 7.44 ± 1.15 pF ($n = 4$, mean \pm SE, $P < 0.01$, paired t -test). (C) Plot from another cell of the dose response curve for salicylate before and after membrane tension delivery. Averaged results show a shift in IC_{50} from 144.77 ± 61.33 to 550.05 ± 221.49 (mean \pm SE).

Membrane tension reduces chloride's binding affinity for prestin

Finally, we confirmed the generality and physiological significance of our results by testing the effects of membrane tension on Cl-anion affinity. In this series of experiments, the chloride concentration was set to the same level intra- and extracellularly, and the effects of membrane tension on NLC were determined for a range of chloride ion concentrations (1–140 mM). NLC was measured first under collapsed conditions and then under pressurized conditions (~ 0.7 kPa). Fig. 3 A illustrates the average shift ($n = 4$ –5) in the dose response curve. The fitted sigmoidal (Hill) functions indicate a $K_{1/2}$ of 1.68 mM under collapsed conditions, and 4.74 mM under pressurized conditions. The shift of V_{pkcm} due to ~ 0.7 kPa pressurization is ~ 20 mV to the right regardless of chloride concentration (Fig. 3 B), indicating that the results are not due to chloride-dependent changes in the susceptibility to membrane tension.

It is important to note that with each type of manipulation available to us, we had to limit the perturbation magnitude to maintain our cell recordings during the lengthy protocols; therefore, we obtained only a limited interrogation of the changes in binding affinity that might be realized by a complete shift between compact and expanded states.

DISCUSSION

The OHC motor is voltage-dependent (31) and possesses a voltage sensor that controls its conformational state (compact/expanded) at rates in excess of 75 kHz (10,11,32). The voltage dependence of the sensor charge movement is shallow, with a Boltzmann slope factor of ~ 29 mV, and thus very large voltage changes (>200 mV)

are required to fully redistribute motors between its two conformations (compact and expanded) (8, 9). The midpoint voltage (V_{pkcm} or V_h) of this operational range can be modified by several manipulations, including membrane tension, prior (prepulse) holding voltage, and temperature. The effect of tension on V_{pkcm} is on the order of a 20 mV rightward (i.e., depolarizing) shift per kPa of intracellular pressure, with the cell being able to withstand only a few kilopascals before it ruptures (15,16). Changes in the holding potential can shift V_{pkcm} tens of millivolts, with the shift being opposite to the prepulse polarity and having maximum effectiveness near normal resting potentials (12,19). Increases in temperature cause a 20 mV rightward shift per 10°C (17,18).

In this work, we exploited prestin's sensitivity to these biophysical forces to test the hypothesis that anions work allosterically by interrogating the effect of the motor conformational state on anion affinity. Although we were only able to interrogate conformation-dependent binding affinity over a limited population shift between compact and expanded states (see Materials and Methods), each perturbation we made to shift the state dependence of prestin motors from the compact to the expanded state reduced the affinity of the tested anion for the motor. We reason that prestin's anion-binding site, which has been tentatively identified in prestin as homologous to the Cl-binding motif conserved in ClC channels (GXXXP (26,33,34)), is altered during induced conformational change to modify binding affinity for anions. We especially note a parallel in the reciprocal nature of the voltage dependence and tension dependence of prestin (piezoelectricity) and the reciprocal nature of anion binding and the conformational state of prestin (allostery). The piezoelectric nature of prestin was first identified by Iwasa (13), who found that membrane tension can cause

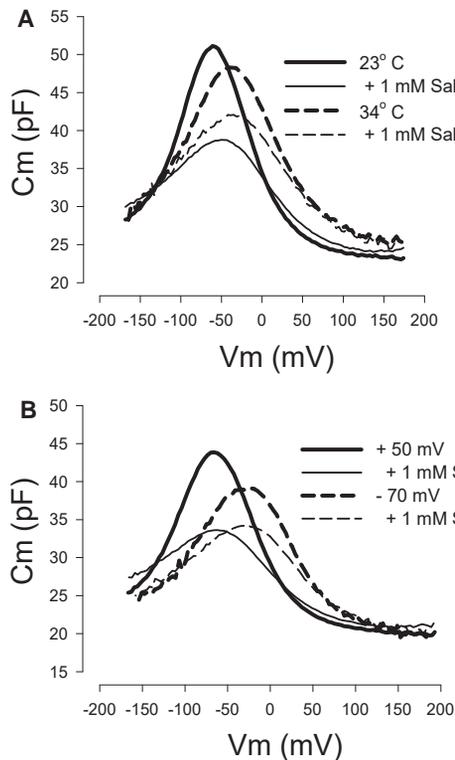

FIGURE 2 Competition between salicylate and chloride for prestin's anion-binding site is dependent on temperature and holding voltage. (A) A representative OHC was whole-cell patched with 140 mM Cl^- in and out, and perfused with 1 mM salicylate first at 23°C (solid lines) and then at 34°C (dashed lines). The reduction of NLC after salicylate perfusion (thin lines) is less under the high-temperature condition. Average reductions of nonlinear peak capacitance for salicylate treatment are 9.9 ± 1.00 pF (mean \pm SE) vs. 5.58 ± 0.73 pF (mean \pm SE) ($n = 4$, $P < 0.05$, paired t -test). (B) A representative OHC was whole-cell patched and perfused with 1 mM salicylate at room temperature. The OHC was held at either -70 mV (dashed lines) or $+50$ mV (solid lines). The reduction of NLC after salicylate perfusion (thin lines) is less at the -70 mV holding potential. The average reduction of nonlinear peak capacitance for salicylate treatment is 10.50 ± 0.16 (mean \pm SE) at positive holding potentials and 6.41 ± 1.05 (mean \pm SE) at negative holding potentials ($n = 4$, $P < 0.005$, paired t -test).

a shift in the voltage dependence of OHC NLC; thus, tension can induce displacement currents in the OHC (14,35). This linkage between deformation and electrical activity is greater in the OHC than in piezoelectric crystals (36), and has been the focus of models that aim to enhance the frequency-dependent effects of electromotility (37). We conjecture that the piezoelectric nature of prestin may ultimately reside in the allosteric action of anions. Furthermore, we hypothesize that the sensitivity of prestin to the range of biophysical perturbations observed to influence the state of the motor may involve anion interactions with the motor. To be sure, the shift magnitudes from membrane tension, temperature, and prepulse are dwarfed by that observed when physiologically tolerable chloride concentrations are changed within the OHC: at the $K_{1/2}$ for the Cl^- -dependent V_{pkcm} shift

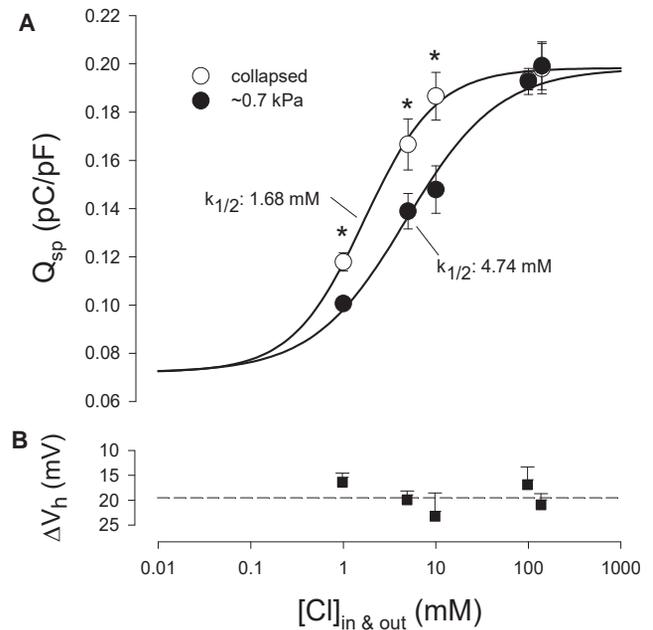

FIGURE 3 Chloride binding to prestin is state-dependent. OHCs were whole-cell patched and NLC was recorded. Chloride concentration was set to the same level intra- and extracellularly, and the effects of membrane tension on NLC were determined for a range of chloride ion concentrations (1–140 mM). NLC was measured first under collapsed conditions and then under pressurized conditions (~ 0.7 kPa). OHC NLC was fitted (Eq. 1) to determine V_h and total nonlinear charge moved (Q_{max}), with Q_{max} normalized to cell surface area (Q_{sp}) for comparison across cells. (A) OHC Q_{sp} is Cl^- -dependent, with $\sim 25\%$ of the charge insensitive to chloride as demonstrated previously (22). Changing prestin's state by application of positive membrane tension shifts the dose response curve to the right. Paired t -test significance (*, $P < 0.05$; $n = 4-5$) is noted in the figure. The fitted sigmoidal (Hill) functions indicate a $K_{1/2}$ of 1.68 mM under collapsed conditions and 4.74 mM under pressurized conditions. (B) The shift of V_h due to ~ 0.7 kPa pressurization is ~ 20 mV to the right regardless of chloride concentration, indicating no chloride-dependent changes in the susceptibility to membrane tension.

(4.8 mM, close to the resting intracellular $[\text{Cl}^-]$ (20)), the shift is ~ 8 mV/mM (22). Thus, we would predict that other perturbations that affect the prestin state, such as changes in the membrane lipid environment of OHCs (38,39) or prestin-transfected cells (40), result from alterations of anion-binding affinity.

The competitiveness of salicylate with chloride for prestin's anion-binding site results from a higher affinity for salicylate over chloride (21). If we assume that chloride and salicylate binding affinity can be manipulated independently, then the reduced binding affinity of chloride by our manipulations could have increased salicylate's effectiveness. This was not the case, and we must conclude that our manipulations affect the binding site in a manner that influences binding of all anions. Thus, the effects of salicylate are direct, and not a result of displacing chloride. This is in line with the variable effects of different species of anions on NLC (25).

In summary, all perturbations that caused V_{pkcm} to shift in the depolarizing direction, i.e., that caused prestin motors to move into the expanded state, reduced prestin's anion-binding affinity. These observations have direct implications for the mechanism of voltage sensing in prestin (Fig. 4). Oliver et al.'s (21) popular model of prestin as a dysfunctional anion transporter, in which an intracellular chloride anion serves as extrinsic voltage sensor, predicts that truncated transport of chloride from its intracellular binding site on prestin to an extracellularly directed intramembranous site within the protein evokes prestin's expanded state. On the contrary, our data necessarily indicate that intracellularly bound anions are released (due to reduced affinity) upon motor expansion, and thus conflict with their model. We maintain that anion binding is associated with motor contraction and OHC shortening, in line with our previous observations that increasing Cl^- intracellularly boosts the number of motors residing in the contracted state (22,23). Of interest, an analysis of a variety of models, including those resulting from intrinsic sensing, extrinsic sensing, and a combination of transporting and sensing mechanisms, found that predicted movements of chloride during transport are associated with the contraction of prestin (41). We believe these fine points of contention with the extrinsic voltage sensor model can be used to argue for a general mechanism of allostery that portrays prestin as a protein of normal character that does not require unusual modes (or models) of action. To be sure, we determined that the sensor charge movement in prestin relies on particular charged residues, as is the case in other voltage-dependent proteins (42), and that prestin's voltage-dependent charge movement can be isolated from its anion transport (26). These data do not imply that models that detect (incorporate) composite charge movement contributions from anions and intrinsic residues are faulty in their

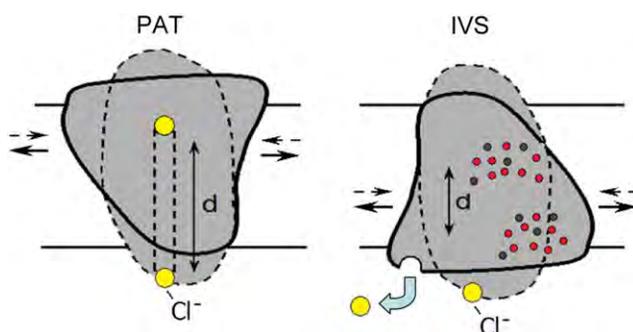

FIGURE 4 Two models representing the events after anion binding to prestin. The left panel depicts the extrinsic voltage sensor model (21), where Cl^- binds and enters the defunct transporter, which in turn triggers an extension of prestin. The right panel depicts the intrinsic voltage sensor model (23–25), where Cl^- binding to prestin allosterically promotes the contracted state, but voltage sensing results from movement of intrinsically charged amino acid residues (red: positive residues; black: negative residues) (26). Our new data confirm that during expansion, anions are released from prestin. (In both panels, d is the perpendicular distance traversed across the membrane field by the voltage sensor.)

assessment of NLC (41,43), as we fully acknowledge that any charged species moving through the membrane field can contribute to NLC. We simply want to point out that the assignment of charge components to effect electromotility or not is not a simple process, and it could be that the movement of a transported anion through prestin (and its resultant displacement current) is unrelated to the mechanism that drives the voltage-dependent mechanical activity of the protein. Thus, the only thing that is absolutely clear to us is that NLC is modulated by anions. Consequently, our new findings and our previous observations that also conflict with the extrinsic voltage sensor model—namely, that 1), changes in the intracellular anion concentration and species shift the voltage dependence of NLC (V_{pkcm}); 2), the anion valence does not correlate with the voltage sensor valence; 3), prestin successfully transports anions; 4), the intrinsic charge contributes to prestin's voltage sensing; and 5), single-site mutations can separate voltage sensing and transport (23,25,26)—lead us to conclude that anions work through an allosteric action on prestin.

Disparities in voltage-sensor charge and electromotility imply slow chloride-driven state transitions in the solute carrier SLC26a5

Outer hair cells (OHCs) drive cochlear amplification that enhances our ability to detect and discriminate sounds. The motor protein, prestin, which evolved from the SLC26 anion transporter family, underlies the OHC's voltage-dependent mechanical activity (eM). Here we report on simultaneous measures of prestin's voltage-sensor charge movement (nonlinear capacitance, NLC) and eM that evidence disparities in their voltage dependence and magnitude as a function of intracellular chloride, challenging decades' old dogma that NLC reports on eM steady-state behavior. A very simple kinetic model, possessing fast anion-binding transitions and fast voltage-dependent transitions, coupled together by a much slower transition recapitulates these disparities and other biophysical observations on the OHC. The intermediary slow transition probably relates to the transporter legacy of prestin, and this intermediary gateway, which shuttles anion-bound molecules into the voltage-enabled pool of motors, provides molecular delays that present as phase lags between membrane voltage and eM. Such phase lags may help to effectively inject energy at the appropriate moment to enhance basilar membrane motion.

hearing | molecular motor

Outer hair cells (OHC) foster mechanical feedback within the mammalian cochlear partition that enhances perception of auditory stimuli by 2–3 orders of magnitude; this is known as cochlear amplification (1, 2). Following the molecular identification of prestin (3), an SLC26 family member (a5) that recapitulates the electromechanical properties of the native OHC's voltage sensor/motor (4, 5), a preponderance of evidence pointed to prestin-based electromotility (eM) as the basis of this boost (6, 7). During the last couple of decades, measures of nonlinear charge movement or capacitance (NLC), an electrical correlate of voltage-dependent conformational changes within the motor protein prestin, have served as surrogate, indeed as signature, of voltage-evoked eM of the OHC (8–12). Intracellular chloride plays an important role in prestin function (13), and recent evidence indicates that anions serve a modulatory, allosteric-like role (14–17). For the most part, anion effects, as well as many other influences on prestin, have been limited to the study of NLC, on the assumption that NLC reports on steady-state characteristics of OHC eM. We now show that this assumption is wrong.

Using simultaneous measures of charge movement and eM, we show disparity between deduced characteristics of prestin motor protein conformation. That is, a dissociation in magnitude and voltage dependence of NLC and eM is revealed by lowering intracellular chloride to physiological levels (≤ 10 mM; ref. 6), all previous comparisons having been made with abnormally high intracellular chloride levels. Furthermore, this chloride effect, which presents as a function of rate and polarity of voltage stimulation, uncovers a mechanism predicted to be frequency dependent *in vivo*, and likely plays an important role in frequency selectivity and efficiency of cochlear amplification. A very simple kinetic model, which recapitulates most known behaviors of prestin, indicates that the chloride effect is due to intermediary, non-voltage-dependent transitions, the kinetics of

which are very much slower than those of prestin's chloride-binding or voltage-dependent state transitions. These slow conformational changes likely derive from prestin's lineage as a slow anion transporter, providing lags between voltage stimulation and mechanical activity, possibly contributing to productive cochlear amplification.

Methods

Recordings were made from single isolated OHCs from the organ of Corti. Hartley albino guinea pigs were overdosed with isoflurane, the temporal bones excised, and the top turns of the cochleae dissected free. Enzyme treatment (1 mg/mL Dispase I, 10 min) preceded gentle trituration, and isolated OHCs were placed in a glass-bottom recording chamber. A Nikon Eclipse E600-FN microscope with 40 \times water immersion lens was used to observe cells during voltage clamp. Experiments were performed at room temperature.

Solutions. Chloride levels were set to bracket the intracellular level in intact OHCs, namely ~ 10 mM (6). An ionic blocking solution was used to remove ionic currents, allowing valid measures of membrane capacitance. The base high Cl solution contained (in millimoles): NaCl 100, tetraethyl ammonium-Cl 20, CsCl 20, CoCl₂ 2, MgCl₂ 1, CaCl₂ 1, Hepes 10. Lower chloride concentrations (10 and 1 mM) were achieved by substituting chloride with gluconate. In a subset of experiments, aspartate was used as the substitute. Base intracellular solutions contains (in millimoles): CsCl 140, MgCl₂ 2, Hepes 10, and EGTA 10. The intracellular and extracellular Cl concentration was set the same to guarantee levels in the subplasmalemmal space of the OHC.

Manipulation of the subsurface cytoskeletal integrity was made with diamide and latrunculin. Diamide works on spectrin to unbundle actin filaments and reduce OHC stiffness (18). On the other hand, latrunculin results in actin depolymerization (19). OHCs were treated with 2 mM diamide in extracellular solutions for 30 min before recordings. Latrunculin A (0.01 μ M) was perfused both intracellularly (via patch electrode) and extracellularly during recording. All chemicals used were purchased from Sigma.

Cell Capacitance and Mechanical Response. An Axon 200B amplifier was used for whole cell recording. Coupled voltage ramps (depolarizing followed immediately by hyperpolarizing ramp) of varying durations from 100 to 5,000 ms were delivered to the cells from a holding potential of 0 mV. In a subset of cells, ramp order was reversed after routine collection and comparison of the two yielded no significant differences. The ramp voltage was set between -250 and $+250$ mV maximum, but span was fixed at 360 mV. For each individual cell, the ramp voltage was set according to V_h of NLC permitting responses to reach steady state to ensure good Boltzmann fits. No averaging was done.

Nonlinear capacitance was measured using a continuous high-resolution (2.56-ms sampling) two-sine stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz) superimposed onto the voltage ramp (20, 21). Capacitance data were fit to the first derivative of a two-state Boltzmann function (9) (see *Supporting Information* for equation), providing Q_{max} , the maximum nonlinear charge moved, V_h the voltage at peak capacitance or equivalently,

at half maximum charge transfer, z , the valence, and C_{lin} the linear membrane capacitance.

Simultaneous eM measurements were recorded with a Prosilica GE680 camera (Allied Vision Technologies). Video sampling of 3.3 ms were achieved with binning and reduced region of interest. Video image resolution was 2.83 pixels per micrometer. The eM video recordings were digitally analyzed with jClamp (www.SciSoftCo.com), allowing synchronous assessment of eM and NLC in time and voltage. The edge of the cuticular plate was used to track OHC length change, the patch electrode providing a fixed point at the basal end of the cell. Sigmoidal fits (four parameters) provided estimates of V_h , maximal movement and slope factor b . Shift of motility against NLC is calculated by subtracting NLC V_h from eM V_h .

Model Assessment. The kinetic model was assessed using Matlab Simulink in conjunction with jClamp. jClamp provides an automation link to Matlab, which allows voltage stimuli to be delivered to and current responses to be obtained from Simulink models. The kinetic model was interfaced to jClamp via a model of the patch clamp amplifier and OHC. The linear component of the patch-cell model possessed an R_s of 5 M Ω , R_m of 500 M Ω , and C_{lin} of 15 pF. The nonlinear component, NLC derived from charge movement of the prestin model, parameters laid out in *Results*. The exact same voltage stimuli and exact same analysis of model two-sine currents were performed as with the biophysical data. Mechanical contraction data of the model, namely eM, was taken as the accumulated residence in the C state. Fits of model NLC and eM were performed the same way as the biophysical data.

Although this parallel approach provides for powerful comparisons between model and biophysical data, it is laborious. Thus, only visual “fits” to the data are presented because no automatic iteration is possible. Instead, each set of model parameters was selected and compiled in Matlab. Then jClamp was used to stimulate, collect, and analyze the resulting model data, as was done

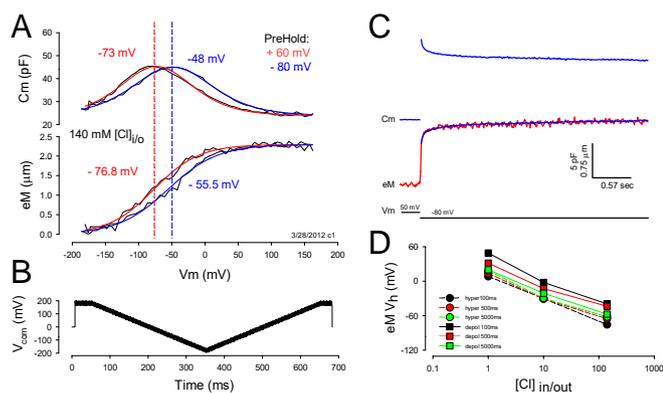

Fig. 1. Nonlinear capacitance and eM are coupled. (A) OHCs possess a capacitance that is nonlinear with voltage. Its peak resides at a voltage, V_h , that changes depending upon holding potential. In this case, V_h is -73 mV after holding the cell at $+60$ mV for one minute (red line). V_h shifts to -48 mV after holding the cell at -80 mV for one minute (blue line). Similar shifts are observed for eM. Fits: (red) NLC V_h -73.10 , z 0.69 , Q_{max} 3.15 , C_{lin} 23.86 ; eM V_h -76.81 , b 33.96 , eM_{max} 2.42 ; (blue) NLC V_h -48.76 , z 0.63 , Q_{max} 3.42 , C_{lin} 23.90 ; eM V_h -55.48 , b 37.13 , eM_{max} 2.41 . (B) Voltage stimulus used for the collection of capacitance and eM. Dual sine superimposed on ramps is used to evaluate C_m (Methods). Measures shown in A were obtained with hyperpolarizing ramps. The effects of ramp duration and polarity are described in subsequent figures. (C) A step voltage from 50 to -80 mV induces an elongation of the OHC (red trace) and simultaneous jump in C_m (blue trace). C_m relaxes with a stretched (multi) exponential time course that is mirrored by eM. The C_m trace was inverted, scaled and overlaid onto the eM trace (blue trace on red), showing similar time courses. (D) eM shifts in the depolarizing direction when intracellular chloride is reduced. The eM and NLC were measured simultaneously with hyperpolarizing and depolarizing ramps at the indicated ramp durations/rates. Regardless of polarity or rate, a large shift of V_h is observed, but the absolute values of V_h are more depolarized with longer depolarizing ramps. Number of cells averaged is the same as indicated in Fig. 3 A–C. SEs are not plotted for clarity. They are for 1, 10, and 140 mM Cl: black squares, 4.5, 3.7, and 3.8 mV; red squares, 5.0, 3.8, and 2.7; green squares, 7.3, 3.8, and 9.6; black circles, 4.6, 4.2, and 3.8; red circles, 3.5, 5.2, and 4.3; and green circles, 5.4, 6.0, and 10.6.

with OHCs. The data were then plotted for comparison with biophysical data, followed by visual determination of goodness of fit. Another choice of model parameters was then made and the process repeated. In consequence, an enormous amount of time was invested in obtaining model data.

Results

Experiment. Under voltage clamp, OHCs display an NLC that is bell shaped with its peak magnitude residing at a voltage (V_h), where prestin’s charge is equally distributed on either side, similar in behavior to an ionic channel’s voltage-sensor charge (22) (Fig. 1A). Coupled to this nonlinear charge movement is a mechanical response of the whole cell (a length change; eM) that follows the charge’s voltage dependence. Shifts in NLC V_h along the voltage axis, known to be induced by changing the long-term holding potential (prepulse) of the OHC or prestin-transfected cells (4, 20, 23), are accompanied by corresponding shifts in eM voltage dependence. In this example (Fig. 1A), a V_h shift of 25 mV for OHC NLC arises, along with a parallel V_h shift of 21.3 mV for eM. Furthermore, Fig. 1C illustrates that the time course of OHC length change follows the time course of NLC during step voltage stimulation, each showing stretched (multi) exponential behavior (23). This tight coupling between NLC and eM is observed when intracellular chloride is high, e.g., 140 mM, the typical intracellular level used for experimentation during the last few decades to study OHCs.

Recently, the level of intracellular chloride was estimated to be ≤ 10 mM in OHCs (6). As noted above with hyperpolarizing prepulses, lowering intracellular chloride is known to shift NLC V_h to depolarized levels (14). We confirm that the same is true for eM (Fig. 1D). Here, voltage ramps (± 180 mV) of different duration/rate (100–5,000 ms or equivalently 4–0.08 mV/ms) and polarity drove eM, while simultaneously summed high-frequency dual-sine stimuli reported on NLC (see *Methods* for details; refs. 20, 21). Although eM V_h shifted to depolarized levels regardless of protocol rate, the faster depolarizing ramps produced a more depolarized V_h . It was surprising that, although lowering intracellular chloride levels shifts both NLC V_h and eM V_h to positive voltages, a disparity between V_h of NLC and eM arises (Fig. 2). As chloride levels reduce, V_h of eM is shifted further to the right than V_h of NLC. In the examples shown, 10 mM chloride produced a disparity of 15.3 mV, and 1 mM chloride produced a disparity of 39.7 mV. This disparity is dependent not only on chloride level, but also on rate and polarity of voltage ramp stimulation (Fig. 3 A–C). Note that there is a chloride-dependent ΔV_h disparity that is greater in the depolarizing ramp direction as rate is increased, reaching an average disparity of about 45 mV with depolarizing 100-ms ramps; but even at very slow ramp rates, a chloride-dependent disparity remains. A large disparity is also observed when we instead use aspartate to replace chloride (Fig. 3C). Finally, there is a decrease in disparity with shorter ramp durations in the hyperpolarizing direction, and with 140 mM chloride, little disparity exists, which accounts for assertions of good electromechanical coupling during the last couple of decades (8–12).

In addition to disparity in voltage dependence, there is disparity in correspondence between maximal charge movement (Q_{max}), estimated from Boltzmann fits to NLC, and maximal eM (eM_{max}), estimated from sigmoidal fits to eM. Q_{max} has been taken to report on the number of elementary charged motors (prestins) in the OHC (8, 9), and consequently, there is a correlation between prestin surface expression and Q_{max} (24). Because it is undisputed that prestin conformational changes drive eM (25), the number of active prestin molecules should correspond to measures of eM, with eM_{max} correlated with Q_{max} . Fig. 3D shows that this is not the case; that is, although chloride reduction significantly reduces Q_{max} , eM does not follow. For example, eM_{max} values (mean \pm SE in micrometers; $n = 9$ –14) for 500-ms hyperpolarizing ramps were 2.19 ± 0.12 @ 1 mM; 2.01 ± 0.20 @ 10 mM; and 2.41 ± 0.28 @ 140 mM chloride. Corresponding Q_{max} values (mean \pm SE in picocoulombs, $n = 9$ –12) were 2.04 ± 0.09 , 2.86 ± 0.09 , and 3.10 ± 0.03 . Neither eM_{max} nor Q_{max} magnitude was significantly different for hyperpolarizing or

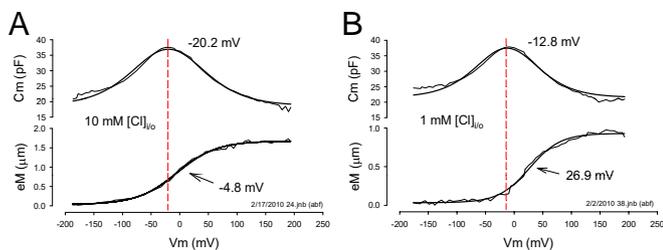

Fig. 2. Reduction of intracellular chloride toward physiological levels reveals disparity in NLC and eM operating voltage range. (A) The 10 mM chloride condition evidences a V_h disparity of 15.3 mV with eM more depolarized than NLC. Fits: NLC V_h , -20.15, z 0.59, q_{max} 3.17, C_{lin} 18.66; eM V_h , -4.87, b 34.58, eM_{max} 1.64. (B) Under 1 mM chloride conditions the disparity is larger, namely, 39.7 mV. Fits: NLC V_h , -12.87, z 0.68, q_{max} 2.38, C_{lin} 21.50; eM V_h , 26.92, b 26.78, eM_{max} 0.9.

depolarizing ramps. The slope factor (b ; *Methods*) of eM with 140 mM at this 500-ms ramp rate was 34.8 ± 0.84 mV, which translates to 17.3 nm/mV maximal sensitivity ($eM_{max}/4b$). This is similar to previously reported values (26, 27).

Iwasa (28) first identified the membrane tension dependence of OHC NLC and introduced a mechanical energy term in the Boltzmann model of prestin (29). In confirmation of its molecular nature, tension dependence was subsequently shown to have direct action on the motor/prestin (4, 5, 10). The susceptibility of fast ramp rate effects to perturbations of whole-cell mechanics is illustrated with turgor pressure manipulations (Fig. 3 E–G). Increasing turgor pressure, which increases membrane tension, eliminates the disparity (ΔV_h) evidenced with 100-ms ramps. Also revealed are disparate changes in V_h of NLC and eM. Whereas, the V_h of NLC shifts in the depolarizing direction during increases in membrane tension regardless of ramp polarity, the direction of V_h shift of eM depends on ramp polarity. That is, hyperpolarizing ramps cause near-equivalent depolarizing shifts in V_h of eM and NLC; depolarizing ramps, on the other hand, cause a hyperpolarizing shift in eM V_h . It is this differing behavior that accounts for the elimination of ΔV_h during increases in membrane tension, and points to a molecular phenomenon.

To ensure that the observations that we observe derive from molecular actions of prestin, rather than mechanical characteristics of the cell, we perturbed the cytoskeleton. We treated OHCs with latrunculin (an agent causing actin depolymerization) and diamide (a spectrin, actin-bundling protein antagonist), each of which is expected to modify the OHC cortical cytoskeleton. Fig. 4 illustrates that only minor changes in the fast rate effects are evident. These small effects we attribute to the influence of the cytoskeleton in controlling tension delivered to the membrane.

Model. In the two-state area motor model of OHC electromotility (29, 30), the accumulation of prestin motors into the contracted state (small surface area) will shorten the cell, and accumulation into the expanded state (large surface area) will lengthen the cell. This two-state model cannot reproduce our data (see below). To understand the molecular events underlying our time- and chloride-dependent observations, we developed an extended, yet very simple kinetic model, schematized in Fig. 5A.

Similar to carbonic anhydrase (31), we assume very fast anion (chloride) binding and unbinding transitions ($X_o \leftrightarrow X_c$). Because the voltage-dependent mechanical activity of prestin is greater than 80 kHz (32), we also assume very fast voltage-dependent conformational transitions ($X \leftrightarrow C$). The transition to state C carries a unit charge, q ; Q_{max} , total charge moved, will reflect the maximal accumulation of motors in that state. The number of motors in state C also equates to magnitude of eM (contraction), providing a Boltzmann-like sigmoidal response. Nestled between the anion-binding and voltage-dependent transitions, resides a non-voltage-dependent transition ($X_c \leftrightarrow X$), which is very much slower than the other two transitions. The kinetics of these slow transitions

is set to have the model resemble prestin's electromechanical behavior. The differential equations describing the model are listed in the *Supporting Information*, where $k_1 = 10^7 * [Cl]_{in}$, $k_2 = 10^7 * k_d$, $\alpha_0 = 75 * \exp(t_m)$, $\beta_0 = 5.58 * 10^8 * \exp(-E_a/RT)$, $\alpha = 10^6 * \exp(zFV_m/2RT)$, $\beta = 583 * 10^9 * \exp(-zFV_m/2RT + t_m/2 - E_a/RT)$, $k_d = 0.001$, $T = 296$ K, $E_a = 38.36 * 10^3$ J/mol, $F = 9.648 * 10^4$ C/mol, $R = 8.315$ J/Kmol, $k = 1.381 * 10^{-23}$ VC/K.

The rates α_0 and β are tension sensitive, because tension is known to increase prestin residence in the expanded (X) state (10, 28), t_m in units kT (eRT/F); rates β and β_0 are equally temperature sensitive, with Arrhenius activation energy, E_a . Here, α and β are voltage dependent, with sensor valence z . At $T = 296$ K, $V_m = 0$ mV, $T_m = 0$ kT, and $[Cl]_{in} = 0.14$ M, initial rates are $k_1 = 1.4e6$, $k_2 = 1e4$, $\alpha_0 = 75$, $\beta_0 = 95$, $\alpha = 1e6$, and $\beta = 1e5$.

Model results recapitulate our biophysical data. Stimulation of the model is with the same voltage protocols used to collect the biophysical data, and analysis is the same. Fig. 5 B–D shows chloride-, rate-, and polarity-dependent disparity similar to the biophysical results illustrated in Fig. 3 A–C. The polarity dependence of the fastest rates with low chloride levels is not as rectified as the biophysical data, the model showing only minor differences, and may result from the extraordinary simplicity of the model. The triangles depict results obtained when intermediary rates, α_0 and β_0 , are set 8 orders of magnitude faster. Under such conditions, the model resembles a fast two-state model, with no disparity between NLC and eM. We reason that at high chloride levels the population of voltage-enabled Cl-bound motors is enriched, and the fast kinetics of the voltage-dependent

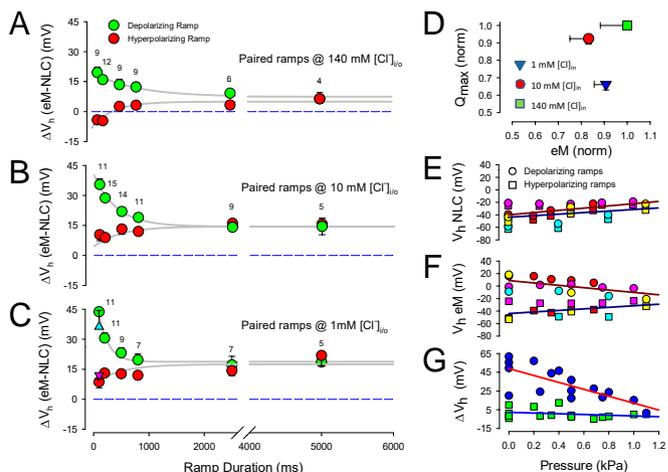

Fig. 3. The eM and NLC are disparate. (A) The eM and NLC operating voltage disparities are dependent on chloride levels, ramp durations/rates, and polarity. With 140 mM chloride intracellular, polarity effects are symmetrical but offset in the depolarizing direction. (B) For 10 mM chloride, the offset is larger, and a depolarizing asymmetry arises at short ramp durations. (C) With 1 mM chloride, the depolarizing offset is larger still, and the depolarizing asymmetry at short ramp durations is also greater. Errors bars are SE and numbers of cells are indicated. Triangles (up, blue: depolarizing ramp; down, purple: hyperpolarizing ramp) depict results obtained with aspartate as the chloride substitute at 100 ms duration ramp. Compare with model results in Fig. 5 B–D. (D) Q_{max} and eM_{max} are not strictly correlated. Normalized Q_{max} and eM_{max} are derived from 500 ms hyperpolarizing ramp data. As chloride levels decrease, Q_{max} decreases, but eM does not follow. Error bars are SE, number as in Fig. 3 A–C. Compare with model results in Fig. 5E. (E) Membrane tension reduces V_h disparity between eM and NLC. V_h of NLC shifts in the depolarizing direction with increase in membrane turgor pressure regardless of ramp polarity. (F) V_h of eM also shifts in the depolarizing direction with hyperpolarizing ramps as tension increases. However, eM V_h shifts in the hyperpolarizing direction when measured with depolarizing ramps. (G) Net effect of shifts in V_h is to reduce V_h disparity as membrane tension increases. ΔV_h obtained by subtraction of data in A and B; $n = 4$. Compare with model results in Fig. 5 F–H.

transitions work on this population to dominate the cell response, thus appearing more similar to a fast two-state process.

Fig. 5E illustrates that the model, similar to the biophysical results in Fig. 3D, exhibits poor correlation between Q_{\max} and magnitude of eM. In this case, Q_{\max} estimates can reduce with essentially no change in eM. Fig. 5 F–H illustrates the effects of tension on kinetic model behavior and shows similarity to the biophysical data of Fig. 3 E–G. Namely, a reduction of the fast ramp (100 ms) ΔV_h disparity results from inverse shifts of polarity dependent eM V_h . NLC V_h , on the other hand, shifts in the depolarizing direction for both polarity ramps. It is important to note that Fig. S1 A–D illustrates that a variety of perturbations to the model recapitulate biophysical behavior of NLC observed during the previous two decades, including prepulse effect, chloride concentration effect, temperature effect, and exponential relaxations of C_m induced by voltage step. The success of the model strongly suggests that an intermediary slow transition governs prestin behavior.

Given that the model recapitulates most of the available biophysical data, we are confident that it can be used to investigate other expected qualities that enable the OHC to function effectively as cochlear amplifier. To this end, we tested the phase characteristics of the model. Fig. S1 E–G shows that (i) eM phase lags that of stimulating membrane potential, (ii) the phase lag is chloride and voltage dependent, and (iii) depending on intermediary gateway kinetics, the phase lag exhibits variable frequency dependence. Fig. S2 confirms that we do find small phase lags in OHC eM.

Discussion

OHC eM is voltage dependent and necessarily coupled to its charged voltage sensor (8, 9, 12, 26, 27, 33). Thus, it is expected that sensor-charge movement, measured as displacement currents or NLC, should correspond to mechanical movements of the cell. In fact, a strict correspondence is predicted based on two-state Boltzmann models that incorporate transition speeds that match the very fast voltage-induced mechanical response (>80 kHz) (32). The incongruence of our data with this scheme, especially at physiological chloride levels, requires rethinking of prestin's molecular mechanism.

Measures of prestin's NLC alone are not sufficient to rule on the existence of kinetic schemes above two states, given that C_m - V_m functions can be fit equally well by two-state Boltzmann or multistate Langevin functions within physiological voltage ranges (34, 35). However, by evaluating simultaneous measures of NLC and eM, we are able to identify at least three state transitions, including fast anion-binding and voltage-dependent ones, and an intermediary slow one. The intermediary state transition controls the delivery of primed (anion bound) motors into a voltage-enabled pool, and likely corresponds to the allosteric-like behavior we have observed previously (16, 17). Thus, rather than a typical allosteric mechanism, chloride binding to the evolutionary

ancient transport-binding site functions to effect a slow conformational change that enables a process (voltage sensing and eM) unrelated to transport per se. We had previously separated NLC and anion transport via mutations in prestin, and identified charged amino residues that contribute to charge movement (36). In consequence, the intermediate transition serves as a gateway controlling the magnitude and voltage dependence of eM, and underlies the disparity between measures of NLC and eM.

We emphasize that our data do not suggest that NLC and eM are intrinsically separable, but that they only appear disparate because our measuring techniques are subject to intermediate rate effects that the disparity highlights. This is somewhat analogous to the recently observed need to integrate sensor charge across long time ranges to reconcile large shifts in the voltage sensor domain Q-V function of Shaker channels (37). Thus, we find that the apparent operating voltage range of prestin depends on the frequency of interrogation of its behavior. With our measures of NLC, we are studying a nonstationary population of voltage-dependent motors, varying according to the kinetics of the intermediary gateway. That is, NLC measures that characterize the voltage-dependent conformational change in prestin at discrete frequencies cannot provide steady-state behavior as previously thought, because we are not dealing with an invariant fast two-state system. The kinetic model starkly illustrates this: when intermediate rates are set very fast, model behavior is similar to fast two-state behavior. As a correspondence, we find that differing V_h is obtained by varying integration times of step-induced charge movement. Thus, past estimates of steady-state prestin behavior have been influenced by this gateway. For example, we and others had assumed that lowering intracellular chloride levels shifts eM correspondingly with NLC in the positive direction along the voltage axis. We now know that eM shift is greater. Physiologically, acoustic frequency stimulation *in vivo* will be influenced by intermediary kinetics corresponding to its equivalent frequency bandwidth. This may underlie some of the differences between low- and high-frequency cochlear behavior. It is important to note that the simple model we provide here has single exponential kinetics, whereas previously observed kinetic characteristics of NLC (e.g., see Fig. 1 NLC time course), which we can now ascribe to this gateway, clearly show that the transition actually has stretched exponential behavior providing control ranging from the submillisecond to the seconds timescale (20, 23). Implementing this kinetic diversity will certainly increase the complexity of the model, but may improve its correspondence with biophysical data. For example, at the present time we needed to decrease the transition rates from the millisecond to the second timescale to obtain the voltage prepulse effect as in Fig. S1A. As noted above, NLC relaxations do have components in this slower time range.

Anions and eM. The operating voltage range of eM is dependent on chloride level (Fig. 1D), showing a greater dependence than that of NLC. In a similar way, Q_{\max} estimates of charge movement do not correlate well with eM. The disparities may be explained because NLC only reports on the voltage-enabled population of motors at interrogation frequencies, whereas eM is evaluated at ramp rates much slower than that of the intermediate transition rates. Still, it is interesting to note that steady-state eM magnitude is little affected by chloride removal. It was previously observed that removal of intracellular chloride abolished eM (13). That observation involved replacement of chloride with pentane sulfonate, which we subsequently showed causes NLC V_h to shift to very hyperpolarized voltages, effectively shifting eM outside practical interrogation voltage ranges (16). In the present study, we successfully evaluate the full range of eM at various chloride levels and show robust mechanical responses, despite large reductions in chloride. We and others have determined the K_d for prestin, ranging from 1 to 6 mM, using measures of NLC (13, 15, 17). Our robust eM observations along with clear indications that NLC measures may not faithfully depict prestin's steady-state

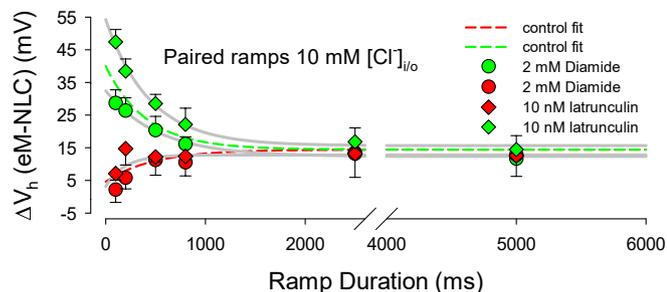

Fig. 4. The eM and NLC V_h disparity is little influenced by cytoskeletal integrity. The dotted lines are fits from the 10 mM chloride plot of Fig. 3B. The effects of diamide and latrunculin are absent with hyperpolarizing ramps (red symbols). On the other hand, diamide slightly reduces and latrunculin slightly increases fast ramp effects.

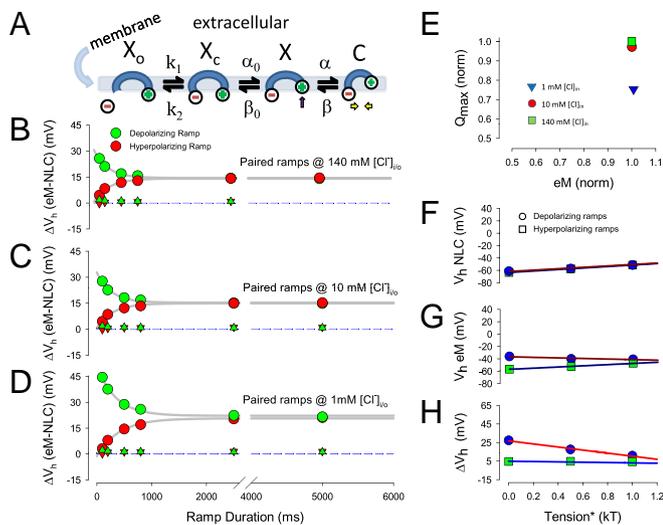

Fig. 5. Kinetic model of prestin. (A) Simple kinetic model of prestin activity within the plasma membrane. X_o state is unbound by anion. The X_c state is bound by anion but intrinsic voltage-sensor charge is not responsive to membrane electric field. Slow conformational transition to X state enables voltage sensing of electric field (arrow depicts positive charged sensor movement into the membrane field). Depolarization moves positive sensor charge outward within the membrane field, simultaneously resulting in compact state C , which corresponds to cell contraction (yellow arrows). (B–D) Kinetic model recapitulates ΔV_h disparity of biophysical data. Plots correspond to those plots of Fig. 3 A–C. Note increasing V_h disparity with chloride reduction and shorter ramp durations. There is a slight asymmetry at fast ramp rates for the 1 mM chloride condition. Triangles depict results obtained when the intermediate transition rates were increased by a factor of $1e8$. No disparity is detected under these conditions, as expected for a simple fast two-state model. (E) Kinetic model recapitulates uncorrelated Q_{max} and eM_{max} of biophysical data. As chloride levels decrease, Q_{max} decreases, but eM does not follow. Compare with biophysical data of Fig. 3D. (F–H) Kinetic model recapitulates membrane tension dependence of biophysical data. Plots correspond to those plots of Fig. 3 E–G. Note similarity of model behavior and biophysical behavior, resulting in reduced ΔV_h disparity as membrane tension increases.

properties indicate that the K_d for prestin mechanical activity needs reassessment.

Models of Prestin. The earliest molecular models of prestin, based on OHC NLC and eM, were simple two-state Boltzmanns (8, 9, 29, 30), corresponding to two area states, compact and expanded. The first observation of tension effects on OHC NLC led to a modified Boltzmann model, where a mechanical energy term supplemented that of electrical energy (28, 29). Those whole-cell experiments correctly implicated a molecular basis, as subsequent experiments revealed (4, 5, 10). Here we find that the disparity between eM and NLC is susceptible to membrane tension, thus directly implicating molecular underpinnings. To be sure, the hallmark of the intermediate transition rate, the C_m relaxation indicative of the shifting Q-V function, is impervious to intracellular pronase treatment (20), does not depend on OHC length (23), and is found in prestin transfected cells (4), as expected for a membrane-based phenomenon. Indeed, the minor effects of present cytoskeletal perturbations on the ΔV_h disparity confirm those observations. In accordance, it must be emphasized that water movements into and out of the OHC that can alter OHC shape are expected to be slow (38), and thus their greatest contribution to the disparity in ΔV_h would be during long ramps, which is just the opposite of what we find. In fact, chloride (water) movement into or out of the cell should depend on ramp polarity but at long durations disparity remains the same for each polarity ramp. In addition, the order of ramp delivery is without effect on the data. We conclude that our results cannot be due to whole-cell mechanical properties or chloride/water movements during

stimulation, and that the success of our model derives from its accurate description of prestin's molecular behavior.

Recently, extensive models, some deriving from OHC measures, incorporating transporter or multistate behavior have been devised to replicate some of the available biophysical data, mostly prestin's anion dependence (39–41). Prestin's anion transporter capabilities are controversial, some groups championing transport, others not (36, 42–44). However, another simple four-state model (sum of two voltage-dependent Boltzmanns) was found to rival an earlier model (45) in goodness of fit of NLC and salicylate's effect on OHC NLC (41). In a subsequent addition (33), the authors suggest that chloride binding could screen intrinsic voltage-sensor charge thus underlying V_h shifts; however, ions of any one polarity are not expected to produce extreme V_h shifts in both positive and negative directions, as has been measured in OHCs (16). In any case, their model cannot reproduce our data, as chloride binding leads directly to fast voltage-dependent reactions. It should be noted, that we previously identified a voltage dependence of NLC relaxations, which could signal that the slow intermediate transition may possess some measure of voltage dependency (23). In subsequent model renditions we intend to evaluate this possibility, and the possible effects of electric field on anion binding. In its present form, however, our simple model derives from typical ligand gated channels (e.g., ACh receptor channels) where fast ligand-binding kinetics leads to very much slower conformational changes that gate open conductance (46, 47). For prestin, the slower, voltage-independent intermediate conformational change enables voltage sensing. It is well known that a voltage-independent transition can affect the characteristics of a linked voltage-dependent one (37, 48, 49). It may be that the other more complicated, although untested (re the host of biophysical data available), models of prestin possess some of the qualities of our model, but to date our model is the simplest capable of recapitulating the widest known set of OHC biophysical data. In league with the transporter models, however, we speculate that the transporter lineage of prestin underlies the slow transition process that controls the fastest known molecular motor.

What Is Required of the OHC as an Amplifier? To provide amplification within the cochlear partition, the OHC must exert its force fast and at the right time. OHCs can respond to sinusoidal voltage stimulation above 80 kHz (32), and although resistor-capacitor (RC) filtering posed initial skepticism due to expected decreases in eM driving force at high acoustic frequencies (26, 50), much work has basically eliminated this concern (14, 51–55). However, one of those potential mechanisms that we envisioned to overcome the RC problem does not survive tests with our model. We previously suggested (14) that should chloride levels fluctuate at acoustic rates near prestin (analogous to stereocilia mechano-electrical transducer Ca^{2+} flux effects on bundle mechanics), this could drive high-frequency mechanical responses, bypassing an RC limit. Our observations indicate that such fluctuations are of limited effect because prestin's intermediary rates will low pass filter responses, with the intermediate transition imposing its time dependence on chloride-driven eM. Nonetheless, chloride flux at rates at or below intermediary rates could significantly affect eM.

Some cochlea models require a phase lag between OHC voltage and OHC force, typically 1.57 rad, thereby delivering force to the basilar membrane at an appropriate phase angle to cancel viscous drag (56–58). This requires a delay between receptor potential and activation of eM. Although various mechanisms have been invoked to establish phase lags in cochlear models, none have been based on intrinsic biophysical mechanisms of the OHC motor. We suggest that the disparity that we observe between NLC and eM may represent a delay proffered by the additional states required to replicate the biophysical data. To this end, we find in the model that phase lags between membrane voltage and eM are generated by the intermediary gateway, and that chloride level and membrane resting potential control lag magnitude (Fig. S1). It must also be remembered that

the gateway is actually multiexponential, thus in addition the model can generate frequency-dependent phase delays depending on the kinetics of the gateway. However, we find that model lag magnitudes are a fraction of 1.57 rad. Indeed, we find a small phase lag in our physiological measures of eM (Fig. S2), thus contributing to those model phase requirements. It should be mentioned, however, that more recent models of OHC-based amplification do not have lags required of older models (59). Based on new concepts, it is not OHC action on the basilar membrane, but instead on the fluid micromechanics of the

subtectorial membrane space that affords amplification (60, 61). Although our data are in harmony with the phase-lag requiring models, it remains to be seen how our predicted phase characteristics of the OHC motor impact on newer models, and whether the throttling kinetics of prestin's intermediary gateway can influence amplification.

Equations

Capacitance data were fit to the first derivative of a two-state Boltzmann function

$$C_m = Q_{\max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin}, \quad b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right),$$

where Q_{\max} is the maximum nonlinear charge moved, V_h is voltage at peak capacitance or equivalently, at half maximum charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature.

Model differential equations are

$$X_o \xrightleftharpoons[k_2]{k_1} X_c \xrightleftharpoons[\beta_0]{\alpha_0} X \xrightleftharpoons[\beta]{\alpha} C$$

$$\frac{dX_o}{dt} = X_c \cdot k_2 - X_o \cdot k_1$$

$$\frac{dX_c}{dt} = X_o \cdot k_1 + X \cdot \beta_0 - X_c \cdot \alpha_0 - X_c \cdot k_2$$

$$\frac{dX}{dt} = X_c \cdot \alpha_0 + C \cdot \beta - X \cdot \alpha - X \cdot \beta_0$$

$$\frac{dC}{dt} = X \cdot \alpha - C \cdot \beta.$$

On Membrane Motor Activity and Chloride Flux in the Outer Hair Cell: Lessons Learned from the Environmental Toxin Tributyltin

Lei Song,^{*‡} Achim Seeger,[‡] and Joseph Santos-Sacchi^{*†‡}

Otolaryngology,^{*} Neurobiology,[†] and Surgery,[‡] Yale University School of Medicine, New Haven, Connecticut

ABSTRACT The outer hair cell (OHC) underlies mammalian cochlea amplification, and its lateral membrane motor, prestin, which drives the cell's mechanical activity, is modulated by intracellular chloride ions. We have previously described a native nonselective conductance (G_{metL}) that influences OHC motor activity via Cl flux across the lateral membrane. Here we further investigate this conductance and use the environmental toxin tributyltin (TBT) to better understand Cl-prestin interactions. Capitalizing on measures of prestin-derived nonlinear capacitance to gauge Cl flux across the lateral membrane, we show that the Cl ionophore TBT, which affects neither the motor nor G_{metL} directly, is capable of augmenting the native flux of Cl in OHCs. These observations were confirmed using the chloride-sensitive dye MQAE. Furthermore, the compound's potent ability, at nanomolar concentrations, to equilibrate intra- and extracellular Cl concentrations is shown to surpass the effectiveness of G_{metL} in promoting Cl flux, and secure a quantitative analysis of Cl-prestin interactions in intact OHCs. Using malate as an anion replacement, we quantify chloride effects on the nonlinear charge density and operating voltage range of prestin. Our data additionally suggest that ototoxic effects of organotins can derive from their disruption of OHC Cl homeostasis, ultimately interfering with anionic modulation of the mammalian cochlear amplifier. Notably, this observation identifies a new environmental threat for marine mammals by TBT, which is known to accumulate in the food chain.

INTRODUCTION

Sensitive hearing in mammals relies on cochlear amplification, and is thought to result from the voltage-dependent motor activity of outer hair cells (OHCs) (Brownell et al., 1985; Ashmore, 1987; Santos-Sacchi and Dilger, 1988). The motor protein prestin, which resides exclusively in the lateral membrane (Belyantseva et al., 2000), is likely key to this process (Zheng et al., 2000; Liberman et al., 2002). Recent studies suggest that prestin activity is highly dependent on the intracellular chloride (Cl) anion. Oliver et al. (2001) found that removing intracellular Cl abolishes the motor's nonlinear charge movement (or nonlinear capacitance, NLC), thereby blocking OHC motility. However, the story is actually more complicated than initially thought, since we discovered that some effects of Cl removal result from induced shifts in prestin's operating voltage range, and not from elimination of motor charge movement (Rybalchenko and Santos-Sacchi, 2003a,c; Santos-Sacchi, 2003). Indeed, substitution of intracellular Cl with other anions, such as sulfonate derivatives or malate, results in a shift of motor function along the voltage axis, the direction of which depends on the substituted anion (Rybalchenko and Santos-Sacchi, 2003b,c): the voltage at peak NLC (V_{pkcm}) ranges from -180 mV for pentane-sulfonate substitution to $+100$ mV for malate substitution. Since Cl is the physiologically abundant intracellular anion, it probably sets the operating

position of NLC and motor function in the OHC. This operating position hovers around the physiological resting potential, namely ~ -70 mV (Dallos et al., 1982).

Considering the importance of Cl ions in OHC function, regulation of Cl transport across the lateral membrane is paramount. Little is known about processes that control chloride flux in OHCs (Gitter et al., 1986; Kawasaki et al., 1999; Rybalchenko and Santos-Sacchi, 2003a,c), though we have identified an unusual stretch-sensitive conductance localized to the lateral membrane, G_{metL} , that passes chloride and consequently can modulate prestin activity. A more detailed understanding of chloride's role in intact OHCs is needed, and could help in understanding normal as well as pathological cochlear function.

The organotin compounds trimethyl (TMT) and triethyl (TET) tin are known to cause auditory dysfunction, which has been attributed to disrupted calcium homeostasis (Clerici et al., 1991; Fechter et al., 1986, 1992; Liu and Fechter, 1995). Indeed, the effects of organotins on other physiological processes also have been linked to their untoward influence on Ca mechanisms (Kishimoto et al., 2001). Interestingly, though, organotin compounds can act as Cl ionophores (Tosteson and Wieth, 1979; Wieth and Tosteson, 1979), with tributyltin (TBT) being three orders of magnitude more effective than TMT at promoting anion exchange diffusion. The halides and hydroxyl anions can participate in heteroexchange with Cl across the membranes of red cells and mitochondria, as well as artificial bilayers (Motais et al., 1977; Selwyn et al., 1970; Wieth and Tosteson, 1979; Tosteson and Wieth, 1979). Intrinsic chloride conductance of the membrane is unaffected, and at concentrations below a few micromolar the intrinsic membrane dipole is unperturbed

(Tosteson and Wieth, 1979). Because TBT readily promotes Cl flux, it is routinely used to equilibrate intracellular and extracellular Cl to calibrate chloride-sensitive fluorescent dyes, such as MQAE (*N*-(ethoxycarbonylmethyl)-6-methoxyquinolinium bromide) (Verkman, 1990; Marandi et al., 2002). Among the organotins, TBT in particular is an internationally recognized environmental threat to marine life since it accumulates in the food chain, and remains a commonly used antifouling compound for large boat bottoms (U.S. Environmental Protection Agency, 2004).

Here we study the effects of TBT on Cl exchange across the OHC lateral membrane to gain insight into the function of the anion's natural pathway, G_{metL} , and assure ourselves of uncompromised control of Cl on both sides of the OHC's lateral membrane. We find rapid and profound effects of TBT on OHC NLC, which are directly related to the toxin's ability to transport Cl across the OHC membrane. Consequently, we have been able to obtain definitive and quantitative information on Cl-prestin interactions in native, intact OHCs. We also conclude that organotin ototoxicity ultimately results from interference with the anionic control of mammalian cochlear amplification, and, accordingly, we identify the marine mammal's auditory periphery as an especially susceptible target for the pervasive environmental toxin TBT.

MATERIALS AND METHODS

Hartley albino guinea pigs were overdosed with halothane. Temporal bones were excised and the organ of Corti was exposed under a dissection microscope in calcium-free extracellular medium. The top three turns of the organ of Corti were dissected from the cochlea, and the dissected segments were digested with dispase I (0.5 mg/ml) in a nominally (no chelator) calcium free extracellular medium for 10–12 min. After resuspension in 1 mM chloride extracellular medium (see below), cells were isolated by gentle trituration. The solution was then placed in a plastic petri dish to allow OHCs to settle. A Nikon Eclipse E600-FN microscope with Hoffmann optics was used to observe cells during the electrical measurements.

The base extracellular solution contained NaCl (140 mM), CaSO₄ (2 mM), MgSO₄ (1.2 mM), and Hepes (10 mM). The intracellular solution contained NaCl (140 mM), CaSO₄ (2 mM), MgSO₄ (1.2 mM), Hepes (10 mM), and EGTA (10 mM). Cl concentrations were 0.1, 0.2, 0.5, 1, 5, 10, 20, 40, 80, 140, and 200 mM. Cl concentration was adjusted by substituting Cl with the divalent anion malate. In a subset of experiments, gluconate was the major substitute. Final solutions were adjusted to ~300 mOsm (except for the solutions that contain 200 mM Cl) with dextrose and adjusted to pH 7.2–7.3 with NaOH. A stock solution of TBT (200 mM) was made in ethyl alcohol (EtOH) and then diluted in extracellular medium to obtain the desired concentrations. To dissociate the effect of TBT from EtOH, in a subset of experiments, TBT was directly mixed with extracellular medium to obtain desired concentrations (under the assumption that TBT totally dissolves in the alcohol-free solution). In these control experiments, the actual concentration of TBT is undetermined but likely to be lower than those equivalent solutions prepared using EtOH stock solution.

A custom-made Y-tube perfusion system was used for the delivery of experimental solutions to individual OHCs during continuous chamber wash with control extracellular solution. Perfusions were made with a range of chloride concentrations in combination with varying TBT levels. For the first set of experiments, we used either 5 or 140 mM Cl extracellular solution with varying TBT concentrations (0.01, 0.1, 1, 10, and 50 μM). In the next set of experiments, TBT concentrations were fixed at 1 μM , but Cl

concentrations were varied (1, 5, 10, 20, 40, 80, 140, and 200 mM). NLC was permitted to reach steady state before any subsequent manipulation. Perfusion speed through the Y-tube was 20 $\mu\text{l}/\text{min}$ with the tip placed 150–200 μm away from the patched cells. In this setup, junction potentials (calculated with Jpcalc; Axon Instruments, Union City, CA) associated with malate are small, and not corrected [<9 mV absolute for the largest changes from 1-mM to 140-mM Cl solutions, assuming a mobility for malate of 0.4 relative to Cl; direct measures of junction potentials were much smaller (2–3 mV)]. For the quantitative analysis of chloride level effects on motor activity, solutions were matched intracellularly and extracellularly (except that intracellular solutions had an additional 10 mM EGTA; see above), thus avoiding junctional potential effects.

Single OHCs were studied under whole-cell voltage clamp. An Axon 200B amplifier was used to hold the cell at 0 mV to remove the electrical drive for Cl ion flux. Thus, the effects of our imposed Cl concentration gradients were studied in isolation. Initial pipette resistances were 4–7 M Ω . Series resistances, which ranged from 5 to 20 M Ω , remained uncompensated for C_m measurements. Before establishing whole-cell configuration, gigohm seals were obtained (1.5–3.5 G Ω), and stray pipette capacitance was neutralized. All data acquisition and analysis was performed with a Windows-based patch-clamp program jClamp (www.SciSoftCo.com). Voltage was corrected offline for the effects of series resistance.

NLC was calculated using a continuous high-resolution (2.56-ms sampling) two-sine stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz) superimposed onto a voltage ramp (200-ms duration) from either –200 to +80 mV or –160 to +120 mV (Santos-Sacchi et al., 1998b). Capacitance data were fit to the first derivative of a two-state Boltzmann function (Santos-Sacchi, 1991),

$$C_m = Q_{\text{max}} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}}, \quad (1)$$

where

$$b = \exp\left(\frac{-ze(V_m - V_{\text{pkcm}})}{kT}\right),$$

Q_{max} is the maximum nonlinear charge moved, V_{pkcm} is voltage at peak capacitance or, equivalently, at half maximum charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature.

Q_{sp} (specific nonlinear charge) was calculated as $Q_{\text{max}}/(C_{\text{lin}} - 6.5)$, where C_{lin} is the linear capacitance, a measure of surface area, obtained from Boltzmann fits (Santos-Sacchi and Navarrete, 2002). A value of 6.5 pF in linear capacitance is the estimated contribution of apical and basal ends of the OHC, and therefore is subtracted to provide only that lateral membrane area that contains prestin (Huang and Santos-Sacchi, 1993; Santos-Sacchi, 2004). To determine unbiased estimates of linear capacitance we employed the following logic and strategy. The capacitance of the OHC is an asymmetric bell-shaped function due to motor surface area change; on average the left side of the function asymptotes at a value 3.5 pF greater than the right asymptote (Santos-Sacchi and Navarrete, 2002). C_{lin} is defined as the minimum capacitance, that is, when all the motors are in the compact state (right side of function). However, since the NLC curve shifts depending on intracellular Cl concentration and substitute anion, in some cases C_{lin} was not directly measurable because the right side was truncated. To assure accurate estimates of C_{lin} across cells with different intracellular Cl concentrations, all cells were first fitted only to the left half of the NLC curve to obtain an initial estimate of Q_{max} and z . Q_{max} and z were then used to estimate motor number ($N = Q_{\text{max}}/ze$), and the offset capacitance proportional to motor surface area change was determined from Fig. 4 c in Santos-Sacchi and Navarrete (2002). By subtracting this offset from the left-side asymptote of the NLC function we obtained an unbiased estimate of C_{lin} . It should be noted, however, that all final estimates of Q_{max} and z reported in this manuscript were determined from fits of Eq. 1 to full NLC datasets. All curve fitting was performed offline with jClamp and derived

parameters were analyzed in Excel and Sigma Plot (Jandel Scientific, San Rafael, CA). Plots were generated by using Sigma Plot. Standard errors are reported.

Chloride flux experiments were performed using fluorescence imaging of OHCs loaded with the Cl-sensitive dye MQAE, obtained from Molecular Probes (Eugene, OR). Isolated OHCs incubated in 1 mM Cl extracellular solution were placed onto coverslips coated with Cell-Tak (BD Biosciences, San Jose, CA). Cells were then moved to a thermostatically controlled microperfusion chamber, and incubated with 10 mM MQAE dye in the dark for 30 min. After excess dye was flushed off the coverslips, cells were examined under an inverted microscope with 60 \times magnification (IX70, Olympus, Tokyo, Japan) and images were captured through a Photometrics (Tucson, AZ) cooled CCD camera and analyzed with the program Metafluor (Universal Imaging, Downingtown, PA). The bath solutions were then changed in the following order: 1 mM Cl, 145 mM Cl, 1 mM Cl with 10 μ M TBT, 145 mM Cl with 10 μ M TBT and 145 mM Cl. The solution exchange rate was 4 ml/min by gravity flow into a 0.6-ml chamber. Measurements were carried out with excitation at 350 \pm 10 nm and emission at 450 \pm 10 nm. For presentation, noncellular background fluorescence, measured simultaneously, was subtracted from cellular responses. Photobleaching of the dye was insignificant on the timescale of our measurements; this is indicated by the return of fluorescence to the same 1 mM Cl pretreatment level after exposure to 145 mM Cl (see Fig. 1).

RESULTS

TBT promotes chloride flux across the OHC membrane

It is firmly established that TBT promotes Cl exchange across membranes (Motais et al., 1977; Selwyn et al., 1970; Wieth and Tosteson, 1979; Tosteson and Wieth, 1979; Verkman, 1990). However, to confirm that TBT also enhances Cl flux in OHCs, experiments were carried out with the use of the Cl-

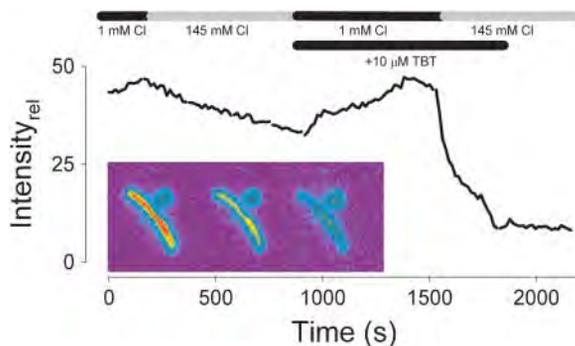

FIGURE 1 TBT promotes enhanced Cl flux across the OHC lateral membrane as measured by the fluorescent, chloride-sensitive dye MQAE. A dye-loaded OHC was perfused with the following solutions (indicated by the bars in the figure): 1 mM Cl, 145 mM Cl, 1 mM Cl with 10 μ M TBT, 145 mM Cl with 10 μ M TBT, and 145 mM Cl. Emission light intensity drops when the intracellular dye is quenched due to an increase in intracellular chloride. The chloride flux during the initial chloride gradient step, i.e., through G_{metL} , is less than that during a subsequent gradient step in the presence of TBT. Time resolution was 7.5 s. (Inset) Another example of an OHC showing fluorescence image changes. Cell width is 10 μ m. At zero time (left panel), the OHC bath was switched from 1 mM to 140 mM Cl extracellular solution. (Middle panel) At 360 s after, and (right panel) 945 s after switch. Flux is through G_{metL} alone, since TBT is absent in this case. The quenching of fluorescence (red \rightarrow green) indicates an increase in intracellular Cl.

sensitive fluorescent dye MQAE. In MQAE-loaded isolated OHCs that were preincubated in 1 mM chloride extracellular solution, a switch to 145 mM extracellular chloride solution caused a quenching of the dye's fluorescence, indicating that an increased chloride gradient resulted in an influx of chloride via the OHC's native conductance G_{metL} (Fig. 1). The addition of TBT markedly enhanced the influx of chloride. Thus, the OHC membrane is no different in its susceptibility to TBT than the other membranes previously studied.

TBT affects NLC only in the presence of a chloride gradient across the OHC

To further study the effect of TBT on OHC chloride flux during perfusion of TBT, we monitored NLC, which we and others have shown to be a very sensitive indicator of intracellular chloride levels (Oliver et al., 2001; Rybalchenko and Santos-Sacchi, 2003c). In the steady-state presence of a chemical gradient of Cl across the OHC lateral membrane (140 mM outside, 5 mM inside), and in the absence of TBT, V_{pkcm} is stable near -10 mV (Fig. 2 A, rightmost trace). This stability under these recording conditions arises from a net balance of Cl movements via G_{metL} and the patch pipette, resulting in a stable Cl activity at the intracellular aspect of prestin. However, in the presence of extracellular TBT, V_{pkcm} shifts leftward (hyperpolarizing direction) and the absolute magnitude of the shift increased with increasing TBT concentration (Fig. 2, A and C, solid symbols). This incrementing shift arises from the enhanced Cl exchange, which more effectively counters pipette washout, since, as we show below, TBT has no effect on prestin itself. At high levels (>10 μ M), TBT caused membrane instability and loss of recordings; we therefore limited most of our work to a 1- μ M concentration.

It is conceivable that TBT may directly interfere with Cl-prestin interactions, thereby contributing to the observed results. To rule out this possibility, we compared the effects of TBT on NLC in the absence of a driving force for Cl transport (5 mM inside, 5 mM outside; Fig. 2 B). In the absence of a gradient, there cannot be a diffusion-based net movement of Cl. However, if TBT were to alter the interaction between Cl and prestin, there would be a dose-dependent effect of TBT upon NLC measures. We chose to use 5 mM intrapipette Cl to ensure that prestin works in the midrange of its dose-response curve (Oliver et al., 2001), allowing alterations in prestin activity to be easily discerned. Under these conditions, perfusion of TBT at varying concentrations did not induce significant shifts of V_{pkcm} or changes in peak capacitance (Fig. 2, B and C, open symbols).

TBT does not directly affect prestin or G_{metL}

Since chloride affects the state probability of prestin (Rybalchenko and Santos-Sacchi, 2003c), it is possible that a chloride gradient can set prestin into a permissive state

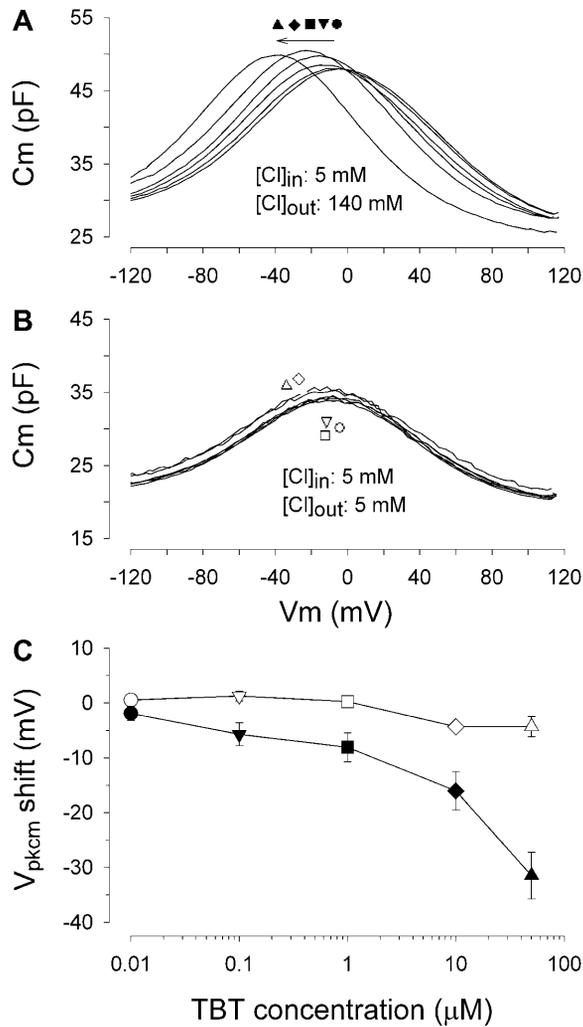

FIGURE 2 Effects of TBT upon V_{pkcm} depend on the chloride concentration gradient across the OHC membrane. (A) A representative cell with the pipette solution containing 5 mM Cl and the extracellular solution containing 140 mM Cl. The NLC curve shifts left with increasing extracellular TBT concentration (from right to left: 0 (rightmost trace), 0.01 (solid circle), 0.10 (solid upside-down triangle), 1.0 (solid square), 10 (solid diamond), and 50 (solid triangle) μM), as the Cl exchange more effectively counters pipette washout. (B) A representative cell with both the pipette and extracellular solution containing 5 mM Cl. Regardless of TBT concentration, the NLC remains virtually unchanged. (C) Average responses of two groups as in A and B ($n = 5-8$); each cell in a group was exposed to the full concentration range. Open and solid symbols represent cells bathed in the extracellular media containing 5 and 140 mM Cl, respectively. Gluconate was used to substitute for Cl in bath solution. Symbol types correspond to different TBT concentrations (as used in A, above). TBT effects were statistically significant (paired t -test; $p < 0.05$) for all concentrations except 10 nM.

whereby TBT could directly act on the protein, in analogy to well known state-dependent effects of blockers on ion channels. To evaluate this possibility, we directly probed the state dependence of TBT effects on prestin by driving the motor into predominantly the expanded or compact state with voltage (-50 and $+50$ mV; no chloride gradient, 140 mM in/out), while noting the effects of TBT on NLC (Fig.

3). The overlapping NLC traces at either holding voltage in the presence or absence of TBT indicates that any state dependence of direct TBT effects on the motor is absent. The difference in the traces obtained at either holding voltage is due to the effect of prior voltage on NLC that we thoroughly described previously (Santos-Sacchi et al., 1998b). In a similar fashion, we also tested nonsaturating chloride conditions (5 mM in, 140 mM out) to determine whether chloride interactions with prestin might be modified by TBT. The basic results were the same—there was no differential action on motor activity by TBT at either holding potential. These data confirm that TBT does not directly affect prestin or its interaction with chloride.

Another possibility that could account for shifts in V_{pkcm} is a direct action of TBT on G_{metL} , which naturally would only be effective in the presence of a Cl gradient. To rule out this possibility, we measured OHC membrane conductance directly during treatments with TBT in the presence of a Cl

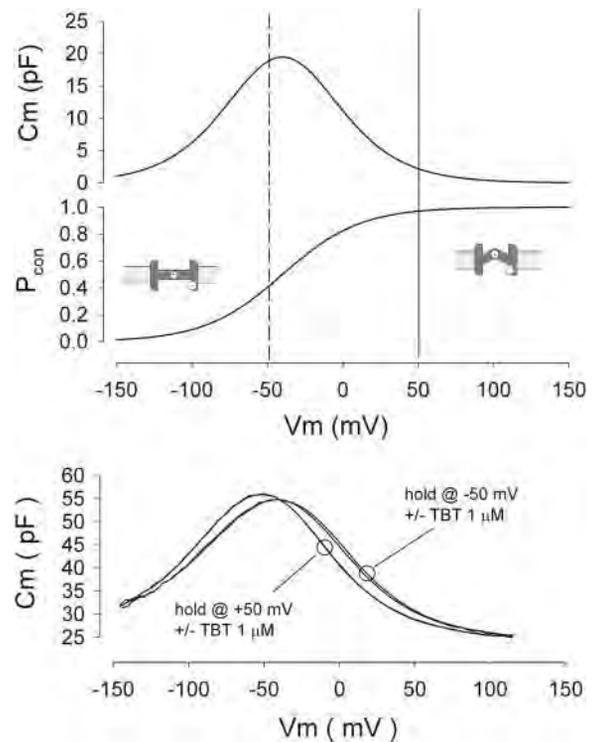

FIGURE 3 TBT does not work on the motor directly in a state-dependent manner. The top two panels indicate the relationship between NLC and motor-state probability, or population distribution of the motors into either the compact or expanded state. Hyperpolarization increases the number of motors in the expanded state. At the two vertical lines the number of motors in each state markedly differs. The lower panel shows four NLC traces. The overlapping traces obtained at $+50$ mV with and without 1 mM TBT test to see if TBT works selectively on the motors when predominantly in the expanded state; those traces obtained under the same conditions except at -50 mV test the effects of TBT when most motors are in the compact state. No Cl gradient is present (140 mM in/out). The overlap of the traces at either holding voltage indicates a lack of a state-dependent effect of TBT directly on the motors. The difference between the traces at each holding potential is fully a result of prior voltage effects on NLC (Santos-Sacchi et al., 1998b).

gradient (5 mM in/ 140 mM out). Fig. 4, *A* and *B*, shows that membrane resistance actually increases slightly, i.e., G_{metL} , which we measure directly, decreases during perfusions with TBT, whereas NLC shows typical effects of Cl modulation (Fig. 4 *C*). Under our ionic recording conditions (see Methods) G_{metL} is mainly responsible for setting R_m . Additionally, the inset of Fig. 4 *A* shows the percent change in membrane resistance caused by 1 μM TBT in the absence of a chloride gradient for different Cl concentrations. TBT decreases conductance by a few percent. These data indicate that TBT does not induce Cl movements by activating G_{metL} or any another conductance.

The effects of TBT on NLC depends on the magnitude and direction of the chloride gradient

Taken together our data thus far, namely, the direct measure of chloride flux with MQAE, the absence of direct effects of

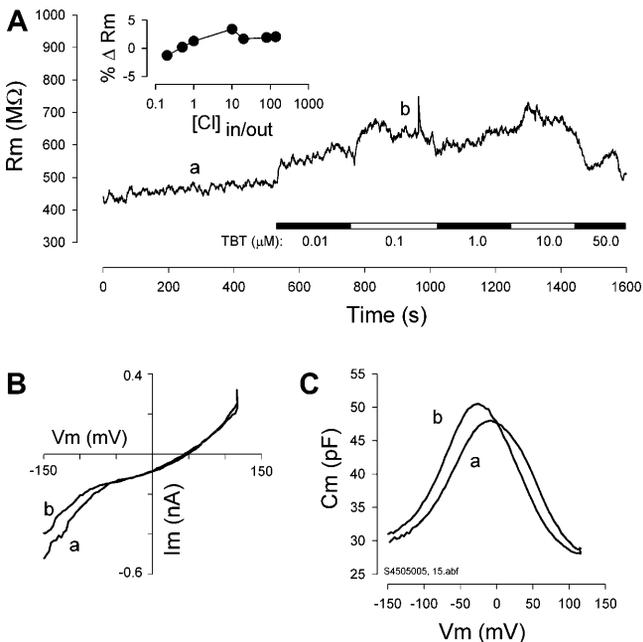

FIGURE 4 TBT does not activate the native Cl pathway, G_{metL} . (A) Continuous measures of R_m (determined with 10 mV step hyperpolarizations at 0 mV holding potential) were made during local perfusion of an OHC with different TBT concentrations with a chloride gradient similar to what we expect in vivo, namely, 140 mM outside/5 mM inside. (Inset) The plot shows the percent change in membrane resistance caused by 1 μM TBT in the absence of a chloride gradient for different Cl concentrations. TBT decreases conductance by a few percent. (B) $i-v$ curves from positions *a* and *b* marked in A. Slope resistance of each curve (*a* and *b*) at 0 mV differs by $\sim 30\%$ as indicated in A. (C) NLC obtained simultaneously at *a* and *b*. During the first 8–9 min, in the absence of TBT, the NLC stabilized, as depicted in C (trace *a*). Upon addition of TBT, membrane conductance actually decreased and is indicated by the $i-v$ curve in B, indicating a reduction of Cl movements through G_{metL} ; however, despite the reduction of Cl movement via membrane conductance, the increase in intracellular Cl via anion exchange diffusion via TBT causes a negative shift in NLC (C, trace *b*). Similar results were obtained in eight cells. These data indicate that TBT does not work by nonselectively increasing membrane conductance or by increasing G_{metL} .

TBT on prestin and G_{metL} , and the requirement for a chloride gradient, strongly indicate that TBT works simply by augmenting the flux of Cl into and out of the OHC in a manner that we have previously shown to occur via G_{metL} (Rybalchenko and Santos-Sacchi, 2003c). The following observations, which show directional and magnitude sensitivity of the chloride gradient on NLC, confirm this conclusion and support the similar conclusions of others (Tosteson and Wieth, 1979; Wieth and Tosteson, 1979; Marandi et al., 2002).

OHCs bathed in 1 mM Cl medium for extended periods of time (up to 2 h) retain a significant concentration of Cl intracellularly, based on initial whole-cell measures of NLC (Fig. 5). The retention of higher chloride levels is likely because the cells are collapsed under this condition, and the stretch-activated G_{metL} is not fully activated. Immediately after establishing whole-cell configuration, V_{pkcm} hovered around -40 mV (Fig. 5 *A*, leftmost NLC curve). At the start of cytoplasmic washout with pipette solutions containing 1 mM Cl, recordings made every 25 s revealed that V_{pkcm} shifted to the right as intracellular Cl levels dropped. Accompanying the shift was a reduction of Q_{max} . Eventually steady-state conditions were reached, indicated by the accumulation of overlapping NLC curves (Fig. 5 *A*). The time course of the pipette washout process was exponential, with time constants of 80.44 ± 7.3 s for V_{pkcm} and 44.87 ± 5.5 s for Q_{max} (mean \pm SE; paired t -test, $p = 0.004$; Fig. 5, *B* and *C*), the difference in time constants possibly indicating independence of the underlying mechanisms responsible for each of the parameters. However, changes in the Boltzmann fit during the shift, resulting from truncations of tail regions of the NLC function due to voltage limitations, conceivably could contribute to this difference. Steady-state levels were reached in 3–5 min, as expected for washout through patch pipettes (Pusch and Neher, 1988); the reason for this stabilization may be that the intracellular Cl concentration finally matched the extracellular concentration or, as noted above, that a stable Cl activity at the intracellular aspect of prestin was achieved. These possibilities are evaluated below.

Since it appears that the impact of TBT on prestin derives from its ionophore effect (Figs. 2–4), a change in the driving force for Cl, namely a change in the mismatch between intra- and extracellular Cl concentrations, should substantially modulate prestin activity, just as occurs with the native conductance G_{metL} (Rybalchenko and Santos-Sacchi, 2003c). To evaluate this possibility, we studied the consequences of changes in extracellular Cl levels with or without the addition of TBT. After steady-state intracellular washout with 1-mM Cl solutions (as in Fig. 6), perfusion of extracellular solutions with graded Cl concentrations (5–140 mM in the absence of TBT) shifted NLC functions back to the left, with a slight change in Q_{max} (Fig. 6, *A*, *C*, and *E*). However, even with the highest Cl concentration extracellularly, V_{pkcm} did not shift more than -20 mV. Furthermore, above 80 mM extracellular Cl, effects seem to saturate (Fig. 6, *A* and *C*),

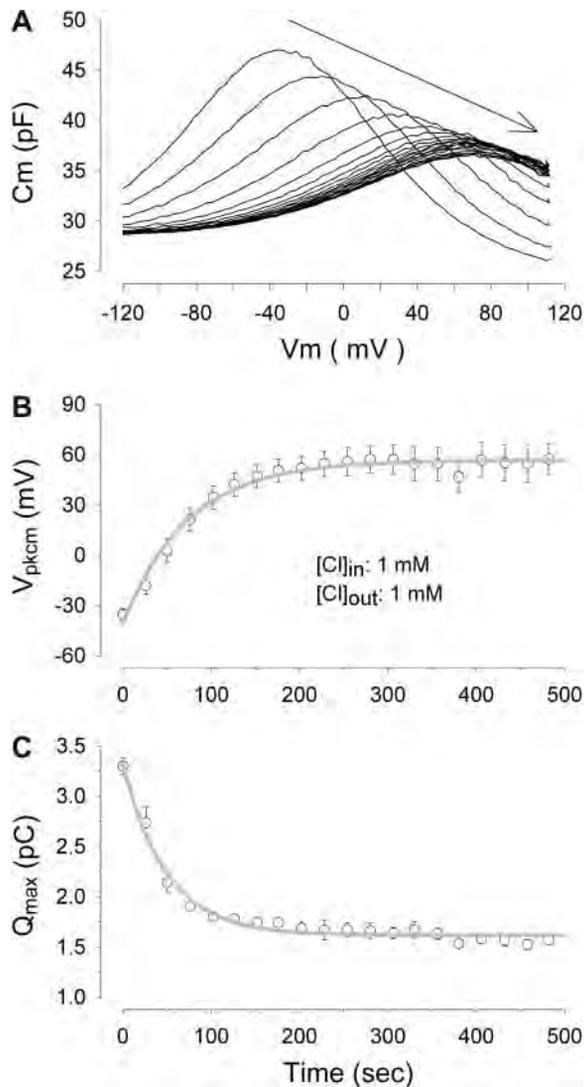

FIGURE 5 Effects of intracellular chloride washout on NLC. Cells were bathed in 1 mM Cl extracellular solutions for up to 2 h to reach steady state. The initial recordings were obtained within 5–10 s after establishment of whole-cell configuration with pipette solutions containing 1 mM Cl. (A) A representative cell with an initial V_{pkcm} near -40 mV. Recordings were made every 25 s until steady state was reached. The NLC curve shifted quickly to the right with the reduction of magnitude. At steady state, NLC curves overlapped. (B and C) Averaged V_{pkcm} and Q_{max} derived from four cells with complete data sets. The thick lines are fits to averaged data and averaged time constants are 80.44 ± 7.3 s for V_{pkcm} , and 44.87 ± 5.5 s for Q_{max} .

indicating the limited capability of the native Cl conductance, G_{metL} , to overcome the continuous pipette-mediated cell washout of Cl (i.e., given a finite G_{metL} (Rybalchenko and Santos-Sacchi, 2003c)).

As we anticipated, the addition of TBT in the perfusion medium augments Cl influx, which is clearly indicated by measures of prestin activity (Fig. 6B). Shown in Fig. 6B are the responses from the same cell depicted in Fig. 6A but now reperfused (after a steady-state return to 1 mM Cl extracellular solutions) with identical Cl concentration steps

containing 1 μ M TBT. In the presence of TBT, V_{pkcm} continuously shifted leftward and Q_{max} increased as extracellular Cl concentration was increased (Fig. 6, B, D, and F). In fact, the initial V_{pkcm} (dashed line, similar to leftmost curve in Fig. 5A but showing a more positive potential due to the delayed start of the initial recording) was recovered when extracellular Cl reached 140 mM, which corresponds to a >-50 mV shift. When the extracellular Cl concentration was increased further to 200 mM (~ 380 mOsm, an unnatural osmolarity and Cl concentration), an additional V_{pkcm} shift of -13 mV was observed (Fig. 6B, leftmost curve). These data clearly show that TBT provides an additional route for Cl influx, whose efficiency, unlike that of the cell's natural Cl conductance, G_{metL} , can more effectively counter the continuous consequences of pipette washout. During the resultant changes in intracellular chloride levels, OHC shape is expected to change as V_{pkcm} shifts; for example, at a fixed holding voltage, a hyperpolarizing shift in V_{pkcm} will be sensed as a depolarizing stimulus by the voltage sensors of the lateral membrane motors. This we observed as a contraction of OHCs when local extracellular Cl perfusion was switched from 1 mM to 80 mM in the presence of TBT, as illustrated in Fig. 7. The magnitude of this contraction indicates that in addition to a voltage-induced contraction, water influx additionally shortens the cell (see Discussion).

We were able to use TBT to study Cl efflux as well as influx, since the compound works by diffusional exchange (Tosteson and Wieth, 1979; Wieth and Tosteson, 1979). In this case, we observed recovery from extracellular perfusions of high Cl concentrations in the presence and absence of TBT (Fig. 8). Initially, cells were patched with 1 mM Cl intra- and extracellularly, and NLC was allowed to reach steady-state conditions, as in Fig. 5. Then cells were loaded with Cl by perfusing with high extracellular Cl in the absence of TBT (either 80 or 140 mM), and allowed to reach steady state again. Upon returning to 1-mM Cl extracellular solutions in the absence of TBT, V_{pkcm} and Q_{max} recovered only partially toward the initial low Cl, control condition (Fig. 8). The subsequent addition of 1 μ M TBT into the extracellular solution quickly completed the recovery toward the control condition (Fig. 8). The inability of G_{metL} to foster a recovery to the same conditions as it permitted before loading may indicate that the conductance is rectified. Alternatively, the conductance may have changed during the intervening time during perfusions (see Discussion).

The chloride- Q_{max} and chloride- V_{pkcm} dose-response function in the intact OHC

NLC in OHCs is clearly influenced by intracellular Cl concentration, and its magnitude and voltage dependence are determined by prestin's Cl dose-response function (Oliver et al., 2001; Rybalchenko and Santos-Sacchi, 2003c). When pipette solutions contain 20 mM Cl, perfusions of higher

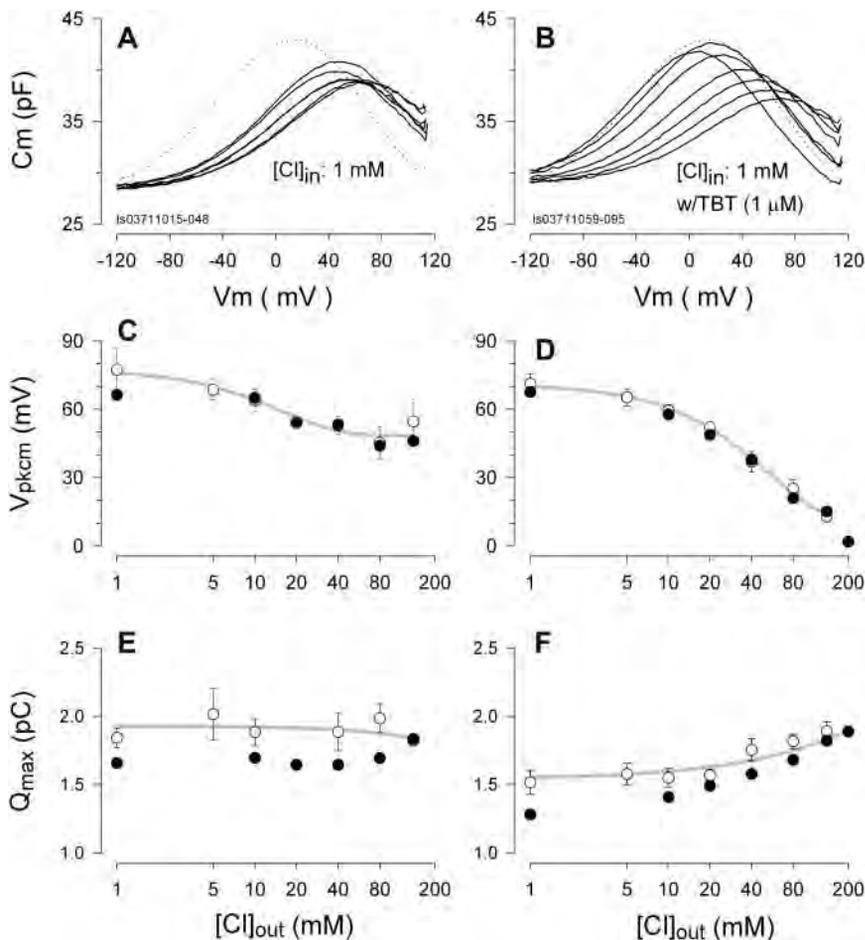

FIGURE 6 Reperfusion of high chloride extracellular solutions recovers prestin activity. (A and B) Response from the same representative cell. With the reperfusion of high Cl extracellular solution, either in the presence or absence of TBT, NLC shifts back toward the original condition (i.e., the first NLC trace measured upon whole-cell pop-in, plotted as *dashed line*, similar to leftmost trace in Fig. 5 A). However, in the absence of TBT, G_{metL} is unable to provide a sufficiently rapid Cl influx to overcome the effects of continuous pipette washout of Cl; the shift of V_{pkcm} did not recover beyond +40 mV (A). With the addition of TBT (1 μM ; B), NLC shifts back to the control level. Derived V_{pkcm} and Q_{max} are plotted in panels (C–F) Solid circles represent the results from the sample cell. Open circles are averages \pm SE.

concentrations of extracellular Cl, with or without TBT, do not significantly shift NLC functions (data not shown), suggesting that Cl - prestin interactions are nearly saturated at this concentration. Oliver et al. (2001) found a $K_{1/2}$ for intracellular Cl of 6.3 mM based on Q_{max} estimates in membrane patches. We measured the NLC functions of intact OHCs under symmetrical intracellular and extracellular Cl concentrations of 0.2, 0.5, 1, 5, 10, 20, 80, and 140 mM. To ensure symmetrical conditions, TBT was used in a subset of experiments, but no statistically significant differences were noted. For example, comparing TBT versus no TBT at 1 mM Cl, Q_{max} was 1.64 ± 0.07 vs. 1.69 ± 0.04 pC (mean \pm SE; $n = 12$, $n = 27$; $p = 0.53$); similarly, for V_{pkcm} , 73.34 ± 4.99 vs. 63.96 ± 3.55 mV ($n = 12$, $n = 27$; $p = 0.14$). As another example, at 80 mM Cl comparisons showed 3.17 ± 0.22 vs. 3.20 ± 0.14 pC ($n = 5$, $n = 10$; $p = 0.94$) and -54.63 ± 6.85 vs. -52.38 ± 5.47 mV ($n = 5$, $n = 10$; $p = 0.80$), respectively. This absence of effects is in line with the data from Fig. 2, and confirmed that the intracellular and extracellular concentrations of Cl were truly equilibrated. Thus, data were pooled, and using a logistic fit, our estimated $K_{1/2}$ for Q_{sp} (Santos-Sacchi et al., 1998a) is 6.06 ± 2.34 mM and slope is 1.02 ± 0.5 (Fig. 9 A); a similar fit was made to the V_{pkcm} data giving 4.48 ± 0.77 and 0.94 ± 0.17 ,

respectively (Fig. 9 B). A significant proportion of motor charge was insensitive to Cl. That is, $\sim 36\%$ of the nonlinear charge movement remained intact in the absence of Cl. It is important to note that the anion used to replace Cl influences V_{pkcm} and Q_{max} (Rybalchenko and Santos-Sacchi, 2003c), and that the insensitive proportion of motor charge can be much larger for other anion substitutes. For example, intracellular washout with malate substitution at 5 mM Cl stabilizes at a Q_{sp} of 0.13 ± 0.005 pC ($n = 19$), whereas substitution with gluconate provides a Q_{sp} of 0.18 ± 0.006 pC ($n = 17$). This difference corresponds to an equivalent shift along the concentration axis of $\sim +9$ mM Cl for malate-based solutions. In other words, the Q_{sp} value with 5 mM Cl in gluconate-based solutions equals the Q_{sp} value measured from 16 mM Cl in malate-based solutions.

The ethanol vehicle for TBT delivery does not influence NLC

In the preparation of TBT stock solution, ethyl alcohol (EtOH) was used to dissolve TBT that otherwise would have been incompletely dissolved in water-based solutions. To evaluate the impact of EtOH, in a subset of experiments, OHCs were perfused with graded concentrations of EtOH

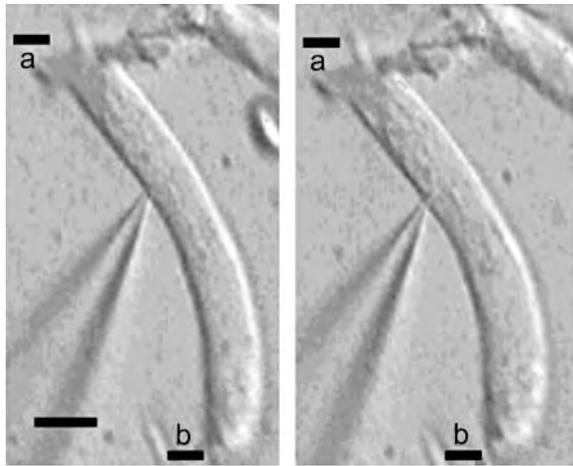

FIGURE 7 Influx of Cl causes OHC contraction. A representative OHC was locally perfused with extracellular medium that contained 1 mM (*left*) and 80 mM (*right*) Cl. TBT (1 μ M) is present in both cases. The fiducial mark is the pipette tip, which remains fixed. Pipette solution contained 1 mM Cl. Small debris are inescapably disturbed by the constant flow. Scale bar (*bottom left*) is 10 μ m. *a*, line at cell apex; *b*, line at cell base.

(Fig. 10). An effect of EtOH on NLC was evident only when the EtOH levels were >1%. In the routine preparation of perfusion solutions that contained TBT, EtOH levels were <0.025%. In the solutions that contained 1 μ M TBT, EtOH level was 0.0005%.

Although a low level of EtOH by itself did not cause significant changes in NLC, it is still possible that EtOH may work synergistically with TBT, as has been demonstrated for other ototoxic agents (Loquet et al., 2000). Therefore in a separate set of experiments, TBT was dissolved in the absence of EtOH. In those cases, the actual concentration of TBT is undetermined but is known to be lower than the amount added (in each of three experiments it was <10 μ M, <1 μ M, and <0.5 μ M). The results were similar to those experiments that employed EtOH as solvent for TBT, indicating that the TBT effect is independent of, and not enhanced by, EtOH.

DISCUSSION

In 1991, we showed that the lanthanide, Gd³⁺, could reversibly block OHC NLC and motility (Santos-Sacchi, 1991); aside from agents that irreversibly damage electromotility (Kalinec and Kachar, 1993), few agents, including salicylate, other lanthanides, and furosemide, have been found to reversibly interfere with lateral membrane motor activity (Dieler et al., 1991; Santos-Sacchi, 2003; Santos-Sacchi et al., 2001; Kakehata and Santos-Sacchi, 1996; Tunstall et al., 1995). After the identification of chloride's preeminent role in promoting prestin activity (Oliver and Fakler, 1999) and the identification of a native pathway for Cl flux within the lateral membrane (Rybalchenko and Santos-Sacchi, 2003c), underlying mechanisms for these

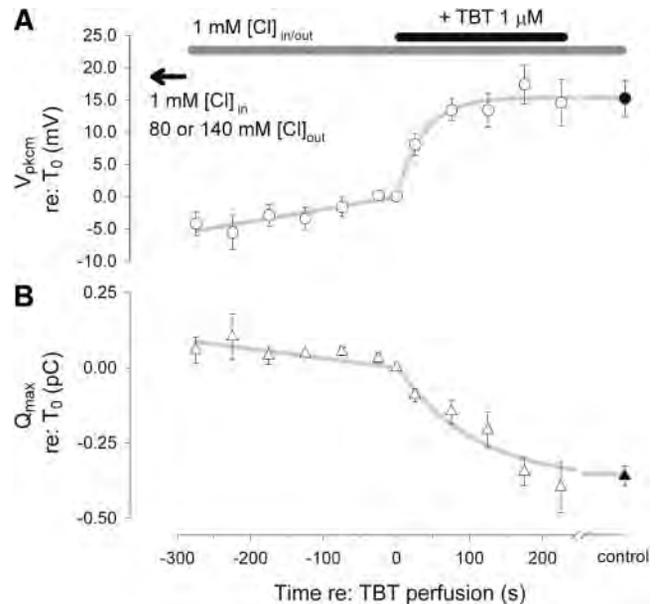

FIGURE 8 TBT enhances Cl efflux. (*A* and *B*) Averages ($n = 7$) of relative V_{pkcm} and Q_{max} during a switch from high to low extracellular Cl. Cells were previously loaded (to steady state) with Cl under high-Cl (80 or 140 mM) extracellular perfusion. Then cells were perfused (starting at -300 s) with 1 mM Cl extracellular medium to unload intracellular Cl. The 0-s mark indicates the beginning of TBT perfusion. Time resolution is 50 s (bin width). During the washout, R_s remained unchanged. The averaged values at the beginning of washout, beginning of TBT perfusion (T0), and the end of washout are 13.2, 12.9, and 13.0 M Ω , respectively. Solid symbols represent control values (1 mM intra/extracellular) before Cl loading. The bars on top show the perfusion strategy. The gray lines are fits to the data; straight line fits were made for the section before TBT, and exponential fits (τ : V_{pkcm} , 35.71 s; Q_{max} , 105.4 s) during TBT perfusion. The control values were used as steady-state end points for the fits.

blocking agents' actions on OHCs have been revealed. Thus, salicylate, though previously shown to have worked intracellularly in its charged form (Kakehata and Santos-Sacchi, 1996), is now known to interfere with the interaction of Cl and prestin (Oliver et al., 2001); the other agents, in addition to possible direct effects on the motor, may interfere with Cl flux across the lateral membrane (Rybalchenko and Santos-Sacchi, 2003c). These observations have been very helpful in understanding the molecular mechanism responsible for cochlear amplification in mammals (see Santos-Sacchi, 2003).

In this study, we report several new observations that have important consequences for understanding OHC function, and how cochlear amplification may be compromised. First, we show that the ionophore TBT can seriously disrupt chloride homeostasis in the mammalian OHC. Direct measures of chloride flux with the chloride-sensitive dye MQAE, as well as direct measures of chloride-sensitive prestin activity, provide strong evidence for this conclusion. To be sure, TBT was without direct effect on the motor and G_{metL} ; the effects were only observed in the presence of a chloride gradient across the OHC membrane, and the

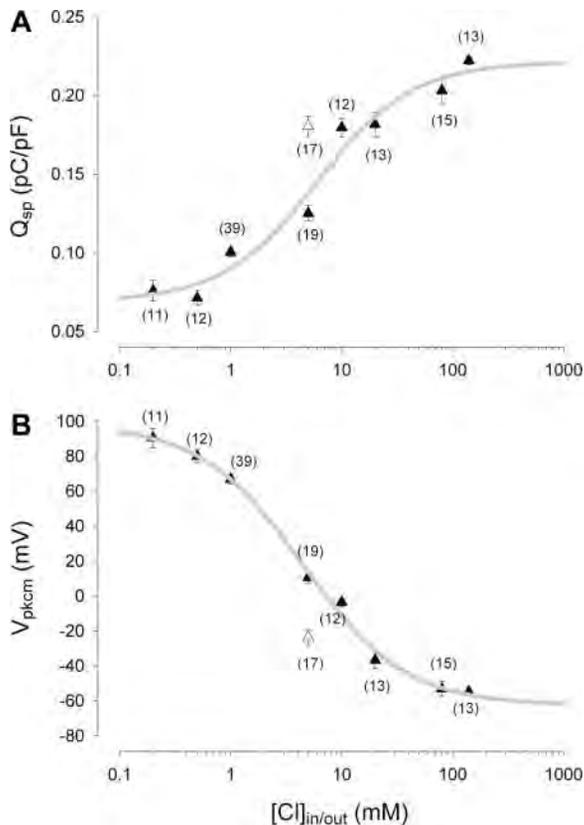

FIGURE 9 Prestin-Cl dose-response relationship. Nonlinear charge density, Q_{sp} and V_{pkcm} as a function of intracellular subplasmalemmal Cl concentrations, are fitted with logistic Hill function (solid triangles, malate as substitute anion). Each point represents the average (\pm SE; numbers in parentheses) from pooled recordings with or without TBT, since no statistically significant differences were found. Q_{sp} and V_{pkcm} were measured after pipette washout reached steady state. $K_{1/2}$ for Q_{sp} is 6.06 ± 2.34 mM and slope is 1.02 ± 0.50 (A); $K_{1/2}$ for V_{pkcm} data is 4.48 ± 0.77 mM, and slope is 0.94 ± 0.17 (B). Open triangles represent values from 5 mM Cl intracellular/extracellular with gluconate as substitute anion. Q_{sp} at steady state is 0.18 as compared to 0.13 in the case of malate substitution, a value that is equivalent to ~ 16 mM Cl inside with malate substitution.

magnitude of effects depended on the magnitude of the chloride gradient, with the direction of effects dependent on the direction of the gradient. This behavior was expected from previous work with this agent (Tosteson and Wieth, 1979; Wieth and Tosteson, 1979), and indeed, TBT is used to equilibrate intra- and extracellular chloride for estimation of chloride levels when using chloride-sensitive dyes such as MQAE (Verkman, 1990; Marandi et al., 2002). Second, given TBT's overwhelming effects we were able to compare the efficacy of G_{metL} in permitting chloride flux across the OHC membrane; NLC measures showed that native flux via this conductance is far less efficient than the flux provided by TBT, indicating that G_{metL} contributes to a regulated mechanism for chloride homeostasis within the OHC. Given such an effective agent as TBT, we were able to confirm uncompromised control over intracellular chloride levels and this allowed us, for the first time, to investigate prestin-

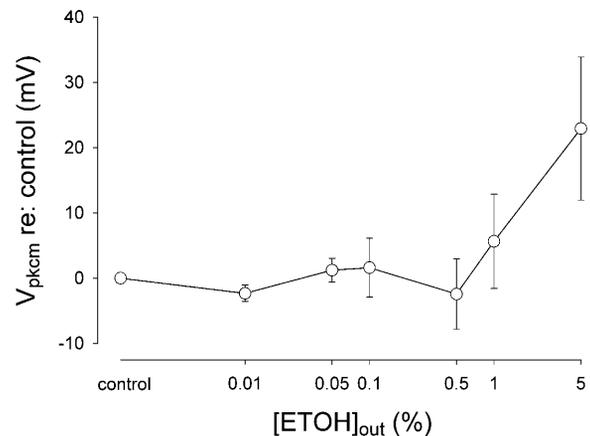

FIGURE 10 Ethyl alcohol shifts the NLC curve to the right at concentrations above 1%. Mean \pm SE of V_{pkcm} shift relative to the control are plotted as the function of EtOH concentration. Intracellular Cl is 5 mM in all cases. Q_{max} (not shown) did not change.

chloride interactions in the intact OHC. Finally, because of TBT's continued presence within marine environments and its accumulation in the food chain, we identify it as a potential hazard for marine mammals.

The operating range of prestin and lateral membrane Cl flux

Under typical whole-cell voltage-clamp conditions, where 140 mM Cl is perfused intra- and extracellularly, V_{pkcm} resides between -40 and -70 mV (Kakehata and Santos-Sacchi, 1995). This operating position is not fixed, since several fundamental biophysical forces have been shown to shift the NLC function along the voltage axis, i.e., to alter the steady-state energy profile of the lateral membrane motor. These forces include membrane tension (Iwasa, 1993; Gale and Ashmore, 1994; Takahashi and Santos-Sacchi, 2001; Kakehata and Santos-Sacchi, 1995), temperature (Meltzer and Santos-Sacchi, 2001; Santos-Sacchi and Huang, 1998), and voltage (Santos-Sacchi et al., 1998b). Recently, we found that alterations of intracellular Cl concentration can do the same, a decrease in concentration causing a shift in the depolarizing direction (Rybalchenko and Santos-Sacchi, 2003c). Depending on the substitute anion, the position of V_{pkcm} can vary between -180 and greater than $+100$ mV.

In the absence of TBT, chloride can permeate the lateral membrane through the stretch-activated conductance, G_{metL} . Under whole-cell voltage clamp, however, the effectiveness of this native conductance in modulating intracellular levels of chloride, in the face of changes in the extracellular Cl driving force depends on the pipette washout rate. Thus, after achieving steady-state conditions in the presence of 1 mM Cl within the patch pipette and extracellularly, an increase in extracellular Cl levels leads to a hyperpolarizing shift in V_{pkcm} , demonstrating that intracellular Cl increases as a result

of the imposed chemical driving force. However, the shift in V_{pkcm} does not recover to initial levels, and indicates that G_{metL} -mediated Cl flux is not sufficient to counteract the continuous washout of Cl by intracellular pipette perfusion. Clearly, if G_{metL} were to provide no barrier to the passage of Cl, the OHC could not use this ion as a modulator of prestin. The limiting nature of this native conductance was confirmed by treatment with TBT, which augmented Cl flux and returned V_{pkcm} further back toward initial conditions. Washout of cellular constituents via pipette is an efficient process, with replacements typically occurring within a few minutes (Pusch and Neher, 1988). It is surprising, therefore, that TBT can work so efficiently against pipette washout of Cl, and it may be possible that the restricted nature of the lateral subplasmalemmal space (LSpS) aids this process (see discussion in Rybalchenko and Santos-Sacchi, 2003c). Of course, in the intact OHC, G_{metL} will not have to struggle against such a powerful buffering mechanism as artificial pipette washout.

In our experiments on efflux of Cl from the OHC, we found a barrier to the complete washout of Cl from the LSpS, after Cl loading (Fig. 8). Whereas the influx of Cl during perfusion of high extracellular Cl competes with pipette washout, the efflux of Cl during perfusion of low extracellular Cl levels should be augmented by pipette washout. Despite this, TBT was required to fully allow Cl efflux, and may indicate some type of rectification of the native conductance, G_{metL} . However, our direct electrophysiological evaluation of G_{metL} showed no rectification near our holding potential of 0 mV (Rybalchenko and Santos-Sacchi, 2003c). Instead, we suspect that the conductance magnitude of G_{metL} may have changed during the shifts between low and high chloride. Perhaps lateral membrane tension was altered, thus altering the activation state of the pathway. Alternatively, exposure of G_{metL} to low Cl levels may have altered its activity, as has been found to occur in K channels (Loboda et al., 2001; Melishchuk et al., 1998).

Anion effects on motor charge movement— Q_{max}

In vivo, the flux of Cl across the lateral membrane through G_{metL} will be governed by membrane potential, membrane tension, and chloride's chemical driving force (Rybalchenko and Santos-Sacchi, 2003c). We have estimated intracellular Cl levels to be <9 mM at the normal in vivo resting potential (see Rybalchenko and Santos-Sacchi, 2003c), which places the cell in a maximally responsive region of the Q_{max} -Cl curve (Fig. 9). Interestingly, we again obtain a Q_{max} -Cl relationship in intact OHCs that differs substantially from that obtained by Oliver et al. in membrane patches (Oliver et al., 2001). Previously, we obtained an estimate of the Q_{max} -Cl function from OHCs by utilizing the conductive power of G_{metL} to control Cl on either side of the lateral membrane (Rybalchenko and Santos-Sacchi, 2003c). In those experiments, Cl concentration ranges from zero to 140 mM were evaluated, but we found that peak NLC could not be decreased below

~0.4 of control levels. This contrasted with the results of Oliver et al. (2001), where even 1-mM concentrations of Cl reduced Q_{max} to 0.15 of control values. In this set of experiments, to ensure against noise and drift caused by zero Cl levels, we did not lower Cl below 0.2 mM and employed TBT to ensure robust control of Cl concentration on either side of the lateral membrane. Nevertheless, we were unable to reduce motor charge movement (Q_{max}) to those levels found by Oliver et al. (2001); our Q_{max} levels at 0.2 mM Cl remain at 0.36 (1.15 ± 0.09 pC; $n = 11$) of saturated values (Fig. 9). Thus, ~36% of motor charge movement is insensitive to Cl, and reinforces our prior suggestions that Cl does not simply serve as prestin's extrinsic voltage sensor (Rybalchenko and Santos-Sacchi, 2003a,c). For that fraction of charge that is regulated by Cl, we find a $K_{1/2}$ (6.06 mM) and slope (1.02) that closely correspond to those measures of Oliver et al. (2001). It should be noted that the other physiological anion that affects prestin is bicarbonate, whose $K_{1/2}$ is 44 mM (Oliver et al., 2001), and which, under our intracellular and extracellular perfusion conditions, cannot reasonably account for the Cl-insensitive component of Q_{max} .

How is it that Cl is only partially responsible for charge movement of the OHC motor? It may be that prestin presents characteristics substantially similar to those of other transporters capable of charge movement under appropriate conditions, as evidenced by presteady-state currents (which are equivalent to an NLC) (Sacher et al., 2002; Hazama et al., 1997). Thus, in the absence of substrate, transporters such as mGAT3 and SGLT1 produce voltage-dependent displacement currents which may depend upon ion binding/dissociation or intrinsic conformational change. Interestingly, the GABA transporter's charge-movement dependence on Cl is not absolute (Sacher et al., 2002). We reason that the OHC motor likely possesses intrinsic charge movement due to conformational change, induced either by voltage or tension. Notably, those displacement currents displayed by transporters are typically abolished by saturating concentrations of appropriate substrate. Are we unaware of a natural substrate for prestin (SLC26a5), which normally works to dilute OHC NLC and motor activity?

Cl effect on OHC mechanics

NLC and electromotility are inextricably related; namely, shifts in V_{pkcm} along the voltage axis are mirrored in the mechanical activity of the OHC (Wu and Santos-Sacchi, 1998; Kakehata and Santos-Sacchi, 1995, 1996; Santos-Sacchi, 1991). Thus, OHC length is expected to change as V_{pkcm} shifts during intracellular chloride modulation simply because the drive to prestin is governed by the position of its Q - V or NLC function along the voltage axis. At a fixed holding voltage, a hyperpolarizing shift in V_{pkcm} will be sensed as a depolarizing stimulus by the lateral membrane motors, causing the cell to contract, as we illustrated (Fig. 7). Viewed as a population of motors, the percentage of motors

occupying the contracted state will increase; or for a given motor, the probability that that motor will reside in the contracted state will increase. A similar effect will also occur when Cl is modulated by pipette perfusion. In addition to direct effects of Cl on the motor, another possible mechanism could contribute to changes in cell length within the timescale that we worked under whole-cell voltage clamp, namely, water uptake after Cl influx. The expected magnitude of the voltage-induced contraction is easily calculated based on known OHC length- V_m functions. The contraction due to water movement can be quite large, and may overwhelm that induced by a perceived change in voltage. The cell in Fig. 7 shows a contraction of 4.4 μm . The average change in V_{pkcm} during a change from 1 mM extracellular solution to a saturating Cl solution (namely, 80 mM or above in 1 μM TBT's presence; Fig. 8) is ~ 15 mV. Given the largest measured mechanical response of 30 nm/mV (Santos-Sacchi and Dilger, 1988), we calculate that a half-micrometer contraction must occur. So in addition to an expected half-micrometer voltage-induced response, we likely have an additional 4 μm response due to water movements.

Based on these results, it is imperative that the consequences of chloride-induced shifts in V_{pkcm} and water movements be considered when evaluating effects of Cl manipulations on OHC mechanical characteristics. For example, OHC stiffness, which has been shown to be voltage-dependent in a manner that mimics electromotility (He and Dallos, 2000), will necessarily change when Cl-induced changes in V_{pkcm} occur, even if motor charge movement remains unaltered. Thus, it is not at all clear whether changes in voltage drive to the motor or changes in motor sensitivity underlie the effects of Cl manipulations on OHC stiffness (He et al., 2003). Indeed, controlling for these shifts is especially important when using anion substitutes such as pentane sulfonate (He and Dallos, 2000), which can cause V_{pkcm} to shift to very negative potentials (Rybalchenko and Santos-Sacchi, 2003b,c). Such a shift would cause the OHC to respond as it would to a depolarizing stimulus, namely, with a decrease in the cell's stiffness. In such a case, evaluations made across a full range of voltages are required for proper assessments of Cl's role.

The ototoxic effect of organotins

In this study we have shown that TBT functions as an ionophore that can bypass the native Cl pathway, G_{metL} . In effect, prestin is no longer subject to Cl modulation, and thus cochlear amplification will likely suffer. Whereas the other organotins, TET and TMT, have been shown to reduce auditory sensitivity in mammals (Clerici et al., 1991; Fechter et al., 1986, 1992; Liu and Fechter, 1995), their major action is considered to be at the inner hair cell/spiral ganglion cell level, and involve disruption of Ca homeostasis.

The ineffectiveness of TBT in the absence of a chloride gradient between intra and extracellular spaces indicates that

TBT does not affect the motor directly, and that any other possible intermediary effect on the motor resulting from TBT treatment is absent within our experimental timeframe; this precludes possible Ca effects as well. Additionally, the observed rapid effects of TBT (within seconds) differs from the slow (>30 min) cell shortening action of other trialkyltins on OHCs (Clerici et al., 1991; Fechter et al., 1986, 1992; Liu and Fechter, 1995). Indeed, Frolenkov et al (2000) showed that intracellular Ca increases caused by ionomycin or ACh, with or without perforated patch, produced no changes in OHC NLC. They did find, however, that phosphorylating and dephosphorylating agents, after 30–60 min incubation, resulted in V_{pkcm} shifts but had no effect on Q_{max} . To be sure, these results cannot be reconciled with our data on TBT effects, which show 1), a requirement for a Cl gradient; 2), simultaneous effects on both V_{pkcm} and Q_{max} ; 3), a dependence on magnitude and direction of the chloride gradient; that is, relative to initial conditions, the degree of V_{pkcm} shift and magnitude of Q_{max} depend on the magnitude of the Cl gradient, and the direction of V_{pkcm} shift depends on the direction of the Cl gradient; 4), rapid onset, within seconds; and 5), insensitivity to intracellular Ca buffer (10 mM EGTA). These observations indicate that the effects of TBT on the OHC result from Cl effects and not those of Ca. Interestingly, though, our results that organotins foster chloride flux across the OHC membrane may partially underlie their observed ability to shorten OHCs (Clerici et al., 1993), since, as we discussed above, binding of chloride ions to prestin increases the probability of the motor's residence in the contracted state.

Finally, we believe that the marine pollutant TBT poses a serious threat to marine mammals in particular, since they share with us the benefits of cochlear amplification. There are a growing number of studies linking TBT to untoward effects on mammalian cellular processes. For example, Akaike's group (Kishimoto et al., 2001) has found that environmentally relevant concentrations (30–100 nM) influence GABAergic neurotransmission, and suggested that some marine food sources which can accumulate TBT at levels of 100 nM or more pose a human health risk. Marine mammals likewise are exposed to this risk, perhaps more so. It will be important to assess the impact of TBT exposure on marine mammal communication.

We thank Dr. John Geibel (Yale Dept. of Surgery) for help with the MQAE dye experiments and the use of his equipment. We also thank Margaret Mazzucco for technical help.

Background & Aims: Progressive liver disease is a severe complication of cystic fibrosis, a genetic disease characterized by impaired epithelial adenosine 3',5'-cyclic monophosphate–dependent secretion caused by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR). In the liver, CFTR is expressed in cholangiocytes and regulates the fluid and electrolyte content of the bile. Glibenclamide, a sulfonylurea and a known CFTR inhibitor, paradoxically stimulates cholangiocyte secretion. We studied the molecular mechanisms underlying this effect and whether glibenclamide could restore cholangiocyte secretion in cystic fibrosis. **Methods:** NRC-1 cells, freshly isolated rat cholangiocytes, isolated rat biliary ducts, and isolated biliary ducts from CFTR-defective mice (Cftr^{tm1Unc}) were used to study fluid secretion (by video-optical planimetry), glibenclamide-induced secretion (by high-performance liquid chromatography in cell culture medium), intracellular pH and intracellular Ca²⁺ concentration transients [2'7'-bis(2-carboxyethyl)-5,6-carboxyfluorescein-acetoxymethylester and Fura-2 f-AM (5-Oxazolecarboxylic acid, 2-(6-(bis(2-((acetyloxy)methoxy)-2-oxoethyl)amino)-5-(2-(2-(bis(2-((acetyloxy)methoxy)-2-oxoethyl)amino)-5-methylphenoxy)ethoxy)-2-benzofuranyl)-, (acetyloxy)methyl ester) microfluorometry], gene expression (by reverse-transcription polymerase chain reaction), and changes in membrane capacitance (by patch-clamp experiments). **Results:** Stimulation of cholangiocyte secretion by glibenclamide and tolbutamide required Cl[–] and was mediated by the sulfonylurea receptor 2B. Glibenclamide-induced secretion was blocked by inhibitors of exocytosis (colchicine, wortmannin, LY294002, and N-ethylmaleimide) and by inhibitors of secretory granule acidification (vanadate, bafilomycin A1, and niflumic acid) but was Ca²⁺ and depolarization independent; membrane capacitance measurements were consistent with stimulation of vesicular transport and fusion. Glibenclamide, unlike secretin and

forskolin, was able to stimulate secretion in Cftr^{tm1Unc} mice, thus indicating that this secretory mechanism was preserved. **Conclusions:** The ability of glibenclamide to stimulate secretion in CFTR-defective mice makes sulfonylureas a model class of compounds to design drugs useful in the treatment of cystic fibrosis with liver impairment and possibly of other cholestatic diseases.

The intrahepatic biliary epithelium extensively modifies hepatocellular bile by increasing its water content and HCO₃[–] concentration. Fluidification of bile and its alkalization are required to meet digestive needs and to facilitate the flux of bile. This function of the biliary epithelium is regulated by gastrointestinal hormones and by paracrine signals that act either through the adenosine 3',5'-cyclic monophosphate (cAMP)/protein kinase A pathway (secretin) or via Ca²⁺ signaling (purinergic receptors).¹

Ductal cholestasis, ie, reduced fluid and electrolyte transport by cholangiocytes, is a central step in the pathogenetic sequence of biliary tree diseases, as exemplified by the progressive liver disease associated with cystic fibrosis (CF), a common genetic defect in which a

Abbreviations used in this paper: BCECF, 2'7'-bis(2-carboxyethyl)-5,6-carboxyfluorescein-acetoxymethylester; bp, base pair; CF, cystic fibrosis; CFTR, cystic fibrosis transmembrane conductance regulator; C_m, membrane capacitance; DIDS, 4,4'-diisothiocyanato-stilbene-2,2'-disulfonic acid; DMSO, dimethyl sulfoxide; IBDU, isolated bile duct unit; Kir, inward rectifier K⁺ channel; MEM, minimal essential medium; NEM, N-ethylmaleimide; NKCC1, Na-K-2Cl cotransporter isoform 1; NRC-1, normal rat cholangiocyte cell line; pH_i, intracellular pH; RT-PCR, reverse-transcription polymerase chain reaction; SUR, sulfonylurea receptor; TEA, tetraethylammonium.

failure of cAMP-regulated Cl^- transport (CF transmembrane conductance regulator; CFTR) causes a secretory failure in a number of epithelia, including the biliary tree.^{2,3} Recently, it was shown that glibenclamide stimulates bile flow at the level of the bile duct epithelium,⁴ a result in apparent contradiction to the known inhibitory effects of glibenclamide on CFTR. Progressive pulmonary disease is the leading cause of death in CF, but as the life expectancy for these patients is extended through improved pulmonary, nutritional, and general medical care, hepatobiliary complications become more frequent and have a negative effect on survival. As a consequence of the ductal cholestasis that results from defective biliary Cl^- and fluid transport, liver inflammation, cholangiocyte damage, and portal fibrosis progressively occur.² Pharmacological improvement of ductal secretion may help to reverse this series of events.

Sulfonylureas are widely used in the treatment of non-insulin-dependent diabetes mellitus (type 2 diabetes) because of their ability to stimulate insulin secretion from pancreatic β -cells.⁵ In this study, we investigated the molecular mechanisms that underlie the recently reported choleric effects of glibenclamide on the bile duct epithelium and its possible exploitation in CF. Our results indicate that in isolated bile duct units (IBDUs), sulfonylureas stimulate fluid secretion by a mechanism that is independent of Ca^{2+} and cAMP signaling but involves vesicle transport and fusion. The glibenclamide effect is maintained in cholangiocytes isolated from CFTR knockout mice. The stimulatory effect of glibenclamide on cholangiocyte secretion in cells lacking CFTR makes this class of compounds an attractive tool to stimulate fluid secretion in CF liver disease, a prototypic cholangiopathy present in up to 30% of CF patients that seriously affects morbidity and mortality.

Materials and Methods

Chemicals and Solutions

Epidermal growth factor, dexamethasone, triiodothyronine, ethylenediaminetetraacetic acid, collagenase IV, collagenase XI, pronase, hyaluronidase, deoxyribonuclease, forskolin, insulin, diethylpicrocarbonate, glibenclamide, 4,4'-diisothiocyanato-stilbene-2,2'-disulfonic acid (DIDS), diazoxide, tolbutamide, tetraethylammonium (TEA), niflumic acid, vanadium oxide, wortmannin, LY294002, colchicine, γ -lumicolchicine, TRI Reagent (Sigma Chemical Company, Milan, Italy), barium- Cl^- , adenosine triphosphate (ATP), diButyryl (dB)-cAMP, bafilomycin A1, and nocodazole were purchased from Sigma. Culture media, α -minimal essential medium (MEM), Dulbecco's MEM, Ham's F12, fetal bovine serum, MEM nonessential amino acid solution, MEM vitamin solutions, glyceryl monostearate, chemically defined lipid concentrate, soybean trypsin inhibitor, penicillin/streptomycin,

gentamicin, trypsin/ethylenediaminetetraacetic acid, and glutamine were purchased from Gibco (Life Technology, Milano, Italy). NuSerum and bovine pituitary extract were obtained from Becton Dickinson (Milan, Italy). Membrane inserts were purchased from Nunc (Mascia Brunelli, Milan, Italy), and Dynabeads M-450 rat anti-mouse immunoglobulin M was purchased from Deutsche Dynal GmbH (Hamburg, Germany). 2'7'-Bis(2-carboxyethyl)-5,6-carboxyfluorescein-acetoxymethylester (BCECF) and Fura-2 were purchased from Molecular Probes (Eugene, OR). Moloney murine leukemia virus reverse transcriptase was obtained from Perkin Elmer (Milan, Italy), whereas a Qiagen QIAquick PCR Purification Kit and Qiagen QIAquick Gel Extraction Kit were purchased from Qiagen GMBM (Ilden, Germany). Anti-*Taq* DNA polymerase antibody was obtained from Clontech (Milano, Italy). The composition of perfusion buffers used was essentially as described previously.^{3,6} In HEPES used to acid load cells, 20 mmol/L NH_4Cl was substituted for equal amounts of NaCl. BCECF, Fura-2-AM, glibenclamide, diazoxide, bafilomycin A1, wortmannin, and LY294002 were prepared as a 1 mmol/L stock solution dissolved in dimethyl sulfoxide (DMSO), whereas nigericin was solubilized in ethanol.

Glibenclamide Secretion in NRC-1 Cell Culture and in Isolated and Perfused Rat Liver

NRC-1 is a well-differentiated normal rat cholangiocyte cell line that maintains a polarized distribution of membrane markers and ion transporters and has been extensively characterized and used.⁷⁻⁹ Cells were grown as previously described⁷⁻⁹ over collagen-coated semipermeable membrane inserts (Nunc, Mascia-Brunelli, Milano, Italy). Experiments were performed in cells cultured for 1 week after they reached confluence and had a transepithelial resistance $>1000 \Omega/\text{cm}^2$ (Millicell-ERS System; Millipore Co, Bedford, MA).⁷ NRC-1 monolayers were exposed to glibenclamide from basolateral side, and at different times, apical supernatant was collected.

Animals received care according to the principles outlined in the *Guide for the Care and Use of Laboratory Animals* (National Academy Press, 1996, 7th edition), and the following protocols were approved by the University of Padua Institutional Veterinary Medicine Service. Sprague-Dawley rats were anesthetized with pentobarbital (50 mg/kg body weight); procedures for isolated and perfused rat liver and setup were performed as previously described.¹⁰ Bile flow was measured gravimetrically in preweighted tubes, and perfusion pressure was monitored continuously. Liver viability was ascertained by monitoring perfusion pressure and oxygen consumption during the course of the experiment and by determining trypan blue distribution on completion.

Glibenclamide and its 2 major metabolites (4-*trans*- and 3-*cis*-hydroxyglibenclamide) were measured by high-performance liquid chromatography in the bile collected from isolated and perfused rat liver or in the supernatant of NRC-1 cell line. Gliclazide (0.1–10 μg) was used as an internal standard. Sulfuric acid 1N was added to bile or to cell overnatant, and, after the addition of *N*-hexane/ethyl acetate (3:1, vol/vol), the

organic phase was dried, dissolved in mobile phase, and injected into a liquid chromatographic system (Agilent Series 1100; Hewlett-Packard, Palo Alto, CA). The analytical column was a reversed-phase LiChrospher RP-Select B obtained from Merck (Darmstadt, Germany). Calibration standard samples were prepared by adding glibenclamide or metabolites to "blank" bile or, in the case of cell overnatants, to a buffer solution. Calibration lines of all analytes were linear in the range investigated: correlation coefficient values (r^2) were consistently >0.9834 . The mobile phase (flow at 1 mL/min) consisted of a mixture of acetonitrile and water (50:50, vol/vol) containing sodium dodecylsulfate (0.01 mol/L) and glacial acetic acid (0.5% vol/vol). The UV detection wavelength was 230 nm.

Intrahepatic Rat Bile Duct Units and Immunopurified Bile Duct Cells

Rats and mice were anesthetized as described previously. IBDUs (ie, sealed fragments of isolated bile ductules in short-term culture that have retained polarity and secrete into a closed lumen) were prepared and purified as previously described^{6,11,12}; they were plated for 24 hours over a thin layer of Matrigel (Collaborative Research Products, Bedford, MA) as previously described.^{6,11,12} Immunomagnetic isolation of cholangiocytes was performed as previously described¹³ by using the OC-2 primary antibody (1:1000; a kind gift of Dr D. Hixson, Brown University, Providence, RI). Histochemical assays for γ -glutamyltranspeptidase indicated purity values of $>95\%$ in all cholangiocyte preparations used. Viability was evaluated by trypan blue exclusion.

Assessment of Ductular Secretion in Intrahepatic Rat Bile Duct Units by Video-optical Planimetry

Expansion of the IBDU lumen over time was quantified by video-optical planimetry as a measure of the ductular secretion rate, as previously described.^{6,11,12} After a 5-minute baseline period, IBDUs were exposed to glibenclamide (100 μ mol/L), to tolbutamide (100 μ mol/L), or to glibenclamide and different inhibitors; the luminal area was then measured every 5 minutes for up to 30 minutes. Serial images of the IBDU were acquired by a JVC TKC 1380 video camera (Galileo Siscam, Firenze, Italy); luminal areas were determined from the recorded images by using an image processor (Arkon; Nikon; Firenze, Italy).

Measurement of Na-K-2Cl Cotransporter Isoform 1 Activity

The effects of glibenclamide on the activity of the $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransporter was assessed by measuring the recovery of intracellular pH (pHi) from NH_4Cl^- -induced alkalization by using the cell-permeant fluorescent pHi indicator BCECF/AM (12 μ mol/L). BCECF loading procedures of IBDU, the microscopic setup, and the measurement and calibration procedures have already been described.¹⁴ Acid and

base fluxes were calculated by using cellular intrinsic and total buffering powers (β_i and β_{tot} , respectively), values previously measured.^{6,11} The rates of pHi changes ($\delta\text{pHi}/\delta t$) were calculated as previously described.^{6,11} The effects of glibenclamide on $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ activity were assessed by measuring the rate of pHi recovery from an alkaline load induced by 20 mmol/L NH_4^+Cl^- .^{6,15} The $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ cotransporter can transport NH_4^+ in stoichiometrical substitution of K^+ . When cells are exposed to NH_4Cl , NH_3 enters the cells by nonionic diffusion and leads to cytoplasmatic alkalization. The subsequent cellular uptake of NH_4^+ by Na-K-2Cl cotransporter isoform 1 (NKCC1) causes pHi acidification, and NKCC1 activity can be measured from the initial phase of the acidification slope.^{6,15}

Measurement of Intracellular Ca^{2+}

Intracellular Ca^{2+} transients were measured by using Fura-2-AM. IBDUs were loaded in tissue culture medium for 20–30 minutes at room temperature with Fura-2-AM (5 μ mol/L). Coverslips with dye-loaded cells were mounted into a heated metal flow-through perfusion chamber, placed on the stage of an inverted Olympus IX 70 microscope (Milano, Italy), and perfused by gravity feed at 1.5–2 mL/min. After a 3-minute baseline period, cells were exposed to glibenclamide (100 μ mol/L) for 10 minutes, and at the end of the experiment, ATP (10 μ mol/L) was used as an internal control. Emitted fluorescence was measured in response to alternate pulses of excitation light (10 milliseconds long) at 340 and 380 nm. The emitted fluorescence (510 nm) was focused on a photomultiplier tube, amplified, digitally converted, and analyzed with Till Vision software (Till Photonics, Martinsried, Germany). Images of the IBDU were acquired by a charge-coupled device camera. The ratio of emitted light from the 2 excitation wavelengths (340 and 380 nm) of Fura-2 provides a measure of ionized cytoplasmic $[\text{Ca}^{2+}]$.¹⁶

Sulfonylurea Receptor, Inward Rectifier K^+ Channel 6.x, and chloride channels (CLC)-3 Gene Expression

Sulfonylurea receptor (SUR) and inward rectifier K^+ channel (Kir) 6.x isoforms and chloride channels (CLC)-3 gene expression were assessed by reverse-transcription polymerase chain reaction (RT-PCR). SUR1 messenger RNA (mRNA) was detected by using the primers 5'-GCAGCCGAGAGCGAGGAA-GATGA-3' and 5'-ACAGCCAGGGCGGAGACACAGAGT-3', which amplified a 539-base pair (bp) fragment. SUR2 mRNA was amplified by using the primers 5'-CGCGGCGGT-CATCGTGCTC-3' and 5'-CGCCGCGCCTGCTCGTAGTT-3', which amplified a 603-bp fragment. SUR2AB mRNA was detected by using the primers 5'-GACAGCCTTTGCG-GATCG-3' and 5'-GCATCGAGACACAGGTGCTG-3', which amplified a 387-bp fragment for SUR2A and a 211-bp fragment for SUR2B. CLC-3 mRNA was detected by using the primers 5'-GCGAGAAAAGTGTAAAGGAC-3' and 5'-TCAAAGC-CCAAAAGATGTA-3', which amplified a 377-bp fragment; Kir 6.1 mRNA was detected by using the primers 5'-TTCTGCG-TTTCTCTTCTCCATCG-3' and 5'-GGGGCTACGCTTAT-

CAATCACAT-3', which amplified a 445-bp fragment. Kir 6.2 mRNA was detected by using the primers 5'-GGAGAG-GAGGGCCCGCTTCGTGTC-3' and 5'-GGCGTAATGAT-CATGCTTTTCGGAGGTC-3', which amplified a 553-bp fragment; 28S mRNA was detected by using the primers 5'-AGAAGGGCAAAGCTCGCTT-3' and 5'-AGCAGGAT-TACCATGGCAAC-3', which amplified a 288-bp fragment. Total RNA was isolated from OC-2 using the TRI Reagent solution (Sigma), according to the manufacturer's instructions. One microgram of total RNA was reverse-transcribed with Moloney murine leukemia virus reverse transcriptase (2.5 U/ μ L). PCR was performed in a thermocycler M. J. Research (M-Medical, Firenze, Italy) with AmpliTaq Gold polymerase and 1 \times GeneAmp buffer (Applied Biosystems Inc, Foster City, CA). PCR was initiated by hot start, followed by 40 cycles of 94°C for 1 minute, 50°C–74°C for 1 minute, and 72°C for 1 minute and by a final extension at 72°C for 10 minutes. Contamination by genomic DNA was ruled out by running samples without a previous RT-PCR phase. Preliminary kinetic analysis was performed to position amplification cycles on the exponential phase of the reaction. Amplification products were electrophoresed on 7% acrylamide gel, visualized by ethidium bromide, and then silver-stained. Purified PCR products were sequenced on an ABI 373A Stretch automated sequencer (Perkin-Elmer, Milan, Italy) to verify the identity.

Patch-Clamp Experiments

Immunopurified cholangiocytes were identified with a Nikon Eclipse E600FN microscope by visualizing antibody-coated magnetic beads (4.5 μ m) bound to the cell-surface antigens. The cells were whole-cell voltage-clamped with an Axopatch 200B amplifier and Digidata 1320A board (Axon Instruments, Union City, CA) by using solutions modified from Barg et al.¹⁷ Extracellular medium contained (mmol/L) NaCl 138, KCl 5, MgCl₂ 1.2, CaCl₂ 2.6, and HEPES 5. The pH was adjusted to 7.4 with NaOH, and osmolarity was adjusted to 310 mOsm with D-glucose. Pipette solution contained (mmol/L) K⁺-gluconate 125, KCl 10, NaCl 10, MgCl₂ 1, HEPES 5, ethylene glycol-bis(β -aminoethyl ether)-N,N,N',N'-tetraacetic acid 10, CaCl₂ 5 (170 nmol/L free Ca²⁺), and Mg-ATP 3; pH was adjusted to 7.15 with KOH. The solution had an osmolarity of approximately 310 mOsm. DMSO was used to dissolve tolbutamide and nocodazole before their addition into the pipette solution. γ -Lumicolchicine was prepared in chloroform. The final concentration of DMSO and chloroform in pipette solutions was 0.1%. Some cells were pretreated with colchicine (50 μ mol/L), γ -lumicolchicine (50 μ mol/L), and nocodazole (10 μ mol/L) in extracellular medium for 30, 30, and 60 minutes, respectively.

Membrane capacitance (C_m) measurements were begun immediately after the establishment of a whole-cell recording condition. Holding potentials of -40 and -80 mV did not provide stable recordings, and it proved difficult to hold the cells for the required prolonged recording periods. Consequently, cells were typically held at 0 mV during C_m measurements. The initial pipette resistance was 4–7 M Ω . Gigohm seals were obtained (1.5–3.5 G Ω), and stray capaci-

tance was compensated before the rupture of the cell membrane. Uncompensated series resistances ranged from 10 to 30 M Ω and remained uncompensated, because the capacitance measurement algorithm is sensitive to introduced system lag. Corrections for series resistance were subsequently made off-line. Capacitance was tracked (every 150 milliseconds) with a high-resolution dual sinusoidal (10-mV peak at both 390.6 and 781.2 Hz) stimulus paradigm.^{18,19} Simultaneously, membrane resistance, series resistance, and holding current were recorded. Transient analysis measurements with 10-mV steps were confirmatory. During our measurements, we were careful to record from isolated single cells because cell groups could have been coupled by gap junctions. It is well known that recordings from single cells in a group of coupled cells present an inflated syncytial capacitance, which could be voltage dependent.²⁰ Another reason for avoiding coupled cell groups is that the use of standard single- and dual-sine measurement approaches is invalidated by a model other than a single resistance-capacitance compartment.¹⁹

For a subset of cells, current voltage relations were investigated with a voltage step series (-100 to $+40$ or 50 mV; 200-millisecond step duration; holding potential of -60 mV) that was delivered to cells near the beginning and several times during the continuous monitoring of C_m . Current voltage (I-V) plots were derived from the last 50 milliseconds of current response. C_m recordings were made until C_m stabilized; typical durations ranged from 10 to 20 minutes. Statistical comparisons were made at steady state. A 4-pole Bessel filter at 10 kHz was used. All data acquisition and analyses were performed with the Windows-based voltage clamp software jClamp (SciSoft, New Haven, CT). Digital photos were captured with jClamp.

Cystic Fibrosis Transmembrane Conductance Regulator Knockout Mice

Congenic B6.129P2-Cftr^{tm1Unc} mice, which possess the S489X mutation that blocks transcription of CFTR,²¹ were used. Heterozygous breeding pairs were obtained from Jackson Laboratories (Bar Harbor, ME) and then bred in our animal facility. Genotypes for each mouse were determined by PCR with DNA isolated from tail clips by following Jackson Laboratories' instructions. Mice were maintained on a liquid elemental diet (Peptamen; Nestle, Milan, Italy) to prevent the intestinal obstruction associated with the CFTR mutation. Wild-type mice received regular solid mouse chow.²¹ Autoclaved tap water in bottles with sipper tubes was provided ad libitum. Mice selected for the experiments reported here were 7 to 8 weeks old without obvious signs of disease or discomfort (average weight, 18 ± 2.3 g for CFTR^{-/-} and 22 ± 1.7 g for their normal (CFTR^{+/+} and CFTR^{+/-}) littermates. For experiments with isolated perfused mouse liver, animals were anesthetized with pentobarbital sodium (50 mg/kg body weight). The abdomen was opened, and the gallbladder was cannulated after distal ligation of the common bile duct.²² The liver was perfused in situ at 5 mL/min with oxygenated HCO₃⁻-containing Ringer buffer and maintained at 37°C. Bile sampling

was started after a stabilizing period of 10 minutes after cannulation. Bile flow was determined gravimetrically, assuming a density of 1 g/mL for bile.

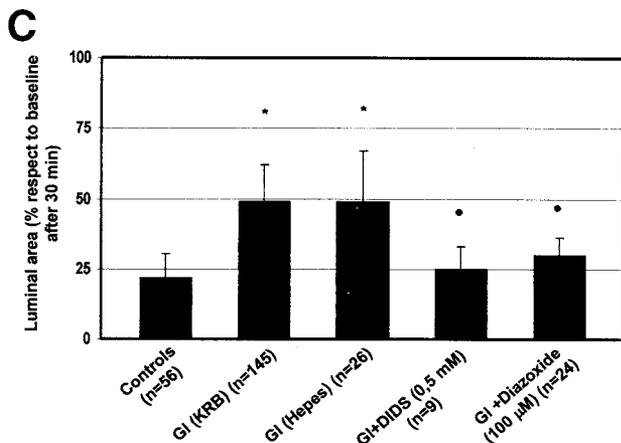

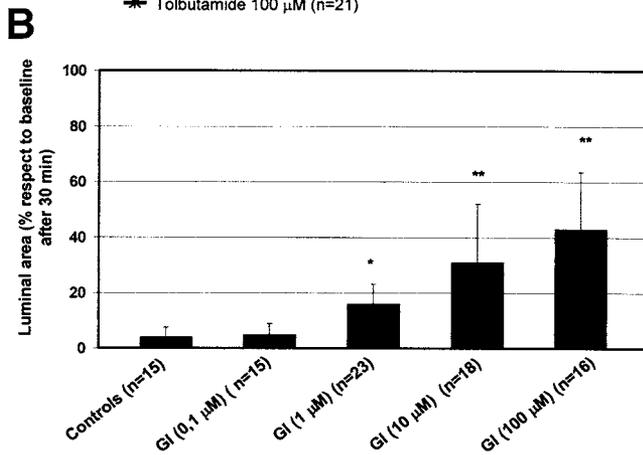

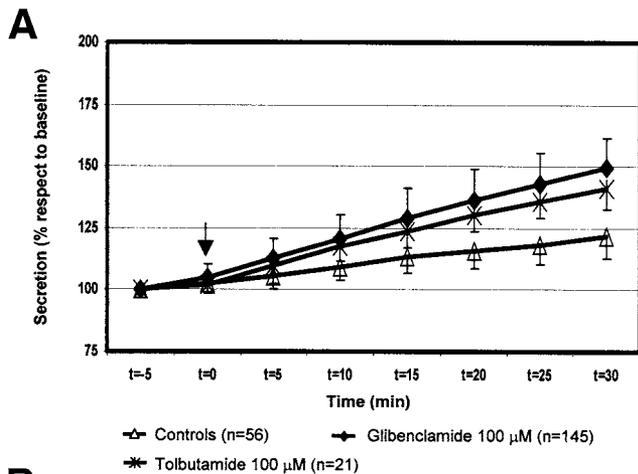

Statistical Analysis

Results are shown as mean ± SD. Statistical comparisons were made with Student *t* tests or analysis of variance, with Tukey post hoc tests where appropriate. GraphPad software (Biosoft, Cambridge, UK) was used; *P* values <.05 were considered significant.

Table 1. Luminal Area Expansion (Percentage With Respect to Baseline) in IBDUs

Variable	Changes (30 min)	n	<i>P</i>

Results

Glibenclamide-Induced Fluid Secretion in Isolated Bile Duct Units

Cholangiocyte secretion was measured, as previously described,⁴ from the change in luminal area induced by exposure of rat intrahepatic bile duct units to glibenclamide (Figure 1A and Table 1). Administration of glibenclamide induced a dose-dependent (0.1–100 μmol/L) increase in luminal area with respect to controls. The increase in luminal area was 16% ± 7% (*P* < .05) at 1 μmol/L and reached the maximal effect at 100 μmol/L: 45% ± 20% (expressed as percentage increase with respect to baseline after 30 minutes; *P* < .01;

Figure 1. Sulfonylureas-stimulated secretion in IBDUs is dose dependent, HCO₃⁻ independent, and Cl⁻ dependent. (A) IBDUs were examined under control conditions for 10 minutes and then for an additional 30 minutes after the administration of glibenclamide or tolbutamide (arrow). Both sulfonylureas induced a significant (*P* < .001) increase in the luminal area. (B) Glibenclamide stimulates secretion in IBDUs in a dose-dependent manner. Columns represent the percentage of luminal area expansion with respect to baseline after 30 minutes of glibenclamide administration (mean ± SD). **P* < .05 and ***P* < .01 vs controls. (C) Perfusion with HCO₃⁻-free buffer (HEPES) did not affect the increase in luminal area induced by glibenclamide, which is inhibited by the Cl⁻ transporter inhibitor DIDS. Diazoxide inhibits the choleric effect of glibenclamide. Columns represent the percentage of luminal area expansion with respect to baseline after 30 minutes of glibenclamide administration (mean ± SD). **P* < .001 vs controls; ●*P* < .05 vs glibenclamide. KRB, HCO₃⁻-containing Ringer buffer; GI, glibenclamide.

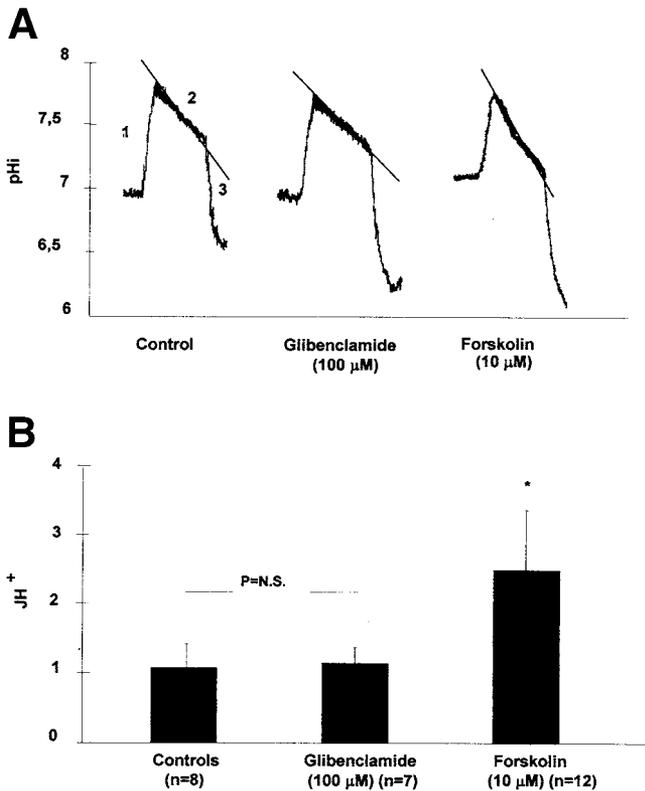

Figure 2. Glibenclamide-stimulated secretion in IBDUs does not involve stimulation of the $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ cotransporter. (A) $\text{Na}^+\text{-K}^+\text{-2Cl}^-$ activity was measured by using the NH_4Cl^- (20 mmol/L) pulse technique¹⁵ (which exploits the ability of NKCC1 to transport NH_4^+ in stoichiometrical substitution of K^+) from the initial rate of acidification (120 seconds) (2) after the NH_3 -induced alkalinization (1); rapid acidification occurred after NH_4Cl withdrawal (3). (B) The graph bars show the transmembrane H^+ fluxes (J_{H^+}) calculated as $\delta\text{pHi}/\delta t \times \beta_i$ (intrinsic buffering power) at pH 7.5. Columns represent the mean \pm SD. * $P < .01$ vs controls. N.S., not significant.

Figure 1B). Glibenclamide-induced choleresis was Cl^- dependent: it was blocked by bumetanide,⁴ an NKCC1 inhibitor, and by DIDS (0.5 mmol/L), a general inhibitor of Cl^- -dependent transport (Table 1). Omission of HCO_3^- from the perfusate (HEPES buffer), conversely, did not inhibit glibenclamide choleresis (Figure 1C and Table 1), thus indicating that, in contrast to secretory events that depend on cAMP or Ca^{2+} signaling,^{3,23} HCO_3^- transport is likely not involved in glibenclamide choleresis. Contrary to a previous hypothesis based on bumetanide inhibition,⁴ direct measurement of NKCC1 activity (Figure 2) showed that glibenclamide did not stimulate NKCC1; on the other hand, forskolin (10 $\mu\text{mol/L}$) administration induced the expected stimulatory effect. NKCC1 activity was as follows: transmembrane H^+ fluxes (J_{H^+}) = 1.08 ± 0.26 $\text{mmol} \cdot \text{L}^{-1} \cdot \text{min}^{-1}$, $\delta\text{pH}/\delta t = 0.08 \pm 0.01/\text{min}$ (pH 7.5; $n = 7$) in controls; $\text{J}_{\text{H}^+} = 2.5 \pm 0.88$ $\text{mmol} \cdot \text{L}^{-1} \cdot \text{min}^{-1}$, $\delta\text{pH}/\delta t = 0.171 \pm 0.06/\text{min}$ (pH

7.5; $n = 12$) in IBDU treated with forskolin (10 $\mu\text{mol/L}$); and $\text{J}_{\text{H}^+} = 1.15 \pm 0.23$ $\text{mmol} \cdot \text{L}^{-1} \cdot \text{min}^{-1}$, $\delta\text{pH}/\delta t = 0.074 \pm 0.01/\text{min}$ (pH 7.5; $n = 8$; not significant vs controls) in IBDU treated with glibenclamide.

Glibenclamide Is Not Secreted by Cholangiocytes

Many drugs induce osmotic bile secretion after their active transport and concentration into the bile. Therefore, we measured the concentration of glibenclamide and of its metabolites 3-*cis*-hydroxyglibenclamide and 4-*trans*-hydroxygliburide in the bile collected from isolated rat livers perfused with 100 $\mu\text{mol/L}$ glibenclamide for 30 minutes and compared it with the concentrations found in the apical overnatant of rat cholangiocyte monolayers after the administration of 100 $\mu\text{mol/L}$ glibenclamide from the basolateral side. The glibenclamide concentration in bile collected from isolated rat livers was 127 ± 21 $\mu\text{mol/L}$ ($n = 4$), whereas that of its metabolites 3-*cis*-hydroxygliburide and 4-*trans*-hydroxygliburide was 490 ± 113 $\mu\text{mol/L}$ and 311 ± 86 $\mu\text{mol/L}$, respectively. Conversely, after basolateral administration of glibenclamide (100 $\mu\text{mol/L}$) to polarized NRC-1 cholangiocyte monolayers, no metabolites were detected in the apical medium, and the glibenclamide concentration linearly increased, reaching only 32.5 $\mu\text{mol/L}$ after a 2-hour incubation (data not shown). This is consistent with diffusion rather than active transport by cholangiocytes. Thus, an osmotic effect by glibenclamide and its metabolites may only partially account for stimulation of hepatocellular bile flow in the isolated perfused rat liver, but not for the secretory effects induced by glibenclamide in isolated cholangiocyte units that are not capable of secreting glibenclamide or its metabolites into the lumen.

Stimulation of Ductal Choleresis Is a Property of Sulfonylurea Compounds and Is Mediated by Interaction With Cholangiocyte Sulfonylurea Receptor 2B

Similarly to glibenclamide, the administration of another sulfonylurea, tolbutamide (100 $\mu\text{mol/L}$), was able to stimulate fluid secretion in IBDUs (Figure 1A and Table 1). Preincubation with diazoxide (100 $\mu\text{mol/L}$), a classic SUR inhibitor, inhibited glibenclamide-stimulated secretion (Figure 1C and Table 1), consistent with the functional involvement of the SUR. Indeed, RT-PCR of mRNA extracted from immunopurified cholangiocytes revealed gene expression of SUR2B, the most widely expressed SUR isoform (Figure 3A), and of Kir 6.1 (Figure 3B), a protein belonging to a family of K^+_{ATP} channels associated with SUR.

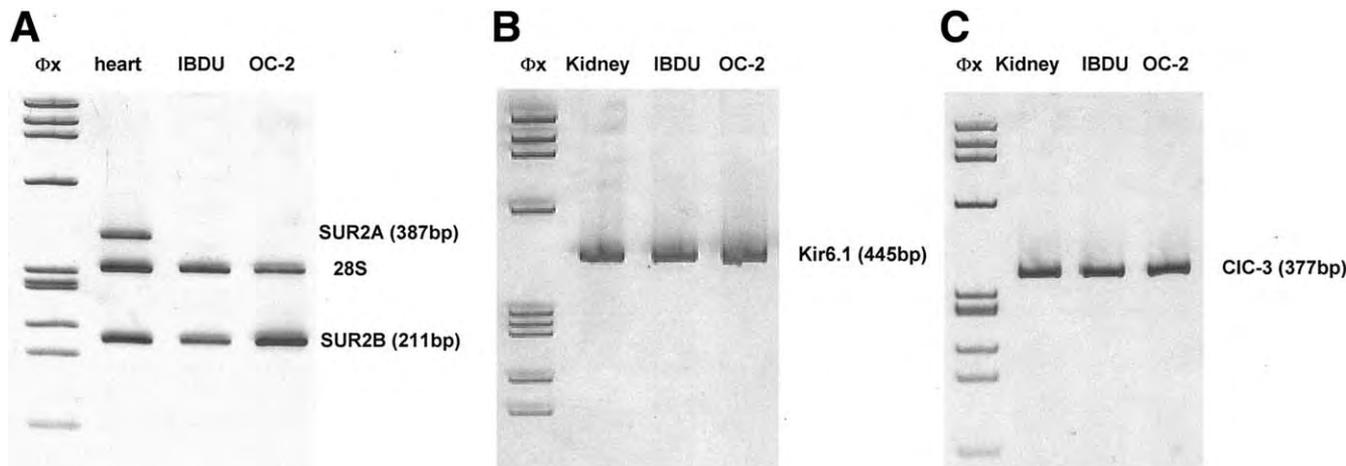

Figure 3. Gene expression of the SUR2B receptor, of the Kir 6.1 K^+_{ATP} channel, and of the CLC-3 Cl^- channel in IBDUs and in immunopurified rat cholangiocytes (OC-2). (A) SUR2AB primers were designed to cross the 177-bp insert in the SUR2A DNA sequence that gives rise to alternative spliced SUR2 variants (the primer pairs should generate PCR fragments of 211 bp for rSUR2B and 387 bp for rSUR2A. In the heart (control tissue), both SUR2 variants are expressed, whereas in IBDUs and OC-2 only the SUR 2B variant is expressed; the ribosomal fraction 28S was used as a housekeeping gene. (B) Kir 6.1, but not Kir 6.2 (data not shown), isoform PCR products are present in IBDUs and OC-2 cells. (C) The CLC-3 Cl^- channel is expressed in IBDUs and OC-2 cells; kidney tissue was used as a positive control.

Stimulation of Ductal Choleresis in Cholangiocytes Is Independent From Depolarization and Stimulation of Ca^{2+} Transients

In β -cells, sulfonylureas trigger insulin secretion by stimulating exocytotic events. Therefore, we tested the effects of several agents known to inhibit vesicular transport in the liver^{24–26} on glibenclamide-mediated choleresis: the microtubule-disrupting agent colchicine (50 μ mol/L; but not the inactive analogue γ -lumicolchicine), 2 phosphoinositol-3' kinase inhibitors (wortmannin 100 nmol/L and LY294002 50 μ mol/L), and *N*-ethylmaleimide (NEM; 1 mmol/L; an inhibitor of Soluble *N*-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) proteins required to permit vesicles to fuse with plasma membrane). All significantly inhibited glibenclamide-induced secretion in IBDUs (Figure 4A and Table 1). Taken together, these results indicate that glibenclamide stimulates vesicle exocytosis in cholangiocytes.

In pancreatic β -cells, the binding of glibenclamide to SUR inhibits the function of K^+_{ATP} channels. The resulting cell depolarization causes Ca^{2+} influx through L-type Ca^{2+} channels, and the increase in intracellular $[Ca^{2+}]$ stimulates exocytosis of insulin. However, in IBDUs, cell depolarization induced by depolarizing concentrations of extracellular K^+ (40 mmol/L)⁴ or by barium (5 mmol/L) and TEA (10 mmol/L) (2 well-known K^+ -channel inhibitors) did not stimulate secretion in IBDUs (Figure 5A and Table 1). Furthermore, neither glibenclamide nor membrane depolarization increased

Ca^{2+} in IBDUs (Figure 5B), whereas after ATP (10 μ mol/L) treatment, the expected Ca^{2+} response was recorded. The mechanism responsible for glibenclamide-induced secretion in cholangiocytes seems, therefore, to be similar to the Ca^{2+} -independent pathway that represents an additional mechanism through which sulfonylureas stimulate insulin secretion in pancreatic β -cells.²³ In this case, exocytosis of insulin-containing granules is dependent on the binding of glibenclamide to granular binding sites and is triggered by increasing osmotic forces inside the secretory granules induced by the cooperation of a V-type H^+ -adenosine triphosphatase (ATPase) and an accompanying shunt conductance provided by a CLC-3 Cl^- channel. Consistent with the predictions of this latter model, glibenclamide-induced fluid secretion was inhibited by V-type H^+ -ATPase inhibitors such as bafilomycin A (1 μ mol/L) and vanadate (100 μ mol/L; Figure 4B and Table 1). Also, glibenclamide-induced secretion was inhibited by niflumic acid, an inhibitor of Cl^- channels, including CLC-3, the gene expression of which was detected by RT-PCR in immunopurified cholangiocytes (Figure 3C).

Capacitance and Conductance Measurements on Isolated Cholangiocytes

To directly assess the possibility of vesicular release, we performed patch-clamp experiments on immunopurified cholangiocytes. Single cells measuring on average $7.06 \pm 1.3 \mu$ m in diameter ($n = 28$) were studied; this size equates to a simple spherical membrane surface area of 156μ m² (Figure 6A). Our measured diameter is

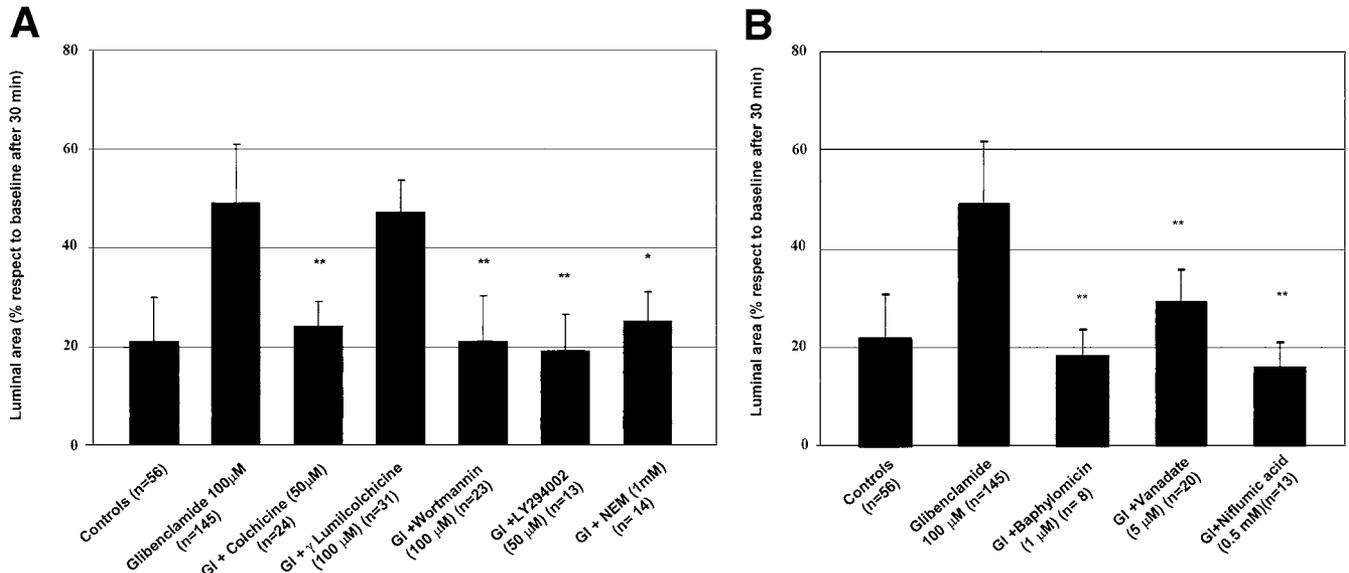

Figure 4. The choleric effect of glibenclamide in IBDUs is mediated by vesicular transport and is inhibited by V-type H⁺ ATPase and CLC-3 Cl⁻ channel blockers. (A) Inhibition by colchicine, phosphoinositol-3' kinase inhibitors (wortmannin and LY294002), and the SNARE inhibitor NEM. (B) Inhibition by V-type H⁺ ATPase inhibitors (bafilomycin and vanadate) and of CLC-3 inhibitors (niflumic acid). Columns represent the percentage of luminal area expansion with respect to baseline 30 minutes after the administration of glibenclamide (mean ± SD). *P < .01; **P < .001 vs glibenclamide. Gl, glibenclamide.

smaller than that found in other reports²⁷ that used cholangiocytes isolated from bile duct-ligated rats, rather than from normal ones, and is consistent with the size reported by Kanno et al¹³ for small duct cholangiocytes. The initial control cell diameter was 7.47 ± 0.91

μm, and C_m was 2.22 ± 1.1 pF (n = 5). On the basis of recent estimates of specific C_m (0.005 pF/μm²),²⁸ this C_m measurement exceeds the expected value of 0.87 pF and indicates that substantial cell membrane folding exists. Even with the more commonly used translation factor of

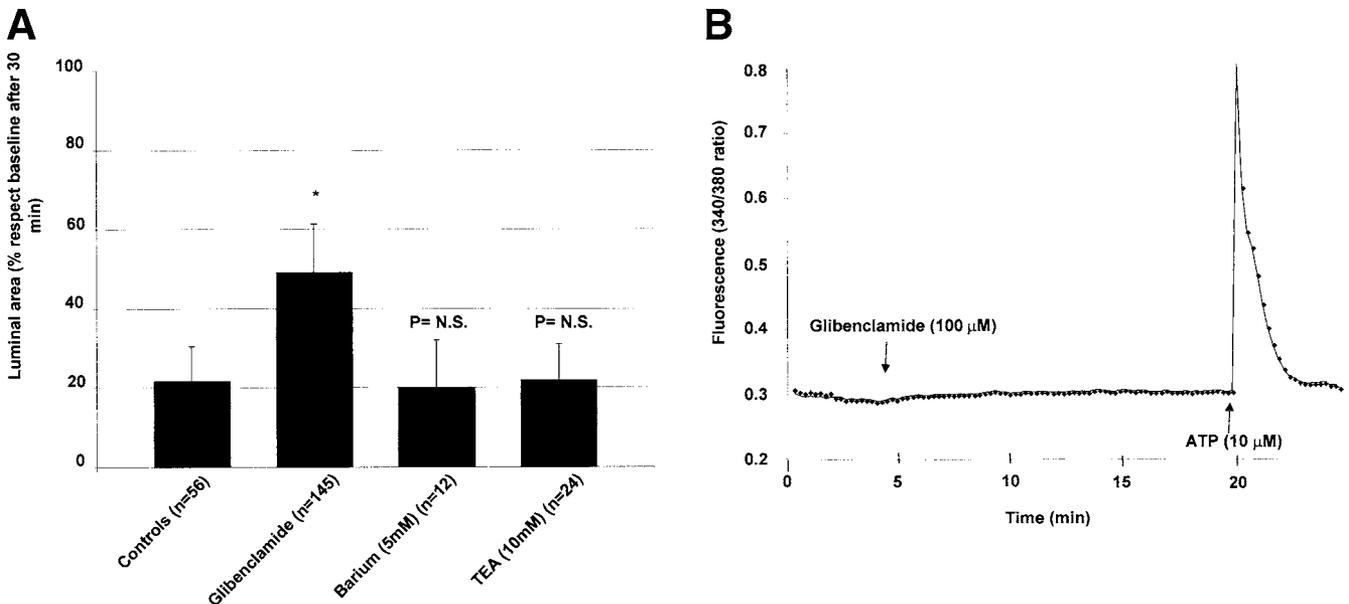

Figure 5. (A) Effects of depolarization on luminal expansion in IBDUs. Depolarizing concentrations of barium and of TEA did not stimulate secretion in IBDUs. Columns represent the percentage of luminal area expansion with respect to baseline after 30 minutes of stimulus administration (mean ± SD). (B) Effect of glibenclamide on intracellular Ca²⁺ levels. A representative tracing is shown of 22 similar experiments showing changes in the ratio of the 2 wavelengths of FURA-2 induced by the administration of glibenclamide. Glibenclamide did not increase intracellular [Ca²⁺] in IBDUs, whereas administration of ATP induced the expected Ca²⁺ increase. Similar experiments (n = 10) were performed by depolarizing the cells with TEA (10 mmol/L), and no significant changes in intracellular [Ca²⁺] were found. N.S., not significant.

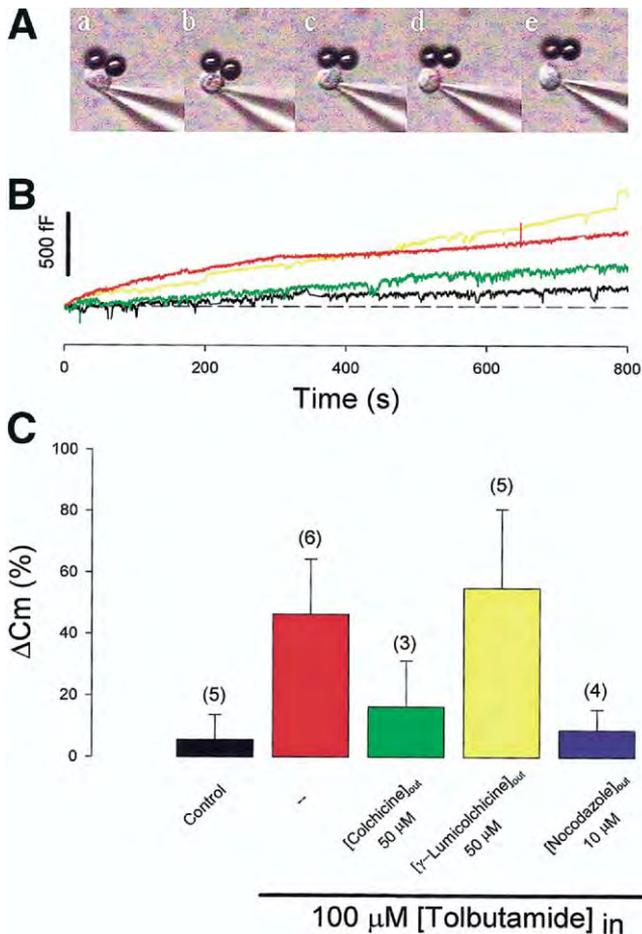

Figure 6. Whole-cell capacitance measurements in cholangiocytes. (A) Isolated cholangiocyte with 2 magnetic beads (diameter, 4.5 μm) attached to the cell membrane. Images a–e were captured at 5 minutes 12 seconds, 7 minutes 10 seconds, 10 minutes 24 seconds, 13 minutes 3 seconds, and 16 minutes 34 seconds after the establishment of whole-cell conditions, respectively. Note the gradual upward shift of beads as the cell swells. The change in surface area is smaller than it appears. This can be appreciated as follows. The initial diameter of the cell at 5 minutes 12 seconds is 7 μm , giving an apparent area of 153 μm^2 ; the final diameter is 10.7 μm , giving an area of 373 μm^2 . The initial capacitance is 1.12 pF, which equates to 224 μm^2 . Thus, the membrane at the beginning is highly folded, and the diameter is underestimated.²⁸ The capacitance at 16 minutes 34 seconds is 1.81 pF, which equates to 362 μm^2 and corresponds well to the measured diameter of the inflated cell. (B) Example C_m recordings for 4 different cells after the establishment of whole-cell conditions; colors correspond to color-coded treatments in (C). Initial capacitance for individual cells was as follows: black, 1.611 pF; yellow, 0.716 pF; red, 1.655 pF; and green, 1.152 pF. (C) Bar graph depicting average results (with SD error lines) for the different cell treatments. See Materials and Methods for details. The number of cells is indicated. Tolbutamide significantly enhanced C_m increases over control-level increases ($P < .05$). Colchicine and nocodazole treatment significantly suppressed C_m changes compared with tolbutamide and γ -lumicolchicine treatment ($P < .05$).

0.01 pF/ μm^2 , C_m measurements suggest significant membrane folding that is not resolved at the light-microscopic level. C_m measurements in control cells were quite stable for tens of minutes (Figure 6B).

After establishment of whole-cell recording with pipettes containing tolbutamide (100 $\mu\text{mol/L}$), C_m increased over the course of several minutes (Figure 6B). Concomitantly, cells swelled; this was easily discerned by the movement of the membrane-bound magnetic beads that followed the contour of the expanding cell outline (Figure 6A). C_m eventually leveled off; at steady state, increases of 56% and 50% were found (Figure 6C). The preincubation of cholangiocytes with either colchicine (50 $\mu\text{mol/L}$ for 30 minutes) or nocodazole (10 $\mu\text{mol/L}$ for 60 minutes) blocked the increase in capacitance caused by tolbutamide. However, an inactive form of colchicine, namely, γ -lumicolchicine (50 $\mu\text{mol/L}$; 30 minutes), was unable to block the effects of tolbutamide (Figure 6C). We also found cells to swell during these treatments, so the increase in cell size (and, possibly, surface area) may not solely underlie the capacitance increases that we found (see Discussion).

Membrane conductance and holding current remained stable during recordings of control cells and cells treated with tolbutamide. Current–voltage relations showed linear, time-invariant currents (Figure 7), which in the example cell actually decreased slightly during tolbutamide treatments. For 6 cells, the membrane conductance at 0 mV was unaffected by tolbutamide during the time when C_m levels significantly increased (0 minutes, 0.985 ± 0.23 nS; 10 minutes, 1.15 ± 0.3 nS; paired t test; $P = .158$). Thus, in our isolated cholangiocytes, we

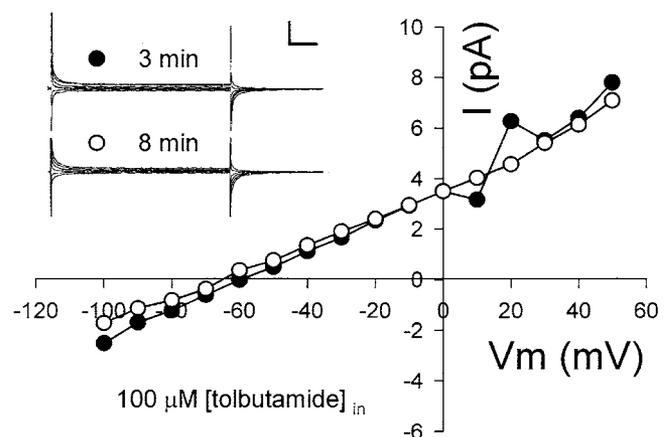

Figure 7. Whole-cell conductance measurements in cholangiocytes. I–V curves at 3 minutes (●) and 8 minutes (○) after the establishment of whole-cell conditions with 100 $\mu\text{mol/L}$ tolbutamide-containing pipette solution. Only a slight decrease in chord conductance was observed in this example. (Inset) Corresponding current traces at selected voltages (200-millisecond pulse duration) of -100, -70, -40, -10, 20, and 50 mV. Note linear, time-independent currents. Voltage at 0 current was stable and negative, near -60 mV; calculated reversal potentials for K and Cl were -86 and -34 mV, respectively. Scale: 40 pA, 31 milliseconds. Traces were filtered at 500 Hz with a digital gaussian filter.

found no evidence for a plasma membrane Cl^- conductance augmented by the increase in C_m .

Glibenclamide Stimulates Bile Flow in Isolated Perfused Mouse Liver and Fluid Secretion in Isolated Bile Duct Units From Cystic Fibrosis Transmembrane Conductance Regulator Knockout Mice

Because glibenclamide is a known CFTR inhibitor, our data thus far suggest that the choleric effect of glibenclamide is mediated by a CFTR-independent mechanism that would likely be maintained in CF. To address this possibility, we tested the effect of glibenclamide in isolated perfused mouse liver and in IBDUs from mice knocked out for CFTR (B6.129P2-Cftr^{tm1Unc}). In isolated perfused mouse liver, glibenclamide increased bile flow in wild-type mice as well as in CFTR knockout mice, and, interestingly, the increase in bile flow was significantly higher in CFTR knockout mice (Figure 8). In IBDUs isolated from 4 wild-type and 4 heterozygous mice, the administration of forskolin (10 $\mu\text{mol/L}$) or secretin (50 nmol/L) significantly increased the luminal area (wild-type—forskolin, $68\% \pm 19\%$, $n = 42$; secretin, $62\% \pm 17\%$, $n = 39$, $P < .01$ vs controls, $12\% \pm 6\%$, $n = 36$; heterozygous—forskolin, $58 \pm 13\%$, $n = 51$; secretin, $57\% \pm 20\%$, $n = 24$; $P < .01$ vs controls, $14\% \pm 6\%$, $n = 31$). In IBDUs isolated from 5 homozygous CFTR knockout mice ($-/-$), the effects of forskolin and of secretin were significantly inhibited

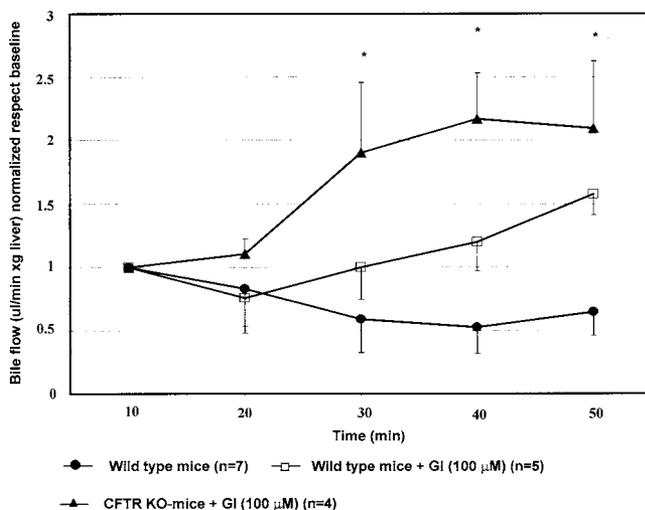

Figure 8. Glibenclamide stimulates bile flow in wild-type and CFTR knockout mice. Glibenclamide stimulates bile flow in isolated perfused mouse livers from wild-type and CFTR knockout mice. Bile flow was significantly increased ($*P < .001$) in wild-type and CFTR knockout mouse livers perfused with glibenclamide (100 $\mu\text{mol/L}$) with respect to wild-type mice. Bile flow is expressed as microliters of bile secreted in 1 minute and normalized for liver weight. Gl, glibenclamide.

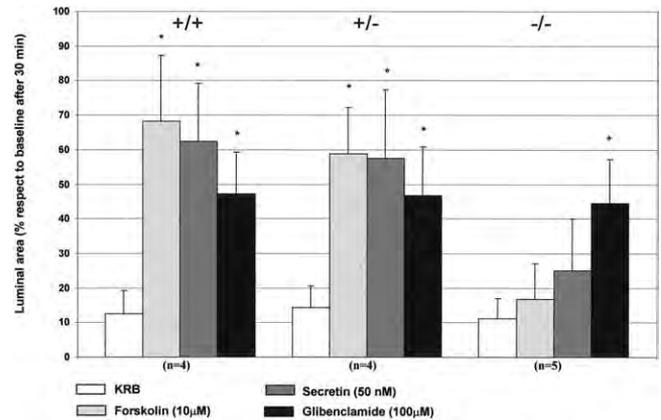

Figure 9. The choleric effect of glibenclamide is maintained in IBDUs isolated from CF mice. IBDUs were examined under control conditions for 10 minutes and then for an additional 30 minutes after the administration of glibenclamide, forskolin or secretin, or vehicle. Each luminal area was normalized by its initial value. Glibenclamide significantly ($*P < .01$ vs controls) stimulated secretion in IBDUs isolated from wild-type (+/+), heterozygous (+/-), and homozygous (-/-) mice. Forskolin and secretin were able to significantly ($*P < .01$) stimulate secretion only in wild-type and heterozygous, but not in homozygous, mice. KRB, HCO_3^- -containing Ringer buffer.

(forskolin, $17\% \pm 10\%$, $n = 54$; secretin, $25\% \pm 17\%$, $n = 41$; $P < .001$ vs wild-type and heterozygous), thus indicating that the fundamental CF secretory defect was maintained in the liver of homozygous mice. Conversely, in CFTR knockout mice, the secretory effect of glibenclamide was maintained and was equal to that recorded in wild-type and heterozygous animals (Figure 9).

Discussion

Strategies aiming at directly stimulating fluid secretion by cholangiocytes may be a useful approach to treat cholestasis in biliary tract diseases,² particularly in CF, in which reduced Cl^- and fluid secretion into the lumen causes inspissation of bile and chronic liver damage. To this end, we have studied the molecular mechanisms underlying the choleric effects of glibenclamide. The interest in this compound derives from previous studies by Nathanson et al,⁴ which showed that glibenclamide, a known CFTR inhibitor, paradoxically stimulates bile flow at the level of cholangiocytes.

Because the mechanism of glibenclamide-induced choleresis was not clarified, we sought to investigate these mechanisms in more detail. Given the inhibitory effects of bumetanide on glibenclamide-induced cholangiocyte secretion, a direct stimulation of Cl^- uptake by the NKCC1 cotransporter¹⁵ was proposed as a possible explanation.⁴ In this study, we have measured the effects of glibenclamide on $\text{Na}^+/\text{K}^+/\text{2Cl}^-$ activity, and, contrary to the previous hypothesis,⁴ we could find no

evidence of NKCC1 stimulation. Our data also show that polarized cholangiocytes⁷⁻⁹ are not able to transport glibenclamide into the apical lumen and that this stimulation of secretion is not due to an osmotic choleresis.

After binding to a specific receptor (SUR), sulfonylureas stimulate an exocytotic release of insulin from pancreatic β -cells.^{5,29} The following observations suggest that the choleric effect of glibenclamide on cholangiocytes may also be due to a receptor-mediated mechanism: (1) tolbutamide, another sulfonylurea, was able to induce luminal expansion in IBDUs to a similar extent; (2) the mRNA for SUR2B was expressed in immunopurified cholangiocytes; and (3) diazoxide, a known SUR inhibitor, significantly inhibited the secretory effect of glibenclamide. Our data also indicate that, similar to their effects on pancreatic β -cells,^{17,29} sulfonylureas are likely to stimulate fluid secretion via vesicular transport in cholangiocytes. In fact, tolbutamide induced an increase in C_m in immunisolated cholangiocytes; in addition, glibenclamide-induced secretion and/or the increase in C_m was inhibited by compounds known to block vesicular transport in the liver, such as colchicine, nocodazole, and wortmannin,²⁴⁻²⁶ and by NEM. These compounds act through different mechanisms; whereas colchicine and nocodazole are microtubule inhibitors, wortmannin is a phosphoinositol-3' kinase inhibitor, and NEM blocks the NEM-sensitive fusion protein.^{30,31} Although none of them can be considered a specific inhibitor of vesicular exocytosis, their consistent inhibitory effect on glibenclamide choleresis and on C_m changes provides strong evidence that glibenclamide stimulates vesicle exocytosis in cholangiocytes.

In the pancreatic β -cell, SUR complexes with Kir 6.x (a Kir sensitive to intracellular concentration of ATP [ATP]_i). In these cells, closure of the K_{ATP} channel induced by glibenclamide interaction with SUR depolarizes the cell, favoring Ca^{2+} influx via L-type Ca^{2+} channels.³² Although expression of the mRNA of the Kir 6.1 K_{ATP} channel isoform was detectable in immunopurified cholangiocytes (Figure 3B), neither the K^+ channel inhibitor TEA nor maneuvers aimed at inducing membrane depolarization in cholangiocytes (barium or high K^+)⁴ were able to induce luminal expansion in IBDUs. Also, in patch-clamp experiments, depolarization did not induce vesicular release; furthermore, neither the administration of glibenclamide nor membrane depolarization increased intracellular Ca^{2+} levels. This is in clear contrast to the 450 nmol/L intracellular [Ca^{2+}] increase induced by depolarization in β -cells.³³ Altogether, these data suggest that, in cholangiocytes, glibenclamide stimulates secretion via a mechanism that is independent from depolarization and Ca^{2+} transients.

In pancreatic β -cells, sulfonylureas are also able to potentiate insulin secretion by acting directly on the exocytotic machinery. Ninety percent of the high-affinity sulfonylurea binding sites in the β -cell are intracellular and seem to colocalize with the insulin-containing secretory granules.^{25,26} Recent studies have also shown that recombinant green fluorescent protein-tagged SUR and Kir colocalize with fluorescent glibenclamide in insulin-containing granules.³⁴ Furthermore, it has been shown that sulfonylureas, being weak acids, can cross biological membranes by diffusion,³⁵ thus inducing a pHi decrease similar to the one originally described by Nathanson et al⁴ in cholangiocytes. Several studies have provided evidence indicating that intracellular binding of sulfonylureas activates a DIDS- and niflumic acid-sensitive CLC-3 Cl^- channel operating in conjunction with a bafilomycin-sensitive V-type H^+ -ATPase. The resulting Cl^- and H^+ influx stimulates the exocytotic machinery and insulin discharge in a depolarization and Ca^{2+} independent way.^{17,36,37} In fact, a low granular pH promotes conformational changes in SNARE proteins, making them more fusogenic.²⁹ Our data in cholangiocytes are consistent with this mechanism; in fact, (1) glibenclamide administration does not increase intracellular [Ca^{2+}] levels; (2) membrane depolarization does not stimulate cholangiocyte secretion; (3) CLC-3 mRNA was detected in cholangiocytes; (4) DIDS, a generic inhibitor of Cl^- channels, and niflumic acid, which inhibits CLC-3, blocked the choleric response to glibenclamide; and (5) the V-type H^+ -ATPase inhibitors bafilomycin A1 and vanadate significantly reduced the secretory response to glibenclamide. Altogether, these data suggest the presence in cholangiocytes of a cAMP- and Ca^{2+} -independent secretory mechanism that is stimulated by sulfonylureas and requires functional exocytotic machinery.

Our capacitance measurements provide further evidence that tolbutamide promotes an increase in cell-surface area; the dependence of this effect on microtubule stability argues for vesicular fusion with the plasma membrane.³⁸ Increases in C_m of approximately 50% were found, similar to our luminal area measurements in IBDUs, and although this may seem large, a complete vesicular release in bile ductal cells of the pig increased the membrane surface area by >100%.³⁹ Actually, an increase in capacitance may arise from several sources, including an increase in membrane surface area due to vesicular fusion and swelling of the cell with attendant thinning of the membrane and unraveling of membrane folds (eg, microvilli). Thinning of the membrane caused by membrane stretch is expected to increase specific C_m , and the resulting increase in whole-cell capacitance can-

not be distinguished electrically from actual membrane accrual. Additionally, tight folding of the membrane may initially limit the accessibility of voltage perturbation across those membranes, and after cell swelling and unraveling, these membranes may then be fully excited and contribute more to C_m measurements. We found that cells readily swelled during our recording and, indeed, shifted the attached magnetic beads (Figure 6A). Although the microtubule destabilizers may be thought to specifically inhibit vesicular release in cholangiocytes,³⁸ they may also somehow affect the other potential mechanisms of C_m increase. Thus, we cautiously hypothesize that at least a component of C_m increase results from vesicular fusion.

Usually we held the cell membrane potential at zero voltage during capacitance measurements, because we observed that cells were not maintained for prolonged periods of time when they were held at negative potentials. Despite this depolarized holding potential, control cells did not show capacitance increases as might have occurred if an influx of extracellular Ca^{2+} via voltage-gated Ca^{2+} channels could induce exocytosis. Indeed, under our recording conditions, measurements do not show inward currents typical of non-inactivating L-type Ca^{2+} channels.

We did not find significant changes in membrane conductance during tolbutamide treatments. Indeed, our isolated cells, before and after these treatments, showed only small linear, time-independent currents, similar to 1 pattern of 3 found by Fitz et al.²⁷ Perhaps our isolation technique favored a particular cell subpopulation. The holding current was remarkably stable during our treatments, and current-voltage relations confirmed these measurements, showing that changes in ionic conductance did not necessarily accompany C_m increases. Although we observed that secretion in IBUs could be inhibited by Cl^- channel blockers, it should be noted that our whole-cell voltage-clamp measurements are unable to assess channel activity within intracellular membrane compartments, such as vesicles; of course, blockers may work at this level. As already shown,^{37,40} CLC-3 channels provide an electrical shunt pathway that permits vesicle acidification by the vacuolar pump before vesicular release. This scenario favors a fluid-phase type of secretory activity in our cholangiocyte preparation.

The transport functions of the biliary epithelium are regulated by different gastrointestinal hormones that stimulate either secretory or absorptive mechanisms.¹ Secretin, the principal stimulatory hormone, increases ductular choleresis through cAMP/protein kinase A-dependent stimulation of Cl^- efflux and HCO_3^- secretion

through the coordinated actions of CFTR and the anion exchanger isoform 2 Cl^-/HCO_3^- exchanger, both located at the apical pole of the cells.^{41,42} Cl^- efflux into the bile can also be mediated by Ca^{2+} -dependent Cl^- channels stimulated by binding of extracellular ATP to P2Y2 purinergic receptors located at the apical pole of cholangiocytes.^{3,23} In addition, a substantial amount of evidence indicates that stimulation of vesicular transport and fusion plays a role in cholangiocyte secretion. In vivo and in vitro studies using fluid-phase markers have shown that cholangiocytes are capable of microtubule-dependent fluid-phase transcytotic transport from the basolateral to the apical domains.^{10,38,43} Furthermore, cholangiocytes possess a dense population of subapical vesicles that undergo a high rate of constitutive exocytosis⁴⁴ that can be stimulated by osmotic stress and by cAMP. Cyclic AMP stimulates the exocytosis of acridine orange in cholangiocytes³⁸ and the apical insertion of vesicles containing aquaporins and ion transporters (such as CFTR and anion exchanger isoform 2) as a means of achieving rapid regulation of biliary ion and fluid transport.⁴⁵

The choleric effect of glibenclamide is a paradox; in fact, because it is a known inhibitor of CFTR, one would expect glibenclamide to inhibit secretion. Thus, the major finding of our study, which is of potential therapeutic relevance, is that sulfonylureas possess the ability to stimulate cholangiocyte secretion, thus promoting a novel cAMP-, Ca^{2+} -, and depolarization-independent exocytotic mechanism, and that this effect is preserved and even more active in experimental animals defective for CFTR. An important line of research in CF aims at finding small molecules able to stimulate fluid secretion in CFTR-defective cells and focuses on compounds able to function as molecules that (1) can serve as chaperones for CFTR, (2) can activate the mutated CFTR, and (3) can stimulate Ca^{2+} -dependent Cl^- conductances.

Direct transfer of these observations to human therapy is not likely, because the K_d for the choleric effects of glibenclamide is approximately 9 $\mu\text{mol/L}$,⁴ a concentration that may result in hypoglycemia. However, our data represent an important proof of concept; the identification of a compound able to stimulate bile secretion independently of CFTR and the 2 major signaling pathways (Ca^{2+} and cAMP) is of major general interest. Sulfonylureas may thus represent model compounds to design drugs for conditions characterized by a failure in cAMP-dependent secretion (such as CF-related liver disease) and possibly other cholestatic conditions in which a defect in Ca^{2+} signaling is present.⁴⁶

Received: 31 December 1998/Revised: 12 March 1999

Abstract. The underlying Boltzmann characteristics of motility-related gating currents of the outer hair cell (OHC) are predicted to generate distortion components in response to sinusoidal transmembrane voltages. We studied this distortion since it reflects the mechanical activity of the cell that may contribute to peripheral auditory system distortion. Distortion components in the OHC electrical response were analyzed using the whole-cell voltage clamp technique, under conditions where ionic conductances were blocked. Single or double-sinusoidal transmembrane voltage stimulation was delivered at various holding voltages, and distortion components of the current responses were detected by Fourier analysis. Current response magnitude and phase of each distortion component as a function of membrane potential were compared with characteristics of the voltage-dependent capacitance, obtained by voltage stair-step transient analysis or dual-frequency admittance analysis. The sum distortion was most prominent among the distortion components at all holding voltages. Notches in the sum (f_1+f_2), difference (f_2-f_1) and second harmonic ($2f$) components occur at the voltage where peak voltage-dependent capacitance resides (V_{pkCm}). Rapid phase reversals also occurred at V_{pkCm} , but phase remained fairly stable at more depolarized and hyperpolarized potentials. Thus, it is possible to extract Boltzmann parameters of the motility-related charge movement from these distortion components. In fact, we have developed a technique to follow changes in the voltage dependence of OHC motility and charge movement by tracking the voltage at phase reversal of the f_2-f_1 product. When intracellular turgor pressure was changed, V_{pkCm} and distortion notch voltages shifted in the same direction. These data have important implications for understanding cochlear nonlinearity, and more generally, indicate the use-

fulness of distortion analysis to study displacement currents.

Key Words: Outer hair cell — Distortion — Gating charge — Membrane capacitance — Turgor pressure

Introduction

In linear systems, input and output signals contain the same in-phase frequency components. In nonlinear systems, stimulus frequencies (single: f_1 ; two-tone: f_1, f_2) produce harmonic and combination distortion components, such as nf_1 , $(n+1)f_1-nf_2$ and $(n+1)f_2-nf_1$ ($n = 1, 2, 3, \dots$). Distortion is readily perceived by the auditory system despite the purity of acoustic stimuli (Goldstein, 1967). Physiological correlates of the perceived distortion exist in responses of auditory nerve fibers (Goldstein & Kiang, 1968; Kim, Molinar & Matthews, 1980), inner hair cells (Nuttall & Dolan, 1990), and basilar membrane vibration patterns (Robles, Ruggero & Rich, 1991, 1997). Such distortion, which is dependent upon normal outer hair cell (OHC) function, clearly reveals the nonlinear nature of peripheral auditory processing. OHCs are the primary source of distortion components in mammals.

The OHC produces voltage-dependent mechanical responses that provide feedback into the basilar membrane, thereby sharpening the passive mechanical vibration of the cochlear partition (Brownell et al., 1985; Ashmore, 1987; Santos-Sacchi & Dilger, 1988; Ruggero, 1992). The cell also possesses a nonlinear gating charge movement or correspondingly, a voltage-dependent capacitance, which correlates well with its mechanical activity (Ashmore, 1989; Santos-Sacchi, 1990, 1991). The underlying nonlinear Boltzmann characteristics of the charge movement and mechanical response are predicted to generate distortion components in the response to single and dual sinusoidal transmembrane volt-

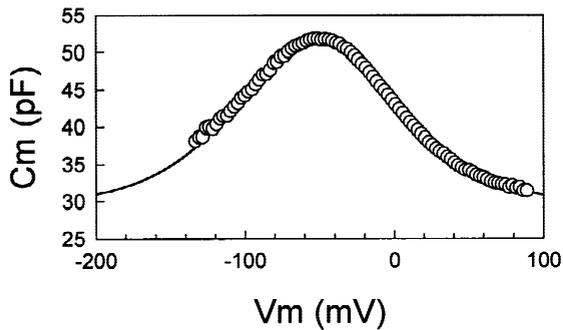

Fig. 1. Outer hair cell voltage-dependent capacitance determined from FFT-based dual-sinusoidal technique (Santos-Sacchi et al., 1998). Fit to Eq. 1 indicates V_{pkC_m} : -52.6 mV; z : 0.71; Q_{max} : 3.22 pC; and C_{lin} : 29.6 pF.

ages. Indeed, OHCs generate mechanical distortions when stimulated under voltage clamp (Santos-Sacchi, 1993) or transcellularly within a pipette microchamber (Hu et al., 1994). The purpose of the present experiments is to describe the features of OHC electrical distortion components that arise from motility-related charge movement. These electrical distortion components reflect the mechanical activity of the OHC and thus are useful in understanding the generation of mechanical distortion that is present in the peripheral auditory system. While the data have important implications for understanding cochlear nonlinearity, more generally, they illustrate the type of behavior expected from nonlinear membrane charge movement regardless of source (e.g., from ionic channels).

A preliminary presentation of these data has been made (Takahashi & Santos-Sacchi, 1997).

Materials and Methods

GENERAL

OHCs and supporting cells were freshly isolated from the organ of Corti of the guinea-pig cochlea and transferred to a $700 \mu\text{l}$ perfusion chamber (Kakehata et al., 1995) filled with an external standard solution. The external standard solution contained (in mM): 142 NaCl, 5.37 KCl, 1.25 CaCl_2 , 1.48 MgCl_2 , 10 HEPES and 5 dextrose, pH 7.2 , 300 mOsm. OHCs were whole-cell voltage clamped using an Axon 200B amplifier with patch pipettes having initial resistances of 2 – 3 $\text{M}\Omega$. Residual series resistance ranged from 3 – 7 $\text{M}\Omega$. To remove voltage-dependent ionic conductances, the external standard solution was replaced with an ionic blocking solution during electrical recording. The external ionic blocking solution contained (in mM): 100 NaCl, 20 TEA, 20 CsCl, 2 CoCl_2 , 1.52 MgCl_2 , 10 HEPES and 5 dextrose, pH 7.2 , 300 mOsm (adjusted with dextrose). The patch pipette solution contained (in mM): 140 CsCl, 2 MgCl_2 , 10 EGTA and 10 HEPES, with pH 7.2 and osmolarity 300 mOsm (adjusted with dextrose). Thus, capacitive currents could be analyzed in isolation (Santos-Sacchi, 1991; Huang & Santos-Sacchi, 1993; Kakehata & Santos-Sacchi, 1995). Salicylate (10 mM) or lutetium chloride (3 mM) was used to reduce

motility related gating charge movement in some experiments (Kakehata & Santos-Sacchi, 1996).

Pipette pressure was modified with a syringe connected to the Teflon tubing attached to the patch pipette holder. Pressure was monitored via a T-connector to a pressure monitor (WPI, Sarasota, FL). δz , longitudinal strain, a unit-less metric, was calculated as $\Delta L/L_0$, where ΔL is the change of cell length due to turgor pressure change and L_0 is the original cell length. All experiments were performed at room temperature (-23°C).

EVALUATION OF MEMBRANE CAPACITANCE

Detailed evaluation of membrane capacitance was made at different potentials by transient analysis of currents induced by a voltage stair step stimulus (-150 to $+50$ mV, 10 mV increments; Huang & Santos-Sacchi, 1993), or by FFT-based admittance analysis of dual voltage sinusoidal stimulation (Santos-Sacchi et al., 1998); the capacitance data were fit to the first derivative of a two state Boltzmann function relating nonlinear charge to membrane voltage (Santos-Sacchi, 1991),

$$C_m = C_v + C_{lin} = Q_{max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin} \quad \text{Eq (1)}$$

where

$$b = \exp\left(\frac{-ze(V_m - V_{pkC_m})}{kT}\right)$$

Q_{max} is the maximum nonlinear charge moved, V_{pkC_m} is voltage at peak capacitance or equivalently, at half maximal nonlinear charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. Series resistance, R_s , was estimated from the decaying time constant and integrated charge of the voltage step-induced current, as fully described elsewhere (Huang & Santos-Sacchi, 1993). Membrane resistance, R_m , was evaluated from steady state current. C_{lin} was estimated from the fit to above capacitance (C_m) equation, and indicates the intrinsic linear capacitance of the membrane upon which rides the bell-shaped voltage-dependent capacitance (C_v).

DISTORTION MEASUREMENT

To evoke distortion components, single or two summed sinusoidal membrane voltages were delivered to OHCs under whole-cell voltage clamp at various holding potentials. Peak amplitude of input stimuli was set between 5 and 26 mV. Input stimulus frequencies and frequency ratios (f_2/f_1) were also varied. The AC stimulus duration was fixed at 51.2 msec, with the sampling at $10 \mu\text{sec}$. Data were filtered at 5 kHz (4-pole Bessel). Steady-state current responses were analyzed by Fast Fourier Transform (FFT) to extract the magnitude and phase of distortion components at $2f_1 \pm f_2$, $2f_2 \pm f_1$, $f_2 \pm f_1$, $2f_1$, and $3f_1$. All data collection and analysis were performed with an in-house developed Window's based whole-cell voltage clamp program, jClamp (www.med.yale.edu/surgery/otolar/santos/jclamp.html), utilizing a Digidata 1200 board (Axon, CA).

Results

After blocking nonlinear conductances in the OHC, the predominant electrical nonlinearity that remains is a voltage-dependent capacitance, which derives from motility-

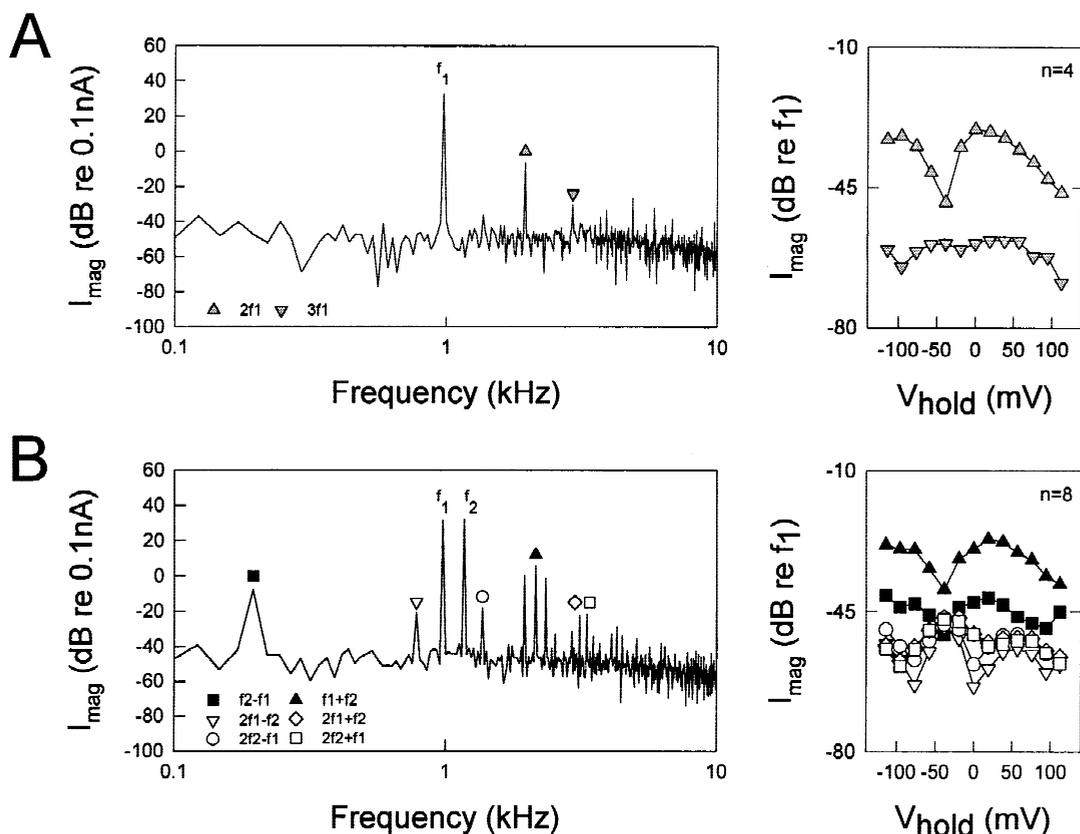

Fig. 2. *Left panels:* Typical frequency spectra of OHC current responses to AC transmembrane voltage stimuli measured under whole cell voltage clamp. Spectra were obtained by fast Fourier transform. Input stimulus frequencies were set at 963 Hz (f_1) and 1156 Hz (f_2); magnitudes were 25 mV peak. Induced currents contained (A) harmonic distortion components ($2f_1$, $3f_1$) and (B) combination distortion components (f_2-f_1 , f_1+f_2 , $2f_1-f_2$, $2f_2-f_1$), as well as peaks at the primary frequencies. The *right panels* illustrate the average effects of holding voltage (-120 to 120 mV, in 20 mV increments) on distortion component magnitudes (dB re: magnitude at f_1). Averaged series and membrane resistances were 4.0 and 259 $m\Omega$, respectively.

related nonlinear charge movement (Fig. 1). Due to this nonlinearity, delivery of single or dual sinusoidal voltages across the OHC membrane elicits current responses that contain the original frequency components as well as distortion components. Fig. 2 (*left panels A and B*) shows typical spectra obtained by FFT analysis of current responses evoked by 25 mV AC transmembrane voltage stimuli (f_1 : 963 Hz and f_2 : 1156 Hz). In addition to the peaks at the input stimulus frequencies (f_1 , f_2), quadratic distortions ($f_2 \pm f_1$), cubic distortions ($2f_1 \pm f_2$, $2f_2 \pm f_1$), and second and third harmonic distortions ($2f_1$, $3f_1$) were detected above the noise floor. The noise floor associated with our measuring system averaged approximately -46.7 dB re 0.1 nA in the 5 kHz bandwidth. Second harmonic, sum (f_1+f_2) and difference (f_2-f_1) distortion components were largest. For example, the largest sum component averaged 27 dB down from f_1 response magnitude. The *right panels* in Fig. 2 show averaged magnitude responses as a function of holding potential. Second harmonic, sum and difference distortion components exhibit magnitude notches near -40

mV, whereas notches in the other distortion component magnitudes appear at voltages above and below that voltage.

Distortion in cochlear supporting cells, e.g., Deiters cells, which lack the voltage-dependent capacitance characteristic of OHCs, was close to the noise floor (Fig. 3), supporting the view that the extensive distortion arising within the OHC is related to its lateral membrane sensor-motors. Indeed, the voltage dependence of distortion components derives from the Boltzmann characteristics of the robust OHC motility-related nonlinear charge movement and is evident in the representative data ($n = 10$) of Fig. 4 where voltage-dependent capacitance is plotted along with distortion component magnitude and phase. The voltage where magnitude minima are observed in second harmonic, sum and difference components corresponds to the voltage at peak capacitance (V_{pkcm}). Associated with the magnitude minima are abrupt phase reversals. The other distortion component minima are also associated with abrupt phase reversals. Changes in stimulus frequencies (f_2 : 0.6–1.4 kHz)

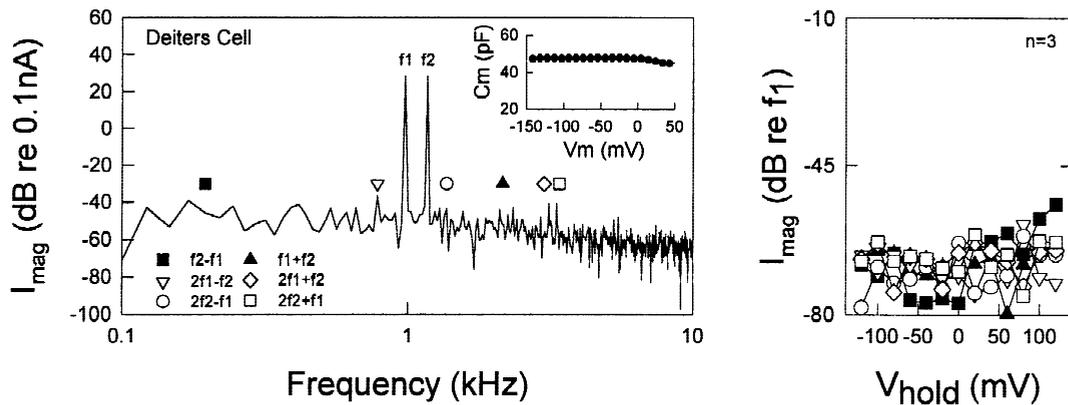

Fig. 3. Distortion components generated in a Deiters supporting cell obtained as in Fig. 2. *Left panel* shows distortion components close to the noise floor. Inset illustrates the linear capacitance of the cell. The *right panel* shows the effect of holding potential. It is clear that supporting cells do not present the degree of nonlinearity that characterizes the OHC.

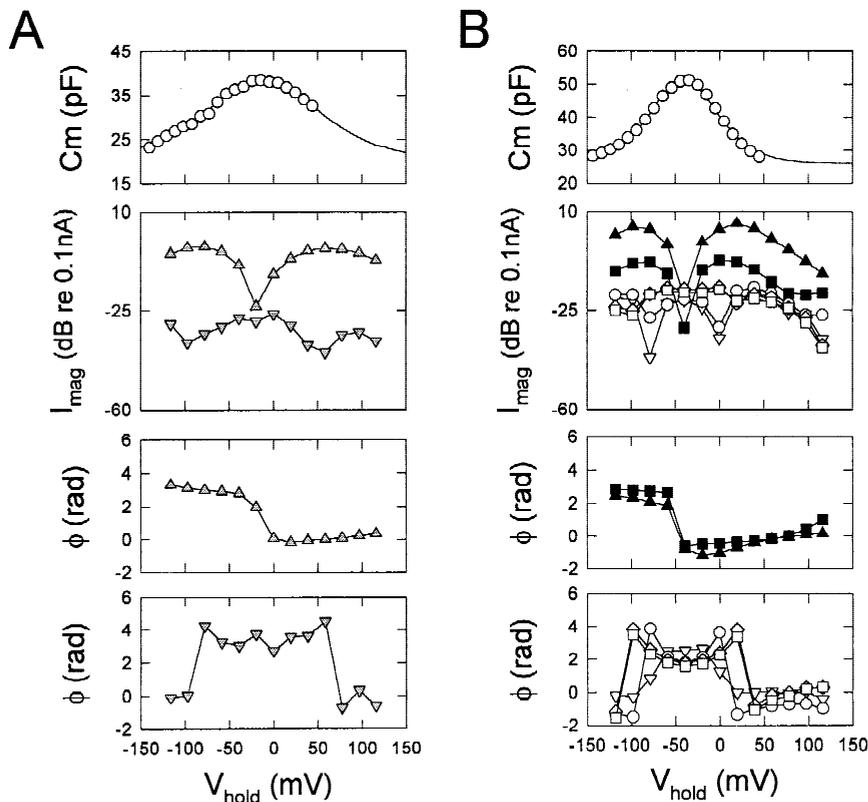

Fig. 4. Relationship between nonlinear capacitance and distortion component magnitude and phase. (A) OHC capacitance was determined by the stair step technique. The solid line indicates a fit of this cell's capacitance to Eq. 1: V_{pkCm} : -12.0 mV; z : 0.59 ; Q_{max} : 3.17 pC; and C_{lin} : 20.3 pF. The bottom panels plot the magnitude and phase of the second and third harmonic. Lines are only connections between symbols. Symbols are as in Fig. 2A. Note that the minima in magnitudes correspond to abrupt phase reversals. (B) The solid line indicates a fit of this cell's capacitance to Eq. 1: V_{pkcm} : -40.6 mV; z : 1.0 ; Q_{max} : 2.61 pC; and C_{lin} : 26.0 pF. The bottom panels plot the magnitude and phase of the combination distortion components. Symbols are as in Fig. 2B. As above, magnitude minima correspond to abrupt phase reversals.

or frequency ratios (f_2/f_1 : 1.1–1.4) did not alter distortion components. Figure 5 shows the intensity functions for the sum and difference components at three holding potentials, -60 , 0 and 60 mV. Distortion decreased at a rate greater than stimulus intensity. Other distortion components showed similar decreases, but in the low range of stimulus intensities disappeared into the noise floor.

Further evidence implicating OHC motility-related

nonlinear charge movement as the source of distortion is derived from charge blocking experiments. Both lanthanides and salicylate blocked voltage-dependence capacitance and distortion. Figure 6 illustrates the effects of 3 mM lutetium chloride on nonlinear capacitance and distortion products. The drop in capacitance is mirrored by a decrease in all distortion components. In the case of salicylate, the reductions were reversible (*data not shown*). The correspondence between distortion prod-

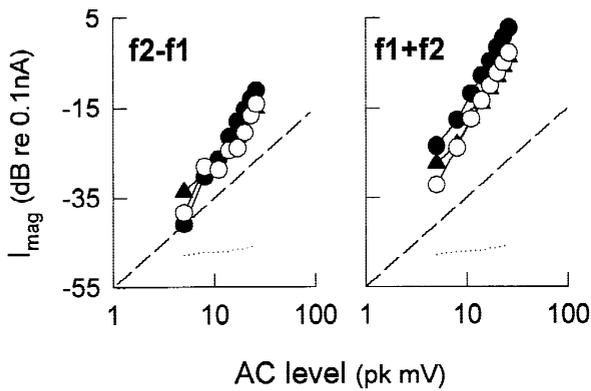

Fig. 5. Sum and difference distortion magnitude as a function of AC stimulus level. Results at three holding potentials are plotted: -60 mV, closed triangles; 0 mV, filled circles; 60 mV, open circles. Both components decrease at a rate greater than the stimulus. The dashed line illustrates a linear relationship. The dotted line is the noise floor.

ucts and nonlinear capacitance can be used to predict alterations in the Boltzmann characteristics. Figure 7 shows the utilization of $f2-f1$ phase reversal to track peak capacitance and V_{pkcm} during changes in OHC turgor pressure. As intracellular pressure is decreased, indicated by the change in OHC longitudinal strain (δz), C_m increases and V_{pkcm} shifts in the negative direction as observed previously using other techniques (Kakehata & Santos-Sacchi, 1995).

Discussion

The present results indicate that membrane-bound nonlinear charge movement, in this case due to motility voltage sensors residing in the OHC lateral membrane, can lead to distortion component generation under whole cell voltage clamp. Classical studies have used linearized impedance analysis to characterize ionic channel gating charge movement (Fishman, Moore & Ponssart, 1977; Takashima, 1978; Bezanilla et al., 1982; Fernandez, Bezanilla & Taylor, 1982). Indeed, similar analyses have been made on OHC motility-related gating charge (Santos-Sacchi, 1991). However, those studies did not evaluate distortion generation. In the OHC, single frequency voltage stimulation generates harmonic distortion and two-frequency stimulation generates combination distortion in the current responses. The largest components were at the second harmonic ($2f$), sum ($f1+f2$) and difference ($f2-f1$) frequencies, but significant responses were obtained at the more complex combination frequencies. The voltage dependence of the distortion component magnitude and phase derive from the Boltzmann characteristics of the OHC's motility-related gating charge. Thus, it was possible to track changes in V_{pkcm} , or equivalently V_h , the voltage at half-maximal charge

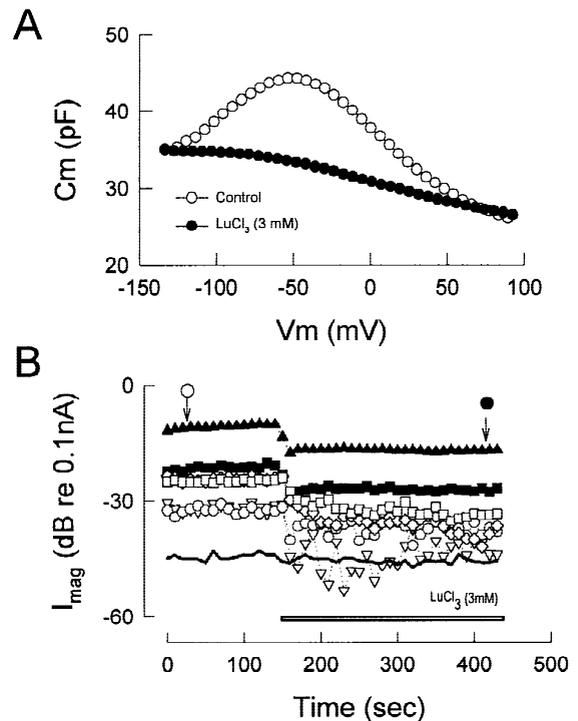

Fig. 6. Effects of charge blocking lutetium chloride on OHC capacitance and distortion. (A) Capacitance (measured with dual frequency admittance technique) of OHC before and after 3 mM LuCl_3 . Fit of control capacitance to Eq. 1 indicates V_{pkcm} : -53.3 mV; z : 0.59 ; Q_{max} : 3.68 pC; and C_{lin} : 23.4 pF. After treatment the function could not be fit reliably, however, at -60 mV nonlinear capacitance is halved by the treatment. (B) After treatment, distortion components measured at a holding potential of -60 mV were down about 6 dB (halved). Symbols are the same as in Fig. 2B.

displacement, by monitoring the phase reversal of the $f2-f1$ distortion component.

The magnitude and phase data are readily predicted from an electrical model of the OHC-patch-clamp system, which includes an electrode resistance in series with a parallel combination of membrane resistance and capacitance, the capacitance being comprised of a linear and voltage-dependent component (*see* Santos-Sacchi, 1993 for details). The voltage-dependent capacitance component is the only nonlinearity in the system. Figure 8 illustrates the response of the model to the same protocols, i.e., single- and two-frequency voltage stimulation, that we used in the experiments on OHCs and supporting cells. The fitted parameters of the two OHCs depicted in Fig. 4 were used in the model to generate the distortion components. The model response compares favorably with the biophysical data (*compare* Figs. 4 and 8), confirming that distortion magnitude minima and phase reversals result from the characteristics of the nonlinear capacitance function, or equivalently, the nonlinear $Q-V$ function. Notably, the nonlinearity in the OHC that we studied is similar to that of ionic channel gating,

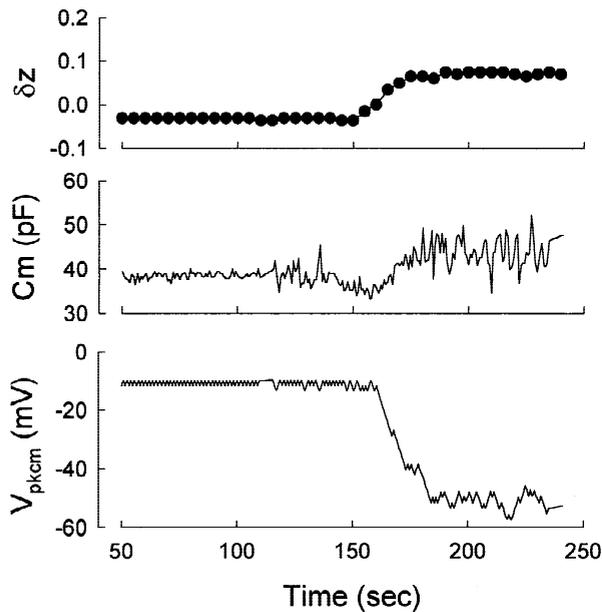

Fig. 7. Utilization of phase data to track changes in Boltzmann characteristics of OHC capacitance. The voltage at which f_2 - f_1 phase reversed (V_{pkcm}) was tracked by altering holding potential in 2 mV increments until a phase reversal occurred, whereupon holding potential was decremented until reversal occurred. The tracking process was continuous while OHC turgor pressure was altered. When turgor pressure was reduced, indicated by an increase in longitudinal strain (δz), C_m increased and V_{pkcm} shifted in the negative direction, in line with previous studies (Kakehata & Santos-Sacchi, 1995).

and therefore it is expected that channel gating will possess a distortion signature that characterizes its voltage-dependent behavior. Indeed, the small distortion components detected in supporting cells may arise from gating of ionic channels. A more selective and detailed analysis directed within an ionic channel's activation voltage range may prove more revealing.

Intermodulation distortion characteristics derived from the form of the mathematical function describing the excited nonlinearity; the magnitudes and phases of distortion are given by the Fourier expansion of the excitation products and are predictable (Dallos, 1973). In the case where a function can be expressed mathematically as a polynomial, AC distortions correspond to the order of the polynomial. Functions of quadratic order produce "quadratic distortions," namely (for dual excitation) $f_2 \pm f_1/2$, and those of cubic order produce "cubic distortions," namely, $2f_1 \pm f_2$, $2f_2 \pm f_1$. Since our data show both types of distortion, it is clear that the two-state Boltzmann function can be characterized by the sum of polynomials with even and odd orders, the relative contribution depending on the holding potential level. Thus, the distortion that we obtained empirically and verified through modeling and experimental perturbation with charge blockers is simply a consequence of the form of an OHC's Q-V function. It should be noted, however,

that memory-less characterizations such as this, as in our model, do not take into account the recently observed dependence of the Q-V function on initial voltage conditions (Santos-Sacchi et al., 1998). Thus, the slight differences between model and data may arise from this dependence.

Our data also indicate the need for caution when performing dual sinusoidal capacitance measures (Rohlicek & Rohlicek, 1993; Donnelly, 1994). Because of the large AC voltages typically used with these techniques, it is possible that distortion generated by membrane nonlinearities can interfere with capacitance measures. We used an FFT-based variation of this technique (Santos-Sacchi et al., 1998), but our signal levels were at 10 mV pk, where little distortion was generated in the OHC.

RELEVANCE TO THE AUDITORY SYSTEM

In the mammal, the range of auditory sensitivity spans greater than 100 dB. In order to process this immense range, the system response (e.g., basilar membrane amplitude) grows nonlinearly with stimulus level. As a result, distortion is generated and is the hallmark of the normal auditory system response; it is indicative of an active process that enhances the mammal's ability to detect and analyze spectral content in the environment, especially near threshold, at high acoustic frequencies (>10 kHz; see Ruggero and Santos-Sacchi (1997) for review). Damage to OHCs interferes with this process, and reduces system nonlinearities.

It is widely held that the active process involves voltage-driven mechanical responses of OHCs which provide feedback into the basilar membrane (Dallos, 1996). The molecular motors that reside in the lateral membrane of the OHC are bidirectional inasmuch as either membrane voltage or tension can evoke gating currents (Santos-Sacchi, 1991; Iwasa, 1993; Gale & Ashmore, 1994; Kakehata & Santos-Sacchi, 1995; Takahashi & Santos-Sacchi, 1998). Furthermore, the cell's voltage-dependent capacitance correlates well with its mechanical activity (Ashmore, 1989; Santos-Sacchi, 1990, 1991). It is expected, then, that nonlinear distortions that characterize the motility-related gating currents also describe concurrent mechanical responses. Indeed, harmonic mechanical responses and harmonic current responses have been observed in response to single sinusoidal stimulation of the OHC under whole cell voltage clamp (Santos-Sacchi, 1993).

Two-frequency evoked distortion components have been measured in the force of stereociliar bundles of Bullfrog saccular hair cells (Jaramillo, Markin & Hads-peth, 1993). From the bundle's resting position, AC stimulation produced distortion responses that were similar to those reported here. Sum and difference compo-

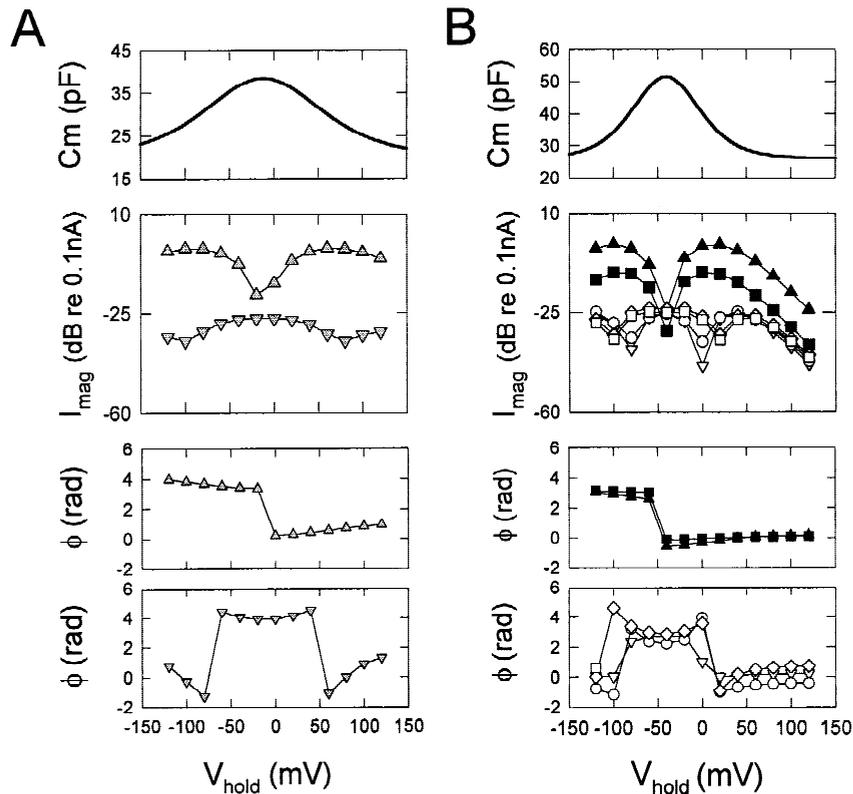

Fig. 8. Model simulation of OHCs under voltage clamp. The model consisted of an electrode resistance (R_s) in series with a parallel combination of membrane resistance (R_m) and capacitance (C_m), the capacitance being comprised of a linear (C_{lin}) and voltage-dependent component (C_v). The panels A and B correspond to those of Fig. 4, whose fitted cell parameters were used to generate the model distortion products shown here. Data were generated using the same stimulus protocols as in Fig. 4. In panel A, the membrane capacitance was modeled as in Eq. 1 with V_{pkcm} : -12.0 mV; z : 0.59; Q_{max} : 3.17 pC; and C_{lin} : 20.3 pF. R_s was 5 M Ω and R_m was 180 M Ω . In panel B, the membrane capacitance was modeled as in Eq. 1 with V_{pkcm} : -40.6 mV; z : 1.0; Q_{max} : 2.61 pC; and C_{lin} : 26.0 pF. R_s was 7 M Ω and R_m was 160 M Ω . The top panels illustrate the capacitance of each model cell, taken from Fig. 4 top panel fits. The symbols of the bottom panels show the generated distortion components as in Fig. 4. The lines simply connect the symbols. Note the similarities between model and biophysical data (Fig. 4).

nents were greatest in magnitude. It might be expected that in an analogous manner to the holding voltage manipulations reported here, stereocilia bundle biasing would produce magnitude and phase alterations in the force distortion components. Since the characteristics of OHC stereociliar bundles are basically the same as those of the lower vertebrate (Russell, Kossl & Richardson, 1992), it is expected that OHC stereocilia will likewise support distortion generation.

Despite the generation of distortion in single hair cells, significant differences exist between the characteristics of single cell distortion and distortion found in the intact auditory system. Indeed, while OHCs may ultimately underlie distortion found in the basilar membrane, inner hair cells and neural elements of the auditory system, it is unlikely that any single nonlinearity in a single hair cell can fully and simply account for the level and frequency-dependent behavior of distortion in the intact system. For example, in the basilar membrane, distortion levels decrease as the f_2/f_1 ratio is increased (Robles et al., 1997), but this ratio dependence is absent in isolated cells. One simple explanation for the *in vivo* dependence, alluded to by Robles et al. (1997) is the requirement for the two frequencies to reside within the excitation region of the cell. Thus, while delivery of disparate frequencies to single isolated cells is guaranteed experimentally, delivery to a single cell *in vivo* depends on the tuning characteristics of the basilar mem-

brane. Only when frequencies are close enough to be within the excitatory bandwidth at a given stimulus level will an OHC receive two-tone stimulation. Another difference between system and cell is that distortion *in vivo* is robust at low stimulus levels. Nonlinearities in single cells are measured and predicted to decrease precipitously as stimulus levels decrease (Santos-Sacchi, 1993). This is shown here for the sum and difference distortion components (Fig. 5), where the rate of drop in magnitude is greater than that of the stimulating frequencies. Essentially, nonlinearities vanish at very small signal levels. In this regard, it should be stressed that the stereocilia transduction (displacement to receptor potential) function has a more significant nonlinearity near threshold than does the OHC motility function, indicating that the former is more likely to underlie the generation of nonlinearities in OHC mechanical responses that impinge on the basilar membrane (Santos-Sacchi, 1993). Thus, stereocilia may dominate distortion product generation whether or not stereocilia themselves are capable of mechanically influencing the cochlear partition. It is certainly conceivable, however, that alteration in the OHC motility nonlinearity may be observable in distortion components should the stereociliar nonlinearity remain stable. That is, modifications to the OHC lateral membrane motor alone will likely influence system nonlinearities.

Finally, a difference between single cell and basilar

membrane distortion that cannot be easily explained is the difference in the magnitude of distortion components. While the simple difference and sum components (f_1+f_2 , f_2-f_1) were greatest in our single cell data, the stereociliar force production data (Jaramillo et al., 1993), and the OHC motility data (Hu et al., 1994), the greatest responses observed on the basilar membrane were the combination components, $2f_2-f_1$ and $2f_1-f_2$. Additionally, single cell distortion products were over an order of magnitude less than the stimulus frequency responses, while basilar membrane distortion could be greater — a result dependent upon tuning characteristics of the basilar membrane (Robles et al., 1997). Thus, it may be argued that the observed differences between intact system and single cell distortion call for an interaction of OHC assemblies to account for system nonlinearity characteristics. In line with this concept, we have recently shown that intact adjacent OHCs are mechanically coupled through supporting cells (Zhao & Santos-Sacchi, 1998). Furthermore, under dual voltage clamp, independent single sine wave stimulation in each cell generates combination distortion components in both cells (Zhao & Santos-Sacchi, 1999). In vivo, the extent of basilar membrane excitation distributions in the high frequency region of the cochlear can be taken to support interaction within OHC assemblies (Russell & Nilsen, 1997).

Abstract There is a growing consensus that outer hair cell (OHC) electromotility underlies the mammalian cochlear amplifier. This voltage-dependent motility is mirrored by a gating current, which along with motility can be altered by tension applied to the cell's plasma membrane. We used localized tension application along the length of the OHC to induce gating currents from membrane microdomains; with this information we mapped the distribution of the OHC's sensitivity to membrane stress before and after disrupting the cytoskeleton with intracellular Pronase. Mechanically induced gating currents, which were susceptible to salicylate, lanthanides and turgor pressure, evidenced a bell-shaped distribution that was restricted to the lateral membrane where the electromotile response resides. After Pronase treatment, gating currents remained intact and restricted. These results confirm that the molecular motors are intrinsically and bi-directionally susceptible to voltage and tension, and provide evidence for limited mobility of OHC motors within the cell's lateral membrane.

Introduction

In mammals, the outer hair cell (OHC) provides mechanical feedback into the basilar membrane which enhances auditory sensitivity and frequency resolving power [7, 29]. The likely underlying cellular mechanism is a unique voltage-dependent somatic mechanical response

that can be driven at acoustic rates [3, 5, 13, 15, 31, 32]. The mechanical response of the OHC is mirrored by an electrical signature, a motility-related gating current, reminiscent of the gating currents that regulate ion channel conductance [4, 30]. This gating current or charge movement can equivalently be measured as a nonlinear, voltage-dependent capacitance whose cellular location maps to the lateral membrane along the central extent of the cylindrical OHC [19]. This is precisely where the elusive molecular motors responsible for the OHC length change reside [8]. In fact, the lateral membrane harbors, almost exclusively, those sensor/motors that drive somatic motility; voltage-dependent ionic channels are largely absent, and reside in the basal membrane [33]. Beneath the motor-containing lateral membrane lies a well-developed cortical cytoskeleton that maintains the cylindrical shape of the cell [17, 37], and may function to limit the lateral diffusion of intramembranous motors.

One of the most notable features of the OHC is its piezoelectric-like behavior; under voltage clamp, not only do voltage perturbations induce mechanical responses and associated gating currents, but mechanical perturbations of the plasma membrane can induce gating currents as well [4, 14, 21, 22, 30]. Indeed, in the intact sensory epithelium, as a consequence of mechanical coupling through supporting Deiters' cells, the mechanical activity of any one OHC can induce gating currents in adjacent OHCs [41]. The susceptibility of OHC mechanical and electrical activity to membrane stress has been surmised to arise from an action on lateral membrane sensor/motors. Here we utilize this phenomenon to assess the extent of motor activity along the longitudinal axis of the OHC. Our data show that the susceptibility to membrane stress is restricted to the same cellular region that harbors the high density of sensor/motors, confirming the hypothesis that rapid changes in OHC membrane tension induce conformational changes in the molecular sensor/motor elements that are measurable as gating charge movements. Furthermore, the nonuniform distribution that we find provides evidence for limited mobility of OHC motors within the cell's lateral membrane.

Materials and methods

General preparation

Guinea pigs were overdosed with pentobarbital. The temporal bones were removed and OHCs were isolated from cochleas by gentle pipetting of the isolated top two turns of organ of Corti in Ca-free medium with collagenase (0.3 mg/ml). The cell-enriched supernatant was then transferred to a 700- μ l perfusion chamber, and the cells were permitted to settle onto the coverglass bottom. All experiments were performed at room temperature ($\approx 23^\circ\text{C}$). A Nikon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical recording. A modified Lebovitz medium (NaCl, 142.2 mM; KCl, 5.37 mM; CaCl_2 , 1.25 mM; MgCl_2 , 1.48 mM; HEPES, 10 mM; dextrose, 5 mM; adjusted to pH 7.2 with NaOH, and adjusted to 300 mosmol/l with dextrose) was used as the standard perfusion solution.

Electrical recordings

Cells were whole-cell voltage clamped with an Axopatch 200B amplifier (Axon Instruments, Calif., USA). Gigaohm seals were obtained at the supra-nuclear region of the OHC membrane prior to whole-cell recording. Patch electrodes had initial resistances of 3–5 M Ω , corresponding to tip sizes of approximately 1–2 μm . The series resistance typically ranged from 8 to 15 M Ω . No series resistance compensation was performed, as this interferes with admittance-based capacitance measures (see below). Pipette solutions were composed of 140 mM CsCl, 10 mM EGTA, 2 mM MgCl_2 , and 10 mM HEPES (buffered to pH 7.2 with CsOH, and adjusted to 300 mosmol/l with dextrose). In order to evaluate non-linear capacitive gating currents in the absence of confounding ionic currents, the standard perfusion solution was replaced with an ionic blocking solution following seal formation {NaCl, 100 mM; tetraethylammonium (TEA), 20 mM; CsCl, 20 mM; CoCl_2 , 2 mM; MgCl_2 , 1.48 mM; HEPES, 10 mM; dextrose, 5 mM; adjusted to pH 7.2 with NaOH, and adjusted to 300 mosmol/l with dextrose; [19, 30]}. In some cases, the extracellular solution contained 10 mM sodium salicylate (replacing NaCl). Additionally, in some cases intracellular Pronase (500 $\mu\text{g}/\text{ml}$), a wide spectrum proteolytic enzyme, was added to the pipette solution to destroy the cortical cytoskeleton [20, 22, 24, 35]. All chemicals were purchased from Sigma (USA). OHCs were held at 0 mV. Currents were recorded as averages of ten responses. Data collection and analysis were performed with a Window's based whole-cell voltage-clamp program, jClamp (<http://www.med.yale.edu/surgery/otolar/santos/jclamp.html>), utilizing a Digidata 1200 board (Axon Instruments, Calif., USA). Patch pipette pressure was modified with a syringe connected to the Teflon tubing attached to the patch pipette holder and monitored via a T-connector to a pressure monitor (WPI, Florida, USA). All experiments were video taped.

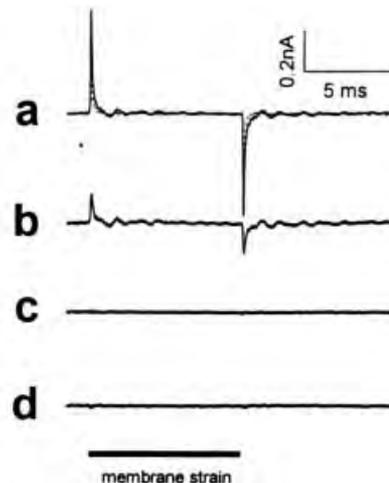

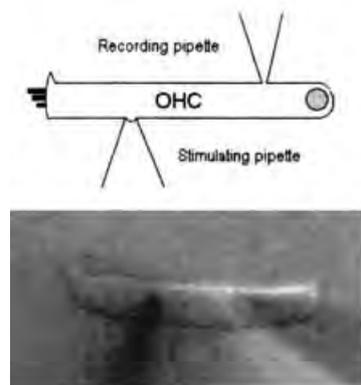

Membrane capacitance and mechanically evoked gating currents

Voltage-dependent OHC capacitance was measured with a continuous high-resolution two-sine voltage stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz) [35]. Sinusoids were superimposed on voltage ramps.

Restricted regions of the OHC lateral membrane were stressed using a micropipette aspiration technique. This technique has been used extensively to study the mechanical properties of membrane, notably by Evans and associates [10]. In fact, Brownell and colleagues [25] have used it to study the mechanical properties of the OHC lateral membrane through aspiration-evoked deformation.

Aspiration was delivered through a solution-filled glass pipette fitted to a computer-controlled piezoelectric device (PZL, Burleigh Instruments, N.Y., USA) within an in-house-designed pipette holder. The pipette tip was heat polished to a final inner diameter of 2.5 μm . The pipette contained bath solution that interfaced with mineral oil in the fluid-tight, rigid plastic pipette holder. Piezoelectrically driven piston movements within the mineral oil were delivered to the pipette solution. To maintain a tight seal between the pipette tip and the cell membrane, the tip was placed on the cell surface at right angles and slight negative pressure was applied. Tip placement by the micromanipulator was visually observed, and recorded on videotape for later measurement. Membrane deformation was induced by movements of the driver's piston stepped in the negative direction (producing suction) in the range of 200 to 800 nm, controlled by the voltage magnitude delivered to the piezoelectric. For the mapping studies, one fixed voltage was used along the cell length. The spatial pattern of stress delivery along the length of the cell was random; that is, there was no particular path along the cell length that was followed. Additionally, since we found that cell collapse altered the magnitude of mechanically evoked gating currents, we maintained the cylindrical shape of the OHC with small pipette pressures for those cells

Fig. 1A–D On the *left* is a schematic and digitally captured image of isolated outer hair cell illustrating the patch pipette at the supra nuclear region and stimulating pipette. **A** Whole-cell current induced by discrete mechanical stimulation of the lateral plasma membrane. The *Solid line* depicts raw current and the *dotted line* shows the transient current artifact with the stimulating pipette off the cell. **B** Mechanically induced current obtained by subtracting current artifact from the raw current response. **C** As in **B**, except the driving piston in the stimulating pipette was absent, and consequently mechanical stimulation of the membrane was lacking. Under this condition, however, the piezoelectric driver was still activated and transient current artifacts were still generated. **D** Absence of response following the stimulation of the supporting Deiters cell membrane. *Black bar* indicates the duration of mechanical stimulus (see text)

used for mapping experiments (see [22] for details). In some cells, repeat measures were made following mapping, and responses were within 10% of initial ones, indicating that delivery of the stimulus was uniform and repeatable along the length of the cell.

Data are derived from cells in the low frequency region of the organ of Corti, 60–70 μm long. These cells were chosen over shorter, high frequency cells so that the distribution within the lateral membrane could be mapped with increased resolution over our previous electrical amputation method [19]. A particular stimulation location was binned within one of ten equally spaced (6–7 μm) regions along the cell length, providing relative measures of response distribution. Eight of those regions corresponded to the lateral membrane (see Results, and schematic of Fig. 4). If we had chosen smaller cells, the number of regions would have been smaller (given our aspiration pipette size).

Oscillations in the current response were generated by a mechanical resonance in the stimulus delivery system, as has been described previously [14]. The magnitude and frequency of the resonance depended on the piezoelectric device and pipette/membrane seal combination. Resonances around 1 kHz were observed and could be reduced by filtering the command voltage to the piezoelectric. These oscillatory currents are real motor-generated currents, and are differentiated from a concurrent electrical artifact (initial few microseconds – see Results). Such high frequency responses are not unusual since the frequency responsiveness of OHC charge movement extends into the tens of kilohertz range [15]. Membrane currents were quantified by either measuring the RMS value during the extent of the mechanical stimulus, or by integrating the current response over that same period. The latter technique was employed when under some experimental conditions exponentially decaying currents possessed minimal oscillations, so that gating charge estimates could be made. Either measure produced quantitatively similar mapping patterns.

Results

Restricted tension application evokes motility-related gating currents

Under whole-cell voltage clamp with ionic currents blocked, discrete mechanical stimulation of the OHC lateral plasma membrane evokes an initial transient followed by small oscillatory currents (Fig. 1). The piezoelectric-driven aspiration pipette that we use to apply membrane stress contributes a short-lived electrical artifact at the onset (dotted line, Fig. 1A) that is subtracted from the raw response to obtain membrane currents (Fig. 1B). In the absence of the aspiration pipette's driving piston, no membrane currents are elicited (Fig. 1C). Supporting cells do not generate membrane currents when stimulated mechanically (Fig. 1D). Digestion of the subsurface cytoskeleton with intracellular Pronase (500 $\mu\text{g}/\text{ml}$) did not abolish mechanically evoked gating currents, similar to results with voltage-induced charge movement [20].

Further evidence indicating that these discretely generated currents derive from OHC sensor/motors residing in the lateral membrane is obtained from the current's sensitivity to agents that block voltage-induced OHC motility and capacitance. Figure 2A shows that salicylate blocks the mechanically elicited membrane current. Additionally, the currents show a bell-shaped voltage dependence that is expected based on macroscopic methods of mechanical stimulation of the OHC [14, 41]. Pan-

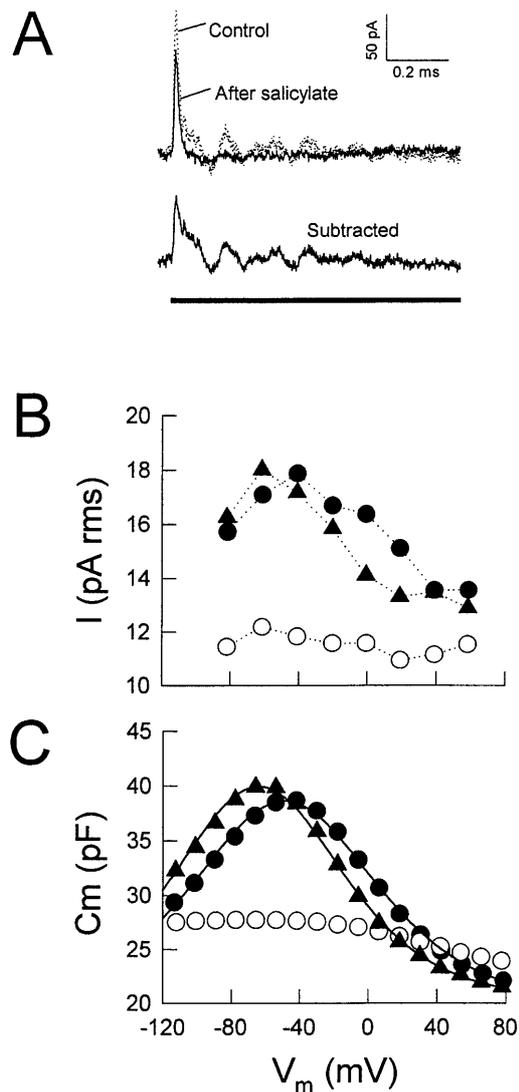

Fig. 2 **A** Dotted line illustrates the raw whole-cell current induced by discrete mechanical stimulation of the lateral plasma membrane. The solid line is the response after perfusing the cell with 10 mM salicylate. Beneath, the subtracted current represents that current sensitive to salicylate. The black bar indicates the duration of mechanical stimulus. **B** Mechanically induced gating current magnitude versus holding membrane potential. Solid circles indicate responses before salicylate (10 mM) treatment, open circles during salicylate treatment, and solid triangles following salicylate washout. **C** Corresponding membrane capacitance as a function of membrane potential. Symbols are as in **B**. Fits to the capacitance data were obtained using the following formula:

$$C_m = C_v + C_{lin} = Q_{max} \frac{zeb}{kT(1+b)^2} + C_{lin}$$

$$b = \exp\left(\frac{-ze(V_m - V_{pkcm})}{kT}\right)$$

where Q_{max} is the maximum nonlinear charge moved, V_{pkcm} is voltage at peak capacitance or half-maximal nonlinear charge transfer, V_m is membrane potential, C_{lin} is linear capacitance, z is valence, e is electron charge, k is Boltzmann's constant, and T is absolute temperature. Before salicylate – Q_{max} : 2.56 pC, V_{pkcm} : -63.7, z : 0.78, C_{lin} : 20.4; after washout – Q_{max} : 2.64 pC, V_{pkcm} : -48.8, z : 0.72, C_{lin} : 20.1. The data during salicylate treatment could not be fit reliably

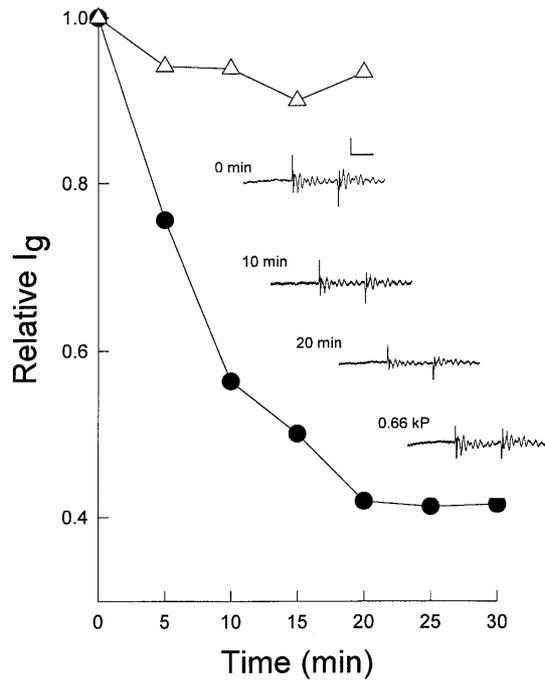

Fig. 3 Mechanically induced gating current magnitude depends on intracellular turgor pressure. Average ($n=3$) relative gating current magnitude is plotted as a function of time after establishment of whole-cell recording (filled circles). The magnitude decreases to less than half of the initial level within 20 min and remains stable after that time. Following stabilization, positive pressure delivered via the patch pipette (≈ 0.6 kPa) increased the average relative gating magnitude to 0.81. The inset depicts mechanically induced gating currents from a single cell during the course of recording. Scale 80 pA, 5 ms. In another five cells (open triangles), positive pipette pressure delivered throughout the recording period blocked the decrease in gating current magnitude

els B and C of Fig. 2 illustrate the voltage-dependent magnitude of the cell's membrane capacitance and mechanically evoked membrane currents. Each is reversibly reduced by salicylate. The shift in the voltage at peak capacitance (V_{pkcm}) evident after washout is possibly due to a reduction of OHC turgor pressure during the recording. This shift is observable in the current-voltage ($I-V$) function as well. Gating currents arise from the small area within the orifice of the stimulating pipette; this was confirmed by treatments with lutetium, a known blocker of motility and nonlinear capacitance that works solely on the extracellular aspect of the lateral plasma membrane [23]. When lutetium was placed within the solution of the stimulating pipette nearly all gating current was abolished; however, when lutetium was placed within the bath solution, gating current was little affected, since the blocking agent could not reach the mechanically activated site (data not shown).

Turgor pressure modulates gating current magnitude

The effect of turgor pressure on the mechanically elicited membrane current was studied in detail. It is known that

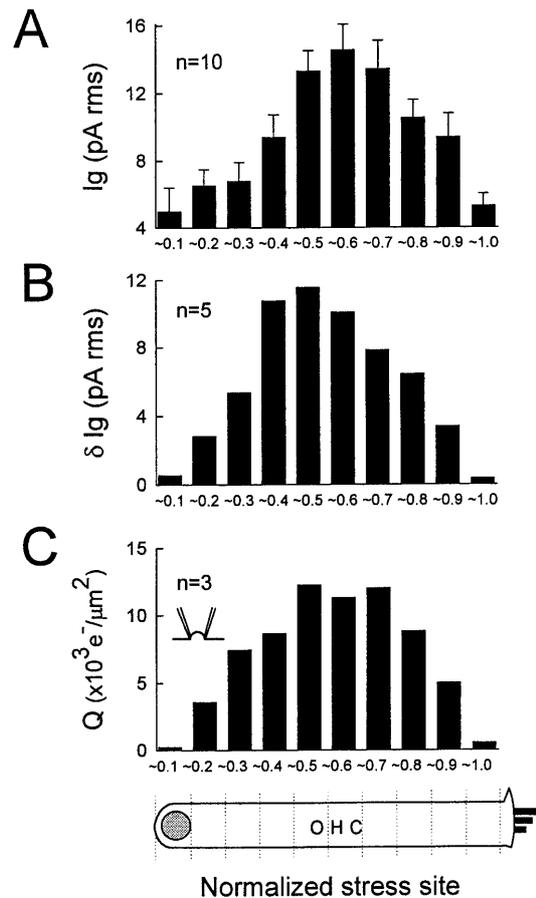

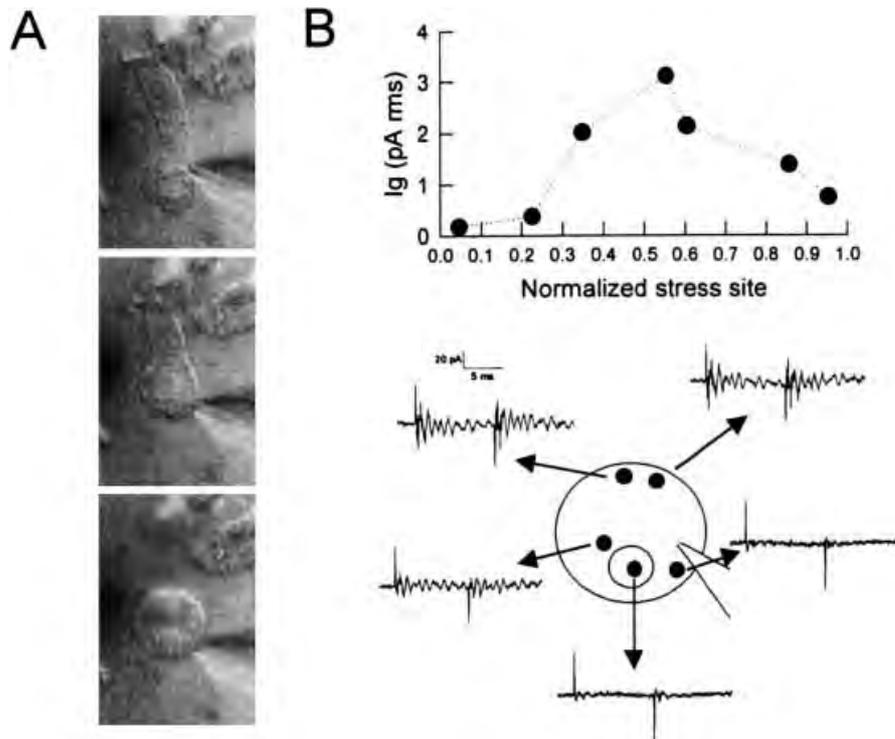

Fig. 4A–C Mechanically induced gating currents are restricted to the lateral membrane of the OHC. **A** Average (\pm SE; $n=10$) gating currents as a function of normalized stress site. **B** Five of the cells in **A** were subsequently treated with 10 mM salicylate, and the salicylate-sensitive gating current obtained through subtraction is displayed. Note minimal currents at cell extremes. **C** In three additional cells, where the exponentially decaying gating current dominated the mechanically evoked response, gating charge was determined via integration. Membrane surface area under the stimulating pipette was calculated based on tip diameter and an assumed hemispheric profile. Charge density is similar to that obtained via voltage stimulation paradigms

the intracellular pressure of the OHC dissipates following establishment of whole-cell voltage clamp [22]. During that time V_{pkcm} shifts in the negative direction and peak capacitance increases. Figure 3A shows that after the establishment of the whole-cell configuration, mechanically elicited membrane currents (filled circles) decrease in size over a time course similar to the known effects on OHC capacitance [22]. Indeed, simultaneously, V_{pkcm} shifts in the negative direction (data not shown). Applying positive pressure through the patch pipette prevents the decrease in gating current magnitude (open triangles). The current trace insets depict, for a single cell, the decrease in gating current magnitude over the course of 20 min; at that time a positive pressure of 0.66 kPa applied to the patch pipette reestablished the initial magnitude of the mechanically evoked current.

Fig. 5A, B Mechanically induced gating currents remain intact and restricted following cytoskeletal disruption. **A** Digitally captured images of an OHC during recording with Pronase-containing intracellular solution. *Top* – after 9 min; during this time control measurements were made. *Middle* – cell is beginning to form a sphere as the cytoskeleton is disrupted. *Bottom* – after 13 min the cell is fully spherical. Diameter is 24 μm . The cuticular plate is on the underside of the cell. **B** Plot shows restricted gating currents obtained while the cell was still cylindrical. The *bottom schematic* illustrates the cell after the cytoskeleton was destroyed. Gating currents were measured at the regions marked by *filled circles*. Note the absence of response over the nuclear region which was determined from video to correspond to the basal membrane

Tension-induced gating currents map to the lateral membrane in a nonuniform manner

Having confirmed that the membrane aspiration-induced currents derive from OHC motors, we used this method to map the distribution of stress sensitivity within the OHC plasma membrane. Single cells were subjected to multiple discrete mechanical stimulations along the length of the cell. Figure 4A shows the average RMS gating current magnitude along the normalized length of the OHC. The response is clearly largest in the central region of the cell, which corresponds to that region where OHC voltage-dependent capacitance and motility reside [8, 19]. Figure 4B plots the extent of the gating current that is susceptible to salicylate; negligible mechanical sensitivity resides at the extremes of the cell. In three cells it was possible to determine gating charge via integration since an exponentially decaying gating current dominated the mechanically evoked response. In Fig. 4C we plot the average gating charge density from these cases and show that the average density within the central portion of the cell membrane, about $10,000 e/\mu\text{m}^2$, is similar to the charge density obtained by voltage stimulation protocols [19].

Motor distribution is maintained following cytoskeletal disruption

Finally, we examined the effects of destroying the OHC's cortical cytoskeleton on the generation and distribution of stress-induced gating currents. In two cells we were able to perfuse intracellularly with 500 $\mu\text{g}/\text{ml}$ Pron-

ase via the patch pipette and map the distribution before and after cytoskeletal disruption. Figure 5 shows an example. Over the course of about 10–15 min, OHCs lose their cylindrical shape and form spheres (Fig. 5A) [20, 22, 24]. In the process, the cortical cytoskeleton is disrupted, leaving free plasma membrane [20]. Before disruption occurred, the cells showed typical distributions of stress-induced gating currents (Fig. 5B, top panels). Following cytoskeletal disruption, gating currents were still evoked by membrane stress, and surprisingly remained restricted in their distribution (Fig. 5B, bottom panels). Having videotaped the experiments, we were able to track and conclusively identify the cell's basal membrane as it changed shape. Over the time course of the experiments (≈ 20 –30 min), lateral diffusion of the molecular motors into the basal plasma membrane did not occur.

Discussion

The OHC is a highly partitioned cell whose sensory activity is augmented by voltage-dependent mechanical activity. OHCs possess a mechano-electrical transduction mechanism within the apical membrane – the stereociliar bundle, and synaptic machinery in the basal membrane. This basic polarization, found in all vertebrate hair cells, has evolved in the OHC, since, additionally, molecular motors responsible for the cell's electro-mechanical transduction are restricted to the lateral membrane [8, 19, 20, 24]. The membrane area comprising the cylindrical cell's lateral membrane can range up to nearly four times that of the combined apical and basal membrane

(e.g., given a 90- μm -long OHC, apical and basal surface area is estimated to be about 750 μm^2 , whereas lateral membrane area is about 2700 μm^2).

The OHC lateral plasma membrane displays an unusually dense population of tightly packed 8- to 10-nm particles that probably represent protein motors embedded in the lipid bilayer [12, 16, 24, 34]. Densities up to 6000/ μm^2 have been reported. Electrophysiological experiments similarly provide motor density estimates ranging from 2500 to 7500/ μm^2 based on voltage-induced gating charge densities from low frequency OHCs [4, 15, 19, 30]. Despite this good correspondence, we have recently shown that the correlation between ultrastructural and electrophysiological estimates of motor density may not hold for high frequency OHCs, where charge density increases more so than membrane particle density [34]. Nevertheless, all estimates clearly indicate that the molecular motors dominate the makeup of the lateral membrane. We now show that the density of mechanically induced charge movement, while not uniform, is similar to those estimates determined through whole-cell voltage stimulation. An average density of 10,000 e-/ μm^2 was found, assuming a hemispherical insertion of the membrane into the aspiration pipette. Oghalai et al. [25] have shown that upon slight suction, this type of membrane deformation is expected with an aspiration pipette of our size. Thus, the co-localization of voltage- and mechanical-sensitive charge movement to the lateral plasma membrane that we report here strongly suggests that we are observing intrinsic piezoelectric-like activity of integral membrane motors. That is, voltage and mechanical sensitivity are features of one molecular entity – the motor, and independent of cytoskeletal requirements, since cytoskeletal disruption with Pronase leaves charge movement intact.

The nonuniform distribution of stress sensitivity along the lateral membrane may arise from a true motor distribution pattern or regional differences in the efficacy of mechanical stimulation due, for example, to membrane stiffness gradients along the cell length. It is clear from the turgor results that changes in the mechanical properties of the membrane can influence the magnitude of charge movements, yet it is not obvious from ultrastructural studies that the lateral wall structure harbors such longitudinal mechanical gradients [28]. However, it is clear that abrupt mechanical changes probably arise at the apical and basal terminal borders of the subsurface cytoskeleton and cisternae that lie beneath the lateral plasma membrane. Nevertheless, the changes in charge density are clearly more gradual. Previously, we had mapped the distribution of voltage-induced charge movement using an electrical amputation technique [19]. In order to evaluate our data that were admittedly limited in spatial resolution we modeled the motor density as evenly distributed along the lateral membrane, and concluded that the apical and basal poles of the OHC were devoid of sensor / motors. While our present data confirm the virtual absence of motors in the apical and basal poles, it appears that a uniform distribution is unlikely.

This is corroborated to some extent by the findings of Zajic and Schacht [40], who showed that in response to K depolarization mechanical responses in the middle of the OHC are larger than at its apical and basal regions. We conclude that the nonuniform distribution of motors is real and must be an expression of restricted lateral mobility within the plane of the cell's plasma membrane.

The OHC's cortical cytoskeleton is extensive; structural similarities have been found between it and the peripheral cytoskeleton of other cell types, including muscle cells and red blood cells [11, 17, 24, 37]. In the red blood cell, band 3 membrane proteins are restricted in their lateral movements by interactions with the subsurface cytoskeleton (see Edidin [9] for review). Agents that disrupt the cytoskeleton can increase lateral mobility by about two orders of magnitude. In the OHC, the cortical cytoskeleton lies beneath that region of the membrane where the dense array of membrane particles resides, and it is possible that interactions with the motors restrict their diffusion to basal and apical compartments of the cell. We have evidence that protein motors are indeed able to diffuse laterally within the lateral membrane itself [36]. Utilizing microdomain photoinactivation of motor charge movements (i.e., voltage-dependent capacitance), we showed that photo exposure of dye marked OHC lateral membrane for extended periods of time irreversibly depleted whole-cell charge movement beyond that expected for an immobile population in the exposed area. Nevertheless, the present data indicate that diffusion of motors into regions normally devoid of motors, viz. the apical and basal regions, does not occur within the time frame of our experiments. For a typical diffusion coefficient of membrane protein untethered by cytoskeleton, e.g., 1 e-9 cm²/s [2], we might have expected to observe gating charge movements in the basal region after 10–20 min. For example, if we assume that the molecular motors within the Pronase-treated spherical OHC are initially restricted to one hemisphere then the time to redistribute the motors equally within the sphere would be:

$$\tau = r_o^2/2D$$

where r_o is the cell radius, and D is the diffusion coefficient [18]. With $r_o=12 \mu\text{m}$ (Fig. 5A), and $D=1\text{e-}9 \text{ cm}^2/\text{s}$, we obtain τ of about 12 min. Clearly, this redistribution did not occur. In fact, τ is an overestimate since the motors in our treated cells occupy far greater than 50% of the membrane surface area. Furthermore, motors would only need to diffuse a few microns in order to occupy the basal membrane. It is not unusual for mobilities to vary within different membrane microdomains. For example, voltage-gated Na channels in neuronal soma diffuse more readily than in the axon hillock (one to two orders of magnitude difference in diffusion coefficients) [2]. Indeed, there is a barrier to the diffusion of Na channels between the two regions of neuronal membrane. Tethering by ankyrin probably plays a role in clustering Na channels at the axon hillock [43], and, interestingly, Winckler et al. [39] suggest that this type of interaction

between membrane protein and the cytoskeleton provides a diffusion barrier for other membrane proteins in the neuron as well. Our data, however, suggest that this type of cytoskeletal barrier is not acting to limit the diffusion of lateral membrane motors into the basal membrane region. The story may be different for voltage-gated ion channels that are restricted to the basal membrane of the OHC [32]. Though it cannot be dismissed that their clustering relies on cytoskeletal elements, as do Na channels, the highly organized nature of the subsurface cytoskeleton found in the lateral membrane is absent in the basal membrane. One further means of restricting ionic channel movements to the basal membrane could arise from the high density of molecular motors within the lateral membrane, which would effectively provide a barrier to diffusion into the motor region from the basal membrane. Indeed, the high density may also limit lateral diffusion within the lateral membrane itself. Recently, Oghalai et al. [26, 27] have shown that lipid mobility in the lateral membrane is quantitatively similar to that of other cell types but is dependent upon membrane voltage and tension, as might be expected if the state of the molecular motors, in addition to their density, were influential.

The susceptibility of mechanically induced gating currents to salicylate is understandable since the drug is capable of blocking the OHC's voltage-dependent charge movement (or capacitance) within seconds of application [23, 38]; a mechanically induced shift of the charge-voltage ($Q-V$) function along the voltage axis is thought to give rise to mechanically induced gating currents [14, 22, 41]. Indeed, for this reason, the mechanically evoked currents possess a bell-shaped voltage dependency. However, while some common characteristics of mechanically and voltage-evoked gating currents, e.g., block by salicylate and lanthanides, are readily explainable, the effect of cell turgor on mechanically evoked gating current magnitude is not simply explained, and deserves some discussion. OHCs normally possess a positive intracellular pressure that helps maintain the cylindrical shape of the cell [6]. Steady state decreases in OHC turgor pressure cause negative dc shifts of the $Q-V$ or capacitance function along the voltage axis until a limiting V_{pkcm} , near -70 mV, is attained [22]. At that point, tension changes have little effect on V_{pkcm} . This phenomenon may play a role in reducing mechanically generated gating currents when the cell is collapsed from its cylindrical shape; however, from our data it appears that mechanically evoked gating currents are reduced in a graded fashion as intracellular pressure is decreased. Even more confounding is the observation that Q_{max} derived from voltage stimulation appears to *decrease* as intracellular pressure is *increased* [14, 22] until, under extreme conditions, charge movement can be blocked substantially [1]. Of course, these findings might suggest an opposite result from what we found. It should be noted, however, that the changes in turgor pressure that we encountered amount to changes of less than 1 kPa, and, within that range, with an intact cytoskeleton, quite

small changes in Q_{max} are expected [22]. Finally, it may simply be that the efficacy of a given stimulus delivered to the membrane patch under the stimulating pipette depends on the degree of resting membrane tension. This might occur if membrane deformation or bending were the effective stimulus. In this regard, we have suggested that after cytoskeletal destruction, the membrane is more sensitive to turgor pressure, as though the cytoskeleton were impeding membrane deformation [22]. This is borne out by independent studies on the stiffness of the OHC lateral wall (combination of the plasma membrane, cortical cytoskeleton and subsurface cisternae) [25], where the component stiffness of the lateral membrane was found to be less than that of the combined cytoskeleton and subsurface cisternae. We can also conclude from these data of Oghalai et al. [25] that our small deformations of the intact lateral wall would not have independently stimulated the lateral membrane, in contrast to the case following Pronase treatment.

The co-localization of a bi-directional voltage/mechanical sensitivity to the lateral plasma membrane underscores an intrinsic feedback mechanism that exists not only within single OHCs but also among OHCs residing within the normally functioning organ of Corti [41]. Just as the motor is restricted to one region of the OHC, the cellular expression of the motor is restricted to only one hair cell type in the mammalian sensory epithelium, viz the OHC. Recently, Dallos and coworkers [42] have identified a protein unique to the OHC which when expressed in nonauditory cells bears the mechanical and electrical signatures of the OHC motor. From this discovery, we can expect more detailed examinations and understanding of the mechanisms responsible for the segregation and mobility of this unique protein within the OHC plasma membrane.

Novel Role of the Mitochondrial Protein Fus1 in Protection from Premature Hearing Loss *via* Regulation of Oxidative Stress and Nutrient and Energy Sensing Pathways in the Inner Ear

Winston J.T. Tan,^{1,*} Lei Song,^{2-4,*} Morven Graham,⁵ Amy Schettino,⁶ Dhasakumar Navaratnam,^{7,8} Wendell G. Yarbrough,^{1,9} Joseph Santos-Sacchi,^{1,8,10} and Alla V. Ivanova¹

Abstract

Aims: Acquired hearing loss is a worldwide epidemic that affects all ages. It is multifactorial in etiology with poorly characterized molecular mechanisms. Mitochondria are critical components in hearing. Here, we aimed to identify the mechanisms of mitochondria-dependent hearing loss using Fus1 KO mice, our novel model of mitochondrial dysfunction/oxidative stress.

Results: Using auditory brainstem responses (ABRs), we characterized the Fus1 KO mouse as a novel, clinically relevant model of age-related hearing loss (ARHL) of metabolic etiology. We demonstrated early decline of the endocochlear potential (EP) that may occur due to severe mitochondrial and vascular pathologies in the Fus1 KO cochlear stria vascularis. We showed that pathological alterations in antioxidant (AO) and nutrient and energy sensing pathways (mTOR and PTEN/AKT) occur in cochleae of young Fus1 KO mice before major hearing loss. Importantly, short-term AO treatment corrected pathological molecular changes, while longer AO treatment restored EP, improved ABR parameters, restored mitochondrial structure, and delayed the development of hearing loss in the aging mouse.

Innovation: Currently, no molecular mechanisms linked to metabolic ARHL have been identified. We established pathological and molecular mechanisms that link the disease to mitochondrial dysfunction and oxidative stress.

Conclusion: Since chronic mitochondrial dysfunction is common in many patients, it could lead to developing hearing loss that can be alleviated/rescued by AO treatment. Our study creates a framework for clinical trials and introduces the Fus1 KO model as a powerful platform for developing novel therapeutic strategies to prevent/delay hearing loss associated with mitochondrial dysfunction. *Antioxid. Innovation

Age-related hearing loss is a serious health problem with few efficient therapies due to its multifactorial etiology and poorly characterized molecular mechanisms. We present evidence that mitochondrial dysfunction/oxidative stress, often associated with inflammatory or mitochondrial diseases, result in a special type of progressive hearing loss manifested by mitochondrial and vascular degeneration in the cochlear stria vascularis, a decrease in endocochlear potential, and early alterations in aging-associated molecular pathways in the inner ear. Remarkably, antioxidant supplementation corrects these electrophysiological, mitochondrial, and molecular pathologies resulting in a significant delay in hearing decline and suggesting approaches to alleviate this type of hearing loss.

Introduction

ACCORDING TO THE World Health Organization (WHO), 360 million people worldwide live with disabling hearing loss (www.who.int/mediacentre/factsheets/fs300/en). The prevalence of hearing loss increases with age; thus, in children it is 1.7%, in adults aged 15 years or more it is about 7%, and it rapidly increases to almost one in three in adults older than 65 years (www.who.int/pbd/deafness/estimates/en). Besides aging (32), a number of other risk factors have been identified, including noise exposure (27, 28, 60, 74), ototoxic drugs (57), hypertension (1), diabetes (26), and smoking (10).

Unrecognized or untreated hearing loss results in widespread effects from difficulties in communicating, and affects productivity and quality of life. It may lead to social isolation, depression, and cognitive decline (2). Uncovering and detailed characterization of the mechanisms of premature hearing decline would provide a foundation for tailored prevention or treatment plans based on “individual broken systems.”

One of the critical components of hearing function is mitochondrial health. The mitochondrion is a versatile energy-producing organelle that regulates vital cellular processes, such as metabolism, calcium and redox signaling, and apoptosis. Mitochondrial involvement in auditory function was recognized by hearing impairment in many patients with mitochondrial diseases and *via* identification of mutations in mitochondrial DNA in patients with maternally inherited deafness (12). Mitochondrial dysfunction-mediated hearing impairment can be inborn or progressive when induced by aminoglycosides, sound exposure, or aging.

Mitochondria contain more than 1500 proteins, but only 14 are encoded by mitochondrial DNA while the rest are nuclear encoded (33). Therefore, one would expect that abnormal activities/loss of many of these mitochondria-residing proteins could affect hearing. However, the significance of nuclear-encoded mitochondrial proteins in hearing is poorly understood with only several hearing loss-linked mutations characterized in humans (73, 17).

In mice, the most extensively studied model is the so-called mtDNA-mutator mouse bearing a mutation in the mitochondrial polymerase gene (Polg) (69) that exhibits a significant elevation of auditory brainstem response (ABR) thresholds at low to middle frequencies by 9–10 months of

age (63). Two other mouse models that lack the antioxidant (AO) enzymes, Gpx1 or Sod1, show enhanced susceptibility to noise-induced hearing loss (45). Scavenging of mitochondrial reactive oxygen species (ROS) by targeting an AO protein catalase to mitochondria in MCAT transgenic mice alleviates hearing loss in aging MCAT mice compared to age-matched WT mice (58, 59).

Recently, our group characterized a transgenic mouse strain that robustly overexpresses the mitochondrial methyltransferase TFB1M (Tg-mtTFB1 mice) and exhibits progressive hearing loss most likely of strial etiology; however, no obvious signs of strial atrophy were detected. Hearing loss in this model was rescued by genetically reducing AMPK α 1 activity (38). While these few models provide strong evidence that mitochondria and mitochondria-generated ROS play essential roles in progressive hearing loss, additional mouse models are required to characterize the spectrum of auditory system pathologies inflicted by mitochondrial dysfunction-induced oxidative stress and inflammation.

Our early studies showed that mitochondrial dysfunction and oxidative stress are the primary pathogenic mechanisms in Fus1-deficient cells and mice. In our KO model (22), loss of mitochondrial protein Fus1 profoundly affects several mitochondrial parameters, such as ROS production, calcium uptake, mitochondrial membrane potential (MMP), respiratory reserve, and mitochondrial fusion (70, 71). As we demonstrated, the perturbed mitochondrial homeostasis/oxidative stress in Fus1 KO mice affect steady-state mitochondrial activities and severely compromise stress response on exposure to asbestos, radiation, infection, or immune stimulation (20, 70, 71, 76). Therefore, we hypothesized that Fus1 KO mice may experience either an inborn hearing defect or develop early progressive age-related hearing loss (ARHL) and that this pathology may be alleviated by improving the redox state in the cochlea.

Here, we established that Fus1 KO mice suffer from the least characterized type of ARHL of strial origin, making this model a valuable tool for studying mitochondrial/oxidative mechanisms of age-related hearing decline. Using this model, we establish and characterize in detail the phenotypic manifestations of premature hearing loss of strial etiology based on Fus1 loss-mediated mitochondrial dysfunction, and identify the target cells and tissues in the inner ear that are most vulnerable to such dysfunction. We also identify molecular pathways responsible for early hearing loss, and explore an AO approach to slow down hearing loss and development of molecular defects in cochlear tissues associated with mitochondrial dysfunction/oxidative stress.

Results

Fus1 KO mice show early-onset progressive hearing loss

Our earlier studies showed that Fus1 KO cells and tissues are characterized with high levels of ROS and insufficient AO machinery (70, 71, 77). Considering the detrimental effects of oxidative stress on hearing (19), we hypothesized that Fus1 KO mice may have progressive hearing loss. We used ABRs to measure hearing levels in Fus1 WT and KO mice of different ages. We found that while young 2-month-old KO mice had similar hearing thresholds to WT mice at middle

frequencies, and slightly elevated thresholds at low and high frequencies (Fig. 1A), 4–5-month-old KO mice had moderately elevated thresholds over the 2–32 kHz frequency range, and 8–10-month-old KO mice had substantial threshold elevations of up to 50 dB across all frequencies. Hearing de-

cline continued further in 12–13-month-old KO mice (Fig. 1A). Age-matched WT mice over the same time period showed no significant changes in thresholds at middle frequencies and a slight threshold elevation at high and low frequencies (Fig. 1B). Hearing decline in WT mice was slow

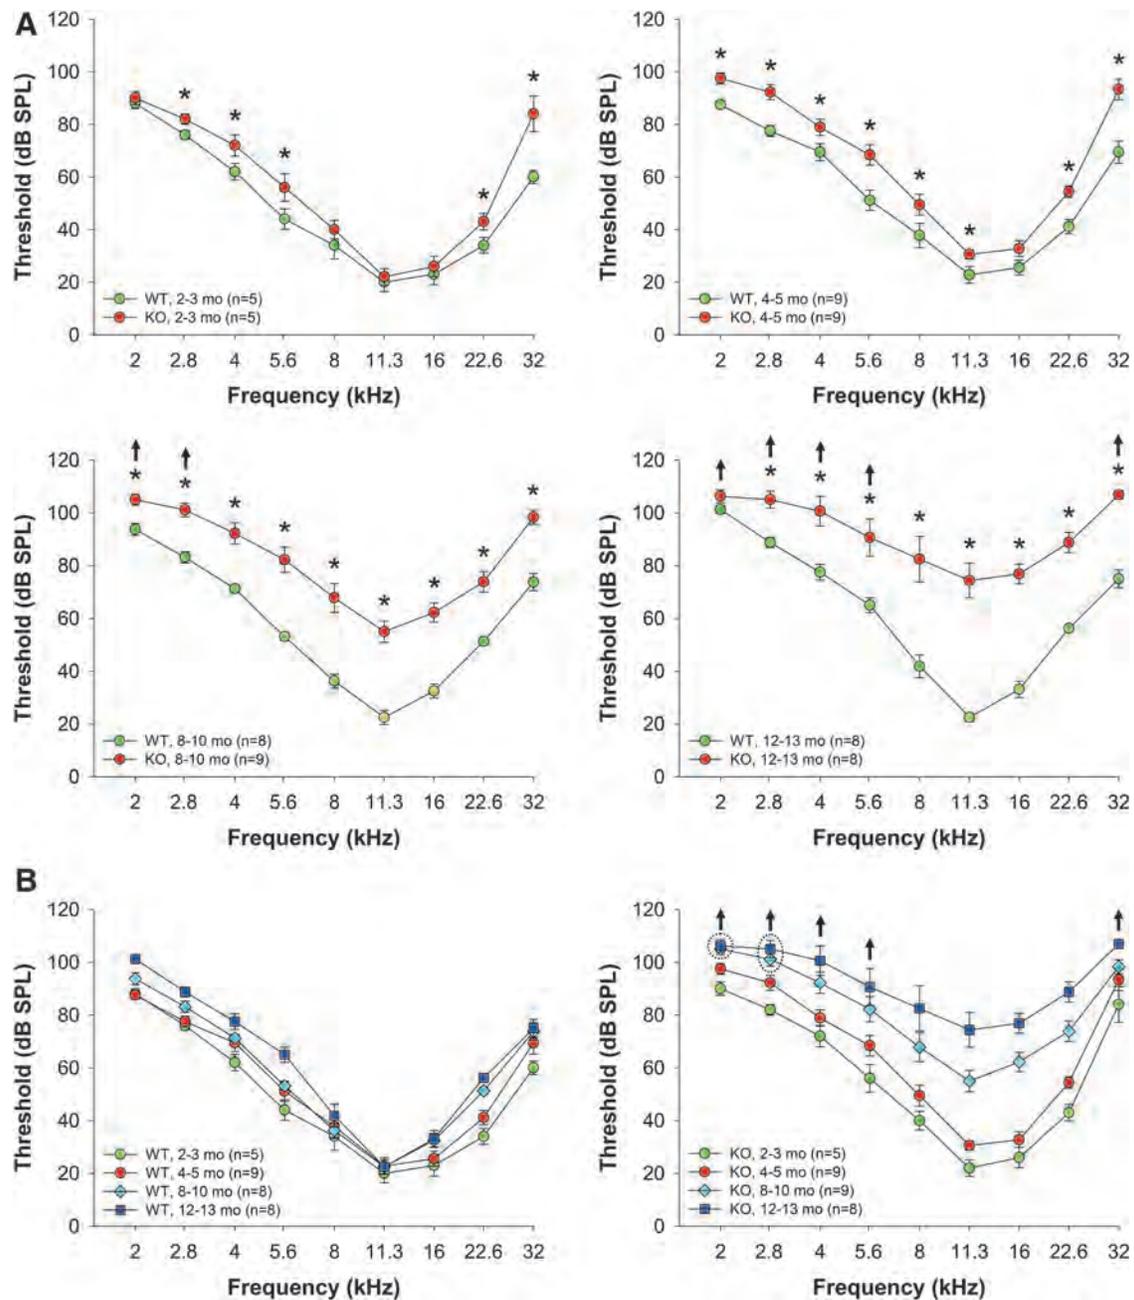

FIG. 1. Age-related changes in hearing thresholds in WT and *Fus1* KO mice. (A) The graphs illustrate hearing thresholds (dB SPL) defined *via* measuring ABRs in WT (green circles) and *Fus1* KO (red circles) mice of different age groups. Fast dynamics of progressive hearing loss is observed in *Fus1* KO mice, which have similar thresholds to WT mice at 2 months of age, significant moderate threshold elevations compared to WT mice at 4–5 months of age, and drastically elevated thresholds at 8–10 months of age. Hearing sensitivity further declined in 12–13-month-old KO mice. (B) The graphs illustrate age-dependent threshold changes in WT and *Fus1* KO mice. In contrast to KO mice, WT mice showed no significant changes in thresholds at midfrequencies with age and only a slight threshold increase at low and high frequencies. Data presented as mean \pm SEM. * $p < 0.05$ (Student's *t*-test, unpaired). \uparrow These data points include mice that showed no response at 110 dB SPL, the upper limit of the ABR recording. Number of mice with “no response” thresholds: 8–10-month-old KO mice at 2 kHz = 2, 2.8 kHz = 1; 12–13-month-old KO mice at 2 kHz = 6, 2.8 kHz = 5, 4 kHz = 2, 5.6 kHz = 1, 32 kHz = 3. ABR, auditory brainstem response. To see this illustration in color, the reader is referred to the online version of this article at www.liebertpub.com/ars

and even 15–18-month-old WT mice had much better hearing than 8-month-old KO mice. Thus, systemic loss of *Fus1* affects hearing at all frequencies starting from 4 to 5 months of age and results in rapid progression of hearing loss thereafter.

Young Fus1 KO mice have robust ABR wave I amplitude that rapidly diminishes with age

Amplitudes and latencies of the initial four ABR waves were analyzed. These waves are the response to 3 ms pips that represent sequential temporal events along the auditory ascending pathway. The amplitude of the waves reflects the number of activated neurons and synchrony of firing, while latency, the elapsed time from sound delivery, reflects the timing of synaptic transmission and nerve conduction. Amplitude and latency analysis of the ABR waves provides information on the integrity of auditory periphery and brainstem pathways. In humans, aging substantially reduces the amplitudes of all principal ABR waves producing significant latency shifts in waves I and III (25).

We compared ABR wave latencies and amplitudes in cohorts of 2- and 8–10-month-old WT and KO mice (Fig. 2). In young WT and KO mice, wave I latencies were similar at the majority of sound levels (Fig. 2B). Strikingly, in 8–10-month-old *Fus1* KO mice, wave I latencies were profoundly delayed with the largest difference at 65–70 dB SPL (sound pressure level) (Fig. 2A).

Interestingly, in young KO mice, wave I amplitude tended to be higher than in WT mice at all analyzed sound intensities and was significantly higher at 60–80 dB SPL (Fig. 2B). However, with age, wave I amplitude became profoundly lower in *Fus1* KO mice (Fig. 2A, B), consistent with the correlation between hearing loss and decrease in wave I amplitude in humans (25). Figure 2C shows further deterioration of wave I parameters along with profound interindividual heterogeneity reflecting variations in the onset of ARHL in 12–13-month-old KO mice. Note that age-matched WT mice still show normal wave I parameters and low interindividual heterogeneity.

Latencies and amplitudes of waves II–IV in *Fus1* KO mice were similar to wave I patterns (Supplementary Fig. S1; Supplementary Data are available online at www.liebertpub.com/ars).

Thus, analysis of the adult *Fus1* KO ABR waveforms reveals profound early changes in the integrity of auditory periphery and brainstem pathways similar to the changes that occur in aged people. These data are consistent with premature aging of the auditory system in *Fus1* KO mice.

Signs of chronic inflammation in the inner ear of aging Fus1 KO mice

In our early studies, we established that *Fus1* loss results in augmented/skewed innate and adaptive inflammatory responses, suggesting a preactivated state of the immune cells in KO mice (20, 70). Thus, we hypothesized that *Fus1* KO mice may have low-grade chronic inflammation in cochlear tissues and surroundings that could affect auditory performance.

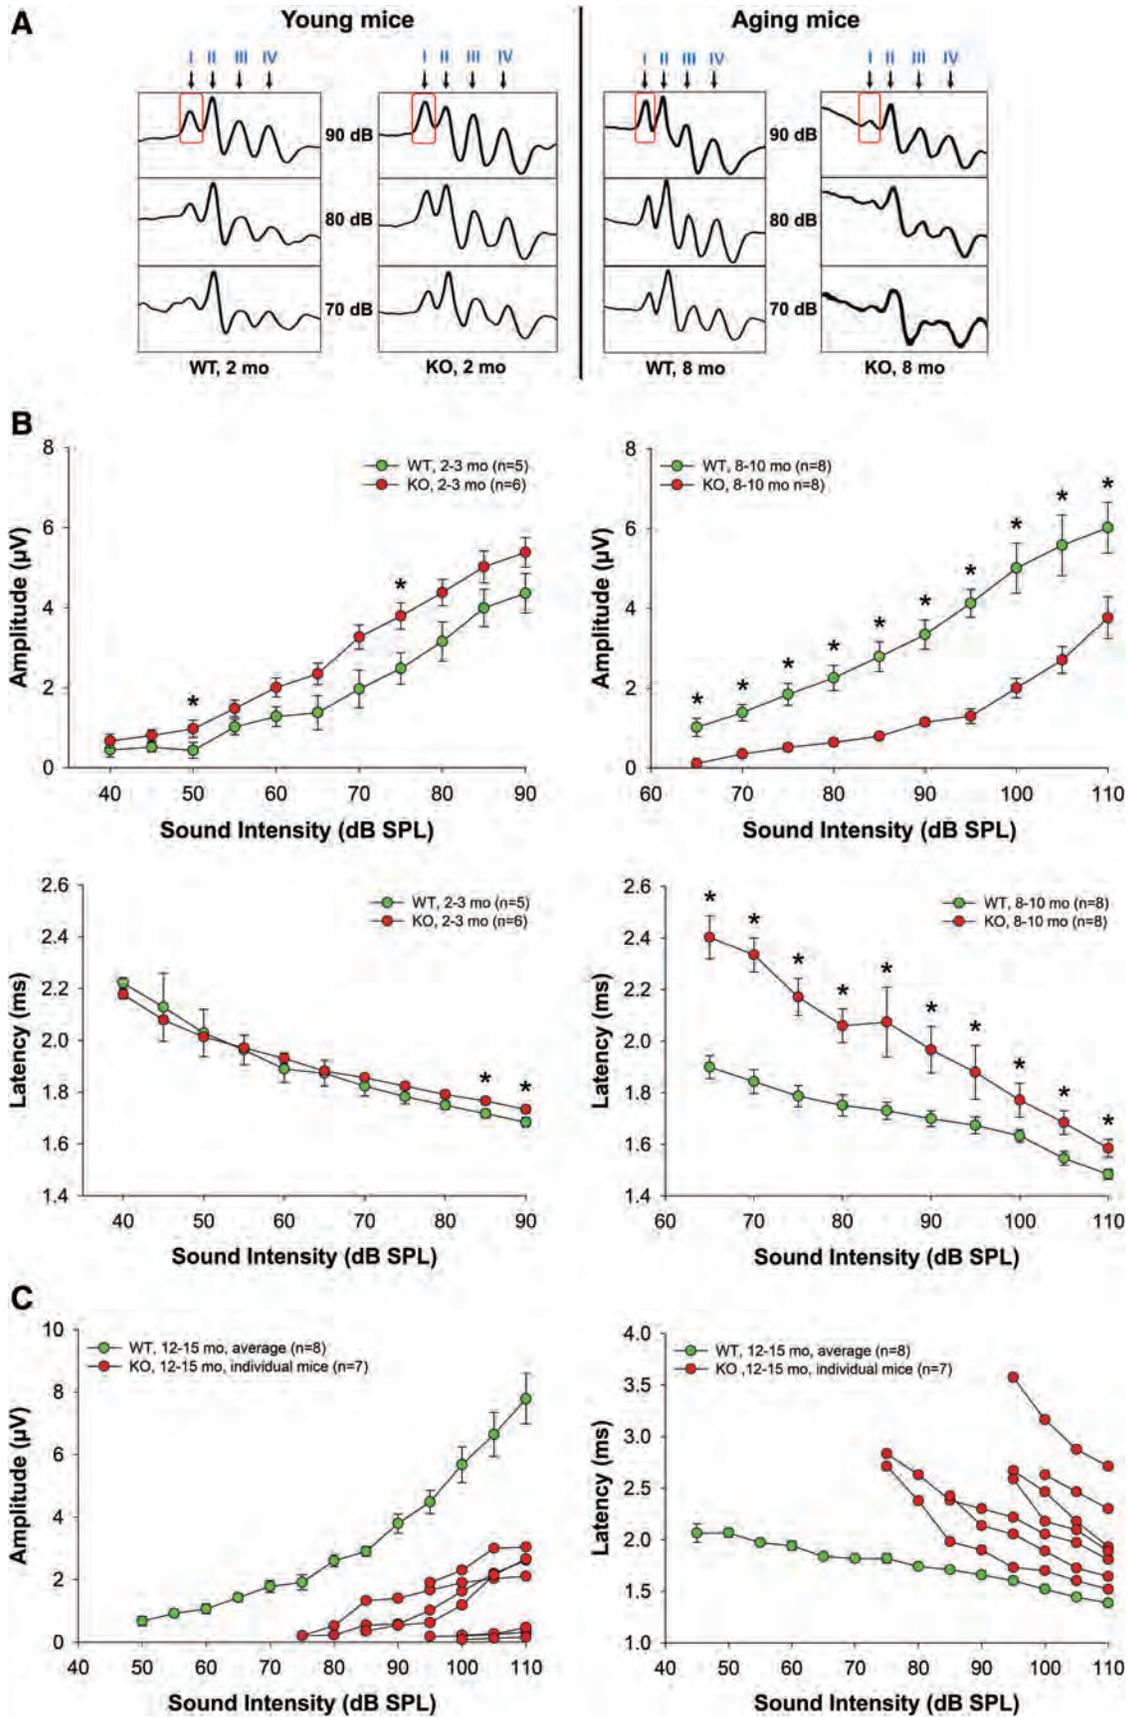

Indeed, hematoxylin and eosin (H&E) staining of bone marrow (BM) cells in the temporal bone surrounding the cochlea showed that in older KO mice, the BM is more hypercellular and myeloid predominant than in age-matched WT mice (Fig. 3A, lower panel). This type of BM histology is often observed in patients with low-grade chronic inflammation that results in an increased systemic level of inflammatory cytokines (68). Staining of BM with Iba-1, a microglia/macrophage-specific calcium-binding protein up-regulated during macrophage activation, confirmed this finding (Fig. 3B, upper panel). BM from temporal bones of young WT and KO mice was phenotypically indistinguishable, suggesting that development of this pathology is age dependent. Staining of cochlear tissues with Iba-1 revealed that the number of activated cochlear macrophages is also higher in KO mice supporting the hypothesis of chronic inflammatory processes in the aging *Fus1* KO cochlea (Fig. 3B, lower panel).

Aging KO mice with severe hearing loss have slight or no changes in auditory sensory and neuronal cell counts but showed reduced number of inner hair cell synapses and type IV fibrocytes in the cochlea

We investigated morphological changes of three major cochlear cell types that could have major effects on hearing: outer hair cells (OHCs), inner hair cells (IHCs), and spiral ganglion neurons (SGNs). Hair cells are the sensory receptors of the mammalian auditory system located within the organ of Corti. The spiral ganglion is a group of nerve cells that receive inputs from hair cells and serve to transfer these signals to auditory brainstem nuclei. Damage to any of these cells results in decreased hearing sensitivity, and because regeneration is absent, this damage is permanent (15, 42, 60).

For IHC and OHC counts, we stained the organ of Corti dissected from the cochleae of 11-month-old mice using the nuclear dye DAPI. Nuclei with uniform size, shape, and staining intensity are characteristic of healthy inner and OHCs (Fig. 3C). Despite the considerable hearing loss in KO mice, both WT and KO mice had mostly intact inner and

FIG. 2. ABR wave I amplitudes and latencies in young (2 months) and old (8–10 months) WT and *Fus1* KO mice at 16 kHz. (A) A schematic of representative ABR waveforms in aging *Fus1* KO mice showing rapid deterioration in wave amplitudes (wave I obtained at 90 dB is boxed for easier comparison) (B) The graphs illustrate the amplitudes (μV , microvolts) and latencies (ms, milliseconds) of ABR wave I as a function of sound intensity (dB SPL) at 16 kHz in young and old WT (green circles) and *Fus1* KO (red circles) mice. At 2 months of age, amplitudes were higher in KO than in WT mice, however, this was reversed at 8–10 months with KO mice having significantly lower amplitudes. Latencies were similar in young WT and KO mice, but were significantly delayed in old KO mice compared with WT mice. The other ABR waves (II, III, and IV) displayed similar changes (data presented in Supplementary Fig. S1). (C) The graphs illustrate prominent interindividual heterogeneity in wave I amplitudes and latencies in old *Fus1* KO mice (red circles). Data for age-matched WT mice (green circles) are averaged with no prominent heterogeneity at the analyzed ages observed. Data presented as mean \pm SEM. * $p < 0.05$ (Student's *t*-test, unpaired). To see this illustration in color, the reader is referred to the online version of this article at www.liebertpub.com/ars

OHCs, and, in general, a well-preserved cochlear structure. SGN count in H&E-stained cochlear sections showed only a marginal, although statistically significant, decrease in the number of SGNs in the KO mouse cochlea (Fig. 3D). It is worth noting, however, that this slight decrease in the number of SGNs could not be responsible for the severe age-related elevation of hearing thresholds and delay in the absolute wave latencies in *Fus1* KO mice.

SGNs are connected to auditory hair cells *via* multiple synapses (65). Recent data have suggested IHC synaptic loss as an important mechanism of hearing loss after auditory damage and aging (28). We immunostained cochlear tissue sections with antibodies to CtBP2/Ribeye, a principal component of the presynaptic ribbon, to compare the numbers of IHC synapses in aging cochleae (60) with young animals that have 14–18 synapses/cell (Fig. 3E). We found an age-related decrease in all three cochlear turns with a more prominent loss in the apical turn in both WT and KO mice. However, the synaptic loss was significantly greater in KO mice (Fig. 3E).

Another histopathological change that was observed in 11-month-old KO mice but not in WT mice was the loss of a small spatially distinct class of fibrocytes (type IV) within the inferior region of the spiral ligament (SL) (Fig. 3F), which is vulnerable to sound exposure and aging. However, the impact of this type of pathology alone on hearing is inconclusive since the presence or absence of type IV fibrocytes does not completely correlate with the degree of hearing threshold shift (74, 27).

EM analysis points to the stria vascularis as the primary target tissue most vulnerable to mitochondrial damage and oxidative stress in aging Fus1 KO mice

Aging (senescence) is characterized by progressive accumulation of macromolecular damage, thought to be due to continuous minor oxidative stress associated with mitochondrial respiration. Earlier we showed that *Fus1*-deficient cells and tissues experience severe oxidative stress (70, 71, 76, 77). Thus, we hypothesized that accumulation of oxidative damage to macromolecules followed by loss of their

function is the underlying cause of premature hearing loss in *Fus1* KO mice. We performed transmission electron microscopy (TEM) analysis to identify cochlear cells dependent on *Fus1* and mitochondrial activities. Cochleae were isolated from 12-month-old WT and KO mice, the age when KO mice have almost no hearing, while WT mice still maintain a robust auditory response (Fig. 1). We performed comparative analysis of four types of cells/tissues that are known to play major roles in ARHL.

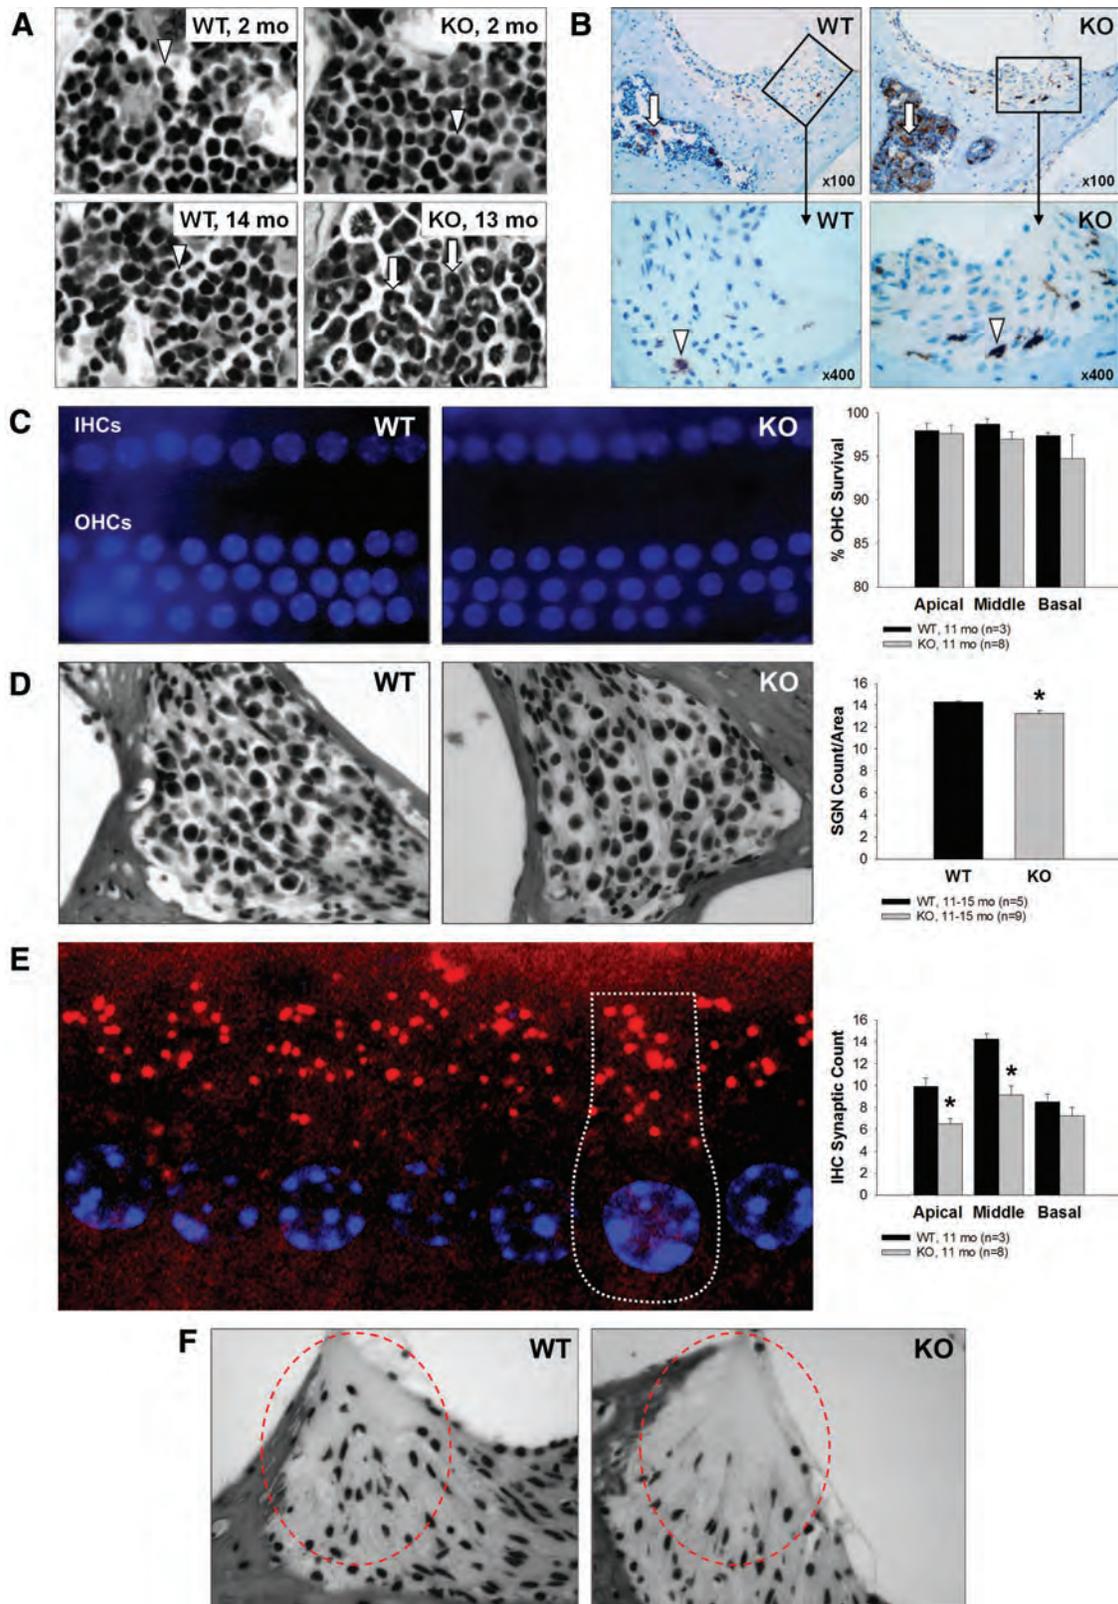

Outer hair cells. In KO OHCs, we did not observe significant deviation from the WT morphology or innervation (data not shown). Also, no difference in mitochondrial morphology was observed between WT and KO OHCs (Fig. 4A).

Inner hair cells. The general morphology of WT and KO IHCs was similar (data not shown). We also observed no difference in the number and structure of mitochondria between WT and KO IHCs (Fig. 4A).

Spiral ganglion neurons. In KO SGNs, we observed modest pathological alterations such as occasional myelin sheath splits (Fig. 4B-I) and areas of nerve fiber degeneration (Fig. 4B-II). At higher magnification, the differences in the morphological structure and sizes of WT and KO mitochondria were easily discernable. Mitochondria in KO SGNs were considerably larger in size and were mostly round in shape. Many of them had electron-lucent content and partially or fully disrupted cristae architecture indicative of mitochondrial pathology/degeneration (Fig. 4B-III).

Stria vascularis and SL. The SV has a dense capillary network and an exceptionally high metabolic rate, the highest of all cochlear tissues (34). The main role of the SV is to produce endolymph, the fluid within the scala media, and generate the endocochlear potential (EP) *via* activation of $\text{Na}^+\text{-K}^+\text{-ATPase}$ pumps for ion balance maintenance. As this process requires a continuous energy supply, the SV has an extensive capillary network and numerous mitochondria

FIG. 3. Chronic inflammation and sensory hair cell, spiral ganglion neuron and inner hair cell synaptic count, and type IV fibrocytes in the cochleae of 12-month-old *Fus1* KO mice. (A) Hematoxylin and eosin-stained cochlear sections showing predominance of activated myeloid progenitor cells (*arrows*) in the bone marrow of the otic capsule in aging *Fus1* KO mice. In contrast, young KO mice and young/old WT mice have compact, undifferentiated myeloid cells (*arrowheads*). (B) Staining with Iba-1, a marker of microglia/activated macrophages, confirmed this finding in the bone marrow (*arrows*), and also revealed an increased infiltration of activated macrophages (*arrowheads*) in the inferior region and along the lateral edge (adjacent to the otic capsule) of the spiral ligament. (C) The images show DAPI-stained IHCs and OHCs from the middle turn of an 11-month WT and *Fus1* KO cochlea. The nuclei (*blue*) are all uniform in size, shape, and staining intensity, which is characteristic of healthy inner and outer hair cells. The graph illustrates the percentage survival of OHCs in the apical, middle, and basal cochlear turns of 11-month-old WT and KO mice. There was no significant loss of OHCs in all three cochlear turns in both WT and KO mice. (D) The representative images and graph illustrate the average number of spiral ganglion neurons in the cochleae of 11-month-old WT and KO mice. There was a marginal but significant decrease in the number of spiral ganglion neurons in the *Fus1* KO cochlea compared with the WT cochlea. (E) Confocal image of IHCs from a 2-month WT cochlea with the nuclei stained with DAPI (*blue*) and presynaptic ribbons stained with CtBP2 (*red*), showing a normal number (14–18) of synapses per IHC. A single IHC is outlined with dotted lines. The graph illustrates the average number of CtBP2-positive IHC presynaptic ribbons on the IHCs from the apical, middle, and basal cochlear turns of 11-month-old WT and *Fus1* KO mice. *Fus1* KO mice had significantly less synaptic ribbons compared to WT mice in the apical and middle turns. (F) Light microscopic images showing substantial loss of type IV fibrocytes in the inferior region of the spiral ligament (*circled*) in 12-month-old *Fus1* KO mice compared with age-matched WT mice. Data presented as mean \pm SEM. * $p < 0.05$ (Student's *t*-test, unpaired). Magnification $\times 400$. IHC, inner hair cell; OHC, outer hair cell. inside marginal cell (MC) processes that interdigitate with intermediate cells (IC) (46). The SL is a dense layer of vascular connective tissue that participates in EP generation (46). The EP enhances the sensitivity of hair cells and, thus, is essential for audition.

TEM analysis showed no abnormality in the SV of aging WT mice while multiple signs of deterioration were observed in the KO SV and SL. First, MC of the SV contained multiple lipofuscin-like dark inclusions (Fig. 4D) that usually correlate positively with oxidative stress and mitochondrial

damage (67). Second, the majority of mitochondria in MCs showed different degrees of pathological changes such as swelling, rounded shape, electron-lucent cytoplasm, as well as partially or entirely disrupted cristae architecture. Many mitochondria were drastically enlarged forming so-called giant mitochondria indicative of defective fission (Fig. 4D). Third, large mitochondria in KO SV were not surrounded by double-layered membrane, characteristic of autophagosomes, and therefore, not targeted for degradation *via* autophagy-like mitochondria in WT SV (Fig. 4E). Fourth, the SV appeared devoid of MC/IC interdigitations, possibly indicating a reduction in IC number, which has been shown to adversely affect EP production (24).

Another layer of pathological change was observed in the SV capillary network. Many capillaries in Fus1KO SV were occluded, filled with electron-dense material and dying blood cells (Fig. 4F). Neither endothelial nor pericapillary cells of KO vessels contained functional mitochondria (Fig. 4F), while WT mitochondria were easily discernable in cells of the capillary wall (data not shown). Moreover, while WT capillaries in SV were surrounded by numerous morphologically normal mitochondria, the KO capillary surroundings consisted of mostly swollen dysfunctional mitochondria and vacuolar structures (Fig. 4F). This suggests that occlusion and degeneration of capillaries in KO SV occur due to capillary cell energy crisis. It is noteworthy that the basal lamina was abnormally thick in KO capillaries compared to WT mice (Fig. 4F). Interestingly, these severe pathological changes were characteristic only for the SV capillaries, while capillaries located in the spiral ganglion from the same cochlea appeared normal reflecting a lower energy demand of this cell type compared to the SV network (Supplementary Fig. S2B).

The KO SL also showed multiple signs of deterioration/ degradation. For example, the type IV fibrocyte area in the SL contained only a few normal fibrocytes while most of them had already been degenerated (Fig. 4G), which is consistent with our light microscopy data. The same type IV fibrocyte area in KO mice showed degenerating vessels, while WT vessels had normal morphology (Fig. 4G).

Thus, based on TEM examination, we concluded that the SV and SL, which showed signs of severe deterioration, are

most likely the primary cause of premature hearing loss in Fus1 KO mice. However, pathological changes in IHCs and SGNs may be contributing factors.

Reduced EP in young adult Fus1 KO mice

The SV and fibrocytes of the SL play major roles in the generation and maintenance of the EP *via* constant ion transport to the endolymphatic space of the cochlea. The EP plays a critical role in maintaining normal hearing sensitivity (4, 61). In view of our EM data showing severe pathology in the SV of KO mice (Fig. 4), we hypothesized that premature loss of hearing in Fus1 KO mice was linked to altered EP. Thus, we measured EPs in 4–5-month-old WT and KO mice (Fig. 5). Representative EP recordings from WT and KO mice are shown in Figure 5B. EP measured in WT mice averaged 101.8 ± 2.1 mV ($n=3$) (Fig. 5C), which is similar to published values. In contrast, the average EP in KO mice was 59.9 ± 7.6 mV ($n=3$), 41.9% lower than in WT mice, $p=0.026592$ (Fig. 5C), which directly demonstrates the importance of SV integrity/functionality for establishing the high EP.

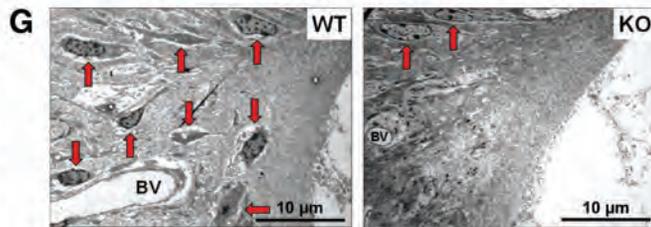

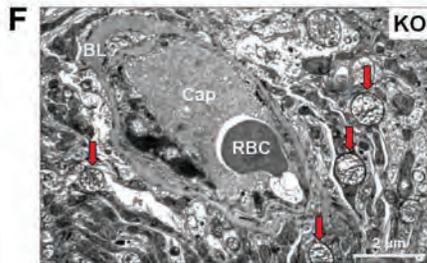

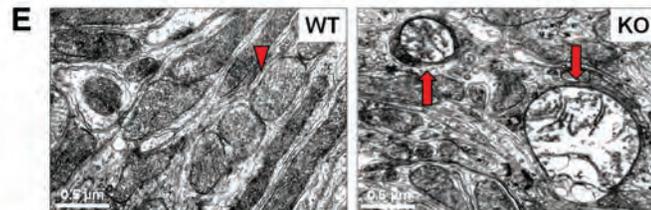

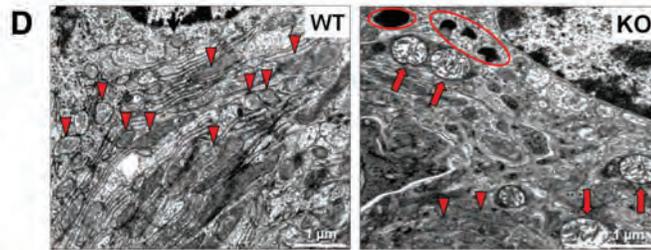

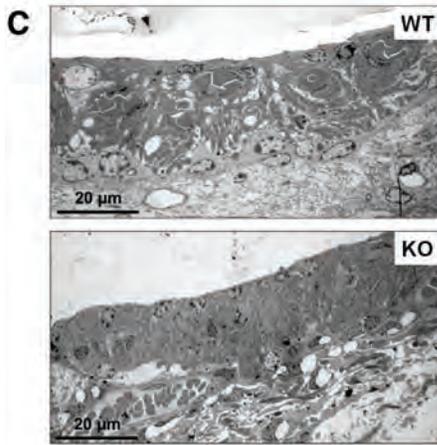

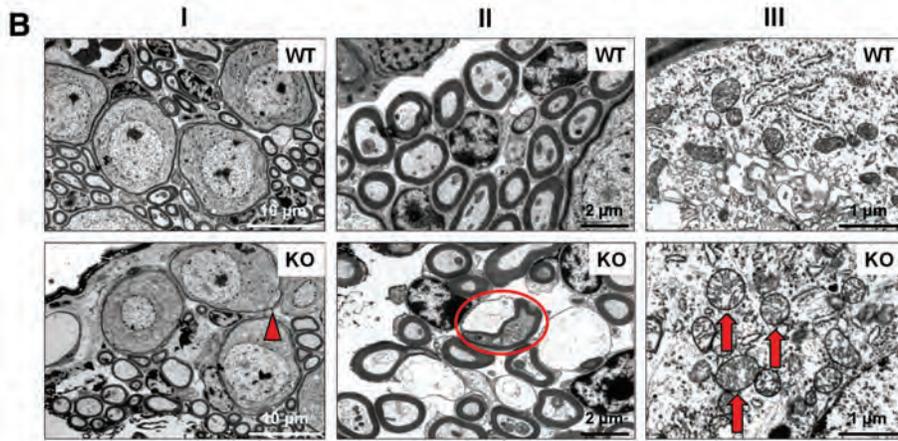

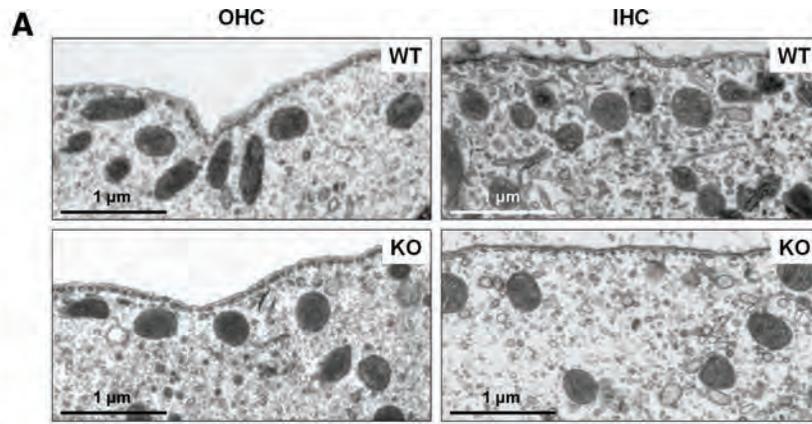

These data suggest that the major mechanism of premature ARHL in Fus1 KO mice is an inability to maintain EP due to, most likely, mitochondrial dysfunction-caused energy crisis in cells of the SV and SL.

Cochlear tissues of 3-month-old Fus1 KO mice show pathological molecular changes in aging-associated pathways, antioxidant and autophagy machineries

To determine the molecular alterations in the KO mouse cochlea that initiate progressive hearing loss, we performed immunoblot analysis focusing on aging-associated pathways. To capture the onset of pathological changes, we analyzed proteins from cochleae of 1- and 3.5-month-old WT and KO mice. Cochleae extracted from five mice per group were pooled together to obtain sufficient protein amounts.

Starting from 1 month of age, we detected potentially detrimental molecular alterations in Fus1 KO mice (Fig. 6 and Supplementary Figure S3A, B). Among proteins of AO machinery, an increase in PRDX1 and a pathological

FIG. 4. TEM analysis of cochlear tissue from 12-month-old Fus1 KO mice. (A) Mitochondria of WT and KO inner and outer hair cells. The number and morphology of mitochondria in the IHCs and OHCs of the organ of Corti are similar in WT and Fus1 KO mice. (B) Spiral ganglion cells in the Fus1 KO cochlea. Pathological signs of degeneration are observed in some regions of the KO cochlea but not in the WT cochlea, such as myelin sheath splits (I, arrowhead), nerve fiber degeneration (II, circled), and abnormal mitochondria in SGNs (III, arrows). KO mitochondria are considerably larger in size, mostly round in shape, and have electron-lucent content and partially or fully disrupted cristae architecture. (C) Stria vascularis of WT and Fus1 KO mice, low magnification. The stria vascularis of the KO cochlea is considerably atrophied compared to that of the WT cochlea. The MC/IC interdigitations present in the WT are not apparent in the KO, possibly indicating IC loss. (D) Comparison of WT and Fus1 KO marginal cells of the SV at higher magnification. Note the mitochondrion-rich cytoplasm (arrowheads) in WT marginal cells, while in KO cells, there are fewer normal mitochondria (arrowheads), presence of multiple swollen “giant” mitochondria (arrows), and numerous electron-dense lipofuscin-like pigment inclusions (circled). (E) Mitochondria of WT and KO marginal cells, high magnification. Note that in the KO cell, large abnormal mitochondria are not a part of autophagosomes (arrows). (F) Vascular pathology in Fus1 KO stria vascularis. Strial capillaries (Cap) in the KO cochlea are occluded, filled with electron-dense gray material and dying RBC. The BL is abnormally thick and there is a lack of functional mitochondria in the capillary wall. Moreover, the area surrounding the blood vessels consists of many swollen and dysfunctional mitochondria (arrows) and vacuolar structures. (G) Inferior region of the spiral ligament in the WT and Fus1 KO cochlea. There is a substantial loss of type IV fibrocytes (arrows) in the KO spiral ligament, and BV also appears to be degenerated. RBC, red blood cell; BL, basal lamina; BV, blood vessels; SGN, spiral ganglion neuron; TEM, transmission electron microscopy. decrease in mitochondrial Sod2 levels were observed (Fig. 6A). Autophagy marker LC3-II showed a Fus1-dependent decrease pointing to an early onset of autophagy dysregulation (Fig. 6D). The most dramatic and consistent changes were found in the PTEN/AKT pathway where total PTEN levels were decreased, while phosphorylation of AKT, a substrate for PTEN phosphatase activity, was increased (Fig. 6B). The level of the mitochondrial kinase PINK1, a mitochondrial quality control protein and PTEN substrate, was also noticeably downregulated (Fig. 6A).

In the adult KO mouse cochlea (3.5 months), we detected escalation of molecular changes observed in younger mice as well as new critical changes (Fig. 6 and Supplementary Fig. S3A, B). The most unexpected change was a dramatic decrease/loss in total AKT levels in 3.5-month-old KO mice in contrast to 1-month-old KO mice that had increased AKT phosphorylation but no changes in total level of AKT (Fig. 6B). This suggests the existence of pathological factors other than PTEN dysregulation that affect AKT translation/degradation in adult KO cochleae. Along with dysregulation of AKT pathway, we observed an apparent mTOR activation (ppS6) in KO cochleae (Fig. 6C). It is noteworthy that mTOR activation (pS6 increase) was observed at both total and phosphorylated levels indicating that Fus1 affects different levels of protein regulation. We also found a further decrease in the levels of AO molecules and a decrease in the level of OxPhos I, a member of mitochondrial respiratory complex I (Fig. 6A). Further decrease in LC3-II levels suggested accumulation of dysfunctional mitochondria due to defective autophagy (Fig. 6D). The PTEN and Pink1 levels in both KO age groups were consistently lower than in WT mice (Fig. 6A, B).

Interestingly, some aging-associated signaling hubs, such as MAPK42/44 and STAT3 (Fig. 6E), as well as apoptotic proteins with the exception of Bax (Fig. 6D) showed no or marginal changes between KO and WT mice in young or adult mice, thus suggesting Fus1 deficiency specifically targets the PTEN/AKT and mTOR/autophagy axes.

Short-term AO supplementation alleviates/corrects pathological molecular changes in cochlear tissues of adult Fus1 KO mice

All molecular pathways analyzed in the present study are mitochondria/energy dependent. In our earlier studies and here

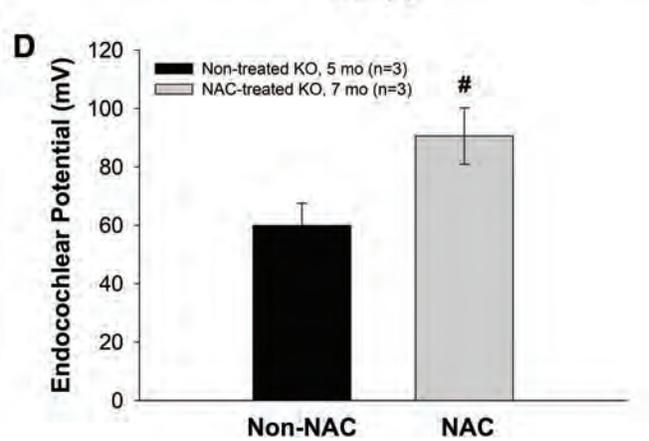

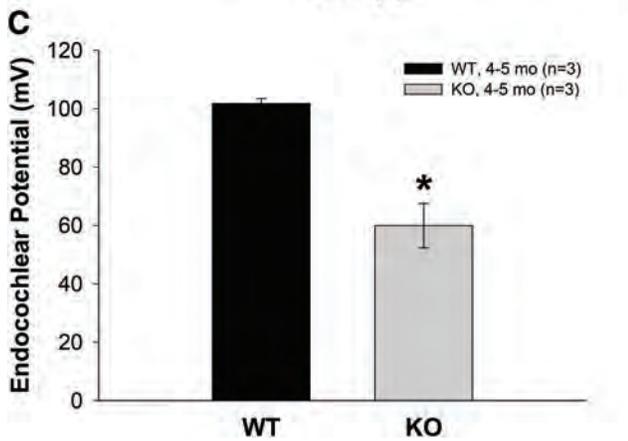

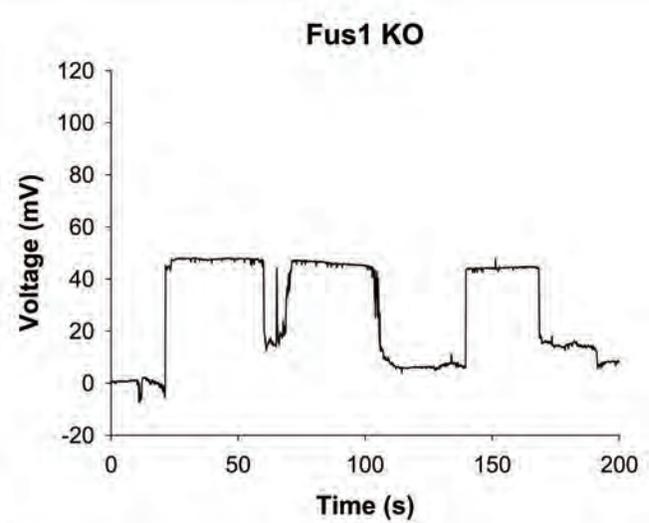

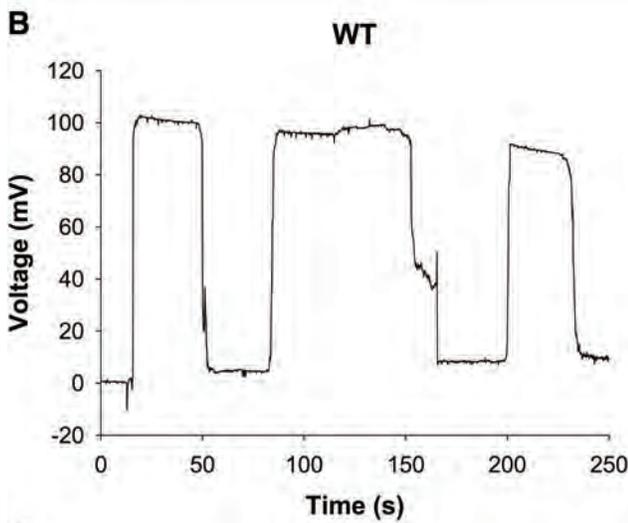

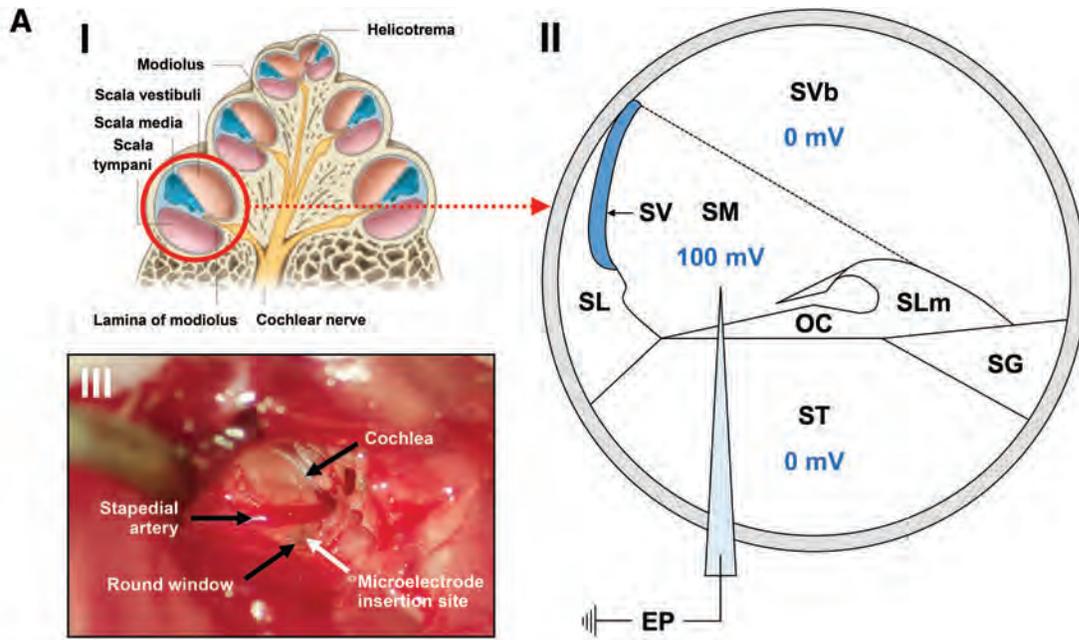

(70, 71, 77) (Fig. 6 and Supplementary Fig. S3A, B), we showed that Fus1-deficient tissues experience chronic oxidative stress that may be detrimental for mitochondria and tissues with high-energy demand such as the cochlea. We hypothesized that relief of oxidative stress may improve mitochondrial activities, alleviate molecular pathology, and slow down hearing loss. To validate this hypothesis, 30 mM N-acetyl cysteine (NAC), an AO compound, was provided in drinking water to 3.5-month-old WT and KO mice for 30 days. Our choice of AO was substantiated by several data sets. First, NAC was one of the three AO supplements that was reported to alleviate hearing pathology in B6 mice when provided for 11 months in a study that tested the long-term effect of 17 different AO compounds (62). Second, NAC was shown to be able to penetrate the blood-brain barrier (BBB) (13), and third, it was shown to prevent mitochondria from oxidative injury, which is critical for our model of mitochondrial dysfunction (29).

To confirm that NAC relieves oxidative stress in the cochleae of KO mice, we compared the levels of AO proteins and found that PRDX1 and OxPhos I level 39 kDa were completely rescued in the cochleae of NAC-treated KO mice compared to WT mice (Fig. 6A). Remarkably, NAC treatment normalized or alleviated Fus1-dependent pathological changes in other aging-related proteins such as autophagy marker LC3-II and proteins from the nutrient (mTOR) and energy (PTEN/AKT) sensing pathways (Fig. 6, red arrows). Interestingly, not all proteins in the analysis were equally sensitive to NAC treatment. Thus, we did not observe significant NAC effects on mitochondrial proteins SOD2 or Pink1 (Fig. 6A), while levels of total and phosphorylated AKT, S6, and PTEN were drastically improved (Fig. 6B, C). This discordant response to AO intervention suggests that NAC may not efficiently penetrate mitochondria, or that in addition to oxidative stress, other pathological processes are associated with Fus1 loss in the cochlea.

Short-term antioxidant (NAC) supplementation prevents progression of hearing loss, improves ABR wave amplitudes, restores EP levels, and improves mitochondrial morphology in SV cells and SGNs in Fus1 KO mice

To determine the effect of AO treatment on progression of hearing loss in KO mice, we treated 4-month-old mice

FIG. 5. Endocochlear potential (EP) measurements in WT and Fus1 KO mice. (A) (I) Drawing of cross section of a cochlea showing the apical, middle and basal (*circled*) turn. (II) Schematic diagram of the cross section of the basal cochlear turn illustrating the method of EP measurement. A 3 M KCl-filled microelectrode was inserted into the perilymph-filled scala tympani (0 mV) from the round window and then advanced into the endolymph-filled scala media (100 mV in a WT mouse) to record the EP. (III) Photograph of a surgically exposed cochlea before EP measurement showing the location of the round window below the stapedial artery (*black arrows*) and the insertion site of the microelectrode (*white arrow*). (B) Representative EP recordings from a 4–5-month-old WT and Fus1 KO mouse. The traces show the voltage (mV) of the scala media as a function of time (s). The electrode was advanced into the scala media, withdrawn back into the scala tympani, advanced again back into the scala media, and further into the scala vestibuli, and then retracted back into the scala tympani, giving three peaks in the trace. (C) The graph illustrates a significant 41.9% reduction in the EP in 4–5-month-old Fus1 KO mice (59.9 ± 7.6 mV) compared with age-matched WT (101.8 ± 1.7 mV) mice. (D) The graph illustrates a 1.5-fold increase in EP in Fus1 KO mice treated with NAC for 3 months (90.6 ± 9.6 mV) relative to non-NAC-treated Fus1 KO mice (59.9 ± 7.6 mV), which is almost a complete restoration of EP to that of WT mice. Data presented as mean \pm SEM ($n = 3$). * $p < 0.05$ (Student's *t*-test, unpaired). # $p = 0.07$ (Student's *t*-test, unpaired). (Fig. A–I reproduced and modified from Drake *et al.* (11a)). FIG. 6. Dynamic changes in aging-related proteins in the cochlea of young and adult WT and *Fus1* KO mice and NAC-mediated changes in these pathways. The results of Western blot analysis are presented as a relative expression or phosphorylation index of several aging-associated groups of proteins in *Fus1* KO compared to WT cochlea. (A) Mitochondrial proteins and antioxidant machinery, (B) PTEN/AKT pathway, (C) mTOR pathway, (D) autophagy and apoptosis, and (E) STAT/MAPK signaling in WT and *Fus1* KO mice at 1 month and 3 months of age were analyzed. The last panel shows relative changes in the analyzed proteins induced by 30 days of NAC supplementation to 3-month-old mice. The number below the bands represents the fold change in protein expression or phosphorylation index in the KO cochlea relative to the WT cochlea. Phosphorylation index is the ratio of phosphorylated protein intensity over total protein band intensity. Loading controls are shown in (F). Red arrows indicate correction of pathological changes in KO cochlea induced by 30 days of NAC supplementation compared to nontreated 3-month-old KO mice. Triangle arrow in (D) points to LC3-II isoform involved in autophagy. To see this illustration in color, the reader is referred to the online version of this article at www.liebertpub.com/ars

with NAC for 3 months. NAC supplementation significantly retarded hearing loss in KO mice making the ABR threshold levels of 7-month-old KO mice comparable to WT mice, while nontreated control KO mice of similar age had profound hearing loss (Fig. 7A). Moreover, NAC prevented both the reduction of wave I amplitudes (Fig. 7B) and the delay in wave I latencies (Fig. 7C), and almost restored the EP in KO mice to the level of 4–5-month-old WT mice (Fig. 5D).

In addition, the effect of NAC at the ultrastructural level in the cochlea of KO mice was examined by TEM analysis (Fig. 8). In nontreated 5–6-month-old *Fus1* KO mice, SV cells and SGNs had swollen mitochondria with disrupted cristae architecture, similar to that observed in 12-month-old KO mice, but not as severe. NAC supplementation of 4-month-old KO mice for 2 months significantly improved the

morphology of mitochondria in SV cells and SGNs completely restoring cristae architecture. These results, therefore, suggest that oxidative stress is one of the major causative mechanisms of ARHL in *Fus1* KO mice.

Discussion

Mitochondria present a unique and crucial set of key intracellular functions (72). The critical role of mitochondria in auditory function and ARHL began to emerge some time ago but is still understudied and underestimated (5). With regard to oxidative stress and mitochondrial function, only a few genes and loci linked to ARHL have been proposed as a result of candidate gene-based association human studies. Among them are AO enzymes superoxide dismutases (SODs) and

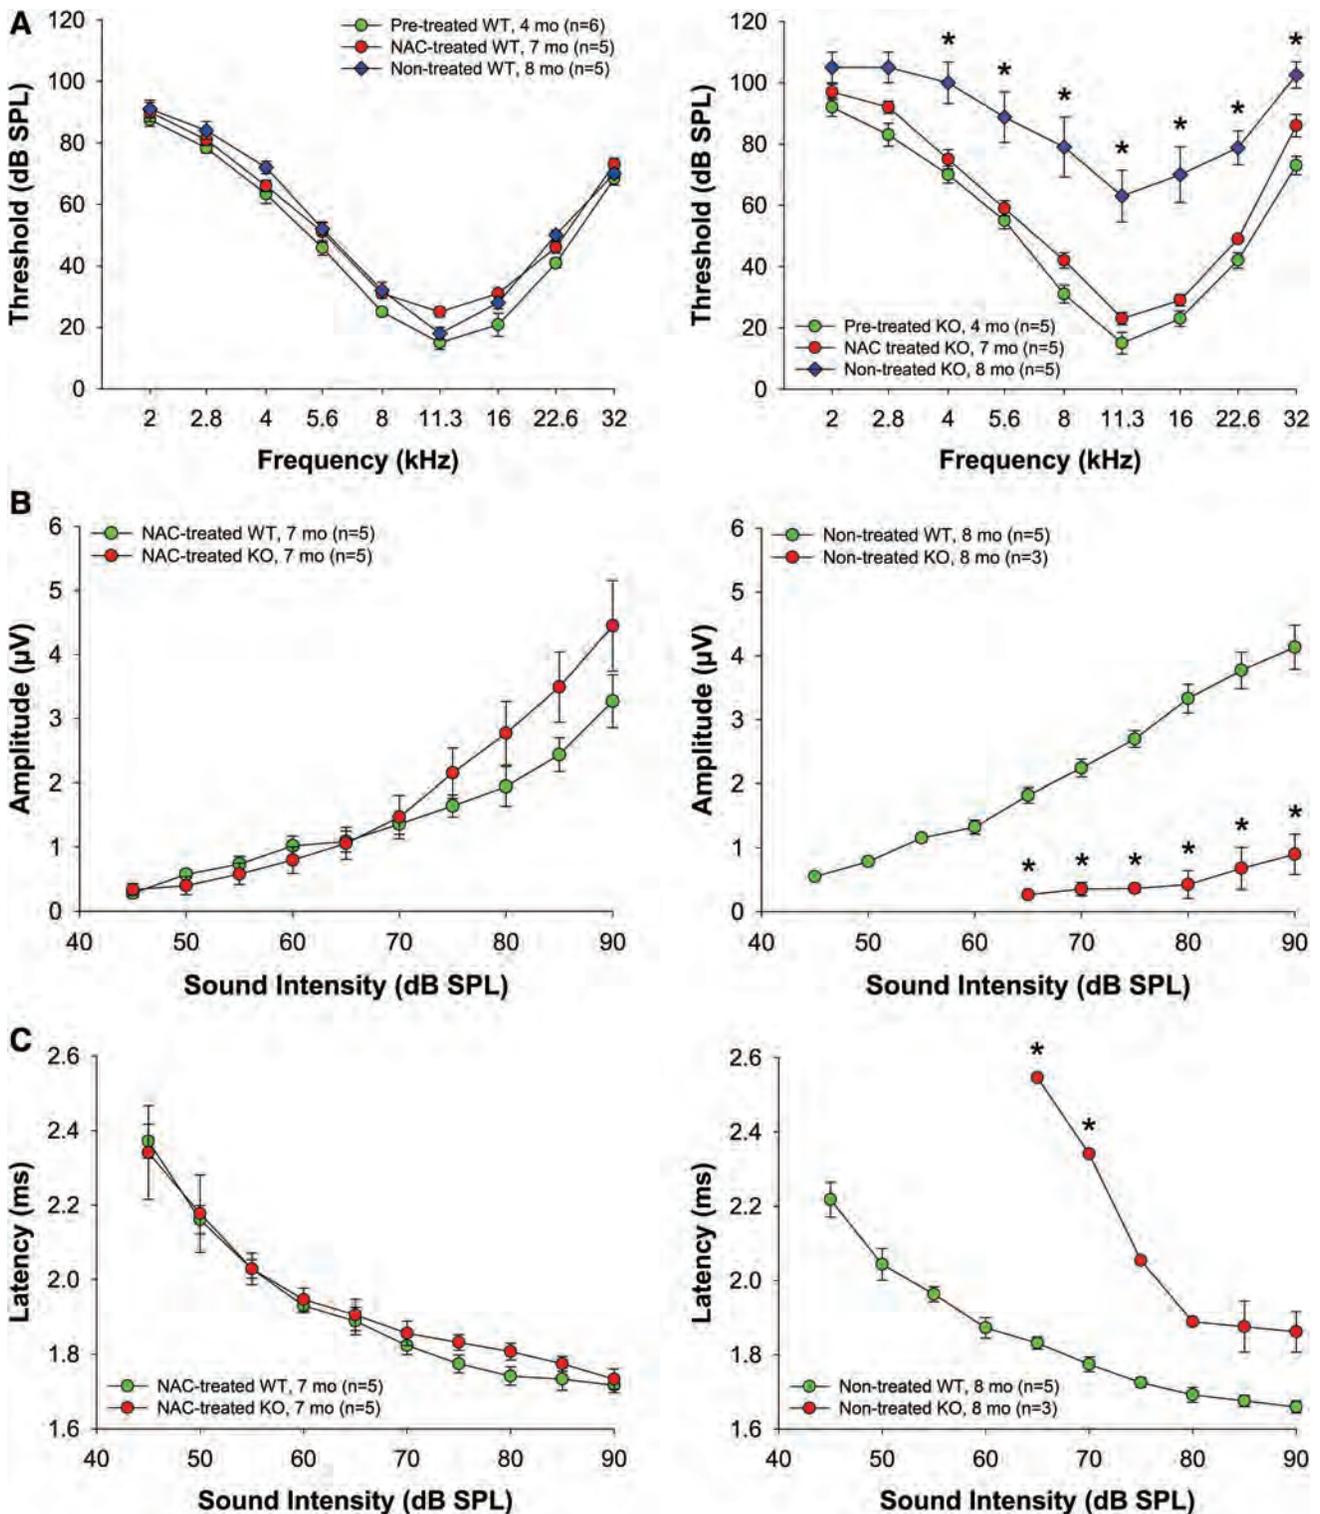

FIG. 7. Effect of NAC supplementation on hearing thresholds and ABR wave I amplitudes in WT and *Fus1* KO mice. (A) The graphs illustrate ABR thresholds in nontreated and NAC-treated WT and *Fus1* KO mice. NAC supplementation for 3 months (red circles) significantly improved the thresholds across all frequencies in *Fus1* KO mice but not in WT mice. (B, C) The graphs illustrate the amplitudes (μ V) and latencies (ms) of ABR wave I as a function of sound intensity (dB SPL) at 16 kHz in nontreated and NAC-treated WT and *Fus1* KO mice. NAC prevented the reduction and delay of wave I amplitudes and latencies, respectively. Data presented as mean \pm SEM. * p < 0.05 (Student's *t*-test, unpaired). To see this illustration in color, the reader is referred to the online version of this article at www.liebertpub.com/ars

glutathione S-transferases (GSTs), and mitochondrial uncoupling proteins (UCPs) that reduce the MMP in mammalian cells (16). Deletions/mutations in mitochondrial DNA or reduced expression of genes from mtDNA has also been associated with ARHL in humans (3, 35, 14). Animal studies largely confirmed the conclusion that oxidative stress, altered levels of AO enzymes, decreased activity of I, II, IV complexes/ altered respiration, and increased mtDNA mutation rate lead to premature hearing loss (23, 37, 39, 48, 63, 69).

Types of mitochondrial dysfunction are defined by the activities of the mitochondrial protein(s) or mitochondrial hub(s) that are defective in a specific tissue. In addition to ATP production, other mitochondrial functions may define the type of dysfunction, such as maintaining calcium concentration within cellular compartments, calcium signaling that mediate responses to outside signals, regulation of the

membrane potential, AO function, apoptosis, and regulation of cellular metabolism (44). It would be logical to suggest that mitochondrial impact on hearing is defined by the type of mitochondrial dysfunction. Thus, additional models of premature hearing loss linked to various mitochondrial activities are urgently needed to understand the basic mitochondrial mechanisms of ARHL and counteract them.

In the current study, we characterized a novel model of ARHL mediated by the loss of the mitochondrial protein Fus1 and determined its molecular mechanisms. In our earlier studies, we established Fus1 as one of the few regulators of mitochondrial calcium handling (71, 72). However, Fus1 KO cells were presented with dysregulation not only in calcium accumulation/distribution but also in calcium-coupled mitochondrial parameters (*via* so-called metabolic coupling), such as ROS production, mitochondrial potential, GSH content, mitochondrial fusion, and calcium signaling mediated *via* NF κ B/NFAT axis. We hypothesized then that disruption of metabolic coupling in mitochondria may result in multiple cellular and systemic pathologies (71, 72).

Indeed, in this study, we provide multiple lines of evidence that Fus1 KO mice are a mechanistically novel, convenient, and clinically relevant model of premature ARHL. We found that besides early and fast progressing hearing decline (Fig. 1), young Fus1 KO animals have paradoxically increased ABR wave amplitudes (Fig. 2). Higher amplitudes normally reflect increased number of firing neurons or higher synchrony of firing. We speculate that higher ABR wave amplitudes in young KO mice may be a result of higher ROS production or altered intracellular calcium/signaling.

In our early work, we established that immune cells from young Fus1 KO mice are chronically activated, which could benefit young mice by better protecting them from acute infection, but may play a detrimental role during aging (20, 71). Here we suggest that heightened ABR responses in the young KO inform a higher metabolic demand, and may underlie the drastic drop of amplitudes and hearing later in life as we observed in aging KO mice (8–10 months) but not in age-matched WT mice (Fig. 2). We did not find that this phenotype is gender specific.

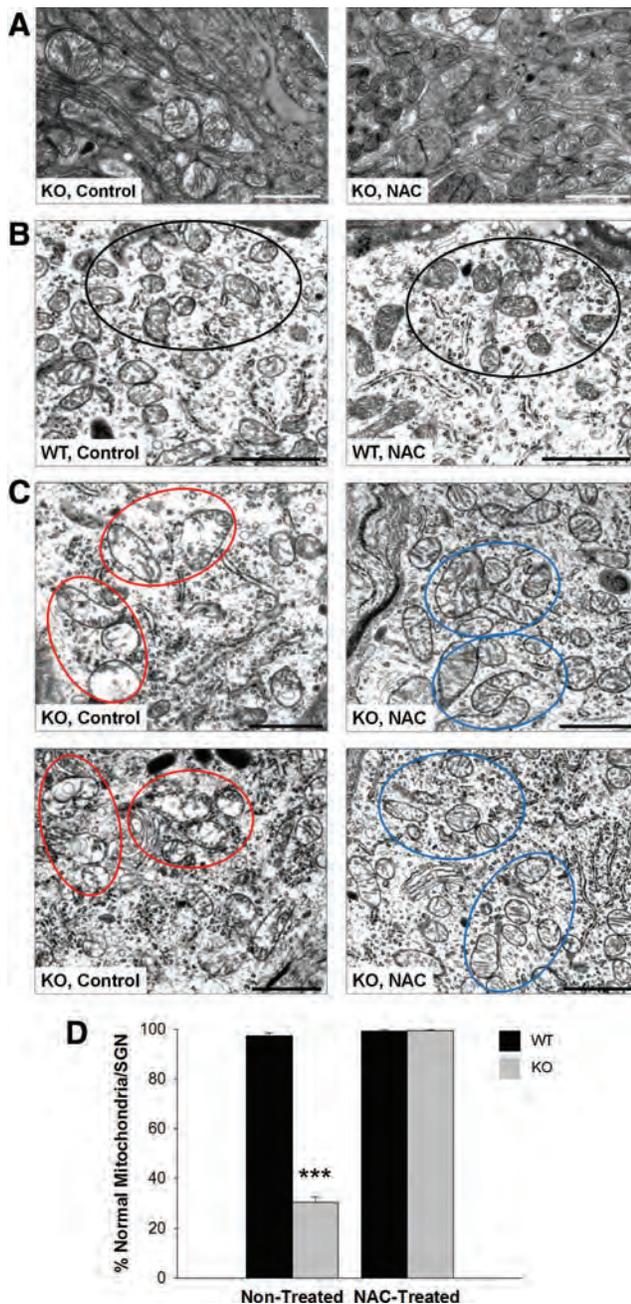

FIG. 8. Transmission electron microscopy (TEM) analysis of cochlear tissue from 5- to 6-month-old non-treated and NAC-treated Fus1 KO mice. (A) Comparison of mitochondria in stria vascularis cells between nontreated and NAC-treated Fus1 KO mice. **(B)** Mitochondria of SGNs from nontreated and NAC-treated WT mice. **(C)** Mitochondria of two representative SGNs from nontreated and NAC-treated Fus1 KO mice. NAC treatment of 4-month-old Fus1 KO mice for 2 months significantly improved the morphology of mitochondria (reduced size and improved cristae architecture) in SV cells and SGNs. Clusters of representative mitochondria are circled in the micrographs. **(D)** The graph illustrates the percentage of morphologically normal mitochondria in SGNs of WT and Fus1 KO cochleae before and after NAC treatment. The number of normal and abnormal mitochondria was counted in each spiral ganglion cell (6–10 microscope fields/cell) and the average percentage of normal mitochondria per SGN calculated. Scale bar = 1 μ m. Data presented as mean \pm SEM. *** p = 0.0000474 (Student's t -test, unpaired). To see this illustration in color, the reader is referred to the online version of this article at www.liebertpub.com/ars

The patterns of ABR wave deterioration in adult KO mice are very similar to the data obtained from studies on aging individuals (25), suggesting that the Fus1 KO mouse is a clinically relevant model of ARHL, and therefore studying the molecular mechanisms of hearing loss in Fus1 KO mice as well as approaches for its prevention could be applicable to humans.

We ruled out death of sensory cells as a primary cause that often underlies age-related sensorineural hearing loss (75). The absence of mitochondrial pathology in OHCs and IHCs also suggests preservation of their bioenergetics levels in Fus1 KO organ of Corti. Although based on the slight but significant decrease in the number of SGNs and IHC synapses as well as on prominent mitochondrial swelling and morphological abnormalities in SGNs corrected by antioxidant treatment, we cannot exclude neural cell involvement at some stages of hearing pathology in KO mice.

However, the severe vascular and mitochondrial structural changes in the SV and SL, with reduced MC/IC interdigitations, strongly suggest that the basis of ARHL in Fus1 KO mice is of metabolic nature. The significant pathological changes of strial capillaries may cause a restrained cochlear blood flow, which can lead to mitochondria-mediated insufficiency in energy production that is needed to maintain ion pumping to the endolymph. The SV is critical for the generation and maintenance of the EP. Reduction in the EP results in a loss of electrical driving force for hair cell transduction current (4, 61). EP measurement in 4–5-month-old mice revealed a significant 41.9% reduction in KO mice (59.9 ± 7.6 mV) compared with WT mice (101.8 ± 2.1 mV) demonstrating that strial dysfunction contributes to cochlear pathology underlying progressive hearing loss in Fus1 KO mice.

Metabolic (based on strial pathology) ARHL is the least studied pathology (4, 64). No human genes that promote strial presbycusis have been identified nor is its pathophysiology well understood (45, 46). Although extensive strial degeneration coincides with hearing loss, EPs have never been measured in humans due to the absence of technology for this invasive measurement. In animal studies, until recently, only two well-studied models, Mongolian gerbils and *Tyrp1*(B-It) mice (8), were known to undergo age-associated EP reduction. Recently, four other strains with modest to severe EP reduction during aging (C57BL/6-Tyr(c-2J) (50), BALB/cJ (47), CBA/CAJ, and NOD.NON-H2(nbl)/LtJ (49)) were described. So far, only one individual gene *Tyrp1*, which codes for tyrosinase-related protein (56), has been linked to age-related EP decline in these strains, although several candidate protein classes had been suggested such as AO machinery, ion channels, exchangers and pumps, immune-related genes, and cell repair genes (6, 46).

Therefore, our novel Fus1 KO model of mitochondrial dysfunction that affects the performance of AO machinery (76, 77), intracellular calcium distribution (71), and immune response (20, 70) may be of a great value for studying the etiology and molecular mechanisms of age-related strial degeneration.

To pinpoint the molecular basis of strial degeneration, we analyzed protein alterations in cochlear tissue of Fus1 KO mice. We used a *logical* candidate-based approach when choosing the proteins for analysis, including pathways and processes linked to (i) nutrient sensing and energy expenditure (PTEN/AKT and mTOR); (ii) mitochondrial activities; (iii) oxidative stress; (iv) apoptosis and autophagy. Our main quest was to identify primary Fus1-dependent molecular

changes that drive other molecular and pathological changes later in life. Therefore, we compared protein levels and their phosphorylation/activation in the cochlea of 1- and 3.5-month-old animals. The most consistent and early alterations were observed in the PTEN/AKT pathway as well as the proteins of AO machinery, allowing us to consider them as the primary molecular events. Phosphatase and tensin homolog (PTEN) is involved in numerous important systemic functions, including anti-aging activities. It was shown to positively regulate longevity (51). Recently, a new metabolic role of PTEN as a positive regulator of energy expenditure through increased oxidative phosphorylation was revealed (52). ROS have been shown to oxidize the active site cysteine on PTEN (Cys124), resulting in inactivation of PTEN and perpetual activation of the AKT pathway (30). Moreover, mitochondrial ROS specifically were shown to inhibit PTEN and activate AKT (9), which is consistent with the molecular events we observed in young Fus1 KO mice.

Based on the ROS scavenging effects in Fus1 KO mice that resulted in rescue of PTEN/AKT pathway, we believe that consistently decreased PTEN levels and activation of AKT in the Fus1 KO cochlea are due to pathologically high levels of ROS. However, the exact nature of PTEN decrease in Fus1 KO cochlea is yet to be confirmed since PTEN is regulated by multiple mechanisms, including but not limited to phosphorylation, oxidation, binding to different partners, and transcriptional regulation (31). Considering the importance of PTEN in aging and hearing, there is no doubt that PTEN regulation is one of the key molecular mechanisms of Fus1 action in protection from premature hearing loss. It is worth noting that in our earlier work we showed that Fus1 is also involved in PTEN regulation in lungs during bacteria-induced inflammatory response (20).

Another important alteration we observed in 3.5-month-old KO mice is the decreased levels of OxPhos 39 kDa, a subunit of mitochondrial respiratory Complex I, a component of the oxidative phosphorylation chain. This decrease was rescued by AO treatment. Low levels of Complex I indicate low ATP levels in KO cochlear tissue since ATP is produced during oxidative phosphorylation. ATP deficiency may lead to an energy crisis and strial malfunction.

In line with PTEN inactivation/pAKT activation in young KO mice, in adult mice we observed activation of the mTOR pathway measured by ribosomal protein S6 phosphorylation, a downstream target of mTOR. mTOR lies at the heart of a nutrient-sensing signaling network that controls cellular metabolism and, thus, aging (21). mTOR activation has been linked to aging in multiple studies [(18), and reviewed in (53)]. It was suggested that aberrant mTOR activation in aging is a response to mitochondrial stress in cells (41), which is consistent with the processes that may take place in the Fus1-deficient cochlea.

Interestingly, in 1- and 3.5-month-old KO cochlea, we observed negative age-related dynamics in accumulation of the autophagy marker LC3-II. Autophagy is an evolutionarily conserved catabolic process that targets proteins and organelles to lysosomes for degradation, followed by recycling of free amino acids and ATP for biosynthesis (68). Autophagy mediates cytoprotective effects (40). During autophagy a cytosolic form of LC3 (LC3-I) is converted *via* conjugation to phosphatidylethanolamine to LC3-II, which is recruited to autophagosomes. High levels of LC3-II reflect a higher autophagy rate and *vice versa*. In our study, based on LC3-II and

Pink1 decrease and accumulation of large swollen mitochondria, we concluded that Fus1 KO cochlear tissues are deficient in autophagy/mitophagy. Moreover, in line with deficient autophagy, we registered activation of mTOR in 3.5-month-old KO mice, which has been shown to suppress autophagy and, thus, promote aging [(43) and references therein]. Normalization of LC3-II levels in Fus1 KO cochleae after AO treatment confirms the link of oxidative stress and autophagy.

Finally, in line with all the data pointing to deficient autophagy/mitophagy in KO cochleae, we showed downregulation of PINK1 (PTEN-induced putative kinase 1) protein in 1- and 3-month-old KO mice. The mitochondrial protein PINK1 is a PTEN-induced putative kinase regulating mitochondrial quality control *via* activation of mitophagy (36). It is a critical protector from age-related diseases linked to dysfunctional mitochondria (7, 54). In the Fus1 KO setting, decreased levels of PINK1 are in line with decreased levels of its upstream regulator PTEN (Fig. 6). In terms of long-term consequences for tissue integrity, PINK1 deficiency could be detrimental for aging Fus1 KO tissues as it leads to inability to withstand oxidative and environmental stress due to defective mitochondrial quality control resulting in accumulation of dysfunctional mitochondria and deterioration of tissues due to energy crisis as we observed in the SV of aging 8–11-month-old Fus1 KO mice.

Apoptotic markers that we used to monitor cell death in young Fus1 KO cochlear tissues showed little difference in expression between KO and WT mice (Fig. 6D, Bcl-X, and Bax), suggesting that deficiency in autophagy may result in other types of cell death in the cochlea (55).

It was also interesting to find, in terms of Fus1 biology, that crucial signaling hubs such as STAT3 (11) and MAPK42/44

(66) showed no major perturbations, suggesting that the antiaging effect of Fus1 is promoted specifically through PTEN/AKT/mTOR pathways partially mediated through control of oxidative stress.

Simple supplementation of the AO NAC to Fus1 KO mice for 1 month increased the level of AO enzymes, normalized PTEN/AKT and mTOR pathways, and protected mitochondria from dysfunction and degradation. Based on our early studies of Fus1 protein biology (70–72), we suggest that normalization of ROS levels in Fus1-deficient tissues helps in recovering mitochondrial integrity, MMP and mitochondrial calcium transport across the membrane and, thus, improve mitochondrial activities, including ATP production and Ca^{2+} distribution, dynamics, and calcium signaling. These changes in different mitochondrial processes could explain the multitude of effects of NAC-mediated ROS scavenging in the Fus1 KO cochlea.

Importantly, NAC supplementation for 3 months produced several highly beneficial changes in hearing of Fus1 KO mice, including prevention of age-related hearing decline, normalization of ABR peak amplitudes, and rescue of the EP. WT mice did not show significant auditory changes in response to NAC treatment at this age, most likely due to the absence of degenerative processes in auditory system at the analyzed age. Short-term NAC treatment also significantly improved the morphology of mitochondria in cells of the SV and SGNs. These results strongly suggest that oxidative stress is one of the major pathogenic factors in ARHL in Fus1 KO mice. It is likely that more potent AOs that specifically target mitochondrial ROS and have better efficacy would produce even more robust rescuing effects in Fus1 KO mice.

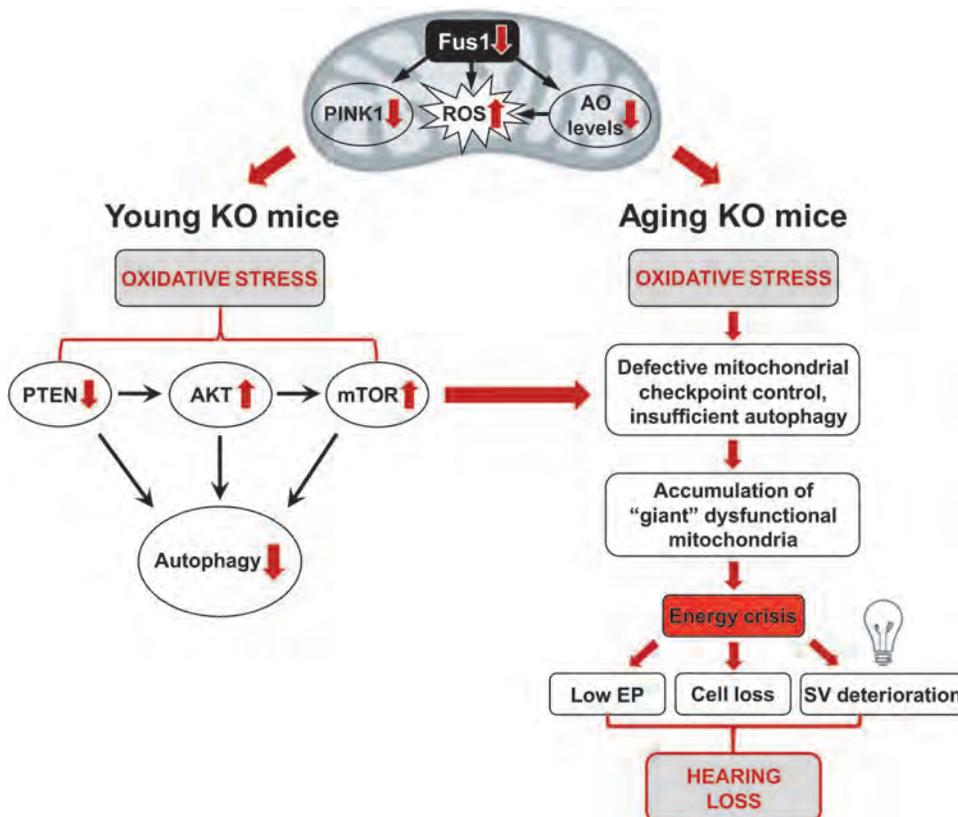

FIG. 9. Hypothetical scheme of molecular and cellular events in the cochleae of young (left) and old (right) Fus1 KO mice leading to premature hearing loss. This model represents a hypothetical pathological chain of events in the cochleae of young and old Fus1 KO mice compared to age-matched WT mice. This scheme was deduced from ABR, TEM, and Western blot analysis of Fus1 KO mouse cochlear tissues. To see this illustration in color, the reader is referred to the online version of this article at www.liebertpub.com/ars

A schematic illustration of our data presented in Figure 9 suggests how loss of *Fus1* results in premature hearing loss that begins with molecular changes in the cochleae of very young *Fus1* KO mice. Our data suggest that efficient targeting of mitochondrial dysfunction-mediated premature hearing loss may require combinatorial approaches that will include AO, anti-inflammatory, anti-TOR, calcium balancing, and other therapies.

Materials and Methods

Fus1 KO mouse model

Fus1 KO mice generated by Dr. A Ivanova (22) were backcrossed to 129sv background in the laboratory of Dr. S Anderson (NCI-Frederick). All animal experiments were performed according to a protocol approved by the Yale University Institutional Animal Care and Use Committee (IACUC) and the animals were cared for according to the recommendations in the “Guide for the Care and Use of Laboratory Animals” (National Institutes of Health). The mice were fed with a standard diet, housed in standard cages (five per cage), and maintained in a 12-h light–12-h dark cycle. They had *ad libitum* access to drinking water and normal diet throughout the experiment. Mice of both genders were used in the study.

NAC supplementation

In all experiments described (30 and 90 days of treatment), N-acetyl cysteine (NAC) (Cat# A7250; Sigma-Aldrich, Inc.) was dissolved in drinking water (30 mM) and supplied *ad libitum* to the mice. For the first 2 days, mice were provided with 15 mM NAC water to acclimate them to the taste and then it was replaced with 30 mM NAC for the remainder of the experiment. NAC water was the only source of drinking water during the experiments. NAC water was changed twice a week.

Auditory brainstem responses

ABR represents the activity of the auditory nerve and the central auditory pathways in response to sounds. ABR measurements were carried out within a sound attenuating booth (Industrial Acoustics Corp.). Mice were first anesthetized with chloral hydrate (480 mg/kg i.p.) and then placed onto a heating pad to maintain body temperature at 37°C. Subdermal needle electrodes (Rochester Electro-Medical, Inc.) were placed at the vertex (active, noninverting), the infraauricular mastoid region (reference, inverting), and the neck region (ground). The acoustic stimuli for ABR were produced and the responses recorded using a customized TDT3 system (Tucker-Davis Technologies, Inc.) controlled by BioSig (TDT), digital signal processing software. Differentially recorded scalp potentials were bandpass filtered between 0.05 and 3 kHz over a 15-ms epoch. A total of 400 trials were averaged for each waveform for each stimulus condition. ABRs were elicited with digitally generated (SigGen; TDT, Inc.) pure tone pips presented free field *via* a speaker (TDT, Inc.; Part FF1 2021) positioned 10 cm from the vertex. Symmetrically shaped tone bursts were 3 ms long (1 ms raised cosine on/off ramps and 1 ms plateau) and were delivered at a rate of approximately 20 per second. Stimuli were presented at frequencies between 2 and 32 kHz and in 5 dB decrements of sound intensity from 90 dB SPL (or

110 dB SPL if thresholds exceeded 90 dB SPL). The ABR threshold was defined as the lowest intensity (to the nearest 5 dB) capable of evoking a reproducible, visually detectable response.

Amplitudes (μ V) and latencies (ms) of the initial four ABR peaks (waves I, II, III, and IV) were then determined at 16 kHz. The most sensitive frequency range of hearing in mice is 11.3–22.6 kHz, and 16 kHz is half octave in-between, so was therefore chosen for analysis. The analysis was carried out offline in BioSig on traces with visible peaks by setting cursors at the maxima and minima (trough) of the peaks. Latency was determined as the time from the onset of the stimulus to the peak, while amplitude was measured by taking the mean of the Δ V of the upward and downward slopes of the peak.

EP measurement

EP was measured in nontreated and NAC-treated WT and *Fus1* KO mice. The method of EP measurement is illustrated in Figure 5A. Mice were deeply anesthetized with sodium pentobarbital (45 mg/kg, i.p.) and placed onto a heating pad to maintain body temperature at 37°C. Animals were then secured onto a stereotaxic mouse head holding adaptor (MA-6 N; Narishige) mounted onto a ball-and-socket stage (Model M-RN-50; Newport Corporation) and a magnetic base (Model 100; Newport Corporation). A silver–silver chloride reference electrode was placed under the skin of the chest. A tracheotomy was first performed and then the round window of the cochlea was exposed *via* a ventral approach by opening the auditory bulla of the temporal bone. A microelectrode (5–15 M Ω 1B150F-4; World Precision Instruments, Sarasota, FL) filled with 3 M KCl was positioned in the round window using a micromanipulator with a pulse motor driving unit (PF5-1; Narishige). An Axon 200A patch clamp amplifier was used for current clamp recording with an Axon Digidata 1321A and jClamp software version 22.8.4 (Scisoft, Inc.). When the microelectrode was inserted into the perilymph of the scala tympani, the voltage was balanced to 0 mV and then the microelectrode was advanced in 5 μ m steps through the basilar membrane and into the endolymph of the scala media to measure the EP. For confirmation of the EP recording, the microelectrode was withdrawn back into the scala tympani, advanced again into the scala media, and continued further into the scala vestibuli, and then retracted back again into the scala tympani. After the EP measurement, the animals were euthanized with an overdose of sodium pentobarbital.

Confocal immunofluorescence

Cochleae were extracted from the temporal bones of 11-month-old WT and *Fus1* KO mice, perfused, fixed for 1 h in 4% paraformaldehyde (PFA) in phosphate-buffered saline (PBS), then washed, and stored in PBS at +4°C. The bony capsule, lateral wall, and modiolus were removed under a dissection microscope using fine forceps. The cochleae were incubated with 5% goat serum in 0.1% Triton/PBS for 30 min at room temperature followed by incubation overnight with mouse monoclonal CTBP2 primary antibody (Cat# 612044; BD Biosciences, Inc.) diluted 1:500 in 2% goat serum/antibody diluent (Cat # S202230-2; Dako, Inc.). The next day, the cochleae were washed thrice in 0.1% Triton X-100/PBS followed by incubation with the secondary antibody Alexa Fluor 568-conjugated rabbit (Cat # A-11011; Thermo Fisher

Scientific, Inc.) at room temperature for 1 h. Mounting on glass slide was done in the DAPI mounting solution (Cat# H-1200; Vector Laboratories, Inc.). During mounting, SLs were dissected away to allow good exposure of the organ of Corti, and the cochleae were separated into three parts, the apical turn (corresponding to frequencies between 200–1.5 kHz), middle turn (1.5–16 kHz), and basal turn (>16 kHz). DAPI-labeled IHCs, OHCs, and IHC synaptic ribbons were visualized with a Zeiss LSM410 laser confocal microscope (Carl Zeiss Microscopy). Sensory hair cell loss was quantitatively evaluated by counting missing hair cells in the apical, middle, and basal turns of the cochlea. Images were collected and analyzed with a ZEN camera and ZEN software. CTBP2-positive synaptic ribbons were counted per IHC (3–5 fields per region, 10–12 IHC per field) and then averaged/region.

H&E staining and immunohistology

Cochleae were fixed in 4% PFA in PBS for 12–48 h, washed in PBS, decalcified in 0.1 M EDTA for 3–4 days, dehydrated through an ethanol gradient, and then embedded in paraffin. Sections of 5 μ m thick in the midmodiolar, vertical plane were stained with H&E, then analyzed using a Nikon Eclipse 80i Microscope (Nikon Instruments, Inc.). The SGN density (cells in 3–5 areas were counted and averaged) in Rosenthal's canal of the basal turn was counted. Immunostaining with rabbit anti-Iba1 antibodies (Wako Chemicals, Inc.) on thin sections was performed using automatic Omni Multimer detection. Statistical analysis was performed using the Student's t-test to compare KO genotype and WT groups.

Cochlear protein lysate preparation and Western blot analysis

Both cochleae from each mouse were harvested, and one was immersed in 4% PFA in 0.1 M phosphate buffer (PB; fixative solution; pH 7.4) and used for immunohistochemical staining. The contralateral cochlea was placed in lysis buffer (RIPA plus protease inhibitor cocktail), perfused with the lysis buffer through the oval and round windows, snap-frozen, and kept at -80°C until required for lysate preparation. For protein lysate preparation, five cochleae from five WT or KO animals were pooled into an Eppendorf tube, 100 μ L of lysis buffer was added to the tube, and the cochlear tissues were homogenized using a plastic mini-pestle. Lysates were sonicated and cleared *via* 15 min of centrifugation at 14,000 rpm in a microcentrifuge (Eppendorf). The supernatants were then transferred to a fresh tube. Western blot analysis of cochlear tissues was performed as described in our previous articles (76, 77).

Antibodies for Western blot analysis

The following antibodies were used in the study: rabbit anti-Sod2 (Cat# ab13533; Abcam), rabbit anti-PRDX1 (Cat# HPA007730; Sigma-Aldrich, Inc.), mouse anti-OxPhos 39 kDa (Cat# 45-8199; Thermo Fisher Scientific, Inc.), and mouse anti-Pink1 (Cat# NBP2-36488; Novus Biologicals). The following antibodies were bought from Cell Signaling Technology, Inc.: rabbit anti-AKT total and pAKT (Cat# 9272 and 3787), mouse anti-pS6 total (Cat# 2317), rabbit anti-ppS6 (Cat# 2221), rabbit anti-pSTAT3 (Cat# 9131), rabbit anti-pMAPK42/44 (Cat# 4695), rabbit anti-Bax (Cat#

5023), mouse anti-BclX (Cat# 2764), and mouse anti-PTEN (Cat# 9552).

TEM analysis

Cochleae from 5–6 month-old and 12-month-old WT and KO mice were extracted and deboned as described above and fixed in 2.5% glutaraldehyde and 2% PFA in 0.1 M sodium cacodylate buffer pH 7.4 for 1 h. After fixation, the cochleae were rinsed in cacodylate buffer, then postfixed in 1% osmium tetroxide in cacodylate, and en bloc stained in 2% aqueous uranyl acetate for a further hour each. The samples were well rinsed, followed by dehydration in an ethanol series, infiltrated with epoxy resin Embed 812 (Electron Microscopy Sciences), and baked overnight at 60°C . Hardened blocks were cut using a Leica UltraCut UC7. Sections (60 nm) were collected on formvar/carbon-coated grids and contrast stained using 2% uranyl acetate and lead citrate. The sample sections were viewed using an FEI Tecnai Biotwin Transmission Electron Microscope (FEI, Hillsboro, OR) at 80Kv. Images were taken using MORADA CCD and iTEM (Olympus) software.

ABSTRACT

We present the first, fully integrated, two-channel implementation of a patch-clamp measurement system. With this “PatchChip” two simultaneous whole-cell recordings can be obtained with rms noise of 8 pA in a 10 kHz bandwidth. The capacitance and series-resistance of the electrode can be compensated up to 10 pF and 100 M Ω respectively under computer control. Recordings of hERG and Na_v 1.7 currents demonstrate the system’s capabilities, which are on par with large, commercial patch-clamp instrumentation. By reducing patch-clamp amplifiers to a millimeter size micro-chip, this work paves the way to the realization of massively parallel, high-throughput patch-clamp systems for drug screening and ion-channel research. The PatchChip is implemented in a 0.5 μ m silicon-on-sapphire process; its size is 3 \times 3 mm² and the power consumption is 5 mW per channel with a 3.3 V power supply.

1. Introduction

The patch-clamp amplifier is a ubiquitous tool for characterizing ion-channel activity. For the screening of pharmaceutical compounds or the characterization of expressed channels, high-throughput patch-clamp systems are being developed, where recordings are made from cells in each well of a 96- or 384-well plate. In these systems the recording is made not with a glass pipette, but from a planar electrode at the bottom of each well (Fig. 1). An important part of such highly-parallel recording systems is a high-density array of patch-clamp amplifiers. We present here a highly miniaturized patch-clamp amplifier with complete whole-cell measurement capabilities.

Important constraints in building massively parallel patch-clamp systems have been the size and cost of the amplifiers, heat dissipation – which restricts the proximity of the amplifiers to the cells – and cross-talk between channels. The integrated “PatchChip” amplifier presented in this paper solves all of these design requirements, and is based on experience from our prototypes (Weerakoon et al., 2009, 2007a,b; Laiwalla et al., 2006a,b,c).

The dual-channel patch-clamp system occupies 3 \times 3 mm² of area and consumes just 5 mW of power per channel. It is fabricated using a standard silicon-on-sapphire fabrication process, which allows parasitic capacitances and cross-talk effects to be minimized.

2. Materials and methods

Fig. 2 shows a block diagram of one channel of the PatchChip system. The two channels of the system are identical. The main signal path is from the electrode current I_{in} to the monitor voltage output $V_{out} = I_{in}R_f$, through operational amplifiers A1, A2, and A3.

Cells are stimulated by controlling the voltage $V_p = V_{clamp}$ at the electrode and measuring the resultant ionic current I_{in} . The goal of the compensation circuits is to allow step changes to be applied to the cell membrane potential V_m while the ionic current I_i is measured. The cell membrane can be modeled as a capacitance C_m in parallel with the membrane resistance R_m . The headstage of the patch-clamp recording system consists of a current-to-voltage transimpedance amplifier A1. The feedback resistor R_f is selectable in eight steps from 50 k Ω to 10 M Ω . Small shunt capacitors stabilize the feedback loop while yielding a bandwidth of a minimum of 300 kHz (with $R_f = 10$ M Ω) when the total capacitance on the input node is 30 pF. A difference amplifier A2 subtracts V_{clamp} from the transimpedance output. The resultant output voltage V_{out} is proportional to the input current, I_{in} .

The output filter A3 represents two poles of a three-pole, 20 kHz anti-aliasing filter. The third pole is presented by an external capac-

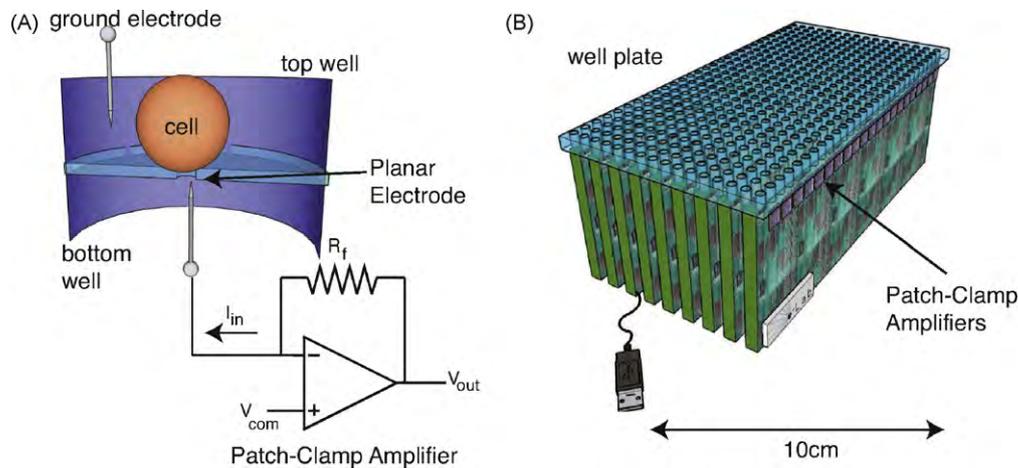

Fig. 1. (A) Patch-clamp amplifier performing whole-cell membrane current recording using a planar electrode. The planar electrode replaces the traditional glass micro-pipette with a micron sized-aperture that is topologically equivalent to the glass tip of the pipette. Cells are introduced into well, and when suction is applied, the cells seal into the aperture. Further suction is applied to rupture the cell so that a whole-cell configuration is established. (B) Using the amplifiers presented in this paper, it is possible to design a high-throughput, automatic patch-clamp system that operates on entire 384-well plates. The wells on B are identical to the one in (A). Requirements for the amplifier are millimeter-size dimensions and minimized heat dissipation, cross-talk and low fabrication cost.

itor and is the only “glue” component required for the analog interface between the PatchChip and the external A–D converter. Similarly, the two-pole input reconstruction filter A6, critically damped with a time constant of $2 \mu\text{s}$, smooths the input command signal V_{com} delivered directly from an external D–A converter and prevents rapid steps from causing nonlinearities and slew-limiting in the other amplifiers of the system.

2.1. Electrode compensation circuitry

The system compensates for the difference between the actual membrane voltage V_m and the clamping voltage V_{clamp} due to the voltage drop across the pipette electrode series resistance R_s . The circuit also compensates for the current i_{prs} drawn by the electrode parasitic capacitance C_{prs} and by the seal leakage-resistance R_L . R_s

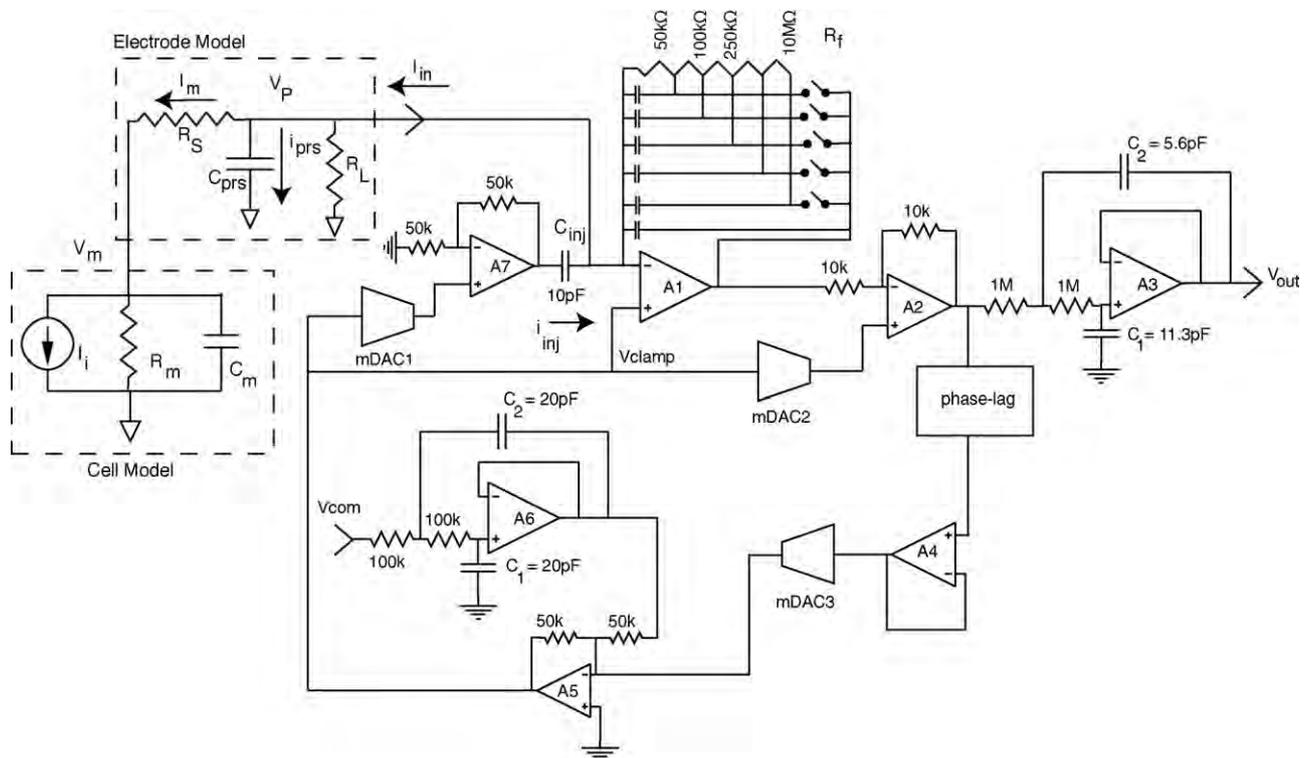

Fig. 2. One channel of the two-channel integrated patch-clamp system and the electrical model of a cell and pipette electrode. The main signal path is from the electrode current I_{in} to the monitor voltage output $V_{out} = I_{in}R_f$, through operational amplifiers A1, A2 and A3. Multiplying digital to analog converter mDAC1 controls the parasitic capacitive compensation, mDAC2 provides leak subtraction, mDAC3 and the phase-lag controller circuit provides series resistance compensation. Input reconstruction and output anti-aliasing filters are also integrated. mDAC1 and mDAC2 are voltage-mode, R-2R DACs with $R = 50\text{k}\Omega$, minimum gains of 0.5, and resolutions of 8 and 10 bits, respectively. mDAC3 is a 9-bit hybrid transconductance-mode DAC with a maximum transconductance of 0.2 mS . Typical values of the electrode and cell elements are $C_{prs} = 5\text{ pF}$, $R_L = 100\text{ M}\Omega$, $R_s = 10\text{ M}\Omega$, $C_m = 30\text{ pF}$, $R_m = 100\text{ M}\Omega$ and peak values of I_i are 1–10 nA.

compensation is necessary for two reasons. First, it allows accurate voltage clamping of the membrane by reducing the errors from the voltage drop across the series access resistance R_s . Second, the compensation reduces the time needed to charge C_m enabling the circuit to monitor ion-channel events occurring immediately after changes in V_{com} is applied (Sigworth, 1995b). The drop across R_s is predicted by adding a fraction of V_{out} to the applied membrane-command potential V_{com} by means of amplifier A5, to obtain V_{clamp} . The fraction of compensated series-resistance is determined by the 9-bit mDAC3, which at full-scale yields compensation for a resistance of $10 \times R_f$. mDAC3 was designed as a hybrid weighted-resistor and R-2R device to minimize the noise gain of the A5 stage. A passive phase-lag compensation circuit is included in the positive-feedback loop if desired, to improve stability when a high percentage of R_s , e.g. more than 90%, is compensated.

For effective R_s compensation the measured current must be equal to the current I_m flowing through R_s . The charging current of the parasitic electrode capacitance C_{prs} and the current through the leakage conductance R_l therefore must first be subtracted from the measurement of I_m . The capacitive-current subtraction is done by injecting a current i_{inj} through an integrated capacitor C_{inj} of 10 pF. The gain α_{inj} of the amplifier A7 is determined by the 8-bit mDAC1 to be between 1 and 2. The compensated capacitance is equal to $(\alpha_{inj} - 1)C_{inj}$.

The differential amplifier A2 is unbalanced when the voltage-output mDAC2 is set to a gain different from its minimum value of 0.5. As its gain increases, subtraction is provided for the excess I_m on the input. The maximum gain of the 10-bit mDAC2 is unity, allowing for compensation of a leakage resistance as high as R_f . All three compensation circuits are controlled using a serial digital control bus. A 64-bit shift register and buffer register store the bit patterns for the mDACs and various switches in one patch-clamp channel.

2.2. Voltage swings and R_f

Modern patch-clamp amplifiers contain an additional ‘‘C-Slow’’ compensation circuit to remove the large current transients due to the charging of the membrane capacitance C_m , which is typically in the range of 20–40 pF. These circuits have been implemented as a first-order state-variable filter (Sigworth, 1995a,b) in which the time constant is roughly 100 μ s to 1 ms. Due to the limited capacitor sizes, and therefore short time constants, that can be realized in a monolithic circuit, we decided not to provide this ‘‘slow capacitance’’ compensation. Instead, this compensation will be provided in software. We rely on the use of a 16-bit or higher resolution A–D converter to digitize the current-monitor signal V_{out} so that the large charging transients can be subtracted digitally.

In the absence of slow-capacitance compensation, the entire charging current of the membrane capacitance must be injected through the feedback resistor R_f . Thus the voltage swing available at the output of amplifier A1 becomes an important issue. We have used a 3.3 V silicon-on-sapphire (SOS) process, so that the analog power-supply voltages are ± 1.6 V. Although the typical membrane-potential excursions are only in the range ± 150 mV, when R_s compensation is in use the excursions of V_p can be an order of magnitude larger.

Consider the case in which a fraction k of the series resistance is compensated. When a voltage step of magnitude ΔV_{com} is applied to V_{com} the effect of the R_s compensation feedback is to produce an initial step $\Delta V_p = \Delta V_{com} / (1 - k)$. For example, a 150 mV step with $k = 0.8$ (80% compensation) yields an initial step of 750 mV. Even ignoring the current through R_l the initial current will be $I_m = \Delta V_p / R_s$ and will have to be sourced through the feedback resistor R_f . Thus the initial voltage at the output of A1 ($V_{out,A1}$) will need

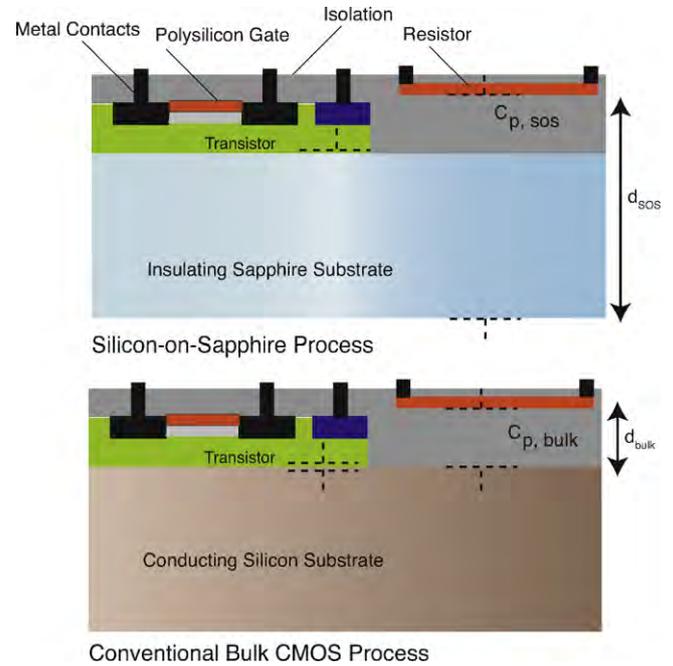

Fig. 3. The patch-clamp system was implemented using silicon-on-sapphire (SOS) technology. The insulating substrate in SOS (top) reduces parasitic capacitance and allows fabrication of large resistors to implement R_f with no degradation in frequency response. The insulating substrate reduces cross-talk between channels and allows devices to operate at faster speeds than conventional bulk CMOS technology (bottom).

to be

$$V_{out,A1} = \frac{\Delta V_{com}(R_s + R_f)}{(1 - k)R_s} \quad (1)$$

If R_f is chosen to be equal to R_s in this example, the initial value of $V_{out,A1}$ must be 1.5 V, very close to the available supply voltage of 1.6 V. To avoid amplifier saturation therefore, two steps must be taken. First, R_f must be kept to a low value, typically 5–10 M Ω in cases where R_s is in this resistance range. Second, amplifier A1 (and also other amplifiers in the circuit) must have a rail-to-rail output swing capability. The characteristics of the operational amplifiers are described in Section 2.4.

The low value of the feedback resistor R_f means that the current-monitor signal of the PatchChip will have a substantial contribution from the resistor’s thermal noise; in a 10 kHz bandwidth this noise is 4 pA rms when $R_f = 10$ M Ω . The thermal noise arising in R_s is also large, and when its value is equal to R_f , its noise is equal to that from R_f at high frequencies $f > f_c$, where $f_c = 1 / (2\pi R_s C_m)$. When R_s compensation is in use, which in effect increases the recording bandwidth beyond f_c , the two resistances R_f and R_s make nearly equal contributions to the noise variance. Thus the low value of R_f does result in increased noise, but the increase is moderate, about a factor of $\sqrt{2}$ over the theoretical minimum noise due to R_s alone.

2.3. Silicon-on-sapphire technology

The PatchChip was implemented using the silicon-on-sapphire (SOS) technology. SOS offers several advantages over conventional bulk CMOS technology, as is illustrated in Fig. 3. First, the absence of a conducting substrate greatly reduces parasitic capacitance and allows the fabrication of large, nearly ideal resistors. In conventional bulk-CMOS processes the source and drain of each transistor is isolated from the substrate by a reverse-biased diode; these diodes contribute a considerable capacitance to each such node in

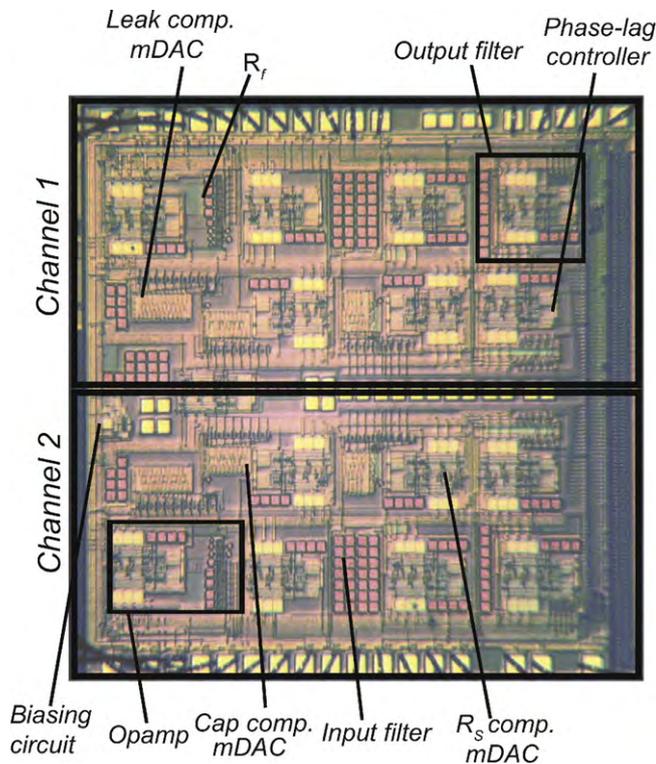

Fig. 4. A micrograph of the test circuit in silicon-on-sapphire technology. The fabricated die contained two channels and occupied just $3 \times 3 \text{ mm}^2$. Each channel has series resistance, parasitic capacitance and leak compensation capability. After initial setup expenditures, each amplifier costs just a few dollars to manufacture.

the circuit. Even resistor elements, which are isolated from the bulk silicon by oxide layers, show considerable parasitic capacitance because the oxide layers are relatively thin. In SOS on the other hand, transistors and resistors are fabricated on top of the thick sapphire substrate (Fig. 3) and therefore experience vastly smaller parasitic capacitances (Culurciello et al., 2007). Second, the non-conducting substrate provides a better means of isolating devices on the substrate, yielding better cross-talk performance between patch-clamp channels. Third, the insulating substrate allows the power supplies for digital and analog parts of this mixed-signal circuit to be separated to obtain better noise performance. Fourth, the lower parasitic capacitance allows SOS devices to perform at faster speeds and lower power than those made using conventional bulk CMOS technology (Culurciello, 2010). The final layout of the microchip implementing the two-channel patch-clamp system is shown in Fig. 4. This layout is the physical implementation of the circuits reported in Fig. 2.

2.4. High-performance operational amplifier design

A low-noise, rail-to-rail, constant-transconductance operational amplifier was designed specifically for this system (Weerakoon et al., 2010). SOS transistors have low output resistance and therefore yield low voltage gains; we therefore made extensive use of cascode circuits, obtaining with this three-stage design a DC gain of 75 dB and a gain-bandwidth product of 12 MHz for unity-gain operation. Fig. 5 shows the fabricated operational amplifier, which occupies an area of less than 0.1 mm^2 . Rail-to-rail operation of the amplifier is needed to maximize voltage swings with the small power-supply voltages. The amplifier reported a $3 \text{ nV}/\sqrt{\text{Hz}}$ of input-referred voltage noise in a bandwidth of 10 kHz, and $<1 \text{ mV}$ of input-referred offset, while consuming 1.4 mW of power. Table 1 reports a summary of the amplifier characteristics.

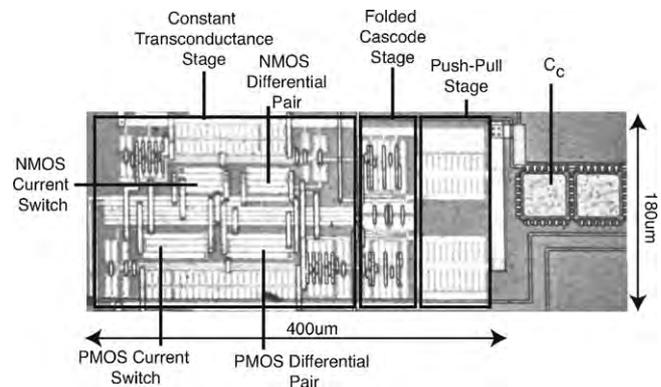

Fig. 5. A die micrograph of the fabricated operational amplifier. The operational amplifier occupies an area of 0.08 mm^2 providing rail-to-rail output voltage and constant gain-bandwidth product over the entire rail-to-rail common-mode range. The capacitor C_c is the frequency-compensation capacitor.

3. Results

We have extensively tested the electrical properties of the two-channel patch-clamp system, and its functionality in patch-clamp recordings from cells. In these tests the system was controlled and data were acquired using the JClamp patch-clamp software (www.scisoftco.com). The results are comparable to those from commercial non-integrated patch clamp amplifiers.

Fig. 6 shows the measured step responses of the series resistance compensation circuit. The time constant τ associated with charging the membrane capacitance C_m through a compensated resistance ($R_S - R_{comp}$) when a step V_{com} is applied (inset), is given by $\tau = C_m(R_S - R_{comp})$. Increasing compensation, R_{comp} approaches R_S and τ decreases, increasing recording bandwidth. Using the series resistance compensation circuit, we compensated 3–4 M Ω of the 4 M Ω electrode series resistance, decreasing the time needed to charge C_m from $\tau = 200$ to $50 \mu\text{s}$ (75% compensation) and about $120 \mu\text{s}$ (100% compensation). Full resistance compensation can only be obtained with the phase-lag compensation circuit, which yields complete compensation at low frequencies but slows the settling time of the system.

Fig. 6 shows the measured step response of the electrode capacitive compensation circuit. When uncompensated, the headstage provides the current i_{prs} needed to charge the parasitic capacitance. This current appears as spikes in the current-monitor signal with the same polarity as V_{com} . When properly compensated, the spikes are greatly reduced in size.

Fig. 7 shows measured simultaneous data from both channels of the system. We applied a large voltage step (100 mV) to one channel with a model cell connected to its input terminal. The cross-talk on the adjacent non-measuring channel is 40 dB lower even with 80% series resistance compensation in use.

Table 1

Measurement results for the operational amplifier designed for the patch-clamp system. A load resistance of 15 k Ω and a 3.3 V power supply was used in the measurements. The operational amplifier met all design specifications.

Die area	0.08 mm ²
Open loop gain	75 dB
Gain-bandwidth product	12 MHz
Input-referred offset voltage	0.4 mV
Input common-mode range	0–3.3 V
Output swing	0–3.3 V
Slew rate	10 V/ μs
Input-referred voltage noise at 10 kHz	$3 \times 10^{-9} \text{ V}/\sqrt{\text{Hz}}$
Quiescent current	430 μA
Input capacitance	2.6 pF

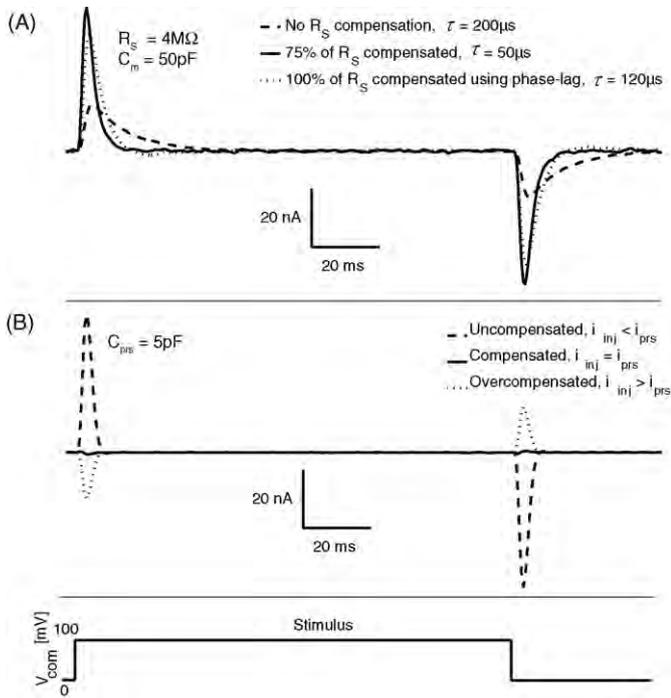

Fig. 6. (A) Measured response of the series resistance compensation circuit when compensating a 4 MΩ electrode series resistance. The time needed to charge C_m was reduced from $\tau=200$ to $50 \mu\text{s}$ (75% compensation) and $120 \mu\text{s}$ (100% compensation with phase-lag). (B) Measured step response of the electrode capacitive compensation circuit when compensating 5 pF at the input. When uncompensated, the headstage provides the current $i_{\text{pr}s}$ needed to charge the parasitic capacitance. This current appears as spikes in the current–monitor signal. When properly compensated, $i_{\text{pr}s} = i_{\text{inj}}$ and the spikes do not appear. When overcompensated, $i_{\text{inj}} > i_{\text{pr}s}$ and the spikes reverse polarity.

Fig. 8 shows a whole-cell recording from an HEK293 cell expressing hERG channels. We compensated the 6.5 pF parasitic capacitance, and 80% of the 4.2 MΩ series resistance present at the input. R_f was set to 5 MΩ. The peak tail current curve in (C) shows the standard voltage dependence of inactivation and activation in the channels.

Sodium-channel currents present a particularly demanding test for a whole-cell recording system. The rapid kinetics and negative-resistance characteristic of these currents requires good R_s compensation. Fig. 9 shows single-sweep recordings from an

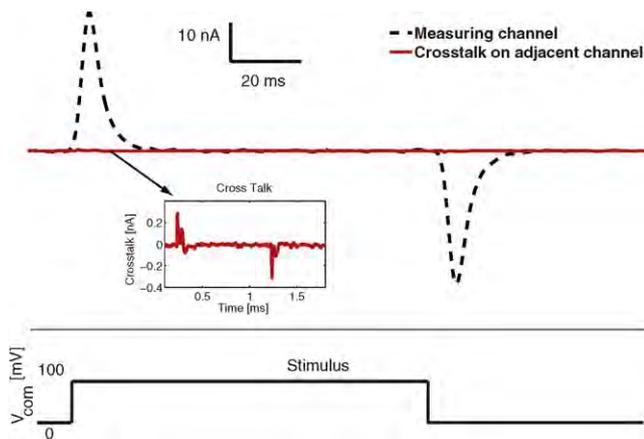

Fig. 7. Measured cross-talk between channels. A voltage step of 100 mV was applied to one channel, which was driving a model circuit with 80% series-resistance compensation. The current–monitor signal in the adjacent non-measuring channel is at least 40 dB lower.

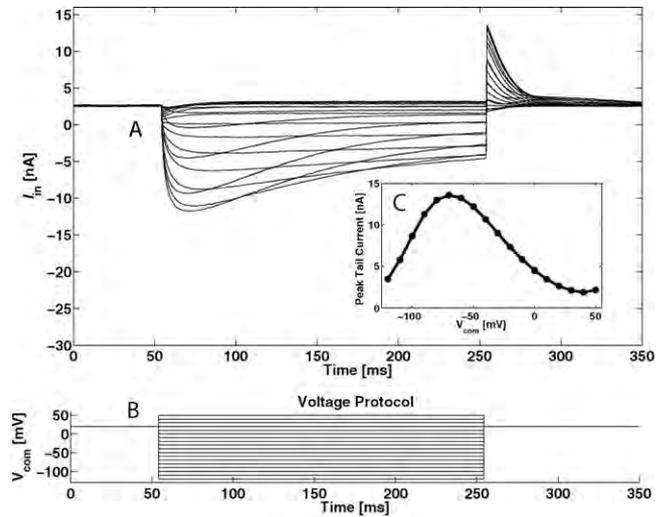

Fig. 8. (A) Single-sweep responses from an HEK 293 cell expressing hERG channels. R_s was 4.2 MΩ of which 80% was compensated. $C_{\text{pr}s}$ of 6.5 pF was fully compensated. C_m was 40 pF. (B) The cells were held at 20 mV and stepped to potentials of -130 mV to 50 mV in 10 mV increments for 200 ms. (C) The tail currents at +20 mV are plotted vs. V_{com} from A. The extracellular solution contained (mM) 117 NaCl, 13 KCl, 10 HEPES, and 5 EGTA. The pipette solution contained 160 KCl, 1 EGTA, and 10 HEPES. Currents were sampled at 100 kHz and filtered at 10 kHz.

HEK293 cell expressing $\text{Na}_v 1.7$ channels. Linear leak and residual capacitance artifacts were subtracted using the $-P/6$ method. This protocol (using six inverted pulse sequences scaled down by a factor of 6, delivered at negative membrane potentials) increases the net rms noise in the traces about threefold. Despite the large cell capacitance ($C_m = 40$ pF) the clamp time constant was 40 μs, giving a faithful current time course. The peak current–voltage curve (Fig. 9) shows steep activation of the channel currents with no evidence of series-resistance error (Estacion et al., 2008).

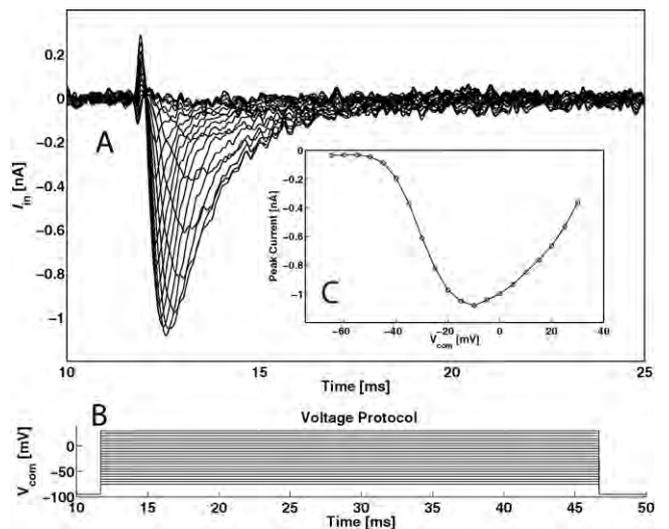

Fig. 9. (A) Single-sweep responses of HEK 293 cells expressing $\text{Na}_v 1.7$ sodium channels, after linear leak subtraction using the $-P/6$ protocol. The leak subtraction increases the net rms noise in the traces about threefold. R_s was 4.5 MΩ of which 80% was compensated. $C_{\text{pr}s}$ of 7 pF was fully compensated. C_m was 40 pF. (B) To generate activation curves, the cells were held at -100 mV and stepped to potentials of -75 to 30 mV in 5 mV increments for 35 ms. (C) The peak currents vs. V_{com} from (A). The current–monitor signal was filtered at 10 kHz and sampled at a 100 kHz rate. The recording was made at room temperature. The extracellular solution contained (in mM) 127 NaCl, 13 KCl, and 10 HEPES. The pipette solution contained 10 NaCl, 140 CsF, 10 HEPES, and 1 EGTA.

Table 2
Key features of the two-channel patch-clamp system.

Technology	0.5 μm silicon-on-sapphire
Number of channels	2 per die
Silicon area	$3 \times 3 \text{ mm}^2$ per die
	$1.5 \times 3 \text{ mm}^2$ per channel
Power consumption	5 mW per channel at 3.3 V
Capacitive compensation	10 pF max
Series resistance compensation	80% up to $10 \times R_f$, or 100% with phase-lag compensation
Leak compensation	Conductance up to $1/R_f$
Current noise	8 pA rms input-referred in a 10 kHz bandwidth ($R_f = 10 \text{ M}\Omega$)
Variable feedback resistor R_f	50, 100, 250, 500 k Ω 1, 2.5, 5, 10 M Ω
Dynamic range	$\pm 20 \mu\text{A}$
Reconstruction filter	2 poles, 60 kHz cutoff
Anti-aliasing filter	3 poles, 20 kHz cutoff
Nonlinearity	<0.1%
Cross-talk between adjacent channels	-40 dB (at 80% series resistance channels compensation)

Table 2 summarizes the key features of the PatchChip. The two-channel system occupies $3 \times 3 \text{ mm}^2$ of area and consumes 5 mW of power per channel. The low power consumption allows the amplifiers to be placed in close proximity to the cells under test. The input-referred noise is 8 pA rms at 10 kHz bandwidth.

4. Discussion

We have implemented a two-channel patch-clamp system in silicon-on-sapphire on a $3 \times 3 \text{ mm}^2$ chip area. The system reports below -40 dB of cross-talk between adjacent channels and the input-referred current noise of the system is 8 pA rms in a 10 kHz bandwidth. The appropriate setting of the feedback resistor, 5–10 M Ω for typical whole-cell recordings, means that the resistor's thermal noise makes a contribution; however this contribution is moderate in comparison to the thermal noise from the series resistance of the electrode-and-cell combination. The system is able to compensate series resistances and parasitic capacitances up to 100 M Ω and 10 pF respectively. The power consumption of the device is 5 mW per channel at 3.3 V. This accurate, low-noise system with electrode compensation can replace a commercial rack-mounted patch-clamp system; more importantly it can also be integrated into a massively parallel, high-throughput, patch-clamp

system that can significantly advance the state-of-the-art in drug screening and ion-channel research.

Received: 14 May 1998/Revised: 24 August 1998

Abstract. The outer hair cell (OHC) from the mammalian organ of Corti possesses a bell-shaped voltage-dependent capacitance function. The nonlinear capacitance reflects the activity of membrane bound voltage sensors associated with membrane motors that control OHC length. We have studied the effects of the lipophilic ions, tetraphenylborate (TPB^-) and tetraphenylphosphonium (TPP^+), on nonlinear capacitance and motility of isolated guinea-pig OHCs. Effects on supporting cells were also investigated. TPB^- produced an increase in the peak capacitance ($C_{m_{pk}}$) and shifted the voltage at peak capacitance (V_{pkCm}) to hyperpolarized levels. Washout reversed the effects. Perfusion of 0.4 μM TPB^- caused an average increase in $C_{m_{pk}}$ of 16.3 pF and V_{pkCm} shift of 13.6 mV. TPP^+ , on the other hand, only shifted V_{pkCm} in the positive direction, with no change in $C_{m_{pk}}$. The contributions from native OHC and TPB^- -induced capacitance were dissected by a double Boltzmann fitting paradigm, and by blocking native OHC capacitance. While mechanical response studies indicate little effect of TPB^- on the motility of OHCs which were in normal condition or treated with salicylate or gadolinium, the voltage at maximum mechanical gain ($V_{\delta L_{max}}$) was shifted in correspondence with native V_{pkCm} , and both changed in a concentration-dependent manner. Both TPB^- -induced changes in $C_{m_{pk}}$ and V_{pkCm} were affected by voltage prepulses and intracellular turgor pressure. TPB^- induced a voltage-dependent capacitance in supporting cells whose characteristics were similar to those of the OHC, but no indication of mechanical responses was noted. Our results indicate that OHC mechanical responses are not simply related to quantity of nonspecific nonlinear charge moved within the membrane, but to the effects of motility voltage-

sensor charge movement functionally coupled to a mechanical effector.

Key words: Cochlea — Gating current — Tetraphenylborate — Motility — Capacitance

Introduction

Acoustic signal processing by the mammalian cochlea is accomplished by two classes of sensory hair cells: the inner hair cells (IHCs) and outer hair cells (OHCs). IHCs are solely mechano-electrical transducers, while OHCs function, in addition, as mechanical effectors. It is believed that the unique voltage-dependent mechanical response of the OHC provides feedback into the basilar membrane, thereby sharpening the passive mechanical vibration of the cochlear partition (Brownell et al., 1985; Ashmore, 1987; Santos-Sacchi & Dilger, 1988; Ruggero, 1992). The OHC demonstrates a nonlinear gating charge movement or, correspondingly, a voltage-dependent capacitance that has characteristics similar to those of OHC motility, indicating that membrane-bound voltage sensor/motor elements control OHC length (Santos-Sacchi, 1990, 1991, 1993; Ashmore, 1989, 1992; Dallos et al., 1991; Iwasa, 1994).

The causal relation between OHC nonlinear charge movement and mechanical response is an important feature in theories of OHC motility where voltage-dependent conformational changes in putative lateral membrane molecular motors fluctuate between two areal states (Santos-Sacchi, 1993; Huang & Santos-Sacchi, 1994; Iwasa, 1994). Accordingly, intrinsic gating charge movement represents the reorientation of charged moieties within a membrane-bound, protein motor molecule. Only this charge movement should be coupled to OHC mechanical activity. Membrane bound charge movement associated with extraneous sources, e.g., the cell's

normal complement of voltage-gated ionic channels or exogenous membrane bound charge, should neither effect nor directly affect OHC motility. Furthermore, blockade of motility-related gating charge should be sufficient to block motility.

To evaluate these predictions, we attempted to induce additional nonlinear charge movement within the OHC plasma membrane with the exogenous hydrophobic ions, tetraphenylborate (TPB^-) and tetraphenylphosphonium (TPP^+). Furthermore, salicylate and Gd^{+3} , known blockers of OHC motility and charge movement (Santos-Sacchi, 1991; Shehata, Brownell & Dieler, 1991; Tunstall, Gale & Ashmore, 1995; Kakehata & Santos-Sacchi, 1996), were evaluated to dissect out contributions of native nonlinear charge movement during hydrophobic ion treatment. Hydrophobic ions such as TPB^- or dipicrylamine have been used to amplify small capacitive signals of secretory vesicle release (Oberhauser & Fernandez, 1995). The ions have also been used as probes of tight junctions (Turin et al., 1991), and membrane structure (Benz & Läuger, 1977; Benz & Nonner, 1981; Dilger & Benz, 1985; Smejtek & Wang, 1991) and function (Reyes & Latorre, 1979; Fernandez, Bezanilla & Taylor, 1982). The TPB^- -induced current is similar, in some ways, to that which arises from voltage-dependent ionic channel gating (Benz & Nonner, 1981).

We report here that TPB^- augments native OHC nonlinear capacitance and produces a negative shift of the equivalent voltages at peak capacitance (V_{pkC_m}) and maximal mechanical gain (V_{dLmax}), but does not enhance the mechanical response. TPP^+ only causes a shift in the voltage dependencies. Such results might be expected from simple charge screening. These data highlight the specific and causal relationship between the native nonlinear capacitance and the mechanical activity of the OHC.

Materials and Methods

METHODS

Guinea pigs were anesthetized with halothane and killed by cervical dislocation. OHCs and supporting cells were isolated enzymatically with dispase I (0.5 mg/ml for 10 min followed by gentle trituration through a polyethylene pipette) in a modified Leibovitz medium which contained (in mM): NaCl 142, KCl 5.37, MgCl_2 1.47, HEPES 5, CaCl_2 2 and dextrose 5; 300 mOsm, pH 7.2. The cells were then transferred to a 700- μl perfusion chamber. All experiments were conducted at room temperature ($\sim 23^\circ\text{C}$). A Nikon Diaphot inverted microscope with Hoffmann optics was used to observe the cells during electrical recording. All experiments were videotaped.

Single OHCs and supporting cells were studied under whole cell voltage-clamp conditions using an Axon 200A amplifier at a holding potential of -80mV . Initial resistances of patch pipettes were 2–3 M Ω , corresponding to tip sizes of 1–2 μm (Hamill et al., 1981). Residual series resistance ranged from 3 to 7 M Ω . All data collection and analysis were performed with an in-house developed Windows-based pro-

gram, **jClamp** (www.med.yale.edu/surgery/otolar/santos/jclamp.html). Ionic blocking solutions were used to remove voltage-dependent ionic conductances so that capacitive currents could be analyzed in isolation (Santos-Sacchi, 1991; Huang & Santos-Sacchi, 1993). The patch pipette solution contained (in mM): CsCl 140, MgCl_2 2, EGTA 10, HEPES 5, with pH 7.2 and osmolarity 300 mOsm (adjusted with dextrose). The external ionic blocking solution contained (in mM): BaCl_2 10, CoCl_2 2, MgCl_2 1.47, NaCl 100, CaCl_2 2, HEPES 5, with pH 7.2 and osmolarity 300 mOsm (adjusted with dextrose). In this solution BaCl_2 replaced the usually employed blockers, CsCl and TEA (Huang & Santos-Sacchi, 1993), because both caused precipitation with sodium tetraphenylboron. The reagents ($\text{Na}^+ \text{TPB}^-$ and $\text{TPP}^+ \text{Cl}^-$) were freshly prepared and applied using the Y-tube method (Murase et al. 1990) at a rate of 0.3 to 0.65 ml/min. These two hydrophobic ions were chosen for their opposite charges, which we presumed might provide for differing effects. We reasoned that the effectiveness in influencing capacitance and motility might depend on the sign of the hydrophobic ion relative to that of the native charge. Whole chamber perfusion was continuous.

A tracking procedure was used to continuously monitor the voltage at peak capacitance (V_{pkC_m}) after obtaining whole-cell configuration (Kakehata & Santos-Sacchi, 1995). Membrane potential was corrected for the effects of residual series resistance. Peak capacitance ($C_{m, pk}$) values were also monitored during the tracking procedure using transient analysis of capacitive currents induced by a -10mV step. Detailed evaluation of total membrane capacitance was made at different potentials by transient analysis of currents induced by a voltage stair step stimulus, and the capacitance function was fit to the first derivative of a two state Boltzmann function relating nonlinear charge to membrane voltage (dQ/dV ; Santos-Sacchi, 1991; Huang & Santos-Sacchi, 1993)

$$C_m = Q_{max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin}$$

where

$$b = \exp\left(\frac{-ze(V - V_{pkcm})}{kT}\right)$$

Q_{max} is the maximum nonlinear charge moved, V_{pkC_m} is voltage at peak capacitance or equivalently, at half-maximal nonlinear charge transfer, V_m is membrane potential, z is valence, C_{lin} is linear membrane capacitance, e is electron charge, k is Boltzmann's constant, and T is absolute temperature.

Pipette pressure was monitored via a T-connector to a pressure monitor (WPI, Sarasota, FL), and modified when required with a syringe connected to the Teflon tubing attached to the patch pipette holder (Kakehata & Santos-Sacchi, 1995). The cylindrical shape of OHCs was maintained during data collection. Measures of voltage-induced (-160 to 40mV , 20mV increment) mechanical responses were made off the video monitor during playback with a differential opto-resistor technique (Santos-Sacchi, 1989; 1991). Mechanical data were fit to a two state Boltzmann function to determine the voltage at maximum mechanical gain (V_{dLmax}).

Dose-response data (charge vs. hydrophobic ion concentration) were averaged and are given as mean \pm SE. A fit was made according to a modified Michaelis-Menten equation with the use of a least-squares routine (Sigma Plot, CA),

$$Q = Q_{max} \frac{C^n}{(C^n + K_b^n)}$$

where Q is the charge induced by the hydrophobic ion, C is hydropho-

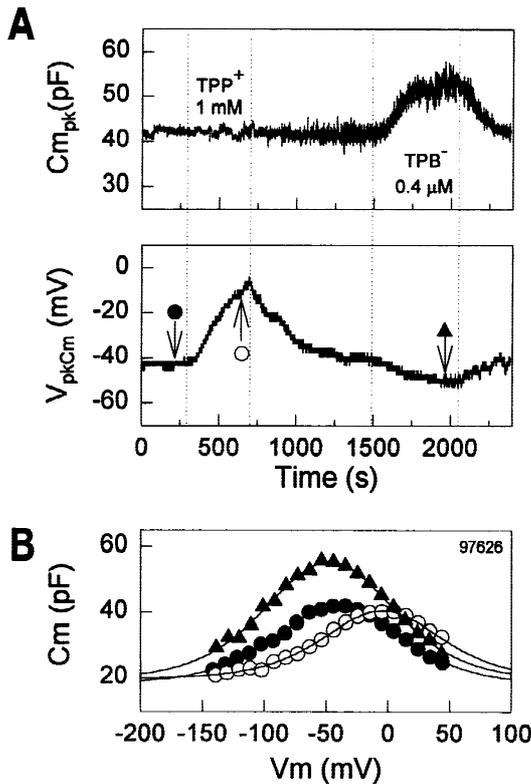

Fig. 1. Effects of TPP^+ and TPB^- on $C_{m_{pk}}$ and V_{pkCm} of an OHC obtained by the tracking technique (A) and the voltage stair step technique (B). (A) After $C_{m_{pk}}$ and V_{pkCm} stabilized, TPP^+ (1 mM) was applied extracellularly at the first dotted line. V_{pkCm} shifted to depolarized levels with no change in $C_{m_{pk}}$. Washout at the second dotted line caused recovery. TPB^- (0.4 μM) was applied extracellularly at the third dotted line. V_{pkCm} shifted slightly to hyperpolarized levels with an increase in $C_{m_{pk}}$. Washout following TPB^- treatment started from the 4th line. Arrows indicate points at which capacitance functions were determined by the voltage stair step technique for the same cell. (B) Fits (solid lines) for the capacitance data indicate $C_{m_{pk}}$, V_{pkCm} , Q_{max} and z of 42.1 pF, -40.2 mV, 3.26 pC and 0.75 (closed circles, control); 40.6 pF, -4.4 mV, 2.69 pC and 0.79 (open circles, TPP^+ treatment); 55.7 pF, -47.4 mV, 5.08 pC and 0.73 (closed triangles, TPB^- treatment).

bic ion concentration, K_D is the dissociation constant, and n is the Hill coefficient.

Results

OHCs possess a capacitance that depends upon transmembrane voltage, and which derives from motility-related gating currents (Fig. 1). Membrane-bound, charged molecules from external sources can also contribute to membrane capacitance. This is illustrated in Fig. 1 where the effects of TPB^- and TPP^+ on $C_{m_{pk}}$ and V_{pkCm} are monitored with the tracking technique described in the methods (Fig. 1A); in addition, a more detailed analysis of membrane capacitance is provided by the stair step protocol (Fig. 1B). Under our experi-

mental conditions, TPP^+ had no effect on $C_{m_{pk}}$, but shifted V_{pkCm} to depolarized levels. In contrast, TPB^- increased $C_{m_{pk}}$ and shifted V_{pkCm} to hyperpolarized levels. Washout reversed the effects (Fig. 1A). The average onset and recovery time constant for 0.4 μM TPB^- was 102.2 ± 25.91 sec ($n = 5$) and 184 ± 60.74 sec ($n = 4$), respectively.

The average steady state shift of V_{pkCm} induced by 1 mM TPP^+ was 33.9 ± 1.7 mV (mean \pm SE; $n = 10$; stair analysis). The difference in $C_{m_{pk}}$ before and during TPP^+ treatment was 0.57 ± 0.3 pF. Higher concentrations of TPP^+ , up to 10 mM, were equally ineffective in altering $C_{m_{pk}}$. On the other hand, the average elevation of $C_{m_{pk}}$ and shift of V_{pkCm} induced by 0.4 μM TPB^- were 16.3 ± 2.7 pF and -13.6 ± 3.04 mV ($n = 15$), respectively.

To study the concentration effects of TPB^- on OHC nonlinear capacitance, TPB^- was applied by 'Y-tube' in increasing concentrations ranging from 0.2 μM to 1 μM , without intermittent washing. Tracking commenced immediately after whole cell configuration, and stair step analysis was performed after V_{pkCm} reached steady state at each concentration. Figure 2A illustrates the TPB^- concentration dependence of OHC $C_{m_{pk}}$ and V_{pkCm} . By gradually increasing the concentration of TPB^- , correspondingly larger increases in $C_{m_{pk}}$ and V_{pkCm} shifts were elicited. Concentrations greater than 1 μM could induce very large capacitances, which compromised the effectiveness of our voltage clamp.

Contributions to the voltage-dependent capacitance observed in Fig. 2A are derived from two distinct sources of nonlinear charge movement (native and TPB^- -induced), which theoretically should be separable analytically. Unfortunately, it is clear from the data that the characteristics of native and TPB^- -induced charge movement are not disparate enough to produce a bimodal capacitance function, which could easily be fit by the sum of two Boltzmann functions. Nevertheless, we have devised a procedure which estimates the TPB^- contribution assuming that in addition to augmenting charge, TPB^- causes a shift in the voltage dependence of OHC native charge movement, as occurred in the presence of TPP^+ . Thus, we first obtained fits (single Boltzmann) of OHC native capacitance prior to TPB^- treatment and used these parameters (all fixed except for V_{pkCm} which was permitted to vary) in subsequent fits (sum of two Boltzmanns) of capacitance in the presence of TPB^- . Figure 2B illustrates the result, and indicates that, opposite to the effects TPP^+ , the native OHC capacitance function is shifted in the negative direction by the negatively charged TPB^- .

This shift in V_{pkCm} was independently confirmed in a group of OHCs where the effects of TPB^- on OHC motility and capacitance were studied in concert. Before and during TPB^- treatment, voltage-induced OHC move-

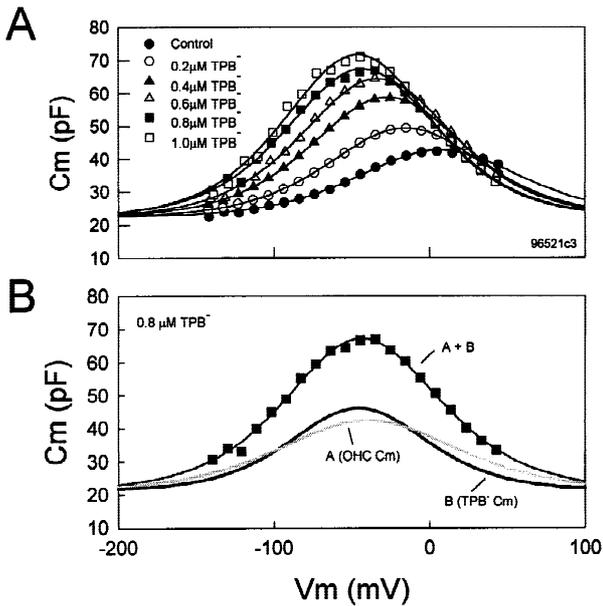

Fig. 2. (A) Concentration dependence of TPB^- effects on $C_{m_{pk}}$ and V_{pkCm} of an OHC. $C_{m_{pk}}$ increased and V_{pkCm} shifted to hyperpolarized levels in a concentration-dependent manner. Fits (solid lines) for capacitance indicate $C_{m_{pk}}$, V_{pkCm} , Q_{max} and z of 42.5 pF, 6.5 mV, 2.89 pC and 0.72 (closed circles, control), 49.4 pF, -15.3 mV, 3.61 pC and 0.77 (open circles, 0.2 μM TPB); 58.8 pF, -26.8 mV, 4.81 pC and 0.78 (closed triangles, 0.4 μM TPB); 64.4 pF, -33.4 mV, 5.48 pC and 0.79 (open triangles, 0.6 μM TPB); 67.2 pF, -43.1 mV, 5.85 pC and 0.79 (closed squares, 0.8 μM TPB) and 71.6 pF, -46.1 mV, 6.26 pC and 0.81 (open squares, 1 μM TPB). (B) Example of extraction technique used to assess the individual contributions of TPB^- -induced and native OHC capacitance to the overall capacitance function. A, native capacitance of OHC; B, TPB^- -induced capacitance; A + B, total capacitance with 0.8 TPB^- treatment. See text for details.

ment and voltage-dependent capacitance were obtained by voltage steps (-160 to 40 mV, 20 mV increment) and stair step analysis, respectively. As shown in Fig. 3A and B, TPB^- had a significant effect on the magnitude of $C_{m_{pk}}$ but little effect on the magnitude of voltage-dependent movement. The ratio of total Q_{max} in the presence of TPB^- to Q_{max} in its absence was 1.71, whereas the corresponding ratio of δL_{max} was 1.06 ($n = 7$). These results indicate that an increase in OHC nonlinear capacitance by an external source does not result in significant enhancement of cell movement. Although TPB^- does not alter the magnitude of OHC motility, its voltage dependence is susceptible. In fact, the effect on $V_{\delta L_{max}}$ corresponds to the effect on the extracted value of native OHC V_{pkCm} (Fig. 3C); both shift in the hyperpolarizing direction in a concentration-dependent manner. This is expected since the voltage dependencies of OHC motility and nonlinear capacitance are known to coincide (Kakehata & Santos-Sacchi, 1995). Within a limited concentration range of TPB^- (0.2–1.0 μM), the response slope is $-32 \text{ mV}/\mu\text{M}$ ($n = 3$). The dose-response data

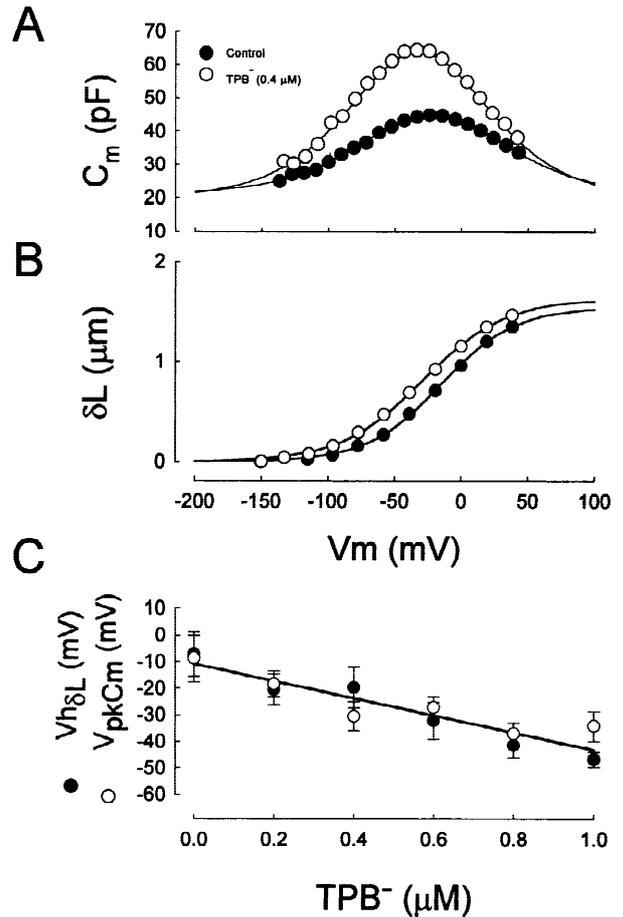

Fig. 3. (A) Voltage-dependent capacitance and (B) voltage-induced length change of seven OHCs measured before and during TPB^- treatment. Length changes induced by 20 mV steps from -160 to 40 mV, but corrected for series resistance. Fits for average overall capacitance data indicate $C_{m_{pk}}$, V_{pkCm} , Q_{max} and z of 44.8 pF, -21.9 mV, 3.69 pC and 0.67 (closed circles, control); 63.9 pF, -32.3 mV, 6.3 pC and 0.72 (open circles, 0.4 μM TPB). Fits for average mechanical data indicate $V_{\delta L_{max}}$ and z of -14.9 mV and 0.9 (closed circles, control); -28.5 mV and 0.81 (open circles, 0.4 μM TPB). Cell length was $64.29 \pm 1.44 \mu\text{m}$ (mean \pm SE; $n = 7$). (C) Correspondence between shifts in extracted OHC V_{pkCm} (determined as in text) and $V_{\delta L_{max}}$ of OHCs treated with TPB^- as a function of concentration. Each point is the mean \pm SE ($n = 3$).

indicate a Hill coefficient of 1.85 ± 0.10 , Q_{max} of $5.38 \pm 0.23 \text{ pC}$, and K_d of $0.50 \pm 0.03 \mu\text{M}$.

Other ways to dissociate the two components of nonlinear charge movement may include delivery of pre-pulse voltages (Santos-Sacchi, Kakehata & Takahashi, 1997, 1998; Santos-Sacchi, 1997), alterations of lateral membrane tension (Iwasa, 1993; Gale & Ashmore, 1994; Kakehata & Santos-Sacchi, 1995), and treatments with salicylate (Tunstall et al., 1995; Kakehata & Santos-Sacchi, 1996) or Gd^{3+} (Santos-Sacchi, 1991), since these manipulations may selectively influence native OHC charge movement.

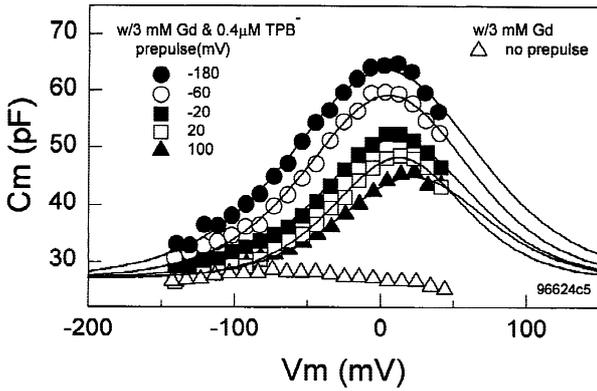

Fig. 4. Effects of 1-sec voltage prepulse on $C_{m_{pk}}$ and V_{pkC_m} of an OHC treated with gadolinium and TPB^- . Once reduction of OHC nonlinear capacitance by Gd^{+3} (3 mM) reached steady state (reduction of $C_{m_{pk}}$ from 41.2 to 28.2 pF), TPB^- (0.4 μ M) was added to the solution. Control capacitance function (open triangles, 3 mM Gd^{+3} , no prepulse) could not be reliably fit. After the appearance of TPB^- -induced capacitance, prepulse effects were studied. $C_{m_{pk}}$, V_{pkC_m} , Q_{max} and z were 63.7 pF, 2.8 mV, 6.28 pC and 0.60 (closed circles, -180 mV prepulse); 59.2 pF, 5.3 mV, 4.86 pC and 0.68 (open circles, -60 mV prepulse); 51.6 pF, 10.3 mV, 3.46 pC and 0.73 (closed squares, -20 mV prepulse); 48.3 pF, 12.5 mV, 2.57 pC and 0.85 (open square, 20 mV prepulse) and 44.9 pF, 22.1 mV, 2.42 pC and 0.76 (closed triangles, 100 mV prepulse).

In the untreated OHC, negative prepulse voltages shift V_{pkC_m} in the positive direction and visa versa, with little effect on $C_{m_{pk}}$ (Santos-Sacchi et al., 1997, 1998). In the TPB^- treated OHC, changes in V_{pkC_m} and $C_{m_{pk}}$ were found (*data not shown*) and could not be accounted for by effects on native charge alone; indeed, these data suggested that TPB^- induced charge movement was susceptible to prepulse effects, as well. To confirm this, gadolinium (3 mM) was first used to block intrinsic OHC nonlinear capacitance, so that TPB^- charge movement could be studied in isolation. Figure 4 illustrates the effects of prepulses on the voltage dependence of the isolated TPB^- -induced nonlinear capacitance. As the prepulse potential decreased from 100 to -180 mV, TPB^- -induced nonlinear capacitance progressively increased in magnitude and V_{pkC_m} became more negative. This is distinctly different from prepulse effects on the intrinsic nonlinear capacitance of the OHC (Santos-Sacchi et al., 1997, 1998).

Positive turgor pressure shifts OHC V_{pkC_m} to depolarized levels and reduces $C_{m_{pk}}$ (Iwasa, 1993; Gale & Ashmore, 1994; Kakehata & Santos-Sacchi, 1995). However, in OHCs treated with TPB^- , whereas positive intracellular pressure also shifts V_{pkC_m} to depolarized levels, $C_{m_{pk}}$ increases (Fig. 5). With 0.4 μ M TPB^- treatment, $C_{m_{pk}}$ and V_{pkC_m} of the cell shown in Fig. 5A were 53.3 pF and -27.2 mV at steady state. Positive intracellular pressure (1.35 kPa pipette pressure) increased $C_{m_{pk}}$ by 6.1 pF and shifted V_{pkC_m} in the depolarized direction by 17.6 mV. The average elevation of

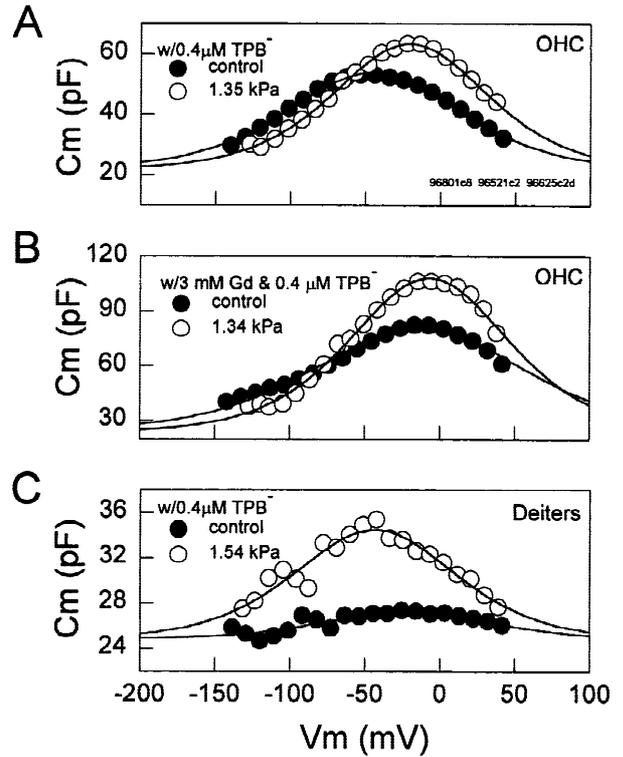

Fig. 5. Effects of positive intracellular pressure on C_m of OHCs (A, B) and Deiters cells (C). (A) After OHC C_m was increased by 0.4 μ M TPB^- and reached steady state, positive intracellular pressure caused a positive shift in overall V_{pkC_m} and increase in $C_{m_{pk}}$. (B) OHC nonlinear capacitance was blocked with Gd^{+3} , and followed by treatment with TPB^- . After $C_{m_{pk}}$ reached steady state, increased intracellular pressure caused a positive shift in V_{pkC_m} and an increase in $C_{m_{pk}}$. (C) TPB^- (0.4 μ M) induced a nonlinear capacitance in Deiters cells. In this case, after reaching steady state, positive pressure caused a negative shift in V_{pkC_m} and an increase in $C_{m_{pk}}$.

$C_{m_{pk}}$ and shift of V_{pkC_m} induced by positive pipette pressure (0.95 \pm 0.14 kPa) was 6.1 \pm 1.35 pF ($n = 4$) and 15.5 \pm 3.66 mV ($n = 4$), respectively. After intrinsic OHC nonlinear capacitance was blocked by gadolinium (3 mM), positive intracellular pressure still increased TPB^- -induced capacitance and shifted V_{pkC_m} in the depolarized direction (Fig. 5B). However, there was a greater increase in $C_{m_{pk}}$ and smaller shift in V_{pkC_m} . Under this condition, the average elevation of capacitance and shift of V_{pkC_m} caused by positive pressure (1.23 \pm 0.16 kPa) was 14.8 \pm 3.74 pF and 5.35 \pm 1.97 mV ($n = 4$), respectively. Positive intracellular pressure affected supporting cells in a similar way (Fig. 5C). The average increase in capacitance was 5.5 \pm 0.83 pF ($n = 4$) by positive pressure (1.37 \pm 0.26 kPa). Similar results were obtained by changing intracellular pressure with hypotonic solutions (*data not shown*).

Salicylate blocks OHC voltage-dependent capacitance and decreases the cell's mechanical response (Kakehata & Santos-Sacchi, 1996). We found that the pres-

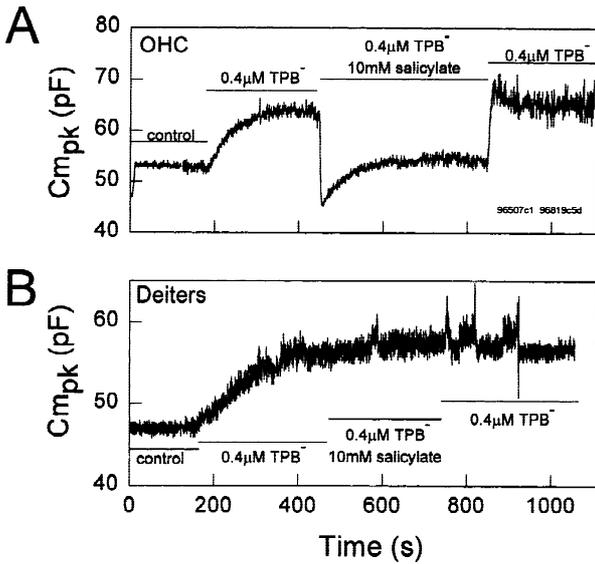

Fig. 6. Effects of salicylate on intrinsic and TPB^- induced nonlinear capacitance. $C_{m_{pk}}$ of (A) an OHC and (B) a Deiters cell monitored by the V_{pkCm} tracking technique. Same treatments were used for both cells. Salicylate specifically blocks intrinsic OHC nonlinear capacitance. Salicylate (10 mM) had no effect on $C_{m_{pk}}$ of the Deiters cell.

ence of TPB^- molecules does not affect the reduction of OHC nonlinear capacitance caused by salicylate. In Fig. 6, $C_{m_{pk}}$ of an OHC and supporting cell were monitored. TPB^- (0.4 μM) increased $C_{m_{pk}}$ of the OHC (top trace) to a steady-state value of 63.8 pF. Subsequent treatment with salicylate (10 mM), reduced $C_{m_{pk}}$ to 45.6 pF, with a time constant of 1.69 sec. The average time constant was 3.79 ± 0.94 sec (mean \pm SE, $n = 8$). This rate is faster than that observed by Kakehata and Santos-Sacchi (1996), and may be due to the presence of TPB^- or the higher perfusion rate used here. Although $C_{m_{pk}}$ recovered partially over the course of salicylate perfusion, reaching 52 pF, no recovery of mechanical response was noted. After removal of salicylate, $C_{m_{pk}}$ increased again due to the reversible effect of salicylate on OHC nonlinear capacitance. The same treatment used for OHCs was applied to supporting cells (Fig. 6, bottom). TPB^- also increased $C_{m_{pk}}$ of Deiters cells, but to a lesser and more variable degree. The average elevation of $C_{m_{pk}}$ by 0.4 μM TPB^- was 9.5 ± 1.2 pF for OHCs ($n = 15$) and 5.5 ± 1.0 pF for Deiters cells ($n = 11$). The latter figure does not include another 11 Deiters cells whose capacitance did not show an increase by at least 5 min after onset of TPB^- treatment. No effect of salicylate on $C_{m_{pk}}$ was found and no mechanical response was detected for TPB^- -treated Deiters cells.

The effects of salicylate (or gadolinium) on OHC motility are not alleviated by TPB^- treatment (Fig. 7). The figure illustrates the effects of TPB^- on C_m and movement of an OHC whose nonlinear capacitance was blocked by intracellular salicylate. Simultaneous mea-

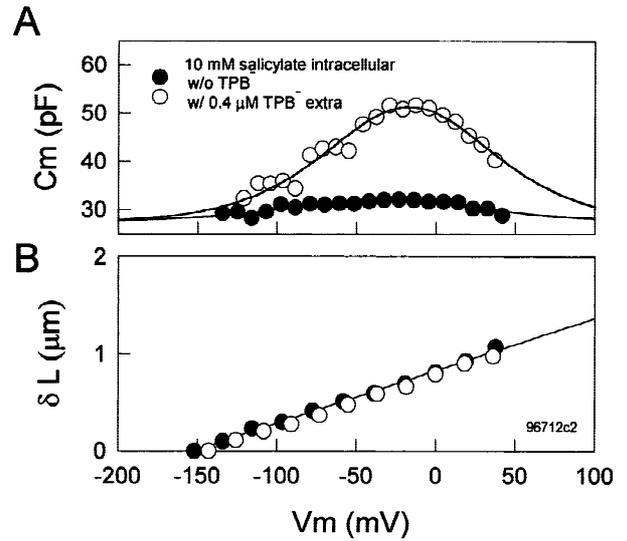

Fig. 7. Effects of TPB^- on (A) capacitance and (B) movement of OHCs whose nonlinear capacitance was blocked by salicylate. Length changes were induced by 20-mV steps from -160 to 40 mV and series resistance was corrected. Capacitance was evaluated with the stair step protocol. Fits (solid lines) for capacitance data indicate $C_{m_{pk}}$, V_{pkCm} , Q_{max} , and z of 32.1 pF, -31.8 mV, 0.82 pC and 0.59 (closed circles, w/o TPB^-); 51.4 pF, -16.9 mV, 2.43 pC and 0.72 (open circles, w/ 0.4 μM TPB^-). Fits for mechanical data indicate $V_{\delta L_{max}}$ and z of 119 mV and 0.091 (closed circles, w/o TPB^-); -9.1 mV and 0.1213 (open circles, w/ 0.4 μM TPB^-). Despite the induction of a prominent nonlinear capacitance by TPB^- , no recovery of the mechanical response was observed. Cell length: 71 μm .

ures of capacitance and voltage dependent movement were made before and during extracellular application of 0.4 μM TPB^- . For this cell, $C_{m_{pk}}$ was reduced to a steady-state level of 32.1 pF by 10 mM salicylate, which is consistent with the results of Kakehata and Santos-Sacchi (1996). During TPB^- treatment, peak capacitance increased to 51.7 pF. Although TPB^- -induced an additional nonlinear capacitance of 19.64 pF and shifted overall V_{pkCm} from -31.83 to -16.28 mV, the difference in maximum length change was only 0.09 μm . The average difference in maximum length change for 3 cells was 0.03 ± 0.02 μm .

Discussion

The present results show that the hydrophobic ion, TPB^- , but not TPP^+ , increases nonlinear charge movement, as evidenced through capacitance measures, in OHCs and supporting cells from the organ of Corti. The enhancement of nonlinear charge movement, which is accompanied by a concentration-dependent shift in the voltage at peak capacitance, is greater for OHCs than for supporting cells. This suggests that membrane structural parameters such as thickness, dielectric constant, dipole poten-

tial, or the degree of the lipid hydrocarbon chain order (Ketterer, Randic & Läuger, 1971; Benz & Läuger, 1977; Reyes & Latorre, 1979; Fernandez et al., 1982) may be different between the two types of cells; another clear difference between the cells is the existence of intrinsic voltage-sensor/motor elements in OHCs. The latter difference is exemplified by the results from salicylate treatments. Salicylate reduced OHC membrane capacitance attributable to intrinsic lateral membrane sensor/motors, which is in agreement with earlier studies (Tunstall et al., 1995; Kakehata & Santos-Sacchi, 1996), but did not reduce the TPB⁻-induced capacitance of supporting cells or OHCs. This evidence further supports the notion that salicylate directly and specifically acts on the sensor/motor of the OHC (Kakehata & Santos-Sacchi, 1996), and not via some nonselective mechanism to impede all charge movement within the membrane.

The characteristics of TPB⁻-induced nonlinear capacitance are similar in some ways to those of the OHC intrinsic capacitance, namely, each has a shallow voltage dependence and is affected by voltage prepulse and membrane tension. However, there are obvious differences which are readily revealed when the OHC's intrinsic nonlinear capacitance is blocked. Whereas the OHC nonlinear capacitance shifts its voltage dependence in the negative direction with positive prepulse (Santos-Sacchi, Kakehata & Takahashi, 1998), the voltage dependence of TPB⁻-induced capacitance does the opposite. Also, whereas positive intracellular pressure decreases OHC peak capacitance (Gale & Ashmore, 1994; Kakehata & Santos-Sacchi, 1995), TPB⁻-induced peak capacitance increases. The reasons for these differences are not obvious, but may possibly relate to differences in sign of the mobile charged species.

Despite some similarities between TPB⁻-induced nonlinear charge movement and OHC intrinsic nonlinear charge movement, the former cannot effect mechanical responses, indicating that TPB⁻ charge movement does not alter lateral membrane motor conformation. Similarly, in frog myelinated nerve, lipophilic dipicrylamine ions did not interact with Na channels (Benz & Nonner, 1981). However, we found that TPB⁻-induced shifts in OHC intrinsic V_{pkCm} which are mirrored by similar shifts in V_{dLmax} . Since TPB⁻ does not directly alter the magnitude of OHC motility, it is probable that the ion's effects on motility are via electrostatic interactions with the motility voltage sensor; that is, the voltage dependence of intrinsic OHC capacitance is likely shifted by TPB⁻, just as it is by TPP⁺.

A variety of evidence indicates that the OHC's native nonlinear charge movement is causally related to the cell's mechanical response. First, blockers of OHC nonlinear capacitance cause reductions in OHC motility (Santos-Sacchi, 1991; Tunstall et al., 1995; Kakehata & Santos-Sacchi, 1996). Second, the kinetics of charge

movement and mechanical response coincide (Santos-Sacchi, 1990, 1991; Gale & Ashmore, 1997). Third, treatments which induce shifts in the voltage dependence of nonlinear charge movement or capacitance similarly shift that of the mechanical response (Fig. 3C; Kakehata & Santos-Sacchi, 1995). Fourth, mechanical stimulation of the lateral membrane elicits the salicylate blockable motility-related gating charge movement (Gale & Ashmore, 1994; Takahashi & Santos-Sacchi, 1997). Finally, the present data indicate that induced nonspecific charge movement cannot evoke or recover blocked mechanical responses.

The apparent discrepancy between the degree of salicylate-induced reduction in capacitance and mechanical response indicated by the closed symbols in Fig. 7, and noted previously (Kakehata & Santos-Sacchi, 1996) may be readily accounted for. First, the relative decrease in capacitance and motility is not known since the pipette contained the drug and the effect is near immediate (Kakehata & Santos-Sacchi, 1996); no pre-drug measures are available. Second, the native nonlinear charge movement is not completely abolished, and in fact may be extended over a wider voltage range than under normal conditions (reduced z), so that measurement could be limited by our ability to deliver extreme voltages. Furthermore, we have previously shown that when the nonlinear capacitance remaining after salicylate treatment is blocked by Gd³⁺, the mechanical response is fully abolished (Kakehata & Santos-Sacchi, 1996). Third, the whole-cell mechanical response magnitude may be dependent upon many physical criteria, including turgor pressure (Shehata et al., 1991; Santos-Sacchi, 1991), whole-cell stiffness (Dallos et al., 1997), and possibly membrane visco-elasticity (Santos-Sacchi et al., 1997, 1998). The linearity of the residual mechanical response may be an expression of a reduction in z which would necessarily provide an apparent linearization within a restricted voltage range.

In summary, TPB⁻ ions increase the magnitude of nonlinear capacitance and modify V_{pkCm} and V_{dLmax} of OHCs. TPB⁻-induced nonlinear capacitance is independent of OHC intrinsic nonlinear capacitance. We conclude that the OHC mechanical response is not simply related to quantity of nonspecific nonlinear charge moved within the membrane, but to the effects of motility voltage-sensor charge movement functionally coupled to a mechanical effector.

ABSTRACT

Capsaicin, the classic activator of TRPV-1 channels in primary sensory neurons, evokes nociception. Interestingly, auditory reception is also modulated by this chemical, possibly by direct actions on outer hair cells (OHCs). Surprisingly, we find two novel actions of capsaicin unrelated to TRPV-1 channels, which likely contribute to its auditory effects *in vivo*. First, capsaicin is a potent blocker of OHC K conductances (I_K and $I_{K,n}$). Second, capsaicin substantially alters OHC nonlinear capacitance, the signature of electromotility – a basis of cochlear amplification. These new findings of capsaicin have ramifications for our understanding of the pharmacological properties of OHC I_K , $I_{K,n}$ and electromotility and for interpretation of capsaicin pharmacological actions.

1. Introduction

The mammalian cochlea contains two types of hair cells with distinct functions. Inner hair cells (IHCs) are responsible for sound detection and its conversion to electrical signals. Whereas, outer hair cells (OHCs) additionally amplify sound stimulus by increasing both the amplitude and frequency selectivity of basilar membrane (BM) vibration. Electrically evoked OHC mechanical activity, whose electrical signature is a nonlinear capacitance (NLC), is a basis of this cochlear amplification (Dallos et al., 2008; He et al., 2006; Santos-Sacchi, 2003; Santos-Sacchi et al., 2006; Zheng et al., 2003). I_K and $I_{K,n}$ are the two major K conductances in OHCs (Housley and Ashmore, 1992, 2006; Mammano and Ashmore, 1996; Santos-Sacchi and Dilger, 1988). I_K activates at potentials more positive than -35 mV and its identity and role is still unclear. $I_{K,n}$, which activates at hyperpolarized potentials, is carried by KCNQ4 channels and controls the resting potential of OHCs (Chambard and Ashmore, 2005; Holt et al., 2007; Kharkovets et al., 2000, 2006; Wu et al., 2010;

Xu et al., 2007). The resting potential is an important component of the driving force for OHC electromotility.

Capsaicin, the natural product of capsicum pepper, is an active ingredient of many spicy foods. Capsaicin selectively activates TRPV-1, a non-selective cation channel (NSCC) in primary sensory neurons, initiating nociception through its depolarizing effects. This is the classical action of capsaicin (Caterina et al., 1997; Szallasi and Blumberg, 1999). Interestingly, we showed that capsaicin reduced cochlear amplification, resulting in an elevation in the threshold of the auditory nerve compound action potential in an *in vivo* study (Zheng et al., 2003). Furthermore, we and others have observed TRPV-1 immunolabeling in OHCs (Ishibashi et al., 2008; Mukherjea et al., 2008; Zheng et al., 2003). From these data, we hypothesized that OHCs were the major target of capsaicin, and activation of TRPV-1 would result in OHC depolarization leading to a reduction in both receptor potential and evoked OHC motility. Therefore, it is of particular interest to understand the action of capsaicin on OHCs at the cellular level.

In this study, we whole-cell voltage clamped isolated OHCs. Surprisingly, capsaicin did not elicit characteristic TRPV-1 currents in the OHCs. Unexpectedly, we found that capsaicin is a potent blocker of OHC K conductances (I_K and $I_{K,n}$) and alters NLC substantially. These novel pharmacological effects of capsaicin have never been reported before and likely contribute to the drug's detrimental action on cochlear amplification *in vivo*.

2. Materials and methods

2.1. OHC preparation

Adult guinea pigs (250–350 g) with positive Preyer's reflex were anesthetized by intramuscular injection of an anesthetic mixture (60 mg/ml ketamine, 2.4 mg/ml xylazine, and 1.2 mg/ml acepromazine in saline) at a dose of 1 ml kg⁻¹ and were then killed by decapitation. The cochleae were rapidly removed from the bulla and dissected in a Petri dish filled with a standard artificial perilymph composed of (mM): NaCl 144, KCl 4, CaCl₂ 1.3, MgCl₂ 0.9, Na₂HPO₄ 0.7, HEPES 10 and glucose 5.6. The osmolarity of the solution was adjusted to 304 mosmol/l with glucose and the pH was adjusted to 7.40 with NaOH. All procedures were performed at room temperature. The organ of Corti dissected from the apical two cochlear turns was digested with dispase I (1.0 mg/ml) for 12 min. Dissociated OHCs, obtained by gentle titration, were placed in a Petri dish and allowed to settle onto the glass bottom. They were continuously perfused with the artificial perilymph. OHCs with lengths ranging from 72 to 75 μm (the upper 3rd turn, used in most of experiments unless otherwise specified) and 48–55 μm (the lower 2nd turn) were chosen for patch recordings. All procedures in this study were approved by the Institutional Animal Care and Use Committee of Oregon Health & Science University.

2.2. Solutions for OHC recordings

All reagents were from Sigma–Aldrich. In the bath solutions, agents were added as 1000 X concentrates. Capsaicin was pre-dissolved in dimethylsulfoxide (DMSO), which was used at a final concentration of 0.1% DMSO. BaCl₂ and 4-AP were pre-dissolved in water. The drugs were gravity delivered at a rate of (0.35 ml min⁻¹) through an array of parallel polyethylene tubes with an inner diameter of ~280 μm at the distal end, which was positioned ~350 μm next to the OHCs. Rapid switching of two different solutions was performed by shifting loaded tubes.

a) Solutions for current recordings: Bath solution contained (in mM): NaCl 142, KCl 5, CaCl₂ 1.5, MgCl₂ 2, Hepes 10 and D-glucose 5.6. The pH was adjusted to 7.40 with NaOH and the osmolarity to 304 mosmol/l with D-glucose. Pipette solution (mM) contained (in mM): KCl 148, CaCl₂ 0.5, MgCl₂ 2, Hepes 10 and EGTA 1. The pH was adjusted to 7.40 with KOH and the osmolarity to 298 mosmol/l with D-glucose.

b) Solutions for NLC recordings: Bath solution (mM) was NaCl 132, CaCl₂ 2, MgCl₂ 2, and Hepes 10. Pipette solution was the same except with EGTA 10. In a subset of experiments, Ca was removed from both intracellular and extracellular solutions by substituting NaCl. The extracellular solution contained 3, 10, 30, 100, 300 and 1000 μM capsaicin. The pH was adjusted to 7.20 with NaOH and the osmolarity to 300 mosmol/l with D-glucose. We have previously shown that DMSO and ethanol at the concentrations used in this report do not affect measures of NLC (Rybalchenko and Santos-Sacchi, 2003; Song et al., 2005).

2.3. Whole-cell recordings of OHCs

In regular current detection procedures, an Axopatch 1-D amplifier (Axon Instruments) was used with its low-pass filter bandwidth set to 1 kHz (four-pole Bessel). Membrane currents were recorded with a Digidata 1322A (Axon Instruments) interface and pCLAMP 8 software (Axon Instruments) at a sampling rate of 10 kHz for episodic I–V commands and with Minidigi digitizer and Axoscope 9.2 software (Axon Instruments) for simultaneous gap-free recording at a sampling rate of 50 Hz. The whole-cell configuration was achieved by rupturing the cell membrane with suction after achieving a high-resistance seal (>1.5 gohm). Stability of the patch was ascertained by monitoring

gap-free recording and cell parameters (cell capacitance (C_{cell}), membrane resistance (R_m) and series resistance (R_s)) during the recordings. The patch pipettes were pulled in four steps from borosilicate capillaries (WPI, 1B150F-4) using a puller (P80/PC Sutter Instrument). In a regular Na⁺ rich bath and K⁺ rich pipette solution, the initial pipette resistance was 6–7 MΩ. The uncompensated R_s (MΩ) were off-line corrected with the equation $V_c = V_u - I \times R_s$ (V_c , corrected clamping voltage; V_u , uncorrected clamping voltage; I , current) in Excel sheets and Origin 7.5 (OriginLab Technical) files. In order to stabilize the liquid junction potential (LJP), a salt bridge (3 M NaCl) with a ceramic tip was used as a reference electrode. The LJP (actual measurement) was 3 mV in the regular Na⁺ rich bath and K⁺ rich pipette solutions. The LJP was corrected in the Excel sheets and Origin 7.5 (OriginLab Technical) files. Data were analyzed by clampfit 9.0 (Axon Instruments) and Origin 7.5 (OriginLab Technical).

2.4. Nonlinear capacitance measurements

OHC capacitance was measured with a continuous high-resolution (2.56 ms) two-sine voltage stimulus protocol (10 mV peak at both 390.6 and 781.2 Hz), and subsequent FFT based admittance analysis as fully described previously (Santos-Sacchi et al., 1998). These small, high frequency sinusoids were superimposed on voltage ramps that spanned ±180 mV. All data collection and most analyses were performed with an in-house developed Windows based whole-cell voltage clamp program, jClamp (www.scisoft.com), utilizing a Digidata 1320 board (Axon, CA). Matlab (Natick, MA) or SigmaPlot was used for fitting the C_m data.

C – V data were fit with the first derivative of a two-state Boltzmann function and a constant representing the linear capacitance (Santos-Sacchi, 1991),

$$C_m = Q_{\text{max}} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{\text{lin}} \quad (1)$$

$$b = \exp\left(\frac{-ze(V_m - V_{\text{pkcm}})}{kT}\right)$$

where Q_{max} is the maximum nonlinear charge moved, V_{pkcm} is voltage at peak capacitance or half-maximal nonlinear charge transfer, V_m is membrane potential, C_{lin} is linear capacitance, z is apparent valence, e is electron charge, k is Boltzmann's constant, and T is absolute temperature.

2.5. TRPV1 immunofluorescence labeling in OHCs of guinea pigs and *Trpv1*^{-/-} mice

The cochleae of guinea pigs, *Trpv1*^{-/-} mice, and the wild type control mice with the same background (Jackson Lab) were dissected and fixed in 4% paraformaldehyde solution overnight. After being washed in 0.02 M phosphate-buffered saline (PBS) for 30 min, the tissues were permeabilized in 0.5% Triton X-100 (Sigma) for 1 h (h) and incubated in 10% goat serum and 1% bovine serum in 0.02 M PBS for 1 h. The tissues were incubated overnight in primary anti-TRPV1 (rabbit polyclonal, RA10110, Neuromics, Edina, MN, USA) diluted to 1:500 with 1% BSA-PBS. After being washed in 1% BSA-PBS for 30 min, the tissues were incubated in Alexa fluor 488 anti-rabbit IgG (diluted to 1:100) and Alexa fluor 568 phalloidin (diluted to 1:50, Invitrogen, Eugene, OR, USA) for 1 h and Hoechst (1 μg/ml, Invitrogen, Eugene, OR, USA) for 15 min. After being washed in 0.02 M PBS for 30 min, the tissues were mounted and observed on a Nikon Eclipse TE 300 inverted microscope fitted with an Olympus Fluview confocal laser microscope system. Negative controls were 1) tissue incubated with 1% BSA-

Net currents (ctrl-cap) are after subtraction from control (ctrl) currents in bath. B. Representative I - V plots of the currents in A. C. Bar graph summary: 300 μM cap blocked outward currents at 0 mV and inward currents at -100 mV. Currents were normalized by the currents in ctrl. * $P < 0.05$. D. Effect of cap (0.1 mM) on steady state activation curve of $I_{K,n}$. Normalized tail-current amplitudes versus prepulse potentials were fitted with a first-order Boltzmann function ($n = 6$): $I = I_{\text{max}} / (1 + \exp((V - V_{\text{half}}) / S))$, where I_{max} is the fully activated current amplitude at the tail-current potential, V_{half} is the potential at half-maximal activation, V is prepulse potentials and S is the slope factors.

PBS to replace the primary antibody, 2) tissue with the primary antibody (TRPV-1) and its blocking peptide (10^4 M) (Neuromics, Edina, MN, USA), and 3) tissues from the *Trpv1*^{-/-} mice.

2.6. Statistics

Data are presented as means \pm SE from n observations. Student's t -test (paired or non-paired as appropriate) was performed using Microsoft Excel software; $p \leq 0.05$ represents a significant difference.

3. Results

3.1. Capsaicin blocks two types of potassium currents in OHCs, I_K and $I_{K,n}$

In our standard Na^+ rich bath and K^+ rich pipette solutions, upper 3rd turn OHCs presented two previously described K^+ currents (Fig. 1A) (Housley and Ashmore, 1992); I_K , a slowly developing outward current showing slight inactivation (activated above -40 mV), and $I_{K,n}$, an inward current which relaxes during large hyperpolarizing steps (-120 mV). Capsaicin (300 μM) reversibly abolished I_K and slightly reduced $I_{K,n}$. The effects are analogous to the previously observed actions of 4-AP (300 μM) (Mammano and Ashmore, 1996) (Fig. 1A). In comparison, Ba^{2+} (10 mM) blocked most of $I_{K,n}$, without a significant block of I_K . The reversal potential

(V_r) of the capsaicin-sensitive current was -83.6 ± 4.3 ($n = 7$), which is comparable to that of the 4-AP and barium-sensitive current (-70.5 ± 0.5 ($n = 3$) and -82.5 ± 0.8 ($n = 4$), respectively), suggesting a high selectivity to K^+ (Fig. 1B) (The K^+ equilibrium potential (E_K) was -88 mV). From step protocols, average reductions in steady state outward currents at 0 mV for capsaicin, 4-AP, and Ba^{2+} were 62.1%, 75.2%, and 59.9%, respectively ($n = 4-7$; $p < 0.05$; Fig. 1C). Average reductions in steady state inward currents at -100 mV for capsaicin, 4-AP, and Ba^{2+} were 10.1%, 12.2%, and 31.2%, respectively ($n = 3-7$; $p < 0.05$; Fig. 1C). The capsaicin elicited reduction in the outward current was concentration-dependent with $\text{EC}_{50} = 103.1$ μM when held at 0 mV (Fig. 1D). Capsaicin depolarized OHCs by 4.005 mV (Fig. 1E), shifting the resting potential, which is driven by $I_{K,n}$ (Housley and Ashmore, 1992), from -67.9 ± 1.5 to -63.9 ± 1.8 mV ($n = 7$, $p < 0.05$), which is consistent with a small but significant inhibition of $I_{K,n}$ by capsaicin.

To further study the effect of capsaicin on $I_{K,n}$, we used lower 2nd turn OHCs, which presented much larger $I_{K,n}$, but little I_K (Fig. 2A). We found that Capsaicin (300 μM) partially inhibited $I_{K,n}$ (Fig. 2A). The I - V plot showed that capsaicin caused a current reduction in the whole range of voltage commands with V_r of capsaicin-sensitive current at ~ -80 mV (Fig. 2B). Average reductions in steady state inward currents for capsaicin are 25.1% (at 0 mV) and 20.9% (at -100 mV) (Fig. 2C). Fig. 2D shows the effect of capsaicin (300 μM) on the steady state activation curve of $I_{K,n}$,

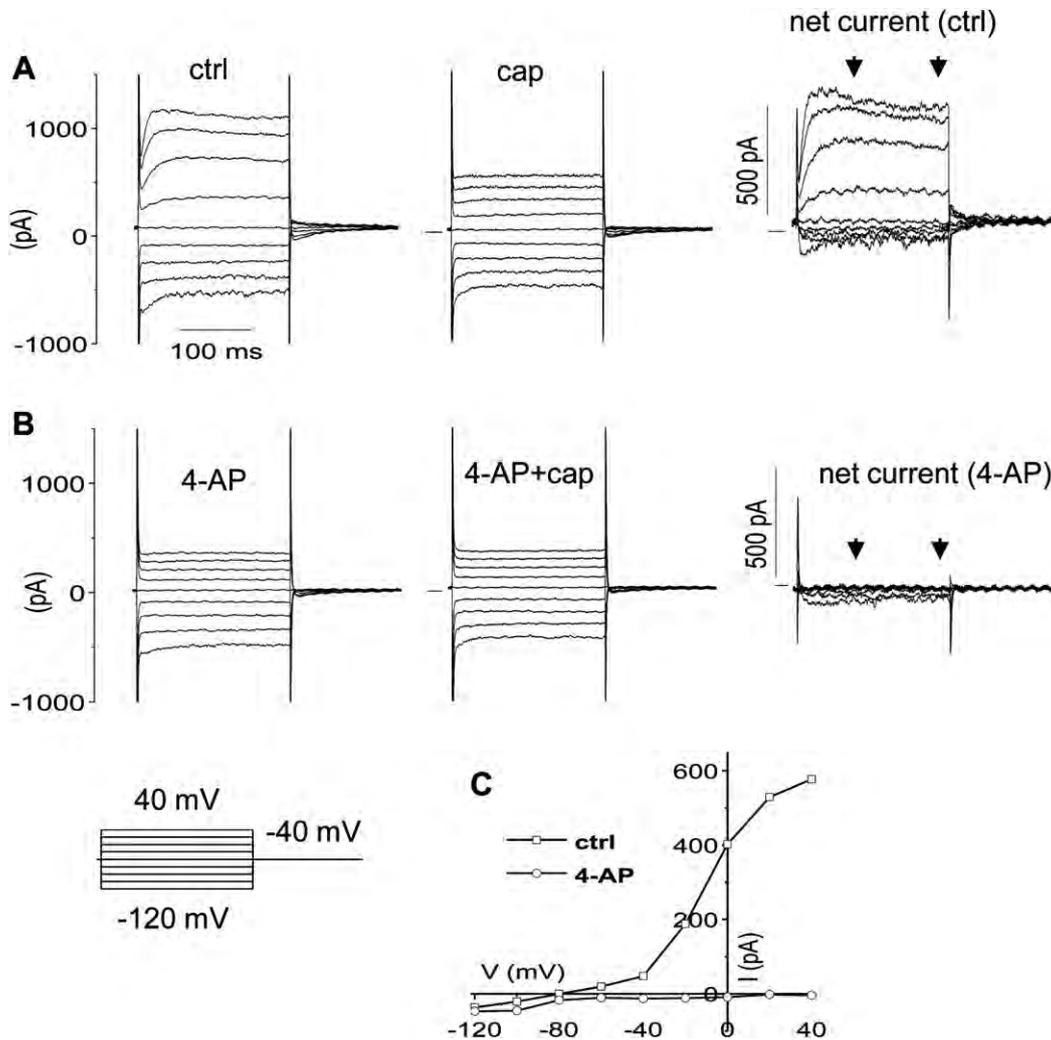

Fig. 3. 4-AP blocks the net capsaicin currents. A. Representative currents in ctrl bath and following application of 300 μM capsaicin (cap). Net currents (ctrl-cap) are after subtraction from ctrl currents in bath. B. Representative currents in 4-AP (300 μM) bath and following application of 300 μM cap. Net currents (cap-sensitive currents) are after subtraction from the currents in 4-AP bath. C. Representative I–V curves of net currents in A and B. The current for each V is the 100 ms average bounded by the arrows.

which was determined from tail currents with the voltage protocol in Fig. 2A. Capsaicin did not significantly shift the V_{half} . The V_{half} (mV) and slope factor (S) (mV) are -91.2 ± 2.3 ($n = 6$) and 20.8 ± 2.1 ($n = 8$), respectively for capsaicin treatment, versus -88.9 ± 2.1 (V_{half}) and 19.7 ± 1.9 (S) for control. The V_{half} of $I_{K,n}$ was consistent with previous findings (Housley and Ashmore, 1992; Jagger and Ashmore, 1999b).

Consistent with the above findings, capsaicin-sensitive currents (the upper 3rd turn OHCs) were blocked by 4-AP (300 μM) and BaCl_2 (10 mM). 4-AP (300 μM) blocked all capsaicin-sensitive outward currents in step protocols ($n = 3$) (Fig. 3). In Fig. 4A, when held at -44 mV (where $I_{K,n}$ is predominantly activated), OHCs presented a net outward current, i.e. a positive current above zero, in continuous gap-free recordings. Capsaicin (300 μM) reversibly inhibited the outward current by shifting it negatively. The shift was reduced in the presence of BaCl_2 (10 mM). In step protocols (Fig. 4. B, C, D, E), BaCl_2 (10 mM) reduced the capsaicin-sensitive current at -40 mV by 89.6% ($n = 3$, $p < 0.05$) and at 0 mV by 55.7% ($n = 3$, $p < 0.05$).

We also tested the effect of capsaicin on I_K and $I_{K,n}$ at the concentration used in our previous *in vivo* study (Zheng et al., 2003). Consistent with that study, 20 μM capsaicin produced a small but significant reduction of I_K and $I_{K,n}$. From step protocols

(shown in Fig. 1), average reductions in steady state outward currents for capsaicin (20 μM) were 8.4% at 0 mV ($p < 0.05$, $n = 10$) and 6.5% at -100 mV ($p < 0.05$, $n = 10$) (Fig. 5).

3.2. Capsaicin alters electromotility

Application of extracellular capsaicin altered OHC nonlinear capacitance, the electrical signature of electromotility. Fig. 6A shows the effects of increasing concentrations on the C–V function. The drug shifted V_{pkcm} to the left and reduced peak capacitance for concentrations over 30 μM . The shifts of V_{pkcm} for concentrations 30, 100, 300 and 1000 μM capsaicin perfusions were 1.67 ± 0.34 , 4.98 ± 1.01 , 25.03 ± 1.34 and 29.94 ± 1.16 mV, respectively (se, $n = 5$, $p < 0.05$). Reductions in nonlinear peak capacitance for concentrations 30, 100, 300 and 1000 μM capsaicin perfusions were 1.21 ± 0.35 , 2.03 ± 0.49 , 3.81 ± 0.58 and 3.39 ± 0.55 pF, respectively (se, $n = 5$, $p < 0.05$). No significant differences were found when cells were held at 0 or -70 mV. The concentration dependence of the V_{pkcm} shift is shown in Fig. 6B. A Hill fit gives a half maximal shift (EC_{50}) at 158 μM ($n = 8$). Removing Ca^{2+} , both extracellular and intracellular, reduced the V_{pkcm} shift at the two highest concentrations, namely -17.3 mV at 300 μM ($p = 0.04$) and -22.3 mV at 1000 μM ($p = 0.07$). This resulted in an increase in the

EC₅₀ to 204 μM. Reducing intracellular and extracellular chloride levels to 1 mM did not alter the ability of capsaicin to shift the V_{pkcm}.

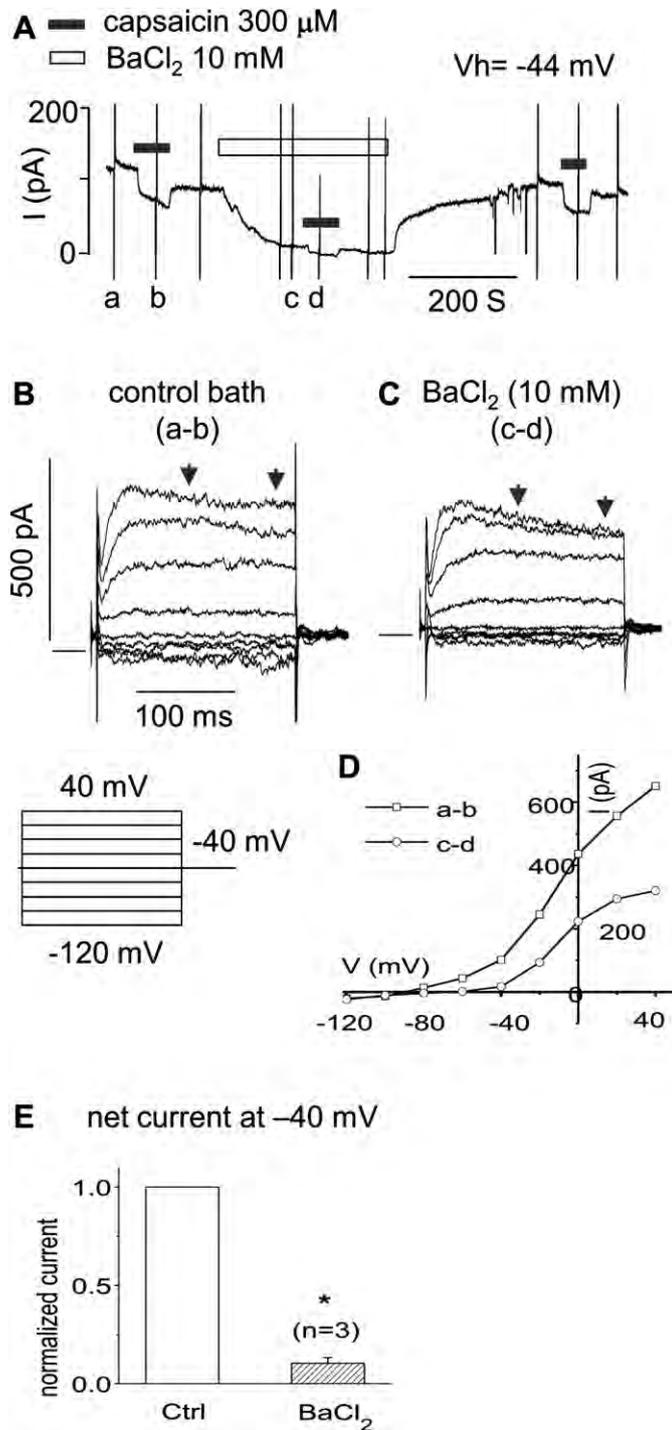

Fig. 4. BaCl₂ partially blocks the net capsaicin currents. **A.** Representative current in gap-free mode at holding voltage of -44 mV. The vertical spike currents, such as a, b, c and d, were caused by the I–V step voltage commands as shown in **B**. **B.** Net capsaicin (300 μM) currents (a–b) in control bath. The zero current was shown as a solid horizontal bar preceding the step currents in **B** and **C**. **C.** Net capsaicin (300 μM) currents (c–d) in the bath with 10 mM BaCl₂. **D.** Representative I–V curves of net currents in **B** and **C**. The current for each V is the 100 ms average bounded by the arrows. **E.** Bar graph summary: the net capsaicin currents at V_h of -40 mV in the control (ctrl) and BaCl₂ (10 mM) bath. The currents were normalized by the currents of ctrl. *P < 0.05, n = 3.

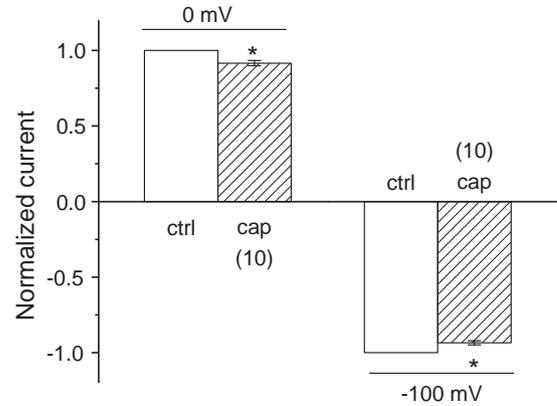

Fig. 5. Capsaicin blocks I_K and I_{K,N} at the concentration (20 μM) used in previous *in vivo* studies. Bar graph summary: 20 μM capsaicin (cap) (n = 10) significantly blocked outward currents at 0 mV and inward currents at -100 mV with step protocols (shown in Fig. 1). Currents were normalized by the currents in ctrl bath. *P < 0.05.

3.3. TRPV1 immunofluorescence labeling in OHCs of guinea pigs and Trpv1^{-/-} mice

TRPV-1 labeling was found in the basolateral membrane of the OHCs and IHCs of the guinea pigs (Fig. 7A) and Trpv1^{+/+} mice

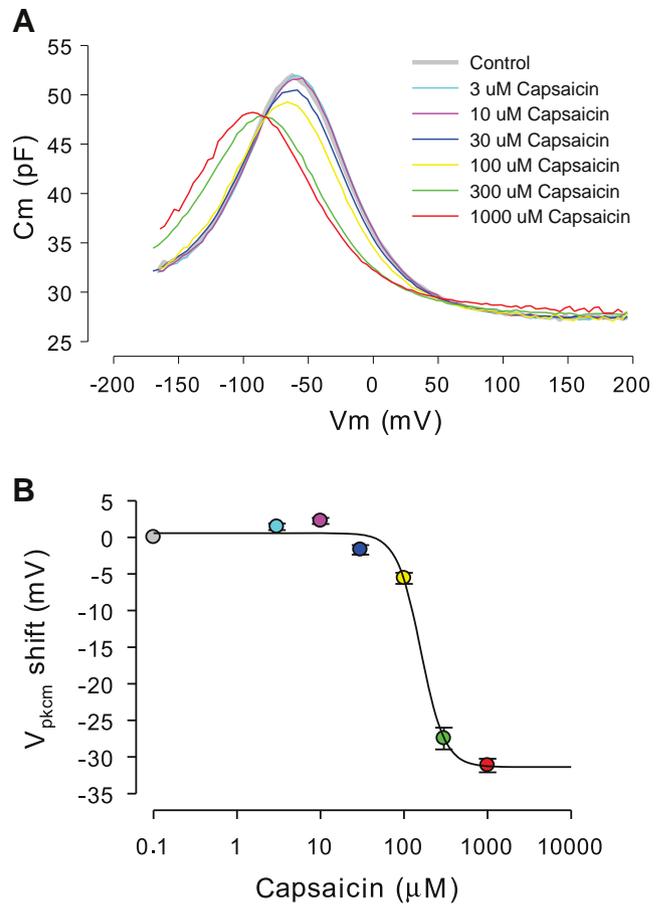

Fig. 6. Representative effects of capsaicin on OHC NLC. **A.** Cm–Vm plots for increasing concentrations of capsaicin. Both a decrease in peak capacitance and shift in voltage at peak capacitance result from drug exposure. **B.** Dose response function with standard errors, showing an IC₅₀ of 158 μM (n = 8). The data are statistically significant at 10uM and above (p < 0.013), showing a biphasic response shift at low concentrations. Peak NLC reduction is significant at 30 μM and above (p < 0.05).

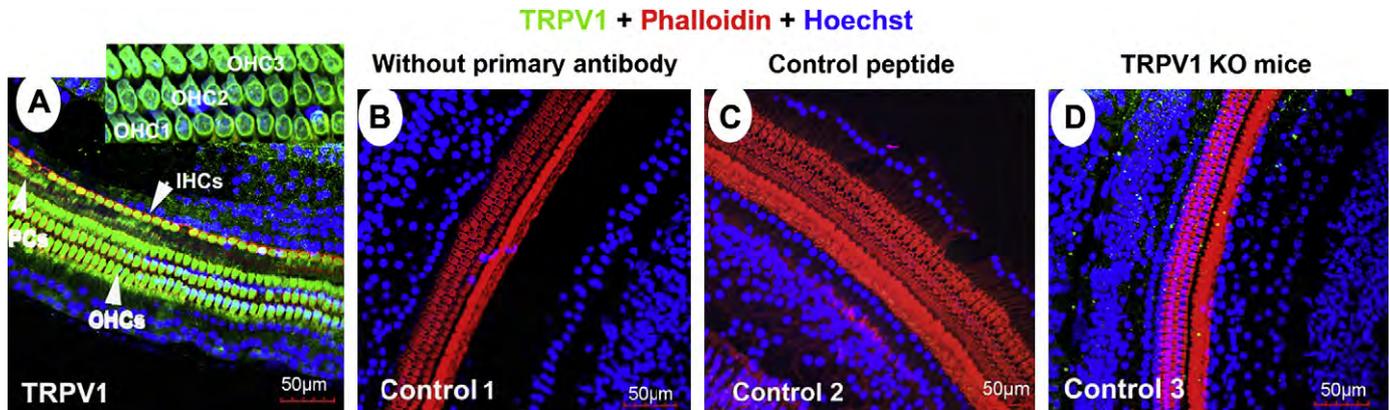

Fig. 7. TRPV1 immunofluorescence labeling of guinea pig and *Trpv1*^{-/-} mice. A, a representative confocal projection image showing TRPV1 immunolabelling in OHCs, IHCs and pillar cells of guinea pigs. The insert shows that TRPV1 is expressed in the basolateral membrane of OHCs. No significant labeling was found in OHCs, IHCs and PCs of negative controls including 1) primary antibody only (B), 2) with control peptide (C) and 3) *Trpv1*^{-/-} mice (D). TRPV1 labeling of *Trpv1*^{+/+} mice is similar to guinea pigs (data not shown).

(similar to guinea pigs, data not shown). No significant TRPV-1 labeling was found in the OHCs and IHCs in the negative controls including 1) primary antibody only (Fig. 7B), 2) with control peptide (Fig. 7C), and 3) the *Trpv1*^{-/-} mice (Fig. 7D). TRPV-1 labeling was also found in supporting cells including pillar cells and Hensen's cells (Fig. 7A).

4. Discussion

4.1. Capsaicin blocks I_K and $I_{K,n}$

There are several types of K currents expressed in adult guinea pig OHCs, I_K and $I_{K,n}$ being the two major ones (Housley and Ashmore, 1992, 2006; Mammano and Ashmore, 1996; Santos-Sacchi and Dilger, 1988). I_K , which activates at potentials more positive than -35 mV, is most prominent in the apical turn (Housley and Ashmore, 1992) and is specifically blocked by 4-AP (Mammano and Ashmore, 1996). $I_{K,n}$, which activates at hyperpolarized potentials more negative than -40 mV, is most prominent in the basal turn and is more susceptible to barium (10 mM) (Mammano and Ashmore, 1996). $I_{K,n}$ is carried by KCNQ4 channels (Chambard and Ashmore, 2005; Holt et al., 2007; Kharkovets et al., 2000, 2006) and dominates the OHC membrane conductance at the resting potential. These conductances are restricted to the basal pole of the OHC (Santos-Sacchi et al., 1997).

Our findings indicate that capsaicin is a potent I_K blocker; 300 μ M capsaicin, similar to 300 μ M 4-AP, abolished most of the current (Fig. 1). The reversal potential (V_r) of the capsaicin-sensitive current (-83.6 mV) was close to that expected for a K conductance (-88 mV), suggesting most of the capsaicin-sensitive current under these conditions was carried by potassium. That 4-AP completely blocked the outward capsaicin-sensitive current in step protocols is another piece of evidence that capsaicin and 4-AP work similarly (Fig. 3). The potency of capsaicin was slightly less than 4-AP; the outward current at 0 mV was reduced by 62.1% for capsaicin (300 μ M) and by 75.2% for 4-AP (300 μ M). Unlike $I_{K,n}$ (KCNQ4), the molecular identity of I_K has not been successfully discovered, although some candidates have been proposed and some efforts have been made (Ashmore and Meech, 1986; Jagger and Ashmore, 1999a).

Capsaicin also reduced $I_{K,n}$. This conclusion is supported by the following findings in the upper 3rd turn OHCs. 1) Capsaicin slightly depolarized OHCs by 4 mV. 2) At -44 mV, where $I_{K,n}$ is the dominant current, capsaicin caused a considerable negative shift of an outward current in gap-free recording (Fig. 4A). 3) The shift caused

by capsaicin was blocked by barium (10 mM). 4) In step protocols, barium (10 mM) significantly blocked the capsaicin-sensitive current (Fig. 4B–E). However, the reduction of $I_{K,n}$, though statistically significant ($p < 0.05$), was quite small for capsaicin (300 μ M), with a reduction of inward current at -100 mV by 12.2%. In comparison, barium (10 mM) reduced the inward current by 31.2%. In the short OHCs (the lower 2nd turn) with larger $I_{K,n}$, capsaicin reduced more inward current (by 20.9% at -100 mV).

Our study is the first to report the blocking effects of capsaicin on K conductances in cochlear hair cells. Capsaicin has been previously reported to block voltage gated K currents in a variety of different cells including Schwann cells, dorsal root ganglion cells, T cells, vertebrate axons, and some mammalian cell lines with an IC_{50} ranging from 23 to 158 μ M (Grissmer et al., 1994). These values are comparable to our observation of 103.1 μ M. More interestingly, capsaicin was found to block a KCNQ current in the vestibular type II hair cells of the gerbil (Rennie et al., 2001) and a delayed rectifier K⁺ current in the vestibular hair cells of frog semicircular canals (Marcotti et al., 1999). Analogous to our findings in guinea pig OHCs, the K conductance of the frog vestibular hair cells was also pharmacologically separated into two complementary components: a capsaicin-sensitive current and a barium-sensitive current (Marcotti et al., 1999).

4.2. Capsaicin alters OHC electromotility

The electrically evoked OHC mechanical response underlies mammalian cochlear amplification (Brownell, 1984; Liberman et al., 2002; Santos-Sacchi et al., 2006). Here we show that capsaicin can significantly reduce NLC and shift its operating voltage range. Changes in NLC are known to correspond to changes in electromotility (see Kakehata and Santos-Sacchi, 1995), and shifts in the operating range are predicted to alter the cell's mechanical gain. We show that capsaicin is not working through changes in intracellular chloride levels, which are known to be important for OHC motor function (Oliver et al., 2001; Rybalchenko and Santos-Sacchi, 2003; Santos-Sacchi, 2003; Song et al., 2005), but may work directly on the motor protein, prestin. It is the first study to report that capsaicin has a direct action on OHC electromotility.

4.3. TRPV-1 considerations

We confirmed that TRPV-1 immunolabeling is observed in normal guinea pig and mouse OHCs, IHCs, and supporting cells (pillar cells

and Hensen's cells), as previously shown by us and others (Ishibashi et al., 2008; Mukherjea et al., 2008; Zheng et al., 2003). However, immunolabeling is absent in *Trpv1*^{-/-} mice. Given these strong data, it is surprising that we did not see characteristic TRPV-1 currents in isolated OHCs at capsaicin concentrations ranging from 0.1 to 600 μ M. There are a couple of possibilities for this quandary. First, it is possible that the native TRPV-1 is functional *in vivo*, but was inactivated during the relatively harsh OHC isolation procedure. It has been reported that isolated OHCs are loaded with more Ca^{2+} and Na^{+} and have less polarized resting potential and significantly reduced input resistance (Mammano et al., 1995). Second, it may be possible that the native TRPV-1 expressed in OHCs is non functional, similar to normal TRPLM3 (Grimm et al., 2007). Consequently, in the first case, the *in vitro* action of capsaicin on I_K , $I_{K,n}$ and NLC of OHCs would be unmasked by block of TRPV-1 resulting from the harsh isolation. The *in vivo* effect of capsaicin on I_K , $I_{K,n}$ and NLC would augment any direct effect of capsaicin on TRPV-1 in accounting for our previous *in vivo* finding of reduced amplification. To be sure, the capsaicin concentration of our *in vivo* study (20 μ M) was found to produce a significant reduction of I_K , $I_{K,n}$ (Fig. 5) and a significant shift of NLC (Fig. 6). Nevertheless, we cannot rule out that capsaicin's action on IHCs and supporting cells may also have contributed to our *in vivo* findings.

In summary, we hypothesize that the reduction of I_K and $I_{K,n}$ by capsaicin led to a depolarization of OHCs, which consequently decreased the driving force for transduction current. The resulting reduced drive for OHC electromotility in combination with the direct action of capsaicin on electromotility was likely causal in reducing cochlear amplification. The possible contributory role of supporting cells and IHCs remains under investigation.

RESEARCH ARTICLE

Tyrosine motifs are required for prestin basolateral membrane targeting

Yifan Zhang^{1,*}, Iman Moeini-Naghani^{1,*}, JunPing Bai^{1,*}, Joseph Santos-Sacchi^{3,4} and Dhasakumar S. Navaratnam^{1,2,3,‡}

ABSTRACT

Prestin is targeted to the lateral wall of outer hair cells (OHCs) where its electromotility is critical for cochlear amplification. Using MDCK cells as a model system for polarized epithelial sorting, we demonstrate that prestin uses tyrosine residues, in a YXXΦ motif, to target the basolateral surface. Both Y520 and Y667 are important for basolateral targeting of prestin. Mutation of these residues to glutamine or alanine resulted in retention within the Golgi and delayed egress from the Golgi in Y667Q. Basolateral targeting is restored upon mutation to phenylalanine suggesting the importance of a phenol ring in the tyrosine side chain. We also demonstrate that prestin targeting to the basolateral surface is dependent on AP1B (μ1B), and that prestin uses transferrin containing early endosomes in its passage from the Golgi to the basolateral plasma membrane. The presence of AP1B (μ1B) in OHCs, and parallels between prestin targeting to the basolateral surface of OHCs and polarized epithelial cells suggest that outer hair cells resemble polarized epithelia rather than neurons in this important phenotypic measure.

KEY WORDS: Golgi, Hair cell, Tyrosine, Cell polarity, Protein sorting

INTRODUCTION

The cochlear amplifier is responsible for the exquisite sensitivity of mammalian hearing (Davis, 1983). There is considerable experimental data implicating electromotility of outer hair cells as integral to this process (Ashmore, 1987; Brownell et al., 1985; Dallos and Evans, 1995; Geisler, 1993; Geisler and Sang, 1995; Russell and Nilsen, 1997; Santos-Sacchi, 2003). Electromotility in outer hair cells is brought about by prestin, a transmembrane protein of the SLC26 family (Zheng et al., 2000), and molecular evidence has now confirmed its importance to cochlear amplification (Gao et al., 2007; Liberman et al., 2002; Mellado Lagarde et al., 2008). The localization of prestin along the lateral wall of these elongated cylindrical cells is critical to

electromotility (Dallos et al., 1991; Hallworth et al., 1993; Huang and Santos-Sacchi, 1993; Kalinec et al., 1992; Yu et al., 2006; Zheng et al., 2000). The presence of prestin along the lateral wall of the cell brings about the voltage mediated elongation and shortening of outer hair cells along its longitudinal axis. How prestin is targeted to the lateral wall of the cell has been indeterminate.

Hair cells are specialized epithelial cells that show features of both epithelial cells as well as neurons. Individual cells form apically located tight junctions with other cells and have apically located stereocilia that are analogous to apically located microvilli (Leonova and Raphael, 1997; Mahendrasingam et al., 1997). Hair cells resemble neurons in containing unstable membrane potentials that result from a plethora of voltage and mechanically sensitive ion channels. These channels are sharply segregated in the cell with mechanically sensitive channels located in stereocilia (Fettiplace, 2009). In contrast many of its voltage and ligand gated ion channels are located at the basolateral surface of the cell (Housley et al., 2006). Inner hair cells, in addition, have synaptic apparatus that is located at its basal pole (Glowatzki et al., 2008).

A large body of work in polarized epithelial cells has shown the segregation of proteins to the basolateral and apical ends of the cell that results in a segregation of function (Farr et al., 2009; Rodriguez-Boulan et al., 2005). This segregation of proteins occurs by sorting of proteins after exit from the Golgi. Since neurons demonstrate a similar segregation of function, it has been proposed that dendritic and axonal compartments are analogous to the basolateral and apical surface respectively of polarized epithelial cells (Bradke and Dotti, 1998; Dotti et al., 1991; Dotti and Simons, 1990; Pietrini et al., 1994). Hair cells, however, pose a dilemma since they have features of both epithelial cells and neurons. Critically, the dendritic and axonal ends of a hair cell are at opposite ends to the expected basolateral and apical ends of the cell. Thus mechanosensitive channels that serve as its receptors are present in stereocilia and not at the basolateral surface as would be expected by its dendritic extrapolation. Similarly, the synaptic apparatus of inner hair cells is located at the basal pole and not at the stereociliary apical end as would be expected by its axonal extrapolation.

A collation of previous experimental data would suggest that protein sorting in hair cells resembles that of polarized epithelial cells rather than neurons. Thus, prior work has shown the basolateral localization of a number of proteins that are classically sorted to the basolateral surface of polarized epithelial cells. These proteins include E-cadherin, β-catenin and Na/K ATPase in mammalian, chicken and zebrafish hair cells (Bian et al., 2011; Clemens Grisham et al., 2013; Leonova and Raphael, 1997; Mahendrasingam et al., 1997). Moreover, AP1B

(μ 1B), a protein subunit in the AP1B clathrin protein complex integral to the basolateral sorting apparatus, is present in hair cells and its loss is important for the sorting of Na/K ATPase to the basolateral surface of hair cells (Clemens Grisham et al., 2013). This protein subunit, which was identified as critical to hair cell function in a forward screening of hair cell dysfunction mutants in zebrafish, is normally present only in epithelial cells and not in other cell types including neurons (Ohno et al., 1999).

In this paper we demonstrate that prestin, the protein responsible for outer hair cell electromotility, is localized along the basolateral surface of polarized epithelial cells using a tyrosine signal motif that is dependent on the AP1B (μ 1B) subunit. These data further support an emerging concept that in hair cells protein sorting resembles that of epithelial cells rather than neurons. Previous work in other polarized CL4 epithelial cells have shown a similar sorting of two proteins, Espin and myosin Xa, associated with the stereociliary apparatus to the apical surface of the cell and prestin to the basolateral surface of the cell. The implications to this concept are significant.

MATERIALS AND METHODS

cDNA constructs and generation of mutants

Single or multiple amino acid substitutions were generated using QuickChange II or QuickChange II Multi site-directed mutagenesis kits (Stratagene, La Jolla, CA) with a gerbil prestin-YFP in pEYFPN1 vector (Clontech, Mountain View, CA) as a template. All mutations were confirmed by DNA sequencing, including the entire coding region.

Antibody labeling

Cells were fixed in 4% formaldehyde, washed in PBS 0.05% Tween 20, 0.05% Triton-X 100 (incubation buffer) three times, and incubated with primary antibody in incubation buffer overnight at 4°C. The primary antibodies were goat anti-prestin antibody (1:500, N-20 prestin, Santa Cruz, CA) mouse anti- β -catenin (1:50, Becton Dickinson), mouse anti-Na/K ATPase (1:20, Affinity Bioreagents), and goat anti-AP1B (μ 1B) (1:100, Santa-Cruz). After three washes in incubation buffer the cells/tissue was incubated with secondary antibody in incubation buffer for 1 hour at room temperature. Secondary antibodies used included goat anti-mouse Alexa 647 (1:200, Becton Dickinson) and Donkey anti-goat (Beckton-Dickinson, 1:200). Actin was detected using Phalloidin Alexa 546 (1:200, Beckton-Dickinson) added to the secondary antibody. Cells were washed in incubation buffer mounted in Vectashield and viewed using a Zeiss 510 laser scanning microscope.

Cochlea processing

Tissue from 3+ week old mice (C57BL/6) were obtained after animals were euthanized using CO₂ asphyxiation in accordance with Yale University IACUC protocol. The temporal bones were isolated and placed in 4% formaldehyde overnight after opening the round and oval windows. Cochlea were removed after micro-dissection of the temporal bones washed in incubation buffer three times and processed for immunostaining as described above.

Cell transfection and imaging

MDCK and LLC-PK cells were a gift from Dr Michael Caplans lab, Yale University (in turn obtained from ATCC) and cells were not subject to STR profiling. MDCK and LLC-PK cells plated on glass coverslips (or where applicable HEK cells and CHO cells) were transiently transfected with constructs using Fugene6 according to the manufacturer's instructions (Promega, Madison, WI). Cells were plated at 100% confluency to ensure polarization, and transfected 36 hours after plating. Cells were fixed at 30 hours after transfection unless otherwise indicated. Cells were imaged by confocal microscopy using a Zeiss LSM 510/510 meta after fixation as previously described (Bai et al., 2011). Image parameters (scan time per pixel, pixel density, z step) were kept constant in a given experimental paradigm to allow reliable comparison.

In siRNA experiments, MDCK cells were electroporated with Prestin YFP and siRNA to the medium subunit of AP1B (μ 1B) as previously described (Gravotta et al., 2007). We used a previously proven siRNA to μ 1B siRNA (μ 1B-M16 sequence 5'-AACAAAGCTGGTACTGGCAAAA-3' (Gravotta et al., 2007)] and a control chicken β -4 siRNA (chick KCNMB4, (Bai et al., 2011)) that were custom synthesized (Dharmacon, Lafayette, CO). Briefly, μ 1B siRNA (or chick KCNMB4 siRNA in control experiments) at 5 nM and PrestinYFP plasmid at 10 nM was resuspended with 1 million trypsinized MDCK cells in 100 μ l of DMEM. Cells were electroporated using a square wave pulse with the following parameters: 300 V for 100 μ s \times 1 and 25 V for 20 ms \times 11 with a 100 ms pause in between. The entire electroporation protocol was repeated once. Cells were incubated on ice for 30 minutes and plated in prewarmed complete medium in 24 well plates on glass coverslips at a density of 350,000 cells per well (100% confluency). The medium was changed daily and cells were fixed and imaged 72 hours later.

Sixteen bit Images were acquired on a Zeiss 510 laser scanning microscope using a 63 \times water immersion lens (N.A 1.4), with fixed laser settings, a scan rate of 6.4 μ s per pixel, a pinhole aperture of 1.0 Airy units, and fixed detector gain. Regions of interest were identified and fluorescence data extracted. We established that the fluorescence intensity was within the linear range and used mean fluorescence density as a measure of protein concentration.

Gated STED

Gated STED, a new method of super resolution confocal microscopy, was used to visualize prestin expression in OHCs. Mouse cochlea were dissected and incubated with anti-prestin antibody (1:100 goat anti-prestin, Santa Cruz, CA) in incubation buffer overnight at 4°C. Tissue was washed three times with incubation buffer and then incubated with donkey anti-goat Oregon Green 488 (1:100, Beckton Dickinson) at room temperature for 1 hour. Cells were washed three times in incubation buffer followed by two washes in PBS. Tissue was mounted in Prolong Gold (Invitrogen) and viewed using a Leica TCS SP8 Gated STED microscope (Vicidomini et al., 2011).

Image processing and data analysis

Images were processed after acquisition using Volocity software (Perkin Elmer, CA). Pearson's correlation was calculated after automated thresholding using the method of Costes et al. (Costes et al., 2004). All results are given as mean \pm s.e.m. Where appropriate, ANOVA with Bonferroni Multiple Comparisons test was used to test for significance in differences (Instat3, CA).

Electrophysiological recording

For electrophysiological recordings 100,000 Chinese hamster ovary (CHO) cells were transfected in 24-well plates using Lipofectamine (Invitrogen, Carlsbad, CA) as previously described (Bai et al., 2011).

Cells were recorded by whole-cell patch clamp configuration at room temperature using an Axon 200B amplifier (Axon Instruments, CA), as described previously (Bai et al., 2011). Cells were recorded 24–48 hours after transfection to allow for stable measurement of non-linear capacitance. Ionic blocking solutions were used to isolate capacitive currents. The bath solution contained (in mM): TEA 20, CsCl 20, CoCl₂ 2, MgCl₂ 1.47, Hepes 10, NaCl 99.2, CaCl₂·2H₂O 2, pH 7.2, and the pipette solution contained (in mM): CsCl 140, EGTA 10, MgCl₂ 2, Hepes 10, pH 7.2. Osmolarity was adjusted to 300 \pm 2 mOsm with dextrose. Command delivery and data collections were carried out with a Windows-based whole-cell voltage clamp program, jClamp (Scisoft, New Haven, CT), using a Digidata 1322A interface (Axon Instruments, CA).

Capacitance was evaluated using a continuous high-resolution 2-sine wave. Capacitance data were fitted to the first derivative of a two-state Boltzmann function:

$$C_m = Q_{max} \frac{ze}{kT} \frac{b}{(1+b)^2} + C_{lin},$$

where

$$b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right).$$

Q_{\max} is the maximum nonlinear charge transfer, V_h the voltage at peak capacitance or half-maximal nonlinear charge transfer, V_m the membrane potential, C_{lin} linear capacitance, z the valence (a metric of voltage sensitivity), e the electron charge, k the Boltzmann's constant and T the absolute temperature. Q_{\max} is reported as Q_{sp} the specific charge density, i.e. total charge moved normalized to linear capacitance. A student's t -test was used to evaluate the effects of mutants on the different parameters of NLC.

RESULTS

OHCs express prestin and other basolateral markers along baso-lateral wall, and express the AP1B ($\mu 1\beta$) subunit

Previous theoretical treatments confirmed by electrophysiological and immunolocalization experiments have demonstrated the localization of prestin along the lateral wall of OHCs. We sought to further confirm these data using high resolution confocal microscopy. Adult mice cochlea were stained with anti-prestin antibodies and visualized using gated STED microscopy. As shown in Fig. 1 prestin is sharply localized along the lateral wall of the OHCs. The protein staining was uniform through the lateral wall. At the basolateral pole of the cell however, there was a patchy clustering of prestin. In contrast, there was a gradual tapering of prestin staining at the apical end of the cell.

The localization of prestin to the basolateral surface of outer hair cells led us to reason that outer hair cells are analogous to polarized epithelial cells with anatomical and functional segregation of the cell into an apical and basolateral compartments. The apical segregation of the stereociliary apparatus and the basolateral segregation of the cochlear amplifier are consistent with this separation. Prior work in hair cells of different species has shown the presence of β -catenin and Na/K ATPase, two proteins identified as classically localized in the basolateral compartment of polarized epithelial cells, to be present in the basolateral surface of hair cells. As shown in Fig. 1 these two proteins – β -catenin and Na/K ATPase – were found to segregate along the basolateral surface of outer hair cells (Fig. 1), further confirming similarities between outer hair cells and polarized epithelial cells. We also determine that OHCs express the AP1B ($\mu 1\beta$) subunit that has been shown to be important for basolateral sorting of proteins in polarized epithelial cells (Fig. 1).

Prestin has several tyrosine residues within a basolateral targeting sequence of which Y520 and Y667 are important for basolateral sorting

In order to establish an experimental model system to tease apart the mechanisms underlying prestin's basolateral targeting, we expressed it in MDCK cells. These cells have a long history of being used as a model system for studying polarized sorting in epithelial cells. As shown in Fig. 2 prestin tagged with YFP at its C-terminus is targeted to the basolateral surface of MDCK cells. The protein shows a similar pattern of distribution to β -catenin and Na/K ATPase, both well known basolaterally targeted proteins. Prestin lacking a YFP tag showed similar targeting to the basolateral membrane (data not shown).

A number of sequence motifs in a protein are important for the targeting of a protein to the basolateral surface of polarized epithelial cells. Prestin has several tyrosine residues contained within a YXX Φ motif in its C-terminus, and lacks other targeting motifs classically associated with basolateral targeting (including

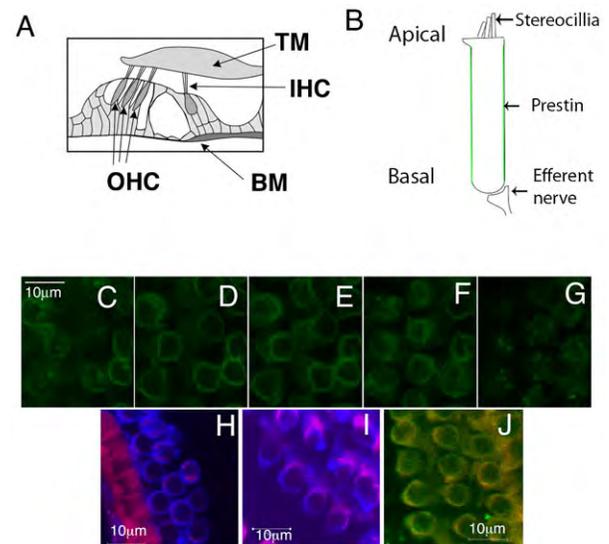

Fig. 1. Prestin in mouse outer hair cells is localized along the lateral wall of the cell along with β -catenin and Na/K ATPase. Shown are cartoons of the organ of Corti (A) and its contained outer hair cells. TM, tectorial membrane; BM Basilar membrane; IHC, inner hair cell; OHC Outer hair cell. (B) A model of an outer hair cell in which prestin is shown lining its lateral wall (green). (C–G) The figure shows serial X-Y sections of mouse outer hair cells labeled with an anti-prestin antibody and then visualized using a Leica gated STED microscope. The sections start at the apical end (left) and end at the basal end (right). There is a uniform labeling of prestin along the lateral wall of the cell (middle three panels). Prestin labeling at the apical end of the cell tapers (C). Similarly, there is a patchy clustering of prestin at the basal pole of the cell (G). Mouse outer hair cells immunostained with antibodies to the basolateral markers β -catenin (H) and Na/K ATPase (I), and demonstrates the localization of these proteins (blue) along the lateral wall of the cell. The cells were counterstained with phalloidin Alexa 546 (red), which shows the presence of the sub cortical lattice of actin along the lateral wall of the cell. (J) The AP1 μ 1B subunit (green) is present in outer hair cells evidenced by antibody labeling of these cells. The figure shows co labeling of these cells with Na/K ATPase (red). Scale bar is 10 microns. These experiments were repeated five times.

dileucine motifs, NPxY) (Brewer and Roth, 1991; Cancino et al., 2007; Gonzalez and Rodriguez-Boulan, 2009; Gravotta et al., 2007; Hunziker et al., 1991; Lin et al., 1997; Matter et al., 1992; Rodriguez-Boulan and Gonzalez, 1999; Weisz and Rodriguez-Boulan, 2009). These include the tyrosine residues Y520, Y526, Y616 and Y667 (shown in cartoon form in the two alternative membrane spanning models of prestin in supplementary material Fig. S1). In order to ascertain the importance of these residues for basolateral targeting, we individually mutated these residues and determined their basolateral localization. As shown in Fig. 2 mutation of Y520Q, and to a lesser extent Y667Q, resulted in a reduced expression of prestin on the basolateral surface of the cell. There was both increased intracellular retention (Fig. 2) of the protein as well as targeting to the apical surface of the cell (Fig. 3).

In order to further confirm that the effects of these mutations were specific in bringing about deficient basolateral targeting we sought to determine the effects of these mutations on the surface expression of prestin in non-polarized HEK and CHO cells. As shown in Fig. 4 wt type prestin and prestin with mutations at Y520 and Y667 were both targeted to the cell surface. However, both these mutations affected the function of the molecule. In CHO cells expressing these mutant proteins, an increase in non-linear

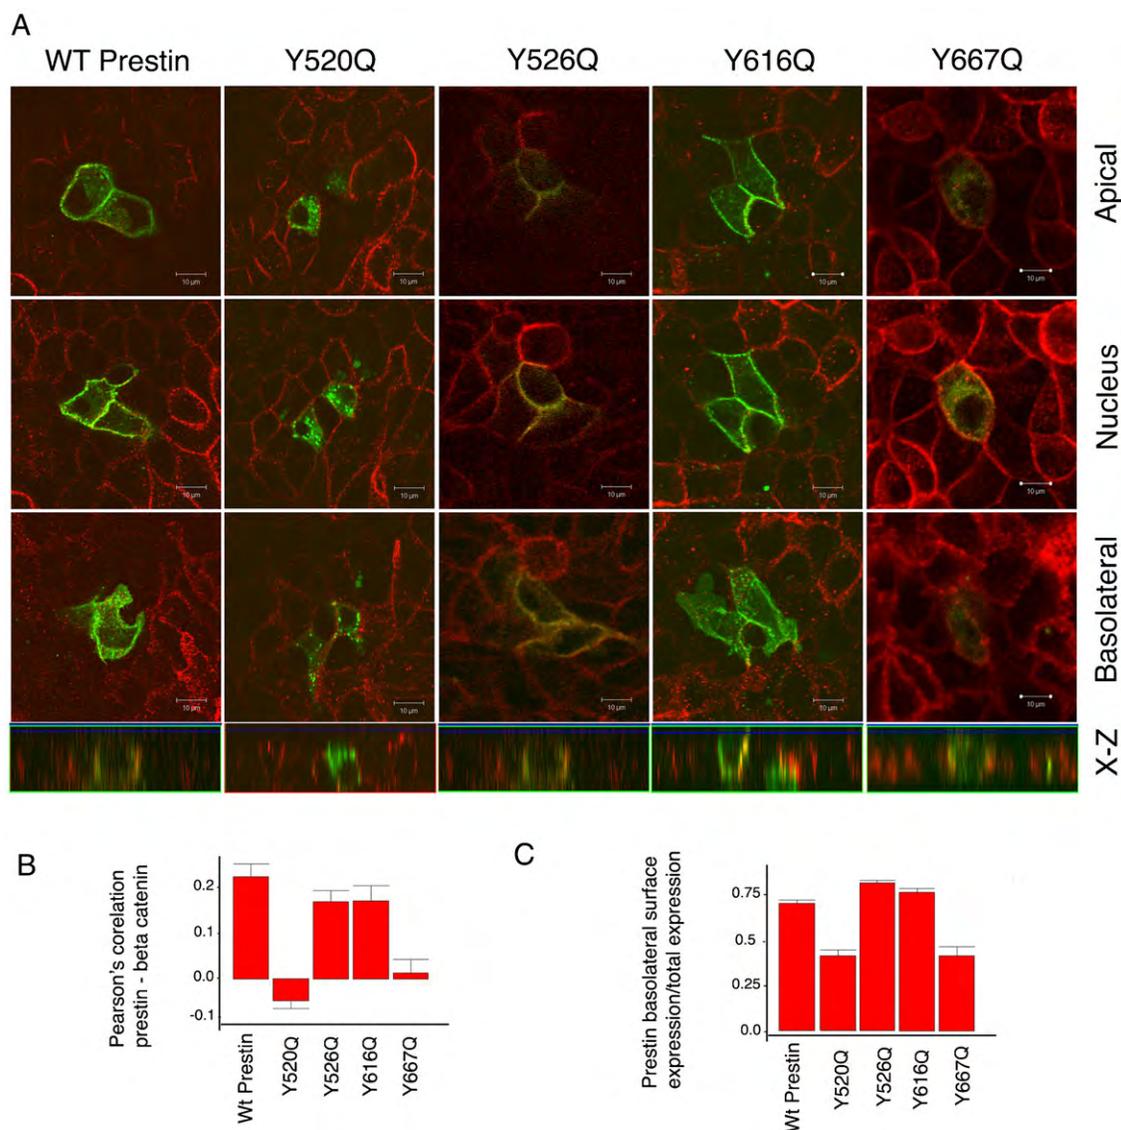

Fig. 2. Y520 and Y667 contained within the YXX Φ motif are important for basolateral targeting of prestin in MDCK cells. The figure shows MDCK cells transiently transfected with wild type prestin and mutations of prestin: Y520Q, Y526Q, Y616Q and Y667Q. The cells were fixed after 36 hours. Prestin was tagged with YFP at its C-terminus (green) and the cells were stained with an antibody to β -catenin. Shown are serial X-Y confocal sections along the z axis (A). The corresponding X-Z sections are shown at the bottom. Mutations at Y520 and Y667 result in a failure to target the basolateral surface of the cell along with intracellular retention of the protein and apical trafficking. (B,C) Pearson's correlation of prestin with β -catenin and a ratio of prestin fluorescence on the surface of the cell compared to the total in the cell. The mean Pearson's correlation values were: wt 0.23 (\pm 0.028SE, $n=7$); Y520Q -0.045 (\pm 0.016 SE, $n=7$); Y526Q 0.17 (\pm 0.025 SE, $n=14$); Y616Q 0.175 (\pm 0.033 SE, $n=14$); Y667Q 0.01386 (\pm 0.03 SE, $n=10$). The differences between wt and Y520Q and Y667Q were considered significant. A one way ANOVA (parametric) with Bonferroni post test comparison yielded a p value of <0.001 for wt vs Y520Q and wt vs Y667Q; wt vs Y616Q and Y667Q were not significant. The mean surface to total ratios were: wt 0.67 (\pm 0.016 SE, $n=22$); Y520Q -0.39 (\pm 0.0129 SE, $n=20$); Y526Q 0.78 (\pm 0.013 SE, $n=13$); Y616Q 0.73 (\pm 0.02 SE, $n=13$); Y667Q 0.40 (\pm 0.044 SE, $n=13$). Here too the differences between wt and Y520Q and Y667Q were significant. A one-way ANOVA (parametric) with Bonferroni post-test comparison yielded a p value of <0.001 for wt vs Y520Q and wt vs Y667Q. The scale bar is 10 microns.

capacitance, the widely accepted functional surrogate for electromotility, was absent with Y520Q and markedly diminished with Y667Q. Supplementary material Table S1 shows the parameters for NLC in these mutants.

The phenol ring within the tyrosine residues (Y520 and Y667) are important for basolateral targeting

We sought to determine the importance of the stereo chemical properties of the tyrosine residue at position 520 and 667 to ascertain its effects on targeting to the basolateral surface of

MDCK cells. We mutated individual tyrosine residues to serine or phenylalanine to mimic the effects of the side chain hydroxyl group and phenol ring respectively. We determined that substitution of tyrosine with phenylalanine at Y520 resulted in near complete recovery in basolateral targeting (Fig. 5). In contrast, mutation of Y520 to a serine residue (to mimic the side chain OH group) resulted in poor delivery of the protein to the basolateral surface (Fig. 5). Similarly, it is unlikely that the effects of these other mutations are mediated by their size or hydrophilicity since mutation of Y520 to alanine failed to restore

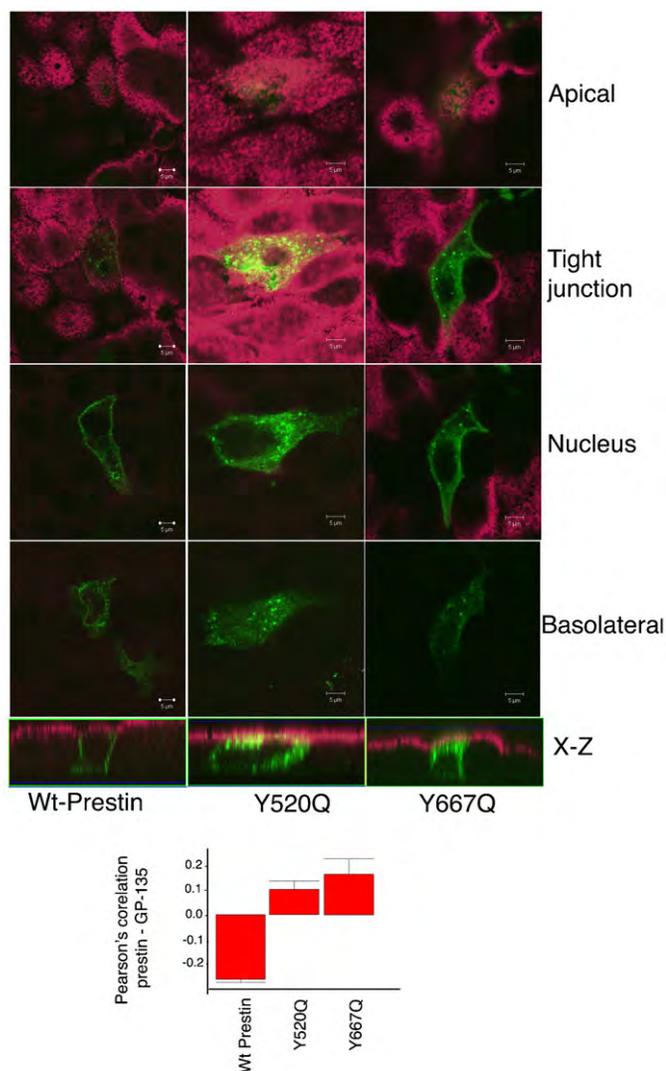

Fig. 3. Mutation of Y520 and Y667 result in increased delivery of prestin to the apical surface of MDCK cells. MDCK cells transiently transfected with wt prestin YFP and the two constructs Y520Q prestin YFP, and Y667Q prestin YFP were fixed at 36 hours and stained with antibody to the apical marker GP130 (podohexin). There is significant apical targeting of Y520Q and Y667Q evident in the serial X-Y sections along the z axis and the corresponding X-Z sections at the bottom. The bottom panel shows Pearson's correlation of prestin YFP and GP130 confirming absent apical targeting of the wild type construct and apical targeting of Y520Q and Y667Q. The mean Pearson's correlation values were: wt -0.027 (± 0.011 SE, $n=7$); Y520Q 0.105 (± 0.035 SE, $n=5$); Y667Q 0.17 (± 0.063 SE, $n=11$). The differences between wt prestin and Y520Q and wt prestin and Y667Q were significant. A one-way ANOVA (parametric) yielded a p value of <0.01 between wt prestin and Y520Q, and a p value of <0.001 between wt prestin and Y667Q. The scale bar is 5 microns.

basolateral targeting of prestin (Fig. 5). Similar effects were seen with mutation of Y667.

Mutation of Y520 and Y667 residues results in retention within the Golgi

Previous experiments in other proteins targeted to the basolateral surface have shown that sorting of proteins is determined at the Golgi. We hypothesized that mutation of tyrosine residues at Y520 and Y667 would result in retention of the protein within the Golgi

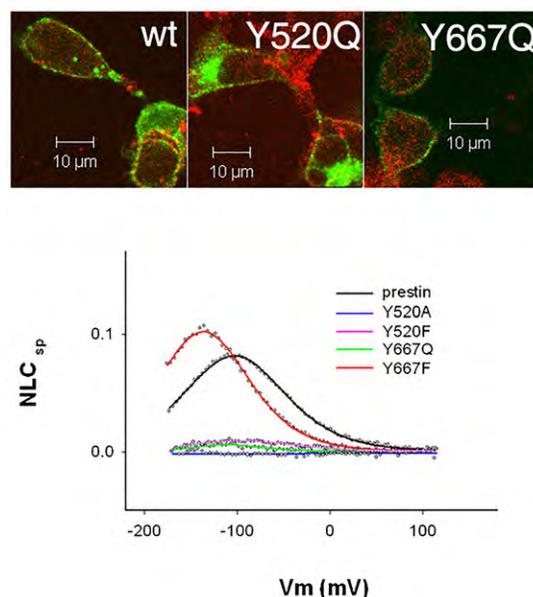

Fig. 4. Mutation of Y520Q and Y667Q results in targeting of prestin to the plasma membrane of HEK cells, and presence of NLC in Y667Q, Y520F and Y667F. The upper panels show HEK cells transfected with wild type prestin-YFP, and the two constructs Y520Q prestin YFP, and Y667Q prestin YFP that were fixed 48 hours after transfection. Cells were stained with antibodies to Na/K ATPase and visualized by confocal microscopy. Wild type prestin YFP, Y520Q prestin YFP and Y667Q prestin YFP all target the plasma membrane as evidenced by its co-localization with plasma membrane Na/K ATPase. The lower panel shows NLC traces of different mutations at Y520 and Y667. The actual values of NLC parameters along with cell numbers are given in supplementary material Table S1. The scale bar is 10 microns.

(and could explain at least partially, the increased amounts of the mutated protein retained within the cell). MDCK cells transfected with prestin YFP, Y520Q, or Y667Q were fixed at different times after transfection and retention within the Golgi determined by co-localization with the Golgi specific protein Giantin (Fig. 6) (Deborde et al., 2008). We determined that mutation of Y520Q resulted in a persistent retention of prestin within the Golgi. In contrast, Y667Q showed retention of prestin within the Golgi, which improved with time. Thus, Y667Q was localized within the Golgi at 12, 20 and 30 hours after transfection but demonstrated increasing efflux from the Golgi at 40 hours. In contrast, wt prestin had made a near complete exit from the Golgi by 20 hours. Y520Q showed little egress from the Golgi with continued retention within that organelle even at 40 hours.

Prestin exit from the Golgi to the plasma membrane is mediated by early recycling endosomes

We then sought to determine the identity of organelles responsible for movement of prestin from the Golgi to the plasma membrane. For these experiments we transfected prestin YFP into MDCK cells. Transfected cells were kept at 19°C to allow accumulation of protein within the Golgi (Golgi block) (Bian et al., 2013). Cells were incubated with transferrin Alexa 647 applied to cells for 10 minutes to label early/recycling endosomes. The cells were then immersed in fresh culture medium and fixed at different time points after raising the temperature to 37°C to release proteins from Golgi block. As shown in Fig. 7 there was co-localization of vesicles containing

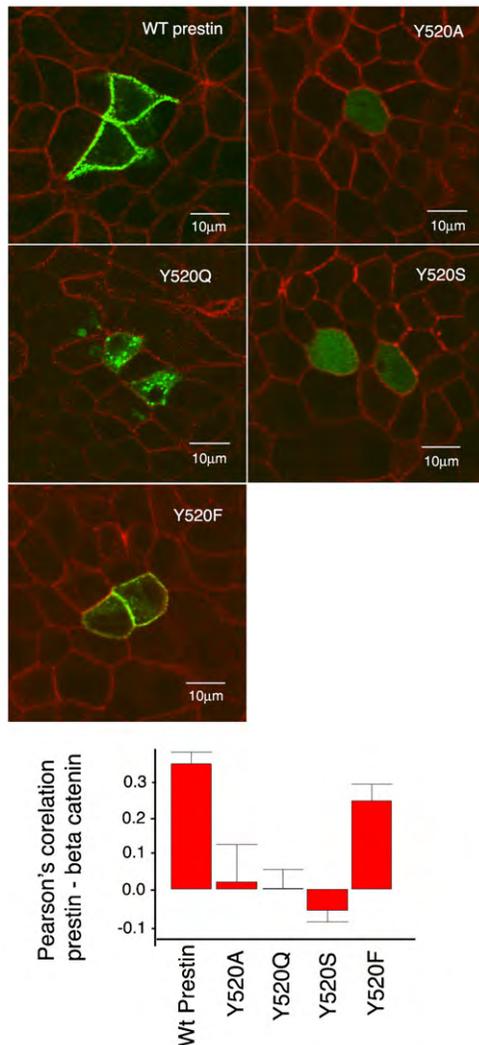

Fig. 5. The phenol ring in the tyrosine residue is critical for the targeting of prestin to the basolateral surface of MDCK cells. MDCK cells transiently transfected with prestin YFP and the mutations Y520Q, Y520A, Y520S and Y520F were fixed 36 hours after transfection and imaged by confocal microscopy. The basolateral wall of the cell was visualized by immunostaining with anti- β -catenin antibody. The mutations Y520A, Y520Q, and Y520S failed to target the basolateral surface of the cell, while Y520F was targeted to the basolateral surface of the cell. Pearson's correlation between prestin YFP and β -catenin confirm the observed co-localization of wild type prestin-YFP with β -catenin and Y520F with β -catenin. The mean Pearson's correlation values were: wt prestin 0.34 (\pm 0.033 SE, $n=8$); Y520A 0.019 (\pm 0.10 SE, $n=5$); Y520Q 0.002 (\pm 0.052 SE, $n=5$); Y520S -0.05 (\pm 0.03, $n=6$); Y520F 0.25 (\pm 0.045 SE, $n=6$). A one way ANOVA revealed significant differences between wt prestin and Y520A ($P<0.01$), wt prestin and Y520Q ($P<0.001$), and wt prestin and Y520S ($P<0.001$). The differences between wt prestin and Y520F were not significant. The scale bar is 10 microns.

both prestin YFP and transferrin Alexa 647. We interpret this data to suggest that prestin YFP use early/recycling endosomes to reach the basolateral surface of the cell.

Prestin targeting to the basolateral surface also involves the AP1B (μ 1B) pathway

In other systems the use of tyrosine motifs for basolateral sorting in polarized epithelial cells has been shown to involve the AP1B

(μ 1B) pathway. We sought to ascertain if AP1B (μ 1B) was important for sorting prestin to the basolateral surface of polarized epithelial cells. In initial experiments we used LLC-PK cells, which lack the AP1B (μ 1B) subunit. In these cells Prestin YFP shows decreased targeting to the basolateral surface of the cell (supplementary material Fig. S2). We then used siRNA knockdown of AP1B (μ 1B) to determine targeting of prestin YFP in MDCK cells. In these cells knock down treatment with siRNA to AP1B (μ 1B) resulted in apical targeting of the protein and reduced expression of the protein on the basolateral surface of the cell (Fig. 8).

DISCUSSION

In this paper we show for the first time that prestin is sorted to the basolateral surface of polarized epithelial (MDCK) cells using a tyrosine motif. We identified two tyrosine residues contained in the cassette YXX Φ motif that are likely important for its localization to the basolateral surface of the cell. Mutation of one of these residues Y520 resulted in apical targeting and intracellular retention of the protein. A second mutation of Y667 resulted in delayed exit from the Golgi to the basolateral surface with initial targeting to the apical surface of the cell and intracellular retention. With increasing time, however, there was progressive localization of this mutant at the basolateral surface of the cell. We believe mutation of these residues resulted in specific loss of basolateral targeting since the mutant protein was targeted to the apical surface of MDCK cells and since the protein showed plasma membrane targeting in non-polarized CHO and HEK cells. Nevertheless, it still remains a possibility that the loss of basolateral targeting resulted from a subtle misfolding of the protein that also affected its normal function. We were unable to demonstrate normal function as measured by the presence of non-linear capacitance in these mutants expressed in CHO cells (Y520Q showed absent NLC while Y667Q showed diminished NLC). In this context, it should be noted that several mutations that also affected prestin function by subtle alterations in its folding, show normal basolateral targeting in MDCK cells (data not shown). We would also like to note previous experiments by Zheng et al. (Zheng et al., 2005), in which mutation of Y520 and Y526 together failed to show targeting to the surface of TSA and OK cells. We do not have an explanation for the discordance in our data although the experiments are not strictly comparable since Zheng et al. (Zheng et al., 2005) were describing the targeting of a double mutant (Y520A and Y526A) while we describe the targeting of single mutations (Y520 or Y667).

Our interpretation that prestin is sorted to the basolateral surface of cells using a tyrosine motif is further substantiated by two other related findings. First, we demonstrate that AP1B (μ 1B) is important for basolateral targeting, since expression of prestin in LLC-PK cells that lack this subunit resulted in decreased basolateral targeting. Moreover knockdown of AP1B (μ 1B) in MDCK cells also resulted in increased apical targeting of prestin with deficient basolateral targeting of the protein. It is now believed that the tyrosine residues are critical for direct interaction with AP1B (μ 1B) and bringing about basolateral targeting of proteins (Bonifacino and Dell'Angelica, 1999; Carvajal-Gonzalez et al., 2012; Fields et al., 2007). We also demonstrate using Golgi block experiments that prestin uses recycling endosomes as a post Golgi transport intermediate to transit from the Golgi to the basolateral plasma membrane. The use of AP1B (μ 1B) has been demonstrated by several other proteins using tyrosine residues contained in a YXX Φ motif to

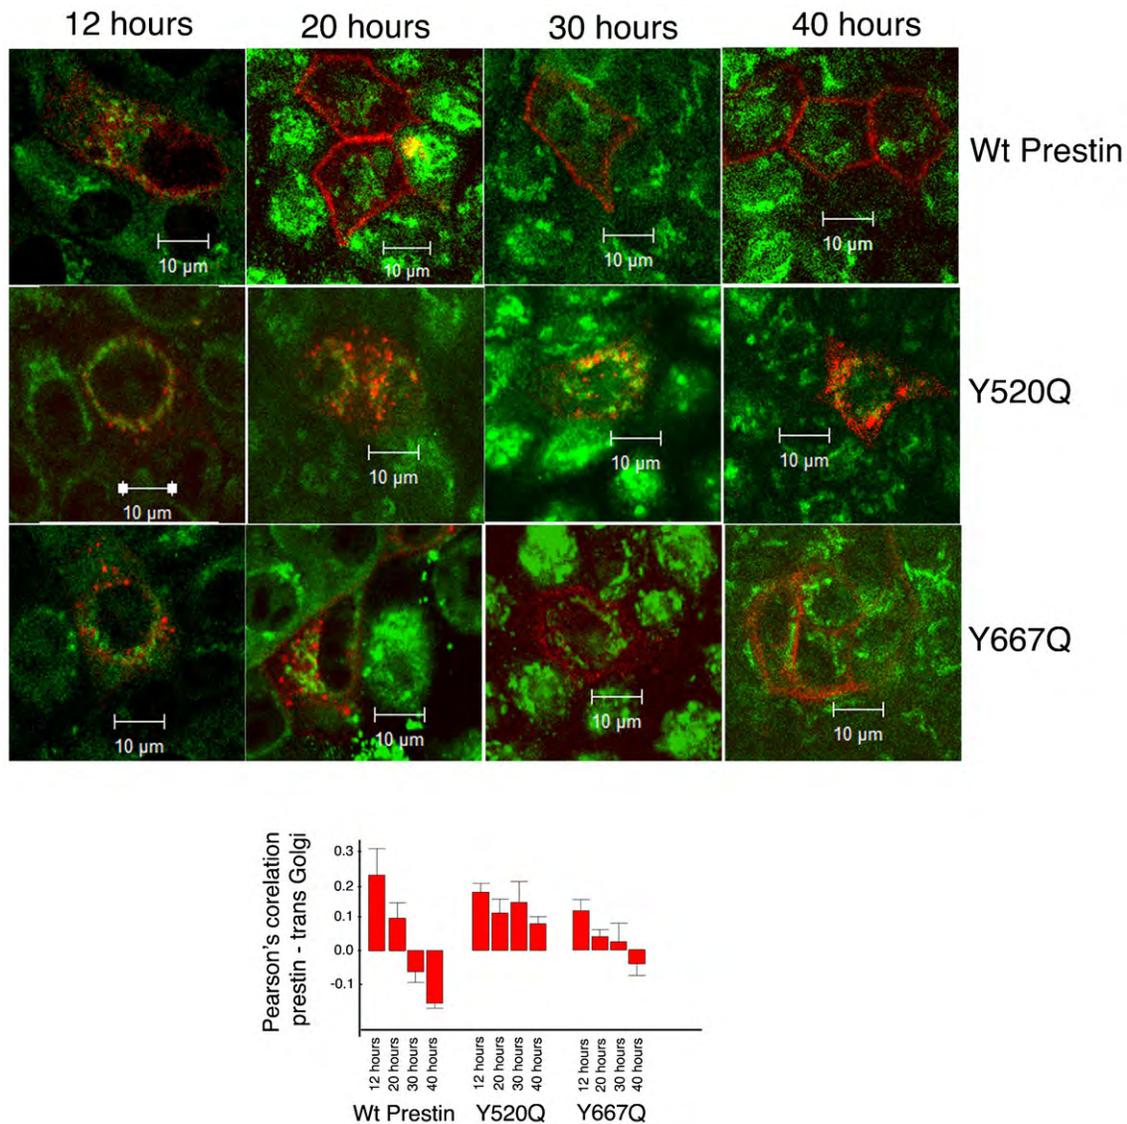

Fig. 6. Egress from the Golgi is poor/absent in Y520Q and delayed in Y667Q. MDCK cells transiently transfected with prestin YFP, and the mutations Y520Q and Y667Q contained in the prestin YFP cassette were fixed after 12, 20, 30 and 40 hours after transfection. The cells were then stained with antibodies to the Golgi protein Giantin. While prestin YFP exits the Golgi at 20 hours, Y520Q does not egress from the Golgi and Y667Q leaves the Golgi after 40 hours. A graphical form of Pearson's correlation between prestin YFP and Giantin at the different time points is shown below. For wt prestin there was a significant difference on one way ANOVA between the Pearson's correlation between prestin and Giantin at all times compared to 12 hours: 12 hours vs 20 hours, $P < 0.05$; 12 hours vs 30 hours, $P < 0.001$; and 12 hours vs 40 hours $P < 0.001$. In contrast, the differences in Pearson's correlation between Y520Q and Giantin at all times compared to 12 hours were not significantly different ($P > 0.05$ on one way ANOVA). For Y667Q the Pearson's correlation with Giantin was significantly different on one way ANOVA between 12 hours and 40 hours ($P < 0.05$), while the remaining two time points were not significantly different (12 hours vs 20 hours, $P > 0.05$; 12 hours vs 30 hours, $P > 0.05$). The mean values for the different time points were as follows: wt prestin 12, 20, 30 and 40 hours: 0.23 (± 0.08 SE, $n=5$), 0.09 (± 0.04 SE, $n=10$), -0.06 (± 0.03 SE, $n=12$), -0.162 (± 0.02 SE, $n=13$); Y520Q 12, 20, 30 and 40 hours: 0.17 (± 0.02 SE, $n=5$), 0.114 (± 0.04 SE, $n=6$), 0.145 (± 0.06 SE, $n=13$), 0.08 (± 0.02 SE, $n=8$); Y667Q 12, 20, 30 and 40 hours: 0.112 (0.03 SE, $n=13$), 0.04 (± 0.02 SE, $n=9$); 0.026 (± 0.05 SE, $n=8$) and -0.04 (± 0.03 SE, $n=8$). The scale bar is 10 microns.

target the basolateral membrane (Adair-Kirk et al., 2003; Ang et al., 2004; Duffield et al., 2004; Fields et al., 2007; Fölsch et al., 1999; Fölsch et al., 2003; Gravotta et al., 2007; Sugimoto et al., 2002). Moreover, the use of transferrin containing endosomes has been shown with basolateral proteins that use a tyrosine motif to exit the Golgi (Ang et al., 2004; Donoso et al., 2009). In prior experiments membrane targeting to the surface of CL4 cells, which are derived from LLC-PK1 cells have been

observed (Zheng et al., 2010). In the absence of data on the expression of AP1B ($\mu 1B$) in CL4 cells used for these experiments or the relative surface expression of prestin in these cells, it is difficult to comment on the significance of these data (Zheng et al., 2010).

The implications to our data are greatest to hair cells. Our data further suggest that hair cells are similar to polarized epithelial cells with differential sorting of proteins to the apical

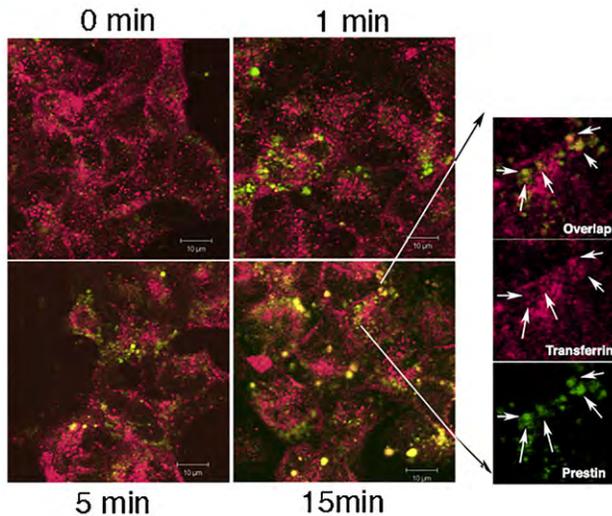

Fig. 7. Prestin YFP uses transferrin containing endosomes to transit from the Golgi to the basolateral membrane. MDCK cells were transiently transfected with prestin-YFP and kept at 19°C to induce Golgi block. Cells were incubated with transferrin - Alexa 647 for 10 minutes. The incubation temperature was raised to 37°C after which cells were fixed at 0, 1 minute, 5 minutes, 10 minutes and 15 minutes. Cells were then imaged with confocal microscopy. Shown are confocal images in the X-Y plane at the basolateral Z axis of the cell that were fixed at different times after raising the temperature to 37°C. With increasing time there is co-localization of prestin-YFP exiting the Golgi with transferrin - Alexa 647. The right hand panels shows merged and individual Alexa 647 and prestin-YFP images of an enlarged area at 15 minutes after raising the temperature to 37°C. Co-localization of prestin YFP and transferrin 647 is demonstrated. The scale bar is 10 microns.

and basolateral surface of the cell. Hair cells could be thought of as having different compartments – an apical surface important for transducing sound and a basal pole that is important for synaptic transmission in inner hair cells and a basolateral pole that is important for housing the cochlear amplifier and its processes. Our data suggest that integral to this segregation of function is the segregation of proteins to different apical and basal compartments of the cell along the lines demonstrated in polarized epithelial cells. Other work has also shown the apical sorting in CL4 cells of proteins identified as important for stereociliary and transduction function in hair cells (Zheng et al., 2010). At least in the context of protein sorting, hair cells seem to have retained features of polarized epithelial cells rather than neurons. The expected segregation of proteins along a dendritic and axonal separation would result in a reversal of the observed localization of proteins in hair cells. Perhaps one explanation for this unexpected finding is that hair cells resemble epithelial cells more than they do neurons. Importantly, hair cells are derived from the embryonic otic placode, a thickened segment of the cranial ectoderm that invaginates separately from the neural tube to form the otocyst. Consistent with its epithelial phenotype, hair cells express the clathrin adaptor protein AP1B (μ 1B) subunit that is present only in polarized epithelial cells and lacking in neurons. Significantly, this subunit is important for the localization of several proteins that, like prestin, use a tyrosine motif to target to the basolateral surface of the cell. It remains to be established if prestin uses tyrosine residues and /or the AP1B (μ 1B) subunit to target to the lateral wall of outer hair cells.

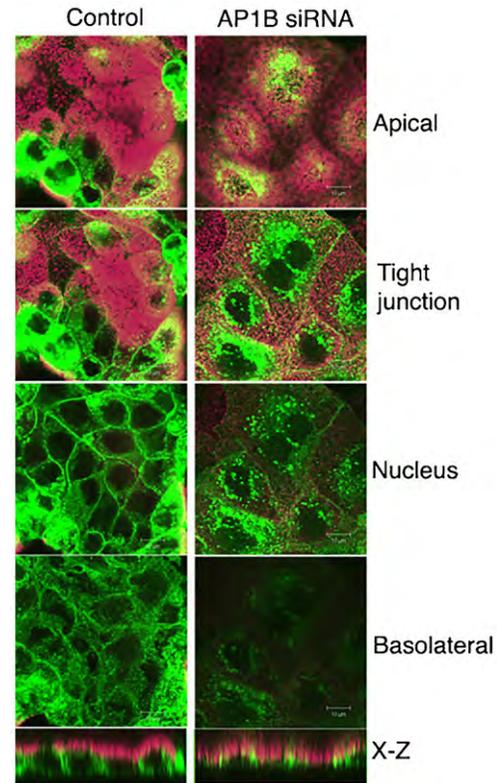

Fig. 8. Targeting of prestin YFP to the basolateral membrane requires AP1B (μ 1B). MDCK cells were electroporated with prestin YFP plasmid and siRNA to AP1B (μ 1B). Cells were plated at confluent density and fixed after 30 hours. Cells were stained with antibodies to the apical marker GP130 and visualized by confocal microscopy. Shown are X-Y images along the z axis of transfected cells. The lowest panel shows the corresponding X-Z sections. Transfection of MDCK cells with siRNA to AP1B (μ 1B) resulted in an apical localization of prestin YFP and near absence in targeting to the basolateral surface. In contrast, cells co-transfected with control siRNA (chicken KCNMB4) resulted in basolateral targeting of prestin YFP. The scale bar is 10 microns.

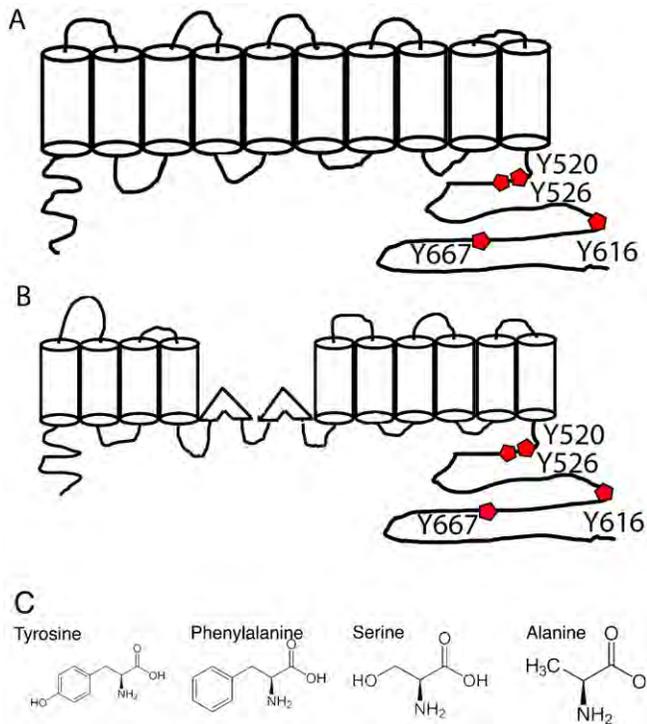

Fig. S1. A cartoon of the localization of individual C-terminal tyrosine residues within the 10 (A) and 12 (B) transmembrane models of prestin are shown. (C) The structure of individual residues including phenylalanine, serine and alanine used to substitute for individual tyrosine residues are compared.

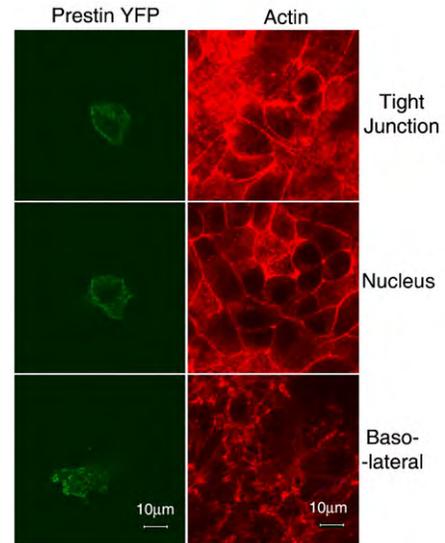

Fig. S2. LLC-PK cells show deficient basolateral targeting of prestin YFP. Confluent polarized LLC-PK1 cells were transfected with prestin YFP (green) and imaged by confocal imaging after fixation 72 hours later. Shown are serial X-Y sections along the z axis of a transfected cell (at the level of the tight junction, nucleus and basolateral surface). The actin cytoskeleton was stained with Phalloidin Alexa 647 (red). There is reduced targeting of prestin at the basolateral surface of the cell.

Table S1. Parameters of non linear capacitance in prestin and specific tyrosine mutants

	Q_{sp} (fC/pF)	V_h (mV)	z	n
Prestin	10.73±1.02	-115.44±4.32	0.78±0.02	7
Y667F	17.57±3.56	-149.18±8.34	0.82±0.02	5
Y667Q	0.92±0.24	-103.39±8.73	0.81±0.05	5
Y520F	2.75±0.75	-97.62±6.03	0.81±0.03	6

Measures of NLC in different mutants of prestin at Y667 and Y520 are compared. Other mutations at these sites did not show NLC. Note that substitution of Y520 and Y667 with a phenyl alanine residue resulted in divergent effects on V_h with the former causing a mild depolarization shift while the latter caused a marked hyperpolarization shift. The latter was also associated with an increase in Q_{sp} .

Effect of Membrane Tension on Gap Junctional Conductance of Supporting Cells in Corti's Organ

HONG-BO ZHAO and J. SANTOS-SACCHI

From the Sections of Otolaryngology and Neurobiology, Yale University School of Medicine, New Haven, Connecticut 06510

ABSTRACT The effects of turgor pressure-induced membrane tension on junctional coupling of Hensen cell isolates from the inner ear were evaluated by input capacitance or transjunctional conductance measurement techniques. Turgor pressure was altered by changing either pipette pressure or the osmolarities of extracellular solutions. Both positive pipette pressure and extracellular applications of hypotonic solutions, which caused cell size to concomitantly increase, uncoupled the cells as indicated by reduced input capacitance and transjunctional conductance. These changes were, in many cases, reversible and repeatable. Intracellular application of 50 μ M H-7, a broad-based protein kinase inhibitor, and 10 mM BAPTA did not block the uncoupling effect of positive turgor pressure on inner ear gap junctions. The transjunctional conductance at a holding potential of -80 mV was 53.6 ± 5.8 nS (mean \pm SEM, $n = 9$) and decreased $\sim 40\%$ at a turgor pressure of 1.41 ± 0.05 kPa. Considering the coincident kinetics of cell deformation and uncoupling, we speculate that mechanical forces work directly on gap junctions of the inner ear. These results suggest that pathologies that induce imbalances in cochlear osmotic pressure regulation may compromise normal cochlear homeostasis.

INTRODUCTION

The supporting cells of the organ of Corti are structurally and electrically coupled together by gap junctions (Jahnke, 1975; Gulley and Reese, 1976; Iurato et al., 1976; Hama and Saito, 1977; Santos-Sacchi and Dallos, 1983; Kikuchi et al., 1995). Such gap junctional coupling among the supporting cells provides for electrical and metabolic uniformity; cochlear homeostasis is believed to rely on intercellular coupling (Santos-Sacchi, 1985, 1986, 1991; Kikuchi et al., 1995).

Gap junction channels are distinguished from other ionic channels since the integration of two aligned hemichannels from adjacent cells is required for normal function. In early work, hypertonic solutions, which cause cell and tissue shrinkage, were found to uncouple gap junctions in several different preparations (Barr et al., 1965, 1968; Goodenough and Gilula, 1974; Loewenstein et al., 1967). More recently, hypotonic treatments, which cause cell swelling, were determined to either increase (Kimelberg and Kettenmann, 1990) or decrease (Ngezahayo and Kolb, 1990) gap junctional coupling. These effects could have been due

to a variety of factors, including direct mechanical influences, changes in nonjunctional resistance, and modulation of intracellular factors that are known to uncouple cells. In the study of Ngezahayo and Kolb (1990), where junctional conductance was studied directly, the decrease in coupling was abolished by 5 mM EGTA in nominally Ca^{2+} -free internal solutions, and was linked to the activity of PKC. In the present report, we used the whole-cell voltage clamp technique to examine the effects of turgor pressure on junctional coupling of isolated pairs or small groups of cochlear supporting cells. Both input capacitance (Santos-Sacchi, 1991; Bigiani and Roper, 1995) and transjunctional conductance measures were used to gauge intercellular communication. We report that data obtained with both techniques indicate that positive intracellular pressure, which is known to induce membrane tension, uncouples gap junctions of supporting cells in Corti's organ.

METHODS

Detailed experimental methods can be found in previous reports (Santos-Sacchi, 1991; Sato and Santos-Sacchi, 1994). In brief, isolated supporting cells or cell aggregates were freshly obtained from the organ of Corti of the guinea pig cochlea by shaking for 5–15 min in nominally Ca^{2+} -free Leibovitz medium containing 1 mg/ml trypsin. To reduce the voltage-dependent ionic currents from nonjunctional membrane during double voltage clamp experiments, cells were perfused with an ionic blocking solution containing (mM): 100 NaCl, 20 TEA, 20 CsCl, 1.25 CoCl_2 , 1.48 MgCl_2 , 10 HEPES, pH 7.2, 300 mosM. In initial experiments, a modified Leibovitz medium was used for measurement of input

Portions of this work were previously published in abstract form (Zhao, H.B., and J. Santos-Sacchi. 1997. *Assoc. Res. Otolaryngol.* St. Petersburg, FL, pp. 15).

capacitance (C_{in})¹ with a single pipette voltage clamp containing (mM): 136.9 NaCl, 5.37 KCl, 1.25 CaCl₂, 1.48 MgCl₂, 10 HEPES, pH 7.2, 300 mosM. Pipette solutions were composed of (mM): 140 KCl, 10 EGTA or BAPTA, 2 MgCl₂, and 10 HEPES, pH 7.2. For double voltage clamp recording, 140 mM KCl was replaced with 140 mM CsCl. Patch electrodes had initial resistances of 2.5–4 MΩ, corresponding to 1–2 μm in diameter. Series resistance (R_s) after whole cell configuration was estimated from the current in response to 10-mV steps (Huang and Santos-Sacchi, 1993). In single Hensen cells, where R_s could be unequivocally determined after whole cell configuration, the average value was 7.16 ± 0.43 MΩ (mean \pm SEM, $n = 48$). Cells were typically held at -80 mV, within the Hensen cell's linear current-voltage range (Santos-Sacchi, 1991). Currents were filtered at 10 kHz with a four-pole Bessel filter (Axon Instruments, Foster City, CA). Intracellular pressure was modified either through the patch pipette with a syringe connected to the Teflon[®] tubing attached to the patch pipette holder or by changing osmolarity with "Y-tube" bath perfusion. Pipette pressure was monitored via a T-connector to a pressure monitor (World Precision Instruments, Inc., Sarasota, FL). All experiments were video tape recorded and performed at room temperature.

Since the input capacitance can be measured by a single pipette voltage clamp and is correlated with junctional conductance (Santos-Sacchi, 1991; Bigiani and Roper, 1995), it can be conveniently used to study gap junctional coupling under conditions of less cellular damage than the double voltage clamp technique. Input capacitance, in conjunction with input resistance (R_{in}), was continually measured on line to monitor junctional coupling. C_{in} and R_{in} were determined from the transient charge and steady state current, respectively, induced by small (-10 mV) test pulses with duration of $18\times$ the clamp time constant at the holding potential; measures were made at ~ 1 – 3 Hz (Santos-Sacchi, 1991).

$$C_{in} = \frac{Q_{in}}{V_{test}} \quad (1)$$

$$R_{in} = \frac{V_{test}}{\Delta I_{\infty}} \quad (2)$$

where

$$Q_{in} = \int_0^{\infty} I_c dt \quad (3)$$

Q_{in} is the charge moved, V_{test} is the voltage of the test pulse, I_c is the capacitive current induced by the test pulse, and ΔI_{∞} is the current difference between the steady state current induced by the test pulse and the holding current at the holding potential.

For the double voltage clamp, each cell in a cell pair was separately voltage clamped using 200A and 200B patch clamps (Axon Instruments). Both cells were clamped at the same holding potentials and a test pulse (10 mV, 10 ms) superimposed only on cell 1. The transjunctional current (I_j) is equal to the current difference (ΔI_2) in cell 2 caused by the test pulses applied to cell 1. The transjunctional conductance (G_j) can be calculated by:

$$G_j = \frac{-\Delta I_2}{V_{test}} \quad (4)$$

where V_{test} is the test pulse voltage applied to cell 1. Data collection and analysis were performed with an in-house developed

windows-based whole-cell voltage clamp program, jClamp (<http://www.med.yale.edu/surgery/otolar/santos/jclamp.html>), using a Digidata 1200 board (Axon Instruments). In some experiments, G_j was measured online at 2–4 Hz and the corresponding video images of recorded cells were digitally captured every 5–10 s under software (jClamp) control. The captured images were printed at $\sim 1,700\times$ and the plane cell areas calculated. To gauge membrane stress, area strain ($\Delta A/A_0$) was calculated, where ΔA is the change of cell area after pressure or osmotic treatment and A_0 is the original cell area.

RESULTS

Hensen cells can be easily distinguished from other inner ear supporting cells by their prominent lipid vacuoles. The number of cells comprising isolates of Hensen cells can be determined under the light microscope, and corresponds to the isolate's C_{in} since Hensen cells are well coupled electrically. Although the size of Hensen cells is variable, the distributions of C_{in} for one, two, and three Hensen cells, whose numbers were visually confirmed, were quite distinct (Fig. 1 A). At the

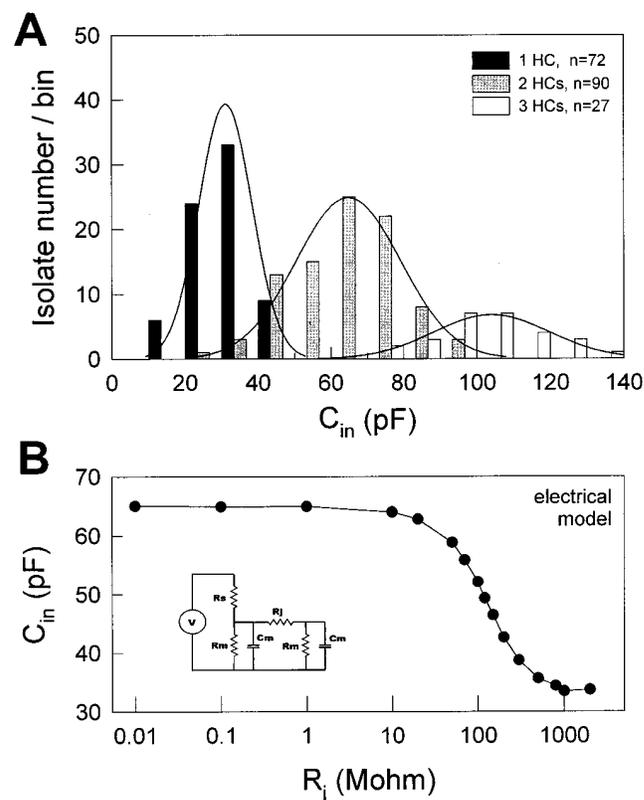

FIGURE 1. (A) The distributions of C_{in} of Hensen cell (HC) isolates. The cell numbers (1, 2, or 3) in the isolates were determined under the light microscope, and the C_{in} was obtained at the holding potential -80 mV. Each bar represents the number of isolates within a bin width of 10 pF. The lines plotted over each histogram represent the fitted Gaussian distribution for the three isolate groups. (B) C_{in} was measured for a coupled two-cell electrical model as transjunctional resistance (R_j) was changed. R_s , 4.7 MΩ; R_{in} , 500 MΩ; C_m , 33 pF. (inset) Coupled two-cell electrical model.

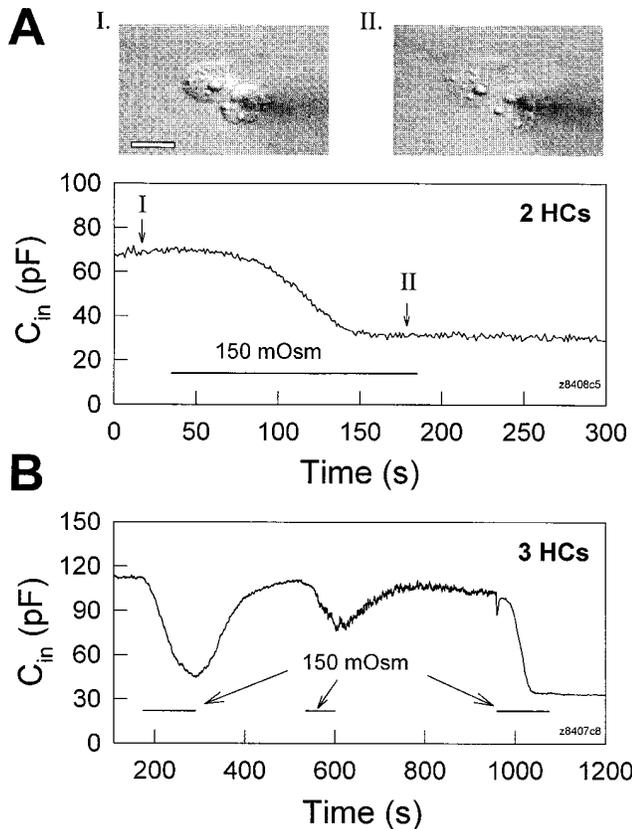

FIGURE 2. Osmolarity-induced turgor pressure increase uncouples Hensen cells. Both bath solution and electrode solution were 300 mosM. (A) When an extracellular 150 mosM solution was perfused (indicated by the horizontal bar) the cell pair swelled (see insets). Concomitantly, C_{in} decreased to half value due to cell uncoupling. R_s , 6.5 M Ω . (insets) Captured cell images before and during the perfusion of the hypo-osmotic solution. The white scale bar represents 20 μ m. (B) Decreases of C_{in} due to hypo-osmotic challenge were reversible and repeatable. In this case, the cells finally fully uncoupled and C_{in} remained at the single cell capacitance level. R_s , 3.8 M Ω .

holding potential of -80 mV, the peaks of the isolate distributions were clearly separated at 31.03 ± 0.86 , 64.75 ± 1.5 , and 103.9 ± 3.05 pF, corresponding to one, two, and three cell contributions, respectively. The number of cells within isolates can also be confirmed using uncoupling agents, such as CO_2 , octanol, or, as we now find, positive turgor pressure, to uncouple the cells. When cells fully uncoupled, C_{in} reached single cell capacitance levels (e.g., Figs. 2 and 3). The correlation of C_{in} with degree of cell coupling is illustrated by real measures of C_{in} in a coupled two-cell electrical model (Fig. 1 B). C_{in} of the electrical model was a monotonic function of transjunctional resistance or conductance, indicating the validity of C_{in} as an indicator of cell coupling.

Positive turgor pressure induced either by osmolarity changes or directly via the patch pipette decreased C_{in}

of cell pairs or three-cell groups (Figs. 2 and 3), but did not reduce single cell capacitance (Fig. 4). This indicates that positive turgor pressure uncouples gap junctions between adjacent Hensen cells.

In Fig. 2 A, bath application of hypo-osmotic solution (150 mosM) caused a Hensen cell pair to swell (insets) and decreased C_{in} of the pair to single cell levels. The uncoupling induced by increased turgor pressure is reversible since return to normal osmolarity solution often restored initial C_{in} values; subsequent reperfusion with hypo-osmotic solution remained effective as an uncoupling stimulus (Fig. 2 B). In single cells, while the same hypo-osmotic treatment caused cell swelling, C_{in} remained stable (Fig. 4 B).

Fig. 3 illustrates the uncoupling effect of cell turgor pressure change induced by patch pipette pressure. As turgor pressure was directly increased to ~ 1.2 kPa via the patch pipette, C_{in} decreased to almost single cell levels (after an initial delay possibly due to pipette plugging), and immediately began to return when the pressure was released (Fig. 3 A). The cells could be permanently uncoupled during the application of prolonged, continuous positive pressure (Fig. 3 B). The uncoupling effect of positive turgor pressure was found in 40 of 42 cell pairs, or three-cell groups. As with osmolarity change, direct application of positive turgor pressure via the patch pipette also did not decrease the measured capacitance in single Hensen cells despite cell swelling (Fig. 4 A, insets).

Although C_{in} can be easily measured by single pipette voltage clamp to gauge the degree of cell coupling, transjunctional conductance cannot be measured directly since transjunctional voltage and current are unknown. Additionally, a quantitative estimate of degree of coupling based on C_{in} is not easily established since C_{in} is a nonlinear function of transjunctional conductance (see Fig. 1 B and DISCUSSION). To further investigate the uncoupling effect of positive turgor pressure on gap junctions in Hensen cells, the transjunctional conductance was directly assessed with a double voltage clamp technique, and corresponding changes of the cell plane surface areas ($\Delta A/A_0$) (i.e., an indicator of membrane strain) were simultaneously measured.

Figs. 5 and 6 illustrate the results of such experiments. Cell areas increased in concert with decreases of transjunctional conductance as positive turgor pressure was delivered to the cells. The changes in cell area were observable before gap junctional uncoupling and occurred faster than G_j decay (Figs. 5 and 6). However, unlike pressure changes induced by pipette pressure, hypo-osmotic shocks produced changes in G_j and cell areas that were quite fast. With extracellular perfusion of a 150-mosM solution, the time constant for G_j decay was 9.53 s in Fig. 6 B, and the average value was 5.1 ± 1.86 s ($n = 6$). In Fig. 6 B, the rise time constant of

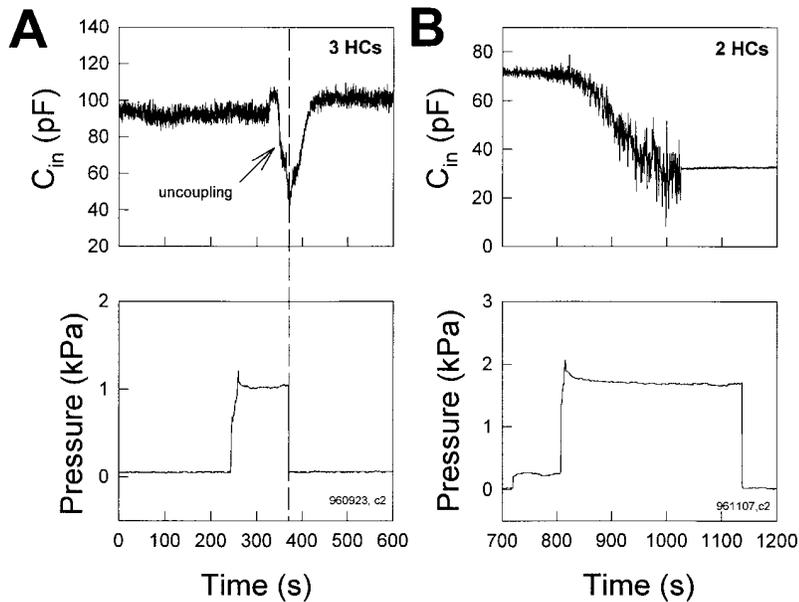

FIGURE 3. Hensen cells uncouple as turgor pressure is directly increased via the patch pipette. (A) In this example, increased pipette pressure caused C_{in} to decrease to single cell levels after an initial delay (possibly due to pipette plugging), but returned to the original level soon after pipette pressure was released. R_s , 9.76 M Ω . (B) A Hensen cell pair uncoupled after prolonged application of pressure. C_{in} decreased from 71.2 pF to a single cell level of 34.7 pF. R_s , 8.5 M Ω .

membrane strain was 4.43 s. The average rise time constant of membrane strain is estimated to be close to or less than that of the average G_j decay since in most cases the swelling fully occurred within the 5–10-s video capture rate. In most, but not all, cases, it was noted that after membrane tension stabilized, transjunctional conductance likewise stabilized (Fig. 5). The correlated and reciprocal changes in G_j and membrane strain

($\Delta A/A_0$) were reversible and repeatable (Fig. 6 A), strongly indicating that G_j decreases were relative to increases of membrane strain; i.e., membrane tension. It should be noted that the latency to G_j change after $\Delta A/A_0$ change is possibly due to the absence of significant membrane stress during the initial cell inflation, which clearly (based on the magnitude of cell enlargement) was accompanied by membrane unfolding.

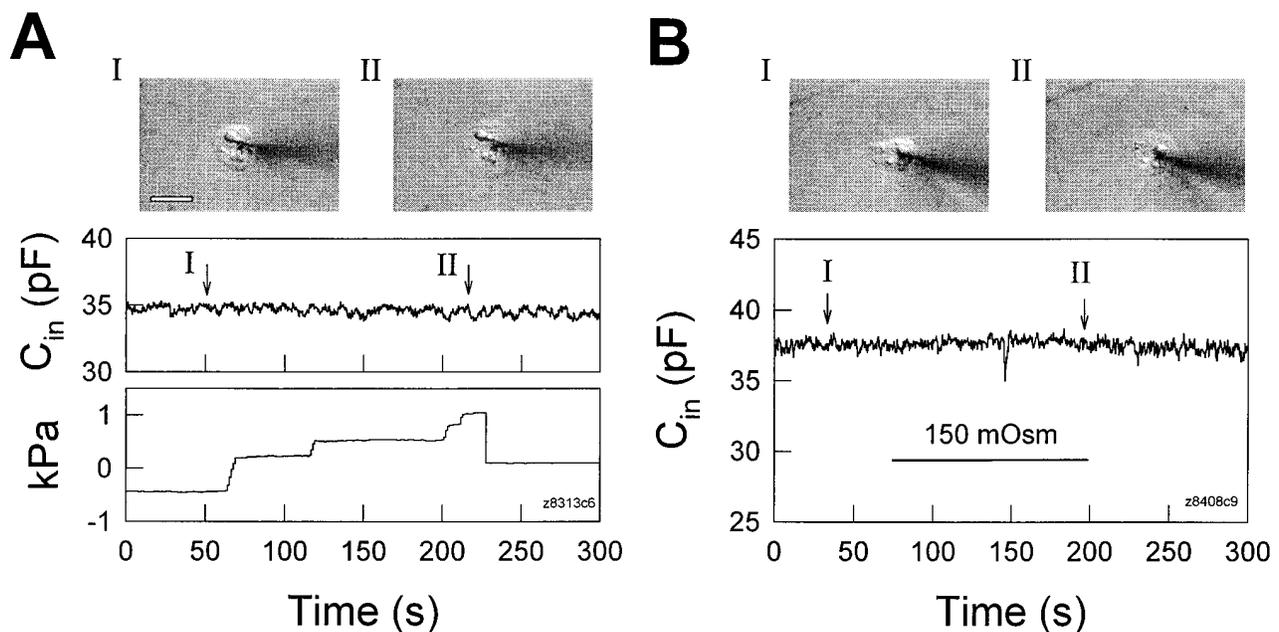

FIGURE 4. Changes of turgor pressure caused either directly via the patch pipette (A) or by perfusion of hypo-osmotic solutions (B) do not decrease the measured capacitance in a single Hensen cell. (insets) Captured cell images before and during applications of positive intracellular pressure. Cell swelling was visible as turgor pressure increased. The white scale bar represents 20 μ m. R_s : (A) 8.4 M Ω , (B) 4.4 M Ω .

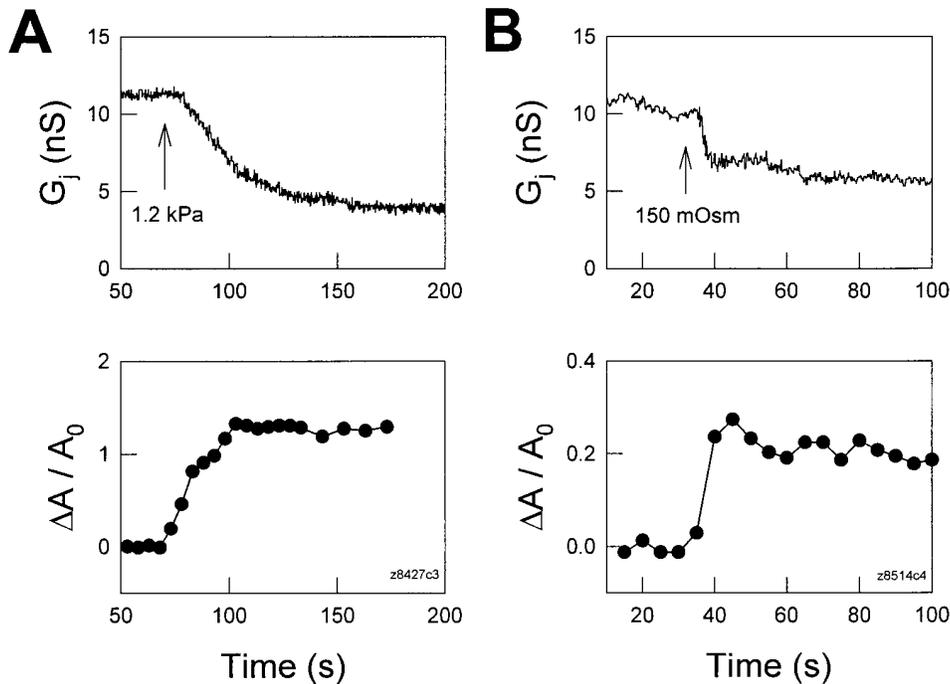

FIGURE 5. Positive turgor pressure-induced reduction in transjunctional conductance is correlated with increases in membrane strain ($\Delta A/A_0$). Transjunctional conductance was measured with a double voltage clamp technique, and membrane strains were calculated from captured images (see METHODS). Each cell in a Hensen cell pair was separately held at -40 mV. The continuous treatments used to increase intracellular pressure began at the arrows. (A) Positive pipette pressure induced an increase in membrane strain and concomitantly reduced G_j . (B) Perfusion of 150 mosM solution also induced an increase in membrane strain and concomitantly reduced G_j . The pipette solution contained $50 \mu\text{M}$ H-7.

Uncoupling of Hensen cell gap junctions by membrane stress was not inhibited by using pipette solutions containing $50 \mu\text{M}$ H-7 (dihydrochloride; Calbiochem Corp., La Jolla, CA), a broad-based serine/threonine kinase inhibitor (Boulis and Davis, 1990) (Figs. 5 B and 6 B). These data imply that the uncoupling effect of positive turgor pressure on inner ear gap junctions is independent of protein kinases, and that the effect is different from previous observations that cell volume changes induced uncoupling of gap junctions via the PKC pathway (Ngezahayo and Kolb, 1990). Nevertheless, cell swelling induced by hypo-osmotic shocks has been linked to increases of another uncoupling agent, intracellular Ca^{2+} (Hoffmann and Simonsen, 1989; Suzuki et al., 1990). However, uncoupling by Ca^{2+} , which occurs at millimolar intracellular concentrations in Hensen cells (Sato and Santos-Sacchi, 1994), can be ruled out since pipette solutions contained 10 mM BAPTA, a fast highly selective calcium chelating reagent, and extracellular and intracellular solutions were nominally Ca^{2+} free. Considering all evidence, the observed uncoupling effect of positive turgor pressure on inner ear gap junctions, which is fast (within seconds), correlated with changes of membrane strain, and independent of protein kinases and Ca^{2+} , is likely to occur via direct mechanical effects on the plasmalemma; i.e., membrane tension.

The effect of membrane tension on gap junctional conductance was further studied by increasing turgor pressure in cell 1 and measuring I_j in cell 2 at different membrane potentials (Fig. 7). Gap junctional conduc-

tance in Hensen cells at a holding potential of -80 mV was $52.9 \pm 12.1 \text{ nS}$ ($n = 51$). As the turgor pressure in cell 1 was increased, I_j decreased (Fig. 7 A). The junctional conductance at different membrane potentials reduced in parallel when the turgor pressure was increased. In those cell pairs where turgor pressure alterations were successfully applied without losing the cells, G_j at -80 mV holding potential decreased $38.3 \pm 9.5\%$ from $50.5 \pm 14 \text{ nS}$ ($n = 9$) at a turgor pressure of $1.41 \pm 0.05 \text{ kPa}$. The V_m dependence of G_j is also visible in Fig. 7. In this case, as the cells were depolarized, G_j decreased (Fig. 7 B). Other V_m dependencies of transjunctional conductance were also found, including V_m insensitivity and an increase with depolarization. Pressure did not alter voltage-dependent behaviors.

DISCUSSION

We provide evidence, based on input capacitance and double voltage clamp measures, that junctional coupling is sensitive to positive turgor pressure-induced membrane tension. Turgor pressure has been used to induce membrane tension in a wide variety of cells, including the outer hair cell (OHC), where it has been shown that motility and motility-related gating current characteristics are directly altered (Iwasa, 1993; Gale and Ashmore, 1994; Takehata and Santos-Sacchi, 1995). Membrane tension (possibly acting via cytoskeletal interactions) is also known to gate stretch-activated ionic channels (Yang and Sachs, 1989), which have been observed in outer hair cells (Ding et al., 1991; Iwasa et al.,

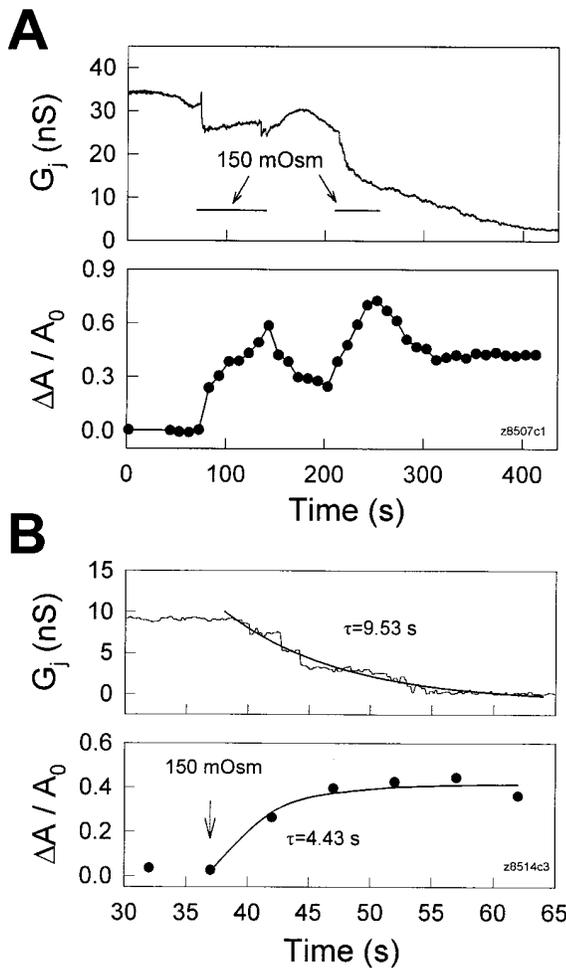

FIGURE 6. (A) Hypo-osmotic solutions induced reversible, concomitant changes in transjunctional conductance and membrane strain. Both cells were held at -40 mV. Repeated applications of 150 mosM solution are indicated by the horizontal bars. (B) The time course of the uncoupling effect caused by hypo-osmotic shock is compared with the increase of membrane strain. The beginning of treatment is indicated by an arrow and continued during the observed period. Thick solid lines represent single exponential fits. Membrane strain appears to have increased before the decrease of G_j . Pipettes contained $50 \mu\text{M}$ H-7.

1991). It is possible that membrane tension also alters gating characteristics of supporting cell gap junctions. We show, however, that unlike stretch channels, inner ear gap junctional conductance decreases with membrane stress. Recently, it has been postulated that gap junction channels possess two distinct gating mechanisms, namely, a voltage gating mechanism and a chemical gating mechanism (Bukauskas et al., 1995; Bukauskas and Peracchia, 1997; Bukauskas and Weingart, 1994). Chemical uncoupling agents, such as CO_2 , H^+ , and Ca^{2+} , may act on sensor elements from the cytoplasmic side. Supporting cell coupling has been shown to be sensitive to a variety of chemical uncoupling agents (Santos-Sacchi, 1985; 1991), and we now

report that supporting cell coupling is voltage dependent as well. The existence of voltage-dependent gap junctional conductance may account in part for previous reports of temperature-induced depolarization on supporting cell coupling ratios (Santos-Sacchi, 1986). Interestingly, junctional voltage dependence is unaffected by concomitant tension-induced junctional conductance change, possibly indicating that an independent tension gating mechanism may exist.

Gap junctions consist of two aligned transmembrane hemichannels (connexons), one from each cell (Revel et al., 1984; Goodenough et al., 1988; Bennett et al., 1991). Each of these hemichannels is formed by six connexin subunits (Kumar and Gilula, 1996; Perkins et

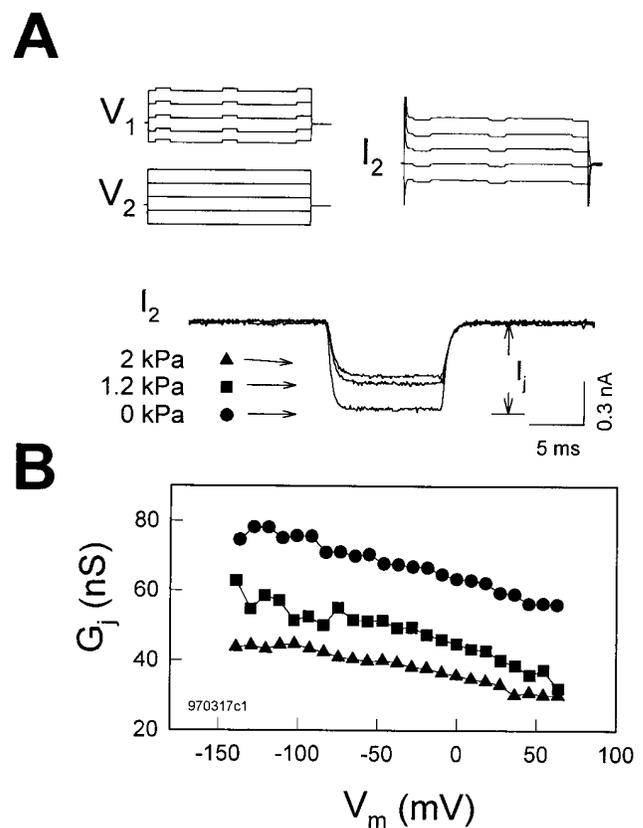

FIGURE 7. Turgor pressure does not affect membrane potential (V_m or V_{i-o}) dependence of gap junctions in Hensen cells. (A) Voltage stimulus protocols for each cell and current trace recorded in cell 2 are plotted (only five traces are shown for clarity). Each cell in a Hensen cell pair was separately voltage clamped at the same holding potential of -80 mV. Voltage steps from -140 to 70 mV for 100 ms in 10 -mV increments were simultaneously delivered into both cells except for 10 mV, 10 -ms test pulses superimposed on cell 1 only. Transjunctional current (I_j) is measured in cell 2. The turgor pressure of cell 1 was directly changed by the patch pipette. Three current traces from cell 2 at different pressures were zeroed and superimposed in the middle. (B) Positive turgor pressure decreased G_j at all membrane potentials. Note G_j decrease as the cells were depolarized. R_i at 0 kPa, 12.5 M Ω ; at 1.2 kPa, 12.7 M Ω ; at 2 kPa, 12.2 M Ω .

al., 1997). Our data indicate that membrane stress acts on inner ear gap junctions in a manner independent of Ca^{2+} , pH, and protein kinases. The rapid and reversible nature of the uncoupling also indicates that the mechanism is not due to some sort of mechanical destruction of the channels. While there may be other unknown links between membrane stress and junctional conductance, it is conceivable that tension may gate gap junction channels by a conformational change in connexon structure, possibly causing only the stressed membrane's hemichannel to close.

Gap junction connexins represent a family of homologous proteins that have differing voltage gating characteristics (Harris et al., 1981; Spray et al., 1981; Bennett et al., 1991; Dahl, 1996). Using immunocytochemistry and transmission electron microscopy, Cx26 was found in gap junctions of the rat (Kikuchi et al., 1995) and gerbil (Forge et al., 1997) organ of Corti. More recently, Cx26, Cx30, Cx32, and Cx43 have been localized to supporting cell regions of the rat cochlea (Lautermann et al., 1997). Such diversity of connexins within the organ may provide for a variety of junctional communication characteristics; for example, rectifying junctional conductance. Indeed, in addition to our direct observation that voltage-dependent junctional communication exists in the supporting cells, we have preliminary evidence that junctional rectification occurs. Directional flow of ions mediated by rectified gap junctions may be crucial for normal cochlea homeostasis (see below).

Since the mid 1980's, gap junctional coupling has usually been studied with double voltage clamp. However, input capacitance and resistance reflect the degree of electrical coupling and can be conveniently measured using a single voltage clamp (Santos-Sacchi, 1991; Sato and Santos-Sacchi, 1994; Bigiani and Roper, 1995). Based on a coupled two-cell model (see Fig. 1 B, inset), and assuming that the individual cells have the same input impedance, the following equations are obtained (Bigiani and Roper, 1995),

$$C_{in} = \frac{(2R_m R_j + 2R_m^2 + R_j^2) R_m^2}{(2R_m R_s + R_m^2 + R_s R_j + R_m R_j)^2} C_m, \quad (5)$$

$$R_{in} = \frac{R_s R_j + 2R_s R_m + R_j R_m + R_m^2}{R_j + 2R_m}, \quad (6)$$

where R_s and R_m are electrode series resistance and nonjunctional membrane resistance, respectively, and C_m is single cell capacitance (see Fig. 1 B, inset). Since R_m is not readily available from recordings, we can solve Eqs. 5 and 6 to remove R_m . R_j can be finally expressed:

$$R_j = \left| \frac{C_{in} R_{in}^2 + 4C_m R_s R_{in} - 2C_m R_s^2 - 2C_m R_{in}^2}{\sqrt{2C_m^2 R_s R_{in} + C_{in} C_m R_{in}^2 - C_m^2 R_s^2 - C_m^2 R_{in}^2}} \right|. \quad (7)$$

C_{in} , R_{in} , and R_s are readily obtained from recordings. Fig. 8 illustrates the measurement of these parameters during an uncoupling event, and the bottom panel shows the estimated G_j based on those data. Changes in estimated G_j mirror pressure-induced changes in C_{in} . It should be noted that R_s changes can also produce changes in C_{in} and R_{in} . For example, to obtain the observed maximum change in C_{in} , an order of magnitude increase of R_s would be required in this case. In our experiments, changes solely in R_s required to produce a comparable change in C_{in} were not observed. Series resistance remained constant, being $7.79 \pm 0.49 \text{ M}\Omega$ ($n = 7$) for cell pairs that were well coupled and $6.34 \pm 1.13 \text{ M}\Omega$ after those same cells were uncoupled with positive pipette pressure.

Finally, how might the turgor pressure dependence of junctional coupling in the organ of Corti affect coch-

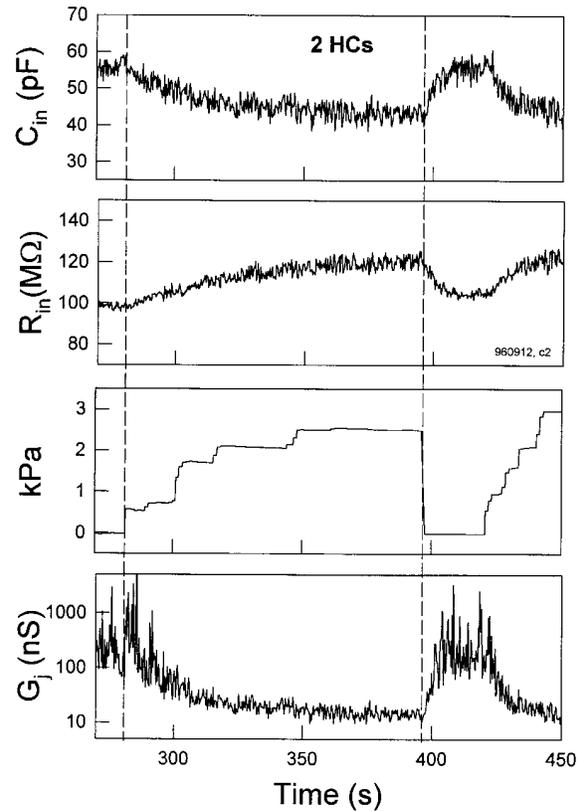

FIGURE 8. Transjunctional conductance is estimated by C_{in} and R_{in} in single pipette voltage clamp. (top) C_{in} decreased and R_{in} simultaneously increased as turgor pressure increased. C_{in} and R_{in} followed changes in pressure. R_s , $8.73 \text{ M}\Omega$. (bottom) G_j is estimated from C_{in} and R_{in} measurements from the cell pair data based on the coupled two-cell model. C_m was set as half of C_{in} , 27.5 pF , at zero applied pressure, and R_s was $8.5 \text{ M}\Omega$. The change in estimated G_j corresponds well to changes in C_{in} . The magnitude of G_j is larger than the largest obtained under double voltage clamp ($\sim 500 \text{ nS}$), and may be due to the fact that cell impedances are not actually identical as required in the model.

lear function? In vivo, the organ of Corti, comprising hair cells and supporting cells, is bathed in two different media, high K^+ endolymph apically and low K^+ perilymph basally. Since the receptor current through hair cells is predominantly carried by K^+ , an accumulation of K^+ within the perilymphatic space along the basolateral region of the hair cells is unavoidable. This would potentially depolarize hair cells with disastrous consequences for both forward and reverse sensory transduction. In the mammal, forward transduction (gating of stereociliar transduction channels) relies on the large driving force present across the hair cell's apical plasma membrane. Voltage gradients across the apical membranes of inner and outer hair cells (i.e., endolymphatic potential minus membrane potential) range from 125 to 150 mV, and drive the K^+ -based receptor currents. Reduction of this gradient (e.g., by membrane depolarization) will reduce the magnitude of receptor potentials and synaptic output. Reverse transduction is a phenomenon that is restricted to the outer hair cell and is believed to provide for the enhanced high frequency selectivity and sensitivity enjoyed by mammals. OHCs, which are additionally mechanically active, possess lateral membrane motors that are driven by voltage (Santos-Sacchi and Dilger, 1988); the cell's mechanical response provides feedback into the basilar membrane, thereby enhancing the stimulus to the primary receptor cells, the inner hair cells (for review see Ruggero and Santos-Sacchi, 1997). Not only will depolarization of the OHC alter the driving force for the mechanical response, but the function relating mechanical response to voltage will be shifted along the voltage axis as well, resulting in an altered gain for the "cochlear amplifier" (Santos-Sacchi et al., 1998). Some mechanisms must prevent such an undesirable scenario. A nutritive and K^+ sinking role for gap junctions

in the avascular organ of Corti has been proposed (Santos-Sacchi, 1985, 1991; Santos-Sacchi and Dallos, 1983). Inner ear supporting cells have been shown to "share" plasmalemmal voltage-dependent conductances due to the high degree of cell coupling (Santos-Sacchi, 1991). The magnitude and stability of their resting potentials is pronounced (close to -100 mV), and likely depends on cell coupling since isolated cell resting input conductance is only ~ 1 nS. At the normal resting potential of this cellular syncytium, an inward rectifier appears continuously activated and may result in K^+ removal from perilymphatic spaces. It should be noted that the large perilymphatic fluid spaces may provide little support in sinking K^+ or directing its movement, since hair cell regions that are likely to experience K^+ elevations are not directly exposed to those spaces. Inner hair cells are closely surrounded by supporting cells, and the region of the OHCs that possesses voltage-dependent conductances (e.g., outward K^+) is restricted to the basal pole of the cell (Santos-Sacchi et al., 1997), which is surrounded by a Deiters cell cup. Recently, Kikuchi et al. (1995) provided morphological evidence detailing epithelial and connective tissue gap junctional systems within the cochlea that may complete the mechanism responsible for recycling K^+ from the perilymphatic space near hair cells to the K^+ -rich endolymph via the stria vascularis. The maintenance of normal fluid space architecture within the inner ear requires fine osmotic control; imbalances can lead to serious auditory and vestibular problems (e.g., Meniere's disease). While at present we do not know the normal physiological significance of tension-dependent gap junctional communication, it is likely that fluid balance disorders in the inner ear will affect gap junctional communication, thus compromising sensory function by indirectly modifying hair cell activity.

We thank Margaret Mazzucco for technical help.

show a characteristic 'U' shape (Fig. 5a). This gives rise to a remarkable chaotic travelling-wave structure which may be seen in the eight lattice 'snapshots' of Fig. 5b–i. Population abundances in the meta-community remain chaotic, but periodic circular waves continuously expand and contract radially as they spread in time across the spatial landscape. Field and model population studies of the Canadian hare–lynx cycle and European vole cycles have found similar travelling-wave structures with spatially distributed U-shaped phase lags^{10,25–27}. Different types of realistic diffusion barrier were introduced into the model but, in general, they failed to destroy the spatial circular wave structure (B.B. *et al.*, manuscript in preparation).

The spatio-temporal structures associated with phase synchronization have important implications for conservation ecology. Even if a disturbance perturbs a local patch population to the brink of extinction, the periodicity of spatial phase synchronization guarantees the recurring arrival of wave fronts in which new colonizers will buffer the endangered population. In contrast to the common view of population synchronization as a cause of global population extinctions¹⁴, it appears that phase synchronization can be important for maintaining species persistence. Our findings indicate that synchronization is a powerful process that has the potential to shape the distribution and abundance of species over all scales, from local to continental. We expect that the complex synchronization phenomena identified here will provide new insight into the dynamics of spatial ecologies and will have important applications to the study of biological rhythms in general. □

Auditory collusion and a coupled couple of outer hair cells

Hong-Bo Zhao & J. Santos-Sacchi

Sections of Otolaryngology and Neurobiology, Yale University School of Medicine, 333 Cedar Street, New Haven, Connecticut 06510, USA

The discrepancies between measured frequency responses of the basilar membrane in the inner ear and the frequency tuning found in psychophysical experiments led to Békésy's idea of lateral inhibition in the auditory nervous system¹. We now know that basilar membrane tuning can account for neural tuning², and that sharpening of the passive travelling wave depends on the mechanical activity of outer hair cells (OHCs)³, but the mechanism by which OHCs enhance tuning remains unclear. OHCs generate voltage-dependent length changes at acoustic rates^{4–8}, which deform the cochlear partition^{9–11}. Here we use an electrical correlate of OHC mechanical activity, the motility-related gating current, to investigate mechano-electrical interactions among adjacent OHCs. We show that the motility caused by voltage stimulation of one cell in a group evokes gating currents in adjacent OHCs. The resulting polarization in adjacent cells is opposite to that within the stimulated cell, which may be indicative of lateral inhibition. Also such interactions promote distortion and suppression in the electrical and, consequently, the mechanical activity of OHCs. Lateral interactions may provide a basis for enhanced frequency selectivity in the basilar membrane of mammals.

The mechanical response of the OHC is mirrored by an electrical signature, a motility-related charge movement, similar to the gating charge movements that control ion-channel conductance^{12,13}. Both gating currents arise from a redistribution of charged voltage sensors across the membrane. The magnitude of the gating current reflects the rate of charge redistribution. In the OHC, the redistribution of motility-related charge is controlled by both voltage and membrane tension; consequently, either can evoke gating currents^{14–16}. Within the organ of Corti, OHCs are indirectly mechanically coupled to each other through contacts with supporting Deiters' cells. The apical regions of OHCs and Deiters' cells are joined by tight junctions and form the plate-like reticular lamina. Basally, the OHCs sit in the cups of Deiters' cells, and the strength of these attachments varies along the length of the basilar membrane¹⁷. This morphology makes it likely that the voltage-induced mechanical responses of one OHC will affect surrounding OHCs. Determining the nature of this interaction may provide insight into the process of fine frequency tuning by OHCs. We studied this interaction by simultaneously recording from adjacent OHCs under dual whole-cell voltage and current clamp.

In isolated pieces of Corti's organ, where cellular relations remain intact, voltage stimulation of an OHC induces mechanical responses and gating currents in that cell (Fig. 1). Transient outward currents are generated by the onset of depolarization, which causes the cell to contract (Fig. 1b). These currents correspond to the displacement of positive charge to the extracellular aspect of the lateral plasma membrane, which holds motility/voltage sensors^{18,19}. The charge–voltage ($Q-V$) function is well described by a two-state

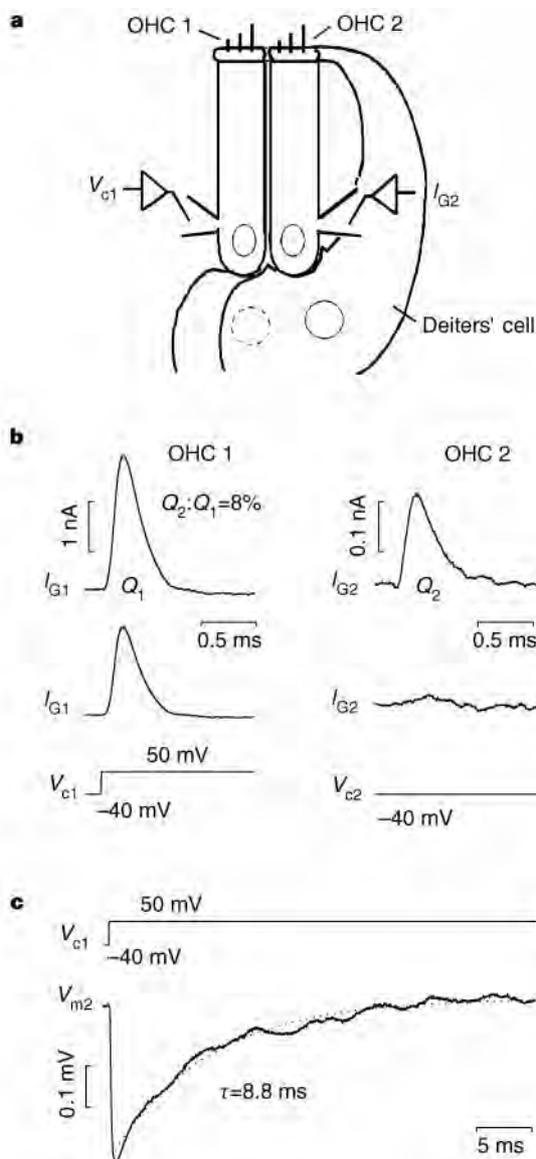

Figure 1 Adjacent OHCs are mechano-electrically coupled. **a**, Schematic illustrating two adjacent OHCs mechanically coupled through Deiters' cells and the recording configuration. **b**, Each cell in a pair was whole-cell voltage clamped to -40 mV. Depolarization of OHC 1 to 50 mV (V_{c1}) generates outward transient currents in both OHC 1 and OHC 2 (I_{G1} , I_{G2} , respectively; top two traces). The charge ratio (Q_2/Q_1) is 0.08 . Following application of negative pressure (~ -0.5 kPa; middle two traces) to the patch pipette of OHC 1, the response in OHC 2 was abolished. The response in the voltage-stimulated cell is decreased somewhat, as expected, owing to a negative shift in its Q - V function¹⁶. **c**, OHC 1 was held under voltage clamp and OHC 2 under current clamp. As a consequence of the impulsive gating current evoked in OHC 2, a negative voltage is developed across its membrane. The trace depicts the average induced potential ($n = 7$) in OHC 2. Dotted line: single exponential fit of 8.8 ms.

Boltzmann function^{12,13}:

$$Q(V) = \frac{Q_{\max}}{1 + b} \quad (1)$$

$$b = \exp\left(\frac{-ze(V_m - V_h)}{kT}\right)$$

where Q_{\max} is the maximum nonlinear charge moved, V_h is the voltage at half-maximal gating-charge transfer, V_m is the membrane potential, z is the valence, e is the electron charge, k is Boltzmann's constant and T is the absolute temperature.

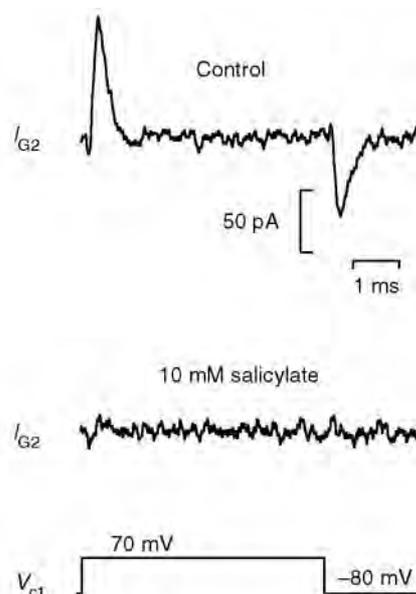

Figure 2 Both OHCs were voltage clamped to -80 mV, and OHC 1 was stepped to 70 mV (V_{c1}). The top trace shows the gating current (I_{G2}) evoked in OHC 2. Perfusion of the cells with 10 mM salicylate abolishes the gating current.

When the stimulated OHC (OHC 1) is depolarized, gating currents are seen in the adjacent OHC (OHC 2). The ratio of charge movement (Q_2/Q_1) in adjacent OHCs can be up to 0.1 . The induced gating current in OHC 2 is not generated by electrical interactions between the cells. Individually isolated cells that are positioned to touch each other do not show this charge coupling. Furthermore, collapse of OHC 1 by negative pipette pressure (-0.25 to -0.5 kPa), which abolishes the cell's normal mechanical activity¹³, eliminates gating currents in adjacent OHCs (Fig. 1b).

As in OHC 1, the magnitude of the gating currents in OHC 2 reflects the rate of charge redistribution; in this case, however, the rate mirrors that of the deformation of OHC 2. This is indicated by the significant correlation between the OHC 1 clamp time constant (which controls the rate of the OHC mechanical response under whole-cell voltage clamp⁶) and gating current magnitude in OHC 2 ($r^2 = 0.63$; $n = 21$). This is expected, because the OHC gating-current magnitude resulting from stretch is related to the velocity of stretch¹⁵. The charge redistribution in OHC 2 generates a voltage with a time course that depends on the cells' membrane time constant ($\tau_m = R_m \times C_m$). We looked at this induced voltage under current clamp. In seven cells, the average time constant of voltage decay induced by the impulsive gating current was 8.8 ms. The average membrane resistance of these cells was 272 ± 28 M Ω (mean \pm s.e.), the membrane capacitance (at the holding potential) was 35.1 ± 2.02 pF and, consequently, $\tau_m = 9.5$ ms. The initial voltage magnitudes were up to 1.2 mV. The polarity of the induced voltage was negative, corresponding to the movement of positive charge to the outside of the cell membrane. The polarity of the voltage change in mechanically coupled cells is opposite to that of the electrically stimulated cell. Direct currents (d.c.) were not observed in adjacent OHCs, confirming the absence of gap-junction-mediated electrical coupling.

Additional evidence indicates that the transient currents and voltages in adjacent OHCs result from mechanical coupling between OHCs, and that these electrical responses are generated by the displacement of motility/voltage sensors. Figure 2 shows that salicylate, a known blocker of OHC gating currents and motility^{20,21}, abolishes the gating currents in adjacent OHCs. In our experiments, salicylate probably has two effects: it blocks both the mechanical response of the stimulated cell and the charge movement in the

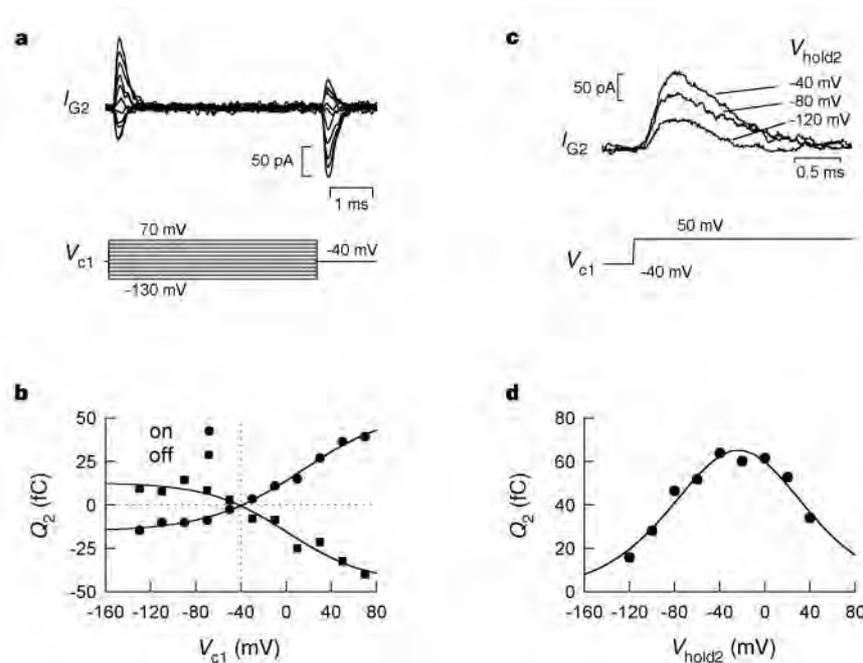

Figure 3 Gating currents are a function of both OHCs' holding potential. **a**, Both OHCs were voltage clamped to -40 mV, and OHC 1 was stepped for 5 ms from -130 to 70 mV (V_{c1}) in 20 mV steps. Gating currents (I_{G2}) in an adjacent OHC are shown in the top trace. The polarity of the currents depends on that of the stimulus voltage in OHC 1. **b**, the Q - V plot (on and off charge in OHC 2 versus voltage of OHC 1) shows a reversal of gating charge sign at the OHC 1 holding potential. The nonlinearity of the response partially reflects the nonlinear nature of the motility

function. **c**, The magnitude of gating current (I_{G2} , top traces) in OHC 2 induced by a fixed voltage step in OHC 1 depends on the membrane (holding) potential of OHC 2. **d**, The Q - V plot (on charge in OHC 2 versus holding voltage of OHC 2) shows that charge magnitude is a bell-shaped function of OHC 2 holding potential. The data were fit (solid line) to equation (2) with Q_{max} (prior determination from Q_2 - V_{c2} function) fixed at 2.99 pC. $\delta V_h = 2.5$ mV; $V_h = -23.5$ mV; $z = 0.65$.

adjacent cell. Further evidence derives from the polarity of the gating currents in adjacent cells (Fig. 3a, b). As expected for a process dependent on the stimulated OHC's mechanical response, the gating current polarity of the adjacent cell reverses at the holding potential of the stimulated cell; depolarization from this potential causes contraction of the cell, whereas hyperpolarization produces elongation. The deformation of adjacent cells will alter the tension on their lateral membranes. Reduced tension effectively shifts the voltage dependence of the Q - V function in the negative direction, and will evoke a positive gating current¹⁶. This agrees with the effects measured in adjacent OHCs. The magnitude of charge movement induced by this shift depends on the adjacent cell's membrane (holding) potential and is given by the difference between the two shifted Boltzmann functions¹⁵:

$$Q(V) = -Q_{max} \delta V_h \frac{ze}{kT(1+b)^2} \quad (2)$$

where δV_h is the magnitude of the V_h shift induced by a change in membrane tension, and b is as in equation (1).

Indeed, this behaviour is seen in our experiments (Fig. 3c, d). The magnitude of gating charge in the adjacent OHC depends on its holding potential, and the bell-shaped function of equation (2) satisfactorily describes the relationship. As the Q - V function mirrors the OHC's motility function¹⁶, the mechanical activity of coupled OHCs will be affected similarly.

Our data show that, as a result of OHC mechanical activity, lateral interactions exist within the organ of Corti that may significantly affect its responsiveness to sound. We have explored some of the consequences of these interactions. When two pure-tone frequencies are presented to a subject, auditory illusions of additional tonal frequencies and measurable physiological counterparts result^{22,23}. Additionally, one tone can be suppressed by another. This distortion arises from nonlinearities in the peripheral auditory system, and in the mammal it results from OHC activity^{24,25}. Even within single isolated hair cells, distortion evoked by two-frequency stimulation

can be generated by nonlinearities of the stereociliar transducer or by OHC motility²⁶⁻²⁸. We tested whether this type of distortion can arise from interactions between OHCs by simultaneously and independently stimulating each cell of coupled pairs with differing voltage frequencies (OHC 1, $f_1 = 813.8$ Hz; OHC 2, $f_2 = 976.5$ Hz) and observing nonlinear interactions. Under these stimulation conditions, both frequencies are present in the current responses of each cell (Fig. 4). The magnitude of the mechanically induced frequency component (for example, f_2 in OHC 1) is a bell-shaped function of holding potential, indicating, as above, that this component is generated by frequency-following shifts in the voltage dependence of the Q - V function of the cell. Furthermore, this mechanically generated frequency component suppresses the voltage-evoked frequency component by up to 10%. Finally, the interaction of the two frequency components gives rise to nonlinear intermodulation distortion in each cell (Fig. 4b). The sum and difference distortion components ($f_2 + f_1, f_2 - f_1$) can be observed as little as 20 dB below the mechanically induced primary.

Our data show that nonlinear mechanical interactions occur among OHCs within Corti's organ, and that these interactions generate distortion and suppression that are similar to those found in the intact organ. The generated distortion, seen only in coupled OHCs, may arise not only from the interaction of intrinsic cellular nonlinearities^{27,28}, but also from nonlinearity in the visco-elastic coupling between cells. The mechanical coupling strength, based on ratios of charge or current, is up to 10%. However, the degree of mechano-electrical coupling among OHCs may be greater *in vivo* than is demonstrated here, as physical coupling in our preparations was probably compromised by the isolation procedure.

It is believed that passive basilar-membrane tuning is enhanced by feedback from OHC mechanical activity³; however, based solely on mechanical activity evoked by passive tuning, sharpening would not be expected. The consequence of OHC coupling is twofold for adjacent cells; the voltage dependence of motility is altered, and a voltage of opposite phase is evoked. These mechanically generated

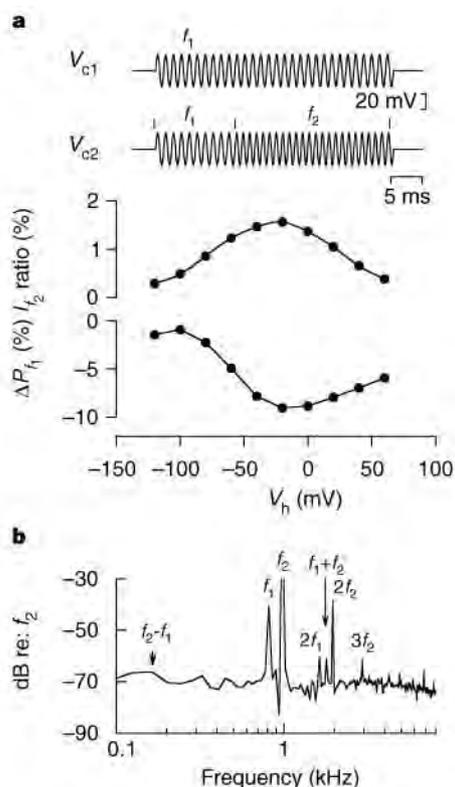

Figure 4 Both OHCs were voltage clamped to -40 mV and independently stimulated with pure sine-wave voltages. **a**, The upper two traces show the voltage stimuli delivered independently to each cell. During the initial part of the stimulus duration, each cell received a 20 mV peak sine wave at $f_1 = 813.8$ Hz; in the latter three-quarters of the stimulus duration, the OHC 2 frequency was switched to 976.5 Hz. Fast Fourier transform analysis was limited to the last half of stimulus duration to avoid transient responses. Comparisons were made before and after uncoupling by collapsing OHC 2. The upper plot shows the ratio of mechanically induced f_2 current (I_{f_2}) in OHC 1 due to f_2 voltage stimulation in OHC 2. The ratio of the power of the f_1 component in the response of OHC 1 before and after OHC 2 was collapsed was also obtained. The change in this ratio (ΔP_{f_1}) is shown in the lower plot. Negative percentage means that the f_1 response after collapse of OHC 2 was larger than that before; in other words, the mechanically induced f_2 component in OHC 1 suppressed the f_1 response in OHC 1. **b**, The spectrum of current response in OHC 2. The magnitude (in dB) is referenced to f_2 magnitude. Besides harmonic distortion products, the peak of sum frequency distortion ($f_1 + f_2$) is clearly visible.

lateral interactions may allow basilar membrane motion to be selectively enhanced at a particular location where passive vibration is maximal. In nonlinear systems, 10% feedback can have enormous consequences. The likely increase in OHC coupling with increasing frequency, supported by morphological evidence¹⁷, may explain the finding that tuning is sharper at higher characteristic frequencies. In this model, distortion in the cochlea arises from the very process that promotes greater frequency resolution. □

Methods

Pieces of the organ of Corti, containing between 3 and more than 50 OHCs with associated Deiters' cells, were freshly isolated from the guinea-pig cochlea, and adjacent OHCs were separately whole-cell voltage clamped at room temperature using an Axon 200A and 200B amplifier. Membrane voltages were corrected for the effects of residual series resistance, which ranged from 3 to 7 M Ω . We used ionic blocking solutions to remove voltage-dependent ionic conductances so that capacitive currents could be analysed in isolation²⁹. Gating currents were extracted using the P/4 technique³⁰. Pipette crosstalk artefacts at the onset of traces (first 50 μ s) were subtracted from the data, using the artefacts obtained in the absence of mechanical coupling. All data collection

and most analyses were performed with an in-house-developed, Windows-based whole-cell voltage-clamp program, jClamp (www.med.yale.edu/surgery/otolar/santos/jclamp.html), using a Digidata 1200 board (Axon).

Abstract. The organ of Corti has been found to have multiple gap junction subunits, connexins, which are localized solely in nonsensory supporting cells. Connexin mutations can induce sensorineural deafness. However, the characteristics and functions of inner ear gap junctions are not well known. In the present study, the voltage-dependence of gap junctional conductance (G_j) in cochlear supporting cells was examined by the double voltage clamp technique. Multiple types of asymmetric voltage dependencies were found for both nonjunctional membrane voltage (V_m) and transjunctional (V_j) voltage. Responses for each type of voltage dependence were categorized into four groups. The first two groups showed rectification that was polarity dependent. The third group exhibited rectification with either voltage polarity, i.e., these cells possessed a bell-shaped G_j - V_j or G_j - V_m function. The rectification due to V_j had fast and slow components. On the other hand, V_m -dependent gating was fast (<5 msec), but stable. Finally, a group was found that evidenced no voltage dependence, although the absence of V_j dependence did not preclude V_m dependence and vice versa. In fact, for all groups V_j sensitivity could be independent of V_m sensitivity. The data show that most gap junctional channels in the inner ear have asymmetric voltage gating, which is indicative of heterogeneous coupling and may result from heterotypic channels or possibly heteromeric configurations. This heterogeneous coupling implies that single connexin gene mutations may affect the normal physiological function of gap junctions that are not limited to homotypic configurations.

Key words: Voltage dependence — Gap junction — Hybrid coupling — Supporting cell — Inner ear — Hearing loss

Introduction

Connexins, the basic protein subunits of vertebrate gap junction channels, derive from a homologous gene family. More than 15 connexin genes have been cloned. Gap junctions comprised of different members of the connexin family have differing voltage gating properties either to transjunctional voltage (V_j) or to membrane potential (V_m or V_{i-o}) (*see* reviews: Bennett et al., 1991; Dahl, 1996; Kumar & Gilula, 1996). Each gap junction channel is composed of two hemichannels (connexons) and each hemichannel is composed of six connexin subunits (Perkins et al., 1997). A homotypic channel consists of two identical connexons and has symmetric voltage gating on either side owing to its symmetric structure. A heterotypic channel is formed by two different connexons and its voltage gating can be asymmetrical owing to its asymmetrical constitution (Barrio et al., 1991; Rubin et al., 1992a; Verselis et al., 1994; White et al., 1994a). A heteromeric channel possesses hemichannels formed by different connexin subunits and little is known about its voltage gating (Brink et al., 1997; Lee & Rhee, 1998).

Physiological and anatomical evidence for gap junctional coupling among the supporting cells of Corti's organ has been obtained both in vivo and in vitro (Jahnke, 1975; Gulley & Reese, 1976; Iurato et al., 1976; Hama & Saito, 1977; Santos-Sacchi & Dallos, 1983; Santos-Sacchi, 1987; Zwislocki et al., 1992; Kikuchi et al., 1995; Forge et al., 1997; Zhao & Santos-Sacchi, 1998). Connexin 26 (Cx26) is extensively distributed among cochlear nonsensory cells, including the supporting cells of Corti's organ (Kikuchi et al., 1995; Forge et

* Present address: Department of Otorhinolaryngology and Communicative Science NA 500, Baylor College of Medicine, Houston Texas 77030, USA

al., 1997). More recently, Lautermann et al. (1998) reported that cochlear supporting cells also contained Cx30 and Cx43; moreover, Cx30 was extensively expressed in a pattern similar to that of Cx26. Ultrastructural, immunohistochemical and physiological studies have found no evidence indicating that sensory cells (inner and outer hair cells) have gap junctions. However, mutations of connexin genes, for example, *GJB2* which encodes Cx26, have been identified in association with a high incidence of nonsyndromic sensorineural deafness (Kelsell et al., 1997; Denoyelle et al., 1998; Estivill et al., 1998; Xia et al., 1998). Little is known about the mechanism by which such a mutation may cause deafness. To some extent, the lack of a complete characterization of the biophysical properties of inner ear gap junctions limits our understanding.

Inner ear gap junctions can be modified by a variety of treatments, such as altering the intracellular activities of Ca^{++} and H^+ , temperature and membrane tension (Santos-Sacchi, 1985, 1986, 1991; Sato & Santos-Sacchi, 1994; Zhao & Santos-Sacchi, 1998). In the present report, the effects of voltage on inner ear gap junctions were explored by a double voltage clamp technique. The principal finding is that cochlea supporting cells display a variety of voltage dependencies, typified by asymmetrical rectification. The variety of asymmetrical voltage gating is indicative of complex heterotypic and/or heteromeric coupling. This heterogeneous coupling implies that single connexin gene mutations may affect the normal physiological function of gap junctions that are not limited to homotypic configurations.

Preliminary accounts of this work have been presented (Zhao & Santos-Sacchi, 1997, 1999).

Materials and Methods

The guinea pig's organ of Corti was freshly isolated and subsequently dissociated by shaking for 5–15 min in nominally Ca^{++} -free Leibovitz medium containing 1 mg/ml of trypsin. The dissociated cells were transferred into a recording chamber. Hensen cells are distinguishable by their bright lipid vacuoles under Hoffman optics (Fig. 1A). A classical double voltage-clamp technique was used to measure transjunctional conductance (G_j). Each cell in a Hensen cell pair was separately voltage-clamped using an Axopatch 200A and 200B (Axon, CA) (Fig. 1A). Test voltages were applied to one cell (cell 1) and transjunctional current (I_j) was measured in the adjacent cell (cell 2). To accurately obtain G_j -voltage relations, calculations were made with corrections for electrode access resistance (R_s) and nonjunctional membrane resistance (R_m) (Neyton & Trautmann, 1985):

$$V_j = V_{c1} - V_{c2} - (\Delta I_1 R_{s1} - \Delta I_2 R_{s2}) \quad (1)$$

$$G_j = \frac{I_j}{V_j} = \frac{-\Delta I_2 \left(1 - \frac{R_{s2}}{R_{m2}}\right)}{V_j} \quad (2)$$

Where V_{c1} and V_{c2} are the clamp voltages applied to cell 1 and cell 2, respectively; ΔI_1 and ΔI_2 are the holding current changes in cell 1 and

cell 2 caused by the test voltage in cell 1. R_{m2} is the nonjunctional membrane resistance of cell 2, where I_j was measured (Fig. 1A). It is clear from recent work that in cases where R_m is greater than 500 m Ω , R_s dominates errors in junctional estimates (Van Rijen et al., 1998), and is readily corrected for. Our residual series resistance is quite small and stable, and membrane resistance is typically greater than 1 G Ω (*see below*). Furthermore, cell pairs that had G_j greater than 20 nS were not included in the data analysis. Data collection and analysis were performed with an in-house developed Window's based whole-cell voltage clamp program, **jClamp** (<http://www.med.yale.edu/surgery/otolar/santos/jclamp.html>), utilizing a Digidata 1200 board (Axon, Foster City, CA.) All experiments were tape recorded and performed at room temperature.

To limit interference from nonjunctional voltage-dependent ionic currents, cells were continuously perfused by an extracellular ionic blocking solution that was composed of (in mM): NaCl 100, TEA 20, CsCl 20, CoCl_2 1.25, MgCl_2 1.48, HEPES 10, pH 7.2 and osmolarity 300 mOsm (Santos-Sacchi, 1991; Zhao & Santos-Sacchi, 1998). Patch pipettes were filled with an intracellular solution that contained (in mM): 140 CsCl, 5 EGTA, 2 MgCl_2 , and 10 HEPES, pH 7.2. After blocking nonjunctional voltage dependent ionic channels, Hensen cells had linear I - V relationships and high membrane resistances ($R_m > 1$ G Ω) (Fig. 1C).

Patch pipettes (Borosilicate Glass, MTW150-4, World Precision, FL) were pulled by a laser, based pipette puller (P-2000, Sutter, CA). A pair of pulled pipettes was used in each double voltage-clamp recording to promote symmetrical recording conditions. Pipettes had initial resistance of 2.5–3.5 M Ω in bath solution. After whole cell configuration was established, the residual series resistance of the electrode was in a range of 3.9–9.8 M Ω , which was measured by the peak of the uncompensated whole cell capacitance current (Huang & Santos-Sacchi, 1993) as both cells were simultaneously stimulated by an identical test pulse. R_s was stable and was 6.09 ± 0.22 M Ω and 6.23 ± 0.34 M Ω (mean \pm SE, $n = 64$) before and after experiments, respectively. In 11 cell pairs, R_s was further validated after one cell of the cell pairs was broken or pulled away by an electrode so that R_s could be unequivocally determined under single whole cell configuration. The measured R_s was 6.17 ± 0.62 M Ω consistent with those values which were determined under double voltage-clamp configuration.

Results

Gap junctions in Hensen cells had asymmetric responses to positive and negative transjunctional voltages (V_j). Macroscopic transjunctional currents were both time and voltage dependent (Fig. 1), and consequently, nonlinear I_j - V_j relationships were obtained at voltage onset and steady state. G_j - V_j relations could be classified into four groups, including one with no apparent voltage-dependence (Fig. 2D). The purpose of our categorizing junctional (and nonjunctional—*see below*) voltage dependencies was to simplify our dealings with the data, emphasize the diversity of response, and make some comparisons to published data.

Two basic asymmetrical V_j -dependencies were identified which showed opposite polarity sensitivities. The one whose conductance increased as V_j was made positive (Fig. 2A) is similar to that obtained from heterotypic channels containing Cx26 components (Barrio et al., 1991; Rubin et al., 1992a,b; Verselis et al., 1994; Dahl et

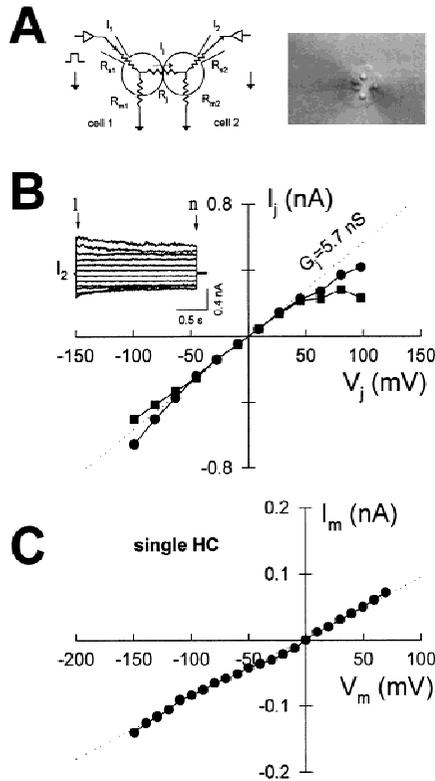

Fig. 1. (A) Schematic drawing and video-captured image illustrate the double voltage-clamp recording in a Hensen cell pair. Scale bar is 20 μ m. Both cells were initially voltage-clamped at -40 mV. V_j was produced by 2 sec voltage steps (V_{c1}) applied to cell 1 in 20 mV increments from -150 to $+70$ mV and cell 2 (V_{c2}) continuously held at -40 mV; the change in V_j is equal to ± 110 mV. Depolarization of the stepped cell corresponds to positive V_j and produces a downward current in cell 2 (I_2). (B) Transjunctional currents in response to V_j stimulation were obtained from a Hensen cell pair. Initial and steady-state transjunctional currents (I_j) were measured at onset (5 msec) and end (2 sec) of voltage steps and are represented by solid circles and squares, respectively. Initial I_j as well as steady-state I_j increased nonlinearly for V_j s greater than $+50$ mV. The dotted line indicates a conductance of 5.7 nS. (C) Typical example of membrane current (I_m) of single isolated Hensen cell as a function of membrane potential (V_m) obtained with the ionic blocking solutions used for coupling studies (see Materials and Methods). Membrane resistance is greater than 1 $\text{G}\Omega$, and the $I_m - V_m$ curve is linear.

al., 1996). The other had a conductance that decreased with positive V_j but changed less with negative V_j (Figs. 1 and 2B). The last group evidenced a slightly asymmetric bell-shaped $G_j - V_j$ relationship (Fig. 2C). While V_j -induced G_j changes typically ranged between 40–50%, in some cases G_j decreased below 20%; this variability probably reflects the heterogeneity of the channel population.

In most cell pairs, the V_j asymmetry was characterized by alternating the stimulus configuration, such that transjunctional conductance was measured in both directions between a cell pair (cell 1 \rightarrow cell 2 and cell 2 \rightarrow

cell 1). An example is shown in Fig. 3. When cell 1 of the pair was stepped to positive potentials, while holding cell 2 constant, steady-state transjunctional conductance, G_{jss} , decreased. On the other hand, when cell 2 was stepped to negative potentials, G_{jss} decreased. Unlike the asymmetry of G_{jss} , G_{j0} was insensitive to V_j gradients. These data illustrate that the asymmetric response to V_j in this cell pair resulted from a junctional conductance decrease only when cell 1 was depolarized, a clear transjunctional effect, and not due to possible asymmetric recording conditions. Furthermore, the conductance plots are nearly mirror images of each other, indicating an absence of V_m contribution in this case. This V_m insensitivity was independently verified by direct measures (see below).

To rule out fast gating effects, we determined the ratio of G_{jss}/G_{j0} in all cells that showed V_j dependence (Fig. 2 A–C). From these cells we found indications of slow (steady state) rectification in 9 out of the 28 cell pairs (Fig. 4). The ratio shows no voltage dependence until positive V_j values are reached, whereupon the ratio falls. This type of behavior strongly indicated that Hensen cells have heterotypic gap junctions, such as those containing Cx26 subunits as observed in oocyte pairs (Barrio et al., 1991; Rubin et al., 1992a,b; Verselis et al., 1994; Dahl et al., 1996).

Interestingly, Hensen cells demonstrate rapid voltage sensitivity of gap junctional coupling with the V_j protocol (Figs. 1 and 2). $V_j - G_j$ functions obtained from onset currents displayed the same asymmetrical behavior as steady state functions. In fact, in some cell pairs, no slow V_j -sensitive gating was observed, and it should be noted that nonlinear onset responses such as these might result not only from V_j sensitivity, but also from V_m sensitivity. This is further investigated below.

V_m -dependent gating was found in most (29/45) Hensen cell pairs (Figs. 5 and 6). In Fig. 5, G_j changes occurred within 5 msec or less after altering V_m , and remained stable for the full recording period. Slow V_m -dependent gap junction gating was never detected in Hensen cells. However, we only explored time periods up to 5 sec.

As with the V_j dependent conductance data, V_m -dependent junctional sensitivities could be categorized into four groups, including one that showed no dependence (Fig. 6). One group showed a decrease in coupling upon depolarization, while another showed the opposite effect (Fig. 6 A and B). The third group demonstrated a bell shaped $G_j - V_m$ function (Fig. 6C).

V_m gating was independent of V_j -gating. This is illustrated in Fig. 7, where comparisons between V_j and V_m dependence are made within the same cell pairs. Figure 7A shows data from a cell pair that lacked V_j -dependent gating; neither G_{j0} nor G_{jss} showed V_j sensitivity. However, G_{jm} decreased with cell depolarization. In another

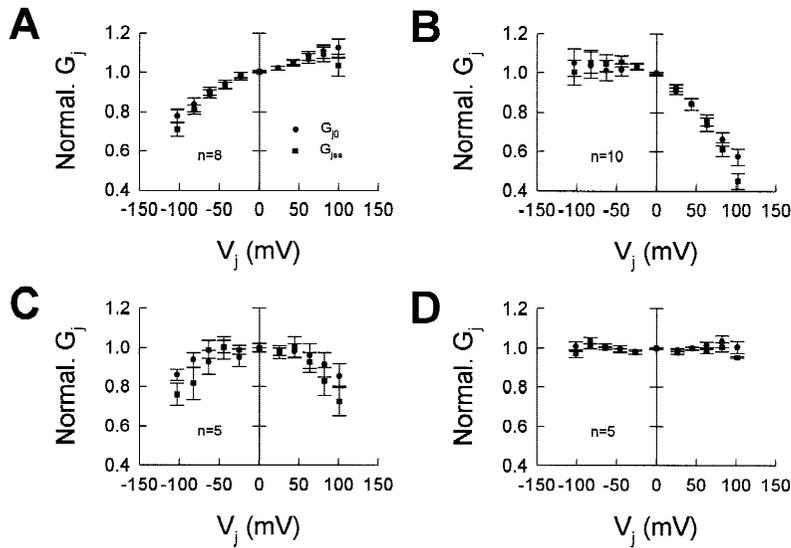

Fig. 2. Gap junctional coupling of Hensen cells presented differing voltage sensitivities for V_j stimulation. Initial transjunctional conductance (G_{j0}) and steady state conductance (G_{jss}) were normalized to the mean conductance at the average of V_j at ± 10 mV. G_j (mean \pm SE; $n = 28$) was 11.8 ± 1.31 nS. Cell pairs that had G_j greater than 20 nS were not included. Holding potential was -40 mV. Error bar represents SE.

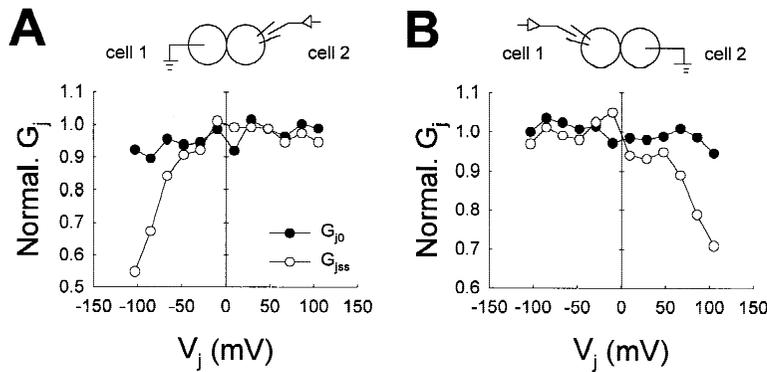

Fig. 3. V_j applied to either cell in the same cell pair identified rectified V_j -dependence. Positive V_j polarity corresponds to depolarization in the stepped cell. (A) Cell 1 was held and cell 2 was voltage-stepped. Rectification occurred at negative V_j , i.e., during cell 2 hyperpolarization. (B) Voltage steps were delivered to cell 1 while cell 2 voltage was held constant. At positive V_j (cell 1 depolarized), G_{jss} decreased. In this cell pair, G_{jss} always rectified at relatively positive polarity of V_j referring to cell 1. For each case onset conductance was fairly stable across voltage. The transjunctional conductance in this cell pair was about 13 nS. $R_{s1} = 4.3$ M Ω , $R_{s2} = 4.9$ M Ω , $R_{m1} = 1591$ M Ω , and $R_{m2} = 962$ M Ω .

cell pair the opposite behavior is illustrated (Fig. 7B). In this case, transjunctional conductance exhibited an asymmetric V_j -dependence, but was insensitive to V_m . Additionally, slow V_j -sensitive gating was undetectable since G_{jss} mirrored G_{j0} ; this further indicates that only a pure fast V_j -dependent gating is present.

Discussion

The most pronounced property of gap junctional voltage gating within cochlear supporting cells is its diverse asymmetry. This asymmetric gating is likely indicative of asymmetric channel structure within each cell, i.e., heterotypic and/or heteromeric junctional channels. Evidence is mounting that nonsyndromic deafness is associated with connexin gene mutations, such as Cx26 (Kelsell et al., 1997; Denoyelle et al., 1998; Estivill et al., 1998; Xia et al., 1998). While a variety of connexin types are present in supporting cells (Lautermann et al., 1998), functional impairments induced by single gene

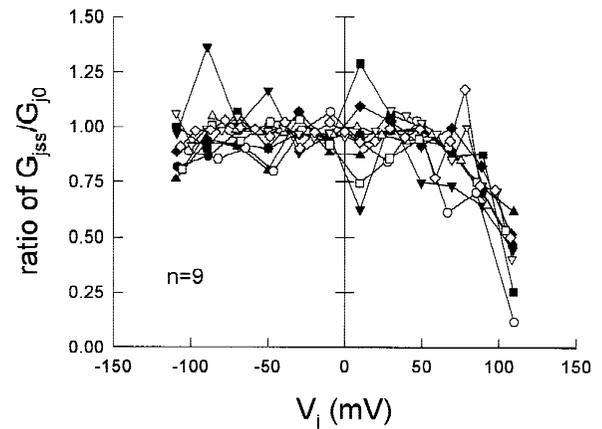

Fig. 4. Ratio of $G_{jss}:G_{j0}$ indicates slow V_j -dependent gating in response to V_j stimulation. Each symbol and line represents a cell pair.

mutations can not be rescued by other coexisting connexins. Our data provide evidence for the occurrence of hybrid gap junction channels in cochlea supporting cells,

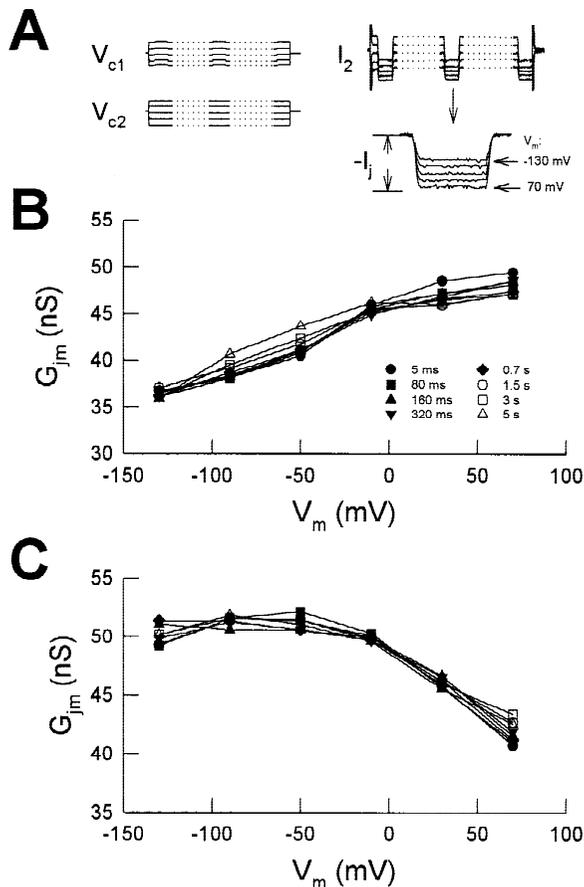

Fig. 5. Gap junction channels in Hensen cells are sensitive to membrane potential (V_m or V_{i-o}). **A** Voltage protocols. Both cells were simultaneously stimulated with voltage steps (V_{c1} and V_{c2}) from -130 to $+70$ mV in 40 mV increments, for a 5 sec duration. A test pulse (10 mV, 10 msec) was superimposed on cell 1 at different times to elicit transjunctional current. For clarity, the full length of waveforms is not shown. Example current traces at different membrane potentials are zeroed and superimposed. **(B and C)** V_m -dependent transjunctional conductance (G_{jm}) at different times is plotted. G_{jm} of the cell pair in panel **B** increased as the cells were depolarized, whereas in panel **C** G_{jm} decreased as the cells depolarized. Despite the opposite polarity dependence of the two coupled pairs, G_{jm} remained stable throughout the recording period.

and indicate that single gene mutations will impair more than just those channels destined to be homotypic. In heterotypic or heteromeric channels, the presence or absence of a single subunit type can have dramatic effects on junctional voltage dependence (Dahl et al., 1996; Brink et al., 1997; He et al., 1999; Li & Simard, 1999) and possibly other gating characteristics (Lee & Rhee, 1998). Thus, the potentially pervasive influence of single connexin gene mutations on diverse gap junction channel types may contribute to its devastating effects on hearing. This indicates, as well, that the diversity of channel types is important for cochlea function.

Cx26 and Cx30 are colocalized in cochlear support-

ing cells (Lautermann et al., 1998). In the paired oocyte expression system, Cx26 can form heterotypic gap junction channels with Cx30 (Dahl et al., 1996). The voltage gating of this heterotypic channel demonstrates remarkable differences from those of the corresponding homotypic channels (Jarillo et al., 1995; Dahl et al., 1996). One of the most distinguishable properties of this heterotypic channel is its slow V_j -dependent gating, rectifying with positive V_j on the Cx30 side of the junction (Dahl et al., 1996). It is likely that this type of heterotypic channel exists in the organ of Corti, since we find similar gating characteristics in cochlear supporting cells (Figs. 1, 3 and 4).

However, in addition to characteristics that are found in known heterotypic channels, we observed properties that are atypical, possibly indicating the existence of heteromeric channels. Although few physiological studies have suggested the existence of heteromeric channels (Brink et al., 1997; Lee & Rhee, 1998), biochemical analyses clearly reveal their presence (Stauffer, 1995; Jiang & Goodenough, 1996; Brink et al., 1997). In our experiments, several observed gating properties might arise from heteromeric channel behavior. First, the existence of fast asymmetric V_j -dependent gating that is distinct from slow V_j -dependent gating and V_m -dependent gating (Figs. 2 and 7B) is inconsistent with behaviors of known heterotypic and homotypic channels (Rubin et al., 1992a,b; Verselis et al., 1994). Second, the occurrence of multiple V_m -sensitivities found in coupled Hensen cells is unusual. While a depolarization-induced increase in conductance (as in Fig. 6A) has been observed in oocyte preparations of vertebrate Cx26 connexins (Rubin et al., 1992a,b), decreases in conductance, as in Fig. 6B, are only seen in insect preparations (Obaid et al., 1983; Verselis et al., 1991; Bukauskas et al., 1992). Bell-shaped V_m dependencies (Fig. 6C) have never been previously reported. Finally, the independence of V_m and V_j gating within the same cell pair is unique (Fig. 7). Considering this evidence and the high probability of heteromeric connexon formation within supporting cells (since at least Cx26, 30 and 43 are coexpressed), heteromeric channels likely exist in inner ear gap junctions.

Although contrary evidence initially existed (Spray et al., 1984, 1986; Riverdin & Weingart, 1988), it is currently accepted that vertebrate gap junctions are gated by voltage, either V_j or V_m (Moreno et al. 1991; 1992; Kumar & Gilula, 1996). Interestingly, although most Hensen cells present voltage-gated junctional conductances, we find an absence of voltage dependence, either to V_j or V_m , in a large proportion of Hensen cells. While this might be expected for coupling derived from cytoplasmic bridges between cells, we typically find that Hensen cell coupling is sensitive to agents that uncouple gap junctions, e.g., octanol or low pH (Santos-Sacchi, 1985; 1991; Sato & Santos-Sacchi, 1994). It should also

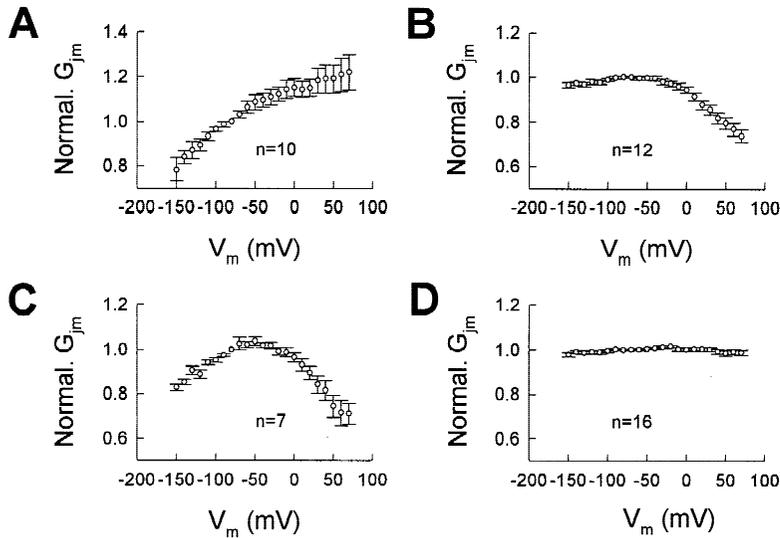

Fig. 6. Coupling of Hensen cells showed multiple V_m -dependences. V_m -dependent G_{jm} was normalized to that at the Hensen cell's holding potential of -80 mV. Error bar represents SE. (A) Conductance increases during depolarization. (B) Above -40 mV, conductance decreases. (C) Conductance is a bell-shaped function of membrane voltage.

be noted that we have used techniques (*see* Materials and Methods) that enable us to accurately deliver voltage and assess its delivery to the cells, so that we can be sure that voltage-clamp problems are minimized. The voltage-gating properties of homotypic and heterotypic channels comprised of connexins identified in supporting cells (Cx26, 30 and 43) show clear voltage dependence. Channels derived from Cx26 and 30 exhibit marked V_j -dependence, whereas homotypic channels derived from Cx43 exhibit weak steady-state voltage dependence (Moreno et al., 1992; Veenstra et al., 1992; Miyoshi et al., 1996). In the inner ear, the expression of Cx43 in cochlear supporting cells was described as relatively weak (Lautermann et al., 1998). Indeed, Forge et al. (1997) did not detect Cx43 antibody labeling in the supporting cell region in gerbil and guinea pig cochlea. Thus, the lack of voltage dependence in many supporting cells is possibly due to either the summed opposed characteristics of the channel populations found in the cell pair or due to heteromeric configurations. Voltage sensitivity may be modulated by allosteric interactions between opposing connexons (White et al., 1994a). It may also be that voltage sensitivity can be modulated by heteromeric interactions within a connexon.

It is well established that V_m -sensitive gating occurs in invertebrate gap junctions (Obaid et al., 1983; Verselis et al., 1991; Bukauskas et al., 1992). Only recently, however, has V_m -dependence been documented in vertebrate gap junctions either in natural tissues (Verselis et al., 1993) or in the paired oocyte expression system (Barrio et al., 1991, 1997; Rubin et al., 1992a; White et al., 1994b; Jarillo et al., 1995). The conductance of channels possessing Cx30 and 43 decreases with depolarization (White et al., 1994b; Jarillo et al., 1995), similar to what we observed in Hensen cells. A V_m dependent conductance also arises when channels possess either Cx26 or

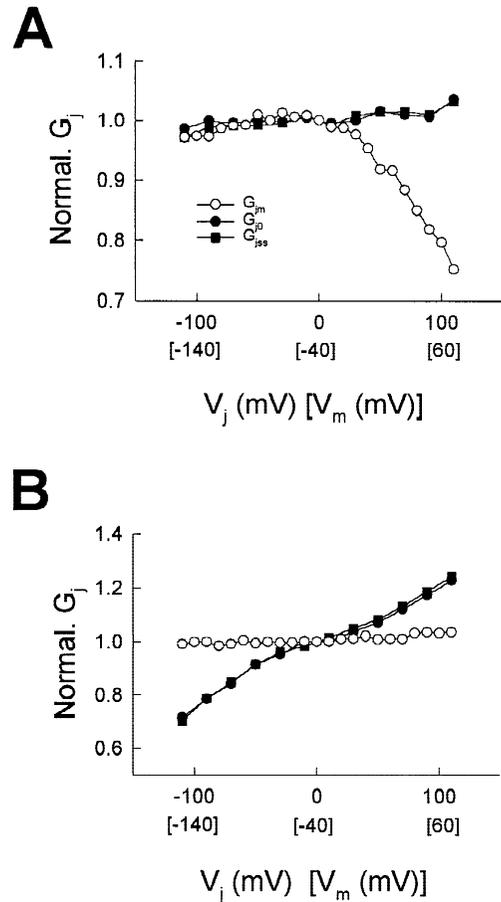

Fig. 7. Voltage-dependent Hensen cell coupling shows independent V_j and V_m sensitivities. (A) In the same cell pair, V_m depolarization reduced junctional conductance but V_j was without effect. (B) In this cell pair the sensitivity is reversed. Coupling was sensitive to V_j stimulation but insensitive to V_m (or V_{i-o}). Note that this pair had fast V_j -dependent gating, but no slow V_j -dependent gating.

45; however, conductance increases upon depolarization (Barrio et al., 1991, 1997; Rubin et al., 1992a). Some Hensen cell pairs have similar gating characteristics to that of Cx26 and 45 (Figs. 5B and 6A). However, while the voltage sensitivity expressed in Hensen cells is greater than that of Cx26, it is quite similar to that of Cx45 (Barrio et al., 1997). Whether Cx45 is present in the inner ear remains to be seen; nevertheless, mutation studies indicate that connexins other than those already identified histochemically also exist (*see below*).

Hensen cells, *in vivo*, are bathed in different media, endolymph (high K^+ and +80 mV) apically and perilymph (low K^+ and 0–10 mV) basally. They contribute to a barrier against ionic diffusion from the endolymph to perilymph caused by the gradients of ions and voltage. These gradients are vitally important for normal sensory function, and it has been proposed, though still remains unproved, that supporting cells help maintain these gradients by sinking K^+ released during hair cell and neural excitation (Santos-Sacchi, 1987; 1991). Recently, an anatomical substrate for the directional sinking of ions through gap junctions has been proposed (Kikuchi et al., 1995). It is currently held that differing connexins may contribute to the formation of functional junctional pathways with variable gating sensitivities and permeabilities (Elfgang et al., 1995; Mills & Massey, 1995; Brink, 1996; Trexler et al., 1996). In fact, non-uniform, directionally limited dye spread in the intact organ of Corti has been found (Santos-Sacchi, 1986; Oberoi & Adams, 1998). Our data that establishes the likelihood of hybrid gap junction channels underscores the possibility of functional pathways within the organ of Corti. It may be that the nonsyndromic hearing loss that arises from connexin mutations occurs because functional pathways are disturbed. So far, three connexin genes, *GJB1* (encoding Cx32), *GJB2* (encoding Cx26) and *GJB3* (encoding Cx31), have been identified in association with hearing impairment (Bergoffen et al., 1993; Kelsell et al., 1997; Denoyelle et al., 1998; Estivill et al., 1998; Xia et al., 1998). These data indicate that the potential variability in heteromeric combinations is even greater than the immunohistochemical data suggest. Furthermore, it is likely that mutations of Cx30 and 43 could also alter heterotypic- or heteromeric-like gap junctional coupling in the inner ear, thus leading to hearing impairment.

ABSTRACT

Background: Fluorescent proteins (FPs) have widespread uses in cell biology. However, the practical applications of FPs are significantly limited due to their rapid photobleaching and misfolding when fused to target proteins. **New Method:** Using a combination of novel and known mutations to eGFP, we developed a well folded and very photostable variant, SiriusGFP.

Results: The fluorescence spectrum indicated that the excitation and emission peaks of SiriusGFP were red-shifted by 16 and 8 nm, respectively. Co-operative effects of two key mutations, S147R and S205V, contribute to its photostability. SiriusGFP tagged to the mitochondrial outer membrane protein Omp25 showed sustained fluorescence during continuous 3D-scanning confocal imaging (4D confocal) compared to eGFP-tagged Omp25. Furthermore, with super-resolution structured illumination microscopy (SIM) we demonstrate marked improvements in image quality and resolution (130 nm in XY axis, and 310 nm in Z axis), as well as, decreased artifacts due to photobleaching.

Comparison with Existing Method(s): Compared to eGFP, SiriusGFP shows a 2-fold increase in photostability in vitro, and folds well when fused to the N- and C- termini of cytoplasmic and membrane proteins. While its quantum yield is ~3 fold lower than eGFP, its decreased brightness was more than compensated by its increased photostability in different experimental paradigms allowing practical experimentation without dynamic adjustment of light intensity or fluorescence sampling times.

Conclusions: We have developed a variant of eGFP, SiriusGFP, that shows over a two fold increase in photostability with utility in methods requiring sustained or high intensity excitation as in 4D confocal or SIM imaging.

1. Introduction

Fluorescent proteins (FPs) are widely used in cellular imaging for recording subcellular events and detailed dynamic processes, including *in vivo* imaging. In the nervous system, fluorescent proteins have been used for temporospatial migration of individual cells and to ascertain numerous physiological phenomena including changes in membrane potential and Ca²⁺ and Cl⁻ levels (Baker, Mutoh et al. 2008; Chen, Wardill et al. 2013; Zhong, Navaratnam et al. 2014). Compared to chemical dyes, genetically encoded FPs have many benefits including 1) precise targeting with fusion proteins 2) avoidance of chemical loading/labelling with consequent cell toxicity and dye leakage/

delocalization. Perhaps the most distinguishing advantage of FPs is genetic labeling that allows potential development of cell-lines and transgenic animals with the gene-editing tool CRISPR/Cas9 and tissue-specific gene expression.

Recently, the expansion in 3D time-lapse (4D) confocal imaging of cells during development and super-resolution microscopic technologies have required brighter, photostable fluorophores for imaging. Photobleaching is one of the major problems for FPs, which limits their applications in biological investigation. Reduced light emission due to photobleaching can be compensated by increases in excitation light intensity and exposure time. These two compensatory mechanisms also accelerate photobleaching (Cranfill, Sell et al. 2016). Moreover, these

compensatory mechanisms are not possible for the fast imaging times used in modern fluorescence imaging techniques. For confocal microscopy and almost all superresolution microscopy methods, photostability is as important a factor as brightness for imaging quality. For super-resolution structured illumination microscopy (SIM), in particular, the requirement of at least 15 frames (3 angles and 5 phases per angle) to generate a single image makes it more sensitive to photobleaching than conventional confocal microscopy (Rego and Shao, 2015; Hong, Wilton et al. 2017).

The green fluorescent protein (GFP) and its variants derived from jellyfish *Aequorea victoria* are the most extensively used FPs. eGFP is the most widely used FP, but has significant drawbacks in biological applications. The chromophore in GFPs, *para*-hydroxybenzylidene-imidazolinone (*p*-HBDI), is formed by sequential autocatalytic cyclization and dehydration/oxidation, after initial folding of the polypeptide chain into a β -barrel conformation. For *p*-HBDI, the *Z-E* isomerization on the exocyclic double bond is the major internal conversion pathway, the non-fluorescent alternative pathway of energy dissipation of the excited fluorophore. The fluorescence quantum yield (ϕ_f) of *p*-HBDI (without the surrounding β -barrel) is < 0.001 in gas phase (Huang, Cheng et al. 2013), and even lower (~ 0.0001) in solvents, while the quantum yield (ϕ_{ZE}) of *Z-E* isomerization is ~ 0.5 (Yang, Huang et al. 2008; Chatterjee, Mandal et al. 2015). The β -barrel scaffold of GFP provides hydrophobic isolation and a rigidly constrained environment for the chromophore, functioning as a protective nest for efficient production of fluorescence. As a result, the quantum yield of GFP can reach up to 0.77 (as reference, 0.80 for frozen *p*-HBDI at 77 K, where the internal conversion pathway is almost eliminated) (Niwa, Inouye et al. 1996; Nielsen, Lapierre et al. 2001).

How irreversible photobleaching of the chromophore in FPs occurs is not clear, although oxygen concentration dependence on photobleaching has been confirmed in many GFP-like FPs. The destruction of chromophores in chemical dyes is preceded by ROS formation from redox reactions with the excited chromophore. The formation of ROS is, in turn, strongly dependent on the local redox environment. The damage to the chromophore in GFP is likely caused by endogenous and exogenous singlet oxygen. For wtGFP or eGFP, self-generated endogenous singlet oxygen (1O_2) occurs when exposed to illumination (Greenbaum, Rothmann et al. 2000; Jimenez-Banzo, Nonell et al. 2008; Bogdanov, Bogdanova et al. 2009). The formation of superoxide was postulated to be the gateway initiating a series of chemical reactions leading to the destruction of the chromophore (Chatterjee, Mandal et al. 2015). Furthermore, solvated electrons produced from solvent radiolysis outside the β -barrel can migrate to the chromophore cavity through a water tunnel near residue His148. Therefore, it is possible to reduce photosensitized 1O_2 by limiting the accessibility of molecular oxygen to the chromophore; a tighter β -can or an allosteric block are two potential ways.

Based on the knowledge of fluorophore photochemistry, we developed a series of eGFP derivatives to increase photostability that can tolerate higher intensity illumination and longer exposure. The best variant, SiriusGFP, contains several folding mutations and two key mutations, S147R and S205V, both of which contribute to significant improvement in photostability over eGFP. Although SiriusGFP has reduced brightness compared to eGFP, it is more than compensated for by an increase in photostability. Practically, this allowed for improved 4D confocal imaging as it eliminated dynamic adjusting of exposure time. Furthermore, SIM images with SiriusGFP show resolution improvement, especially in the Z axis. The optical properties were determined with purified protein of SiriusGFP, and compared to eGFP. The photobleaching mechanism of SiriusGFP was determined to be oxygen-dependent under oxygen-depletion in both high and low intensity illumination. This contrasts with eGFP that shows different mechanisms and sensitivities to oxygen with high and low laser power. Our new green FP, SiriusGFP, provides improved capabilities for superresolution and time-lapse microscopy.

2. Methods

2.1. Gene construct and mutations & cell culture

Mutagenesis was performed using the Quick Change method adapted from Stratagene QC protocol. Mutations were verified by DNA sequencing the entire gene. We used eGFP-N1 as the backbone vector. HEK-293 and HeLa cells were cultured in Dulbecco's modified Eagle's medium (DMEM, high glucose) containing 50 U/ml penicillin and streptomycin (1%), 10% fetal bovine serum (FBS) at 37 °C in a CO₂ incubator (5%).

The sequences of SiriusGFP and the intermediates of SG205 and SG147 are as followed.

SG205: eGFP-S205V/A206K

SG147: eGFP-S147R/A206K

SiriusGFP: eGFP-S30R/Y39N/F99S/N105T/S147R/M153T/V163A/S205V/A206K

2.2. Fluorescent protein extraction from cell lysis

Cultured HEK-293 cells were grown in 10 cm dishes and transiently transfected with eGFP and SiriusGFP plasmid, respectively. After 48 h of incubation, the cells were scraped with a plastic scraper after a brief rinse in DPBS. Cells were resuspended in 200 μ l of EBC buffer (50 mM Tris, 120 mM NaCl, 0.5% NP40, pH 7.5) containing Protease Inhibitor cocktail (ThermoFisher, PI-88665), vortexed at 4 °C for 15 min to lyse the cells, and then centrifuged at 14,000 rpm for 20 min (4 °C). The supernatant containing solubilized fluorescent proteins was aspirated and used for further experimentation.

2.3. Expression and purification of eGFP and SiriusGFP

SiriusGFP and eGFP proteins were expressed in *E. coli* and purified by immobilized metal ion affinity chromatography. eGFP and SiriusGFP genes were subcloned in the pQE-801 vector (Qiagen) using BamHI and HindIII restriction sites. The vector is designed to provide a six-histidine tag on the N-terminus of the expressed eGFP and SiriusGFP for affinity purification. The complete tag sequence fused to the actual eGFP and SiriusGFP proteins was MRGSHHHHHHGS. The constructs were transformed in *E. coli* BL21(DE3), spread on LB plates containing 100 μ g/ml ampicillin (LBA), and incubated overnight at 37 °C. A single colony from each construct was inoculated in 50 ml LBA and incubated for 16 h at 37 °C without shaking. The resulting seed culture was added to 500 ml LBA in a 2-liter baffled Erlenmeyer flask, and incubated at 37 °C in an orbital shaker (150 rpm) until OD₆₀₀ reached 0.6–0.7. The flasks were quickly cooled under running tap water and the cultures injected with 0.5 mM isopropyl β -D-1-thiogalactopyranoside (IPTG) to induce protein expression. The cultures were incubated with shaking (150 rpm) for a further 22 h at 15 °C until it reached a final density OD₆₀₀ \sim 5. Cells were pelleted by centrifugation (4000 g/10 min) and the pellets resuspended in 40 ml Buffer A: 50 mM NaH₂PO₄ (titrated to pH 8 with NaOH), 300 mM NaCl. Temperature was kept at 4 °C throughout cell lysis and purification steps. After addition of protease inhibitor cocktail (10 μ g/ml each of aprotinin, leupeptin, pepstatin, chymostatin) and 10 mM imidazole, the cell slurry was sonicated using a Bredson digital sonifier (6 cycles of 30 s each, at 67% amplitude). Cell lysates were centrifuged for 40 min at 15,000 g, and the supernatant added to a 1 ml bed volume of Ni-NTA agarose resin (Qiagen) and gently nutated for 1 h. The resin was loaded on a column and sequentially washed with 10 ml Buffer A plus 10 mM imidazole, and 10 ml Buffer A plus 20 mM imidazole. Fluorescent proteins were eluted using Buffer A containing 250 mM imidazole and dialyzed against 1 L of 20 mM Tris (titrated to pH 7.5 with HCl) and 150 mM NaCl. Protein concentration was measured with the Bradford method (Bradford, 1976; ThermoScientific/Pierce Coomassie Protein Assay Kit), using bovine serum albumin as a calibration standard. Both eGFP and SiriusGFP proteins ran as a single band

at ~25 kDa molecular weight on SDS-PAGE gel (Bio-Rad Mini-Protean TGX gel, 4–15%). Typical protein yields for both eGFP and SiriusGFP were about 40 mg per liter of culture.

2.4. Optical properties

The absorbance spectroscopy of purified FPs was performed in 150 mM NaCl, 20 mM Tris, pH 7.5 with an Agilent 8453 UV–vis spectroscope. The fluorescence spectra of purified FPs was obtained in the same buffer in a FluoroMax-3 (Jobin Yvon Horiba). The quantum yields were calculated from the spectral readout.

2.5. Wide-field photobleaching on live cells

The cultured cells were grown on glass coverslips (No.1, 0.13–0.16 mm thick, 15 mm round, Warner Instr., USA). Transient transfection with the plasmid of interest was performed using lipofectamine-2000 (Invitrogen, Life technologies). After transfection, the coverslips were mounted on a quick change chamber and platform (RC-42LP and QE-1, Warner Instr., USA). Fluorescence images were acquired using an oil-immersion objective (N.A. = 1.30, Plan Fluor 100× Objective, Nikon, Japan) with a Nikon Eclipse Ti equipped with a 200 W metal-halide lamp (Lumen200, Prior Scientific, USA) as the fluorescence illumination source. Shutter and filter wheel (Lambda10-3 optical filter changer with smart shutter, Sutter Instr., USA) were connected between the microscope and the illumination source, in which Semrock ET430/24x-32 was used as the excitation filter for CFP, Semrock ET500/20x-32 as the excitation filter for YFP and Chroma HQ520LP as the emission filter. A 14-bit back-illuminated EMCCD camera system (128 × 128 pixels, 24 μm array, Andor iXon^{EM} + DU-860E, USA) was used to record the fluorescence images under 430 or 500 nm excitation. All peripheral hardware control, image acquisition and image processing were achieved and/or synchronized on a PC computer via a 16-bit/1-MHz USB Data Acquisition System (Personal Daq/3000 Series, IOtech, USA) by using customized software (jClamp & FastLook, SciSoft, USA; www.SciSoftCo.com). Photobleaching data and fluorescence images were achieved with our ratiometric imaging system controlled by jClamp & FastLook. Photobleaching efficiency at a wavelength of 430 nm is higher than at 500 nm, although the absorption at 430 nm is much lower than 500 nm. Because of this enhanced bleaching capability and to optimize our identification of photostable products, we bleached GFP variants at 430 nm (approximately 1 mW with the 100X objective). Stable optical power at the utilized wavelengths was confirmed using an analog optical power meter (ThorLabs PM30-130, w/ S130 A Slim Sensor). The 430 nm filter was used for 60 ms at the beginning of each episode and then the filter changed to 500 nm, an image acquired, and then the filter changed back to 430 nm for bleaching for a further 2 s. This procedure was performed reiteratively for 400 episodes. Filter changes required 100 ms. There is a 200 ms interval time between two successive episodes, and the excitation filter remained at 430 nm between successive episodes. The photobleaching curves were measured in GFP variants expressed in the cytosol of HEK-293 cells. The average fluorescence intensity of regions of interest (ROI) was measured, and the background fluorescence was subtracted using FastLook and ImageJ. Data were analyzed with Matlab, Origin 2016 and SigmaPlot 10.0.

2.6. Confocal photobleaching on live cells

The photobleaching of live HeLa cells was performed on a Zeiss LSM 710 duo confocal scanning microscope with an OPSS laser at 489 nm (100 mW at maximum power). HeLa cells were grown on 35 mm glass-bottom culture petri dishes (P35GC-1.0-14-C, MatTek, USA), and transfected with eGFP/SG205/SG147/SiriusGFP plasmids using Lipofectamine 2000 (Invitrogen, USA) followed by 24 h incubation at 37 °C. Before imaging, culture media in petri dishes was changed to a

neutral buffer of 0.2 mM NaCl, 100 mM sodium Malate, 300 mOsm, pH 7.20 after a rinse with PBS. All photobleaching data were fit by a single exponential decay function, $Y = Y_0 + Ae^{-x/t}$, where Y_0 is the constant offset representing the residual fluorescence after photobleaching reaching a steady state (R^2 ranged from 0.97–0.99). The laser power was measured with an analog optical power meter (ThorLabs PM30-130, w/ S130 A Slim Sensor).

2.7. Oxygen-depletion photobleaching

The photobleaching of PFA-fixed HeLa cells are performed in the same Zeiss LSM 710 duo confocal microscope. The oxygen-depletion buffer containing COT was prepared as previously described (Olivier, Keller et al. 2013). Mercaptoethylamine (MEA, Sigma-Aldrich 30,070) was dissolved in deionized water as 1 M stock solution, then adjusted to pH 8 by glacial acetic acid (Avantor Performance Materials). The stock solution was stored at 4 °C and used within a week. β-mercaptoethanol (BME, Sigma M3148) was used without dilution as a 14.3 M solution. Cyclooctatetraene (COT, Sigma-Aldrich 138,924) was diluted in DMSO as 200 mM stock solution and stored at 4 °C. Protocatechuic acid (PCA, Sigma-Aldrich 37,580) was dissolved in deionized water as 100 mM stock solution, then adjusted to pH 9 with KOH aq. The stock solution was stored at 4 °C and used within a month. Protocatechuic acid 3,4-dioxygenase from *Pseudomonas* sp. (PCD, Sigma-Aldrich P8279) was dissolved in 100 mM Tris–HCl (pH 8) containing 50 mM KCl, 1 mM EDTA and 50% glycerol as 5 μM stock solution, and stored at –20 °C.

Before oxygen-depletion treatment and confocal imaging, HELA cells transfected with eGFP-Omp25 or SiriusGFP-Omp25 were fixed with 4% PFA for 10 min, and the coverslips rinsed with PBS 3 times. Cells were treated with 0.2% Triton X-100 in PBS for 15 min to permeabilize cell membranes. Coverslips were rinsed with PBS 3 times. Confocal imaging was performed with a Zeiss LSM710 Duo confocal scanning microscope in freshly made oxygen-depletion solution of 10 mM PBS-Tris (pH 7.5) containing 10% (w/v) glucose, 10 mM MEA, 50 mM BME, 2 mM COT, 2.5 mM PCA and 50 nM PCD. This oxygen-depletion solution was abbreviated as pcaPCD in the Fig. 2. Controls were in 10 mM PBS-Tris buffer containing 10% glucose. The maximum optical power of the OPSS laser is 100 mW, and 5% (low intensity) and 50% (high intensity) were the percentage of laser power used for photobleaching.

2.8. Photobleaching on purified protein embedded in gel

Photobleaching rates on purified proteins of GFPs embedded in polyacrylamide gel were measured by Zeiss LSM710 laser-scanning confocal microscopy, following a previously described protocol (Cranfill, Sell et al. 2016). This experiment was designed to produce a homogenous population of immobilized protein of known concentration which was photobleached. Briefly, 20% polyacrylamide-1 μM FP solution was polymerized by addition of ammonium persulfate and TEMED. The 20% polyacrylamide-1 μM FP solution was then injected into a space between a coverslip and glass slide. After polymerization of the acrylamide the outside edges of the coverslip were sealed with Cytoseal to prevent dehydration around the edges. The slides were maintained in the dark at 4 °C overnight before photobleaching and imaging.

2.9. Confocal 4D imaging

Confocal 4D imaging of live HeLa cells transfected with eGFP-Omp25 and SiriusGFP-Omp25, respectively. We used a Yokogawa CSU-X1 spinning disc confocal microscope for image acquisition. The 3D confocal Z-stack scanning was done continuously to maximize photobleaching.

2.10. Structured illumination microscopy (SIM)

HEK-293 or HeLa cells were transfected with eGFP-Omp25 or SiriusGFP-Omp25, and incubated at 37 °C in a CO₂ incubator (5%). The targeting protein embedded in the outer membrane of mitochondria in HEK-293 or HeLa cells. Before imaging, cells were fixed with 4% PFA and then rinsed with PBS buffer. Structured Illumination Microscopy (SIM, DeltaVision-OMX, Applied Precision, GE life) was performed in PBS. The XY and Z resolution were measured with the lines perpendicularly across individual mitochondrial membranes at XY and XZ/YZ axes, respectively. Gaussian fitting of the readout traces gives full width at half maximum (FWHM) of each peak. Averages of over 100 peaks in SIM images were measured to ascertain the resolution of the imaging technique.

3. Results

3.1. Optical properties of SiriusGFP

Mutations of F99S/M153 T/V163 A in Cycle3 GFP help folding and maturation by avoiding aggregation traps (Fukuda, Arai et al. 2000), and S30R/Y39 N/N105 T help fast folding in super-folder GFP/YFP (Pedelacq, Cabantous et al. 2006; Andrews, Schoenfish et al. 2007; Ottmann, Weyand et al. 2009). A206 K mutation makes GFP fully monomeric even at high concentrations (Zacharias, Violin et al. 2002), which eliminates the multimerization/ aggregation of GFP in fusion proteins.

Upon illumination, the neutral chromophore HBDI of wtGFP is excited and converted to the anion excited state, via excited state proton transfer (ESPT), in the picosecond timescale. It was reported that the mutant S205 V of wtGFP has ESPT 30 times slower than in wtGFP through an alternative proton wire via T203 to E222 (Shu, Leiderman et al. 2007; Fang, Frontiera et al. 2009). And ESPT in S205 A is 15 times slower than wtGFP (Erez, Gepshtein et al. 2011; Wineman-Fisher, Simkovitch et al. 2014). Our previous work on chloride-sensitive YFP also indicated that S205 V in eYFP substantially increased the photostability (Zhong, Navaratnam et al. 2014). However, the double mutant of eGFP-T203 V/S205 V is still fluorescent when excited at 488 nm (data not shown), confirming that the majority of its chromophore stays in the anionic state, and ESPT is not necessary for fluorescence emission in eGFP.

Currently, Emerald GFP is the most photostable GFP variant, but exhibits a very fast initial fluorescence decay to about 50% before reaching a photostable state (Tsien, 1998; Cubitt, Woollenweber et al. 1999). This fast decay component makes Emerald less ideal for long term imaging or superresolution imaging. The key mutation in Emerald GFP is N149 K. We tested this mutation based on SG205 (S205 V/A206 K) by generating several mutants including N149 K, S147 H/N149 K, and Y145 F/S147 P/N149 K, respectively. However, all of these mutants still showed the fast initial decay (data not shown).

Based on the photobleaching results of the intermediate mutant SG147 (S147R/A206 K), we generated a mutation S147R that also increased both fluorescence lifetime (Tau) and residual fluorescence after photobleaching (Y₀). The increased Tau and Y₀ may be attributed to the protective effect of charge repulsion of positive ions (including protons) by the bulky Arginine side chain. Consistent with this possibility SiriusGFP has a pK_a of 5.29 that also implies a proton repulsion effect of S147R near the phenolic group of the chromophore (Fig. S1D).

The UV-VIS spectroscopy of purified FPs revealed that SiriusGFP has a major excitation peak at 504 nm and a minor peak at 396 nm (Fig. 1A), indicating that the chromophore has two protonation states of the phenolic group, and that the protonated state is responsible for the minor peak. The extinction coefficient of SiriusGFP and eGFP are not significantly different (56,600 M⁻¹ cm⁻¹ at 504 nm for SiriusGFP, compared to 55,000 M⁻¹ cm⁻¹ at 488 nm for eGFP). The emission peak of SiriusGFP is at 516 nm (with a shoulder at ~550 nm) instead of

508 nm for eGFP (with a shoulder at ~540 nm). When excited at 400 nm SiriusGFP has the same emission peak at 516 nm (Fig. S1E), implying that ESPT occurs in SiriusGFP. Since the main proton pathway via Ser205 to Glu222 for ESPT was blocked by the mutation of S205 V, the alternative pathway via T203 is probably involved in ESPT of SiriusGFP. A proportion of Glu222 in SiriusGFP should be in the anionic state as a proton acceptor, while the majority of molecules maintains its chromophore in an anionic state along with a neutral Glu222. The ratio between the absorption intensities of the bands A:I in SiriusGFP (peak at 396 and 504 nm, respectively) is 1:3.75, whereas this ratio is 4 : 1 in wtGFP (peak at 400 nm and 488 nm). The fluorescence quantum yield (φ_f) of SiriusGFP is significantly reduced compared to eGFP (0.214 for SiriusGFP and 0.60 for eGFP) (Fig. S1C). Thus, the brightness (extinction coefficient X quantum yield) of SiriusGFP is 12,112 M⁻¹ cm⁻¹, while eGFP is 33,000 M⁻¹ cm⁻¹. These results imply that there are more competing pathways for deactivation of the excited state of SiriusGFP than that of eGFP. The decreased φ_f could be attributed to the increased τ-torsion on the chromophore by an absence of a constrained H-bond between Ser205 and the phenolic group of p-HBDI, which makes the phenolic group in SiriusGFP more flexible than that in eGFP. The τ-torsion (less than 90°) on the methylene bridge (the only exocyclic double bond) facilitates internal conversion and deactivation to ground state (Huang, Cheng et al. 2013) that can compete with the radiative relaxation as fluorescence.

The excitation and emission peak are both red-shifted from eGFP (Ex 488 nm, Em 508 nm) to SiriusGFP (Ex 504 nm, Em 516 nm), implying that the energy gap in SiriusGFP is narrower than that of eGFP and has more vibration levels in the S₀ and S₁ state.

When photobleaching transfected HeLa cells with a scanning laser at 489 nm (~1500 μW at the objective) in a confocal microscope, exponential decay curves with different lifetimes (Tau) and residue offsets Y₀ were noted, and shown in Fig. 1B. The average lifetime (Tau) of SiriusGFP (118.3 s) is more than twice that of eGFP (50.1 s), with the intermediate mutants having values that lay between (Tau of SG205 is 104.4 s and SG147 is 76.3 s (Fig. 1C)). An ANOVA analysis on fluorescence lifetimes (Tau) among the four GFP variants indicates highly significant differences (p < 0.01). Thereafter, using Tukey-Kramer Multiple Comparisons Test for Tau pairwise comparison, Q values were 23.4 for eGFP and SiriusGFP, 19.2 for eGFP and SG205, 8.6 for eGFP and SG147, 5.1 for SiriusGFP and SG205, 13.7 for SiriusGFP and SG147, and 9.3 for SG205 and SG147. Note that a Q value of 3.6 or greater denotes a significant difference. Y₀ is the offset value with single exponential decay fitting, and represents the residual steady state fluorescence after photobleaching. Y₀ for SiriusGFP is 15.1% and is three fold that of eGFP (5.1%). Similar to Tau, the intermediate mutants had values that lay between that of eGFP and SiriusGFP (7.2% for SG205 and 12.5% for SG147 (Fig. 1C, D)). An ANOVA analysis on Y₀ among the four GFP variants also indicates significant differences (p < 0.01). As with Tau, these intermediate values resulted in a smaller degree of confidence in statistical differences of Y₀ between the SiriusGFP and the intermediate mutants when compared to SiriusGFP and eGFP. The Q values for Y₀ pairwise comparison were 36.7 for eGFP and SiriusGFP, 8.2 for eGFP and SG205, 27.6 for eGFP and SG147, 27.8 for SiriusGFP and SG205, 8.9 for SiriusGFP and SG147, 18.9 for SG205 and SG147. These data suggest that mutation of S205 V and S147R both contribute to the increase of Tau and Y₀. The combination of S205 V and S147R makes SiriusGFP superior to eGFP, although with a tradeoff in φ_f.

To compare brightness and photostability with the same amount of eGFP and SiriusGFP, the normalized photobleaching curves showed that the two variants have different rates of decay, and intersect at 167 s under constant laser power (~1500 μW) (Fig. 1E). The integrated area under curves are 423 for eGFP and 437 for SiriusGFP. The residual fluorescence of SiriusGFP is near four-fold higher than that of eGFP at the end of the long tail. With greater light intensity, the decay curves intersect at a shorter time point. Thus, for experiments requiring high

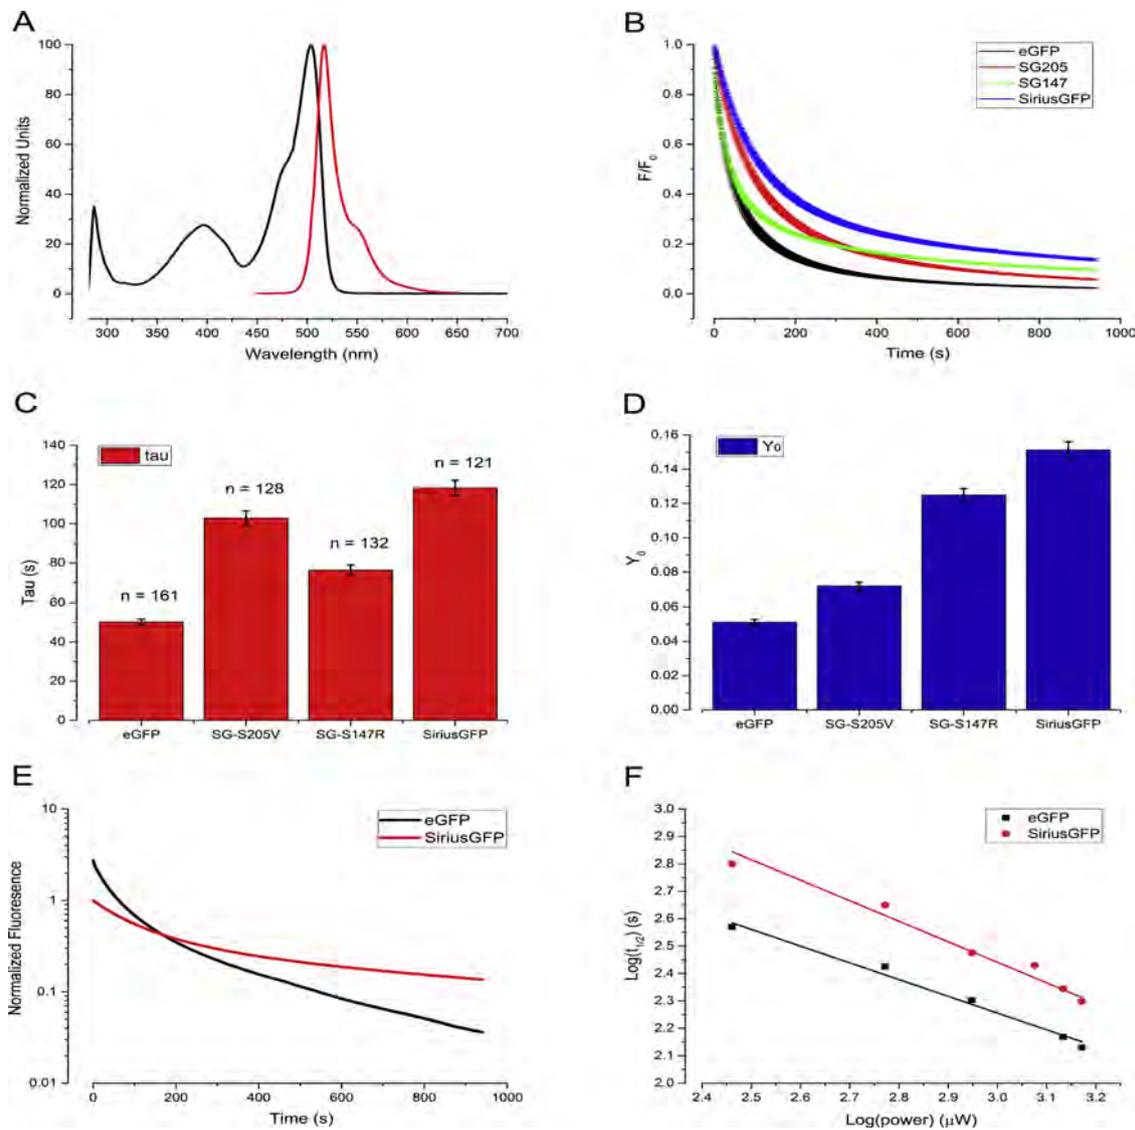

Fig. 1. Optical properties of SiriusGFP compared to eGFP. **(A)** The UV-vis spectrum of SiriusGFP indicates that the protonate chromophore exists in a minor proportion. Shown is the UV-vis absorbance and fluorescent spectrum of purified SiriusGFP in a buffer of 150 mM NaCl, 20 mM Tris, pH7.5. SiriusGFP has a major excitation peak at 504 nm and a minor peak at 396 nm, implying that the protonated chromophore exists in minor proportion. **(B)** SiriusGFP is more photostable than eGFP. Shown are the photobleaching curves of eGFP, SG205, SG147, and SiriusGFP expressed in HeLa cells. Fluorescence was detected by laser irradiation of live cells at 489 nm on a Zeiss confocal microscope (Zeiss LSM 710 duo). We determined that the photostability of SiriusGFP is > 2.4 fold higher than that of eGFP. The ratio of integrated areas under the curves is 1 : 1.99 : 1.88 : 3.34 for eGFP : SG205 : SG147 : SiriusGFP. The optical power of scanning laser at 489 nm was \sim 1500 μ W. Each curve is the average of > 100 cells with standard error accounting for the variability in the thickness of each line. **(C)** SiriusGFP shows increased photobleaching time constants compared to eGFP. Photobleaching data can be fit by a single exponential decay function, $Y = Y_0 + Ae^{-x/t}$, where Y_0 is the constant offset representing the residual fluorescence after photobleaching reached a steady state (R^2 ranged from 0.97–0.99). The single exponential fitting on photobleaching curves determined that the lifetime (Tau) of SiriusGFP is 118.3 s, 102.9 s for SG205, 76.3 s for SG147, compare to 50.1 s for eGFP under the same photobleaching conditions. The cell numbers (n) are shown on the top of each sample. The error bar is standard error. ANOVA analysis of Tau values shows high confidence in statistically significant differences (p -value 2.42×10^{-50}). **(D)** Residual fluorescence in SiriusGFP is greater than eGFP after prolonged photobleaching. Y_0 represents the residual fluorescence after photobleaching; 15.1% for SiriusGFP compared to 12.5% for SG147, 7.2% for SG205 and 5.1% of eGFP. The error bar is standard error. **(E)** The choice of eGFP and SiriusGFP depends on the intended duration of an experiment. The normalized photobleaching curves with the same amount of eGFP and SiriusGFP show the two curves crossing at 167 s. At the end of long tail, the residual fluorescence of SiriusGFP is 3.76-fold higher than that of eGFP. The integrated area is 423.4 for eGFP, and 437.6 for SiriusGFP, confirming that SiriusGFP emits more photons upon prolonged exposure. Conversely, the number of photons emitted in short durations is greater in eGFP, which is therefore preferred in experiments with short fluorescence emission. **(F)** Across a range of light intensities SiriusGFP maintains its superior photobleaching characteristics compared to eGFP. Shown is a log-log plot of photobleaching rates versus illumination laser power of the laser-scanning confocal microscope using purified SiriusGFP and eGFP embedded in polyacrylamide (see method section). SiriusGFP shows slower rates of photobleaching at different light intensities compared to eGFP. Data were fitted to the equation $\log(F) = -\alpha \log(P) + c$, where F is the photobleaching half-time constant and P is the illumination power, α is 0.61 for eGFP and 0.75 for SiriusGFP, while c is 4.1 for eGFP and 4.7 for SiriusGFP.

intensity light SiriusGFP offers significantly greater advantages when longer exposures are required. These data also indicate that SiriusGFP emits more photons during long exposures or under high power illumination, although less than eGFP at the onset of exposure. In fact, at a given light intensity, the longer the exposure time the greater the

differential advantage in photons emitted by SiriusGFP.

We also measured the photobleaching rates of GFPs with purified proteins embedded in polyacrylamide gel by laser-scanning confocal microscopy (Fig. 1F). This log-log plot of photobleaching rates versus illumination power showed nearly linear relationships that indicates an

accelerated photobleaching of eGFP and SiriusGFP (Cranfill, Sell et al. 2016). The decay slope of SiriusGFP is similar to that of eGFP, but the lifetime is almost doubled. The photobleaching results measured with purified FPs in gel are similar to that in transfected cells.

Due to the long fluorescence tail of SiriusGFP, normal 3D confocal microscopy or superresolution microscopy, such as SIM, imaging quality can benefit.

3.2. Oxygen-depletion photobleaching

To explore the mechanisms of photobleaching in SiriusGFP we carried out photobleaching experiments with confocal microscopy under conditions of oxygen depletion. HELA cells separately transfected with eGFP-Omp25 and SiriusGFP-Omp25 were fixed in 4% PFA followed by oxygen-depletion treatment. Omp25 is a mitochondrial outer membrane protein, localized to the mitochondrial outer membrane anchoring by a single transmembrane segment at the C-terminal. Overexpression of OMP25 results in perinuclear clustering of mitochondria in transfected cells (Nemoto and De Camilli, 1999). eGFP and SiriusGFP were fused on the N terminus of Omp25. Photobleaching of eGFP and SiriusGFP was performed under aerobic and anaerobic conditions at low and high laser power. When photobleaching with low laser power (~150 μ W) both eGFP and Sirius GFP show sensitivity to oxygen. In contrast, at high laser power (~1500 μ W) photobleaching of eGFP is not oxygen dependent, while SiriusGFP shows oxygen-dependence (Fig. 2). In all these conditions SiriusGFP remained more photostable than eGFP. It is believed that GFP's differential sensitivity to oxygen under differing intensities of light points to different mechanisms of photobleaching (Tsien, 1998; Greenbaum, Rothmann et al. 2000; Jimenez-Banzo, Nonell et al. 2008; Grigorenko, Nemukhin et al. 2015). High photon flux may lead to higher-order photobleaching due to a multi-photon effect (Chen, Zeng et al. 2002). Our data indicate that the photobleaching mechanisms of SiriusGFP are different from that in eGFP, particularly in high intensity light. We infer that SiriusGFP is resistant to high-order photobleaching in high intensity light.

3.3. Practical applications 1. 4D confocal scanning

To test the performance of SiriusGFP in confocal microscopy, we

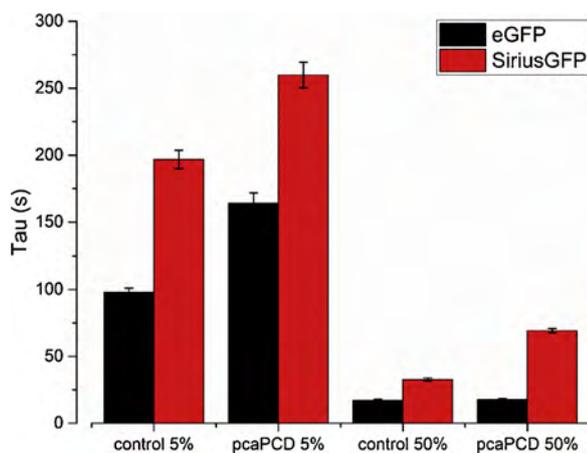

Fig. 2. Photobleaching of SiriusGFP-Omp25 is oxygen dependent across a range of light intensities and contrasts with eGFP-Omp25. Shown are the photobleaching time constants of eGFP and SiriusGFP in PFA-fixed HeLa cells with (pcaPCD – see section 7 in Methods) and without (control) oxygen-depletion solution under low and high optical power illumination, respectively. The percentage of laser power (5% and 50%) at 489 nm used for photobleaching corresponded to measured light intensities of 150 μ W (5%) and 1500 μ W (50%) at the objective. The error bar is standard error. At high and low intensity light, photobleaching of SiriusGFP is oxygen dependent. In contrast, eGFP is oxygen dependent only in low intensity light.

carried out an experiment with 4D confocal imaging on live HeLa cells. Cells were transfected with eGFP-Omp25 and SiriusGFP-Omp25 and imaged live in PBS (Fig. 3). In this experiment, 3D confocal Z-stacking scanning was done in continuous mode to maximize photobleaching. The 4D confocal imaging results indicate a dramatic improvement of image clarity due to the photostability of SiriusGFP (more than 30 min) compared to eGFP (~10 min). Indeed, after longer exposure (60 min) under the same conditions, SiriusGFP-Omp25 cells continued to exhibit vivid images of intracellular mitochondria (Fig. S3). For instance, the outline of mitochondria were not visible after 60 min of continuous imaging of OMP25 eGFP, but were clearly visible with Sirius GFP.

3.4. Practical applications 2. Structured illumination microscopy (SIM)

We sought to ascertain if SiriusGFP improved the quality of super-resolution microscopy, where the demands on photostability are pronounced. We used structured illumination microscopy (SIM) to explore the advantages of SiriusGFP. The SIM images of fixed HEK-293 cells expressing SiriusGFP-Omp25 was compared to eGFP-Omp25. The image resolution of SIM with SiriusGFP was significantly improved (Fig. 4).

Quantitative measures in Z planes, in particular, show marked improvement in image quality. We repeated the SIM imaging of fixed HeLa cells expressing SiriusGFP-Omp25 and eGFP-Omp25, respectively. Peak to peak Gaussian fitting of over 100 peaks showed an XY resolution of SiriusGFP-Omp25 to be 130 ± 1.4 nm, similar to eGFP-Omp25 with an XY resolution of 131 ± 1.8 nm ($p = 0.546$). In contrast, the Z axis resolution of SiriusGFP-Omp25 was 310 ± 4.6 nm and significantly improved ($p = 0.0017$) over that of eGFP-Omp25 at 335 ± 5.6 nm. These values of SiriusGFP are approaching the limit of SIM resolution (Gustafsson, 2000; Heintzmann and Huser, 2017). Both total photon number and point of spread function (PSF) are key determinants of image quality and resolution. The increased resolution in the Z axis indicates that more photons were collected by the photoelectronic detector with SiriusGFP-Omp25 compared to eGFP-Omp25 since the PSF should be similar.

Although the XY resolution is similar by analysis of profile peaks after the Gaussian fitting of SIM, absent in the quantitative assessment were the qualitative differences in these two FPs. The majority of mitochondria using eGFP-Omp25 demonstrated absent membrane segments on the Z reconstructions (top and bottom profiles) while those using SiriusGFP-Omp25 were much more integrated (Fig. 4). In the XY plane, the mitochondrial membrane labeled with SiriusGFP-Omp25 showed very clear and detailed images; for instance, fission-fusion processes and twisted structures under stress. In contrast, many parts of the mitochondrial membrane labeled with eGFP-Omp25 showed broken/ discontinuous profiles that are likely artifacts from photobleaching (Fig. 5) (Figure.S4). The slower photobleaching of SiriusGFP made superresolution imaging better with more detailed information of subcellular organelles, and also produced less imaging artifacts than eGFP.

4. Discussion

We have developed an improved version of eGFP, named SiriusGFP, that shows a more than 2-fold increase in photostability compared to eGFP and is able to fold well with both N and C terminal fusion proteins. Prestin-SiriusGFP with SiriusGFP fused to the C-terminus of prestin, and SiriusGFP-Omp25 with SiriusGFP fused to the N-terminus of Omp25 both fold well. We have confirmed the obvious biological applicability of SiriusGFP using SIM and 4D confocal microscopy, and explored photobleaching mechanisms for SiriusGFP and eGFP. A number of points about the mechanism of photostability bear discussion below.

In GFPs, there is a seesaw-like action on protonation between the chromophore (p-HBDI) and Glu222. In wtGFP, the chromophore is

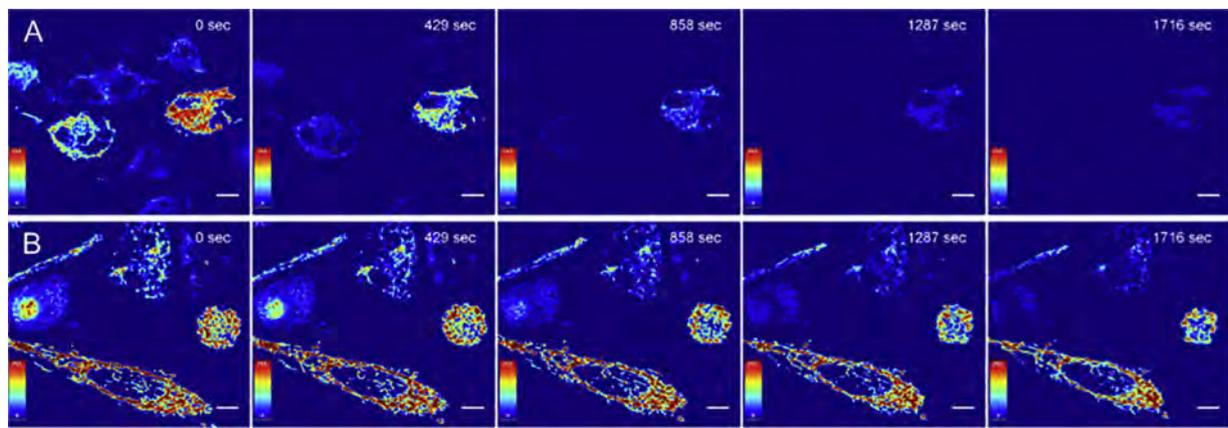

Fig. 3. Continuous confocal 4D imaging of live HeLa cells, in PBS, transfected with eGFP-Omp25 (A, upper panel) and SiriusGFP-Omp25 (B, lower panel), respectively. The confocal Z-stack scanning was continuous, and lasted 30 min. The color table for intensity is shown in the images. The data show SiriusGFP to be significantly resistant to photobleaching with markedly improved image quality even at 30 min. In contrast eGFP shows rapid degradation of image quality owing to photobleaching even at 7 min (429 s). The scale bar is 15 μm .

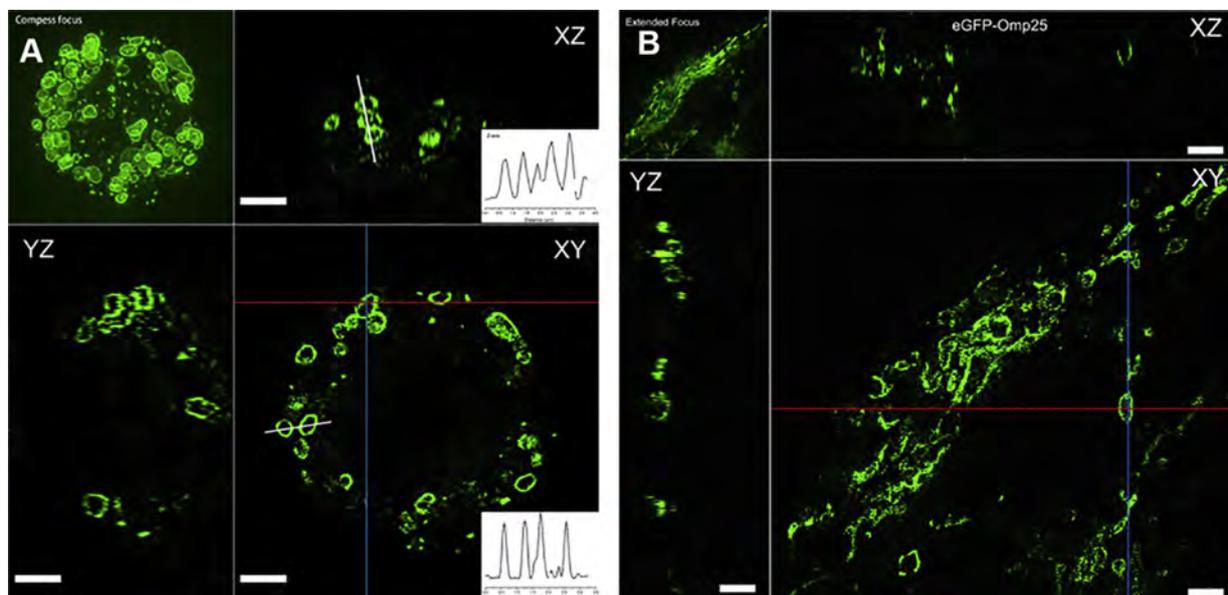

Fig. 4. SiriusGFP enhances SIM image quality, particularly in the Z axis. (A) Shown is the XYZ profile of SiriusGFP-Omp25 transfected HEK-293 cells captured by Structured Illumination Microscopy (SIM, DeltaVision-OMX, Applied Precision, GE life). The blue and red lines indicate the locations where the YZ (upper panel) and XZ (left panel) profiles were obtained. One can distinguish individual mitochondria even from Z axis images. The same image with extended focus has been attached to the left-upper corner. Two line measurements (white line) were performed on individual mitochondria in the Z and XY axes (right inset), respectively. We then used Gaussian fitting of the readout traces to obtain estimates of full width at half maximum (FWHM). (B) Shown is the XYZ profile of eGFP-Omp25. Many of Z profile of mitochondrial outer membrane were missing, and even some of XY profile also showed many discontinuous lines. The scale bar in A is 2.5 μm and B is 2.2 μm .

mainly protonated (80% in neutral state), while Glu222 is correspondingly in a deprotonated anion state. This proton movement is brought about by excited state proton transfer (ESPT). In contrast, the chromophore of eGFP is deprotonated (anion state) while Glu222 is protonated (neutral) at physiological pH (Bettati, Pasqualetto et al. 2011). In SiriusGFP, the chromophore is mixed with the major deprotonated (anion state) and the minor protonated form at a ratio of 4:1 (80% in anion state), and the same emission peak can be observed when excited at ~ 398 nm, indicating ESPT exists in SiriusGFP. But the minor protonated population that absorbs at 396 nm may not be the reason why SiriusGFP is more photostable than eGFP because wtGFP has larger absorption peak at 400 nm, while it is less photostable than eGFP.

Photobleaching in GFPs induced by UV/visible light or X-ray was determined to be related to Glu222 decarboxylation as a point of primary damage and the consequent rearrangement of the H-bond network (van Thor et al., 2002; Bell, Stoner-Ma et al. 2003; Royant and Noirclerc-Savoie, 2011; Arpino, Rizkallah et al. 2012). Glu222

contributes to the rigidity of the chromophore cavity by H-bonding adjacent residues and a cluster of water molecules. The decarboxylation of Glu222 results in the collapse of the H-bonding network next to the chromophore, and further promotes non-irradiative relaxation to the ground state or chromophore destruction (Royant and Noirclerc-Savoie, 2011). Still, there is a gap in our understanding of Glu222 decarboxylation and final chromophore destruction.

Light or X-ray irradiation on FPs can produce radical species by electron transfer (ET) from the excited chromophore. It was suggested that in wtGFP and PA-GFP the excitation of chromophore may promote charge transfer from Glu222 to the chromophore. This induces a biradical state that then relaxes back to the ground state or occasionally leads to decarboxylation of Glu222 that, in turn, leads to permanent chromophore destruction (Adam, Carpentier et al. 2009). The Kolbe mechanism was proposed to be responsible for the photoinduced decarboxylation of Glu222 in wtGFP (van Thor et al., 2002). However, after ultrafast ESPT in femtosecond scale the excited chromophore is

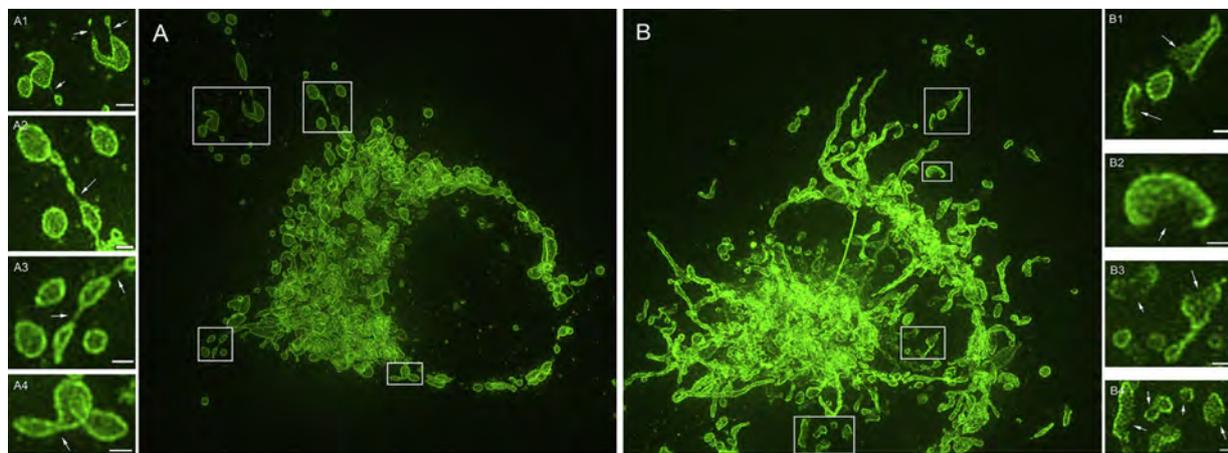

Fig. 5. (A) SiriusGFP shows qualitative enhancement in SIM images in the XY plane. A SIM image of SiriusGFP-Omp25 in HeLa cells. This sample was fixed with 4% PFA and imaged in PBS. The insets are the enlarged area of the white boxes. The uniformity of the mitochondrial outer membrane and the z-axis accumulation was very well achieved. A number of details can be discerned in the high quality images including mitochondrial fusion/fission (A1-3, arrows) and bended/twisted (A-4, arrows) structures shown in the insets.

(B) In the XY plane of eGFP is qualitatively inferior to SiriusGFP in SIM imaging. A SIM image of eGFP-Omp25 in HeLa cells. This sample was fixed with 4% PFA and imaged in PBS. The insets are the enlarged area of the white boxes. The uniformity of the mitochondrial outer membrane was interrupted by obvious breaks (B1-4, arrows) and the Z-axis accumulation cannot be well achieved due to the photobleaching of eGFP. The patchy depletion of the mitochondrial outer membranes are notable (B, B1-4). These images are in contrast to those obtained with SiriusGFP, where mitochondrial outer membranes show consistent and uniform patterns with no artifactual loss (A, A1-4). The scale bars are 0.5 μm .

turned to an anionic state that may not be able to be an electron acceptor. Moreover, in eGFP the chromophore is dominantly in the anion state. Another photophysical pathway had been proposed that triggers redox reactions inside GFP (Bochenkova, Klaerke et al. 2014), in which the chromophore anion HBDI⁻ undergoes a photodetachment upon absorption of one-photon UV or multi-photon visible light to produce a solvated electron and a radical chromophore. Thereafter, the photo-oxidized radical chromophore can accept an electron as an oxidant in Glu222 decarboxylation.

The interruption of the proton wire between HBDI and Glu222 by S205 V may hinder the electron transfer, therefore reducing the possibility of the biradical state and further chromophore destruction. However, the double mutant of eGFP-T203 V/S205 V that lacks both possible pathways of ESPT also shows photobleaching (data not shown), implying that the photobleaching pathway may not be limited by Glu222 damage.

4.1. Z-E isomerization

Upon excitation of chromophore *p*-HBDI of GFPs, the Z-E isomerization undergoes the τ -torsion around the only exocyclic double bond with a τ angle smaller than 90°, followed by internal conversion (IC) mostly to the ground state of Z isomers. The τ -torsion transiently disrupts the conjugated π -electron system for reversible loss in fluorescence, which could be the major non-radiative decay channel for the excited state S_1 of *p*-HBDI in GFPs (Chatterjee, Mandal et al. 2015).

In eGFP, the first excited state S_1 deactivates mainly via fluorescence with high quantum yield (~0.60) attributed to limiting τ -rotation around the only exocyclic double bond by H-bond network.

That the quantum yield ϕ_f of SiriusGFP is smaller than that of eGFP is probably due to less constraints on the phenolic group of *p*-HBDI; the lack of H-bond binding on Ser205 facilitates τ -torsion and thereby could increase internal conversion by facilitating τ -torsion along the methylene bridge between imidazolinone and phenolate moieties. Meanwhile, the τ -torsion with less constraints in SiriusGFP may also increase the possibility of internal conversion from S_n to S_{n-1} (e.g., $S_1 \leftarrow S_2$ or $S_2 \leftarrow S_3$). This in turn can decrease the possibility of electron-detachment and subsequent chromophore destruction. Quantum yield is proportional to brightness, but may not directly affect photostability.

That is, lower quantum yield does not mean higher photostability. For instance, most red FPs have low quantum yield (< 0.20) but are still easily photobleached (Cranfill, Sell et al. 2016). The electron transfer during deactivation may be the critical step for chromophore damage.

The methylene bridge between imidazolinone and phenolate moieties can perform τ -torsion for internal conversion or lead to Glu222 decarboxylation and chromophore destruction, depending on how many photons are absorbed by the chromophore and if ROS or solvated electrons nearby are available. A nearby oxygen can accept a photoelectron from the anionic GFP chromophore to form superoxide radicals on the exocyclic methylene bridge of the chromophore. This superoxide radical consequently undergoes a further series of chemical reactions resulting in the cleavage of the exocyclic bridging bond of the chromophore resulting in permanent bleaching (Grigorenko, Nemukhin et al. 2015). The electron transfer in eGFP may occur from the chromophore anion to external oxidants via an intermediate aromatic residue, Tyr145 (Bogdanov, Acharya et al. 2016). Substitution of key residues controlling electron transfer to external oxidants would be expected to increase photostability, although the detailed effects on different substituted residues need further investigation (Hosoi, Hazama et al. 2015). We tested mutation of Y145I and Y145E in eGFP and SiriusGFP. Both mutants showed dimmed fluorescence (data not shown), perhaps due to the over 3-fold decrease in the extinction coefficients of Y145I or Y145E (Bogdanov, Acharya et al. 2016). S147R associating with H148 at the entrance of access to the phenolic group of the chromophore may help block exterior ROS. Both its positive charge and bulky side chain could contribute to the photostability without the fast decay phase seen in N149K in Emerald-GFP. The photobleaching results (Fig. 1B) suggest that S147R may play an important role in blocking the entrance of external oxidants or, alternatively, affecting the electron transfer efficiency to external oxidants.

In summary, photobleaching is one of the major problems for genetically encoded FPs, which limits their application in biological investigations. We have developed a FP, SiriusGFP, that shows significant improvement in photostability over eGFP in high and low intensity illumination. While Sirius GFP has reduced brightness compared to eGFP, its 2-fold increase in photostability allows for much improved imaging requiring high or prolonged intensity light. In practical terms this gain in stability allows imaging without a dynamic adjustment in

exposure time and light intensity with increasing experimental time. Our new FP will provide improved capabilities for superresolution and time-dependent confocal microscopy.

Abstract

Background: Chloride is the major anion in cells, with many diseases arising from disordered Cl⁻ regulation. For the non-invasive investigation of Cl⁻ flux, YFP-H148Q and its derivatives chameleon and Cl-Sensor previously were introduced as genetically encoded chloride indicators. Neither the Cl⁻ sensitivity nor the pH-susceptibility of these modifications to YFP is optimal for precise measurements of Cl⁻ under physiological conditions. Furthermore, the relatively poor photostability of YFP derivatives hinders their application for dynamic and quantitative Cl⁻ measurements. Dynamic and accurate measurement of physiological concentrations of chloride would significantly affect our ability to study effects of chloride on cellular events.

Methodology/Principal Findings: In this study, we developed a series of YFP derivatives to remove pH interference, increase photostability and enhance chloride sensitivity. The final product, EYFP-F46L/Q69K/H148Q/I152L/V163S/S175G/S205V/A206K (monomeric Cl-YFP), has a chloride K_d of 14 mM and pK_a of 5.9. The bleach time constant of 175 seconds is over 15-fold greater than wild-type EYFP. We have used the sensor fused to the transmembrane protein prestin (gerbil prestin, SLC26a5), and shown for the first time physiological (mM) chloride flux in HEK cells expressing this protein. This modified fluorescent protein will facilitate investigations of dynamics of chloride ions and their mediation of cell function.

Conclusions: Modifications to YFP (EYFP-F46L/Q69K/H148Q/I152L/V163S/S175G/S205V/A206K (monomeric Cl-YFP) results in a photostable fluorescent protein that allows measurement of physiological changes in chloride concentration while remaining minimally affected by changes in pH.

Introduction

Chloride is the major anion in cells, and plays various physiological roles. For example, chloride is a key determinant of intestinal fluid secretion and cell volume primarily through affecting osmotic gradients [1–3]. Chloride is also important in setting neuronal resting membrane potential through a number of chloride channels and inhibitory neurotransmitter receptors that have chloride conductance [4]. As a natural consequence of affecting these diverse phenomena many diseases result from disordered Cl⁻ regulation [5]. These diverse effects of chloride underscore the need to accurately and dynamically measure physiological intracellular chloride concentration.

While many proteins work to regulate intracellular Cl⁻, others are regulated by intra- and extracellular Cl⁻. For example, the unique membrane protein prestin in outer hair cells (OHCs),

SLC26a5, functions as an ultrafast molecular motor, converting electrical to mechanical energy. This protein is thought to bring about cochlear amplification in mammals, which is responsible for the exquisite sensitivity of mammalian hearing. Intracellular chloride ions in the 0–10 mM range regulate the behavior of prestin, shifting its voltage responsiveness by –2 mV per mM of chloride (with gluconate as the counter anion). These *in vitro* findings have been supported by *in vivo* experiments demonstrating effects of chloride on cochlear amplification [6]. Hence, dynamic monitoring of intracellular Cl⁻ concentrations near prestin's intracellular chloride binding site will aid in understanding chloride's role in cochlear amplification. We previously have used the fluorescent dye MQAE to measure chloride flux in OHCs [7], but the technical problems with this approach are overwhelming. Consequently, we have worked to develop a genetically encoded

chloride sensor that can be tagged on the intracellular C-terminus of prestin, sensing chloride fluctuation during prestin activity.

Over the last decade, engineered fluorescent proteins (FPs) were developed as genetically encoded indicators allowing non-invasive monitoring of intracellular ion fluctuations, such as Cl^- [8–11], pH [12,13], and Ca^{2+} [14–16]. FPs are also quite useful for measuring membrane potential [17–19] and other cell biological phenomena. Most of them are GFP-based variants or FRET pair probes, like CFP-YFP.

EYFP, GFP-S65G/V68L/S72A/T203Y, has proven to respond rapidly and reversibly to concentration changes of halides, which enables YFPs to be genetically encoded Cl^- sensors in living cells. YFP-H148Q and its derivatives [8], including CFP-YFP-based Clomeleon [9], were introduced as genetically encoded chloride indicators, in which H148Q enhances the halide affinity due to better binding cavity access via a solvent channel, thereby favoring chromophore protonation following halide binding to reduce fluorescence [20]. The K_d of YFP at pH 7.5 is 777 mM, and 154 mM for YFP-H148Q, far removed from intracellular $[\text{Cl}^-]$ under physiological conditions. In the YFP-H148Q library, I152L and V163S exhibit higher chloride affinity with a K_d of 88 mM and 62 mM, respectively [10,21,22]. The triple mutant of YFP-H148Q/I152L/V163S was adopted in the CFP-YFP-based emission ratiometric Cl^- indicator (Cl-sensor) [11]. In Cl-sensor, the real sensor for chloride is the YFP mutant itself with $K_d \sim 30$ mM, instead of requiring a peptide linker between CFP and YFP, or an extrinsic sensor such as calmodulin in Cameleon [23]. In YFPs, the halide-binding cavity near the chromophore has the ability to modulate the protonation state of the chromophore, and this is the basis of YFP's chloride sensitivity. In the CFP-YFP based indicator, CFP is insensitive to halides, providing an *in situ* ratiometric calibration for YFP.

Compared to calcium FP-sensors, the YFP-based chloride sensor has less sensitivity (high mM scale instead of μM or nM), less photostability and is usually accompanied by significant, confounding pH effects near physiological pH. To date, YFP-based Cl^- indicators are limited in their application because of these three reasons. In this study, we developed a series of YFP mutants extending previous work. We introduced a positive charged residue, Q69K, into the halide-binding cavity to decrease pK_a , and two folding mutations, F46L/S175G, to enhance folding. Furthermore, we uncovered a key mutation in the proton delivery pathway, S205V, which 1) increased the time constants of photobleaching 15-fold greater than wild-type EYFP, 2) lowered the pK_a away from physiological pH, and 3) enhanced the chloride sensitivity to 14 mM. These improvements provide for a superior chloride sensor. Finally, using this new enhanced chloride sensor, we demonstrate dynamic flux of chloride in the mM range into prestin expressing HEK cells.

Results

ClSM, a YFP Modification with Intermediate Chloride Sensitivity and pH Dependence

In designing a chloride sensitive YFP we evaluated and adopted a number of amino acid changes that had previously been shown to enhance fluorescence and stability. The maturation of YFP includes two phases, peptide chain folding and chromophore formation. F46L significantly accelerates chromophore oxidation, while the well-known folding mutations of F64L, M153T, V163A and S175G facilitate the folding process of the peptide chain [20,24]. These mutations that affect folding and the rate limiting chromophore oxidation step also affect chloride sensitivity. F64L counteracts the conformational change in orientation caused by

V68L in the YFP variant Venus, and also induces reduced halide sensitivity by preventing halide ion access to its binding site [24]. V68L is included in native EYFP, and we therefore opted to not include F64L in our new Cl^- sensor. Since V163A may also be involved in eliminating chloride sensitivity in Venus by presumed shortening of the side chain, we introduced V163S, with a longer side chain that enhances halide sensitivity [10] while simultaneously maintaining photostability. Similarly, S175G that breaks an existing hydrogen bond network facilitates folding and enhances fluorescence intensity of Venus [24,25] and ECFP [25], and was incorporated in our constructs. M153T by virtue of its smaller side chain and increased flexibility [26] has also been shown to facilitate folding and increase fluorescence intensity. However, this mutation seemed to affect the expression of YFP in several of our constructs and was therefore not incorporated in our final constructs.

There are nine residues in the halide-binding cavity near the chromophore of YFP that have direct interaction or a distance of less than 5 Å from the binding halide anion, namely, Q69, R96, V150, I152, V163, F165, Q183, L201 and Y203 [20]. T203Y is the key mutational difference between YFP and GFP, and I152L/V163S already exist in the sequence of EYFP-H148Q/I152L/V163S from which we began our development effort. Q69 is fairly close to the chromophore anion inside the β -barrel of YFP. It was previously reported that Q69K could promote the anionic form of the chromophore to hinder its protonation, and therefore reduce the apparent pK_a to 6.1, with little effect on its other sensitivities [27]. But we found that the mutant Q69K when added to EYFP-H148Q/I152L/V163S folds poorly at 37°C, which was previously reported in EYFP-V68L/Q69K [27], possibly resulting from the extra length of the Lysine side chain and disturbing the hydrogen-bond network in the halide-binding cavity. Fortunately, this folding problem of Q69K can be compensated by the folding mutation of F46L. F46L can greatly accelerate the oxidation of the chromophore at 37°C, the rate-limiting step of maturation of chromophore, without changing the pK_a of EYFP [24]. The new construct, EYFP-F46L/Q69K/H148Q/I152L/V163S, which we term **ClSM**, expressed very well in HEK-293 cells, showing bright fluorescence. The pK_a of **ClSM** was reduced to 6.5~7.1 and was dependent on the chloride concentration (0.2 mM and 140 mM, respectively). The chloride sensitivity of **ClSM** remained at ~ 30 mM (data not shown). Interestingly, the alternative replacement of Q69 with arginine could barely fold to exhibit fluorescence in transiently transfected HEK-293 cells, probably because of the large side chain of the arginine residue. In this study, all further mutants are made based on **ClSM**.

Mutations to Reduce pH Sensitivity Resulted in Enhanced Photostability and Further Increased Chloride Sensitivity

Positive charges in the halide-binding cavity close to the YFP chromophore not only increase the affinity of halide binding, but also promote the anion state of the chromophore, which in turn can reduce the pK_a of the chromophore by dispersing negative charge over the conjugated structure of the chromophore. So our first strategy for improvement was introducing more positively charged residues into the halide-binding cavity.

We evaluated the addition of another positive charge besides Q69K into the halide-binding cavity of **ClSM** attempting to reduce confounding pH effects by single-site mutation of the individual residues V150, F165, Q183, L201 to lysine or arginine. However, all of the double-charge mutants (V150K/R, F165K/R, Q183K/R, L201K/R, each in combination with Q69K) could not fold to exhibit fluorescence, even in the presence of two additional folding mutations of M153T and S175G, as well as

F46L. The double-charge mutants of Q69K/F165K and Q69K/L201K express somewhat better, but still showed lower than normal YFP fluorescence. We concluded that the double-charge residues in the halide-binding cavity can significantly affect the folding of YFP. We speculate that this could result from difficulty in burying an extra positive charge (in addition to R96 and Q69K) into the cavity proximal to the chromophore, due either to excess electrostatic forces or cavity size limitations.

The other strategy to lower the pK_a of the YFP-based chloride sensor is to set a barrier within the proton delivery pathway to the phenolate anion of the chromophore, which is protonated via a hydrogen bond network composed of the main chain of residue N146, the side chain of S205 and a bridging water molecule linked with a surface water molecule. The protons are delivered from the external solvent into the YFP β -barrel through this hydrogen bond network. If the proton delivery pathway is blocked or impeded, lower pH (higher $[H^+]$) is needed to overcome the obstructed proton access, indicating that pK_a is reduced. We chose S205 as the essential target site to impede proton access. S205 was substituted with other neutral residues without hydroxyl groups, such as alanine, leucine, isoleucine, and valine. Interestingly, we found that in addition to its influence in altering pK_a , S205 substitutions also enhanced photostability. Valine substitution of S205 has the best photostability. The percentage of residual fluorescence after photobleaching is the highest with this mutant S205V. Thus, the time constant of fluorescence photobleaching is 175 s compared to the **Cl₅M** bleaching time constant of ~ 10 s (**Fig. 1**). Note that the folding mutations S175G or M153T does not enhance photostability.

Work from the Tsien laboratory has shown that the tendency for YFP dimerization can be greatly reduced or eliminated by mutating the hydrophobic amino acids in the dimerization interface to positively charged residues [28]. The order of effectiveness is A206K>L221K>F223R. The dissociation constant K_d of mYFP-A206K derived from the association constant (K_a) is much higher than that of mYFP-L221K and mYFP-F223R

[29]. Because prestin can oligomerize, we included the A206K mutation into the construct to make a monomeric version that will avoid aggregation when making fusion proteins with a targeting protein. Therefore, EYFP-F46L/Q69K/H148Q/I152L/V163S/S175G/S205V and its monomeric version with A206K, now termed **Cl-YFP** and **mCl-YFP (or mClY for short)**, respectively, were characterized in detail to determine their pK_a and chloride sensitivity.

Cl-YFP and mCl-YFP are significantly less pH sensitive than Cl₅M, with a pK_a of ~ 5.3 for Cl-YFP (data not shown) and a pK_a of ~ 5.9 for mCl-YFP (**Fig. 2A**), both of which are far removed from physiological pH conditions. The pK_a of mCl-YFP is slightly higher than that of Cl-YFP, indicating better access for protons to reach the chromophore. This is likely due to a smaller steric barrier on the dimer interface. Although Cl-YFP and mCl-YFP have similar time constants for photobleaching, about 175 s, the percentage of residual fluorescence after bleaching was different; 50% and 65%, respectively (**Fig. 1**). Finally, mCl-YFP has a higher chloride sensitivity of 14.4 mM (**Fig. 2B**) compared to the previously reported best value of ~ 30 mM for all YFP variants [11]. It should be noted that the larger reduction in fluorescence (F/F_0) for low pH (**Fig. 2A**) versus high chloride (**Fig. 2B**) likely arises because protonation of the chromophore directly quenches the fluorescence of YFP, while chloride binding would change the proton affinity of chromophore, consequently reducing fluorescence intensity. Residual fluorescence that we measure likely depends on the oxidation equilibrium of fluorophor under the given spectrum and level of illumination such as optical power. It might be that if we changed these photobleaching conditions or solution pH that these asymptotic levels would differ. The point that we make is that under the same photobleaching conditions the relative response differs among mutations, with our mCl-YFP showing the best bleaching time constant, best pK_a and best K_d for chloride as well as the strong capability of removing YFP dimerization. The important point about bleaching is that it is minimized during the course of an experiment.

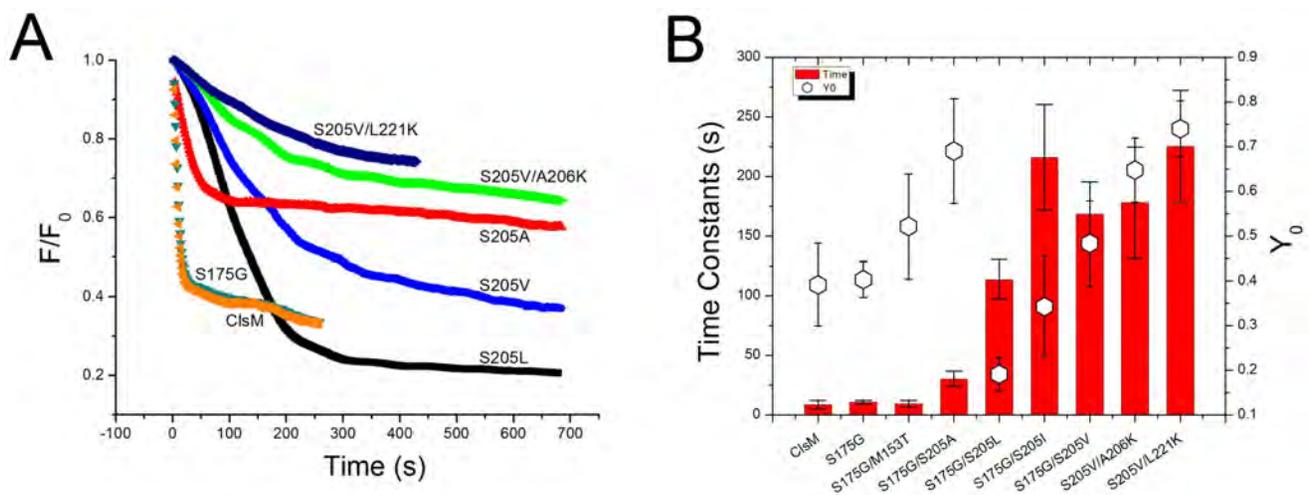

Figure 1. Photobleaching dynamics of YFP chloride sensor mutations. (A) Representative traces of some YFP variants photobleached at 430 nm. All variants are based on the EYFP-F46L/Q69K/H148Q/I152L/V163S (**Cl₅M**). Photobleaching data were fit by a single exponential decay function, $Y = Y_0 + Ae^{-x/t}$, where Y_0 is the constant offset representing the residual fluorescence after photobleaching (R^2 ranged from 0.96–0.99). It is notable that the mutant Cl₅M-S175G/S205V/A206K (mClY, green curve) has a long time constant of 175 s under our photobleaching conditions, which is much longer than wild-type YFP and **Cl₅M** each at ~ 10 s. **(B)** The red columns are the time constants of fluorescence decay during photobleaching, and Y_0 is the constant offset of fluorescence exponential decay by photobleaching, representing the residual fluorescence when photobleaching reached a stable state. The folding mutations of S175G and M153T did not enhance the photostability of **Cl₅M**, while the mutations of S205 did increase the time constants of fluorescence decay.

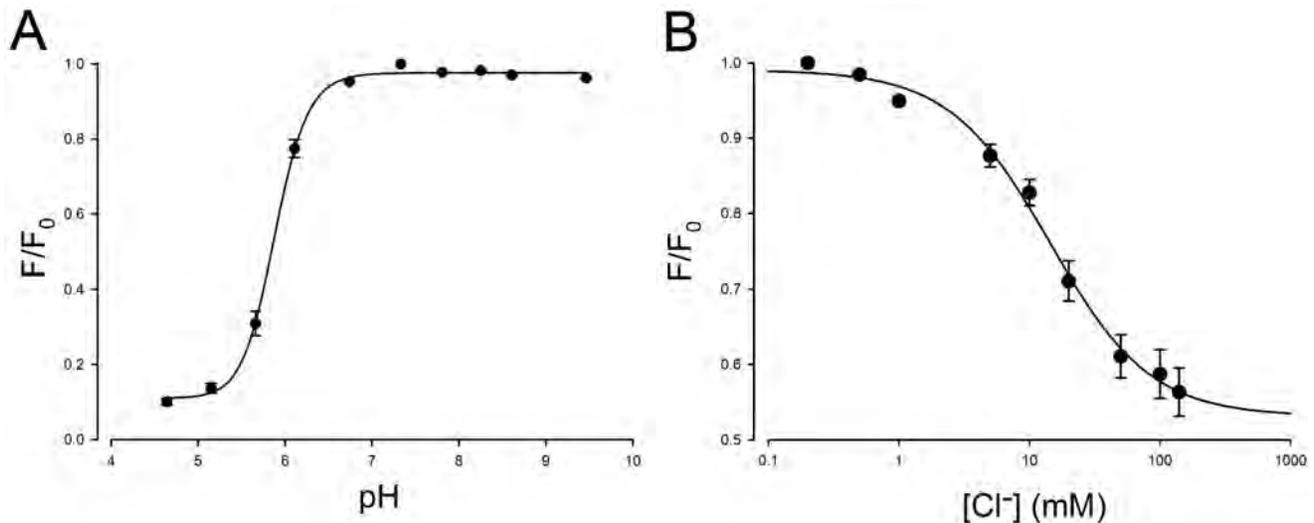

Figure 2. pH-sensitivity and chloride sensitivity of mCl-YFP measured by local perfusion of individual cells. (A) The pH-sensitivity of mCl-YFP fluorescence with a pK_a of 5.88 calibrated with a fixed 0.2 mM Cl^- solution containing 100 μ M TBT and 50 μ M Nigericin. F_0 is the initial fluorescence at pH 7.20. For each data point, fluorescence data of more than 35 cells were averaged. Note in each case that the pK_a is far removed from physiological pH. (B) The chloride sensitivity of mCl-YFP with a K_d of 14.4 mM at a fixed 0.2 mM Cl^- solution using 100 μ M TBT and 50 μ M nigericin at pH 7.20. F_0 is the initial fluorescence under 0.2 mM Cl^- . For each data point, fluorescence data of more than 25 cells were averaged. The sensitivity is doubled compared to previous YFP-based Cl^- sensors, and within the physiological range of cellular Cl^- changes. doi:10.1371/journal.pone.0099095.g002

The Outer Hair Cell Protein Prestin Shows Dynamic Chloride Movement that is Demonstrable with the Enhanced Chloride Sensor

To test our improved chloride sensor, mCl-YFP was fused to the C-terminus of the OHC motor protein, prestin, and transfected the construct into HEK-293T cells. After 24 hrs of incubation, chloride flux into the transfected cells was monitored during changes in extracellular chloride from 0.2 mM Cl^- to 140 mM Cl^- (Fig. 3). The standard bath solution contained 0.2 mM chloride. Upon perfusion with higher chloride solutions, the fluorescence dropped immediately demonstrating chloride influx. The most sensitive response was near the K_d of the sensor. Standard calibration of the sensor with 100 μ M TBT and 50 μ M nigericin provides a translation of fluorescence response to chloride concentrations. TBT and nigericin are ionophores that allow Cl^- and H^+ ions to pass freely through the cell membrane.

In experiments using prestin-mClY, we noted a decrease in fluorescence upon exposure to increasing concentrations of extracellular chloride, compared to mCl-YFP fused to the control membrane protein CD80 (a B cell protein, the extracellular portion of which acts as a co-stimulatory molecule of T cells, and has no known chloride transport function). The relative reduction in fluorescence was proportional to the concentration of extracellular chloride applied to the cell. Although the differences in individual mean fluorescence did not reach statistical significance, the rates of change per extracellular Cl^- were significantly different (slope difference: 0.02 unit/100 mM Cl^- ; $p < 0.05$), and indicates a more rapid transmembrane flux of Cl^- with prestin when extracellular Cl^- increases. The dilution of sub-membranous Cl^- into the cytosolic pool of Cl^- likely limits the accumulation of the anion near the plasmalemma. Importantly, prestin-mClY demonstrated unchanged prestin function evidenced in parameters of charge movement in the membrane (non-linear capacitance, data not shown). Moreover, there was tight correlation between estimates of intracellular chloride concentration determined by changes in voltage at peak capacitance (V_h) [7,30]

and decrease in fluorescence intensity in prestin-mClY. Both methods of estimating Cl^- concentration are concordant with a rise in intracellular peri-membranous Cl^- concentration of < 10 mM, when cells were perfused with 140 mM Cl^- . Note that there was an increase in intracellular chloride concentrations with both prestin-mClY and CD80-mClY, although the reduction in fluorescence with prestin was more marked. We interpret these data to suggest that prestin enhances a basal Cl^- influx into the cell. The rise in intracellular juxta-membrane chloride concentration is due to a complex contribution from prestin activity (conductance or transport), native channels and transporters in the HEK cell, and diffusional dilution into the cytoplasm away from the plasma membrane. Resolving these issues will require additional work.

Discussion

Here we report the development of a powerful fluorescent chloride sensor that displays 1) superior photostability, 2) reduced susceptibility to $[H^+]$ fluctuations near physiological pH, and 3) enhanced chloride sensitivity to permit assessment of low-level physiological changes in $[Cl^-]$. For example, the K_d estimates of Prestin sensitivity to chloride range from 1–6 mM [7,31,32], and the fused Prestin/mCl-YFP sensor will be ideal for monitoring chloride levels in the OHC sub-plasmalemmal compartment where chloride concentrations have been speculated to fluctuate and affect prestin function [33–35]. Additionally, we demonstrate here dynamic changes in intracellular chloride concentration in response to changes in extracellular chloride that we attribute to prestin. It is unclear if this increase in intracellular chloride concentration is a result of transporter activity or a more channel-like conductance [36–38]. We are confident that the benefits of the probe will extend to other physiological preparations, as well.

Protonation & Cl^- Binding

We used known characteristics of YFP and previous iterations of other chloride sensor homologues to engineer our new sensor. In

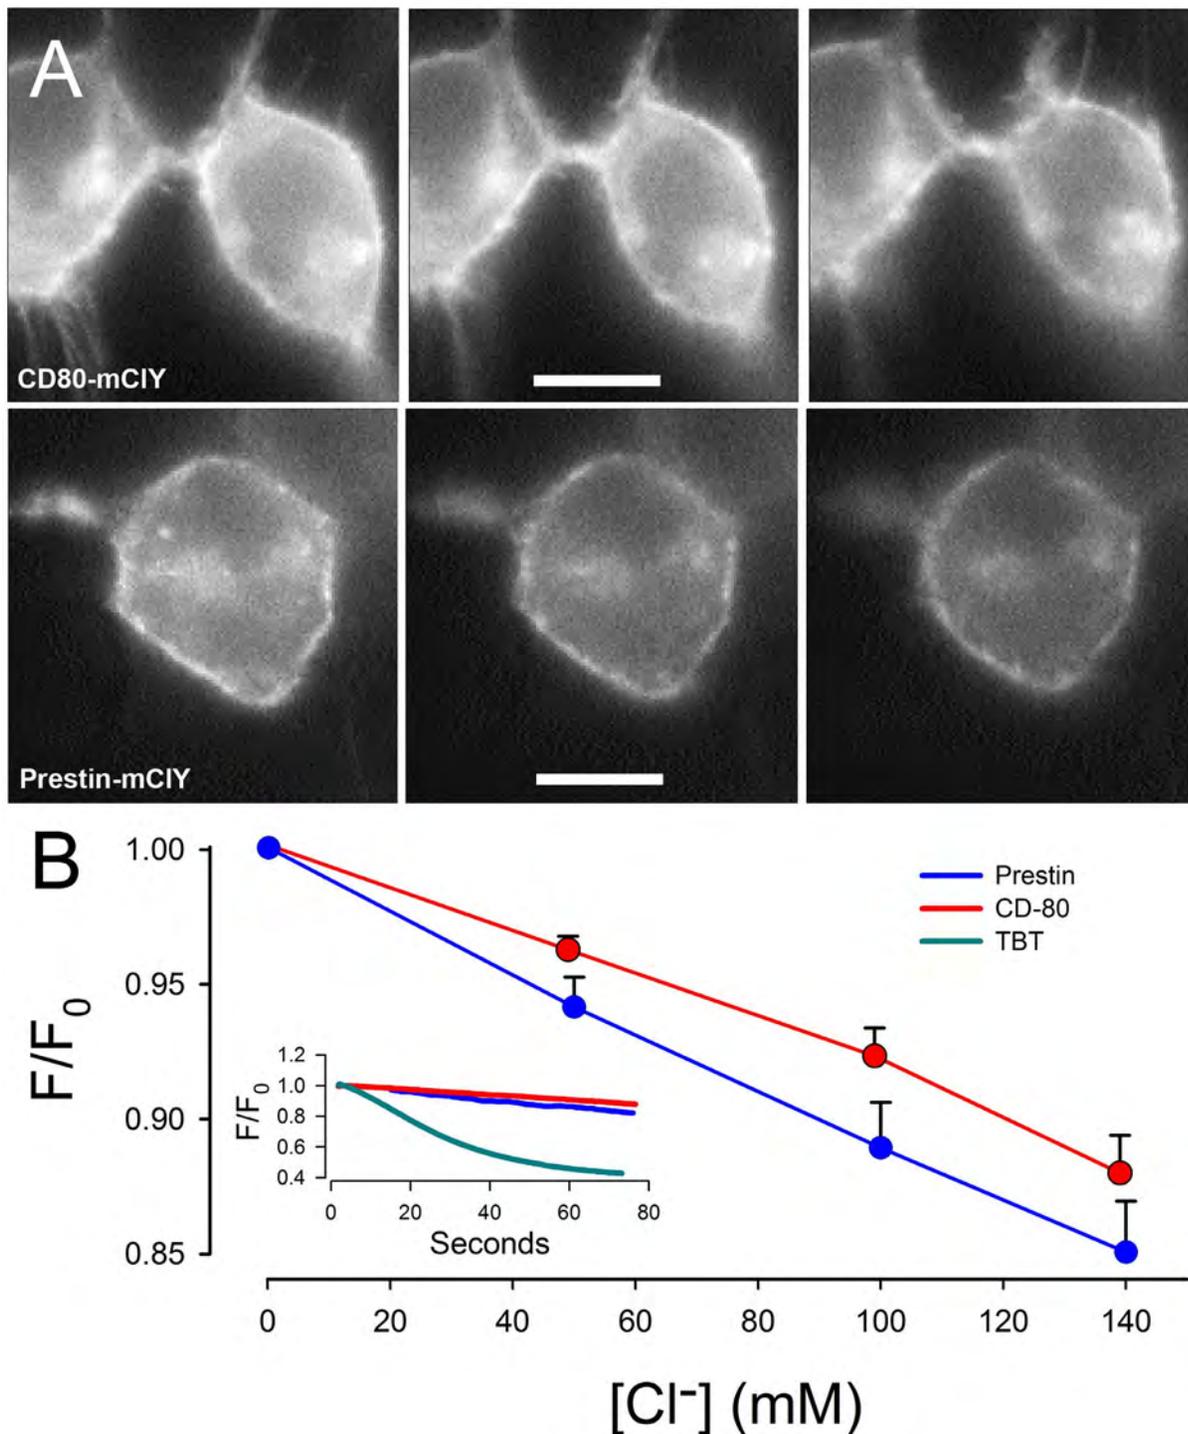

Figure 3. Prestin dependent Cl^- flux in HEK-293T cells. (A) Two panels show representative fluorescence change on HEK-293T cells transiently transfected with CD80-mClY (upper) and Prestin-mClY (lower), respectively, under local perfusion of high K^+ solution with different Cl^- concentration, indicating a chloride flux into the cells. In the image panel, the perfused chloride concentration was $<0.2\text{ mM}$ (left), 50 mM (middle), and 140 mM (right). All images were acquired at the same time. The bar in middle lane was $10\text{ }\mu\text{m}$. These three lanes were in the same time scale. (B) The graph illustrates the effects on mean (\pm se, standard error) YFP fluorescence intensity upon local perfusion by High K^+ (Na^+ -deficient) solution with different Cl^- concentrations (19 cells expressing Prestin-mClY and 12 cells expressing CD80-mClY). The decrease in YFP fluorescence is more marked in cells expressing Prestin-mClY than CD80-mClY. All data have been compensated for photobleaching according to the photobleaching curve that was measured just prior to perfusion. Inset shows YFP fluorescence changes in two typical cells expressing Prestin-mClY and CD80-mClY, when perfused with $140\text{ mM } Cl^-$ from the bath solution containing $0.2\text{ mM } Cl^-$. This active but slower movement of Cl^- is contrasted with the rapid passive equilibration of intracellular Cl^- achieved by the addition of the ionophores TBT ($100\text{ }\mu\text{M}$) and nigericin ($50\text{ }\mu\text{M}$) while perfusing with 140 mM extracellular Cl^- .
doi:10.1371/journal.pone.0099095.g003

previous published YFP variants, alterations in the Cl^- sensitivity is usually accompanied by alterations in confounding pH effects because halide binding promotes the protonation of the chromophore, and vice versa [8,11,20]. The relationship of pK_a and halide sensitivity of YFP variants exhibits features that imply positive cooperativity of protonation and halide-binding [8,39]. In some variants of GFP, pH-sensitivity is exploited to measure compartmental pH [12,40], but for FRET-based studies, the sensitivity of YFP to environmental pH is highly undesirable because it can interfere with the interpretation of the energy transfer efficiency or distance estimation between donor and acceptor. Indeed, YFP variants with low pH and halide sensitivity have been developed, namely Venus [24,25] and Citrine [27]. Despite the apparent interdependence of pH and halide sensitivity, each can be separated.

In YFP, pK_a is mainly determined by two factors: the negative charge density on the phenolic oxygen of the chromophore and the local proton availability in the surrounding environment. The negative charge of chromophore anion mainly distributes on the phenolic oxygen or the carbonyl oxygen of imidazolinone as two major resonance structures. If the phenolate negative charge can delocalize over the conjugated skeleton to the carbonyl oxygen of imidazolinone, the phenolic oxygen would have less negative charge to attract protons for protonation, indicating that the pK_a would decrease. Our first strategy to decrease pK_a was to introduce as many positive charged residues as possible into the halide-binding cavity that is adjacent to the carbonyl oxygen of imidazolinone. Positive charges can help maintain the chromophore's anionic state, and also likely provide a large fraction of anion-binding energy for increasing halide sensitivity. In our study, Q69K decreased the pK_a to 6.5–7.1 from 7.1–8.0 depending on the chloride concentration, and F46L resolved the folding problem caused by Q69K.

The local proton availability around the phenolic group of chromophore is proportional to the pH value of the external solution depending on proton accessibility. If the proton has unencumbered access to the phenolic anion of the chromophore, the pK_a will be higher. When proton access along the proton delivery pathway is encumbered, the pK_a value will decrease, indicating that a higher H^+ concentration is needed to overcome the more difficult delivery. Therefore, the other strategy to decrease the pK_a was to identify mutations of some key residues that can block or raise the barrier within the proton delivery pathway to the phenol group of the chromophore. In the proton delivery pathway from the external solvent to the phenolic group of the chromophore, a water molecule adjacent to the chromophore phenolate forms H-bonds with the side chain of S205 and the main chain of N146, linking the chromophore phenolate with a surface water molecule within H-bond range (Fig. 4). Upon binding a halide ion, the distance between the bridging water molecule and the nearest surface water molecule increases to 4.7 Å, likely due to conformational rearrangement. S205 is the only residue that can be mutated to affect the bridging water molecule linked with a surface water molecule. Interestingly, S205 plays an important role for photostability, as it links E222 and the chromophore. In keeping with this possibility we also found that S205 mutations affect the photostability of the fluorophore, in addition to its effects on pK_a .

Photostability

Using selective screening assays and directed evolution strategies, highly photostable variants of mOrange and TagRFP were developed by Tsien's group [41]. Nevertheless, the YFP photobleaching mechanism and details of the photo-reactive process

remain poorly understood. We tried to endow our chloride sensor with higher photostability using a structure-guided strategy.

As noted above, we view S205 as being important for both proton delivery and photostability because of the hydrogen-bond chain network between the chromophore phenolate, S205 and E222 (Fig. 4B). Both GFP and YFP show decarboxylation of E222, evidenced as a loss of 44 Daltons (CO_2), upon intense illumination, and in the case of YFP it is associated with photobleaching [42–44]. Continuous illumination irreversibly photobleaches YFP into a weakly fluorescent species, which absorbs at 390 nm and fluoresces at 460 nm, similar to its spectroscopic properties as free chromophore [42]; this behavior indicates that the photon-induced chemical destruction happens within the chromophore via excited states, while the protein is partially unfolding and aggregating [43,44]. Though the detailed mechanism of how the E222 decarboxylation of YFP induces chromophore destruction remains to be determined, it could involve the hydrogen bond network between the chromophore and E222. In YFP-H148Q, E222 could be either H-bonded to S205 or to the nitrogen on the imidazole ring of the chromophore, but not to both at the same time (Fig. 4).

We found that the mutation S205V increased YFP photostability (bleach tau = ~175 s) more than 15 fold over wild-type YFP or C1sM. In fact, not only is its photostability enhanced, but the possible H-bond network rearrangement afforded by the mutation of S205 reduces pK_a , and improves chloride sensitivity, indicating that a new equilibrium was reached between the chromophore protonation and halide-binding. S205A, S205L and S205I similarly cannot support proton transfer in the absence of a hydrogen bond donor or acceptor at position 205. S205A, which is less bulky than S205V, provides a bleach time constant of ~30 s. S205L and S205I, which have larger side chains than S205V, show bleach time constants of ~110 s and ~220 s, respectively. This may indicate that side chain size or rotational freedom of residue 205 is important for photostability.

Interestingly, it was reported that wtGFP-S205V and wtGFP-S205A slow down the travel time through the excited-state proton transfer pathway (ESPT) from several tens of picoseconds to a few nanoseconds by rearranging E222 and Thr203 to form an alternative ESPT pathway without S205 [45,46]. It is unlikely that this would occur in YFP because it lacks the corresponding neutral form of the chromophore that wtGFP possesses, and the orientation of Y203 in YFP cannot permit its phenolic group to interact in an alternative H-bonding network for proton transfer. Furthermore, any potential effects of these mutations on GFP photobleaching were not reported.

In summary, we have developed an YFP-based chloride sensor that has enhanced chloride sensitivity and photostability, while possessing reduced confounding pH effects. We have used it to measure sub-membranous chloride flux in HEK cells when fused to the transmembrane protein prestin, and show that it is capable of monitoring changes in intracellular chloride at levels expected to have physiological impact. We also note that the stability of our YFP mutants could be useful in studies where photobleaching plays a key role, for example in single molecule [47] and superresolution microscopy [48] methodologies.

Methods

1. Gene Construct and Mutations

Mutagenesis was performed using the Quick Change method adapted from Stratagene QC protocol. Mutations were verified by sequencing the entire gene. The vector is EYFP-N1. The

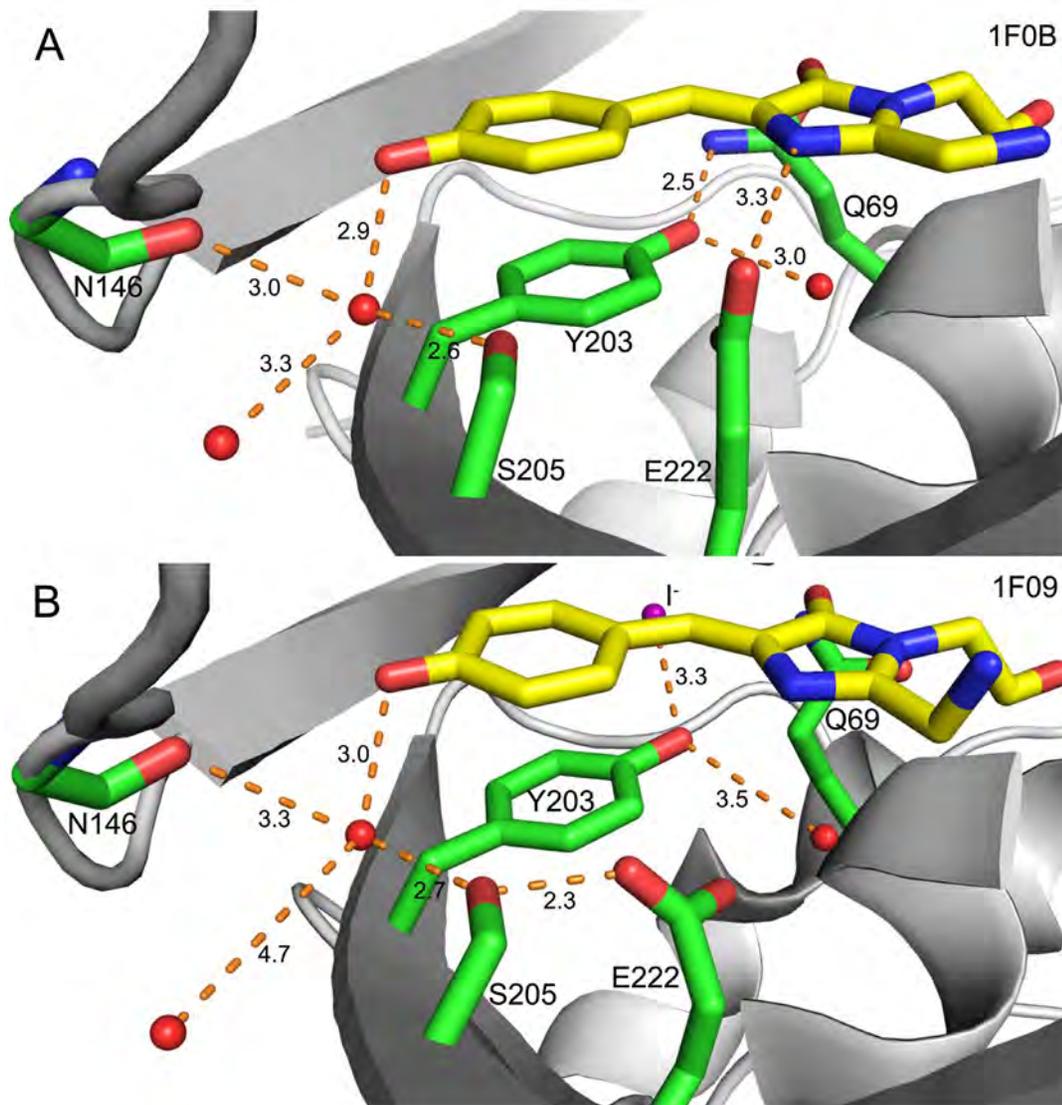

Figure 4. The H-bond network comprising the proton transfer pathway within the chromophore (in Yellow) of YFP-H148Q drawn with PyMol. Water molecules displayed as red balls. **(A)** YFP-H148Q without halide-binding (PDB: 1F0B). The phenolic oxygen of the chromophore is H-bonded to a water molecule that is also H-bonded to the side chain of S205 and the main chain of N146; additionally, there is a H-bond to a surface water molecule that is exposed to exterior solvent. E222 is H-bonded to the nitrogen on the imidazole ring, indicating that E222 is protonated, while the phenolic group of Y203 forms H-bond with Q69 and a nearby water molecule. Notably, there is no H-bond between S205 and E222 whose nearest distance is 3.9 Å. **(B)** iodide-bound YFP-H148Q (PDB: 1F09). The water molecule H-bonded to N146, S205 and the phenolic oxygen of the chromophore was separated away from the surface water molecule, whose distance increased to 4.7 Å. The deprotonated E222 forms H-bond to S205 that is in the H-bond chain with protonated chromophore, while the phenolic group of Y203 is near H-bonding distance with iodide, which may be a reason why YFPs are halide-sensitive since Y203 is the unique residue of YFP from GFP.
doi:10.1371/journal.pone.0099095.g004

sequences of EYFP-H148Q/152L/V163S and ClsM were synthesized by GeneWiz (USA).

2. Cell Culture & Excitation Ratiometric Imaging System

HEK-293T cells were cultured on glass coverslips (No. 1, 0.13–0.16 mm thick, 15 mm round, Warner Instr., USA), which were mounted on a quick change chamber and platform (RC-42LP and QE-1, Warner Instr., USA). Transient transfection with the plasmid of interest was done using lipofectamine-LTX with Plus Reagent (Invitrogen, Life technologies). Fluorescence images were acquired using an oil-immersion objective (N.A. = 1.30, Plan Fluor 100× Objective, Nikon, Japan) with a Nikon Eclipse Ti equipped with a 200W metal-halide lamp (Lumen200, Prior Scientific, USA)

as the fluorescence illumination source. Shutter and filter wheel (Lambda10–3 optical filter changer with smart shutter, Sutter Instr., USA) were connected between the microscope and the illumination source, in which Semrock ET430/24x-32 was used as the excitation filter for CFP, Semrock ET500/20x-32 as the excitation filter for YFP and Chroma HQ520LP as the emission filter. A 14-bit back-illuminated EMCCD camera system (128×128 pixels, 24 μm array, Andor iXon^{EM+} DU-860E, USA) was used to record the fluorescence images under CFP or YFP excitation. All peripheral hardware control, image acquisition and image processing were achieved and/or synchronized on a PC computer via a 16-bit/1-MHz USB Data Acquisition System (Personal Daq/3000 Series, IOtech, USA) by using customized

software (jClamp & FastLook, SciSoft, USA; www.SciSoftCo.com). The average fluorescence intensity of regions of interest (ROI) was measured, and the background fluorescence was subtracted using ImageJ. The excitation ratios (F_{500}/F_{430}) of fluorescence intensity were then determined. The emission spectrum of mCl-YFP has the same shape as wt-YFP, with the peak around 527 nm. This was determined at an excitation of 485 nm using a microplate reader (TECAN infinity M1000 Pro). The determinations of photobleaching, pK_a and chloride sensitivity were made using HEK-293 cells expressing YFP mutants directly in the cytosol, and not with membrane bound fusion proteins, which avoids the possibility of confounding results caused by limited expression or dim fluorescence. Data were analyzed with Matlab, Origin 8.0 and SigmaPlot 10.0.

3. Photobleaching

Photobleaching data and fluorescence images were achieved with our ratiometric imaging system controlled by jClamp & FastLook. Photobleaching efficiency at a wavelength of 500 nm is lower than at 430 nm, although the absorption at 430 nm is much lower than 500 nm. Because of this enhanced bleaching capability and to optimize our identification of photostable products, we bleached at the CFP excitation wavelength of 430 nm (approximately 17 μ W). At the beginning of every episode, the excitation filter was changed to the YFP filter (500 nm) by the filter wheel and an image was captured by the camera and then the excitation filter was changed back to CFP filter (430 nm) for bleaching until the next acquisition. Filter change and acquisition took about 100 ms. The protocol includes 400 episodes and 200 ms interval time between each episode. CFP excitation remained on during intervals. Stable optical power at the utilized wavelengths was confirmed using an analog optical power meter (ThorLabs PM30–130, w/S130A Slim Sensor). Photobleaching of mCl-YFP did not shift its emission peak.

4. pK_a Measurement

The pK_a of the YFP mutants were directly measured from the fluorescence change of the transfected HEK-293T cells under local perfusion (Y-tube) with low $[Cl^-]$ solutions (0.2 mM Cl^-) at different pH values containing 50 μ M nigericin and 100 μ M TBT, which eliminates pH and Cl^- gradients across the cell membrane, respectively. A Hill function (SigmaPlot, unconstrained, 4 parameters, $y = y_0 + \frac{ax^b}{c^b + x^b}$) was fitted to the data points to calculate the apparent pK_a .

5. Chloride Sensitivity Calibration

The chloride sensitivity of YFP mutants was measured from the fluorescence change of the transfected HEK-293T cells under local perfusion (Y-tube) with near neutral solutions (pH 7.20) of

different $[Cl^-]$ containing 50 μ M nigericin and 100 μ M TBT, according to the standard nigericin-tributyltin equilibrating protocol. A Hill function (SigmaPlot, unconstrained, 4 parameter) was fitted to the data points to calculate the apparent K_d . Local perfusion were performed with high K^+ solution (Na^+ -deficient) to minimize any pH effect on the chloride sensor by native membrane Na^+/H^+ exchanger.

6. Chloride Flux Promoted by Local Perfusion

The chloride flux into HEK-293 cells expressing prestin-mClY or CD80-mClY was measured by fluorescence change during local perfusion using high K^+ solutions containing different chloride concentrations at pH 7.20. Photobleaching compensation was corrected based on the photobleaching time constant that was measured prior to Cl^- perfusions. ImageJ was used to define a region of interest around membrane sections that were free from movement artifact in which fluorescence intensity changed with perfusion with different Cl^- concentrations. Perfusion data were analyzed using mixed model repeated measurements with a group-specified compound symmetry structure within SAS software. The repeated-measures design was used for the experiment of comparing the Cl^- influx pattern between prestin and CD80 constructs. Since each cell was perfused with a series concentration of extracellular Cl^- , fluorescence measured within each cell was correlated. A repeated measures analysis using the procedure of Proc Mixed in SAS software (Cary, NC) was performed to model the change of fluorescence per extracellular Cl^- . The dependency between repeated measures for same cell was incorporated into analysis by using a group specified compound symmetry covariance structure, which assumes common variance and covariance within group and accounts for the heterogeneous structure between groups. The interaction between group and concentration of Cl^- was included in the model to examine the difference of rate of change in fluorescence between groups [49,50].

7. Data Availability Statement

All data are supplied in the manuscript, including information on point mutations. Further requests can be made to the corresponding author.

Acknowledgments

We thank Mr. Fangyong Lian for help with statistical analysis, and thank Dr. John P Geibel in Yale School of Medicine for helpful discussion. Gerbil prestin was kindly provided by Dr. Peter Dallos and Dr. Jing Zheng.

Author Contributions

Conceived and designed the experiments: SZ JSS. Performed the experiments: SZ. Analyzed the data: SZ JSS. Contributed reagents/materials/analysis tools: DN. Wrote the paper: SZ DN JSS.
