Osteoblastic Oxygen Sensing Prolyl Hydroxylases Regulate Bone Homeostasis by Controlling both Osteoclastogenesis and Angiogenesis. Colleen Wu*[1], Erinn Rankin[1], Edward LaGory[1], Rebecca Andersen[1], Steven Rhodes[2], Tremika Wilson[3], Khalid Mohammad[3], Alesha Castillo[4], Theresa Guise[3], Ernestina Schipani[3], Amato Giaccia[2]. [1]Stanford University, USA, [2]Indiana University Medical School, USA, [3]University of Michigan, USA, [4]VA Palo Alto Health Care System, USA

The osteoblastic niche houses cells of osteoblastic and hematopoietic lineages across varying oxygen tensions. However, the contribution of this oxygen gradient to bone homeostasis is poorly understood. The prolyl hydroxylase enzymes (PHD 1-3) are oxygen sensors, which control hypoxic signaling. To elucidate the role of these crucial oxygen-sensing enzymes in the osteoblastic niche, we generated knockouts of each PHD isoform and isoform combination within osteoblasts. Using these genetic mouse models we demonstrate that PHD enzymes act as a molecular rheostat of HIF activation to differentially regulate two important aspects of bone physiology; cross talk between osteoblasts and osteoclasts and osteogenic/angiogenic coupling. Combined inactivation of Phd2 and Phd3 within osteoblasts leads to augmented synthesis and secretion of OPG resulting in a subsequent decrease in osteoclast numbers and an increase in trabecular bone volume. Unexpectedly, these changes in bone homeostasis were not associated with HIF- mediated neo-angiogenesis as vascular density was not altered in PHD2 and PHD3 deficient mice. Genetic deletion of Hif-2α caused the complete abrogation of PHD2 and PHD3 mediated suppression of bone turnover whereas constitutive activation of Hif-2α within osteoprogenitor cells phenocopied mice lacking functional osteoblastic PHD2 and PHD3. Thus, HIF-2α was both necessary and sufficient for osteoblast-mediated inhibition of osteoclastogenesis. In contrast, genetic loss of all three PHD isoforms in osteoblasts resulted extreme HIF signaling activation, leading to a series of deleterious effects including aberrant hematopoiesis, and extreme blood vessel formation associated with an excessive augmentation of trabecular bone volume. Importantly, loss of Phd2 and Phd3 protected ovariectomized mice against bone loss by normalizing the OPG to RANKL ratio. Taken together, we identify a previously unknown relationship between PHD/HIF signaling and RANK/RANKL/OPG axis, revealing a role for PHD/HIF signaling in the regulation of bone homeostasis that is independent of angiogenesis. Our findings have important clinical implications as the OPG/RANK/RANKL signaling axis is a key molecular driver of pathological bone loss and we demonstrate that precise regulation of hypoxic signaling through the selective rather than collective inactivation of PHD isoforms is required to modulate OPG to protect against osteoporosis and prevent potential tissue toxicity.

Vascular Smooth Muscle Cell LRP6 Inhibits Noncanonical Wnt Signaling and Arteriosclerotic Calcification In Diabetic LDLR-/- Mice. Su-Li Cheng[1], Bindu Ramachandaran[1], Abraham Behrmann[1], Jian-su Shao[2], Karen Krchma[1], Megan Mead[1], Lawrence Brill[1], Bart Williams[3], Dwight Towler*[4]. [1]Sanford-Burnham Medical Research Institute, USA, [2]MD Anderson Cancer Center, USA, [3]Van Andel Research Institute, USA, [4]Sanford-Burnham Medical Research Institute, USA

Msx-Wnt signaling regulates osteogenic differentiation during bone formation and the arterial calcification of type 2 diabetes. The canonical Wnt co-receptors LRP5 and LRP6 play overlapping roles in bone; however, contributions to vascular disease are poorly understood. Therefore, we generated SM22-Cre;LRP6(fl/fl);LDLR-/- mice to ablate the LRP6 gene in the vascular smooth muscle cell (VSMC) lineage of LDLR-/- mice – a background susceptible to high fat diet (HFD) -induced vascular calcification. As compared to LRP6(fl/fl);LDLR-/- controls, SM22-Cre;LRP6(fl/fl);LDLR-/- sibling cohorts exhibited significantly increased aortic calcification following 3 months of HFD-challenge (1.3-fold; p =0.002). No differences were noted in body composition, blood glucose, or lipids. Pulse wave velocity, an index of vascular stiffness, was increased by LRP6 deficiency. This paralleled increases in aortic and circulating osteopontin (OPN), a matrix cytokine that regulates arteriosclerotic disease. Survey of Wnt ligand and Fzd receptor expression in LRP6-deficient aortas revealed upregulation of Wnt7b and Wnt4 – two ligands supporting noncanonical signaling – along with Fzd10. Western blot and immunohistochemistry confirmed Wnt7b and Fzd10 protein accumulation. To better understand signaling mechanisms, we transfected HEK293T cells with OPN promoter – luciferase reporter constructs, mapping regulatory responses to LRP6 and Fzd10. Fzd10 expression significantly upregulated OPN promoter activity, and localized to a regulatory element between -135 and -45 relative to the start site of transcription. Induction was augmented by Wnt7b and Wnt5a, and completely inhibited by co-expression of LRP6. Fzd10 induction of NFAT-dependent transcription, a hallmark of noncanonical calcium signaling, was also inhibited by LRP6 and independent of LRP6 structural motifs required for canonical signaling. Using mass spectroscopy, complexes containing LRP5 and specific members of the protein arginine methyl transferase (PRMT) family were found to interact with LRP6. The nuclear-cytoplasmic distribution of PRMTs and arginine methylation were perturbed in LRP6-deficient aortas, and co-expression of specific PRMT family members differentially regulated LRP6-inhibited OPN promoter activity. Thus, loss of aortic LRP6 upregulates expression of noncanonical Wnt ligands, receptors, and signals in VSMCs, driving the expression of prosclerotic gene regulatory programs via PRMT-modulated relays.

Direct Transformation of Chondrocytes to Bone and Vessel Cells in Patients with Osteoarthritis (OA). Yan Jing*[1], Yinshi Ren[2], Baozhi Yuan[3], Joseph Borrelli[4], Yin Xiao[5], Ying Liu[2], Chuanju Liu[6], Ding Bai[7], Jian Feng[8]. [1]USA, [2]Texas A&M Baylor College of Dentistry, USA, [3]University of Wisconsin, USA, [4]Texas Health Physicians Group, Arlington, TX, USA, [5]Institute of Health & Biomedical Innovation, Queensland University of Technology, Brisbane, Australia, Australia, [6]New York University, USA, [7]State Key Laboratory of Oral Diseases (Sichuan University), Department of Orthodontics, West China Stomatology Hospital of Sichuan University, China, [8]Texas A&M Health Science Center, USA

Although OA is the most common degenerative skeletal disorder, there has been an intensive ongoing debate regarding the initial site of the disease: articular cartilage or subchondral bone. One commonly-held belief is that some chondrocytes directly form bone without going through endo-chondrogenesis, which is accelerated in OA, leading to osteosclerosis. To test this hypothesis, we use an immunostain assay to initially demonstrate that DMP1, a matrix protein highly expressed in osteocytes, is expressed in hypertrophic chondrocytes and osteocyte (Ocy)-like cells in calcified cartilage (Fig a). These Ocy-like cells remain in their original cartilage lacunae and distribute in pairs. Acid-etched SEM images in mice reveals that these directly-formed Ocys are round in shape with few dendrites lying on cement line (Fig b). The cell lineage tracing results from crossing Aggrecan-Cre^{ER} & Rosa 26-lacZ mice demonstrate that the chondrocytes in the articular cartilage directly transform into bone cells (Fig c). We also obtain mRNAs from a 5-mon-old pig's non-calcified, calcified cartilage and subchondral bone respectively using laser capture technique. The quantitative RT-PCR data shows much higher levels of ALP (28- or 12.5-fold), TRAP (5.9- or 3.4-fold), and OSX (4.6- or 5-fold) in calcified cartilage compared to non-calcified cartilage and subchondral bone separately, indicating hypertrophic chondrocyte can remove mineral and future transform to bone cells. Finally, we extend the animal studies to directly address whether the above finding has clinical relevance in OA patients. Using FITC-confocal imaging techniques, we show sharp increased Ocy-like cells in calcified cartilage matrix from OA knee samples, which are round in shape with short deformed dendrites (Fig d). The combined histological (H&E, Safranin O and SEM) images show bone-like islands in non-calcified and calcified areas, which have no direct link with subchondral bone (Fig e-f). In those cartilage surrounded bone islands, some of Ocys are in paired and some of them directly surrounded by hypertrophic chondrocytes. Interestingly, some chondrocytes are TRAP positive and express VEGF and α-SMA, suggesting they can remove matrices and participate in angiogenesis (Fig g-i). Based on the above findings, we conclude that at least some of chondrocytes directly transform into Ocys in the normal articular cartilage, which is greatly accelerated in OA patients (Fig j). Roles of Osteoblast-derived VEGF in Osteoblastic Differentiation and Bone Formation During Bone Repair. Kai Hu*[1], Bjorn Olsen[2]. [1]Harvard School of Dental Medicine, USA, [2]Harvard School of Dental Medicine, USA

Vascular endothelial growth factor (VEGF) plays pivotal roles in the communication between blood vessels and bone cells during bone turnover and repair. However, the precise mechanisms are not fully elucidated. To examine roles of osteoblast-derived VEGF in bone repair, a tibial monocortical defect (0.8 mm hole) was made in mice with Vegfa deleted from osteoblast precursors (Osterix-cre; Vegfa flox/flox, CKO mice) and WT littermates (Vegfa flox/flox). At D3 after surgery, CKO mice exhibited reduced numbers of vessels and macrophages. Strong correlation (R^2=0.877) between vessel density and macrophage number indicated that VEGF may be required for macrophage-mediated angiogenesis. At D7, intramembranous ossification (IO) occurred at injury holes while endochondral ossification (EO) was observed in the wounded periosteum. Within the injury hole, μCT showed less mineralization in CKO than in WT mice (1.98±0.79% vs. 10.74±2.47% (BV/TV)), and aniline blue staining indicated reduced collagen accumulation (17.56±2.56% vs. 37.99±2.35% (collagen area/total area)). Decreased mineralization/collagen ratio (11.56±3.51% vs. 30.45±6.6%) also suggested a delay in osteoblast maturation, in further support of compromised IO. To probe cellular mechanisms of IO in this injury model, a Cre-induced transgene, ZsGreen, was introduced. Although the number of ZsGreen+ cells, representing osteoblast precursors and their descendants, was not reduced at injury sites in CKO mice at D7, bone sialoprotein (BSP) and osteocalcin (OCN) levels were greatly decreased. In addition, CKO mice exhibited fewer blood vessels, and the vessel density was positively correlated with BSP and OCN levels. This suggested an association between angiogenesis and osteoblast differentiation. In areas of periosteal EO, WT mice showed gradual degradation of cartilage and recruitment of osteoclasts and blood vessels. In contrast, CKO mice exhibited delayed replacement of cartilage by bone. At D28, a new cortical layer appeared outside the original bone collar in both WT and CKO mice. A decrease in the callus thickness and bone volume in CKO mice, of 47.19±15.43% and 55.44±6.23%, respectively, indicated a reduction in remodeling capability. In summary, VEGF produced in osteoblastic lineage cells is required at various stages of bone repair. The findings add to the understanding of VEGF functions and may contribute to the development of novel strategies to improve bone repair and regeneration.

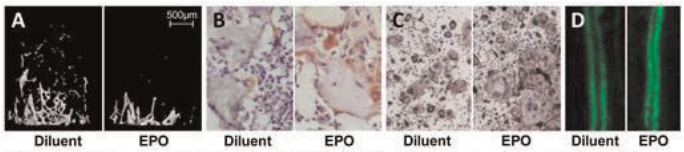
Erythropoietin reduces bone formation and stimulates bone resorption: new insights into endocrine regulation of bone remodeling. Sahar Hiram-Bab*[1], Tamar Liron[2], Naamit Deshet-Unger[3], Avi Salamon[2], Moshe Mittelman[4], Max Gassmann[5], Kristin Franke[6], Martina Rauner[7], Ben Wielockx[8], Drorit Neumann[3], Yankel Gabet[9]. [1]Department of Cell & Developmental Biology, Sackler Faculty of Medicine, Tel Aviv University, Israel, [2]Department of Anatomy & Anthropology, Sackler Faculty of Medicine, Tel-Aviv University, Israel, [3]Department of Cell & Developmental Biology, Sackler Faculty of Medicine, Tel-Aviv University, Israel, [4]Department of Medicine, Tel Aviv Sourasky Medical Center, Sackler Faculty of Medicine, Tel-Aviv University, Israel, [5]Institute for Veterinary Physiology, Vetsuisse Faculty & Zurich Center for Integrative Human Physiology (ZIHP), University of Zurich, Switzerland, [6]Institute of Pathology, Technische Universität Dresden, Germany, [7]Medical Faculty of the TU Dresden, Germany, [8]Institute of Pathology, Dresden University of Technology, Germany, [9]Department of Anatomy & AnthropologySackler Faculty of Medicine, Israel

The negative effect of hypoxia on bone metabolism is well established but its mechanism of action is not fully understood. Hypoxia triggers the production of erythropoietin (EPO), a hormone most recognized for its hematopoietic function. An increasing number of roles unrelated to red blood cell production, have been attributed to EPO, many of which are mediated by non-erythroid cells. In light of the controversy on the effect of increased serum levels of EPO on the skeleton, we investigated here the effect of the hormone on bone metabolism using EPO overexpressing (Tg6), and EPO-administered adult mice. In these models, the increase in EPO levels is similar to its physiologic increase at high altitude. Using microcomputed tomography, histology and serum markers we found that high EPO levels result in a severe trabecular bone loss, due to increased bone resorption and reduced bone formation. This bone loss consisted of reduced trabecular number, but not thickness, with no effect on the cortical bone compartment. A similar bone response was observed with high and low doses, with no difference between intermittent and continuous administration modes. Using FACS and specific surface markers, we found that EPO targets the monocytic lineage by increasing the number of monocytes/macrophages, pre-osteoclasts and mature osteoclasts in bones. In contrast with the attenuation of bone formation in vivo, EPO treatment in vitro did not inhibit osteoblast differentiation and activity, as demonstrated by RT-qPCR of marker genes and mineralization assays. However, EPO strongly stimulated osteoclastogenesis (TRAP staining) and pit resorption (measured in calcium-phosphate-coated wells) in a cell-autonomous manner. Furthermore, our data

indicate that EPO receptor signaling in osteoclast precursors involves the Jak2 and PI3K pathways, but is independent of the MAPK/MEK pathway. These findings demonstrate that EPO strongly regulates bone mass by stimulating osteoclastogenesis and propose a new mechanism for hypoxia-induced bone loss.



EPO induced trabecular bone loss (A, micro-CT), by stimulating osteoclastogenesis in vivo (B, histology) and in vitro (C, TRAP), and by attenuating bone formation (D, calcein-labeled histology).

Loss of *Nf1* in Osteoprogenitors Affects Fracture Resistance at Multiple Levels of Bone Organization. Mathilde Granke*[1], Jean de la Croix Ndong[2], Sasidhar Uppuganti[2], Guillaume Vignaux[2], Alexander Makowski[3], Daniel Perrien[1], Florent Elefteriou[2], Jeffry Nyman[1]. [1]Vanderbilt University Medical Center, USA, [2]Vanderbilt University, USA, [3]Department of Veterans AffairsVanderbilt University, USA

Mutations in the *NF1* gene can cause skeletal abnormalities, including tibial bowing, fracture and pseudarthrosis. The reason why fractures occur in NF1 children remains unclear, in part because previous mouse models, based on *Nf1* ablation in the early mesenchymal lineage, are characterized by severe development phenotypes that complicate the interpretation of the bony phenotypes observed. In this study, we used inducible Tet^{off}-based *Osx*-cre transgenic mice crossed to *Nf1*$^{flox/flox}$ mice (*Nf1*$_{Osx}^{-/-}$) to assess how post-natal ablation of *Nf1* in osteoprogenitors affects bone's fracture resistance.

At 2 weeks of age, repression of cre activity was stopped by withdrawal of doxycycline from the drinking water, leading to *Nf1* ablation in post-natal osteoprogenitors. Mice were euthanized at 6 wks, 14 wks, and 34 wks of age (n≥7/age/genotype). Femoral midshafts were i) scanned with µCT to obtain tissue mineral density (TMD), porosity, and cortical thickness; ii) analyzed with ^{1}H NMR to assess bound water; and iii) subjected to 3pt bending to estimate strength and modulus. Reference point indentation (BioDent, 10 cycles at 0−2N) was performed on the tibiae (5 indents with 500µm spacing on the anterior side opposite to the tibiofibular junction) to obtain average creep indentation (avCID) and average loading slope (avLS).

Nf1 ablation in post-natal osteoprogenitors did not affect stature but inhibited the age-related increase in bone strength, with structural and material strength being significantly lower in *Nf1*$_{Osx}^{-/-}$ compared to WT mice at 34 wks (Fig). Compared to WT, *Nf1*$_{Osx}^{-/-}$ mice also had a thinner cortex and higher porosity at 34 wks (Fig). At the material level, *Nf1* deletion also impeded the age-related increase in TMD (Fig). Similarly, indentation resistance declined less in *Nf1*$_{Osx}^{-/-}$, with the probe tip penetrating deeper (higher avCID, lower avLS) in *Nf1*$_{Osx}^{-/-}$ compared to WT bone tissue (Fig). Finally, water bound to the matrix decreased from 6 to 14 wks of age in both genotypes, and was less in *Nf1*$_{Osx}^{-/-}$ versus WT bone at 34 wks of age (Fig).

Similar to observations from NF1 patient biopsies, loss of *Nf1* from osteoprogenitors in mice causes increased porosity and decreased mineralization. This study shows that this translates into a loss in fracture resistance at different levels of bone organization (structural and tissue), thus providing useful parameters to predict bone alteration in children with NF1, prior to overt bone bowing and fracture.

Mechanical Signals Improve Bone Quality Compromised by Type 2 Diabetes, Potentially by Enhancing the Bone Marrow Mesenchymal Stem Cell Population and its Paracrine Regulation of Bone-forming Osteoblasts. M. Ete Chan*[1], Gregory Lee[1], Danielle Green[1], Benjamin Adler[1], Gabriel Pagnotti[1], Vihitaben Patel[1], Clinton Rubin[2]. [1]Stony Brook University, USA, [2]State University of New York at Stony Brook, USA

Type 2 diabetes (T2D) is clinically linked to an increased bone fracture risk. Previous studies have shown that low intensity vibration (LIV), acting as a surrogate for the mechanical components of exercise, significantly improves bone quality, an outcome associated with increased bone marrow mesenchymal stem cell (MSC) populations. However, it is not known if these stimuli can modulate bone in a model of T2D, or if these signals will influence the lineage selection of MSC in T2D model. Combining *in vivo* and *in vitro* approaches, this study investigates (1) the impact of LIV on bone mechanical strength in T2D, and (2) the role of MSCs, by themselves and in relation to other bone marrow cells, in responding to LIV. Using a murine model of T2D in an 8-week study, thirty 5w old male C57BL/6J mice were divided into 3 groups (n=10): regular diet (RD; 10kcal% fat), high fat diet (HF; 45kcal% fat) and high fat diet with LIV (HFv). LIV was delivered via a vertically oscillating plate (30min/day, 5 day/wk at 90Hz and 0.2g) to HFv, while HF and RD were sham-handled. Biomechanical testing showed that while the tibiae of HF had lower stiffness (-22%) and elastic modulus (-45%) than RD (p=0.03), LIV increased these properties in HFv by +27% and +108%, respectively, as compared to HF (p=0.02). LIV also increased cortical thickness (+2.1%, p=0.009) and bone marrow MSC populations (+53%, p<0.05). The effect of LIV on MSC proliferation was examined with isolated MSC (2,500 cells/1.9cm^2) in two groups (n=4): While one group received 30min of LIV, another group was sham handled (control). After 48hrs, the vibrated MSCs

proliferated 177% more than the non-vibrated MSCs (p=0.04). Further, conditioned medium from vibrated and non-vibrated MSCs were transferred to a distinct set of osteoblasts (OBs) (n=4). OBs with conditioned media from vibrated MSCs proliferated 70% more than the OB receiving control medium (p=0.03), implicating that signaling molecules secreted by MSCs modulated OB proliferation. In summary, T2D, induced by a high fat diet, compromised bone mechanical properties, while LIV improved mechanical strength despite T2D. The salutary impact of these mechanical signals may, in part, be achieved directly by increasing MSC proliferation, and indirectly via paracrine promotion of bone-forming OBs to promote osteogenesis.

N-cadherin Restrains Parathyroid Hormone (PTH) Activation of Lrp6/β-catenin Signaling and Its Bone Anabolic Action. Leila Revollo*[1], Jacqueline Kading[2], Jiemin Li[2], Sung Yeop Jeong[2], Gabriel Mbalaviele[3], Roberto Civitelli[3]. [1]Washington University, Division of Bone & Mineral Diseases, USA, [2]Washington University, USA, [3]Washington University in St. Louis School of Medicine, USA

Formation of a complex between parathyroid hormone (PTH), PTH/PTHrP 1 receptor (PTH1R), and Lrp6 has been linked to PTH signaling and anabolic action. Since N-cadherin regulates canonical Wnt/β-catenin pathway by interacting with Lrp5/6 via axin, we hypothesized that N-cadherin may also modulate PTH signaling and osteoanabolic action by interfering with Lrp6 signaling. We tested this hypothesis in N-cadherin-ablated bone marrow stromal cells (BMSC) from mice with a selective deletion of the N-cadherin gene (*Cdh2*) in osteoprogenitors (*$Cdh2^{flox/flox}$::Osx-Cre; cKO*). Co-immunoprecipitation experiments using control BMSC from *$Cdh2^{flox/flox}$ mice* showed that PTH1R interacts with Lrp6, but not Lrp5 nor N-cadherin. This interaction was enhanced by exposure to $PTH_{1\text{-}34}$ in *cKO cells,* but not in control. In BMSC and MC3T3-E1 cells, $PTH_{1\text{-}34}$ promoted PKA-dependent β-catenin stabilization via C-terminus phosphorylation (S675), and Tcf/Lef transcriptional activity. PTH-induced phosphorylation of β-catenin at S675 was accentuated in *cKO* BMSC relative to control. Consistent with enhanced β-catenin stabilization, $PTH_{1\text{-}34}$ stimulated expression of Tcf/Lef target genes, *Lef1* and *Axin2*, to a larger degree in mutant cells compared to control. These suggests that *Cdh2*-ablated cells are more responsive to activation of β-catenin signaling by PTH. Increased PTH responsiveness in N-cadherin deficiency extends to PTH anabolic effect *in vivo*. Treatment with intermittent human $PTH_{1\text{-}34}$ (80μg/kg bw, sc, 5x/week, 4 weeks; iPTH) increased trabecular thickness and bone volume/tissue volume in *cKO* to a significantly larger extent than in control mice, assessed by μCT imaging. On bone histomorphometry, iPTH significantly increased mineral apposition rate and bone formation rate in *cKO* mice, contrasting with more modest changes in control mice. While osteoclast and osteoblast surface per bone surface were modestly affected, serum CTX increased to a similar extent in response to iPTH in mice from both genotypes, and serum P1NP was significantly increased in iPTH-treated *cKO* mice but not in control. These findings suggests that N-cadherin restrains PTH activation of bone formation, but not bone resorption. Since LRP6 is involved in osteoprogenitor differentiation and PTH anabolic effect, we propose that N-cadherin functions as a ''buffer'' for Lrp6 at the cell surface, thus modulating Lrp6/PTHR1 interaction and consequently the intensity of PTH-induced activation of Lrp6/β-catenin responses.

Androgens Reduce Skeletal Mechanoresponsiveness in Adult Male Mice. Michaël Laurent*[1], Mieke Sinnesael[1], Ludo Deboel[1], Peter Delisser[2], Vanessa Dubois[2], Evelien Gielen[3], Lance Lanyon[4], Joanna Price[2], Geert Carmeliet[1], Frank Claessens[2], Dirk Vanderschueren[1]. [1]Katholieke Universiteit Leuven, Belgium, [2]University of Bristol, United Kingdom, [3]University Hospitals Leuven, Belgium, [4]Royal Veterinary College, United Kingdom

Introduction: Testosterone and exercise synergistically induce muscle hypertrophy and can be used to treat cachexia in chronic diseases. Whether androgens also influence bone's response to mechanical loading or unloading is incompletely understood.

Methods: 16-week-old male C57Bl/6J mice were sham-operated or orchidectomized (ORX) and given placebo or anabolic doses of testosterone (T) or dihydrotestosterone (DHT) by s.c. silicone implants. These groups (n=7-11) received unilateral tibia loading (3x/w for 2 weeks, 40 cycles, 2400 με peak strain) started after 1 or 10 days, or unilateral Botox® injection on day 0 with 3 or 19 weeks follow-up.

Results: By two-way ANOVA, there was a significant interaction between androgen status and the osteogenic loading response. Cortical thickness was increased by T and DHT in control limbs but these groups partially (T) or completely (DHT) failed to exhibit the loading-related increase seen in sham and ORX. Trabecular bone volume also showed relatively larger load-related increases in ORX. T and DHT restored periosteal bone formation to sham levels but completely suppressed the load-related increase. Both loading and androgens suppressed skeletal RANKL/OPG mRNA ratios. ORX decreased and T increased the percentage of sclerostin-immunoreactive osteocytes (but not serum sclerostin), and loading no longer affected osteocytic sclerostin expression in ORX and T. Botox and ORX synergistically induced trabecular bone loss at 3 weeks compared to internal control limbs, which was mitigated by androgens. The degree of muscle paralysis as well as calf muscle volumes and -weights were not affected by androgens. After 19 weeks, there was still a trabecular deficit in sham-Botox limbs, which was completely restored by T and DHT. Osteocyte-specific (Dmp1-Cre) androgen receptor knock-out mice showed identical skeletal responses to loading or disuse.

Conclusion: Androgens suppress both the osteogenic response to mechanical loading and disuse-related bone loss in adult male mice. This effect seems related to their antiresorptive actions and upregulation of sclerostin, independent of muscle volume. If confirmed in humans, our results suggest that androgens or loading may compensate the effect of each other's absence on bone loss; loss of both stimuli has a synergistic negative impact, while anabolic doses of both are unlikely to provide additive benefits.

Synovial insulin resistance is linked to osteoarthritis in type 2 diabetes. Sharon Ansboro*[1], Robert Maynard[2], Daisuke Hamada[2], Christopher Farnsworth[2], Robert Mooney[3], Michael Zuscik[4]. [1]The Center for Musculoskeletal Research, USA, [2]Center for Musculoskeletal Research, USA, [3]University of Rochester Medical Center, USA, [4]University of Rochester School of Medicine & Dentistry, USA

Obesity induced type 2 diabetes (T2D) and associated systemic metabolic dysregulation is widely accepted as a risk factor for osteoarthritis (OA). Characteristic to T2D is resistance of tissues to insulin. We hypothesize that in OA, reduced insulin signalling attributed to insulin resistance in the synovium may initiate and exacerbate OA disease progression. We investigated insulin receptor (IR) expression and signalling in human fibroblast-like synoviocytes (FLSs) isolated from synovium of T2 diabetic and non-diabetic patients undergoing knee arthroplasty. A genetic approach was used to target insulin signalling in lubricin expressing (PRG4 positive) synovial tissues in obese, T2D mice to further to the hypothesis.

Human synovial tissue was analysed for IR expression via immunohistochemistry and for insulin activation of pAKT signalling via Western blotting. Effects TNFa and insulin on catabolic gene expression, and MMP1 and MMP13 protein levels were assessed in FLSs isolated from these tissues. To assess the role of FLS insulin signalling on spontaneous OA development in an obesity induced T2D model, male PRG4-Cre C57BL/6J mice were bred with IR fl/fl mice. Mice were placed on HF (60% kcal) or low-fat (10% kcal) diets at 5 weeks of age. After 16 weeks on diet, knee joint morphology was assessed via histology to visualize osteophytes and changes in articular cartilage.

Human FLSs were shown to be insulin responsive with dose dependent phosphorylation of IR and Akt. Synovial tissue harvested from T2D patients was insulin resistant, evidenced by a remarkable loss of AKT phosphorylation compared to synovium from non-diabetic patients (Fig. 1). TNFa, a pro-inflammatory cytokine elevated in T2D, markedly increased expression of cartilage degrading proteases in human FLSs including *ADAMTS4*, MMP13 and MMP1. Insulin treatment inhibited all of the TNFa responses by >50% (Fig. 2). Consistent with these findings, ablation of the IR in PRG4-Cre^{ERT2};$IR^{f/f}$ mice mimicked the knee joint changes that we have previously reported in HF mice. Compared to $IR^{f/f}$ controls, tamoxifen-induced PRG4-Cre^{ERT2};$IR^{f/f}$ mice showed spontaneous formation of osteophytes and early degenerative changes in the articular cartilage, effects that are observed in $IR^{f/f}$ HF mice (Fig. 3).

These notable changes in knee joint morphology suggest that loss of insulin signalling in PRG4-expressing FLSs disrupts the normal joint homeostasis and may initiate and exacerbate OA disease progression.

[1]Robert-Bosch-Krankenhaus, Germany, [2]NeuRA, UNSW, Australia, [3]University of Pittsburgh (at the time the work was done), USA, [4]Indiana University School of Health & Rehabilitation Sciences, USA, [5]Jean Mayer USDA HNRCA At Tufts University, USA, [6]United Osteoporosis Center, USA, [7]University of Maryland School of Medicine, USA, [8]Geneva University Hospital & Faculty of Medicine, Switzerland, [9]Montpellier University Hospital, University Montpellier 1, MacVia-LR, France, [10]Washington University School of Medicine, USA, [11]Gérontopôle de Toulouse, Centre Hospitalo-Universitaire de Toulouse (CHU Toulouse), France, [12]Eli Lilly & Company, USA, [13]Eli Lilly & Company, France

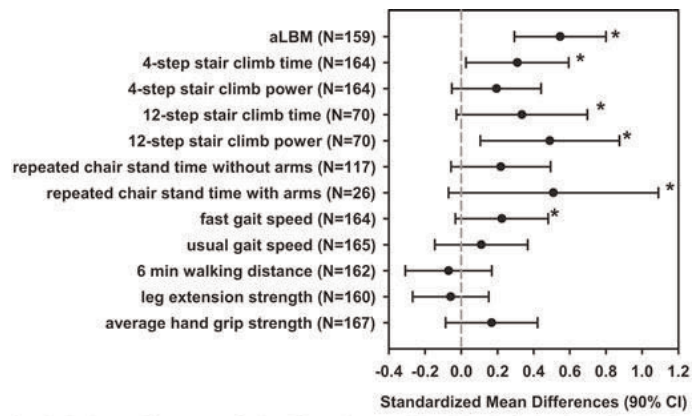
Purpose: This trial was designed to test whether the anti-myostatin monoclonal antibody LY2495655 (LY) could increase appendicular lean body mass (aLBM) and improve physical performance in elderly fallers with low muscle strength. NCT01604408.

Methods: Subjects randomized (N=201) were aged ⩾75 yrs, had ⩾1 fall in past yr, low hand grip strength (≤37 kg [men]; ≤21 kg [women]) and low performance on a 5-time chair stand (5XCS) test without arms (⩾12 s). LY 315 mg or placebo (pbo) was administered as 3 SC injections of 1.5 mL every 4 wks for 20 wks, followed by a 16 wk observational period. The primary objective was to assess the change from baseline to 6 months for aLBM for LY compared to pbo. Secondary and exploratory outcomes included 5XCS without arms (or with arms for subjects unable to do it without arms), 4-step stair climbing time and power (and same over 12-steps at equipped sites), fast and usual gait speed over 4 m, 6 min walking distance, isometric leg extension strength, hand grip strength, and incidence of falls. The 2-sided alpha level was set a priori at 0.05 for the primary analysis (ITT including all subjects with a baseline and ⩾1 post baseline value) and 0.1 for all performance based measures (PBMs).

Results: Subjects were 70% women, aged 82±5 yrs (mean±SD), with BMI=26.5±4 kg/m^2. Study groups were balanced for baseline aLBM (14.9±2.2 kg [women]; 21.9±3.1 kg [men]) and PBMs. LY subjects tended to have more pre-existing conditions and a higher risk of falls and fractures. Treatment was discontinued early in 19.6% of LY vs 14.1% of pbo arm. The change in aLBM from 0 to 6 months was +0.43 kg (SE 0.12; p<0.001) larger in LY than in pbo (+2.5%). Several power intensive PBMs (stair climbing, repeated chair stands, and fast gait speed) were improved in LY vs pbo subjects (Fig. 1). The incidence of falls per subject-yr was 1.6 (LY) vs 2.0 (pbo) (NS).

One death due to ischemic colitis occurred in an 87 yr old LY subject with a history of surgery for abdominal aortic aneurysm. At least 1 adverse event of fracture was reported in 6 pbo vs 10 LY subjects (NS). Injection site reactions were more frequent in the LY arm (30% vs 9%) and most often mild, requiring treatment discontinuation in 2 LY subjects. No safety issues related to muscle were observed.

Conclusions: In older fallers with low muscle strength, 6 months of LY treatment increased aLBM and consistently improved power intensive PBMs.



Standardized mean differences are for the difference between LY and placebo for the change from baseline to 6 months. A repeated measures mixed models for the changes from baseline was fitted for each endpoint. N=sample size of analysis for each measure including LY and placebo subjects. * p-value <0.1 for treatment effect including 3 and 6 month visits. Endpoints measured in seconds were multiplied by -1.

Fall Risk Assessment Predicts Fall Related Osteoporotic and Hip Fracture in Older Women and Men. Martin Nilsson*[1], Joel Eriksson[2], Anders Odén[3], Helena Johansson[4], Mattias Lorentzon[5]. [1]Centre for Bone & Arthritis Research At the Sahlgrenska Academy, Sweden, [2]Centre for Bone & Arthritis Research, Sweden, [3]Consulting Statistician, Sweden, [4]Geriatric Medicine, Department of Internal Medicine & Clinical Nutrition, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, [5]Geriatric Medicine, Center for Bone Research at the Sahlgrenska Academy, Sweden

Purpose: Falls are one of the most common causes of disability in older adults. Only 1 in ten falls results in serious injury. Fall risk assessment instruments predict falls but it is unknown to what extent they predict serious health outcomes such as hip fracture.

Methods: Using the Senior Alert register, we identified 128,596 older patients (82.4±7.8 years (mean±SD), 59.6 % women) who had a fall risk assessment using the Downton Fall Risk Index (DFRI) at baseline. DFRI is a composite index (0-11) of established risk factors for falls. Fractures, resulting in a hospital visit, and mortality were investigated in the Swedish patient register and cause of death register. The predictive role of DFRI was calculated using a Cox proportional hazards model with age, sex, height, weight, and prevalent osteoporotic fracture as covariates, taking time to outcome or end of study into account.

Results: During the follow up (>80,000 patient years) 6,699 patients suffered an osteoporotic fracture. Among those patients, 2,557 sustained a hip fracture. The incidence of hip fracture was three times higher in patients with a high DFRI-score (7-11) (3.2%) compared to those with a low score (0 or 1) (1.1%, $p<0.001$). DFRI independently predicted osteoporotic fracture (Hazard Ratio, HR/per DFRI-step (95% confidence intervals) 1.06 (1.05-1.17)) and hip fracture (HR 1.14 (1.11-1.16)). DFRI more strongly predicted hip fracture (HR 1.33(1.26-1.40) vs. 1.09(1.06-1.12)) in 70-year old than in 90-year old patients ($p<0.001$).

Conclusions: In conclusion, our data provide evidence that fall risk assessment using DFRI independently predicts fall-related hip fracture and other osteoporotic fractures in older men and women, indicating its clinical usefulness to identify patients who would benefit from interventions.

The Influence of Exercise on the 3D distribution of Cortical and Trabecular Bone across the Proximal Femur: The HipHop Study. Sarah Allison*[1], Kenneth Poole[2], Graham Treece[2], Andrew Gee[2], Carol Tonkin[2], Winston Rennie[3], Jonathan Folland[1], Greg Summers[4], Katherine Brooke-Wavell[5]. [1]Loughborough University, United Kingdom, [2]University of Cambridge, United Kingdom, [3]University Hospitals of Leicester, United Kingdom, [4]Derby Hospitals NHS Foundation Trust, United Kingdom, [5]Loughborough University, United Kingdom

Regular exercisers have a lower fracture risk, despite exercise having only modest effects on aBMD. This discrepancy may be explained by exercise producing localised structural changes that are not captured by aBMD. We previously demonstrated that regular, but brief, multidirectional hopping exercise increased BMC at the femoral neck in the exercise leg (EL) versus the control leg (CL) of older men (The HipHop Study). The aim of the present study was to determine the distribution of cortical mass, thickness and density changes across the entire proximal femur, using the cortical bone mapping technique.

Fifty, healthy older men had hip QCT scans taken at baseline and after one year of performing short, daily bouts of single-legged hopping exercises (x50 multidirectional hops per session on the randomly allocated leg). Cortical bone mapping identified thickness, mass and density and nearby trabecular density distributions on each femur, which was then registered to an average femur. Statistical parametric mapping was used to identify changes of these parameters over time in the exercise leg (EL) and control leg (CL), and also significant differences between legs. Results were displayed as a 3D colour map over the surface of the proximal femurs. All hip QCT scans and map analyses were blinded to the leg allocation.

Of the fifty men that participated in the study, thirty-four (age 70±4 years) exercised for 12-months, attending 92±9% of prescribed exercise sessions. Throughout the femur, cortical mass increased significantly more in the EL (+2.7%) compared to the CL (+1.6%); P=0.0019, but substantially larger changes (over 6%) were evident at localised regions of the femoral neck and shaft (Figure 1). Trabecular density also increased noticeably more in the EL (+6.4) versus CL (+4.5%); P=0.0127, with the inferior region of the femoral neck increasing by over 12% with exercise. Cortical density increased in both the EL (+1.8%, P=0.0001) and the CL (+1.6%, P=0.0013), whereas the cortical thickness changes (EL +0.5%; CL -0.2%; P=0.1358) were not statistically significant.

Our findings show that brief bouts of single-legged hopping exercises can significantly increase cortical mass and trabecular density over a relatively short time frame, at regions of the femoral neck that may be important to structural integrity. These exercise induced changes were localised rather than being evenly distributed across the proximal femur.

Effects of Vitamin D and Multimodal Exercise on Prevention of Injurious Falls in Older Women. Kirsti Uusi-Rasi*[1], Radhika Patil[2], Saija Karinkanta[2], Kari Tokola[2], Pekka Kannus[2], Christel Lamberg-Allardt[3], Harri Sievanen[2]. [1]UKK Institute for Health Promotion Research, Finland, [2]The UKK Institute for Health Promotion Research, Finland, [3]University of Helsinki, Finland

This two-year randomized (double blind for vitamin D) placebo-controlled intervention trial assessed the effects of exercise and vitamin D on the risk of falls and injurious falls in older Finnish women. 409 women aged 70 to 80 years were randomly assigned into one of the four groups: 1) 20 µg vitamin D + exercise (D^+Ex^+), 2) 20 µg vitamin D + no exercise (D^+Ex^-), 3) placebo + exercise (D^-Ex^+), and 4) placebo + no exercise (D^-Ex^-). Included participants had at least one fall during the previous year, no use of vitamin D supplements, no regular exercise at baseline, and no contraindication to exercise. Multimodal supervised exercise training was given twice a week for 12 months, and once a week for the subsequent 12 months. In addition to monthly fall diaries, functional lower limb strength (5 times chair stand), dynamic balance (6.1 m backwards walking) and mobility (normal walking speed) were assessed at 6-month intervals. Cox-regression models were used to assess hazard ratios (HZ; 95% CI) for falls and injurious falls. Generalized linear mixed models and logistic regression models were used to estimate between-group differences in physical performance using age, height, and weight as covariates.

There was no difference in the rate of all falls between groups, but compared with the reference group (D^-Ex^-), D^+Ex^+ and D^-Ex^+ groups had less injurious falls requiring medical care (0.28; 0.10 to 0.76 and 0.17; 0.05 to 0.59, respectively), while D^+Ex^- did not differ from D^-Ex^- (0.84; 0.41 to 1.71). Chair-stand time improved in both Ex groups compared to the D^-E^- group; for D^+Ex^+ (p=0.054), and more significantly for the D^-Ex^+ (p=0.027).Walking speed was maintained in the D^-Ex^+ group (p=0.007), while declined in other groups with no significant difference compared to D^-Ex^-. A combined analysis of the improvement either in time (for complete 6.1m walk) or distance (for incomplete walk) in backwards walking from baseline to the end was significantly greater in D^+Ex^+ compared to D^-Ex^- (p=0.017).

Exercise was beneficial for balance and mobility, whereas vitamin D had no effect on these physical performance traits. Exercise was also associated with reduced risk for injurious falls requiring medical care, although the rate of all falls was similar in all groups.

Use of Hypnotics and SSRI is Associated with Increased Risk of a Fall-Related Injury, Osteoporotic Fracture and Hip Fracture in Older Women and Men. Daniel Sundh*[1], Martin Nilsson[2], Joel Eriksson[3], Dan Mellstrom[4], Mattias Lorentzon[5]. [1]"institute of Medicine, Sahlgrenska Academy", Sweden, [2]Centre for Bone & Arthritis Research At the Sahlgrenska Academy, Sweden, [3]Centre for Bone & Arthritis Research, Sweden, [4]Sahlgrenska University Hospital, Sweden, [5]Geriatric Medicine, Center for Bone Research at the Sahlgrenska Academy, Sweden

BACKGROUND

The fracture risk assessment tool FRAX is used clinically to estimate 10-year risk of fracture, but only oral glucocorticoids can be entered as a risk medication. Hypnotics and selective serotonin re-uptake inhibitors (SSRI), have been linked to increased fall risk and risk of hip fracture, but whether or not this risk increase is independent of FRAX risk factors is unclear.

METHODS

Using the Senior Alert register, we identified 128,596 older patients (82.4 ± 7.8 years (mean ± SD)) with information regarding age, sex, height, weight and prevalent fall-related injury at baseline. Incident fall-related injury, osteoporotic and hip fracture as well as prevalent fracture, diseases causing secondary osteoporosis and mortality were investigated in the Swedish patient- and cause of death register. Drug dispensation data was obtained from the Swedish prescribed drug register. Use of SSRI and hypnotics was investigated in relation to prevalent fall-related injury and fracture using χ^2 test. Cox proportional hazard models were used, taking time to outcome or end of study into account. Models with fracture as outcome were adjusted for FRAX-variables (age, height, weight, sex, prevalent fracture, secondary osteoporosis, rheumatoid arthritis and glucocorticoid use) while fall-related injury was adjusted for age, height, weight, sex and prevalent fall-related injury.

RESULTS

During the follow up (>80,000 patient years) 15,220 patients suffered a fall-related injury, 6,699 an osteoporotic fracture and 2,557 a hip fracture.

Both use of hypnotics and SSRI were associated with prevalent fall-related injury and fracture (Table 1A). Both medications predicted incidence of hip fracture and osteoporotic fracture independently of other risk variables in FRAX (Table 1B). SSRI and hypnotics predicted incident fall-related injury, also after adjusting for previous falls (Table 1B).

CONCLUSIONThe results of this study demonstrate that use of both SSRI and hypnotics is associated with increased risk of both osteoporotic and hip fracture, independent of FRAX risk factors, indicating that taking also these risk medications into account could improve fracture prediction in older women and men. Furthermore, our results suggest that the observed fracture risk increase is likely to be due to increased susceptibility to falls.

Table 1. Use of SSRI and hypnotics predict hip fracture

	SSRI		Hypnotics	
A	**Yes (n=22,435)**	**No (n=106,161)**	**Yes (n=24,601)**	**No (n=103,995)**

Regulation of *Osteocalcin* expression and neuro-endocrine functions by HDAC4. Arnaud Obri*, Munevver Makinistoglu, Gerard Karsenty. Columbia University, USA

It was recently shown through genetic means that in the mouse and in humans, the bone-derived hormone osteocalcin regulates glucose metabolism and male fertility. Furthermore, in the mouse, undercarboxylated osteocalcin crosses the blood-brain barrier, binds to neurons of the hippocampus and is necessary for several cognitive functions, the most severely affected by the absence of osteocalcin being spatial learning and memory. The biological importance of the functions fulfilled by osteocalcin begs the question of the regulation of expression of this gene in osteoblasts. Since it is already known that this regulation involves transcription factors such as Runx2 and ATF4, we asked if it might also involve chromatin remodeling enzymes. Indeed, we show that the class II histone deacetylase, HDAC4 interacts tightly with the transcription factor ATF4. This interaction stabilizes ATF4, allows it to accumulate in the nucleus and enhances its ability to transactivate the *Osteocalcin* promoter. To verify the biological relevance of these molecular observations, we generated mice lacking *Hdac4* only in osteoblasts. $Hdac4_{osb}$-/- mice display low *Osteocalcin* expression, hypoinsulinemia with impaired insulin secretion, hypotestosteronemia, low sperm count, and infertility. Moreover, a Morris Water Maze test revealed a significant decrease in learning and memory in $Hdac4_{osb}$-/- mice. To verify that these functions are related to the interaction that was noted in vitro between HDAC4 and ATF4, we generated compound mutant $Hdac4_{osb}$+/-;$Atf4_{osb}$+/- mice. These $Hdac4_{osb}$+/-;$Atf4_{osb}$+/- mice also display a decrease in *Osteocalcin* expression, low circulating levels of undercarboxylated osteocalcin and hypoinsulinemia. By demonstrating that at least one chromatin remodeling enzyme affects *Osteocalcin* expression, this study identifies a second level of regulation of *Osteocalcin* expression and of its endocrine and cognitive functions.

Analysis of Osteocalcin's Cognitive Function in WT Mice and of its Signaling in Neurons. Lori Khrimian*, Stylianos Kosmidis, Eric Kandel, Gerard Karsenty. Columbia University, USA

It was recently shown that in the mouse, the bone-derived hormone osteocalcin (OCN) is necessary for several cognitive functions such as the prevention of anxiety and depression, and to an even larger extent, learning and memory. Remarkably for this set of functions, osteocalcin does not rely on Gprc6a, which is not expressed in the brain. In view of these results, this study asked two questions: Is OCN sufficient to improve cognitive functions in wild type (WT) mice; and what is the signaling pathway that it uses in hippocampal neurons? To determine if OCN is sufficient to improve cognitive functions in young adult mice, WT 2-month old mice were implanted with pumps delivering vehicle or OCN intracerebroventricularly (ICV). After one month of infusion, animals were subjected to behavioral testing. Animals receiving OCN showed a significant decrease in anxiety-like behavior. In view of these findings, we next asked if OCN could improve cognition in older mice, by delivering ICV 10 ng/hr OCN in 16-month-old WT mice, for one month. At the end of this infusion period, we assayed for memory and other hippocampal functions through the Novel Object Recognition test. Mice that received OCN demonstrated a significant improvement in memory and all hippocampal functions. These results indicate that OCN is sufficient to improve cognition in WT mice regardless of their age. In an effort to uncover the mechanisms whereby osteocalcin signals in hippocampal neurons, we asked whether it uses the same signaling molecules it has been shown to use in other target cells. This analysis showed that phospho CREB (pCREB), which is essential for optimal spatial learning and memory in rodents, is markedly decreased in the hippocampus of *Ocn*-/- as compared to WT mice. Of note, the decrease in pCREB accumulation was more pronounced in *Ocn*-/- mice born from *Ocn*-/- mothers, which is consistent with the recently described influence of maternal OCN on brain development. Conversely, an acute stereotactic injection of uncarboxylated osteocalcin directly into the hippocampus of WT animals was sufficient to dramatically increase pCREB levels, compared to the hemisphere injected with vehicle. These results suggest that the receptor of OCN in hippocampal neurons might be a GPCR, as it is peripheral tissues.

Defective Muscle-Bone Interplay Severely Impairs Bone Homeostasis in ALS Mice. Ke Zhu*[1], Jianxun Yi[2], Yajuan Xiao[2], Yumei Lai[1], Pingping Song[1], Wei Zheng[1], Hongli Jiao[1], Di Chen[1], Jingsong Zhou[2], Guozhi Xiao[1]. [1]Department of Biochemistry, Rush University Medical Center, USA, [2]Department of Molecular Biophysics & Physiology, Rush University Medical Center, USA

Skeletal muscle loading is a primary source of anabolic mechanical stimuli for bone throughout life. However, effects of muscle unloading on bone in diseases with muscle atrophy are poorly understood. Amyotrophic lateral sclerosis (ALS) is a neuromuscular disease characterized by progressive muscle atrophy. This study determined if and how the bone homeostasis is impacted in the G93A mice, a well-established ALS mouse model, before and after the onset of muscle atrophy. Results showed that four-month-old G93A mice with severe muscle atrophy displayed a dramatic reduction of bone mass compared to their sex- and age-matched wild type (WT) control mice. Bone formation was greatly impaired in G93A mice as demonstrated by defective activation of the AKT and ERK/MAPK signaling pathways in mesenchymal stromal cells, reduced formation and expansion of the osteoprogenitor population in bone marrow, and inhibited osteoblast differentiation and mineralization apposition rate in the G93A bones. In the meantime, osteoclast formation induced by M-CSF and RANKL was enhanced in G93A versus WT primary marrow monocyte cultures. In vivo osteoclast differentiation and bone

resorption were strikingly accelerated in G93A compared to WT mice. Furthermore, osteocytes embedded in the G93A bone matrix expressed elevated levels of sclerostin and RANKL proteins and reduced level of b-catenin protein. Finally, analyses of osteoblast and osteoclast parameters of 2-month-old G93A mice that did not display muscle atrophy revealed no significant impairment in bone remodeling. These results suggest that defective muscle-bone interplay in ALS mice severely impairs bone homeostasis by inhibiting bone formation and activating bone resorption.

PPARβ Deficiency Decreases Bone Formation Concomitantly to Increased Bone Marrow Fat Infiltration and Muscle Weakness. Nicolas Bonnet*[1], He Fu[2], Beatrice Desvergne[2], Serge Ferrari[3]. [1]University Geneva Hospital (HUG), Switzerland, [2]Center for integrative Genomics, Faculty of Biology & Medicine, University of Lausanne, Switzerland, [3]Geneva University Hospital & Faculty of Medicine, Switzerland

Pparß-/- mice have recently been reported to display characteristic features of muscle wasting and weakness as well as increased bone resorption and bone loss. Whether bone formation is also altered and which mechanisms couple bone and muscle deficiency in these mice however remains unclear. Body composition was evaluated in Pparß-/- and Pparß+/+ female mice from 1 to 18 months by DXA and bone forming indices and gene expression investigated by histomorphometry and qPCR at 18 month of age.

Compared to Pparß+/+, Pparß-/- had lower handgrip force and treadmill running distance, as well as decreased gastrocnemius mass, accompanied by a lower ratio of type I/II fibers and fat infiltrations. Muscle metabolic gene expression, i.e. Mip, Hif, Foxo3, was lower in Pparß-/- vs Pparß+/+, whereas Pparγ expression was increased (all $p<0.05$). Moreover, Mstn muscle expression was higher and circulating myostatin increased more with age in Pparß-/- than Pparß+/+ (+4.4 vs +2.9 fold, $p<0.05$).

From 1-to 18-months, TB lean and BMD gain were lower in Pparß-/- vs Pparß+/+ (+111.4% vs +156.2% and +58.6% vs +78.3%, respectively, $p<0.01$). At 18 months of age, Pparß-/- had lower endocortical and perioteal BFR (-44% and -100% vs PPARß+/+, $p=0.09$ & $p<0.05$, respectively) as well as significantly lower femoral BV/TV, CtTV, CtBV, and strength compared to Pparß+/+. In addition Pparß-/- accumulated more bone marrow fat with age (+217% of adipocyte volume vs Pparß+/+, $p<0.05$). Osteoblast differentiation (Runx2, Osterix, Coll1a, Ctnnb) and oxidative function (Foxo1, Hmox) were lower in Pparß-/- vs Pparß+/+. In addition, in vitro, primary osteoblast and mesenchymal stem cell from Pparß-/- bone marrow showed a lower proliferation and a higher differentiation into adipogenic lineage associated with high Pparγ and Fabp4 expression (+212% and +1032% vs Pparß+/+, $p<0.001$).

These results indicate that Pparß expression maintains muscle mass and bone formation with aging, while preventing fat infiltration in these tissues. These effects are mediated by an inhibition of myostatin and Ppar gamma expression, thereby enhancing differentiation of the osteoblastic lineage. These observations point to PPparß as a potential target to prevent the age-related decline in musculo-skeletal functions.

Targeting RANK/RANKL as a novel treatment for muscle weaknesses and dystrophic conditions. Nicolas Dumont[1], Sébastien Dufresne[1], Patrice Bouchard[1], Éliane Lavergne[1], Charles Godbout[1], Antoine Boulanger-Piette[1], Sandrine-Aurélie Kake-Guena[2], Paul C. Pape[2], Renu Sarao[3], Josef M. Penninger[3], Jérôme Frenette*[4]. [1]Université Laval, Canada, [2]Université Sherbrooke, Canada, [3]IMBA, Austria, [4]Université Laval, Can

Receptor-activator of nuclear factor kB (RANK), its ligand RANKL and the soluble decoy receptor osteoprotegerin (OPG) are the key regulators of osteoclast differentiation and bone. Although there is a strong association between osteoporosis and skeletal muscle atrophy/dysfunction, the functional relevance of a particular biological pathway that regulates synchronously bone and skeletal muscle physio-pathology is still elusive. One key determinant of muscle contractility is the Ca^{2+} pump called sarco/endoplasmic reticulum Ca^{2+} ATPase (SERCA) which transfers Ca^{2+} from the cytosol into the lumen of the SR, making Ca^{2+} available for the next contraction. Here we show that selective deletion of RANK in skeletal muscle greatly increases the activity of SERCA (> 200% increase) in fast-twitch *extensor digitorum longus* (EDL) but not slow-twitch *soleus* (SOL) muscles. The large increase in SERCA activity in denervated EDL muscle is likely to be associated with the significantly increased force production upon selective deletion of RANK in these muscles. Similarly, the inhibition of RANKL/RANK with OPG-Fc greatly increases force in muscles from dystrophic mdx mice compared to those from normal mice (233% gain in force relative to PBS-treated mdx mice) and prevents the loss of SERCA expression and activity. To understand more precisely the contribution of RANK in muscular dystrophy, we then generated a RANK/dystrophin double-deficient mouse model and showed that RANK deletion preserves muscle force, reduces significantly muscle damage and increases SERCA activity in dystrophic mice. RANK/RANKL interaction is thus a new and key actor in several models of muscle weaknesses and myopathies and its inhibition represents a new therapeutic avenue for several muscular diseases.

Sarcopenia and Increased Body Fat in Sclerostin Deficient Mice. Andrew Krause*, Toni Speacht, Peter Govey, Yue Zhang, Jennifer Steiner, Charles Lang, Henry Donahue. Penn State College of Medicine, USA

While the absence of mechanical load results in muscle and bone loss, very little is known regarding the interaction of bone and muscle during the absence of mechanical load. To address this issue we examined changes in bone and muscle in mice deficient in Sost the gene that encodes sclerostin. Previous studies have shown Sost knockout (KO) mice were resistant to unloading induced by hind limb suspension (HLS) (1) as were mice given sclerostin antibody (2). To explore possible interactions between muscle and bone during unloading, we examined the hypothesis that both bone and muscle from Sost KO mice are resistant to HLS induced atrophy.

Mice (4m male C57Bl/6J) globally deficient in Sost since birth (Sost KO), and wild type (WT) controls were exposed to HLS or maintained in control cages for 2 weeks (4 groups, n=4-9/group). Mice were subjected to baseline and endpoint μCT scans. Total body weight and quadriceps weight were recorded and per cent muscle and fat quantified by 1H-NMR.

At baseline, Sost KO mice displayed significantly greater trabecular bone volume relative to WT. Loss of trabecular bone following 2 weeks of unloading was significantly attenuated in Sost KO (Fig.1). Sost KO displayed reduced loss of trabecular BV/TV (-4% vs. -47%, $p<0.05$), trabecular thickness (-2% vs. -41%, $p<0.05$), and trabecular number (+6% vs. -15%, $p<0.05$). All mice were of similar weight at the start of study; however, Sost KO displayed significantly more adipose tissue and less lean tissue than WT mice (Fig. 2). HLS resulted in a further gain of fat and loss of muscle in Sost KO. HLS resulted in decreased quadriceps weight in WT (Figure 3). Quadricep weight was decreased in Sost KO controls relative to WT controls but did not decrease further after HLS.

These are the first studies to examine skeletal muscle in Sost KO mice exposed to unloading. While Sost KO gained bone and were resistant to unloading, they displayed dramatic sarcopenia and increased adiposity. Previous studies did not observe sarcopenia in mice given anti sclerostin antibody for three weeks nor were these mice resistant to HLS-induced muscle loss. (2). Our results suggest that long term sclerostin deficiency, while having positive effects on bone, may have deleterious effects on muscle. If confirmed, these findings should be considered when developing therapeutic protocols using sclerostin antibody.

HDAC5 Controls MEF2C-Driven Sclerostin Production by Osteocytes. Marc Wein*[1], Jordan Spatz[2], Shigeki Nishimori[1], John Doench[3], David Root[3], Daniel Brooks[4], Mary Bouxsein[5], Paola Divieti Pajevic[6], Henry Kronenberg[1]. [1]Massachusetts General Hospital, USA, [2]Harvard-MIT Division of Health Sciences & Technology (HST), USA, [3]Broad Institute, USA, [4]Beth Israel Deaconess Medical Center, USA, [5]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [6]Massachusetts General Hospital & Harvard Medical School, USA

Osteocytes secrete paracrine factors that regulate the balance between bone formation and destruction. Among these molecules, sclerostin (encoded by the gene SOST) inhibits osteoblast function, and is an osteoporosis drug target. The molecular mechanisms underlying SOST expression remain largely unexplored. To investigate mechanisms controlling sclerositn production by osteocytes, we have developed a system in which lentiviral-mediated shRNA gene silencing can be used to interrogate candidate gene function in vitro using Ocy454 cells, a novel murine osteocytic cell line. Here, we report that HDAC5 negatively regulates sclerostin levels in osteocytes, both in vitro and in vivo. HDAC5 shRNA increases, whereas HDAC5 overexpression decreases SOST expression, as assessed by RT-qPCR and ELISA in Ocy454 cells. Micro-CT shows that 8 week old female global HDAC5-/- mice have 32.4% lower trabecular BV/TV in the distal femur than WT controls. The bones of the HDAC5-/- mice show increased levels of SOST mRNA (83% increase from calvarial RNA assessed by RT-qPCR compared to wild type littermates), a greater fraction of sclerostin-positive cortical osteocytes (61.4% positive in WT mice, 85.2% positive in HDAC5-/- mice), and decreased Wnt activity (based on RT-qPCR for for AXIN2 and immunohistochemistry for non-phosphorylated beta-catenin). In Ocy454 cells, Hdac5 binds and inhibits the transcriptional activity of Mef2c, a transcription factor crucial for SOST expression, based on co-immunoprecipitation and luciferase reporter assays. HDAC5 deficiency leads to increased Mef2c association and histone 3 lysine 27 acetylation at a conserved SOST enhancer 45 kB downstream from the gene's transcription start site, as assessed by chromatin immunoprecipitation. MEF2C shRNA abrogates increased sclerostin secretion due to HDAC5 knockdown. Finally, endogenous Hdac5 associates with this same enhancer region by chromati immunoprecipitation in Ocy454 cells, suggesting direct regulation of SOST gene expression by Hdac5 in osteocytes. Taken together, these results demonstrate that HDAC5 functions in osteocytes as a negative regulator of MEF2C-driven sclerostin production. Studies are ongoing to determine the upstream signals that regulate HDAC5 function in these cells.

Ift80 balances canonical and non-canonical hedgehog signaling pathways during osteoblast differentiation and bone development. Xue Yuan*[1], Shuying Yang[2]. [1]University At Buffalo, USA, [2]State University of New York At Buffalo, USA

Increasing studies have shown that intraflagellar transport (Ift) proteins play crucial roles in bone development and remodeling. Ift80 is one of the Ift complex B proteins. Partial mutations of *Ift80* in humans cause two diseases: Jeune asphyxiating thoracic dystrophy and short rib polydactyly type III with severe bone abnormalities. Our previous *in vitro* study demonstrated that Ift80 regulates osteoblast (OB) differentiation likely through the Hedgehog (Hh) signaling pathway. We further characterized the role and mechanism by which Ift80 regulates Hh canonical and non-canonical signaling pathways, OB differentiation and bone development *in vivo*. We generated *Ift80* conditional knockout mice ($Ift80^{flox/flox}$) and specifically deleted *Ift80* in OB precursor cells (OPCs) by using the *osterix-Cre* (*Osx-cre*) transgenic line. We found that the OB-specific deletion of *Ift80* resulted in apparent growth retardation, markedly lower bone mass and longer hypertrophic cartilage. About 70% of OPCs derived from the $Ift80^{flox/flox}$/*Osx-cre* calvaria bone had either lost or shorten cilia. Compared to the $Ift80^{flox/flox}$ cells, $Ift80^{flox/flox}$/*Osx-cre* cells completely lost osteogenic capacity and had significantly less ALP activity. Deletion of *Ift80* dramatically reduced the expression of BMP2, Osx, osteocalcin and RUNX2. Ectopic expression of BMP2 or RUNX2 partially restored the osteogenic differentiation ability in $Ift80^{flox/flox}$/*Osx-cre* OPCs. Moreover, deletion of *Ift80* significantly inhibited the transcription of the Hh target genes Gli1 and Patched, and the signaling activity of Gli2, a critical transcriptional factor in Hh canonical signaling pathway; but dramatically elevated the activity of RhoA, the important downstream effector of non-canonical Hh signaling pathway. The cells with overactive RhoA had greater stress fiber density, which inhibited OB differentiation. Either the reorganization of the stress fibers with cytochalasin D or the inhibition of $G_{\alpha i}$ or phosphoinositide 3-kinase with pertussis toxin or LY294002, respectively, partially rescued the deficiency of osteogenic differentiation in $Ift80^{flox/flox}$/*Osx-cre* OPCs by blocking RhoA activation. Our results revealed a new mechanism through which Ift80 balances the Hh-Gli2 canonical and Hh-$G_{\alpha i}$-RhoA non-canonical pathways in OB differentiation using an *in vivo* genetic model. Thus, IFT80 could be a potential therapeutic target for the treatment of bone diseases.

A subset of mesenchymal stem/progenitor cells responds to stress and constitutes a major source of new osteoblasts during fracture repair *in vivo*. Dongsu Park*[1], Joel A. Spencer[2], Charles P. Lin[2], David T. Scadden[3]. [1]Baylor College of Medicine, USA, [2]Wellman Center for Photomedicine & Center for Systems Biology, Massachusetts General Hospital, USA, [3]Center for Regenerative Medicine, Massachusetts General Hospital, Harvard Stem Cell Institute, USA

The constant remodeling of the mammalian skeleton has been long hypothesized to be dependent on the presence of mesenchymal stem cells (MSCs) with unknown *in vivo* identity. Despite recent progress in uncovering *in vivo* MSC markers, such as Nestin or αSMA, the substantial heterogeneity and wide tissue distribution of these markers hamper in vivo demonstration of stem cell identity and multi-lineage potential. In particular, the physiologic locations of true MSCs and their contribution to fracture repair have not been clearly elucidated. We have previously shown that transient activation of the *myxovirus resistance-1* (*Mx1*) promoter genetically marks MSC-like cells in vivo. While they meet the current definitions of MSC *in vitro*, the $Mx1^+$ stem/progenitors exhibit osteo-lineage restricted i*n vivo*. Here, we demonstrate *in vivo* characteristics and dynamics of endogenous skeletal stem/progenitor cells (SSPCs) in bone repair. The combination of osteo-lineage cell tracing models and time-lapse intravital imaging of induced microfractures revealed the relocation of endogenous $Mx1^+$ SSPCs to fracture sites during the first few days after injury, in which critical events in the early repair process occur. Notably, sequential *in vivo* imaging of SSPCs in the fracture site of *Mx1/Nestin-GFP* or *Mx1/αSMA-GFP* dual reporter mice revealed that $Mx1^+Nestin-$ SSPCs rather than *Nestin*-GFP^+ perivascular cells are the source of new osteoblasts during fracture healing *in vivo*. Surprisingly, these $Mx1^+$ SSPCs are

αSMA-GFP positive, suggesting that the combination of *Mx1* and *αSMA* distinguish endogenous SSPCs from other mesenchymal populations in bone marrow. Our findings further define *in vivo* identification of skeletal stem/progenitor cells with physiological roles in bone remodeling and regeneration. These data indicate that a subset of MSCs is much more dynamic than other populations and is highly influenced by physiologic selection pressures.

Diacylglycerol kinase Ñ (DGKÑ) is a critical regulator of bone homeostasis by modulating c-FOS levels in osteoclasts. Ali Zamani*[1], Pamela Hesker[2], Justus Katungi[3], Roberta Faccio[4]. [1]Department of Orthopedics, Washington University, St. Louis, Missouri, USA, [2]Washington University in St Louis School of Medicine, USA, [3]Washington University in St.Louis-Orthopaedic Surgery Department, USA, [4]Washington University in St Louis School of Medicine, USA

Although PLCγ2 is a critical modulator of osteoclast (OC) development under inflammatory conditions, its high homology with PLCγ1 renders PLCγ2 specific targeting difficult. In contrast, diacylglycerol (DAG), a downstream product of PLCγ2 catalytic activity, is strictly controlled by tissue specific diacylglycerol kinases (DGKs), which convert DAG into phosphatidic acid. Since we have previously shown that DAG controls OC functions, we sought to examine the role of DGKs in bone homeostasis. DGKζ was the most highly expressed isoform in bone marrow derived macrophages (BMMs) and OCs. Strikingly, DGKζ deficiency resulted in a substantial osteoporotic bone phenotype, with sparse trabecular pattern, thinning of the cortical bone, and a marked increase in periosteal OCs. The severity of the bone phenotype was exacerbated using the serum-induced model of arthritis, which led to extensive joint osteolysis in DGKζ-/- mice compared to WT. In vitro, DGKζ-/- BMMs formed higher number and larger OCs with increased resorptive capacity, as further documented by increased expression of markers associated with differentiation, fusion, and resorption. Surprisingly, while no differences in RANKL signaling were noted, M-CSF stimulation induced a significant increase in c-FOS protein levels in DGKζ-/-cells compared to WT. Because DGKζ deficiency leads to DAG accumulation, we hypothesized that M-CSF enhanced c-FOS levels via DAG. Indeed, MCSF induced a time dependent accumulation of DAG with significantly higher levels in DGKζ-/- cells compared to WT. To demonstrate the impact of DAG on c-FOS expression, we exposed WT cells to PMA, a DAG analog, and found dose-dependent elevation of c-FOS. Furthermore, a c-FOS luciferase reporter driven by the DAG responsive element (TRE) rapidly induced c-FOS expression. Finally, to demonstrate the relevance of M-CSF/DAG/c-FOS signaling in osteoclastogenesis, we turned to PLCγ2+/- BMMs, which have reduced DAG production and fewer OCs. We hypothesized that genetic deletion of DGKζ in PLCγ2+\- mice would rescue OC formation by restoring DAG levels. Indeed, the OC defect observed in PLCγ2+/- cultures was rescued by the deletion of DGKζ. To our knowledge, this is the first report demonstrating that DGKζ is a critical regulator of bone homeostasis by controlling c-FOS levels downstream of M-CSF. Together this data demonstrates that modulation of DGKζ activity could lead to new promising therapeutic strategies for pathological bone loss.

FoxO1 inhibits bone mass accrual through its expression in neurons of the locus coeruleus. Daisuke Kajimura*, Gerard Karsenty. Columbia University, USA

Congruent lines of investigation have identified the broadly expressed transcription factor FoxO1 as a mediator of multiple physiological processes in a wide variety of organs. Moreover, biochemical studies have shown that phosphorylation of FoxO1 in response to extracellular signals prevents its nuclear translocation and therefore decreases its transcriptional activity. This aspect of FoxO1 biology is relevant to the regulation of bone mass because the hormone adiponectin triggers the phosphorylation of FoxO1 in neurons of the locus coeruleus and it is thought that this may be one mechanism whereby adiponectin inhibits sympathetic nervous system output. To determine if it is the case and to elucidate how FoxO1 might regulate the sympathetic tone we generated and analyzed mice lacking FoxO1 only in neurons of the locus coeruleus ($FoxO1_{LC-/-}$). When compared to littermate controls, $FoxO1_{LC-/-}$ mice demonstrate, at all time points analyzed, a marked decrease in the activity of the sympathetic nervous system as determined by measuring norepinephrine content in the brainstem, urinary elimination of epinephrine, and expression of *Ucp1* in brown adipose tissue. As a consequence of this decrease in the activity of the sympathetic nervous system, $FoxO1_{LC-/-}$ mice experience a high bone mass phenotype because of a decrease in bone resorption and an increase in bone formation parameters. To understand how FoxO1 could exert such a significant influence on the sympathetic regulation of bone mass we performed a gene expression survey. This analysis identified *Dbh,* a locus coeruleus-specific gene that encodes the initial and rate-limiting enzyme in the synthesis of catecholamines, as being down regulated in the $FoxO1_{LC-/-}$ mice. A molecular study showed that FoxO1 binds to and trans-activates the promoter of *Dbh*. These results uncover the first transcriptional mechanism responsible for the sympathetic regulation of bone mass and identify a novel, long range, mechanism whereby FoxO1 regulates bone mass in vivo.

Osteoporotic fracture (FX) is heritable (BMD-adjusted heritability: 35%~69% in European descent Caucasians), suggesting that genetic variants contribute to FX risk independent of BMD. Among 56 previously reported BMD associated genome-wide significant (GWAS) loci, only 6 were also genome-wide significantly associated with FX risk. Most of these GWAS SNPs are likely to be in LD with un-genotyped causal variants responsible for underlying fracture susceptibility. Thus, identifying causal variants is a necessary step to study the underlying biology of FX risk. The availability of new exome genotyping chips with 235,933 protein-coding variants (non-synonymous, splice sites and stop altering SNPs selected from ~18,000 genes) provides a feasible way to identify causal variants in the exome. We conducted an exome-chip analysis to identify novel functional coding variants that are associated with FX risk. The exome-chip was genotyped in 10 Cohort studies comprising 44,130 adult Caucasians participants (8,781 FX cases and 35,349 controls; 86% female). FX (excluding fingers, toes, skull, pathological fractures and those resulting from high trauma) phenotypes were obtained by interview and confirmed in most studies through medical record review. Since observed MAF of most genotyped variants (78%) was ≤ 1%, we performed gene-based collapsing tests (allele-count and SKAT tests) in each study to identify rare coding variants (MAF ≤ 1%) associated with FX.

Covariates adjusted in the models included age, age^2, sex, weight, height, ancestral genetic background, sub-cohorts and estrogen use. For family-based studies, a kinship matrix was incorporated into test statistics to take into account within-family correlations. An inverse-variance fixed effect meta-analysis (seqMeta package) was used to combine results from 10 studies. The most significant association was found in the *PPM1J* gene ($p=7.6x10^{-12}$). Other novel associations that achieved genome-wide significance ($p < 4.2x10^{-6}$, Bonferroni correction) were found in *WAC*, *DAZL*, *MRPS23* and *SMPDL3B* genes. We also performed single variant association analysis for variants with MAF > 1%. The most significant, novel association was found for a missense variant, SNP K450E in SLFN14 gene ($p=7x10^{-6}$). Other strong associations ($p < 5x10^{-5}$) were found for previously reported loss-of-function variants V667M and A1330V in *LRP5* and a common variant in *SLC25A13*. In summary, our analysis identified novel, rare, missense variants associated with FX. A larger exome-chip meta-analysis with an additional ~20,000 samples is underway to increase the statistical power of identifying coding functional variants.

Osteoblast-specific Overexpression of Human WNT16 Increases both Cortical and Trabecular Bone Density and Improves Bone Structure in Mice. Imranul Alam*, Mohammed Alkhouli, Rita O'Riley, Weston Wright, Dena Acton, Amie Gray, Michael Econs. Indiana University School of Medicine, USA

Previous genome-wide association studies have identified common variants in genes associated with bone mineral density (BMD) and risk of fracture. Recently, we identified SNPs in WNT16 that were associated with peak BMD in premenopausal women. To further identify the role of WNT16 in bone mass regulation, we created transgenic (TG) mice over-expressing human WNT16 in osteoblasts on B6 background using 2.3-kb rat Col1α1 promoter. We compared bone phenotypes and performed serum biochemistry analysis between TG and wild-type (WT) mice. Compared to WT mice, WNT16-TG mice exhibited significantly higher ($p<0.0001$) whole body aBMD (16-21%) and BMC (16-28%) at 6 and 12 weeks of age in both male and females. μCT analysis of trabecular bone at distal femur revealed 3-fold (male) and 14-fold (female) higher ($p<0.0001$) BV/TV, 31% (male) and 74% (female) higher Tb.N, 52% (male) and 99% (female) higher Tb.Th but 29% (male) and 46% (female) lower Tb.Sp in TG mice compared to WT littermates (Figure 1). The cortical bone at midshaft femur also showed 22% (male) and 14% (female) higher ($p<0.005$) BA/TA and 14% (male) and 8% (female) higher cortical thickness in the TG mice (Figure 1). Serum biochemistry analysis at 12 weeks of age showed that both Ca and P levels were similar between male WT and TG mice but female TG mice had 11% higher P level and male TG mice had 20% higher serum ALP and 23% higher OC compared to WT mice. In addition, 14% (male) and 22% (female) lower CTX/TRAPc5b ratio was observed in TG mice compared to WT animals, suggesting that WNT16 affects both bone formation and resorption parameters. Also, expression of ALP and OC genes were upregulated in male TG mice compared to WT littermates. Our data indicate that WNT16 is critical for positive regulation of both cortical and trabecular bone mass and structure, and that this molecule can be targeted for therapeutic interventions to treat osteoporosis or other low bone mass and high bone-fragility conditions.

Gut Microbiota Plays a Pivotal Role in the Bone Loss Induced by Sex Steroid Deficiency. Jau-Yi Li*[1], Benoit Chassaing[2], Michael Reott[1], Jonathan Adams[1], M. Neale Weitzmann[1], Andrew Gewirtz[2], Roberto Pacifici[1]. [1]Emory University School of Medicine, USA, [2]Center for Inflammation, Immunity & Infection, Georgia State University, USA

Postmenopausal osteoporosis results, in part, from the chronic inflammatory state caused by sex-steroid deficiency. One of the involved mechanisms is increased production of TNFα by activated T cells but the nature of the antigens (Ags) driving T cell activation is unknown. The intestine contains trillions of microbes known as the microbiota. The microbiota is crucial for the induction, training, and function of the host immune system, contributes to inflammatory processes, and regulates bone mass accrual. To determine the role of microbiota to the bone loss of sex-steroid deficiency, germ-free (GF) mice and mice housed in standard conditions (control mice) were treated with vehicle or Leuprolide, a GN-RH agonist that blocks sex-steroid production mimicking ovariectomy, at 375 μg/month for 10 weeks starting at 10 weeks of age. Before euthanizing, fecal DNA was subjected to quantitative PCR to confirm GF status. Attesting to successful induction of hypogonadism, Leuprolide markedly decreased the weight of the uterus and ovaries in all mice. μCT analysis at sacrifice revealed that GF mice had a higher trabecular bone volume (BV/TV), and cortical bone volume (Ct.Vo) in the distal femur and the spine, as compared to controls. Demonstrating a role for gut microbiota, Leuprolide caused a greater bone loss in control mice than in GF mice in all regions of interest. The difference in Leuprolide-induced loss of bone volume between control and GF mice was ~20 % in the spine, ~27 % in the femoral metaphysis, ~30 % in the femoral epiphysis and ~38 % in the femoral cortex. Serum levels of CTX, a marker of bone resorption, were increased ~2-fold by Leuprolide in control but not in GF mice. GF mice had a ~50 % smaller increase in bone marrow (BM) cells than control mice in response to Leuprolide. Moreover, Leuprolide increased the frequency of TNFα+CD4+ and TNFα+CD8+ T cells in the BM in control mice but not in the BM of GF mice. In summary these findings demonstrate that gut microbiota plays a significant role in inducing bone loss and increasing bone turnover in sex-steroid deficient mice by providing the Ags required for BM T cell expansion and increased TNFα production. We suggest that the composition of gut microbiota may be involved in regulating the magnitude of bone loss experienced by postmenopausal women.

Blood-circulating microRNAs are indicative of Fractures at the Femoral Neck in post-menopausal Women. Matthias Hackl*[1], Susanna Skalicky[1], Sylvia Weilner[2], Peter Dovjak[3], Peter Pietschmann[4], Johannes Grillari[2]. [1]TAmiRNA GmbH, Austria, [2]Department of Biotechnology, University of Natural Resources & Life Sciences Vienna, Austria, [3]Salzkammergut-Klinikum Bad Ischl, Gmunden, Vöcklabruck, Austria, [4]Department of Pathophysiology & Allergy Research, Medical University of Vienna, Austria

Osteoporosis is characterized by a systemic reduction in bone mass leading to increased bone fragility and consequently elevated risk of bone fractures. Several guidelines have been introduced to assist the assessment of fracture risk, such as the integration of basic clinical parameters with bone mineral density (BMD). However, individualized fracture risk assessments based on genetic analyses have not yet been implemented in the clinical praxis.

Recently, microRNAs (miRNAs) have been identified to be secreted into the bloodstream from cells of various tissues, thus, possibly indicating local pathological processes. In addition, proof exists that miRNAs play an important role in the control of homeostasis between bone anabolism and catabolism (''osteomiRs''). However, it is not well established whether imbalances in bone remodeling are also reflected in the levels of circulating miRNAs, and could therefore be utilized as non-invasive biomarkers of osteoporosis.

In this study we describe the use of miRNA qPCR arrays for quantification of 175 microRNAs in serum samples obtained from 7 patients with recent osteoporotic fractures at the femoral neck (FN), and 7 age-matched control samples (C). Differential expression analysis was performed by non-parametric analysis and p-values were adjusted for multiple testing using BH false-discovery rate. Under these conditions 6 microRNAs reached significance of adj.$p < 0.05$ (Fig. 1), of which 4 have previously been described as osteomiRs. For example, miR-133b, which is known to regulate osteogenic differentiation by repression of RUNX2 transcription factor, was found down-regulated in recently fractured patients, while miR-10a, which is targeting inhibitors of osteogenesis, was found up-regulated.

The potential use of these microRNAs as markers of osteoporotic fractures was confirmed by ROC analyses and calculation of AUC values (Fig. 2). All miRNAs were further assessed by overexpression and knockdown in an in vitro model of osteogenic differentiation using adipose tissue-derived stem cells.

Overall, these data provide first proof that circulating microRNA levels are altered in post-traumatic patients suffering from osteoporosis, and that these microRNAs might be involved in the regulation of bone metabolism. Future studies will show, whether this knowledge can be used to improve current diagnostic methodologies to predict fracture risk and treatment response in osteoporosis patients.

Wnt-Lrp5 signaling regulates fatty acid metabolism in the osteoblast. Julie Frey[1], Zhu Li[1], Jessica Ellis[1], Charles Farber[2], Susan Aja[1], Michael Wolfgang[1], Thomas Clemens[3], Ryan Riddle*[1]. [1]Johns Hopkins University School of Medicine, USA, [2]University of Virginia, USA, [3]Johns Hopkins University, USA

The interaction of Wnt ligands with frizzled receptors and the closely-related Lrp5 and Lrp6 co-receptors is critical for many aspects of osteoblast function. In this study, we identify a previously unrecognized Wnt-dependent function unique to the Lrp5 co-receptor that enables osteoblasts to oxidize fatty acids. Mice lacking the Lrp5 co-receptor specifically in osteoblasts and osteocytes exhibit the expected reductions in postnatal bone mass but also develop an increase in body fat with corresponding reductions in energy expenditure. These changes in body composition and metabolism were not the result of deviations in glucose metabolism, as random fed and fasting glucose measurements, as well as formal glucose and insulin tolerance testing, revealed normal responses in the Lrp5 mutant mice. Rather, genetic ablation of Lrp5 in bone cells was associated with increased levels of plasma triglycerides and free fatty acids, without changes in the metabolic profile of the liver, muscle, or brown adipose. These phenotypes were not observed in mice lacking the Lrp6 co-receptor in osteoblasts and osteocytes. However, the development of visceral fat was correlated with the functional activity of Lrp5 in osteoblasts, as mice engineered to express a high-bone mass mutant Lrp5 allele ($LRP5^{G171V}$) in bone are leaner than controls with reduced plasma lipid levels. In this context, Wnt-initiated signals downstream of Lrp5 regulate the expression of key enzymes required for fatty acid β-oxidation as microarray analysis of mRNA isolated from Lrp5-deficient calvarial osteoblasts and quantitative PCR analysis of samples collected from the long bones of mutant mice revealed reductions in the expression of *Acsl1, Acadl*, *Acads*, *Acadvl*, and *Cpt1b*, the rate-limiting enzyme in fatty acid oxidation. Moreover, oxidation of oleate was significantly reduced in cultures of Lrp5-deficient osteoblasts, while acute stimulation with Wnt10b or LiCl enhanced the expression of enzymatic mediators of fatty acid oxidation and the oxidation of oleate by wild-type osteoblasts *in vitro*. Together, our data suggest a direct link between bone cell metabolism and whole-body energy expenditure and that Wnt-Lrp5 signaling regulates basic cellular activities beyond those associated with fate-specification and differentiation in bone. We speculate that therapeutic approaches designed to stimulate bone formation by targeting Wnt-Lrp5 signaling may also positively influence whole-body metabolism.

The $GABA_BR1$ Modulates Skeletal Actions of Chronic Hyperparathyroidism by Controlling PTH Secretion and Ca^{2+}-responsiveness of The Parathyroid Glands. Hanson Ho[1], Jenna Hwong[1], Alfred Li[1], Christian Santa Maria[1], Zhiqiang Cheng[1], Amanda Herberger[1], Chia-Ling Tu[1], Jean-Pierre Vilardaga[2], Wenhan Chang*[1]. [1]Endocrine Research Unit, Department of Veterans Affairs Medical Center, University of California San Francisco, USA, [2]University of Pittsburgh, School of Medicine, USA

To define the mechanisms underlying the enhanced PTH secretion and the right-shifted Ca^{2+} set-point in the inhibition of PTH secretion in the primary hyperparathyroidism (HPT), we generated a mouse model (PTC-CaSR-Het) with heterozygous knockout (KO) of the calcium-sensing receptor (CaSR) gene targeted specifically to parathyroid cells (PTCs). These mice showed elevated serum Ca^{2+} (sCa) and PTH (sPTH) levels and increased body weights and produced skeletal anabolism as indicated by increases in bone size (Tb.TV), trabecular (Tb) bone mass (Tb.BV/TV), and number (Tb.N) by micro-computed tomography (μCT) (see Table below). We further found that PTCs express the type B γ-aminobutyric acid (GABA) receptor 1 ($GABA_BR1$), which is another member of family C GPCR and has strong structural homology to the CaSR. By fluorescence resonance energy transfer (FRET) and bimolecular fluorescence complementation (BiFC) technologies, we confirmed that the CaSR and $GABA_BR1$ form strong heteromeric protein complexes in HEK-293 cells transfected with the cDNAs of the fluorescent protein-tagged receptors. To test whether the $GABA_BR1$ critically mediate PTH secretion and alter Ca^{2+}-responsiveness of PTCs at basal and HPT states, we compared sCa^{2+} and sPTH levels and skeletal phenotypes among PTC-CaSR-Het mice, PTC-$GABA_BR1$-Hom mice, which have both alleles of *Gabbr1* genes deleted in PTCs, double PTC-CaSR-Het/$GABA_BR1$-Hom KO (DKO) mice, and their control (Cont) littermates. The secretory capacities and Ca^{2+} set-points of parathyroid glands (PTGs) cultured from these mice were also assessed. Interestingly, the PTC-$GABA_BR1$-Hom mice showed reduced sCa and sPTH levels and decreases in body weight, bone size (Tb.TV), Tb bone mass (Tb.BV/TV), and thickness (Tb.Th) (Table below). Furthermore, the mineral and skeletal phenotypes of PTC-CaSR-Het and PTC-$GABA_BR1$-Hom mice were mutually alleviated in the DKO mice. PTGs cultured from the PTC-CaSR-Het mice showed a profound increase in the maximal secretion (3-4 fold) and a right-shift in Ca^{2+} set-points from 1.3 to 1.5 mM vs Cont PTGs (see Figure below), but these effects were completely abrogated by concurrent ablation of the *Gabbr1* genes in the PTGs of the DKO mice. Our data support the concept that the parathyroid $GABA_BR1$ critically control mineral and skeletal homeostasis at basal and HPT states by promoting PTH secretion and by inhibiting the Ca^{2+}-responsiveness of PTCs potentially by physically interacting with the CaSR.

ERRalpha, a pro-Bone metastatic factor : Implication in metastatic Niche and prostate Cancer Stem Cells phenotype. Mathilde Bouchet[1], Anais Fradet[1], Carine Delliaux[2], Lamia Bouazza[1], Francesco Pantano[1], Xavier Leroy[3], Akeila Bellahcene[4], Vincent Castonovo[4], Philippe A.R. Clezardin[5], Martine Duterque-Coquillaud[2], Edith Bonnelye*[6]. [1]INSERM1033, France, [2]CNRS UMR8161, France, [3]Institut de Pathologie-Centre de Biologie-Pathologie, France, [4]University of Liege, Belgium, [5]INSERM & University of Lyon, France, [6]Faculte de Medecine RTH Laennec, France

Up to 80% of patients dying from prostate carcinoma have developed bone metastases that are incurable. Because we found the orphan nuclear receptor ERRa (Estrogen receptor related receptor alpha) expressed in bone metastases from prostate cancer patients, we modulated its expression in PC3 cells. We showed that human PC3 cells over-expressing wild-type ERRa (PC3-ERRa) increased rapidly and dramatically, in 3 weeks only, osteolytic bone lesions in SCID mice (n=10) (1,20 ± 0,34* for osteolysis (mm2) and 18,5 ± 5,4** for skeletal tumor burden (TB/STV)(%)) compared to that observed with PC3-CT cells (0,49 ± 0,22 (osteolysis) and 2 ± 0,73 (TB/STV)). Surprisingly bone destruction was combined with new bone formation, as 70% of the metastatic limbs that were bearing PC3-ERRa cells had mixed lesions compared with CT-PC3 that only developed osteolytic lesions. Osteoclasts were directly affected in vivo and in vitro which was associated with the stimulation of pro-osteoclastic factors mRNA of Cox2, MMP1, RANK, and Cathepsin K by PC3-ERRa. On the other hand, a statistical stimulation of bone formation in calvaria culture and in MC3T3 was observed when cells were co-cultured with PC3-ERRa compared to PC3-CT. That was combined with the up-regulation of ET1, Wnt3a and Wnt5a mRNA and protein by PC3-ERRa which may explain the occurrence of bone formation in the skeletal lesions. Interestingly, tumoral microenvironment was also affected by PC3-ERRa cells, as mouse periostin (POSTN), was over-expressed by the cancer-associated-fibroblasts in vivo which was probably due to the fact that TGFb2 was stimulated in PC3-ERRa cells in vitro and in vivo. Moreover, we found that over-expressing ERRa in PC3 inhibits spheres formation (in presence or absence of POSTN) which was associated with a decrease in the enforcers of the stem cell phenotype and pluripotency Nanog and Oct4 expression in vivo. Finally we showed that elevated expression of ERRa mRNA in prostate carcinoma (cohort of 60 patients) is also associated with high level of ET1, Cox2, POSTN and Wnt5a. In conclusion, our data provided for the first time evidence that ERRa can promote both osteolysis and osteosclerosis in animal models of prostate cancer bone metastases via the stimulation of pro-osteoclastic and pro-osteoblastic factors. These data also suggest an implication of ERRa in the stromal niche via the TGFb2/POSTN/Wnt signaling and in the inhibition of the self-renewal capacity and pluripotency of tumor cells.

WNT5A Inhibits Skeletal Metastases of Prostate Cancer in Mice and Is Associated with a Longer Patient Survival. Stefanie Thiele*[1], Andy Göbel[2], Sandra Hippauf[2], Tilman D. Rachner[2], Michael Muders[2], Susanne Fuessel[2], Ricardo Bernhardt[3], Franz Jakob[4], Martina Rauner[5], Lorenz Hofbauer[6]. [1]Germany, [2]Uniklinikum Dresden, Germany, [3]Technische Universität Dresden, Germany, [4]University of Würzburg, Germany, [5]Medical Faculty of the TU Dresden, Germany, [6]Dresden University Medical Center, Germany

Prostate cancer is the most common cancer type in elderly men and often metastasizes to bone in advanced stages. Early detection could therefore help to prevent cancer progression and skeletal metastases. Thus, it is important to find prognostic markers that predict the aggressiveness of prostate cancer. Wnt proteins are implicated in carcinogenesis and especially WNT5A has been discussed to influence the clinical outcome of various cancer types, including prostate cancer. In addition, WNT5A stimulates osteogenic differentiation. Hence, WNT5A may not only be involved in prostate cancer development, but also in the formation of subsequent skeletal metastases. Here, we determined the role of the WNT5A expression profile in prostate cancer *in vitro* and *in vivo*.

A tissue microarray was created using a cohort of 397 mainly high-risk prostate cancer patients who underwent radical prostatectomy, and was stained for WNT5A. Effects of WNT5A knock-down or overexpression on proliferation and apoptosis of prostate cancer cell lines (PC3, C42B, MDA-PCa-2b) were examined *in vitro*. *In vivo,* WNT5A was overexpressed in luciferase-labeled PC3 cells (PC3-Luc) which generate osteolytic lesions. To determine the impact of WNT5A on tumor growth PC3-Luc cells were injected subcutaneously, intratibially or intracardially into nude mice.

Expression of WNT5A was higher in prostate cancer patients as compared to patients with benign prostatic hyperplasia ($p<0.05$). Patients with high WNT5A levels had a higher probability for a longer survival than those with low WNT5A expression ($p=0.025$). *In vitro*, WNT5A overexpression in PC3 cells reduced proliferation by 39%, and simultaneously induced apoptosis 2-fold (as determined by caspase 3/7 activation, annexin V/PI-positive cells, PARP cleavage, and DNA fragmentation). Knock-down of WNT5A yielded opposite results. Similar effects were seen in C42B and MDA-PCa-2b. *In vivo,* subcutaneous tumor growth and tumor growth within the bone microenvironment was inhibited in nude mice injected with WNT5A-overexpressing PC3-Luc cells compared to mice injected with PC3-Luc cells (-90% and -85%, $p<0.05$). Moreover, while 80% of the mice receiving PC3-Luc cells developed bone metastases and bone lesions, overexpression of WNT5A abolished this process.

These data indicate that WNT5A exhibits anti-tumor effects in prostate cancer and may be suitable as a prognostic marker and novel therapeutic target for prostate cancer and associated skeletal metastases.

Modeling osteogenic sarcoma: insight into tumor initiation and progression. Jianning Tao*, Brendan Lee. Baylor College of Medicine, USA

Osteogenic sarcoma (OS) is the most common malignant tumor of bone with a predilection for adolescents and young adults. Human OS occurs sporadically and bone tumor initiation and progression are poorly understood. We describe here the generation of characterization of a genetically engineered mouse model of OS based on conditional expression of truncated Notch1 protein. All animals spontaneously developed bone tumors including OS-like with 100% penetrance. The tumors, developed through Rbpj-dependent canonical pathway, model human OS including morphology, metastatic behavior, cytogenetic complexity, and genome-wide expression profiling. We demonstrated that Notch activation combined with p53 loss synergistically accelerates OS development in mice, though p53 driven OS is not dependent on canonical Notch signaling, revealing a dual dominance of Notch oncogene and p53 mutation in the development of OS. Because of similarity between murine OS and human OS, our authenticated model can be used not only to address cancer mechanisms of OS but also as a valuable platform for developing novel therapeutic strategies.

Runx2 Phosphorylation Increases Migration and Invasive Activity of Prostate Cancer Cells and is Associated with Metastatic Disease. Chunxi Ge*[1], Guisheng Zhao[2], Xiang Zhao[2], Yan Li[3], Hui Li[3], Binbin Li[5], Giuseppe Pannone[4], Pantaleo Bufo[4], Angela Santoro[4], Francesca Sanguedolce[4], Simona Tortorella[4], Marilena Mattoni[4], Silvana Papagerakis[5], Evan Keller[3], Renny Franceschi[3]. [1]Pom Univ of Michigan School of Dentistry, USA, [2]University of Michigan School of Dentistry, USA, [3]University of Michigan, USA, [4]University of Foggia, Italy, [5]University of Michigan School of Medicine, USA

The osteogenic transcription factor, Runx2, is abnormally expressed in prostate cancer where it stimulates expression of several metastasis-associated genes. During normal bone development, Runx2 transcriptional activity is activated by signals known to be hyperactive in prostate cancer including the ERK/MAP kinase pathway, which phosphorylates Runx2 at Ser 301 and Ser 319. This study examines the role of these phosphorylation sites in Runx2-dependent activation of metastasis-associated gene expression, *in vitro* migration and invasive activity of prostate cell lines as well as the relationship between Runx2 phosphorylation and tumor stage. Runx2 was preferentially expressed in more invasive prostate cancer cell lines (PC-3> C4-2B > LNCaP). Furthermore, the ratio of Runx2-S319-P/total Runx2 as well as P-ERK/total ERK was greater in PC-3 and C4-2B versus LNCaP cells. Phosphorylated Runx2 had an exclusively nuclear localization and was enriched in PC3 cultures while total Runx2 had a cytoplasmic and nuclear distribution. Overexpression of wild type Runx2 increased *Mmp9*, *Vegfa* and *Spp-1* mRNA and increased *in vitro* migratory and invasive activity in PC-3 cells as well as the non-tumorigenic prostate cell line, RWPE1. In contrast, a phosphorylation-deficient Runx2 mutant (Runx2-S301A,S319A) had greatly reduced activity. Analysis of tissue microarrays from 129 patients revealed strong nuclear staining with a Runx2-S319-P-specific antibody in primary prostate cancers and metastases. P-Runx2 staining was positively correlated with Gleason score and occurrence of lymph node metastases. Little or no Runx2 phosphorylation was detected in normal prostate tissue, benign prostate hyperplasia or prostatitis indicating that Runx2 phosphorylation is closely associated with prostate cancer induction and progression towards an aggressive phenotype.

Micro-RNA-mediated Targeting of Runx2 Reduces Breast Cancer Metastasis and Progression of Osteolytic Disease. Hanna Taipaleenmaki*[1], Gillian Browne[2], Jacqueline Akech[3], Andre Van Wijnen[4], Janet Stein[5], Eric Hesse[6], Gary Stein[7], Jane Lian[8]. [1]University Medica Center Hamburg-Eppendorf, Germany, [2]Department of Biochemistry & Vermont Cancer Center, University of Vermont College of Medicine, USA, [3]University of Massachusetts Medical School, USA, [4]Mayo Clinic, USA, [5]Vermont Cancer Center, University of Vermont College of Medicine, USA, [6]University Medical Center Hamburg-Eppendorf, Deu, [7]University of Vermont, College of Medicine, USA, [8]University of Vermont College of Medicine, USA

Progression of breast cancer to metastatic bone disease is associated with an aberrantly elevated expression of Runx2, which promotes the disease progression by activating many genes involved in the 'vicious cycle' of cancer-induced bone disease. Because transcription factors are not readily targetable for therapeutic intervention, our goal was to evaluate the potential clinical use of Runx2-targeting miRNAs to reduce tumor growth and bone metastatic burden. Expression analysis of a panel of miRNAs regulating Runx2 revealed a reciprocal relationship between the abundance of Runx2 protein and two miRNAs, miR-135 and miR-203. These miRNAs are highly expressed in normal breast epithelial cells where Runx2 is not detected, and conversely are absent in metastatic breast cancer cell lines and tissue biopsies that express Runx2. Reconstituting metastatic MDA-MB-231-Luc cells with miR-135 and miR-203 reduced the abundance of Runx2 and the expression of the metastasis-promoting Runx2 target genes IL-11, MMP-13, and PTHrP. Additionally, tumor cell viability decreased and cell migration was suppressed *in vitro*. *In vivo* implantation of MDA-MB-231-luc cells expressing miR-135 or miR-203 into the mammary gland, followed by additional intratumoral administration of the synthetic miRNAs reduced tumor growth and importantly, spontaneous metastasis to bone. Furthermore, intratibial injection of these miRNA-expressing cells impaired tumor growth in the bone environment, inhibited bone resorption and secondary metastasis to lung. We conclude that miRNAs targeting Runx2 are protective against metastasis, while deregulated expression of Runx2 in aggressive tumor cells is related to the loss of specific Runx2-targeting miRNAs. Our studies have also demonstrated for the first time that delivery of synthetic miRNAs is a viable therapeutic strategy to target transcription factors for the prevention of metastatic bone disease.

Intravital 2-photon imaging reveals tumour-associated macrophages as the cellular targets underlying the anti-tumour activity of bisphosphonates in vivo. Michael J Rogers*[1], Simon Junankar[1], Charles E McKenna[2], Shuting Sun[2], Tri Giang Phan[1]. [1]Garvan Institute of Medical Research, Australia, [2]University of Southern California, USA

Bisphosphonate (BP) drugs target rapidly to the skeleton and are the gold standard treatment to inhibit osteoclastic bone resorption in patients with metastatic bone disease. BPs also decrease tumour growth and metastasis outside the skeleton in mouse tumour models. In recent clinical trials, adjuvant treatment with zoledronic acid alongside standard therapy also increased disease-free survival, and reduced local tumour recurrence and soft tissue metastases in estrogen-deficient women with early breast cancer. However, the exact mechanisms underlying these anti-tumour effects of BPs are not known since BPs are generally considered to have little, if any, effect on cells in soft tissues outside the skeleton other than a transient effect on circulating monocytes. To finally answer this question we determined the cell types capable of internalising fluorescently-labelled BP in 4T1 mammary tumours in live mice. Within minutes of tail vein injection, intravital 2-photon imaging revealed the flow of BP into mammary tumours via the disorganised tumour vasculature. BP then diffused into mammary tumour tissue from leaky vessels and bound to microcalcifications that were rapidly engulfed by $F4/80^+$ tumour-associated macrophages. Intravital imaging of individual macrophages in tumours of live mice also revealed the uptake of BP by pinocytosis. Flow cytometric analysis of the mammary tumours 24 hours after iv injection of BP confirmed that cellular uptake of BP occurred predominantly by $CD11b^+F4/80^+$ macrophages, but not by tumour cells or $CD11b^+F4/80^-$ tumour-infiltrating leukocytes. BP did not accumulate in normal mammary tissue. These studies provide conclusive evidence that, under certain circumstances, BPs can be rapidly internalised by tumour-associated macrophages outside the skeleton. The disorganised and leaky vasculature of tumours facilitates the local diffusion of BP and uptake by macrophages, enhanced by the presence of microcalcifications. Given the important role of macrophages in promoting tumour progression and metastasis, our studies strongly suggest that the anti-tumour activity of BPs in vivo occurs via effects on tumour-associated macrophages rather than by direct effects on tumour cells.

Reduced Cortical Bone Mass in Mice with B Lymphocyte-Specific Androgen Receptor Inactivation. Jianyao Wu*[1], Anna Borjesson[2], Anna Wilhelmson[3], Åsa Tivesten[3], Sofia Moverare Skrtic[4], Claes Ohlsson[4]. [1]Sahlgrenska Academy, University of Gothenburg, Sweden, [2]Center for Bone & Arthritis Research, Sahlgrenska Academy, Sweden, [3]Wallenberg Laboratory for Cardiovascular & Metabolic Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, [4]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden

Sex steroids are chief regulators of gender differences in the skeleton, and male gender is one of the strongest protective factors against osteoporotic fractures. Male mouse models with general inactivation of the androgen receptor (AR) have reduced trabecular and cortical bone mass. Recent studies using cell-specific inactivation of the AR demonstrate that testosterone acting via the AR in osteoblast-lineage cells increases the trabecular bone mass. However, the AR expressing cell type mediating the effects of androgens on cortical bone is unknown. The immune system is a crucial regulator of bone homeostasis and it has been proposed that B and T lymphocytes are involved in the bone-sparing effect of sex steroids. We hypothesized that the AR in immune cells might mediate the effects of androgens on cortical bone mass. The aim of the present study was, therefore, to determine the possible role of the AR in B and T lymphocytes for cortical bone homeostasis using mouse models with cell-specific inactivation of the AR.

To assess the role of the AR in T lymphocytes, we generated T cell-specific male AR^- mice (using LCK-Cre). However, these mice had unchanged cortical bone parameters (cortical thickness, area and volumetric bone mineral density) as analyzed by μCT in the mid-diaphyseal region of femur. To determine the role of the AR in B lymphocytes, we generated B cell-specific male AR^- mice (using CD19-Cre, deleting the AR from the pre-B cell stage). Importantly, the B cell-specific AR^- mice displayed significantly reduced cortical bone area ($-13\pm3\%$, $p<0.01$) and thickness ($-9\pm2\%$, $p<0.01$) compared with control mice. The reduced cortical thickness was mainly caused by reduced periosteal circumference. To validate these findings, we developed a second mouse model with B cell-specific inactivation of the AR using Mb1-Cre mice (deleting AR from the pro-B cell stage). These mice also had reduced cortical bone area ($-10\pm3\%$, $p<0.05$) and thickness ($-8\pm2\%$, $p<0.01$) compared with control mice. In contrast, osteoblast-specific inactivation of the AR (using Osx1-Cre) did not affect the cortical bone parameters in male mice, confirming the results from previous osteoblast-specific mouse models.

In conclusion, we demonstrate that B cell-specific AR inactivation results in reduced cortical bone mass. Based on these findings, we propose that the AR in B lymphocytes may, at least partly, mediate the stimulatory effects of androgens on cortical bone mass.

T cell expression of CD40L potentiates the bone anabolic activity of PTH by promoting osteoblastogenesis and bone formation. Jerid Robinson*[1], Jau-Yi Li[2], Abdul Malik[2], Michael Reott[3], Lindsey Walker[1], Jonathan Adams[1], M. Neale Weitzmann[2], Roberto Pacifici[2]. [1]Emory University, USA, [2]Emory University School of Medicine, USA, [3]Emory University School of Medicine, USA

T cells are required for intermittent parathyroid hormone (iPTH) treatment to increase bone volume and strength. One of the involved mechanisms is increased production of the osteogenic Wnt ligand Wnt10b by bone marrow T cells. However, additional mechanisms might play a role. T cells provide proliferative and survival cues to SCs through CD40L, a surface molecule of activated T cells that induces CD40 signaling in SCs. Thus a cross-talk between T cells and SCs mediated by the CD40L contributes to maintain an adequate pool of osteoblastic cells. To investigate the role of CD40L in the anabolic activity of iPTH 6 week old WT and CD40L-/- mice were injected daily with vehicle or iPTH (80μg/kg/day) for 4 weeks. Femurs and spines were then harvested and analyzed by μCT scanning. iPTH induced a lower increase in bone volume (BV/TV) in CD40L-/- mice as compared to WT controls in both regions. Indices of bone structures were also improved less potently by iPTH in CD40L-/-mice than in WT mice. iPTH had similar effects in cortical bone in WT and CD40L mice, consistent with the fact that T cells potentiate the trabecular but not the cortical anabolic effects of iPTH. Mechanistic studies revealed that iPTH increased bone formation more potently in WT than in CD40L -/- mice. Moreover, iPTH increased the number of SCs, stimulated SC proliferation and differentiation, and blocked SC apoptosis in WT mice but not in CD40L-/- mice. To investigate the specific role of T cell expressed CD40L, T cell deficient TCRβ-/- mice were subjected to adoptive transfer of WT T cells and CD40L -/- T cells. Reconstituted mice were then treated with vehicle or iPTH for 4 weeks. We found that iPTH induced a significant increase in BV/TV, indices of bone structure, and bone formation in TCRβ-/- mice reconstituted with WT T cells. By contrast iPTH did not exert a significant anabolic activity in T cell deficient mice and mice with T cells lacking CD40L expression. In conclusion, our data show that T cell expressed CD40L potentiates the bone anabolic activity of iPTH. Activation of CD40 signaling in SCs by T cell expressed CD40L is required for iPTH to increase SC proliferation, differentiation and lifespan.

Continuous PTH Treatment Induces Bone Loss through T Cells Produced IL17. Jau-Yi Li*[1], Lindsey Walker[2], Abdul Malik[1], Michael Reott[3], Jonathan Adams[4], M. Neale Weitzmann[1], Roberto Pacifici[1]. [1]Emory University School of Medicine, USA, [2]Emory University, USA, [3]Emory University School of Medicine, USA, [4]Emory University School of Medicine, USA

Hyperparathyroidism in humans and continuous PTH treatment (cPTH) in mice stimulate bone resorption and cause bone loss by regulating RANKL/OPG production by stromal cells (SCs) and osteoblasts. Reports have shown that T cells markedly potentiate the bone catabolic effect of cPTH by inducing CD40 signaling in SCs through their surface receptor CD40L. In addition, cPTH stimulate T cells to secrete the osteoclastogenic cytokine TNF, a factor that potentiates the osteoclastogenic activity of RANKL. A search for additional mechanisms by which T cells potentiate cPTH induced bone loss revealed that in vivo cPTH treatment for 2 weeks increased by ~2-3 fold the frequency of Th17 cells in the BM. Th17 are a highly osteoclastogenic population of CD4+ cells defined by the capacity to produce IL-17, a potent inducer of RANKL and TNF production. To investigate the mechanism by which cPTH expands Th17 cells we assessed Th17 cell differentiation, proliferation and homing. We found that cPTH increased the differentiation of naïve CD4+ cells into Th17 cells. However, cPTH did not regulate Th17 proliferation and homing. Th17 cell differentiation is induced by several cytokines including TGFβ, IL-6 and TNF. All of these factors are upregulated by cPTH. We found that cPTH increased the relative frequency of Th17 cells in the BM in WT mice, but not in TNF-/- mice. Moreover, cPTH increased IL-17A mRNA levels and the expression of the Th17-inducing transcription factors RORα and RORt in BM CD4+ T cells in WT but not in TNF-/- mice. These findings reveal that cPTH expands Th17 cells through TNF. To investigate the contribution of Th17 cells to cPTH induced bone loss, mice were treated with cPTH and either Irr. Antibody (Ab) or anti IL-17 Ab for 2 weeks. IL-17 Ab completely blocked the loss of trabecular and cortical bone (as measured by μCT), and the increase in bone resorption (as measured by histomorphometry and serum CTX). By contrast, treatment with Irr Ig did not antagonize the bone catabolic effects of cPTH. Furthermore, IL-17 Ab completely blocked the increase in SC production of TNFα and RANKL induced by cPTH, demonstrating that cPTH stimulates SC osteoclastogenic function through T cell produced IL17. In summary, these findings demonstrate that cPTH polarizes the differentiation of CD4+ cells toward the Th17 subset via TNF, and that cPTH induces bone loss through IL-17. Neutralization of IL-17 may thus represent a novel therapeutic strategy for hyperparathyroidism.

Tmem178 modulates bone homeostasis via a novel negative feedback loop targeting endoplasmic reticulum Ca^{2+} mobilization in osteoclasts. Corinne Decker*[1], Deborah Novack[2], Roberta Faccio[2]. [1]Washington University in St. Louis, USA, [2]Washington University in St. Louis School of Medicine, USA

PLCγ2 catalytic activity triggers Ca^{2+} fluxes leading to robust activation of NFATc1, the central transcription factor of osteoclastogenesis (OCG). Despite PLCγ2's essential role in promoting OC formation, its therapeutic targeting is impeded by high homology with the ubiquitously expressed PLCγ1. To identify specific mediators downstream of PLCγ2, we performed a gene array comparing WT and PLCγ2-/- OC precursors. Transmembrane protein 178 (Tmem178), an uncharacterized integral membrane protein, is a novel PLCγ2-dependent gene that is upregulated by RANKL in WT cells. In striking contrast to the osteopetrotic phenotype of PLCγ2-/- mice, Tmem178 deficiency leads to a significant 35% decrease in trabecular bone accompanied by enhanced OC numbers (KO 25.7+/-4.4, WT 12.5+/- 1.9). Tmem178-/- OC precursors are more sensitive to RANKL in vitro as shown by rapid induction of TRAP, DC-STAMP, and calcitonin receptor, suggesting that Tmem178 acts in a negative feedback loop downstream of RANKL-PLCγ2. As the addition of LPS or TNF to Tmem178-/- preOCs further exacerbates OCG, we tested Tmem178's role in restraining pathological bone loss using 2 models of inflammatory osteolysis: supracalvarial LPS and serum-transfer arthritis. In both conditions Tmem178 null mice suffer profound bone loss due to significant increase in OCs compared to WT mice. Thus, Tmem178 regulates OCG and bone mass in basal and pathological states. Increased OC numbers and responsiveness to RANKL are often associated with augmented NF-kB and MAPK activation. Remarkably, we found no changes in these pathways in Tmem178-/- preOC. Nevertheless, NFATc1 total protein levels and nuclear translocation are strikingly amplified in Tmem178-/- cells. To determine how Tmem178 controls NFATc1 levels we measured cytosolic Ca^{2+} in preOCs stimulated with RANKL and found a higher immediate spike and sustained increase in $[Ca^{2+}]$ in null cells compared to WT. By immunofluorescence and co-immunoprecipitation, we detected Tmem178 in the endoplasmic reticulum (ER) where it interacts with Stim1, a known regulator of Ca^{2+} mobilization during OCG. Importantly, ectopic Tmem178 suppresses thapsigargin-induced ER Ca^{2+} release and likewise dampens RANKL-stimulated NFATc1 and OCG. These findings suggest that Tmem178 is a previously unknown fine-tune regulator of ER Ca^{2+} stores. In sum, we define Tmem178 as a critical mediator of bone homeostasis via a novel negative feedback loop targeting the RANKL-Ca^{2+}-NFATc1 axis.

Inflammation-Induced Hypercytokinemia and Myeloproliferation Underlie Osteopenia in Scurfy Mice; the Animal Model For Heritable Autoimmune Disease IPEX. Yousef Abu-Amer[1], Tim Hung-Po Chen*[2], Gaurav Swarnkar[2], Gabriel Mbalaviele[1]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University School of Medicine, USA

Immune surveillance through regulatory T cells (Tregs) plays a crucial role in bone homeostasis. The development and function of Tregs requires the Foxp3 gene product. The mouse model of autoimmune disease IPEX (Immune dysregulation, Polyendocrinopathy, Enteropathy, X-linked) syndrome, namely *Scurfy* (*Sf*), bears a loss-of-function mutation in *Foxp3*. Both IPEX and Sf result in multi-organ inflammation. Herein, we report that *Sf* mice exhibit severe bone loss mediated by accelerated osteoclastogenesis (OCG). Biochemical studies suggest that Foxp3 deficiency results in upregulation of NEMO/IKKg gene in T helper cells through loss of Foxp3/NEMO interaction, thereby trigging NF-kB mediated over-production of pro-OCG cytokines (e.g. M-CSF, RANKL, IL-17 and TNF). In this study, we use molecular, cellular and pharmacological approaches to study how loss of Foxp3 prompts osteolysis. Using hematopoietic stem cell flow analysis of bone marrow cells (BMC), we observed a 2.5x increase of $lin^{-}Sca\text{-}1^{+}c\text{-}kit^{+}$ hematopoietic stem cells (LSK HSCs) and 2x increase for granulocyte/macrophage progenitors (GMPs) in *Sf* relative to WT BMC. Interestingly, using *ex vivo* OCG assay, fluorescence-activated cell sorted LSK HSCs derived from *Sf* BMC exhibited significantly increased (5x) OCgenic potential than GMPs, implying that inflammatory condition in *Sf* mice affects osteoclast progenitors at very primitive stage. *Sf* LSK HSCs exhibited greater sensitivity to M-CSF signaling and contained 5x more PU.1+ *Sf* LSK HSCs than WT. *In vivo* administration of M-CSF neutralizing antibody (Ab) as well as crossing *Sf* hemizygous female with *Op* heterozygous male (half reduction of systemic M-CSF level) attenuated but not entirely reversed osteopenia in *Sf* and OCG *ex vivo* . Contrarily, *in vivo* administration of IL-17 neutralizing Ab or RORg inhibitor failed to reverse osteopenia, questioning the importance of IL-17 for autoimmune osteopenia in the context of Treg deficiency. Intriguingly, the immunosuppressive mTOR inhibitors, rapamycin and pp242, also had similar effect as the M-CSF Ab. Mechanistically, M-CSF antibody, M-CSF genetic ablation, rapamycin and pp224 all reduced GMP frequency in *Sf* BM, suggesting that they act either directly or indirectly at the HSC level. Taken together, our study suggests that Foxp3 deficiency leads to osteopenia owing to dysregulation of NF-kB and subsequent cytokine-mediated hyperproliferation of myeloid precursors and presents a target for therapeutic intervention.

PARP1 is a Potent Negative Regulator of Bone Resorption. Chao Qu*[1], Samer Abu-Amer[2], Susan Grimston[3], Sheri Bonar[4], Jacqueline Kading[2], Gaurav Swarnkar[5], Monika Fey[5], Michael Hottiger[5], Yousef Abu-Amer[3], Roberto Civitelli[3], Gabriel Mbalaviele[3]. [1]Washington University in St Louis, USA, [2]Washington University School of Medicine, USA, [3]Washington University in St. Louis School of Medicine, USA, [4]Washington University in St. Louis, USA, [5]University of Zurich, Switzerland

Accumulating evidence indicates that poly(ADP-ribose) polymerase 1 (PARP1) regulates non-apoptotic functions, including transcriptional regulation. Evidence also shows that PARP1 undergoes various post-translational modifications, including caspase-mediated proteolytic cleavage at aspartate 214 ($PARP1^{D214}$ site). To investigate PARP1 role in skeletal homeostasis, we characterized knock-in mice globally expressing non-cleavable PARP1 ($PARP1^{D214N/D214N}$ mice). Although $PARP1^{D214N/D214N}$ mice are grossly normal and fertile, bone volume/total volume (BV/TV) measured by μCT is significantly higher in 8 weeks old mutant mice compared to wild-type (WT) mice (0.35 ± 0.02 vs. 0.24 ± 0.03, $p<0.005$). Bones are also stiffer in mutant mice relative to WT mice (65.83 ± 16.17 N/mm vs. 42.51 ± 12.32 N/mm, $p<0.05$). To gain insights into the cellular mechanisms underlying this phenotype, we studied RANKL- and M-CSF-induced osteoclast (OC) differentiation of mouse bone marrow macrophages (BMMs). Intriguingly, a single allele of non-cleavable PARP1 ($PARP1^{+/D214N}$) is sufficient to suppress OC differentiation by >90%, and $PARP1^{D214N/D214N}$ arrests this process. During OC formation, PARP1, but not $PARP1^{D214N}$, is fully degraded, suggesting that this protein negatively regulates OC formation. To further test this hypothesis, we leveraged the fact that activation of NOD-like receptor (NLR) family, pyrin containing 3 (NLRP3) inflammasome targets PARP1 for cleavage at $PARP1^{D214}$ site. We find that activation of the NLRP3 inflammasome promotes the cleavage of WT, but not $PARP1^{D214N}$; genetic or pharmacological inhibition of the NLRP3 inflammasome not only prevents PARP1 cleavage, but also inhibits of OC formation. Conversely, mice expressing constitutively activated NLRP3 (CA-NLRP3) inflammasome in myeloid cells, exhibit increased OC formation in vivo and decreased BV/TV compared to WT mice (0.24 ± 0.04 vs 0.12 ± 0.02, $p<0.05$). Furthermore, we find that PARP1 is barely detectable in BMMs expressing CA-NLRP3 inflammasome compared to WT cells. In summary, we find that PARP1 negatively regulates OC development, and its stability and abundance are at least in part controlled by the NLRP3 inflammasome during

osteoclastogenesis. Thus, we have uncovered a novel function of PARP1 in bone homeostasis.

Bisphosphonate Drug Holiday and Fracture Risk. Annette Adams*[1], John Adams[2], Marsha Raebel[3], Beth Tang[2], Jennifer Kuntz[4], Vinutha Vijayadeva[5], Elizabeth McGlynn[2], Wendolyn Gozansky[3]. [1]Kaiser Permanente Southern California, USA, [2]Kaiser Permanente Center for Effectiveness & Safety Research, USA, [3]Kaiser Permanente Colorado, USA, [4]Kaiser Permanente Northwest, USA, [5]Kaiser Permanente Hawaii, USA

Purpose: Among women with ⩾3 years exposure to bisphosphonates (BPs), we compared the incidence of osteoporosis-related fragility fractures in those who discontinued BPs for at least 12 months (drug holiday) to those who continued to use BPs (persistent use).

Methods: This retrospective cohort study included women aged ⩾45 years from 4 Kaiser Permanente (KP) regions who initiated BP use between January 1, 1998 and December 31, 2009. Drug holiday was defined as ⩾12 months with BP use at 0% adherence. Persistent use status required ongoing use at ⩾50% adherence. The primary outcome of interest was the first occurrence of an incident clinical osteoporosis-related fragility fracture, identified from the electronic medical record (EMR) via ICD-9-CM codes. All subjects were followed until fracture, disenrollment from the health plan, death, or December 31, 2012. From the EMR, we collected information on the following potential confounders and effect modifiers: race/ethnicity; age; body mass index (BMI); comorbidities; history of previous fragility fracture; lowest T-score prior to cohort entry; fall risk; ten-year fracture risk; and prior/concomitant use of bone-active medications. Persistent users and drug holiday subjects were compared with regard to several demographic and clinical characteristics. Time-varying Cox proportional hazards models were used to compare osteoporosis-related fracture incidence between the two groups.

Results: The cohort of 28620 women, observed for 111997 person-years, included 17123 (59.8%) persistent BP users and 11497 (40.2%) drug holiday subjects. The drug holiday group had: fewer comorbidities, higher baseline T-scores, and lower fracture and fall risk scores. A total 3,571 osteoporosis-related fractures were observed. The unadjusted rate ratio (RR) for any osteoporosis-related fractures for drug holiday compared to persistent use was 0.87 (95% CI 0.81-0.94), but RR=1.0 (95% CI 0.9-1.2) for hip fractures only. The time-varying models suggested no differences in fracture risk (hazard ratio (HR) 0.90, 95% CI 0.80–1.00), after adjustment for baseline fall and fracture risk, comorbidities, and other bone-active medication use. Similarly, no difference in hip fracture risk was observed (HR 0.84, 95% CI 0.68–1.03).

Conclusion: Women who undertake a holiday from BP use are not at greater risk of osteoporosis-related fragility fractures, nor hip fractures specifically, than are women who continue to use BPs persistently.

Effects of Two Years of Teriparatide, Denosumab and Combination Therapy on Peripheral Bone Density and Microarchitecture: The DATA-HRpQCT Extension study. Joy Tsai*[1], Alexander Uihlein[2], Sherri-Ann Burnett-Bowie[1], Robert Neer[1], Yuli Zhu[3], Nicholas Derrico[3], Katelyn Foley[3], Hang Lee[4], Mary Bouxsein[5], Benjamin Leder[6]. [1]Massachusetts General Hospital, USA, [2]Northwestern Memorial Faculty Foundation, USA, [3]Massachusetts General Hospital, Endocrine Unit, USA, [4]Massachusetts General Hospital, Biostatistics Center, USA, [5]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [6]Massachusetts General Hospital Harvard Medical School, USA

Background: In postmenopausal women, 24 months of combined denosumab (DMAB) and teriparatide (TPTD) increased hip and spine BMD more than either drug alone. The effect of combined DMAB and TPTD therapy on peripheral cortical and trabecular bone density and microarchitecture, however, is unknown.

Methods: We randomized 94 postmenopausal osteoporotic women ages 51-91 to receive TPTD 20-ug SC QD, DMAB 60-mg SC Q6 months, or both (COMBO) for 24 months. Women were excluded if they had ever used IV bisphosphonates (BPs) or oral BPs in the past 6 months. Total, trabecular and cortical density (Tot.vBMD, Tb.vBMD, Ct.vBMD), cortical thickness (Ct.Th) and trabecular microarchitecture were measured by high-resolution peripheral QCT of the distal radius and tibia at 0, 3, 6, 12, 18, and 24 months.

Results (Fig): At both the radius and tibia, Tot.vBMD and Tb.vBMD increased in the DMAB and COMBO groups but not in the TPTD group. The increase in Tot.vBMD in the COMBO group was greater than that in either monotherapy group at both sites ($p<0.005$ for all between-group comparisons). The increase in Tb.vBMD in the COMBO group was greater than in either monotherapy group at the radius ($p<0.002$ for both comparisons). Ct.vBMD decreased in the TPTD group but increased or was maintained in the DMAB and COMBO groups at both sites. The increase in tibial Ct.vBMD in the COMBO group was greater than in either monotherapy group ($p<0.002$ for both comparisons). Ct.Th did not change in the TPTD group but increased in the other groups at both sites. The increase in Ct.Th at the tibia was greater in the COMBO group than either monotherapy group ($p<0.001$ for both comparisons).Trabecular number increased in the COMBO group more than in the DMAB group (p=0.044). Changes during the 2nd year were notable for progressive increases in total vBMD and Ct.Th in the COMBO group. Ct.vBMD decreased linearly over 2 years in the TPTD group, which is in contrast to the observed changes in radius aBMD by DXA where the decline is limited to the first year.

Conclusions: Two years of combined DMAB and TPTD therapy increases radius and tibia total vBMD, increases radius Tb.vBMD, and increases tibia Ct.Th more than either drug alone. Furthermore, the TPTD-induced decrease in Ct.vBMD is fully prevented by DMAB co-administration. The combination of DMAB and TPTD results in the most favorable changes in peripheral bone density and geometry and may prove a useful intervention in women at high risk of fracture.

Denosumab Restores Cortical Bone Loss at the Distal Radius Associated With Aging and Reduces Wrist Fracture Risk: Analyses From the FREEDOM Extension Cross-over Group. John P. Bilezikian*[1], Claude Laurent Benhamou[2], Celia J.F. Lin[3], Jacques P. Brown[4], Nadia S. Daizadeh[3], Peter R. Ebeling[5], Astrid Fahrleitner-Pammer[6], Edward Franek[7], Nigel Gilchrist[8], Paul D. Miller[9], James A. Simon[10], Ivo Valter[11], Cristiano A.F. Zerbini[12], Cesar Libanati[3]. [1]Columbia University, USA, [2]Orléans Hospital, France, [3]Amgen Inc., USA, [4]CHU de Québec Research Centre, Canada, [5]The University of Melbourne, Australia, [6]Medical University, Austria, [7]Medical Research Center Polish Academy of Sciences, Poland, [8]The Princess Margaret Hospital, New Zealand, [9]Colorado Center for Bone Research, USA, [10]George Washington University, USA, [11]CCBR, Estonia, [12]Centro Paulista de Investigação Clinica, Brazil

Purpose: The skeleton is 80% cortical bone, and cortical bone loss is a major determinant of increased fracture risk. Denosumab (DMAb) has been shown to increase BMD at sites of cortical bone, including the radius, a skeletal site not responsive to most osteoporosis treatments. DXA measurements over time allow for tracking changes in BMD and mass, known predictors of fracture risk. Here, we evaluated changes over time in radius BMD and wrist fracture incidence during 3 years of placebo (Pbo) and during 5 subsequent years of DMAb therapy in the FREEDOM and its Extension (EXT) trials.

Methods: We evaluated 2207 women who enrolled in the EXT and received Pbo during FREEDOM (3 years), and DMAb 60 mg Q6M during EXT (5 years) (Cross-over group); all women received daily calcium and vitamin D. A subset of these women (n=115) participated in a distal radius DXA substudy and were evaluated at baseline and during FREEDOM and EXT. Analysis of mean percentage changes in BMD over time from FREEDOM and EXT baselines consisted of a repeated measure model. Wrist fracture rates (per 100 subject-years), rate ratios, and 95% confidence intervals (CI) were computed.

Results: At FREEDOM baseline, the mean (SD) 1/3 radius T-score was –2.53 (1.18). During FREEDOM, daily calcium and vitamin D alone resulted in a

progressive and significant loss of BMD at the 1/3 radius (–1.2%); however, during EXT, DMAb halted and reversed bone loss (Figure). With 5 years of DMAb treatment, a significant gain in BMD (1.5% at EXT Year 5) was observed, compared with EXT baseline. The wrist fracture rate during the Pbo period in FREEDOM was 1.02 (0.80–1.29) per 100 subject-years. During the first 3 years of EXT, while BMD recovered to the original baseline levels in response to DMAb, the wrist fracture rate remained comparable to the FREEDOM Pbo rate (Table); and with 2 additional years, BMD increased further, and the wrist fracture rate declined to levels significantly lower than the FREEDOM Pbo rate (rate ratio=0.57, 95% CI=0.34–0.95; p=0.03).

Conclusion: In untreated women with postmenopausal osteoporosis, cortical bone density at the radius declined despite calcium and vitamin D supplementation. DMAb treatment for 3 years reversed this bone loss, and 2 additional years of treatment resulted in further BMD gains that translated to significantly lower wrist fracture rates. These data provide evidence, for the first time, of the clinical importance of reversing cortical bone loss.

Teraparatide Stimulates Bone Formation Rapidly in the Human Femoral Neck. Felicia Cosman*[1], David Dempster[2], Jeri Nieves[3], Hua Zhou[1], Marsha Zion[1], Catherine Roimisher[1], Yvonne Houle[4], Robert Lindsay[1], Mathias Bostrom[4]. [1]Helen Hayes Hospital, USA, [2]Columbia University, USA, [3]Columbia University & Helen Hayes Hospital, USA, [4]Hospital for Special Surgery, USA

Background: Teriparatide (TPTD) rapidly increases bone formation in cancellous and cortical bone of the iliac crest, ultimately increasing bone mass and reducing risk of vertebral and nonvertebral fractures. However, hip BMD improvements with TPTD are modest and there are no data confirming that TPTD reduces hip fracture risk because the study was underpowered for that outcome. Objective: In order to learn more about the effects of TPTD on the femur, we performed a double blind trial of TPTD vs Placebo (PBO) in patients about to undergo a Total Hip Replacement (THR) for osteoarthritis. Methods: Participants were randomized to receive daily TPTD or PBO for an average of 6.1 weeks prior to THR (range 4.6-11.8 weeks). After an average of 3 weeks of study medication, tetracycline labels were administered following standard protocol. During the THR, an intact sample of the femoral neck (FN) was procured, fixed, and sectioned transversely. Four envelopes (cancellous, endocortical, intracortical and periosteal) were analyzed. Mineralized surface (MS/BS) and mineral apposition rate (MAR) were measured and bone formation rate (BFR) calculated. Serum PINP and CTX levels were obtained at baseline and at THR. 39 individuals were enrolled and data are presented on the first 26 analyzed (16 postmenopausal women, mean age 72+9; 10 men, mean age 69.8+7.7). Results: The figure shows tetracycline uptake in cancellous bone from individuals on PBO and TPTD, with substantially more labeled surface in the TPTD-treated subject. Median BFR, MS/BS and MAR by treatment group for each bone envelope are shown in the Table. In both cancellous and endocortical bone, BFR and MS/BS were 2-4 fold higher in TPTD than in PBO ($p<0.05$). MAR was higher in both cancellous and intracortical envelopes in TPTD compared to PBO ($p<0.05$). In the periosteum, BFR was high in both groups (relative to other envelopes), without significant group differences. In TPTD treated subjects, PINP and OC increased by over 130% ($p<0.0004$), while CTX did not increase significantly. PINP increments correlated with BFR ($r=0.5$; $p<0.02$). PINP and CTX did not change in PBO. Conclusions: TPTD stimulates bone formation rapidly in the femoral neck, with prominent effects in cancellous and endocortical envelopes. These findings provide a mechanistic basis for TPTD-mediated improvement in hip strength. This study is the first demonstration of the effect of an osteoporosis medication on cellular activity in the human femur.

Romosozumab and Teriparatide Effects on Vertebral Cortical Mass, Thickness, and Density in Postmenopausal Women With Low Bone Mineral Density (BMD). Tristan Whitmarsh*[1], Graham Treece[1], Andrew Gee[1], Michael Bolognese[2], Jacques P. Brown[3], Stefan Goemaere[4], Andreas Grauer[5], David Hanley[6], Carlos Mautalen[7], Christopher Recknor[8], Yu-Ching Yang[9], Cesar Libanati[6], Kenneth Poole[1]. [1]University of Cambridge, United Kingdom, [2]Bethesda Health Research Center, USA, [3]CHU de Québec Research Centre, Canada, [4]Ghent University Hospital, Belgium, [5]Amgen Inc., USA, [6]University of Calgary, Canada, [7]Centro de Osteopatías Médicas, Argentina, [8]United Osteoporosis Center, USA, [9]Amgen Inc., USA

Purpose: Romosozumab (Romo) is a monoclonal antibody that binds sclerostin and stimulates bone formation while decreasing bone resorption. Recently, 12 months of Romo was shown to increase DXA lumbar spinal BMD by 11.3% in a phase 2 international, randomized, placebo-controlled trial (McClung, *NEJM* 2014). DXA measurements, however, do not generally distinguish cortical versus trabecular changes, nor identify the location or distribution of added bone mass. We assessed cortical parameters from the L1 vertebral computed tomography (CT) scans obtained in that same clinical trial by mapping the vertebral bone surface and measuring the global and local changes.

Methods: We evaluated baseline and 12 month L1 CT scans from postmenopausal women treated with Romo (210 mg SC QM, n=17), teriparatide (TPTD, 20 µg daily, n=19), and placebo (n=20). Cortical measurements were performed, blinded to treatment, using the Stradwin software tool, which is able to measure and map cortical BMD (CBMD), trabecular BMD directly adjacent to the cortex (TBMD), cortical thickness (CTh), and cortical mass (CMass=0.1 × CTh × CBMD) (Treece, *Med Image Anal* 2010, 2012). Transferring these maps to a canonical vertebral surface allows evaluation and topographical illustration of longitudinal changes and determining differences between treatments.

Results: Treatment groups were balanced at baseline (Table). Romo resulted in a mean (95% CI) CTh increase of 11.2% (9.0 to 13.4), a CBMD increase of 1.6% (0.2 to 2.9), a TBMD increase of 22.2% (19.2 to 25.3), and a CMass increase of 12.7% (10.8 to 14.7). Cortical maps show the topographical locations of the increase in CTh, CMass, and TBMD compared with placebo (Fig). TPTD resulted in smaller changes: a CTh increase of 5.6% (3.9 to 7.4), a TBMD increase of 17.4% (12.2 to 22.6), a CMass increase of 4.6% (3.4 to 5.8), and a slight but not significant CBMD reduction of 0.5% (–1.8 to 0.7). The improvements in CTh ($p<0.001$), CBMD ($p=0.04$), and CMass ($p<0.001$) with Romo were significantly greater than those observed with TPTD. The only significant change in the placebo group was a reduction of 4.3% (–6.7 to –1.9) in TBMD.

Conclusion: Treatment with Romo was associated with significant improvements in cortical parameters of the vertebrae, which were greater compared with placebo or TPTD. This study confirms the robust bone forming effects of Romo and provides new insights into the cortical changes on the vertebra in response to Romo treatment.

The Long Term Effects of Abaloparatide (BA058) On Micro-CT and Histomorphometry in Osteopenic Cynomolgus Monkeys. Aurore Varela*[1], Solomon Haile[2], Nancy Doyle[2], Susan Y. Smith[1], Robert Guldberg[3], Gary Hattersley[4]. [1]Charles River Laboratories, Canada, [2]Charles River, Canada, [3]School of Mechanical Engineering, Georgia Institute of Technology, USA, [4]Radius, USA

Abaloparatide (ABL) is a analog of PTHrP(1-34) being developed for osteoporosis treatment. This study evaluated the effects of ABL for 16 months in aged osteopenic, ovariectomized (OVX) monkeys. Four groups were OVX and one group underwent Sham surgery. After a 9-month bone depletion period, animals received daily SC injections of either vehicle (Sham and OVX controls) or ABL at 0.2, 1 or 5 µg/kg. Animals received calcein, 15 and 5 days prior to euthanasia. Cancellous bone histomorphometry was performed at the femoral neck and lumbar vertebra (L2) while cortical bone was evaluated at the femur mid-diaphysis. Micro-CT was performed on T12 vertebral body, L6 trabecular cores, distal femur and humeral cortical beam. In the cancellous bone of OVX control animals, 25 months post OVX, a slight decrease in BV/TV was observed with increases in osteoblast surface, wall thickness, double label surface (L2), mineralizing surface, osteoid volume, osteoid surface and bone formation rates. Effects of OVX were substantial in cortical bone dynamic parameters with increases in most label-derived parameters of bone formation, but with little effect on cortical structures. With micro-CT, similar slight decreases in BV/TV were noted at trabecular sites (distal femur -7%, T12 -14%, L6 core -26%) in OVX controls and minimal decreases in cortical vBMD were measurable (distal femur -4%, T12 -5%, beam 4%). At L2, ABL completely counteracted the OVX-related decrease in bone structural parameters (BV/TV) at ⩾ 1 µg /kg, significantly increased wall thickness at all doses and increased the formation period. At the femoral neck, dose-dependent increases in BV/TV were noted. At L2 and femoral neck, minor increases in trabecular thickness and trabecular number contributed together to the bone gains. With micro-CT, similar increases in BV/TV were noted at trabecular sites (distal femur up to +19%, T12 +25%, L6 core +35%). At cortical sites, increases in endocortical labeled surfaces and endocortical bone formation rate were noted in animals administered 5 µg/kg with no effects on cortical geometry. Similarly with micro-CT, no significant changes were noted in cortical bone geometry, but importantly with no increase in cortical porosity. In summary, treatment with ABL at ⩾ 1 µg /kg to OVX monkeys completely restored the OVX-induced cancellous and cortical bone loss at clinically relevant sites by increasing bone formation without affecting cortical porosity.

Heterozygous deletion of Wntless in the osteoclast lineage causes osteopenia demonstrating that osteoclasts are a critical source of Wnt proteins in the developing skeleton. Megan Weivoda*[1], Ming Ruan[1], Christine Hachfeld[1], Larry Pederson[1], Rachel Davey[2], Jeffrey Zajac[3], Jean Vacher[4], Richard Lang[5], Bart Williams[6], Sundeep Khosla[7], Jennifer Westendorf[1], Merry Jo Oursler[1]. [1]Mayo Clinic, USA, [2]University of Melbourne, Australia, [3]Austin Hospital, Australia, [4]Institut De Recherches Cliniques De Montréal, Canada, [5]Cincinnati Children's Hospital Medical Center, USA, [6]Van Andel Research Institute, USA, [7]Mayo Clinic College of Medicine, USA

Wnt signaling is crucial for normal skeletal development and adult bone homeostasis. Although several cell types in the skeleton are known to produce Wnts, the contribution of these cellular sources to skeletal Wnt signaling is not clear. Osteoclasts secrete multiple Wnts including Wnt1, Wnt3a, and Wnt10b. We hypothesized that osteoclasts are a critical source of Wnts in skeletal development. The membrane-associated chaperone, Wntless (Wls), is required for intracellular Wnt transport and Wnt secretion. To assess the contribution of osteoclast-derived Wnts to skeletal development, transgenic Cd11b or cathepsin K (Ctsk) promoter Cre mice were crossed with Wls flox mice to obtain animals with heterozygous deletion of Wls in the osteoclast lineage (Cd11b/Wls^{Het} and Ctsk/Wls^{Het}). *In vivo* dual-energy X-ray

absorptiometry analysis showed Cd11b/Wls^{Het} and Ctsk/Wls^{Het} mice exhibited decreased bone mineral density in the spine and femur at 6 weeks of age. Animals were sacrificed at 8 weeks. Bone marrow was isolated for analysis of osteoclast Wls expression and Wnt protein secretion *in vitro*. Femurs were assessed by peripheral quantitative computed tomography (QCT), micro computed tomography (CT), and histomorphometry. Wls protein was significantly reduced in bone marrow osteoclast cultures from Cd11b/Wls^{Het} and Ctsk/Wls^{Het} animals as compared to littermate control cultures. Total protein secretion by Ctsk/Wls^{Het} mature osteoclasts was unaltered compared to controls; however, Ctsk/Wls^{Het} osteoclast secretion of Wnt1, Wnt3a, and Wnt10b was significantly reduced. Peripheral QCT analysis of Cd11b/Wls^{Het} and Ctsk/Wls^{Het} femurs showed significant reductions in cortical bone area, thickness, and density, as well as significant decreases in total and trabecular density. MicroCT analysis revealed a 60% reduction in cortical thickness in the cancellous region of the Ctsk/Wls^{Het} femurs; trabecular microCT parameters were unchanged. Interestingly, endocortical osteoblast numbers were decreased by 70%, and osteoclast numbers were significantly increased. The decreased cortical phenotypes of Cd11b/Wls^{Het} and Ctsk/Wls^{Het} mice are strikingly similar to the decreased cortical phenotypes of mice with osteoblast specific deletion of Lrp5/Lrp6 or ß-catenin. This suggests that osteoclasts are a prime source of anabolic Wnts in the cortical region. These data demonstrate that osteoclast lineage-derived Wnts play an essential role in skeletal development.

Deletion of LRP6 in Different Stages of Osteoblastic Lineage of Cells Impairs Bone Formation at Different Postnatal Stages. Changjun Li*[1], Hui Xie[2], Janet Crane[3], Xu Cao[3], Mei Wan[1]. [1]Johns Hopkins University School of Medicine, USA, [2]Johns Hopkins Medical Institution, USA, [3]Johns Hopkins University, USA

Bone-forming osteoblast lineage of cells is derived from bone marrow mesenchymal stem cells (MSCs).Low-density lipoprotein receptor-related protein 6 (LRP6) is a positive regulator for bone formation, and mutations in LRP6 are associated with human bone disorders. However, the role of LRP6 in different stages of osteoblast lineage of cells remains largely unknown. It was reported that transgenes that use control regions from the nestin gene mark bone marrow perivascular MSCs. In this study, we generated two mouse models, in which LRP6 was specifically deleted in either mature osteoblasts or in bone marrow MSCs by crossing *osteocalcin-Cre* or *nestin-Cre* mice with *LRP6^{flox}* mice and investigated the changes of osteoblastogenesis and bone formation.

LRP6^{flf}::osteoclacin-Cre mice (named "*OC-KO*") had normal body weight and length compared with their wild type littermates, whereas *LRP6^{flf}::nestin-Cre* mice (named "*Nes-KO*") demonstrated reductions in body weight and length at 1 and 3 months of age. Bone architecture measured by µCT showed marginal changes in bone mass in the primary spongiosa area but a reduction in the secondary spongiosa of femurs at 3 month-old *OC-KO* mice. The remodeling area of *OC-KO* mice showed a decreased bone formation rate as detected by Goldner's Trichrome staining and calcein double labeling. On the contrary, *Nes-KO* mice exhibited a significant reduction in bone mass in both primary and secondary spongiosa area of femurs. The results suggest that LRP6 deficiency in osteoblasts primarily affected trabecular bone remodeling in adults, whereas LRP6 deficiency in MSCs impaired both postnatal bone acquisition and bone remodeling. Bone histomorphometric and immumohistochemical analysis showed that both *OC-KO* and *Nes-KO* mice exhibited significant reduction in the number of bone surface osteoblasts but marginal changes in the number of osteoclasts, indicating the primary role of LRP6 in regulating osteoblast lineage of cells. Further characterizing the cellular mechanisms of the reduced osteoblastogenesis in both mutant mice revealed that LRP6 deficiency in osteoblasts mainly impaired the differentiation of osteoblasts, whereas LRP6 deficiency in MSCs led to the reduced pool of osteoblast-forming osteoprogenitors due to the diminished survival and proliferative capacity of MSCs. Thus, LRP6 is a key positive regulator for osteoblastogenesis with distinct functions in different differentiation stages of osteoblastic lineage of cells.

Hedgehog Induces Osteoblast Differentiation through IGF-mTORC2 Signaling. Yu Shi*[1], Jianquan Chen[2], Courtney Karner[3], Fanxin Long[3]. [1]Washington University in St. Louis, USA, [2]Washington University, USA, [3]Washington University School of Medicine, USA

Hedgehog (Hh) signaling critically regulates the endochondral bone formation in vivo. It is further known that Hh signaling directly induces osteoblast differentiation via the Gli family of transcription factors. However, the osteogenic effectors downstream of Gli are largely unknown. Here by RNA sequencing, we found that components of the Igf signaling pathway were induced by Hh activation during osteoblast differentiation in vitro. Moreover, Hh activated Igf-mTORC2-Akt signaling in a Gli-dependent manner. Knockdown of Igf2, Igf1r or the mTORC2-specific component rictor, similar to pharmacological inhibition of Akt, suppressed Hh-induced osteoblast differentiation in vitro. We further discovered that IGF synergized with Hh signaling via Akt-dependent Gli2 stabilization. To test the physiological contribution of Igf signaling to Hh-induced osteoblast differentiation, we deleted Igf1r in the mouse embryo by using the Gli1-CreERT2 knockin allele that expresses CreERT2 (tamoxifen (TM)-inducible Cre) from the endogenous Gli1 genomic locus. TM-induced deletion of IGF1R in Gli1-expressing cells prior to osteoblastogenesis diminished bone formation without affecting cartilage development. Take together, these results support a model wherein Hh induces IGF signaling which in turn augments the Hh response to stimulate osteoblast differentiation. This study therefore establishes a cross-regulatory relationship between Hh and Igf signaling in bone.

BMP-Alk3 signaling exerts opposite effects on trabecular versus cortical bone formation in postnatal mice. Joohyun Lim*[1], Fanxin Long[2]. [1]Washington University in St. Louis, USA, [2]Washington University School of Medicine, USA

Bone morphogenetic proteins (BMPs) were discovered for their ability to induce ectopic bone. Although it is well established that BMP signaling is essential for cartilage development during endochondral bone formation, how physiological BMP signaling directly regulates bone formation in postnatal mice remains unclear. To fill this knowledge gap, we conditionally deleted the type I BMP receptor Alk3 in osteoblast-lineage cells. Alk3 mutants were normal in size and weight but had thinner cortical diameter compared to littermate controls due to reduced osteoblast activity in the periosteum. This result therefore corroborates the anabolic function of BMP signaling in bone formation. Unexpectedly, however, Alk3 deletion significantly increased cancellous bone formation due to increased osteoblast numbers and mineralizing surface, without affecting osteoclast numbers and function. Furthermore, Alk3 deletion significantly increased BrdU-positive osteoblast precursors in the chondro-osseous junction, indicating that Alk3 negatively regulates the proliferation of osteoblast progenitors. Collectively, these results demonstrate that Alk3-dependent BMP signaling in osteoblast-lineage cells has opposing roles in cancellous versus cortical bone formation in postnatal mice. Because Alk3 deletion greatly suppressed Sost expression by osteocytes, we speculate that Alk3 normally restricts the proliferation of osteoblast progenitors in the trabecular bone region through Sost-mediated inhibition of Wnt signaling. To test whether Alk3 function is mediated by the Smad proteins, we deleted Smad4 in osteoblast-lineage cells by using the same genetic approach. Interestingly, Smad4 deletion also increased cancellous bone formation and reduced cortical diameter, but to a lesser degree than Alk3 removal. Thus, our data support a model in which BMP-Alk3 signaling exerts opposite effects on trabecular versus cortical bone formation in postnatal mice, and that these effects are mediated through both Smad-dependent and independent mechanisms.

The homeodomain protein TGIF regulates several physiological processes and plays crucial roles in cell fate determination and tissue homeostasis. TGIF is phosphorylated in numerous cell systems, yet the responsible kinase(s) remains unidentified. In an effort to address this issue, we interrogated the Eukaryotic Linear Motif (ELM) database, and found that TGIF possesses a potential GSK3β phosphorylation site (T235 and T239). We then showed that indeed GSK3β can directly phosphorylate TGIF, as demonstrated by in vitro kinase assays and western blotting using an antibody that specifically recognizes TGIF phosphorylated at T235/T239. Functionally, we found that mutation of T235/T239 resulted in decreased TGIF turnover, providing an initial hint that phosphorylation by GSK3β might hinder TGIF stability. In fact, suppressing GSK3β activity through either genetic or chemical approaches triggered decreased TGIF polyubiquitination and clearance. Thus, similar

to β-catenin, phosphorylation of TGIF by GSK3β leads to its ubiquitination and degradation. As GSK3β is a key kinase in Wnt signaling, we then investigated whether TGIF played a physiological role in this pathway. Remarkably, expression of TGIF enhanced Wnt-induced gene expression, whereas TGIF deficiency elicited the opposite effects. Mechanistically, TGIF appeared to promote β-Catenin accumulation, interfering with the assembly of the β-Catenin destruction complex. Furthermore, activation of Wnt signaling induced the expression of TGIF itself in many cell lines, revealing an ability of TGIF to govern a feed-forward loop that sustains Wnt signaling.

Given that Wnt signaling is a potent regulator of osteoblast differentiation and bone formation, we then tested whether TGIF was capable to enhance this pathway in osteoblasts (OBs) and bone formation in vitro and in vivo. Expressing TGIF increased OB differentiation in the pre-OB cell lines, ST2 and C3H10T1/2 through Wnt signaling activation, as TGIF depletion was sufficient to blunt Wnt3a-induced osteoblast differentiation in these cell systems. In vivo, TGIF-/- mice display decreased osteoblast differentiation and low bone mass. More importantly, deletion of TGIF prevented the high bone mass phenotype seen in mice harboring heterozygote deletion of the Wnt signaling inhibitor DKK1. This study therefore establishes TGIF as a component of the Wnt signaling machinery that is required for efficient Wnt-induced osteoblast differentiation and bone formation.

PTH/PTHrP Receptor Signaling in Osteoprogenitors is Essential for B Lymphocyte Differentiation, Maturation, and Mobilization in Mice. Cristina Panaroni*[1], Keertik Fulzele[2], Vaibhav Saini[3], Rhiannon Chubb[4], Paola Divieti Pajevic[5], Joy Wu[6]. [1]Stanford University School of Medicine, USA, [2]Massachusetts General Hospital; Harvard Medical School, USA, [3]MGH, Harvard Medical School, USA, [4]Endocrine Unit, Massachusetts General Hospital, USA, [5]Massachusetts General Hospital & Harvard Medical School, USA, [6]Stanford University School of Medicine, USA

The osteoblast lineage is a major regulator of various hematopoietic lineages by providing specialized niches for their development in bone marrow (BM). We have previously demonstrated that ablation of Gsα in Osterix-positive (Osx) osteoprogenitors in mice results in osteopenia accompanied by developmental arrest of B-lymphocyte precursors in BM. Because PTH treatment has been shown to enhance osteoblast support of B lymphocyte differentiation *in vitro*, we hypothesized that PTH/PTHrP receptor (PPR) might be the G-protein coupled receptor upstream of Gsα in osteoprogenitors, mature osteoblasts, or osteocytes that regulates B lymphocyte maturation in the BM. Here we show that B lymphocyte development in BM is regulated by PPR signaling only in osteoprogenitors. No impaired B cell development was found when PPR was ablated in mature osteoblasts or osteocytes. On the contrary, and similar to mice depleted of Gsα in osteoprogenitors, Osx-PPR knockout (KO) mice exhibit a severe osteoporotic phenotype and a specific reduction in B cell precursors, as previously reported. Surprisingly, the overall number of total B lymphocytes in BM was not significantly reduced due to a 3-fold increase in mature B cells, which were mainly located along the endosteal bone. In case of BM failure, hematopoiesis can take place in the spleen. Therefore, we investigated the spleen of Osx-PPRKO mice but observed no extramedullary hematopoiesis, suggesting impaired maturation and retention of B cells in the BM of Osx-PPR KO mice. Intra-tibial injection of labeled B lymphocytes revealed a 27-fold increase in the number of labeled mature B cells in the BM and 6-fold decrease in labeled mature B cells in the spleen of Osx-PPR KO mice, further supporting increased retention of B cells in BM. We next examined the main adhesion molecules involved in B lymphocyte migration/adhesion. The integrin α4β1 is abundantly expressed on B lymphocytes and strongly interacts with its stromal ligand VCAM1 to increase adhesion to the microenvironment. Interestingly, we found a 3-fold increase in VCAM1 expression in bone, and *in vivo* treatment with VCAM1 neutralizing antibody reduced the frequency of mature B cells in the BM of Osx-PPR KO mice by 50%. In summary, PPR signaling in early osteoprogenitors, but not mature osteoblasts and osteocytes, is necessary for B cell differentiation, maturation, and mobilization.

FGF23 regulates bone mineralization in a vitamin D and Klotho-independent fashion. Sathish Kumar Murali*[1], Paul Roschger[2], Ute Zeitz[1], Klaus Klaushofer[3], Olena Andrukhova[1], Reinhold Erben[4]. [1]Dept. of Biomedical Sciences, University of Veterinary Medicine, Austria, [2]L. Boltzmann Institute of Osteology, Austria, [3]Hanusch HospitalLudwig Boftzmann Institute of Osteology, Austria, [4]University of Veterinary Medicine, Austria

Fibroblast growth factor-23 (FGF23) is a phosphaturic hormone secreted by osteoblasts and osteocytes in response to vitamin D and phosphate. Lack of Fgf23 or of Klotho (Kl), the co-receptor for FGF23, leads to severe impairment of bone mineralization in mice. However, the mechanisms underlying the Fgf23- and Klotho deficiency-associated defects in bone mineralization are still poorly understood. To examine the vitamin D independent role of FGF23 and Klotho in bone mineralization, we crossed $Fgf23^{-/-}$ or $Kl^{-/-}$ mice with mice expressing a non-functioning vitamin D receptor ($VDR^{\Delta/\Delta}$). As expected, $Fgf23^{-/-}$ and $Kl^{-/-}$ mice were characterized by increased serum 1,25 $(OH)_2D_3$, and impaired bone mineralization as evidenced by μCT and histomorphometric analysis. The mineralization defect in $Fgf23^{-/-}$ and $Kl^{-/-}$ mice was associated with increased bone mRNA expression of ANK (progressive ankylosis), ENPP1 (ectonucleotide pyrophosphatase phosphodiesterase 1), ENPP3 (ectonucleotide pyrophosphatase phosphodiesterase 3), and osteopontin (OPN) as compared to wild-type and $VDR^{\Delta/\Delta}$ mice. In addition, we found increased pyrophosphate levels and OPN protein expression in bones of $Fgf23^{-/-}$ and $Kl^{-/-}$ mice. Ablation of vitamin D signaling in $Kl^{-/-}/VDR^{\Delta/\Delta}$ compound mutants normalized serum Fgf23 levels, bone mineralization, bone pyrophosphate levels, and bony expression of ANK, ENPP1, ENPP3, and OPN, suggesting that the mineralization defect observed in $Kl^{-/-}$ mice is entirely due to $1,25(OH)_2D_3$-driven upregulation of the mineralization inhibitor OPN, and of the pyrophosphate-regulating factors ANK, ENPP1, ENPP3. However, despite normalization of bone pyrophosphate levels, bone mineralization remained impaired and OPN protein expression remained increased in $Fgf23^{-/-}/VDR^{\Delta/\Delta}$ compound mutants relative to wild-type and $VDR^{\Delta/\Delta}$ mice. Differentiated primary osteoblasts isolated from $Fgf23^{-/-}$ mice, but not those isolated from $Kl^{-/-}$ mice, showed cell autonomous increases in OPN mRNA and protein expression as compared to wild-type cells. In addition, treatment of differentiated primary osteoblasts isolated from wild-type mice with recombinant FGF23 decreased OPN protein expression. Taken together, our data suggest that Fgf23 but not Klotho has a vitamin D independent role in bone mineralization through direct regulation of OPN.

Deletion of PTH1R expression from limb mesenchyme affects systemic mineral ion homeostasis. Yi Fan*[1], Beate Lanske[2], Tatsuya Kobayashi[3], Tadatoshi Sato[1], Michael Densmore[4]. [1]Harvard School of Dental Medicine, USA, [2]Harvard School of Dental MedicineHarvard Medical School, USA, [3]Massachusetts General Hospital, USA

PTH is secreted by the parathyroid glands in response to low serum calcium and vitamin D levels. It signals through the parathyroid hormone 1 receptor (PTH1R) in kidney and bone to regulate mineral ion homeostasis and bone remodeling. We generated a viable novel mouse model, *Prx1Cre;PTH1R$^{fl/fl}$*, by ablating the PTH1R at the early limb bud stage in order to explore the contribution of PTH1R expression in long bones to modulate systemic mineral ion homeostasis. We confirmed efficient and specific deletion of PTH1R in adult limbs and calvaria. H/E & von Kossa staining showed reduced amounts of trabecular and cortical bone in *Prx1Cre;PTH1R$^{fl/fl}$* limbs at P0, 3 and 6 weeks of age. qPCR analyses revealed decreased expression of osteoblast and some osteocyte markers, with exception of *Mepe*, *Dmp1*, *Opn* and more importantly *Fgf23* mRNA. Also, normal FGF23 protein expression was detected in mutants by immunohistochemistry.

To examine changes in systemic mineral ion homeostasis we measured various biochemical parameters. Whereas serum Ca^{2+} and PTH levels were unchanged, serum Pi, $1,25(OH)_2D_3$, and iFGF23 levels were significantly decreased in mutants. Notably, a marked reduction in *Galnt3 expression*, an enzyme required for O-glycosylation of FGF23, was detected in *Prx1Cre;PTH1R$^{fl/fl}$* bones, signifying that a failure in proper post-translational modification of FGF23 could be responsible for the lower circulating FGF23 levels.

Moreover, changes in the expression of renal genes involved in balancing mineral ion homeostasis, such as *Klotho*, *Napi2a*, *CalbindinD$_{28K}$*, were found in mutants. Interestingly, renal *1a(OH)ase* expression in mutants was normal but its expression in limbs was significantly decreased, indicating that the lower serum $1,25(OH)_2D_3$ could be due to the local loss of PTH1R in limbs.

To further explore the regulation of FGF23 by PTH, 2-week old mutants and littermate controls were daily injected with hPTH(1-34) or vehicle for 1 week. FGF23 mRNA expression was upregulated in control limbs but remained unchanged in the mutants. Although controls responded with the expected increase in serum calcium and decrease in serum phosphate no changes in serum calcium were seen in the mutants, while serum phosphate significantly decreased.

In summary, our data suggest that PTH1R in limbs is required for induction of FGF23 mRNA and is essential to regulate systemic mineral ion homeostasis.

Phosphate-induced signaling cascade is regulated by Trps1 in mineralizing cells. Maria Kuzynski[1], Morgan Goss[2], Callie Mobley[1], Dobrawa Napierala*[2]. [1]University of Alabama at Birmingham, USA, [1]University of Alabama at Birmingham, USA, [2]University of Alabama At Birmingham School of Dentistry, USA

The availability of phosphate is one of the critical factors regulating biomineralization. Phosphate supports biomineralization not only as a component of inorganic phase of mineralizing tissues, but also as a signaling molecule that acts on target cells and induces molecular changes supporting biomineralization. It has been demonstrated that phosphate-induced Erk1/2 activation is bi-phasic and promotes expression of mineralization-related genes. Many of these genes have promoters enriched in GATA consensus elements suggesting that GATA transcription factors

play role in regulation of gene expression in response to phosphate. Trps1 is a GATA-type transcription factor that is expressed during development of skeletal and dental tissues. Our previous data from Trps1-KO and Col1a1-Trps1 transgenic mice implicate Trps1 in biomineralization, however its precise role in this process is unknown. To understand how Trps1 regulates biomineralization, we generated odontoblastic cell lines deficient for Trps1 (Trps1-KD) and overexpressing Trps1 (Trps1-OE). Cellular and molecular analyses of these cell lines uncovered that Trps1-deficieny results in a loss of the mineralization potential, associated with decreased expression of Phospho1 and TNAP phosphatases, and Runx2 and Sp7 osteogenic transcription factors. In contrast, Trps1-overexpression results in delayed and decreased mineralization as well as decreased expression of genes regulated by phosphate. Analyses of phosphate-induced Erk1/2 activation uncovered disturbed second Erk1/2 activation peak in both Trps1-KD and Trps1-OE cells in comparison with controls. These data implicate Trps1 in phosphate-induced signaling cascade and suggest that Trps1 regulates the biomineralization process by controlling expression of a subset of phosphate-responsive genes.

Mechanisms Underlying Ectopic Mineralization in a Mouse Model of Diffuse Idiopathic Skeletal Hyperostosis. Hisataka Ii[1], Sumeeta Warraich[1], Neil Tenn[1], Diana Quinonez[1], David Holdsworth[1], James Hammond[2], S. Jeffrey Dixon*[1], Cheryle Séguin[1]. [1]The University of Western Ontario, Canada, [2]University of Alberta, Canada

Equilibrative nucleoside transporter 1 (ENT1) mediates the passive flow of adenosine across cell membranes. We previously reported that mice lacking ENT1 (*ENT1*$^{-/-}$) exhibit progressive ectopic mineralization of spinal tissues including intervertebral discs (IVDs) – a phenotype resembling diffuse idiopathic skeletal hyperostosis (DISH) in humans. Our objective was to investigate the mechanisms underlying ectopic mineralization in *ENT1*$^{-/-}$ mice. Intact IVDs were isolated from wild-type and *ENT1*$^{-/-}$ mice at 2 months of age (prior to detection of disc mineralization), 4 and 6 months of age (when extensive mineralization was detected in IVDs). Tissues were processed for RNA extraction and real-time PCR, subjected to enzymatic dissociation for cell isolation and culture, or fixed for histological evaluation. Characterization of wild-type tissues demonstrated that, in contrast to brain and visceral organs, ENT1 is the primary nucleoside transporter expressed in the IVD. This observation was confirmed functionally by measuring uptake of [^{3}H]2-chloroadenosine in cultures of IVD cells isolated from wild-type mice. No differences in candidate gene expression were detected in intact IVDs isolated from *ENT1*$^{-/-}$ mice compared to wild-type mice at 2 or 4 months of age. However, at 6 months of age, expression of regulators of mineralization including *Mgp*, *Enpp1*, *Ank*, *Spp1* and *Alpl* were significantly reduced in *ENT1*$^{-/-}$ mice compared to wild-type. To assess whether changes detected in *ENT1*$^{-/-}$ mice were cell autonomous, cultures of annulus fibrosus cells were established. Cultures from *ENT1*$^{-/-}$ IVDs demonstrated greater alkaline phosphatase activity than wild-type cells when isolated from mice at either 2 or 6 months of age. *ENT1*$^{-/-}$ cultures also showed greater mineralization than wild-type cells at 2 months of age. Cultures of cells from 6-month-old *ENT1*$^{-/-}$ mice exhibited significantly greater expression of *Ibsp*, *Enpp1*, *Spp1, Alpl* and *Runx2* than wild-type cultures. Interestingly, histological evaluation of intact IVDs demonstrated aberrant alkaline phosphatase activity in cells of the inner annulus fibrosus in *ENT1*$^{-/-}$ mice. Together, these findings suggest that both cell-autonomous and systemic mechanisms disrupt expression of alkaline phosphatase and other regulators of mineralization, which in turn results in ectopic calcification of spinal tissues in *ENT1*$^{-/-}$ mice. These observations may provide new clues as to the pathogenesis of DISH in humans.

***Gli1* haploinsufficiency disrupts postnatal bone homeostasis under physiological and pathological conditions.** Yoshiaki Kitaura*[1], Hironori Hojo[2], Yuske Komiyama[3], Tsuyoshi Takato[3], Ung-Il Chung[4], Shinsuke Ohba[5]. [1], Japan, [2]The Center for Disease Biology & Integrative Medicine, USA, [3]The university of Tokyo, Japan, [4]University of Tokyo Schools of Engineering & Medicine, Japan, [5]The University of Tokyo, Japan

Hedgehog (Hh) signaling plays important roles in various development processes. The signaling exerts its biological effects through the Gli-mediated transcription of its target genes. In the mammalian skeleton, Hh input is required for the specification of *Runx2*-positive osteoblast precursors during endochondral ossification. In contrast to the established roles of Hh signaling in skeletal development, the evidence of its roles in adult bone homeostasis is not complete. In the present study, we aimed to identify roles of Gli1, a transcriptional activator induced by Hh signaling activation, in postnatal bone homeostasis. The body weights of the 8-week-old *Gli1*$^{-/-}$ mice were approx. 20% lower than those of the WT and *Gli1*$^{+/-}$ mice, which suggested systemic abnormalities by complete loss of *Gli1* gene. Therefore, we analyzed the skeletal system in *Gli1*$^{+/-}$ male mice. *Gli1* haploinsufficiency caused decreased bone mass with reduced bone formation and accelerated bone resorption; that is, an uncoupling of the bone metabolism. Hh-mediated osteoblast differentiation was largely impaired in cultures of *Gli1*$^{+/-}$ precursors, and the impairment was rescued by the *Gli1* expression by the adenoviral transduction. In addition, *Gli1*$^{+/-}$ precursors showed premature differentiation into osteocytes and increased ability to support osteoclastogenesis. These data suggest that the uncoupling of bone metabolism is caused by the premature differentiation of *Gli1*$^{+/-}$ precursors into osteocytes that have greater capacities to support osteoclastogenesis. When we compared fracture healing between wild-type and *Gli1*$^{+/-}$ adult mice, we found that the *Gli1*$^{+/-}$ mice exhibited impaired fracture healing with insufficient callus formation by three-dimensional μ-CT analyses. In the histological analyses on sections stained with the hematoxyline-eosine (H-E) and alcian blue revealed that both of soft and hard callus were reduced in the *Gli1*$^{+/-}$ mice compared to WT mice; both endochondral ossification and intramembranous ossification were affected by *Gli1* haploinsufficiency during the fracture healing process at a postnatal stage. Thus, we propose that Gli1 acting downstream of Hh input contributes to adult bone metabolism under both physiological and pathological conditions, in which this molecule not only promotes osteoblast differentiation but also acts as a repressor for osteoblast maturation toward osteocytes to maintain normal bone homeostasis.

Prolonging JAK/STAT signaling by deletion of osteocytic SOCS3 results in a profound sex-divergent change in trabecular bone mass. Holly Brennan*[1], Rachelle Johnson[2], Emma Walker[1], Gordon Smyth[3], Nicos Nicola[3], T. John Martin[4], Natalie Sims[2]. [1]St Vincent's Institute of Medical Research, Australia, [2]St. Vincent's Institute of Medical Research, Australia, [3]Walter & Eliza Hall Institute, Australia, [4]St. Vincent's Institute of Medical Research, Australia

The SOCS (suppressor of cytokine signaling) family of proteins limit the duration of JAK/STAT cytokine signaling. SOCS3 binds directly to receptors that play key roles in bone metabolism, including glycoprotein 130 (gp130), leptin receptor and G-CSF receptor, thereby inhibiting receptor-associated JAK tyrosine kinase activity. SOCS3 expression in the osteoblast lineage is stimulated by parathyroid hormone (PTH), mechanical loading and IL-6/gp130 family cytokines, which all increase bone formation, at least in part, by acting on the osteocyte.

To investigate the role of osteocytic SOCS3 in bone remodeling, we examined the skeletal phenotype of mice with SOCS3 conditionally deleted in osteocytes (DMP1Cre.SOCS3f/f). Femora were analyzed by microCT, and tibiae by histomorphometry, during development (2-week-old), growth (6-week-old), and early and late adult bone remodeling (12- and 26-week-old).

DMP1Cre.SOCS3f/f mice demonstrated a sex-divergent phenotype in trabecular bone, after sexual maturation. At 2 weeks of age, trabecular bone volume (BV/TV) was significantly greater (3-fold, $p<0.01$) in male and female DMP1Cre.SOCS3f/f mice compared to age- and sex-matched controls (DMP1Cre.SOCS3w/w). Trabecular thickness and number were also significantly higher. This high bone mass phenotype was significant also at 6 weeks of age in both sexes. However, at 12 weeks of age, while both male and female DMP1Cre.SOCS3f/f mice demonstrated a high level of bone remodeling, including significantly greater osteoid surface and volume ($p<0.01$), osteoblast surface ($p<0.0001$) and osteoclast surface ($p<0.05$), the effect of SOCS3 deletion on trabecular bone mass was profoundly different between sexes. In 12-week-old female DMP1Cre.SOCS3f/f mice, BV/TV was increased 7-fold ($p<0.0001$), such that the marrow space was almost entirely filled with rapidly remodeling bone. In contrast, males exhibited a ~50% reduction in BV/TV ($p<0.05$) compared to age- and sex-matched controls. At 26 weeks, male mice retained their low BV/TV, and the high bone mass phenotype of the females completely resolved to wildtype levels.

These data indicate that SOCS3-mediated inhibition of osteocytic JAK/STAT signaling restrains both bone formation and resorption, with the balance being sex- and age-specific. The striking sexually divergent phenotype at 12 weeks indicates that osteocytic JAK/STAT signaling is a key influence that determines sexual dimorphism in adult trabecular bone remodeling and bone mass.

Plasma Sphingosine 1-Phosphate Levels and the Risk of Osteoporotic Fractures: The Ceor Study. Mohammed-Salleh Ardawi*[1], Abdulrahim Rouzi[2], Nawal Al-Senani[2], Mohammed Qari[3], Shaker Mousa[4]. [1]Center of Excellence for Osteoporosis Research & Department of Clinical Biochemistry & KAU Hospital, Faculty of Medicine, King Abdulaziz University, Saudi Arabia, [2]Center of Excellence for Osteoporosis Research & Department of Obstetrics & Gynecology & KAU Hospital, Faculty of Medicine, King Abdulaziz University, Saudi Arabia, [3]Center of Excellence for Osteoporosis Research & Department of Haematology & KAU Hospital, Faculty of Medicine, King Abdulaziz University, Saudi Arabia, [4]The Pharmaceutical Research Institute, Albany College of Pharmacy & Health Sciences, USA

Background: In vivo and in vitro studies showed that sphingosine 1-phosphate (S1P) to act as a coupling factor stimulating osteoclastogenesis and controlling the migration of osteoclast precursosrs between blood and bone compartments. Also, S1P is known to stimulate osteoblastss proliferation, migration and survival. We

hypothesized that postmenopausal women with elevated plasma S1P levels might be related to greater risk for osteoporosis-related fractures (ORFs).

Methods: We studied, the association between circulating S1P [measured by ELISA kit (Echelon Biosciences Inc., USA)] and ORF risk in 707 postmenopausal women (age ⩾50 yrs), in a population-based study with a mean follow-up period of 5.2 ± 1.3 years. Multivariate Cox proportional-hazards regression models were used to analyze fracture risk, adjusted for age, body mass index, and other confounding risk factors.

Results: Plasma S1P levels (μmol/L) were significantly higher in women with ORFs (7.23 ± 1.79) than in those without ORFs (5.02 ± 1.51) (P<0.0001). High S1P levels were strongly associated with increased fracture risk. After adjustment for age and other confounders, the relative risk was >6.2-fold among postmenopausal women for each 1-SD increment increase in plasma S1P level. Women in the highest quartile of S1P levels had a 10-fold increase in fracture risk. Results were similar when we compared S1P at the 1-year visit to an average of 2-3 measurements. Fracture risk attributable to S1P levels was 31.5% in the highest quartile. Associations between S1P levels and fracture risk were independent of bone mineral density and other confounding risk factors.

Conclusions: High plasma S1P level appears to be a strong and independent risk factor for ORFs among postmenopausal women and could be a useful biomarker to improve fracture risk assessment.

Bone Material Strength as measured by microindentation in vivo is decreased independently of BMD in patients with fractures. Frank Malgo*[1], Neveen Hamdy[2], Socrates Papapoulos[2], Natasha Appelman-dijkstra[3]. [1]Leiden University Medical Center, Netherlands, [2]Leiden University Medical Center, The Netherlands, [3]LUMC Centre for Bone Quality Dept of Endocrinology, The Netherlands

Background: Bone strength depends on bone mass, architecture and composition. Besides a decrease in Bone Mineral Density (BMD), altered microarchitecture and biomechanical properties of bone contribute to fracture risk. A new technique of microindentation has been introduced for the in vivo measurement of the biomechanical properties of bone. We hypothesized that Bone Material Strength (BMS) as measured by microindentation would be lower in patients with osteopenia or osteoporosis and a fracture compared to those without.

Methods: We performed microindentation in 65 men and women with (Fx+) or without fractures(Fx-) and with osteopenia or osteoporosis as measured by DXA. Patients with metabolic bone diseases were excluded. Microindentation was performed using the Osteoprobe® Reference Point Indenter(Active Life Scientific Inc., Santa Barbara,CA. USA) in the midshaft of the tibia.

Results: Fx+ patients were older (60.0 years ± 14.0 vs. 51.9 years ± 15.3; p=0.044) and used more alcohol than Fx- patients (21% of patients vs. 0%; p=0.033), but there was no significant difference in the number of patients who were active smokers, had type 2 diabetes or used corticosteroids, nor in mean BMD values, BMI, serum levels of calcium, PTH or 25-OH vitamin D between groups. After adjusting for age, alcohol use and type 2 diabetes, BMS was significantly lower in Fx+ patients than in Fx- patients (BMS 78.5±0.9 vs. 84.1±4.6; p=0.010). Separate analysis of subjects with osteopenia (n=41) showed that Fx+ patients with osteopenia had significantly lower BMS values than Fx- patients with osteopenia (BMS 79.3±0.9 vs. 86.0±1.5; p=0.004). BMS was comparable in Fx+ patients with osteopenia and in Fx + patients with osteoporosis, BMS 79.3±0.9 vs. 76.7±2.1 (p=0.267) respectively, in the presence of significant differences on both the lumbar spine 0.91 g/cm^2 ± 0.02 vs. 0.78 g/cm^2 ± 0.02 (p=0.001) and the femoral neck 0.72 g/cm^2 ± 0.01 vs. 0.56 g/cm^2 ± 0.03 (p<0.001).

Conclusion: This study is the first to show that Bone Material Strength is significantly lower in fracture patients with osteopenia and comparable to fracture patients with osteoporosis. Our data suggest an aspect of altered bone quality contributing to bone fragility independent of BMD. Further studies are required to establish the value of Bone Material Strength as a predictor of fracture risk, especially in patients with osteopenia.

Effect of Vertebral Artifact and Exclusions on Fracture Prediction from Lumbar Spine BMD and TBS (Trabecular Bone Score): The Manitoba BMD Cohort. William Leslie*[1], Suzanne Morin[2], Lisa Lix[1], Sumit Majumdar[3], Didier Hans[4]. [1]University of Manitoba, Canada, [2]McGill University, Canada, [3]University of Alberta, Canada, [4]Lausanne University Hospital, Switzerland

Background: Age-related spondylosis is common and degrades lumbar spine DXA scan quality. Spine TBS (trabecular bone score) may be less sensitive to spondylosis but has not been studied in relation to fracture outcomes.

Methods: Using a registry of all clinical DXA results for Manitoba, Canada, we identified women age >40y with baseline spine DXA (GE Prodigy) from years 1999-2011. Vertebral exclusions were identified by ISCD-certified physicians at the time of initial clinical reporting. Spine TBS was measured by researchers at the University of Lausanne blinded to clinical outcomes. BMD and TBS T-scores were derived for the total spine, individual vertebral levels, minimum/maximum, and (if there were vertebral exclusions) the non-excluded and excluded levels. Incident major osteoporotic fractures (MOFs) and clinical vertebral fractures (VFs) were identified from population-based health services data, and fracture discrimination estimated from area under the ROC curve (AUROC).

Results: 47,736 women met the inclusion criteria. 15,938 (33%) had vertebral exclusions and these varied by level: L4 98%, L3 63%, L2 14%, L1 10%. Vertebral exclusions had a large effect on the BMD T-score (non-excluded levels -1.6, excluded levels -0.4) and on the TBS T-score (non-excluded levels -1.4, excluded levels -0.5). AUROC for predicting MOF from total spine BMD T-score was 0.673 in women without vs 0.642 with vertebral exclusions; non-excluded levels had higher AUROC (change +0.016) but excluded levels had worse AUROC (change -0.007). AUROC for MOF from total spine TBS T-score was 0.644 in women without vs 0.613 with vertebral exclusions; non-excluded levels had higher AUROC (change +0.010) but excluded levels had worse AUROC (change -0.037). Similar results were seen for clinical VFs based upon BMD (AUROC change non-excluded levels +0.026, excluded levels -0.011) and TBS (AUROC change non-excluded levels +0.019, excluded levels -0.055). In women with vertebral exclusions, BMD or TBS T-score for L1 showed higher AUROC for MOF prediction than for any other vertebral level, and minimum T-score showed better MOF prediction than maximum T-score.Summary: Spine DXA artifacts requiring vertebral exclusions affect both spine BMD and TBS. Excluded levels had higher BMD and TBS and worse fracture prediction. Exclusion of levels affected by artifact improved fracture prediction. BMD reporting procedures excluding lumbar spine artifacts also appear to be applicable to TBS.

Prospective Association between Novel Biomarker of Oxidative Stress and Hip Fracture in Postmenopausal Women. Shuman Yang*[1], Diane Feskanich[2], Walter Willett[2], Heather Eliassen[2], Tianying Wu[3]. [1]University of Cincinnati, USA, [2]Departments of Nutrition & Epidemiology, USA, [3]Department of Environmental Health, USA

Background: Human studies suggest that oxidative stress is a risk factor for osteoporosis, but its relationship with fracture risk is poorly understood. The purpose of the present study was to investigate the association between biomarker of oxidative stress and hip fracture in postmenopausal women.

Methods: We conducted a prospective study in the Nurses' Health Study among 996 postmenopausal women aged 60 years or older at baseline blood collection in 1989-1990. Plasma fluorescent oxidation products (FlOP)_320 was measured at 320/420 nm (excitation/emission) wavelengths. FlOP_320 is formed when oxidation products such as lipid hydroperoxides, aldehyde, and ketones react with DNA in prescence of metals. FlOPs generated from many different pathways (lipid, protein and DNA oxidation) reflect a global oxidation burden. FlOP assay is 10-100 times more sensitive than measurement of malondiadehyde (A specific lipid oxidation marker). We used Cox proportional hazards regression model to investigate the association between baseline FlOP_320 and risk of hip fracture, adjusting for age,

body mass index, history of osteoporosis, history of hypertension, prior fracture, physical activity, alcohol intake, postmenopausal hormone therapy, calcium intake, vitamin D intake, carotenoid intake, smoking status, fasting status, and time and month of blood draw.

Results: Forty four hip fractures (4.4%) were identified during the follow-up (Maximum = 23 years). In the multivariable model, the hazard ratios (HR) of hip fracture in the second and third tertiles of FlOP_320 were 2.17 (95% confidence interval [CI] = 0.90-5.26) and 2.80 (95% CI = 1.18-6.67), respectively, in comparison with the lowest tertile, and the risk increased linearly with increasing FlOP_320 (P for trend = 0.019). After stratifying our analysis by time of follow-up (<10 and ⩾ 10 years), we found similar risk estimates of hip fracture in both time intervals as the overall association between FlOP_320 and hip fracture. As an oxidation marker, we did not find significant interaction of FlOP_320 with fasting status (P = *0.358)*, alcohol intake (P = 0.126), current smokers (P = 0.955) and history of hypertension (P = 0.854) in assessing risk of hip fracture.

Conclusions: In this prospective study, higher plasma FlOP_320 was an independent risk factor for hip fracture. The marker may help improve the assessment of hip fracture risk in postmenopausal women.

Table 1. Association between plasma fluorescent oxidation products and risk of hip fracture

	Tertile 1	Tertile 2	Tertile 3	P for trend
N	331	331	334	—
Range (FI/ml)	< 335	≥ 335; < 546	≥ 546	—
Median (FI/ml)	270	404	1337	—
Incidence of hip fracture (n, %)	9 (2.7%)	15 (4.5%)	20 (6.0%)	—
Adjusted for age	1 (ref)	1.81 (0.79, 4.14)	2.51 (1.14, 5.52)	0.012
Adjusted for age and hypertension	1 (ref)	1.78 (0.78, 4.06)	2.35 (1.07, 5.18)	0.015
Adjusted for multiple risk factors*	1 (ref)	2.17 (0.90, 5.26)	2.80 (1.18, 6.67)	0.019

Values are hazard ratios (95% confidence interval), unless otherwise specified. FlOP = Fluorescent oxidation products, FI = Fluorescent intensity units.
*Risk factors included age (continuous), history of hypertension (yes/no), body mass index (< 25, ≥ 25 and < 30, ≥ 30 and <35, and ≥ 35 kg/m^2), fasting status (< 8 and ≥ 8 hours), time and month of blood draw, alcohol intake (In quartiles: 0, > 0 and <1, ≥ 1 and < 6.7, and ≥ 6.7 g/day), physical activity (In quartiles: < 5.2, ≥ 5.2 and < 12.7, ≥ 12.7 and < 25.9, and ≥ 25.9 MET-hours/week), total calcium intake (In quartiles: < 667, ≥ 667 and < 969, ≥ 969 and < 1347, and ≥ 1347 mg/day), total vitamin D intake (In quartiles: < 187, ≥ 187 and < 303, ≥ 303 and < 536, and ≥ 536 IU/day), total carotenoid intake (In quartiles: < 6.2, ≥ 6.2 and < 9.0, ≥ 9.0 and < 12.8, and ≥ 12.8 1000 IU/day), history of osteoporosis (yes/no), smoking status (current smokers, past smokers, non-smokers), postmenopausal hormone therapy (yes/no) and prior fracture (yes/no).

Beyond BMD: Trochanteric Soft Tissue Thickness Predicts Hip Fracture in Older Adults. Alyssa Dufour*[1], Arunima Awale[1], Douglas Kiel[1], Ann Schwartz[2], Deborah Kado[3], Eric Orwoll[4], Mary Bouxsein[5], Marian Hannan[6]. [1]Hebrew SeniorLife, USA, [2]University of California, San Francisco, USA, [3]University of California, San Diego, USA, [4]Oregon Health & Science University, USA, [5]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [6]HSL Institute for Aging Research & Harvard Medical School, USA

Hip fractures are disabling events and 25% of adults over 50 years will die in the year following fracture. Low BMD is a well-accepted major risk factor, yet up to half of those suffering a hip fracture do not have low BMD; alternative methods of assessing fracture risk are needed. To look beyond BMD, we examined the relation between factors that influence the load applied to the hip in a sideways fall and risk of hip fracture in men and women from the Framingham Osteoporosis Study.

In a nested case-control study, we measured trochanteric soft tissue thickness (STT, mm) of both hips from whole body DXA scans (Lunar DPX-L) done in 1996-2001 (baseline). Averages of right and left hip STT measurements were used for analyses. Factor-of-Risk (FoR) was defined as the ratio of attenuated force applied to the hip in a sideways fall divided by femoral strength. Attenuated force (N) was calculated from height (m) and weight (kg) and incorporated the cushioning effect of STT. Femoral strength (N) was estimated from femoral neck BMD using published cadaveric femoral strength testing. Incident hip fractures were confirmed by interview and review of medical records through 12/31/08. Hip fracture cases were matched to 4 non-fracture controls by sex and age ±3 years. We used conditional logistic regression to calculate odds ratios (OR) and 95% confidence intervals (CI) for a 1 SD decrease in BMD and STT or a 1 SD increase in FoR and the risk of hip fracture. We adjusted for femoral neck BMD (g/cm^2) in STT models only. AIC indicated model fit (lower values=better).

In 190 participants, at baseline, average age was 69 years (±9, range 45-87), BMI was 28 kg/m^2 (±5.2), BMD was 0.801 g/cm^2 (±0.137) and 76% were female. There were 38 incident hip fractures over 9±3.8 yrs follow-up (mean STT: 40.2mm ± 17.9) and 152 age- and sex- matched controls (mean STT: 50.6mm ± 21.5). Lower BMD predicted hip fracture (OR=2.9, p=.0002)(Table). Hip fracture risk increased 2.4-fold higher per 1 SD (21.21mm) decrease in STT, even after adjustment for BMD (OR=1.8). Increased FoR was also predictive of hip fracture (OR=2.9). Using the AIC statistic, we found that a model including STT and BMD was the best predictor of hip fracture.

These results show strong evidence that STT, easily measured from DXA scans, is predictive of hip fracture independent of BMD. Future work should consider this effect compared to FRAX score and, with larger numbers of hip fractures in both men and women.

OR and 95% CI for association between BMD, Trochanteric Soft Tissue Thickness and Factor of Risk with hip fracture per 1 standard deviation change.					
	Mean (SD)	OR	95% CI	p-value	AIC[3]

Gene Panel Diagnostics for Disorders with Abnormal Bone Mass: Results From 50 Patients. Uwe Kornak*[1], Ralf Oheim[2], Peter Krawitz[1], Tomasz Zemojtel[3], Michael Amling[2], Stefan Mundlos[1], Peter N. Robinson[1]. [1]Charité-Universitaetsmedizin Berlin, Germany, [2]University Medical Center Hamburg-Eppendorf, Germany, [3]Labor Berlin - Charité Vivantes GmbH, Germany

Disorders with abnormal bone mass have their origin in skeletal development and/or homeostasis. Common consequences are reduced mechanical stability leading to bone deformation or fractures, as well as chronic pain and hematological, immunological, and neurological complications. The spectrum ranges from rare early-onset forms to the very common medical problem late-onset osteoporosis. While the role of common genetic polymorphisms for the susceptibility to late-onset osteoporosis has been extensively investigated the role of rare variants is still poorly defined. In order to offer comprehensive genetic testing at an affordable cost we developed a next-generation sequencing-based gene panel comprising coding and non-coding regions relevant for disorders with abnormal bone mass. We here present exemplary genotyping results of 50 patients with early-onset disorders as well as common late-onset osteoporosis. A special focus will be put on osteoporosis cases in which we unexpectedly identified bona fide mutations in the *FGFR1*, *LRP5, RUNX2, and WNT1* genes, respectively, thus proving the relevance of the rare-among-the-common hypothesis. In these cases genetic diagnostics can radically change the interpretation of disease phenotype, prognosis and recurrence risk and can be the basis for an optimal individualized therapeutic strategy.

Suppression of osteoprotegerin by glucocorticoids may underlie their adverse effects on cortical bone mass. Marilina Piemontese*[1], Jinhu Xiong[2], Rajamani Selvam[1], Priscilla Baltz[1], Stuart Berryhill[1], Erin Hogan[1], Robert Weinstein[2], Stavros Manolagas[2], Charles O'Brien[2]. [1]University of Arkansas for Medical Sciences, USA, [2]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

Glucocorticoid administration causes low bone mass by acting directly on osteoblasts and osteoclasts. However, most studies in mice have focused on the trabecular compartment and the effects of glucocorticoids on the cortical compartment are less well characterized. Here we have analysed the impact of glucocorticoids on cortical bone by treating mice with placebo or prednisolone (2.1 mg/kg/day) for 28 days. Prednisolone administration reduced femoral BMD as measured by DEXA, compared to placebo treated mice, but did not change body weight. Prednisolone also reduced cortical thickness and increased cortical porosity at the metaphysis of femur, as measured by microCT, and this was associated with a decline in strength, as assessed by 3-point bending. Histological analysis of tibial sections revealed elevated osteoclast number at the endocortical surface of prednisolone treated mice, compared to placebo treated mice. Consistent with these findings, expression of osteoclast specific genes, such as calcitonin receptor and tartrate resistant acid phosphatase, was increased in the cortical bone of prednisolone treated mice. These changes in osteoclasts were associated with reduced expression of osteoprotegerin (OPG) in osteocyte-enriched cortical bone. In contrast, expression of receptor activator of nuclear factor kappa-B ligand (RANKL) was unaffected by prednisolone. OPG protein in the bone marrow supernatants was also reduced by prednisolone. These results suggest that glucocorticoids increase osteoclast number in cortical bone by acting on osteoblast lineage cells. To determine whether glucocorticoid action directly on osteoclasts also contributes to the changes in cortical bone, we used mice in which osteoclasts are protected from the actions of glucocorticoids by transgenic expression of 11beta-hydroxysteroid dehydrogenase type 2, an enzyme that inactivates glucocorticoids. Administration of prednisolone to these mice or their control littermates resulted in similar amounts of cortical bone loss and strength. These findings suggest that the detrimental effects of glucocorticoids on the cortical bone compartment result from suppression of OPG production by osteocytes.

Deletion of the androgen receptor in osteoblast progenitors (using Prx1-Cre) reduces bone mass and precludes the effects of orchidectomy in cancellous, but not cortical, bone. Semahat Serra Ucer*[1], Aaron Warren[2], Shoshana Bartell[3], Srividhya Iyer[3], Li Han[3], Julie Crawford[2], Charles O'Brien[3], Maria Jose Almeida[3], Stavros Manolagas[3]. [1]University of Arkansas for Medical Sciences, USA, [2]Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA, USA, [3]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

In males, androgens are critical for the acquisition of bone mass in both the cortical and cancellous bone compartment during growth and for its maintenance throughout life. Mice with global deletion of the androgen receptor (AR) exhibit low cortical and cancellous bone mass. On the other hand, targeted deletion of AR in osteoblasts or osteocytes results in lower cancellous bone mass, but it has no effect on the cortical compartment. And, as we report elsewhere in this meeting, AR deletion from osteoclasts (using LysM Cre) has no bone phenotype. It is still possible, however, that the effects of androgens on the cortical compartment result from actions on osteoprogenitors. We have, therefore, generated mice with conditional deletion of an AR allele in pluripotent mesenchymal progenitors, using Prx1-Cre (AR flox;Prx1-Cre). At 7 weeks of age, when androgen levels start to rise in mice, the skeletal phenotype of AR flox;Prx1-Cre male mice was indistinguishable from the AR flox littermate controls by micro-CT. At 12 and 26 weeks of age, however, the AR flox;Prx1-Cre exhibited a 30% and 45% decrease of cancellous bone volume, respectively; as well as lower trabecular number and connectivity. Cortical thickness was unaffected at all ages. We next sham-operated or orchidectomized (ORX) 20-week-old AR flox;Prx1-Cre and AR flox mice, and examined their skeletons 6 weeks later. ORX caused the expected decrease in BMD at the femur in AR flox mice as compared to the sham-operated littermates. In contrast, the effect of ORX on femoral BMD was completely abrogated in the AR flox;Prx1-Cre mice. ORX also decreased cancellous bone volume and trabecular number in the femur of control mice, while it had no effect in the AR flox;Prx1-Cre mice. In contrast to our findings in cancellous bone, both control and AR flox;Prx1-Cre mice lost similar amount of cortical bone with ORX. These results demonstrate that AR deletion in the osteoblast lineage recapitulates the effects of ORX in cancellous bone, indicating that the protective effects of androgen on cancellous bone result from AR-mediated effect of androgen in osteoblast progenitors or their descendants. The protective effects of androgens on cortical bone mass, on the other hand, must be mediated by cells other than those of the osteoblast or the osteoclast lineage.

Prolyl Hydroxylase 2 (PHD2) controls Bone Homeostasis through increasing Erythropoietin Production via HIF2α. Martina Rauner*[1], Kristin Franke[2], Lorenz Hofbauer[3], Ben Wielockx[2]. [1]Medical Faculty of the TU Dresden, Germany, [2]Technische Universität Dresden, Germany, [3]Dresden University Medical Center, Germany

Prolyl hydroxylase 2 (PHD2) regulates hypoxia-inducible factor α (HIFα) transcription factors and thus, erythropoietin (EPO) production. Under normoxic conditions, HIFα is constantly inactivated through hydroxylation by PHD2. Due to the embryonic lethality of PHD2 knock-out mice, its precise role in erythropoiesis and tissue homeostasis has long remained unknown. Recently, we generated a conditional knock-out (cKO) mouse lacking PHD2 in EPO-producing cells. These mice have high levels of EPO and an increased hematocrit, which is dependent on HIF2α. In this study, we determined the role of PHD2 in bone.

Total, trabecular, and cortical bone density at the femur was significantly decreased by 12%, 20%, and 5% in cKO as compared to wild-type (WT) mice. Results were confirmed using histomorphometry, showing a 38% decrease in bone volume in the tibia, accompanied by microarchitectural changes including fewer trabeculae (-33%) and an increased trabecular spacing (+59%) in cKO mice. Bone resorption was not affected, as determined using serum levels of C-terminal telopeptide of type I collagen and tartrate-resistant acid phosphatase, and the histological evaluation of osteoclasts. In addition, conditional knock-out of PHD2 using the lysM-cre and vav-cre lines did not result in an altered bone phenotype. In contrast, osteoblasts function was severely impaired. Serum levels of procollagen type I N-terminal propeptide and osteocalcin were decreased by 30-40% in cKO mice. In line with that, the mineralized surface, the mineral apposition rate, the bone formation rate, and the osteoblast surface were reduced by 35-50%. Because cKO are characterized by high serum EPO levels, we next assessed the bone phenotype in EPO-treated mice. Similar to cKO, mice treated with 3 U EPO per day for 28 days had a lower vertebral trabecular bone mineral density (-18%) and a lower local rate of bone formation (BFR: -29%). To further pinpoint which downstream signals are involved in the bone phenotype of cKO mice, we used PHD2/HIF1α (P2/H1) and PHD2/HIF2α (P2H2) double-knock-out (DKO) mice. While P2/H1 DKO mice, which also have high EPO levels, showed a similar bone phenotype as cKO, including decreased bone density and bone formation, bone density was restored in P2/H2 DKO mice, which have normal EPO levels.

Thus, PHD2 controls bone homeostasis at least in part through increasing HIF2α-dependent EPO production and thus, is a novel player in osteohematology.

An O-glycosylation on Fibronectin Mediates Hepatic Osteodystrophy by Interacting with α4β1 Integrin. Carla Sens*[1], Nina Kawelke[1], Anja von Au[1], Inaam Nakchbandi[2]. [1]University of Heidelberg & Max-Planck Institute of Biochemistry, Germany, [2]Max-Planck Institute of Biochemistry & University of Heidelberg, Germany

Patients with autoimmune liver disease experience increased circulating levels of a fibronectin (FN) isoform that is characterized by the presence of O-glycosylation called oFN by 40% ($p<0.05$) compared to healthy controls. This isoform significantly inhibits osteoblast differentiation *in vitro* (as measured by nodule formation, alkaline phosphatase activity or osteocalcin). Injection of oFN in mice over two weeks results in decreased BMD by 17%, osteoblasts by 45% and BFR by 60% compared to vehicle-treated mice (all $p<0.05$). Enzymatic O-deglycosylation of oFN normalized nodule formation *in vitro*. Three possible O-glycosylation sites have been described in FN. Mutations in these three sites followed by transient transfection in primary newborn murine osteoblasts and evaluation of osteoblast differentiation were performed. This allowed localization of the responsible O-glycosylation site at AA 33 of the variable region. Indeed, simultaneous addition of oFN and an antibody that recognizes this O-glycosylation (glyc-Ab) normalized osteoblast differentiation. Further, oFN decreased pERK by 50%, while oFN+glyc-Ab normalized and the transfection with the mutated construct increased pERK two-fold. This suggests that oFN acts by inhibiting integrin-mediated signaling. The variable region of FN binds to α4β1 or α4β7 integrin. Differentiating osteoblasts express α4 and β1 but not β7 by flow cytometry. oFN decreased surface expression of α4β1 by 62%, while oFN+glyc-Ab normalized α4 expression. Based on these findings we hypothesized that α4β1 mediated oFN effects on osteoblasts. An antibody that binds to α4β1 (PS/2) was added to osteoblasts treated with oFN. Osteoblast differentiation *in vitro* and pERK normalized in the presence of oFN+PS/2 suggesting that α4β1 mediates the inhibition of oFN on the osteoblasts. To test this *in vivo* we injected oFN in mice in which β1 integrin was deleted in osteoblasts (col-α1(I)-cre $\beta1^{fl/fl}$). In these mice oFN failed to decrease BMD in contrast to controls. This suggests that b1 integrin on the osteoblasts is needed to mediate oFN effects.

In summary, oFN elevation in patients with hepatic osteodystrophy results in inhibition of osteoblast activity. An O-glycosylation in the variable region of fibronectin mediates this effect. This O-glycosylation acts by interfering with a4b1 integrin-mediated signaling. We have thus characterized the defect and the receptor mediating bone loss in patients with hepatic osteodystrophy.

What generates porosity in cortical bone?. Nicolai Lassen*[1], Thomas Andersen[2], Jean-Marie Delaisse[3], Søren Harving[4], Ellen Hauge[5], Gete Eschen[6], Jesper Thomsen[7], Annemarie Brüel[8]. [1]Vejle Hospital, Denmark, [2]Vejle Hospital - Lillebaelt Hospital, IRS, University of Southern Denmark, Denmark, [3]Vejle Hospital, IRS, University of Southern Denmark, Denmark, [4]Department of Orthopaedic Surgery, Aalborg Hospital, Denmark, [5]Aarhus University Hospital, Denmark, [6]Department of Plastic Surgery, Aarhus Hospital, Denmark, [7]Aarhus University, Denmark, [8]University of Aarhus, Denmark

Cortical bone has a considerable, but often disregarded, contribution to the overall strength of bone. The physiological process greatly affecting bone strength is bone remodelling. A cortical bone remodeling unit is commonly described to involve a cutting cone of osteoclasts (OC) excavating a tunnel (called a Haversian canal), a reversal zone generating an osteogenic environment, and a closing cone where bone forming osteoblasts (OB) refill the canals until only a narrow canal remains. With age, not only the number but also the diameter of Haversian canals increases, resulting in increased porosity, which weakens the bone. Herein, we aim at identifying the biological activities leading to increased porosity.

We used therefore human bone specimens from five proximal femurs and two fibulae. We took benefit of sections cut in the longitudinal direction of the Haversian canals, making it possible to follow the sequential remodeling steps. Serial sections were immunostained for OC (TRAcP and cathepsin K) and OB (Runx2 and CD56) markers, thereby allowing 3D reconstructions of the distribution of OC and OB activities in a remodelling unit.

The analysis revealed that so-called "reversal" surfaces were not only lined by typical osteoprogenitor cells expressing Runx2 and CD56, but also by OCs exerting "secondary" resorption on the lateral surfaces of the canals, and thus widening them. In a 2D analysis, 35% of the detected reversal surfaces showed secondary resorption, but the systematic 3D analysis of 21 Haversian canals with remodeling events revealed that all reversal surfaces showed secondary resorption. Furthermore, the 3D analysis revealed that secondary resorption occurred mostly on early reversal surfaces (close to the cutting cone), where OCs and osteoprogenitors were closely interacting. Later reversal surfaces (close to the osteoid) were only lined with osteoprogenitors.

In conclusion, in cortical bone remodeling the reversal phase does not simply represent a switch turning off the resorption of the cutting cone and turning on pro-osteogenic activities, as would commonly be expected from a "reversal" phase. It rather appears as a bone remodeling step where OCs and OB-lineage cells compete, thereby determining how much bone will be removed laterally, and how soon the bone removed by the OC can be replaced by bone forming OBs.

Dysregulated innate immune responses mediate chronic inflammation leading to osteoarthritis. Evangelia Kalaitzoglou*[1], Mary Beth Humphrey[2]. [1]OUHSC, USA, [2]University of Oklahoma Health Sciences Center, USA

Obesity increases the risk of developing OA in weight-bearing and non-weight-bearing joints suggesting that both mechanical and non-mechanical factors associated with obesity increase the risk of OA. Chronic, low-grade inflammation may provide a critical link between obesity and OA. Abnormal innate immune responses in obesity, likely mediated via free fatty acid (FFA) activation of Toll-Like Receptor 4 (TLR4), increase pro-inflammatory mediators, such as tumor necrosis factor-α (TNFα), and contribute to the development of OA. TREM2, paired with DAP12, inhibits TLR-induced cytokine responses in macrophages and therefore may provide protection from high-fat diet induced OA. We hypothesize that high fat diet- induced OA is partly mediated by dysregulation of innate immune responses to FFA leading to increased pro-inflammatory cytokines driving abnormal cellular and tissue responses within joints resulting in OA. To test our hypothesis, macrophages derived from wild type (WT) and DAP12-deficient (DAP12 KO) mice were stimulated with endotoxin free FFA (palmitic and lauric acid) and proinflammatory cytokines, ERK and NFκB activation, as measured by IKBa degradation, were evaluated. WT and TREM2-deficient (TREM2 KO) mice were placed on a high fat diet for 3 months and knee joints evaluated histologically for OA changes. Our studies show that WT macrophages have dose and time-dependent ERK activation and IKBa degradation as well as TNFα production in response to palmitic acid and lauric acid. Compared to WT macrophages, DAP12 KO macrophages have increased TNFα production and ERK and NFκB activation in response to palmitic acid and lauric acid stimulation, indicating that DAP12 negatively regulates FFA-induced responses in macrophage. TREM2 KO mice on a high fat diet have increased histological changes of early knee osteoarthritis compared to WT mice. Ongoing studies with mice on a high fat diet will reveal whether TRL4 KO mice are protected from high-fat diet induced OA when compared to DAP12 KO mice that may have early or more severe osteoarthritis. In conclusion DAP12 and TREM2 signaling complex has an immunoregulatory function in FFA stimulated cytokine responses in macrophages. TREM2 KO mice have accelerated OA compared to WT mice on a high fat diet. By examining how high fat diet alters innate inflammatory and metabolic pathways associated with OA, we hope to develop novel therapeutic targets to prevent or suspend the progression of osteoarthritis.

Increasing 25-hydroxyvitamin D levels over time: The Study of Women's Health Across the Nation (SWAN). Deborah Mitchell*[1], Hang Lee[2], Gail Greendale[3], Jane Cauley[4], Sherri-Ann Burnett-Bowie[1], Joel Finkelstein[1]. [1]Massachusetts General Hospital, USA, [2]Massachusetts General Hospital, USA, [3]University of California, Los Angeles, USA, [4]University of Pittsburgh Graduate School of Public Health, USA

The importance of vitamin D for bone health as well as its potential role in nonskeletal health has garnered much recent attention. Population-based studies investigating temporal trends in 25-hydroxyvitamin D (25OHD) have reported conflicting results. Our goal was thus to investigate changes in mean 25OHD levels over time and predictors of these changes in the Study of Women's Health Across the Nation (SWAN), a multi-center, racially and ethnically diverse cohort of women. 1582 women had 25OHD measured in 1998-2000 (at age 48±3 years) and again in 2009-2011 (at age 60±3 years). 25OHD was measured by liquid chromatography-tandem mass spectrometry in a single batch. Over this interval, the mean 25OHD level increased by 6.5 ng/mL (95% CI 5.9 to 7.0), from 21.5±9.8 to 28.0±11.5 ng/mL ($p<0.001$ after adjustment for age, BMI, menopausal status, study site, and season of blood draw). As expected, baseline mean 25OHD levels varied by race/ethnicity (14.0 ng/mL (African-American), 25.4 ng/mL (Caucasian), 19.8 ng/mL (Chinese), 18.3 ng/mL (Hispanic), and 24.0 ng/mL (Japanese) ($p<0.001$)). However, the magnitude of increase was similar among groups, ranging from 5.3 ng/mL (Caucasian) to 8.7 ng/mL (Chinese) (Figure 1). The observed increases in 25OHD did not vary by socio-economic status (SES), education level, or acculturation. At the 2009-2011 visit, 49% of subjects reported taking a multivitamin or vitamin D supplement; the adjusted increase in 25OHD was higher among supplement users (10.1 vs. 3.2 ng/mL, $p<0.001$). Using the Institute of Medicine definition of vitamin D deficiency as 25OHD < 20 ng/mL, the proportion of deficient women decreased from 43% to 24% ($p<0.001$) over the interval. Among those who reported using supplements at the 2009-2011 visit, the proportion deficient decreased from 35% to 6% ($p<0.001$) while the proportion decreased from 51% to 39% among non-users ($p<0.001$). Rates of 25OHD < 20 ng/mL were significantly lower among supplement users of all racial/ethnic groups ($p<0.001$ for all comparisons at the 2009-2011 visit) (Figure 2). In summary, we observed an increase in average 25OHD levels as well as a decrease in the proportion of subjects with vitamin D deficiency in this observational cohort over an approximately 11 year interval. Subjects of all races/ethnicities as well as of differing SES, level of education, and degree of acculturation had similar changes. Use of vitamin supplements was a major determinant of changes in 25OHD levels.

Serum 25 Hydroxyvitamin D (25(OH)D), Bone Mineral Density (BMD) and Fracture Risk across the Menopausal Transition: Study of Women's Health Across the Nation (SWAN). Jane Cauley*[1], Gail Greendale[2], Kristine Ruppert[3], Yinjuan Lian[3], John Randolph[4], Joan Lo[5], Robert Neer[6], Sherri-Ann Burnett-Bowie[6], Joel Finkelstein[6]. [1]University of Pittsburgh Graduate School of Public Health, USA, [2]University of California, Los Angeles, USA, [3]University of Pittsburgh, USA, [4]University of Michigan, USA, [5]Kaiser Permanente, USA, [6]Massachusetts General Hospital, USA

Circulating 25(OH)D has been linked to fracture risk but to our knowledge, there is no information on whether 25(OH)D predicts fracture over the menopausal transition or whether 25(OH)D is associated with changes in BMD over the menopausal transition. We studied 1620 women enrolled in the bone cohort of the Study of Women's Health Across the Nation (SWAN). Women attended up to 11 clinic visits for an average follow-up of 9.5 years. 25(OH)D was measured at the 02 clinic visit, 2 years after enrolling in SWAN. At this time, 1207 (74.5%), were pre or early perimenopausal; 116(7.2%) late perimenopausal, 77(4.8%) postmenopausal based on bleeding patterns. Menopausal status or had hysterectomy was unknown for 220 (13%). The mean 25(OH)D (ng/ml) was 21.6 but differed markedly by race/ethnicity; White, 25.2; Black, 14.1; Chinese, 20.1 and Japanese, 23.5, $p<0.001$); 703 (43%) had a value < 20ng/ml. The mean age of the women at time of 25(OH)D measure was 48.5 ± 2.7, with no difference by race/ethnicity. Body mass index (BMI) (kg/m^2) was greatest in Black women, 31.8; lower in White women, 28.2 and lowest in Japanese, 23.5 and Chinese, 23.2 women. Incident non-traumatic fractures that occurred after visit 02 were ascertained at each annual visit initially by self-report and later, confirmed by radiographic report. A total of 88 women experienced an incident non-traumatic fracture. Cox proportional hazard models were used to calculate the hazard ratio (HR) (95% confidence interval (CI)). Each 10 ng/ml increase in 25(OH)D was associated with a 25% lower fracture risk, even after adjusting for BMI, BMD

and other important confounding variables, Table. Women with 25(OH)D >20 ng/ml had a 42% lower risk of fracture. Exclusion of women who were already postmenopausal at visit 02 had no effect. Longitudinal analyses of BMD across the menopausal transition were confined to the subset of 791 women for whom a final menstrual period (FMP) could be determined. The mean 25(OH)D level in this subgroup (21.2 ng/ml) was similar to the total population. We compared rates of spine and hip BMD changes in women from -5 to -1 yr before the FMP, 1 year before to 2 years after FMP and 2 to 5 years after FMP. We found no association between (25(OH)D and transmenopausal bone loss. We conclude that women with higher 25(OH)D levels at midlife have a lower risk of subsequent fractures. Vitamin D supplementation may be warranted in women with 25(OH)D <20 ng/ml.

Table: 25(OH)D and fracture over the menopausal transition

25(OH)D	Base Model[1] HR(95% CI)	Multivariate Model[2] HR(95% CI)
per 10 ng/ml increase	0.75(0.58, 0.96)	0.75(0.57, 0.997)
≥ 20 vs <20 ng/ml	0.55(0.35, 0.86)	0.58(0.35, 0.96)

Intestinal Calcium Absorption Decreases Dramatically After Gastric Bypass Surgery, Despite Optimization of Vitamin D Status. Anne Schafer*[1], Deborah Sellmeyer[2], Connie Weaver[3], Amber Wheeler[4], Lygia Stewart[5], Stanley Rogers[4], Jonathan Carter[4], Andrew Posselt[4], Dennis Black[4], Dolores Shoback[6]. [1]University of California, San Francisco & the San Francisco VA Medical Center, USA, [2]The Johns Hopkins Bayview Medical Center, USA, [3]Purdue University, USA, [4]University of California, San Francisco, USA, [5]San Francisco VA Medical Center & the University of California, San Francisco, USA, [6]VA Medical Center, USA

Roux-en-Y gastric bypass (RYGB) surgery has negative effects on the skeleton. RYGB can result in vitamin D malabsorption. Additionally, the bypassed duodenum and proximal jejunum are usual sites of active, transcellular calcium (Ca) uptake. However, Ca absorption occurs throughout the intestine, and those who have undergone RYGB might maintain sufficient Ca absorption, particularly if vitamin D status is optimal. We determined the effects of RYGB on fractional Ca absorption in the setting of optimized vitamin D status and recommended Ca intake, hypothesizing that these efforts would mitigate against post-op declines in Ca absorption and bone mass.

A prospective cohort of 33 obese men and women (body mass index 45 $\pm$7 kg/m^2) had serum 25-hydroxyvitamin D [25(OH)D] levels repleted and maintained at ⩾30 ng/mL before and after RYGB. Total daily Ca intake of 1200 mg was maintained with individually-dosed Ca citrate supplements. Fractional Ca absorption was measured pre-op and 6 months post-op with a dual stable isotope method. Isotope enrichment was determined by inductively coupled plasma mass spectrometry. Laboratory measures and bone mineral density (BMD) by DXA were assessed. We report here the first 22 participants' pre- and post-op data.

Mean 6-month weight loss was 33 kg (Table). Fractional Ca absorption decreased from 0.33 $\pm$0.14 to 0.07 $\pm$0.04 ($p<0.001$), despite serum 25(OH)D levels of 41 (pre-op) and 38 (post-op) ng/mL. PTH level increased, and urinary Ca decreased. Bone turnover markers increased markedly, and BMD decreased at the total hip and femoral neck. Greater percentage weight loss and decreases in IGF-1 and IGF-binding protein 3 levels were correlated with larger percentage decreases in fractional Ca absorption (Spearman's ρ 0.51, 0.50, and 0.59, respectively; all p-values ≤0.04). Those with larger percentage decreases in fractional Ca absorption had greater increases in serum CTX, but changes in fractional Ca absorption and BMD were not correlated.

We conclude that even with maintenance of 25(OH)D levels ⩾30 ng/mL, fractional Ca absorption decreases dramatically after RYGB. These findings suggest that in addition to addressing vitamin D deficiency, clinicians must ensure sufficient Ca intake post-op, although the approach to Ca supplementation needs to be established. Among RYGB patients, those who lose the most weight may have the most severe declines in Ca absorption. Strategies to avoid long-term skeletal consequences should be investigated.

Fractional Ca absorption and other parameters, before and after RYGB

Variable	Pre-op	6 months post-op	p-value
Weight (kg)	127 ± 19	93 ± 15	<0.001
BMI (kg/m^2)	45 ± 8	33 ± 6	<0.001
Fractional Ca absorption	**0.33 ± 0.14**	**0.07 ± 0.04**	**<0.001**
25(OH)D (ng/mL)	41 ± 10	38 ± 13	0.21
24-hour urinary Ca (mg)	145 ± 96	105 ± 77	0.02
Serum Ca (mg/dL)	9.2 ± 0.3	9.2 ± 0.3	0.55
PTH (pg/mL)	47 ± 31	53 ± 21	0.04

Vitamin K1 supplementation does not improve bone health even among postmenopausal women with low baseline serum vitamin K1: Secondary analyses from the ECKO trial. Maryam Hamidi*[1], Hanxian Hu[1], Olga Gajic-Veljanoski[1], Judy Scher[1], Angela M. Cheung[2]. [1]University Health Network, Canada, [2]University Health Network-University of Toronto, Canada

Background: Observational studies have shown associations between vitamin K1 insufficiency and impaired bone health status in postmenopausal women. However, the findings of clinical trials suggest that vitamin K1 supplementation in healthy postmenopausal women does not improve bone health. Conversely, clinical trials have shown vitamin K2 supplementation to be beneficial to bone health in frail and elderly women with osteoporosis. Therefore, it has been hypothesized that vitamin K supplementation may improve bone health in postmenopausal women, only if they have subclinical vitamin K deficiency. So far, no studies have examined the effect of vitamin K1 supplementation on bone health in postmenopausal women with low baseline serum vitamin K concentrations. Objectives: To examine whether vitamin K1 supplementation reduces bone loss, as measured by BMD, and bone turnover (BTM) in postmenopausal women with osteopenia and low fasting serum concentrations of vitamin K1. Methods: This is a secondary analysis of the ECKO trial including 161 women who had baseline fasting serum vitamin K concentrations ≤ 1 nmol/l. In the ECKO trial 440 postmenopausal women with osteopenia were randomized to receive vitamin K1 (5mg/d) or placebo for 2-4 years to examine the effect of vitamin K on bone health. All study participants were advised to maintain a total daily intake of 1500 mg of calcium and 800 IU of vitamin D throughout the study. BMD outcomes were 2-year change in lumbar spine, femoral neck, total hip and ultradistal radius BMD. BTM outcomes were 2-year change in osteocalcin, C-terminal telopeptide and percentage of under-carboxylated osteocalcin. We used two-sample t-test for all outcomes. A 2-sided p-value < 0.05 was considered statistically significant. All analyses were performed using SAS 9.3. Results: Median fasting serum vitamin K1 at 2-years was 17.4 (IQR:9-27.9) nmol/l for the treatment group, and 1.05 (IQR:0.6-1.75) nmol/l for the placebo group. There were no significant differences between the two groups in any of the bone health outcomes. There was a significant difference between 2-year change in serum concentrations of vitamin K1 between the two groups ($p<0.0001$). We found no interactions between group and 2-year change in 25-hydroxyvitamin D concentrations. Conclusion: Vitamin K1 supplementation (5mg/d) for 2 years does not improve bone health status in postmenopausal women with osteopenia who have low fasting baseline serum vitamin K concentrations.

Trabecular Plate-Rod Morphology and Connectivity are Abnormal and Associated with Reduced Bone Stiffness in Women Treated with Glucocorticoids. Ji Wang[1], Bin Zhou[1], Kyle Nishiyama[1], Stephanie Sutter[2], X Guo[1], Emily Stein*[3]. [1]Columbia University, USA, [2]Columbia University Medical Center, USA, [3]Columbia University College of Physicians & Surgeons, USA

Glucocorticoids (GCs) increase fracture risk through mechanisms distinct from their effects on bone density. We previously reported that postmenopausal women using oral GCs have lower volumetric bone density, cortical thickness and thinner, more widely and irregularly spaced trabeculae compared to controls. In this study, we further investigated structural mechanisms associated with fragility in these patients using individual trabecula segmentation (ITS)-based morphologic analysis. This three-dimensional model independent technique is based upon high-resolution peripheral quantitative CT scans and directly measures individual trabeculae, characterizing trabecular (Tb) type (plate vs. rod), orientation and connectivity. We hypothesized that GC treated women would have fewer Tb plates and less Tb connectivity compared to controls. Women treated with oral GCs for >3 months (n=30) were matched by age and race with women never exposed to GCs (n=60). Mean age was 68 yrs (67% Caucasian).

Among GC-treated subjects, 67% had rheumatologic disease, mean dose of prednisone was 8 mg/d, and treatment duration was 3 years. Areal BMD by DXA was similar at all sites. By ITS at the radius, GC subjects had significantly lower directly measured bone volume fraction (-13%;p<0.03), fewer Tb plates (-7%;p<0.03) and tended to have fewer Tb rods (-4%;p=0.08). They had significantly fewer axially aligned trabeculae (-16%;p<0.03), lower connectivity between plates (-19%;p<0.02) and between plates and rods (-17%;p<0.02). At the tibia, GC-treated women tended to have lower bone volume fraction (-8%;p=0.052), had significantly fewer Tb plates (-6%;p<0.02), fewer axially aligned trabeculae (-14;p<0.01) and less connectivity between plates (-14%;p<0.02). They tended to have less connectivity between plates and rods (-10%;p=0.06). Whole bone stiffness by finite element analysis, was lower among GC subjects at both radius (-16%;p<0.005) and tibia (-11%;p<0.02). Lower stiffness was associated with lower bone volume fraction, fewer plates, fewer axially aligned trabeculae, and less Tb connectivity (r=0.59-0.70;p<0.001 for all). The ITS images below, with plates in green and rods in red, show fewer Tb plates in GC-treated subjects. In summary, GC-treated women had fewer Tb plates, a less axially aligned Tb network and less Tb connectivity. These features were associated with lower stiffness and may be novel mechanisms for biomechanical compromise in postmenopausal women treated with GCs.

Medical Comorbidity and Osteoporosis Are Associated with Subsequent Initiation of Proton Pump Inhibitors. Laura Targownik*[1], Zoann Nugent[2], William Leslie[1]. [1]University of Manitoba, Canada, [2]University of Manitoba, Canada

Introduction: Observational studies have demonstrated an association between proton-pump inhibitors (PPI) use and the occurrence of fractures. Persons with greater frailty may be more likely to be prescribed PPIs, and frailty may also be associated with reduced bone mineral density (BMD) and fracture. Therefore, we aimed to determine whether either greater degrees of medical comorbidity and/or the presence of pre-existing osteoporosis is associated with subsequent prescription of PPIs.

Methods: We used the Manitoba BMD Database, which contains all DXA results for Manitoba, Canada, with linkages to population-based health services databases, to identify residents who underwent DXA testing from 2001-2011. Persons with a previous prescription for PPIs, prior history of fracture or prior osteoprotective medication use were excluded. Global comorbidity was assessed using Johns Hopkins Aggregate Diagnostic Groups (ADGs), which is an enumeration of health care visits for specific indications over the previous year. Osteoporosis and osteopenia were based on WHO criteria using femoral neck BMD. Subjects were followed for the next 5 years for becoming new PPI users (defined as pharmacy dispensations with >90 days continuous use). Cox proportional hazards modelling was performed to evaluate predictors of subsequent PPI initiation.

Results: Of the 27,028 persons meeting the inclusion criteria, 11.0% initiated PPIs over the next 5 years. Subjects with high medical comorbidity (>6 ADGs) were significantly more likely to be prescribed PPIs than those with low comorbidity (18.9 vs 6.1%, p<0.0001). Persons with osteoporosis were also more likely to be prescribed PPIs than those with normal BMD (13.5% vs. 10.3%, p=.0011). Multivariable regression showed that pre-existing osteoporosis, greater medical comorbidity, older age, and higher BMI were all independently predictive of future PPI use (Table).- Conclusions: Pre-existing osteoporosis and multiple medical comorbidities predict the future use of PPIs. As both osteoporosis and medical comorbidity are associated with an increased risk of fracture, this may represent an alternate explanation for the association between PPI use and fracture. Further work is required to determine whether PPI use remains a risk factor for future fracture when controlling for this increased propensity for PPI prescription among those at highest risk for fracture.

Table: Predictors of PPI Initiation Following Performance of DXA

Predictor	Hazard Ratio	95% CI Limits	
Total Subjects	27028

Asfotase Alfa: Sustained Improvements in Hypophosphatasia-related Rickets, Physical Function, and Pain During 3 Years of Treatment for Severely Affected Children. Katherine Madson*[1], Cheryl Rockman-Greenberg[2], Agustin Melian[3], Scott Moseley[3], Amy L. Reeves[4], Tatjana Odrljin[3], Michael Whyte[1]. [1]Shriners Hospital for Children-Saint Louis, USA, [2]University of Manitoba, Canada, [3]Alexion Pharmaceuticals Inc, USA, [4]Shriners Hospitals for Children, USA

Hypophosphatasia (HPP) is the rare inborn error of metabolism characterized by low alkaline phosphatase activity and defective skeletal and dental mineralization due to inactivating muta-tion(s) within the tissue-nonspecific alkaline phosphatase (TNSALP) gene. Our preliminary reports of severely affected children aged 5-12 yrs treated for 6 mos with asfotase alfa, a bone-targeted recombinant human TNSALP, demonstrated bone healing with improved skeletal mineralization as assessed by radiographic scales, DXA BMD Z-scores, and iliac crest biopsy.[1,2,3] Here, we report comprehensive data from 3 yrs of treatment with asfotase alfa in these patients. This multinational, open-label study assessed radiographic changes of rickets using a Radiographic Global Impression of Change (RGI-C) scale and a Rickets Severity Scale (RSS).[4] Data from patients treated for 3 yrs were compared to their baseline (BL), and compared to 2-yr historical control (HC) data. In addition, we evaluated BMD Z-scores, physical function (6-minute walk test [6MWT]), strength and agility (eg, one-legged stationary hop on the Bruininks-Oseretsky Test of Motor Proficiency [BOT-2]), comfort/pain (Pediatric Orthopedic Society of North America [POSNA] Pediatric Outcome Data Collection Instrument [PODCI]), and disability (Child Health Assessment Questionnaire [CHAQ]).

During this extension study, 12/13 pts (1 withdrew: elective surgery) received 3 yrs of therapy with asfotase alfa up to 6 mg/kg/wk SC. At BL, all patients had rachitic disease, abnormal gaits, and 8 (62%) had muscle weakness. With asfotase alfa treatment, significant improvement in rickets was observed during the first 6 mos, and was sustained at 2 yrs (RGI-C: p<0.0001 vs HC; RSS: p=0.0025 vs HC) and at 3 yrs (RGI-C: p=0.0078 vs BL). DXA BMD Z-scores improved (p=0.0875) through 3 yrs. The Table shows 6MWT, BOT-2 one-legged stationary hop, CHAQ disability, PODCI comfort/pain scores, and height Z-scores which all improved through 3 yrs. The most common adverse events (AEs) were injection site reactions. There were no deaths, serious AEs, or withdrawals due to AEs. 12 pts tested positive for anti-asfotase alfa antibodies; 2 pts had neutralizing antibodies without apparent effect on clinical efficacy. Severely affected children with HPP who received asfotase alfa experienced rapid and continued improvements including healing of rickets, physical function, and reduced pain and disability that are sustained through 3 years.

Table: Function and Growth Measures in Children with HPP Treated with Asfotase Alfa

	Baseline	6 months	2 years	3 years
6-Minute Walk Test: Distance Walked – Percent Predicted				
Median (Min, max)	61% (29%, 82%)	85% (52%, 100%)	83% (73%, 92%)	87% (82%, 96%)
p-value*	--	<0.0001	<0.0001	<0.0003
BOT-2 One-legged Stationary Hop (# hops)				
Median (Min, max)	0 (0, 29)	4 (0, 35)	19 (0, 35)	21 (9, 34)
p-value*	--	0.0006	0.0026	0.0030
CHAQ Disability (lower scores = less disability)				
Median (Min, max)	1.0 (0.0, 2.3)	0.3 (0.0, 0.5)	0.0 (0.0, 1.8)	0.0 (0.0, 1.5)
p-value*	--	0.0068	0.0019	0.0029
PODCI Comfort/Pain Scores (higher scores = less pain)				
Median (Min, max)	39 (18, 55)	55 (23, 57)	55 (42, 57)	56 (26, 57)
p-value*	--	0.0553	0.0080	0.0336
Height Z-scores (less negative value = improvement)				
Median (Min, max)	-1.3 (-6.6, -0.0)	-1.1 (-6.9, -0.1)	-0.8 (-6.5, -0.0)	-0.8 (-6.1, 0.1)

Efficacy and Safety of a Human Monoclonal Anti-FGF23 Antibody (KRN23) in Cumulative 4-Month Dose Escalation (KRN23-INT-001) and 12-Month Long-Term Extension Study (KRN23-INT-002) in Adult Subjects with X-Linked Hypophosphatemia (XLH). Thomas Carpenter*[1], Xiaoping Zhang[2], Erik Imel[3], Mary Ruppe[4], Thomas Weber[5], Mark A. Klausner[2], Takahiro Ito[2], Maria Vergeire[2], Jeffrey S. Humphrey[2], Francis Glorieux[6], Anthony Portale[7], Karl Insogna[1], Munro Peacock[8]. [1]Yale University School of Medicine, USA, [2]Kyowa Hakko Kirin Pharma Inc, USA, [3]Indiana University School of Medicine, USA, [4]The Methodist Hospital, USA, [5]Duke University Medical Center, USA, [6]Shriners Hospital for Children & McGill University, Canada, [7]University of California San Francisco, USA, [8]Indiana University Medical Center, USA

Purpose: X-linked hypophosphatemia (XLH) is an inherited metabolic bone disease caused by mutations of PHEX, with abnormally elevated serum FGF23 resulting in low serum phosphorus (Pi), inappropriately normal 1,25 dihydroxyvitamin D [1,25$(OH)_2$D] levels, short stature and skeletal deformities. Single (IV and SC) and 4 monthly SC doses of KRN23 increased TmP/GFR, serum Pi, and 1,25$(OH)_2$D in adults with XLH. Here we report the long-term efficacy and safety of KRN23 using a monthly dosing regimen throughout the initial 4-month period and a subsequent 12-month extension of titrated dosing in adults with XLH.

Methods: 22 adults with XLH were treated with up to 16 doses of open-label SC KRN23 (0.05-1 mg/kg) every 28 days according to a dosing algorithm. Primary outcomes were the percentage of subjects attaining predetermined serum Pi ranges and safety. Biochemistry and immunogenicity were assessed periodically during each dosing interval and up to 81 days after the last dose.

Results: All subjects had baseline serum Pi <2.5 mg/dL. After 4 cumulative doses in the first study, mean serum Pi reached clinically meaningful level during the 12 dosing intervals in the extension study. Maximum serum Pi levels were reached 7-14 days after each of 12 doses. On Day 7, 44.4% to 71.3% of subjects achieved serum Pi levels in the target range of >2.5 to ≤3.5 mg/dL; 0-16.7% between 3.5 and 4.5 mg/dL, and none >4.5 mg/dL. TmP/GFR followed a similar pattern as serum Pi; 1,25$(OH)_2$D levels peaked at Day 7 post-dosing and tended to decrease with subsequent doses. KRN23 was well tolerated; there were no deaths, life-threatening AEs, or treatment-related serious AEs; 2 subjects were discontinued because of AEs (nephrolithiasis, restless leg syndrome). 14 subjects (63.6%) had treatment-related AEs, the most common being injection-site reactions (5), arthralgia (3), restless leg syndrome (2), injection-site pain (2), and decreased neutrophil count (2). There were no changes in renal ultrasound, ECG, safety laboratory parameters, or physical examinations; no subject developed anti-KRN23 antibodies. Mild hypercalcemia occurred intermittently in 2 subjects and 3 subjects had transient hypercalciuria.

Conclusions: Blocking FGF23 activity by SC administration of KRN23 every 28 days for an extended period of up to 16 months demonstrated a favorable safety profile and increased serum Pi, TmP/GFR and 1,25$(OH)_2$D.

Deficits in Cortical Bone Density and Microstructure in Type 2 Diabetes: Framingham HR-pQCT Study. Elizabeth (Lisa) Samelson*[1], Mary Bouxsein[2], Elana Brochin[3], Xiaochun Zhang[3], Ching-An Meng[3], Kerry Broe[3], Mary Hogan[3], Danette Carroll[3], Robert McLean[4], Marian Hannan[5], L. Adrienne Cupples[6], Caroline Fox[7], Douglas Kiel[8]. [1]Hebrew SeniorLife, Harvard Medical School, USA, [2]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [3]Institute for Aging Research, Hebrew SeniorLife, USA, [6]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, [5]HSL Institute for Aging Research & Harvard Medical School, USA, [6]Boston University School of Public Health; NHLBI Framingham Heart Study, USA, [7]National Heart Lung & Blood Institute, National Institutes of Health, USA, [8]Hebrew SeniorLife, USA

Risk of fracture, particularly at the lower leg, is 2-fold higher in older adults with type 2 diabetes (T2D), despite having normal or increased areal BMD, relative to those without T2D. Since DXA underestimates fracture risk in T2D patients, new methods are needed to identify skeletal fragility in this vulnerable population. Evidence from small clinical studies of postmenopausal women suggests T2D is associated with deficits in cortical microarchitecture. We conducted a community based study of men and women to compare bone microarchitecture by HR-pQCT between those with and without T2D, and determine the association between bone microarchitecture and HbA1C level.

This study included 627 members (367 women, 260 men) of the Framingham Offspring Cohort, who attended a baseline examination (2005-08), including evaluation of T2D and A1C, and underwent HR-pQCT scanning at the tibia and radius 6 yr later. T2D was defined as glucose >126 mg/dl or use of T2D medication. A1C (%) was measured from morning fasting blood. Linear regression was used to calculate means and correlations for the association between volumetric bone density (vBMD), geometry, and microstructure indices of trabecular and cortical bone and T2D and A1C, adjusted for age, sex, and weight.

Mean baseline age was 65 yr (range, 45-84) and included 71 cohort members (40 men, 31 women) with T2D. At the tibia, total and trabecular vBMD and number were higher in those with T2D than those without T2D; however, the differences were not significant (TABLE). In contrast, persons with T2D had significantly lower cortical vBMD and higher cortical porosity. A similar pattern was seen with increasing A1C level: trabecular indices were better with increasing A1C but cortical bone indices were worse, although significance was limited to trabecular number. There were no other differences in HRpQCT bone indices in those with and without diabetes or by A1C level. At the radius, we found no significant association between bone HRpQCT indices and T2D or A1C.

In this community-based study of women and men, we showed that T2D and increased A1C are associated with deficits in cortical microstructure and density at the distal tibia. It remains unknown whether deficits in cortical bone explain increased fracture risk observed at the lower leg in diabetes. These results help to identify areas to target for investigation of the mechanism responsible for skeletal fragility in diabetic bone.

Association between volumetric bone density (vBMD), geometry, and microstructure indices of trabecular and cortical bone at the tibia and diabetes and HbA1C, Framingham HRpQCT Study (N=627)

High Incidence of Osteoporotic Fractures Following Hematopoietic Stem Cell Transplantation. Xerxes Pundole[1], Heather Lin[2], Andrea Barbo[2], Huifang Lu*[3]. [1]The University of Texas MD Anderson Cancer Center, USA, [2]UT MD Anderson.org, USA, [3]UT MD Anderson Cancer Center, USA

Background: Survivors following hematopoietic stem cell transplantation (HSCT) are increasing and rapid bone loss is common, but the incidence of fractures is unknown. Bone remodeling and the temporal sequence of bone loss following HSCT is complex and much remains unknown.

Methods: We performed a chart review of adult patients that underwent a HSCT at MD Anderson Cancer Center from January 1, 1997 to December 31, 2011 and followed them retrospectively to identify incident fractures. Fractures were identified by utilizing physician billing codes and confirmed by reviewing clinic notes and/or reports of radiologic evidence. Rates of fracture were compared with the US general

population using estimates from the 1994 National Health Interview Survey (NHIS). Gender, age at time of HSCT, indication and type of HSCT, were assessed as risk factors using regression analysis based on the Cox proportional hazard model.

Results: A total of 7,650 patients underwent a HSCT in the 15 year period. The mean age at the time of HSCT was 49.29 (± 13.51) years with a median of 51 (range: 18 - 81) years. Forty-five percent of the patients were female. The most common reason for undergoing a HSCT was a hematological malignancy (89.5%). Approximately 8% (n=631) developed a fracture with about 11% (n=440) in those that received an autologous transplant and 5% (n=191) in those that received an allogeneic transplant. The median time to fracture hadn't been observed. By year 5, 12% of HSCT patients had experienced a fracture and 23% by year 15. A Cox proportional hazard model showed that those ⩾ 50 years at the time of HSCT had a 1.9 times greater hazard of developing a fracture as compared to those < 50 years (Hazard Ratio (HR) = 1.9, p-value < .001); patients who received autologous HSCT had larger hazard of developing a fracture than those who received allogeneic HSCT (HR=1.58, p-value <.0001), after adjusting for sex and race. The Kaplan Meier plot showed that the time to develop a fracture was greater in those had underwent an allogeneic HSCT in comparison to autologous HSCT (log rank p-value <.0001). Age and gender specific fracture incidence rates following HSCT were significantly greater than that of the US general population in all sub groups. The striking difference was an approximately 10 times greater risk in 45-64 year old males and females and an even greater risk (approximately 15 times higher) in males >65 years of age at the time of HSCT. Males had more vertebral fractures (56%) and females had more (53%) non-vertebral fractures (X^2 = 5.07, p-value = 0.024).

Conclusion: Fractures rates following HSCT are increased, especially at age > 45 years and this corresponds to the increased hazard we observed in those > 50 years of age at the time of HSCT. This study is the first to quantify the magnitude of the problem. Evaluation of a comprehensive set of risk factors is necessary.

Bone Microarchitecture assessed by HR-pQCT as Predictor of Fracture Risk in Postmenopausal Women: The OFELY Study. Elisabeth Sornay-Rendu[1], Stephanie Boutroy[2], François Duboeuf[3], Roland Chapurlat*[4]. [1]INSERM UMR1033, Université de Lyon, France, [2]INSERM U1033 & Université de Lyon, France, [3]INSERM UMR1033 & Université de Lyon, France, [4]E. Herriot Hospital, France

Several cross-sectional studies have shown that alterations of bone microarchitecture (MA) contribute with low areal BMD to skeletal fragility but the independent contribution of cortical and trabecular (Tb) architecture to the risk of fracture has not been evaluated prospectively in women. The aim of this study was to prospectively investigate the prediction of fragility Fx by bone MA assessed by HR-pQCT in postmenopausal women.

We measured at the 14th annual follow-up of the OFELY study bone MA at the distal radius and tibia with HR-pQCT (XTreme CT, Scanco Medical AG, Bassersdorf, Switzerland) in addition to areal BMD with DXA in 588 postmenopausal women, mean(SD) age 68(9) yr.

During a median[IQ] 7.1[0.9] yr of follow-up, 101postmenopausal women sustained an incident fragility fracture including 61 women with a major osteoporotic Fx (MOP Fx: hip, clinical spine, shoulder or wrist). After adjustment for age, women who sustained Fx had significant alterations of total and Tb volumetric densities (vBMD) at both sites, cortical parameters (area and thickness at the radius, vBMD and porosity at the tibia), trabecular number (TbN), connectivity density, stiffness and estimated failure load at both sites, compared with control women.

After adjustment for age, prevalent Fx, T score hip, menopausal age and current tobacco use, each quartile decrease of several baseline values of bone MA at the radius was associated with significant increased fracture risk with adjusted hazard ratios [HR(95%CI)] of 1.28(1.02-1.64) for Tt.vBMD, 1.37(1.09-1.72) for Tb.vBMD and 1.28(1.02-1.61) for TbN. For MOP Fx, Tb.vBMD or TbN in the lowest quartile was associated with increased fracture risk with adjusted HR of 2.25(1.21-4.18) and 2.05(1.11-3.78) respectively. At the tibia, each quartile decrease of Tt.vBMD, stiffness and failure load was associated with adjusted HR of 1.47(1.06-2.04), 1.49(1.06-2.08) and 1.49(1.06-2.08) respectively for MOP Fx.

We conclude that alterations of bone MA predict the risk of fracture in postmenopausal women. Their assessment may play an important role in identifying women at high risk of fracture who could not be adequately detected by BMD measurement alone, and who may benefit from a therapeutic intervention.

Clinical Presentation of Primary Hyperparathyroidism: a Five-Year Study. Cristiana Cipriani*[1], Federica Biamonte[2], Daniele Diacinti[3], Piergianni Biondi[2], Orlando Raimo[4], Sara Piemonte[5], Jessica Pepe[6], Elisabetta Romagnoli[7], John Bilezikian[8], Salvatore Minisola[1]. [1]"Sapienza", University of Rome, Italy, [2]Department of Internal Medicine & Medical Disciplines, "Sapienza" University of Rome, Italy, [3]Department of Radiology, "Sapienza" University of Rome, Italy, [4]Department of Interla Medicine & Medical Disciplines, "Sapienza" University of Rome, Italy, [5]Department of Internal Medicine & Medical Disciplines, "Sapienza", Italy, [6]Department fo Internal Medicine & Medical Disciplines, "Sapienza" University of Rome, Italy, [7]"Sapienza", University of Rome, Italy, [8]Columbia University College of Physicians & Surgeons, USA

The clinical presentation of Primary hyperparathyroidism (PHPT) is characterized in most developed countries as asymptomatic. Assessment for kidney stones (KS) is not routinely conducted in subjects who do not have any history of signs of renal involvement. Similarly, assessment for vertebral fractures (VF) is not routinely conducted in subjects who do not have any previous history or symptoms. In this study, we evaluated the prevalence of KS, and VF in a cohort of patients diagnosed with PHPT over a 5-year period.

We studied 140 PHPT patients [127 women (18 pre- and 109 postmenopausal) and 13 men; mean age 63.2±11 yrs] consecutively referred to our Mineral Metabolism Unit, 2009-2013. All patients had abdominal ultrasound, 3-site DXA (Lumbar spine, femoral neck (FN),total hip (TH)] and distal 1/3 radius (R). Antero-posterior and lateral X-rays of thoracic and lumbar spine were performed in 131 patients.

KS were detected in 77/140 patients (55%); 16.4% of patients had bilateral KS. Spine X-ray showed vertebral fractures in 46/131 patients (35.1%): 19.1% of patients had one VF, 9.2% had two and 6.9% had more than two VF. 62.9% of patients had osteoporosis by T-score at any site, 31.4% had osteopenia alone, and only 5.7% had normal BMD. Among patients with VF, 25.9% had osteoporosis by DXA and 9.1% had osteopenia. Mean age of patients with only KS (57±13.7) was significantly younger than that of patients with only VF (69.3±6.5) and only osteoporosis (63.6±9.6)($p<0.05$ for both)

The prevalence of asymptomatic patients was 54.3% [69 women (8 pre- and 61 postmenopausal) and 7 men; mean age 64.±11.3]. Among asymptomatic patients, 35.5% had KS, 33.3% had VF and 65.8% had osteoporosis. Table 1 shows the prevalence of the association between different complications in asymptomatic, symptomatic and the total cohort of patients.

Our data show that KS and VF are highly prevalent among PHPT patients, even in those classified as asymptomatic. While VF are frequent among older subjects even in absence of osteoporosis, KS are mostly observed in younger patients. To our knowledge, this is the first study that reports prevalence of target organ complications among so-called "asymptomatic patients". Our results emphasize the need of a thorough evaluation in asymptomatic patients, before classifying them as suffering from mild disease.

Table 1. Prevalence of the association between different complications among asymptomatic, symptomatic and the total cohort of patients

	ASYMPTOMATIC	SYMPTOMATIC	TOTAL
KS + VF + OP*	8.3%	16.9%	12.2%
KS + VF	11.1%	22%	16.8%
KS + OP*	21%	41.5%	30.7%

*Osteoporosis evaluated by BMD

Osteosarcoma invasiveness and recurrence are controlled by exosome-induced tumor initiating cells. Paul Daft*[1], Majd Zayzafoon[2], Joan Cadillac[2]. [1]The University of Alabama At Birmingham, USA, [2]University of Alabama at Birmingham, USA

Osteosarcoma (OS) is the most common primary malignant bone cancer in children. Although the management of this devastating disease has improved in the last 20 years, its post-surgical recurrence and distant metastasis still pose a grim prognosis. It is thought that a small subset of invasive tumor cells called tumor-initiating cells (TICs) is associated with the most lethal characteristics of cancer. In OS, TICs were identified to express high levels of c-kit and Stro-1. We discovered that OS TICs also express high levels of α-CaMK-II. The genetic and pharmacologic inhibition of α-CaMK-II significantly decrease the number of TICs and result in 98% of OS cells being c-kit and Stro-1 negative, which we defined as Dormant Tumor Cells (DTCs). Furthermore, we discovered that TICs secrete large amounts of nanosized vesicles (exosomes). Therefore, we hypothesized that the growth and metastasis of osteosarcoma relies on α-CaMK-II controlled exosome release that regulates the development of tumor-initiating cells. Using fluorescence-activated cell sorting, we isolated TICs ($CD117^+$, $Stro\text{-}1^+$) and DTCs ($CD117^-$ and $Stro\text{-}1^-$) from 143B OS cells. TIC-secreted exosomes were visualized by cryo-electron microscopy and measured to be 50–130 nM and confirmed by western blotting for their expression of flotillin-1 and CD63. NanoSight nanoparticle analysis demonstrated that TICs secret 75% more exosomes than DTCs and the pharmacologic inhibition of α-CaMK-II decreases exosome numbers by 60% when compared to control. Adding TIC-secreted exosomes to DTCs results in a 70% increase in Notch1 protein levels and transforms DTCs into TICs by significantly increasing CD117 (300%), Stro-1 (200%) and Nanog (200%) protein levels. Furthermore, we discovered that TIC-secreted exosomes contain significantly more (80%) of the Notch1 regulating miR-199b and miR146a when compared to DTC exosomes. Hind limbs-containing OS tumors were then amputated, and tumor recurrence was monitored. Pulmonary metastasis/recurrence in saline treated mice was 100% two months after amputation and decreases to 12% in mice treated with CaMKII inhibitors. TICs were the predominant cells in the metastatic and recurrent tumors as shown by their expression of Sox2 and NANOG. Finally, we intratibially injected TICs or DTCs into 6-week old mice. We show that 100% of mice injected with TICs develop tumors and only 25% of DTCs did so, while TIC tumors secrete 800% more exosomes in the blood than DTC tumors.

Foxo1 Expressed in Osteoblasts Promotes the Leukemogenic Properties of β-Catenin by Activating Notch Signaling. Aruna Kode*[1], Ioanna Mosialou[1], Sanil J Manavalan[1], Julie Teruya Feldstein[2], Govind Bhagat[1], Ellin Berman[2], Stavroula Kousteni[1]. [1]Columbia University Medical Center, USA, [2]Memorial Sloan-Kettering Cancer Center, USA

Osteoblasts affect self-renewal and expansion of hematopoietic stem cells (HSCs) and homing of healthy hematopoietic and tumor cells into the bone marrow. Moreover, in the mouse, constitutive activation of β-catenin (Ctnnb1CAosb mice) in osteoblasts is sufficient to alter the differentiation potential of myeloid and lymphoid progenitors and to trigger the development of acute myeloid leukemia (AML). Because the same genetic event is associated with AML development in humans we sought to better understand its molecular bases. For that purpose we examined in vivo whether FoxO1, a transcription factor known to interact with β-catenin, affects its AML inducing properties. Deleting one allele of FoxO1 mice from the osteoblasts of leukemic Ctnnb1CAosb mice prevented the appearance of anemia, peripheral monocytosis, neutrophilia and lymphocytopenia that are otherwise observed in Ctnnb1CAosb mice. Similarly, FoxO1 haploinsufficiency in osteoblasts of Ctnnb1CAosb mice prevented the shift in the differentiation of HSCs to the myeloid lineage and the increase in the LSK+/CD150+/CD48- subset of long term repopulating HSC progenitors (LT-HSCs). Histological analysis showed that myeloid and megakaryocyte dysplasias observed in Ctnnb1CAosb mice and associated with their AML phenotype were also rescued in Ctnnb1CAosb;FoxO1osb+/- animals. As a result FoxO1 haploinsufficiency in osteoblasts prevented the early lethality of Ctnnb1CAosb mice since Ctnnb1CAosb;FoxO1osb+/- mice lived and were healthy for at least one year, the entire time that they were observed. At the molecular level FoxO1 interacts with β-catenin in osteoblasts to induce expression of the Notch ligand Jagged-1 which initiates the dysmyelopoiesis leading to AML. ChiP/Re-ChiP assays and transient transfection experiments showed that this interaction requires the formation of a β-catenin/FoxO1 complex at two distinct locations in the regions of the Jagged-1 promoter. It also leads to subsequent activation of Notch signaling in LT-HSC progenitors. These events induce the leukemogenic transformation of HSCs. These findings identify FoxO1 through its expression in osteoblasts as a factor affecting hematopoiesis and provide a molecular mechanism whereby the FoxO1/activated β-catenin interaction results in AML. They further support the notion that targeting the bone marrow niche may be a new strategy to treat leukemia and raise the prospect that FoxO1 oncogenic properties may occur in other tissues.

Large-scale Temporal Gene Expression Profiling Reveals Potential NOTCH1 Target Genes Responsible for Cartilage Fibrosis and Degradation. Zhaoyang Liu*[1], Anthony Mirando[2], Regis O'Keefe[2], Michael Zuscik[3], Matthew Hilton[4]. [1]University of Rochester Medical Center, USA, [2]Department of Orthopaedics & Rehabilitation, Center for Musculoskeletal Research, University of Rochester Medical Center, USA, [3]University of Rochester School of Medicine & Dentistry, USA, [4]Duke University Musculoskeletal Research Center, USA

Notch signaling is critical in regulating cartilage development and homeostasis. Recent studies have identified elevated levels of Notch signaling in osteoarthrits (OA) cartilage, however the downstream Notch targets responsible for OA development remain unclear. To address this issue, we developed several Notch gain-of-function (GOF) *in vivo* and *in vitro* models. We first generated two cartilage-specific Notch GOF *in vivo* mouse models: *Acan1Cre^{ERT2}*; *Rosa-NICD1* and *Col2Cre*; *Rosa-rtTA$^{fl/+}$*; *tetON-NICD1* (tetON NICD1). Both animal models exhibit early and progressive OA-like phenotypes, including articular cartilage fibrosis and degradation, meniscus degeneration, and synovial tissue expansion as early as two months of age. Immunohistochemical analyses of the articular cartilage revealed significant induction of fibrotic and catabolic factors in the mutant articular cartilage, including COL3A1, MMP13, and Aggrecanase (NITEGE). Lineage tracing with *Acan1Cre^{ERT2}; R26R$^{fl/+}$; Rosa-NICD1$^{fl/+}$* mice revealed invasion of a non-*Acan1* expressing fibrotic cell population at the surface of the mutant articular cartilage, likely originating from the synovium. Additionally, TUNEL staining in both mutant models demonstrated enhanced chondrocyte apoptosis. To identify novel early and late Notch responsive target genes in cartilage, we performed high throughput RNA-seq of P2 primary chondrocytes isolated from tetON NICD1 and control mice and induced Notch signaling with doxycycline treatments for 6h and 48h *in vitro*. Notch activation induced 451 genes at 6h and 1249 genes at 48h, including Notch pathway genes (*HeyL*, *Notch3*, *Jag1*, etc.), cartilage degradation enzymes (*Mmp13*, *Mmp9*, *Adamts4*, *Ctsc*, etc.), fibrous collagens (*Col3a1*, *Col4a1*, *Col5a1*, etc.), growth factors (*Pdgfb*, *Tgfb1*, *Tgfb2*, etc.), and cytokines/chemokines (*Il6*, *Ccl20*, *Cxcl1*, etc.). Notch activation also down-regulated the expression of 75 genes at 6h and 867 genes at 48h, including cartilage-related collagens (*Col2a1*, *Col9a1*, *Col11a1*, etc.) and chondrogenic genes (*Sox9*, *Sox5*, *Sox6*, *Acan1*, *Matn1*, etc.). Collectively, these data have identified novel Notch target genes in cartilage, and demonstrated that sustained Notch signaling suppresses the chondrogenic phenotype and promotes cartilage fibrosis and degradation, implicating the Notch signaling pathway as a potential therapeutic target for OA.

Glut1-dependent glucose uptake in osteoblasts is necessary for bone formation before and after birth and whole-body glucose homeostasis. Jianwen Wei*, Junko Shimazu, Gerard Karsenty. Columbia University, USA

The regulation of insulin secretion and sensitivity by the bone-derived hormone osteocalcin naturally raises the following question: Why does bone regulate glucose metabolism? A first step in answering this question might be to define the functions of glucose in bone. We first showed through hyperinsulinemic euglycemic clamps that bone uptakes glucose, mostly in an insulin-independent manner, and that the amount of glucose up-taken by bone is nearly one fifth of what is up-taken by muscle, the organ up-taking the largest amount of glucose in the mouse. Moreover, studies conducted in isolated cells established that osteoblasts or osteoclasts uptake one third of the amount of glucose up-taken by myoblasts. Consistent with the insulin-independent nature of this process, the glucose transporter Glut1 appears to be 100 fold more abundant than any other glucose transporters in bone cells. Accordingly, in cell-based assays glucose uptake is decreased 70% in osteoblasts lacking *Glut1* and is increased 20% in osteoblasts overexpressing modestly (2 fold) *Glut1*. Glycogen content is also decreased in *Glut1*-deficient osteoblasts. In vivo, the absence of *Glut1* in osteoblast progenitors dramatically delays the onset of bone formation in mouse embryos and significantly decreases the size of embryos whereas the deletion of *Glut1* in differentiated osteoblasts only, results in two distinct phenotypes. The first one is a decrease in all parameters of bone formation including the osteoblast number that leads to a low bone mass in adult *Glut1$_{osb}$*-/- mice. The second phenotype seen in adult *Glut1$_{osb}$*-/- mice is an osteocalcin-dependent glucose intolerance and insulin resistance. Conversely, mice overexpressing *Glut1* in differentiated osteoblasts display a high bone mass because of an increase in bone formation parameters, and a better glucose tolerance and insulin sensitivity than control littermates. Molecular studies performed in wild type and mutant osteoblasts demonstrated that by limiting AMPK activity, glucose normally favors mTOR signaling in osteoblasts and thereby collagen synthesis and bone formation; osteocalcin synthesis and glucose metabolism. In summary, Glut1-dependent glucose uptake in cells of the osteoblast lineage is a significant regulator of bone formation pre and post-natally, and of whole-body glucose homeostasis. The extent of the functions of glucose in osteoblasts provides a rationale for the regulation of glucose metabolism by bone.

Brown Adipose Tissue Indices a Bone Anabolic Effect Through an Uncoupling Protein 1- Mediated Elevation of Central Neuropeptide Y Expression and Reduced Sympathetic Tone. Amy Nguyen[1], Herbert Herzog[1], Paul Baldock*[2]. [1]Neuroscience Division, Garvan Institute of Medical Research, Australia, [2]Garvan Institute of Medical Research, Australia

Brown adipose tissue (BAT) remains a putative therapy for obesity, due to its ability to dissipate energy through the actions of uncoupling protein-1 (UCP-1), which is expressed in the mitochondria of brown adipocytes. Interestingly, a positive correlation between BAT and bone mass has been identified, linked to the bone anabolic effect of reduced sympathetic tone. However, several critical questions remain: i) what component of BAT is responsible for the bone anabolic effect, and ii) what is the pathway by which BAT activity regulates sympathetic tone. This study, for the first time, examines UCP-1, BAT and bone mass using a mouse model deficient in UCP-1 (UCP-1 KO), and identifies a central NPY circuit whereby UCP-1 activity regulates sympathetic tone.

Six week old male UCP-1 KO and wild type mice were housed for 10 weeks either at thermoneutrality (30℃), where UCP-1 is inactive, or under mild cold-stress (22℃), where UCP-1 would be activated for thermogenesis. At 30℃, no differences in cancellous or cortical bone parameters were apparent.

However, under conditions of permanent mild cold-stress (22℃), UCP-1 KO mice displayed reduced cancellous bone volume (21%, $p<0.05$), trabecular number, thickness mineralizing surface compared to wild type mice. UCP-1 KO mice also exhibited reduced femur length, and cortical periosteal and endosteal perimeters, with no differences in body weight.

A similar, although reduced, effect was also observed in female mice.

Critically, cold-stressed UCP-1 KO displayed reduced hypothalamic neuropeptide Y (NPY) expression compared to wild type. We have shown that cold-stress elevates NPY, which inhibits central tyrosine hydroxylase neurons in the hypothalamus, reducing sympathetic tone to protect bone during chronic stress (1). Thus the decrease in NPY in UCP-1 KO would release the sympathetic inhibition, raising sympathetic output as noted previously in the BAT-deficient Misty mouse (2).

Thus UCP-1 activity during mild cold-stress is protective of bone mass, indicating that thermogenesis initiated during cold-stress plays a positive role in bone mass. Moreover, we demonstrate that the central NPY/sympathetic circuit is involved in this BAT-Bone pathway.

Exercise regulation of marrow fat in the setting of PPARγ agonist treatment. Maya Styner*[1], Xin Wu[2], William Thompson[3], Gunes Uzer[3], Zhihui Xie[2], Buer Sen[4], Andrew Romaine[2], Gabriel Pagnotti[5], Clinton Rubin[6], Martin Styner[2], Mark Horowitz[7], Janet Rubin[1]. [1]University of North Carolina, Chapel Hill, School of Medicine, USA, [2]University of North Carolina, USA, [3]University of North Carolina, USA, [4]University of North Carolina At Chapel Hill, USA, [5]Stony Brook University, USA, [6]State University of New York at Stony Brook, USA, [7]Yale University School of Medicine, USA

Marrow adipose tissue (MAT), associated with skeletal fragility and hematologic insufficiency, remains poorly understood. We have shown that exercise prevents MAT accumulation while promoting bone formation, a response that may depend on caloric expenditure. In contrast, we hypothesized that exercise would not be able to overcome the powerful adipogenic biasing of mesenchymal stem cells that accompanies PPARγ agonist therapy and leads to increased MAT. Thus, we tested the response of MAT and bone to running exercise in the setting of the PPARγ agonist rosiglitazone (Rosi). Eight week-old female C57BL/6 mice were treated with +/- Rosi 20 mg/kg/day incorporated into a regular chow diet (RD). Exercise groups were provided voluntary access to running wheels (RD-E, Rosi-E), running ~12 km/d. Femoral MAT and tibial bone quantity were assessed by μCT (lipid binder osmium) as previously described (Styner et al. *Bone* 2014). Total femur MAT was 4.5-fold higher in Rosi relative to RD ($p<0.0001$). As expected, exercise suppressed MAT in RD-E mice by half compared with RD ($p<0.01$). Surprisingly, MAT acquisition in Rosi fed mice also responded to exercise in all regions tested: epiphysis, metaphysis and diaphysis (figure 1), although MAT did not return to control levels ($p<0.001$ for total femur). Tibial mRNA in Rosi-treated mice demonstrated ⩾ 3-fold increase in perilipin, fatty acid synthase (FASN) and fat-specific protein 27 (FSP27) compared to RD. While exercise attenuated Rosi-induced FASN, it failed to decrease lipid-droplet associated markers perilipin and FSP27. This suggests that while exercise can alter the metabolic usage of MAT, essentially burning calories, it cannot fully overcome adipogenic biasing of stem cells. Rosi decreased bone quantity as expected; importantly, exercise was not able to overcome bone deficit in Rosi-E group. In summary, Rosi induced MAT accumulation throughout the femur and, while exercise partially limited Rosi induction of MAT volume, perhaps through fuel usage, it was unable to overcome the negative effects of Rosi on bone quantity. Our results suggest that MAT supplies fuel for energy needs of exercise, but that exercise cannot overcome the pathologic effects of PPAR agonists on bone health.

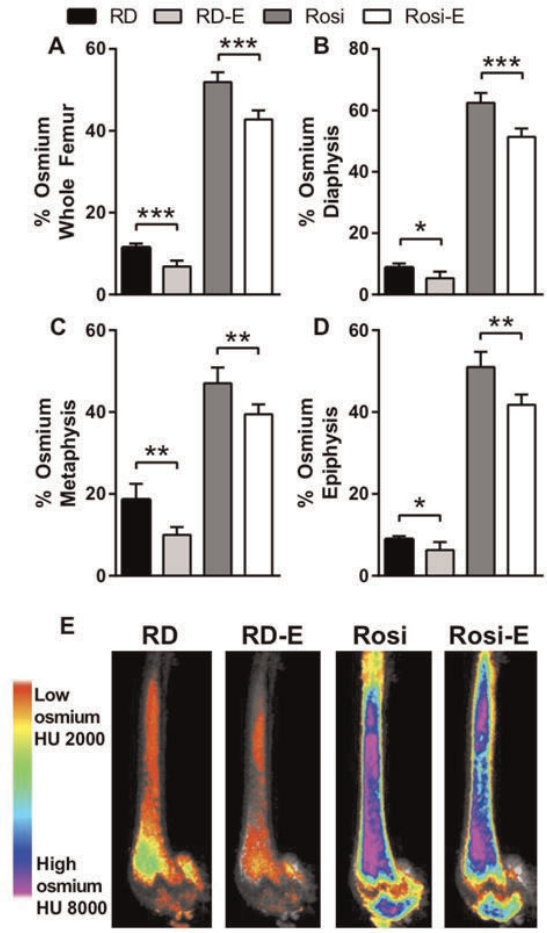

Figure 1. Exercise attenuates marrow adipose tissue in RD and Rosi treated mice. Eight-week-old C57BL/6 mice were treated with oral rosiglitazone (Rosi) or a regular diet (RD), and subdivided into voluntary running exercise groups for six weeks (RD-E, Rosi-E). **A-D,** Quantification of marrow adipose tissue (MAT) via μCT imaging of lipid-binder osmium as mm^3 of osmium per femoral volume, in indicated regions. **E,** Each image represents an average of n=5 mice, color labeled to demonstrate distribution of MAT.

Placental morphology is differentially related to offspring skeletal size and volumetric density assessed by pQCT. Christopher Holroyd[1], Clive Osmond[1], David Barker[1], Susan Ring[2], Deborah Lawlor[2], J.H. Tobias[3], George Davey Smith[2], Cyrus Cooper[4], Nicholas Harvey*[5]. [1]MRC Lifecourse Epidemiology Unit, University of Southampton, Southampton, UK, United Kingdom, [2]MRC Integrative Epidemiology Unit, University of Bristol, Bristol, UK, United Kingdom, [3]Avon Orthopaedic Centre, United Kingdom, [4]University of Southampton, United Kingdom, [5]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom

We have previously demonstrated that placental size is positively related to indices of offspring skeletal size shortly after birth. It is not known if such associations persist into later postnatal life and whether placental size might be differentially associated with measures of bone size and density. We investigated relationships between placental morphology and bone size and volumetric density during adolescence in a population-based mother-offspring cohort.

The Avon Longitudinal Study of Parents and Children (ALSPAC) recruited women from the former region of Avon, UK. In 1991, from April to December, 12,942 babies were born at term. Placentas were preserved in formaldehyde, and in 2010 a sample of 1746 placentas were measured and photographed. At 15 years the children underwent a pQCT scan (Stratec XCT2000) in order to assess tibial size, geometry and volumetric density at the 50% site. Pubertal stage was assessed by Tanner Stage Questionnaire.

Complete placental, pQCT and pubertal assessment data were available for 421 children [mean (sd) age 15.5 (0.27) years]. After adjustment for sex, gestational age at birth, age and pubertal stage at pQCT scan, and mother's weight, height, age and parity, placental area was positively associated with endosteal circumference ($r=0.24$, $p<0.001$), periosteal circumference ($r=0.19$, $p<0.001$) and cortical area ($r=0.09$, $p=0.06$); in contrast placental area was inversely associated with cortical density ($r=-0.14$, $p=0.004$). Similar associations were documented for placental volume.

These findings confirm previous associations between placental size and offspring skeletal development and that these relationships persist into later childhood/adolescence. Furthermore, they support the concept that cortical density may be lower in larger cross-section tubular bones, most likely a mass reducing adaptation to the greater strength conferred by the distribution of material further from the centre of the bone.

The Choice of Pediatric Reference Database Changes Spine Bone Mineral Density Z-scores but Not the Relationship with Prevalent Vertebral Fractures. Leanne M Ward*[1], Kerry Siminoski[2], Shayne Taback[3], Celia Rodd[3], Robert Stein[4], Annie M Sbrocchi[5], Josephine Ho[6], Ronald M Grant[7], Elizabeth A Cummings[8], Robert Couch[2], David A Cabral[9], Stephanie Atkinson[10], Nathalie Alos[11], Nazih Shenouda[1], Mary Ann Matzinger[1], Brian Lentle[12], Frank Rauch[5], Jinhui Ma[13], and the Canadian STOPP Consortium[14]. [1]University of Ottawa, Canada, [2]University of Alberta, Canada, [3]University of Manitoba, Canada, [4]University of Western Ontario, Canada, [5]McGill University, Canada, [6]University of Calgary, Canada, [7]University of Toronto, Canada, [8]Dalhousie University, Canada, [9]University of British Columbia, Canada, [10]McMaster University, Canada, [11]Université de Montréal, Canada, [12]University of British Columbia, Canada, [13]Children's Hospital of Eastern Ontario, Canada, [14]National Pediatric Bone Health Working Group, Canada

Aim and Objectives: To assess the disparity in lumbar spine BMD Z-scores (LS-BMDZ) generated by different reference databases and evaluate whether the relationship between LS-BMDZ and prevalent vertebral fractures (VF) varies with the choice of BMD reference database.

Patients and Design: 186 children with recently diagnosed leukemia underwent LS-BMD; Z-scores were generated on four reference databases. Prevalent VF were assessed by the Genant semi-quantitative method. Logistic regression assessed the association between VF (sustained in 15.6% of children)and LS-BMDZ (either as a continuous factor, or a binary risk factor at ± 2.0 SD). The prediction performance was assessed using both the area under the curve (AUC) for receiver operating characteristics and the net reclassification improvement (NRI) (compared to the Hologic version 12.3 normative database).

Results: The proportion of children with LS-BMDZ $\leq$ -2.0 ranged from 15% to 48%. Using the -2 SD cut-off, the logistic regression model assessing the relationship between LS-BMDZ and VF yielded odds ratios (OR) from 2.3 (95% CI: 1.0, 5.3) to 5.0 (95% CI: 2.0-12.4), AUC from 0.60 (95% CI: 0.51, 0.70) to 0.66 (95% CI: 0.56, 0.76), and NRI from -0.64 (95% CI: -1.02, -0.26) to -0.08 (95% CI: -0.35, 0.18). In contrast, with standardized LS-BMDZ used as a continuous risk factor, the ORs were distributed across a narrow range from 2.4 (95% CI: 1.6, 3.7) to 2.6 (95% CI: 1.6, 4.1), the AUC ranged from 0.71 (95% CI: 0.59, 0.82) to 0.72 (95% CI: 0.60, 0.83) and the NRI ranged from -0.17 (95% CI: -0.57, 0.22) to -0.06 (95% CI: -0.45, 0.33).

Conclusions: The use of a LS-BMDZ cut-off to define pediatric osteoporosis is problematic given the large variation in LS-BMDZ depending upon the choice of reference database that is used, as well as the variability in the association between LS-BMDZ (expressed as a binary variable) and prevalent VF, and in the prediction performance across different reference databases. On the other hand, if LS-BMDZ is used as a continuous variable, the association between vertebral fractures and LS-BMDZ across reference databases is not influenced by the choice of reference data.

Absence of ER cation channel *TMEM38B*/TRIC-B causes recessive osteogenesis imperfecta by dysregulation of collagen post-translational modification. Wayne Cabral*[1], Elena Makareeva[2], Masaki Ishikawa[3], Aileen Barnes[1], MaryAnn Weis[4], Felicitas Lacbawan[5], David Eyre[6], Yoshihiko Yamada[3], Sergey Leikin[7], Joan Marini[8]. [1]Bone & Extracellular Matrix Branch, NICHD, NIH, USA, [2]Section on Physical Biochemistry, NICHD, NIH, USA, [3]Molecular Biology Section, NIDCR, NIH, USA, [4]Department of Orthopaedics & Sports Medicine, University of Washington, USA, [5]Department of Medical Genetics, Children's National Medical Center, USA, [6]University of Washington Orthopaedic Research Labs, USA, [7]National Institutes of Health, USA, [8]National Institute of Child Health & Human Development, USA

Recessive osteogenesis imperfecta (OI) is caused by mutations in genes encoding proteins involved in post-translational interactions with type I collagen. A novel form of recessive OI has recently been reported in Bedouins from Israel and Saudi Arabia, caused by a homozygous deletion of exon 4 and surrounding intronic sequence of *TMEM38B*. *TMEM38B* encodes TRIC-B, an integral ER membrane monovalent cation channel proposed to be involved in Ca^{++} release from intracellular stores. However, the molecular mechanisms through which this founder mutation causes an OI phenotype are unknown. We identified a 20 month-old girl with moderately severe OI who is the offspring of consanguineous parents from Saudi Arabia, and is homozygous for the *TMEM38B* founder mutation. She has recurring long bone fractures, ligamentous laxity and blue sclerae. Her fibroblasts were used to investigate the mechanism of OI caused by the *TMEM38B* deletion. *TMEM38B* transcripts are 25% of control level, and include six alternatively spliced forms. Although one minor transcript is in-frame, complete absence of TRIC-B protein was confirmed by immunoblot. Consequently, proband cells have decreased steady-state intracellular and ER luminal Ca^{++} concentrations. Furthermore, Ca^{++} stores were more rapidly depleted upon ATP-induced Ca^{++} flux from the ER in patient cells. We also identified alterations in proband type I collagen post-translational modification and conformation. Proband collagen has increased electrophoretic migration of alpha chains on SDS-Urea PAGE, consistent with a 30% reduction in collagen helical lysine hydroxylation, despite increased LH1 protein and transcripts. The detection of lower stability collagen species (comprising 30-40% of total collagen) on DSC and decreased procollagen pericellular processing indicate an abnormal procollagen conformation, as do increased intracellular levels of chaperones PDI and GRP/BiP. Extracellular matrix deposited by proband fibroblasts in culture contained only collagen with normal stability, resulting in a 30% reduction of collagen content. Further, FKBP65, which is stabilized by Ca^{++} and required for collagen telopeptidyl hydroxylation by LH2, as well as fibrillar crosslinking, was decreased in proband fibroblasts. These data support a role for TRIC-B in intracellular Ca^{++} mobilization. We propose that absence of TRIC-B causes OI by dysregulation of multiple collagen-specific chaperones and modifying enzymes in the ER through Ca^{++} modulation.

Greater Bone Mineral Accrual after the Adolescent Growth Spurt Results in Stronger Bones in Young Adulthood: Evidence from 20-year follow-up of the Pediatric Bone Mineral Accrual Study. Saija Kontulainen*, James Johnston, Hassanali Vatanparast, David Cooper, Adam Baxter-Jones. University of Saskatchewan, Canada

Introduction: The peak accrual rate for bone mineral content (BMC) occurs within the first year after the adolescent growth spurt (i.e., age of peak height velocity, PHV) in both sexes. It is unknown if BMC, fat or lean tissue accrual during this rapid skeletal development will have a longer-term impact on bone strength in adulthood. Our purpose was to assess the role of adolescent total body BMC, fat and lean tissue accrual after the age of PHV on adult bone strength at the radius and tibia.

Methods: Participants were from the Saskatchewan Pediatric Bone Mineral Accrual Study (1991-2011). Eligible participants had DXA-derived total body BMC, fat and lean tissue mass measured at 1-year post-PHV (n=98, 51 females) or change in these variables between PHV and 1-year post-PHV (n=75, 40 females), and pQCT-derived forearm and lower leg scans obtained in young adulthood (mean age 29.3, SD 2.3 years). We used linear regression to assess if BMC, fat or lean mass at 1-year post-PHV, or their changes, contributed to the prediction of validated pQCT bone strength

indices at the distal (4%) and shaft sites of radius (65%) and tibia (66%) in young adulthood, when controlling for adult body and muscle size.

Results: Total body BMC at 1-year post-PHV was an independent, positive determinant of adult bone strength in all measured sites (Table 1). Fat mass at 1-year post-PHV was negatively associated with adult bone strength at both sites of radius and at the tibia shaft (Table 1). Lean mass was excluded from the models due to multicollinearity (VIF>5). BMC gain from PHV was an independent predictor of adult bone strength at the distal radius and tibia (Table 1).

Conclusion: These unique longitudinal findings suggest that greater bone mineral accrual after the peak in the growth spurt may lead to greater bone strength in adulthood while higher fat mass at the same time point may hinder attainment of bone strength at the radius and tibia in young adulthood. This evidence highlights the importance of skeletal growth on adult bone strength and supports efforts aiming to optimize development in body composition in adolescence to enhance prevention of osteoporosis and bone fragility.

Improved Survival with Asfotase Alfa Treatment in Pediatric Patients with Hypophosphatasia at High Risk of Death. Michael Whyte*[1], Cheryl Rockman-Greenberg[2], Christine Hofmann[3], Edward C.W. Leung[2], Scott Moseley[4], Kenji P Fujita[4], Agustin Melian[5], David Thompson[5], Johannes Liese[3]. [1]Shriners Hospital for Children-Saint Louis, USA, [2]University of Manitoba, Canada, [3]University Children's Hospital, University of Wurzburg, Germany, [4]Alexion Pharmaceuticals, USA, [5]USA

Hypophosphatasia (HPP) is the rare metabolic bone disease caused by loss-of-function mutation(s) in the tissue-nonspecific alkaline phosphatase (TNSALP) gene. Mortality rates are considered to be 50%-100% in the infantile and perinatal forms of HPP[1]. Here, we report significantly better survival in severely affected, high-risk, pediatric HPP patients (pts) during treatment with asfotase alfa (an investigational bone-targeted TNSALP replacement) compared with untreated age-matched historical control (HC) HPP pts. Data were pooled from 2 multicenter, Phase 2, open-label, ongoing studies of asfotase alfa for perinatal and infantile HPP (n=37) and compared with data from a multicenter, retrospective, chart review study of untreated HC pts (n=48) matched for age and HPP severity. Enrollment criteria included: age ≤ 5 years, and history of rachitic chest deformity, and/or respiratory compromise, and/or pyridoxine-responsive seizures (HPP complications associated with a high risk of death[2]). Kaplan-Meier analyses of overall survival and invasive ventilation-free (IVF) survival included sensitivity analyses controlling for age at enrollment and calendar year of diagnosis. Baseline characteristics were similar between treated and HC pts. Abnormally shaped chest, respiratory distress, and pyridoxine-responsive seizures were documented in 81% vs. 83%, 73% vs. 83%, and 35% vs. 21% of treated vs. HC pts, respectively. Median age (min, max) at symptom onset was 1 (0, 5.5) vs. 0 (0, 5.9) months for treated vs. HC pts, respectively. Median duration of treatment was 1.8 (0, 5) years. Survival was significantly better in pts treated with asfotase alfa compared with HC (Figure 1). Over the analysis period, 89% (33/37) of treated pts survived vs. 27% (13/48) of HC pts ($p < 0.0001$). Median survival time was 8.9 months for HC pts. In contrast, the high survival rate for treated pts at data cutoff precluded calculation of median survival time. IVF survival was also markedly improved in treated pts: 84% (21/25) required no invasive ventilation and survived, compared with 25% (12/48) of HC pts ($p<0.0001$). Better survival and IVF survival likely reflect improved mineralization of the rib cage and its influence on respiratory function[3]. Significance was retained in sensitivity analyses. Asfotase alfa treatment significantly improved survival and invasive ventilation-free survival in pediatric patients severely affected by HPP and at high risk of death.

Figure 1. Kaplan-Meier analysis of overall survival. Hypophosphatasia patients treated with asfotase alfa showed significantly greater survival compared to (untreated) historical control patients

Bone Fractures in Children and Adults with Autism Spectrum Disorder. Ann Neumeyer[1], Julia O'Rourke[1], Alexandra Massa[1], Hang Lee[2], Elizabeth Lawson[3], Christopher McDougle[1], Madhusmita Misra*[4]. [1]Lurie Center for Autism, Massachusetts General Hospital & Harvard Medical School, USA, [2]Biostatistics Center, Massachusetts General Hospital, USA, [3]Massachusetts General HospitalHarvard Medical School, USA, [4]Pediatric Endocrine & Neuroendocrine Units, Massachusetts General Hospital & Harvard Medical School, USA

Purpose: We have previously reported lower bone mineral density (BMD) in peripubertal boys with autism spectrum disorder (ASD) than in typically developing controls. However, it is not clear whether lower BMD in ASD results in an increased risk for fracture.

Methods: In this study, we examined rates and types of fracture in a large sample of children and adults with ASD (n= 18,152 for children 3-22 years and 4,215 for adults 23-50 years) vs. those without ASD (n= 6,311,505 for children and 11,438,194 for adults), by querying a national database of ED visits (the National Emergency Department Sample 2010) over a one-year period. We hypothesized that those with a diagnosis of ASD would display higher rates of fractures at the hip and spine compared to those without a diagnosis of ASD both in children and adults (based on our previous data for bone density).

Results: In the 3-22 year old patient population, those with ASD had a higher risk of hip fracture than those without ASD [odds ratio (OR) 3.33, $p<0.0001$], and this difference was more marked in girls [OR 8.1 in girls with ASD ($p=0.0005$), and 2.0 in boys with ASD ($p=0.06$)]. In contrast, compared to those without ASD, upper extremity fractures were less common in boys with ASD ($p<0.0001$). Spine fractures were too few to be analyzed. Observed differences across groups persisted after controlling for age. Similar to our data in children with ASD, adults with ASD 23-50 years old had a higher OR for hip fractures than adults without ASD (OR 11.7, $p<0.0001$) in both men (OR 6.8, $p<0.0001$) and women (OR 24.8, $p<0.0001$). Also, adult men without ASD had a higher risk for upper extremity fractures than those with ASD, and no increase in the risk for spine fractures. In contrast, women with ASD compared with those without ASD had a higher OR for upper extremity fractures (OR 2.27, $p=0.0038$), and spine fractures (OR 10.61, $p=0.0034$). Children and adults with ASD were younger than those without ASD, and differences across groups persisted after controlling for age.

Conclusion: Previous reports of lower bone density in children with ASD compared with typically developing controls are concerning for a higher risk of fractures (particularly of the hip) in this population. This is worrisome given the high morbidity associated with hip fracture. Further studies are necessary to better understand the decreased bone density in autism and its implication for fracture development.

1099

Pentosidine and degree of mineralization are increased in bone from fractured-patients with type 1 diabetes mellitus. Delphine Farlay*[1], Laura Armas[2], Evelyne Gineyts[3], Robert Recker[2], Georges Boivin[4]. [1]INSERM, UMR1033; Université De Lyon, France, [2]Creighton University, USA, [3]INSERM U1033, Université de Lyon, France, [4]INSERM, UMR1033; Universite De Lyon, France

Type 1 diabetes (T1D) is associated with increased fracture risk, not explained by the measurement of bone mineral density (BMD). If T1D causes deterioration in "bone quality" rather than reduction in BMD (bone mass) is an important question and little investigated in human. The aim of this study was to analyze the bone matrix (organic and mineral) of iliac bone biopsies, from T1D patients with fragility fracture (FX, n=5), sex and aged-matched T1D patients without fracture (non-FX, n=5), and to compare them to controls (CTL, n=5). All the analyses were performed separately on cortical (cort) and trabecular (trab) bone. Data were then correlated with patient' information (Weight, Body mass index, duration of diabetes), and Laboratory data (HbA1c, 25(OH)D, creatinine, IGF-1). Non-enzymatic cross-links (pentosidine, PEN), and enzymatic cross-links (PYD and DPD) were examined by HPLC after extraction from embedded bone slices. Degree of mineralization (DMB) was assessed by quantitative microradiography, microhardness was measured by microindentation and bone material properties were obtained by FTIRM. We confirmed that trabecular bone from FX-T1D patients contained significantly higher levels of PEN than in CTL (p=0.04). In bone from non-FX T1D, PEN was not significantly increased but tended to be higher than CTL. PYD was not modified in either T1D group compared to CTL. DPD was decreased in non-FX, only in cortical bone. In trabecular bone from FX-T1D, DMB was higher compared to both CTL (p=0.04) and non-FX T1D (p=0.04). Microhardness tended to increase in non-FX and FX T1D, both in cortical and trabecular bone. Mineral maturity, crystallinity and carbonation were not modified, confirming the absence of an effect on bone remodeling activity. Interestingly, we found significantly positive correlations between HbA1c and PENtrab, HbA1c and DMBtotal, PENtrab and DMBtotal (Fig.). Correlations with DMB were confirmed by mineralization index measured by FTIRM. This suggested that in T1D, HbA1c can predict both accumulation in bone of pentosidine and lead to a higher DMB. Indeed, it appears that bone from FX-T1D is more mineralized than both non-FX T1D and CTL. In conclusion, we showed that high serum HbA1c impacts both organic and mineral matrix in bone biopsies. Increase in both Pen and DMB were observed in bone from FX-T1D. Association of both high PEN and degree of mineralization could stiffen bone matrix and lead to fractures.

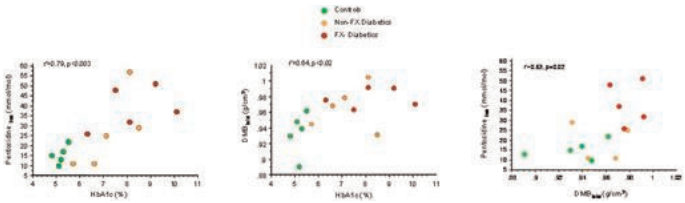

Figure: Spearman correlations between HbA1c, pentosidine and degree of mineralization

Elevated Sphingosine 1-Phosphate Levels are Associated with Vertebral Fractures in Patients with Type 2 Diabetes Mellitus. Mohammed-Salleh Ardawi*[1], Daad Akbar[2], Abdulrahim Rouzi[3], Nawal Senani[4], Ali Ahmad[5], Mohammed Qari[6]. [1]Center of Excellence for Osteoporosis Research & Department of Clinical Biochemistry & KAU Hospital, Faculty of Medicine, King Abdulaziz University, Saudi Arabia, [2]Center of Excellence for Osteoporosis Research & Department of Internal Medicine & KAU Hospital, Faculty of Medicine, King Abdulaziz University, Saudi Arabia, [3]Center of Excellence for Osteoporosis Research & Department of Obstetrics & Gynaecology & KAU Hospital, Faculty of Medicine, King Abdulaziz University, Saudi Arabia, [4]Center of Excellence for Osteoporosis Research & Department of Obstetrics & Gynaecology, Faculty of Medicine & KAU Hospital, King Abdulaziz University, Saudi Arabia, [5]Center of Excellence for Osteoporosis Research, King Abdulaziz University, Saudi Arabia, [6]Center of Excellence for Osteoporosis Research & Department of Haematology & KAU Hospital, Faculty of Medicine, King Abdulaziz University, Saudi Arabia

Background: Patients with type 2 diabetes (T2DM) are at increased risk of vertebral fractures (VFs) compared with non-T2DM subjects, due to poor bone quality. Recent studies in non-diabetic subjects have demonstrated that high sphingosine 1-phosphate (S1P) levels are associated with VFs independent of bone mineral density (BMD). We investigated the changes in plasma S1P levels in relation to VFs among postmenopausal women with T2DM.

Methods: We assessed cross-sectionally 482 postmenopausal women with T2DM and 482 age-matched postmenopausal women without T2DM who were recruited at diabetic clinics and primary health care centers for inclusion in a bone health survey. The main outcome measures wereplasma S1P [measured by ELISA method (Echelon Biosciences Inc., USA)] (overnight fasting samples), BMD, and bone turnover markers. Lateral X-rays of the thoracic and lumbar spine were taken to diagnose VFs.

Results: Plasma S1P levels were increased among women with T2DM as compared with non-T2DM controls (P<0.001). Plasma S1P levels were higher when T2DM women were stratified by the number of VFs (P<0.001). Multiple logistic regression analysis showed that plasma S1P levels were positively associated with 1 VF (odds ratio [OR]=2.35, (CI:1.12-4.26), P=0.012), 2 VFs (OR=2.61, (CI:1.31-4.86), P=0.004), and ⩾ 3 VFs (OR=6.62, (CI:2.92-23.1) P<0.001). Plasma S1P levels were inversely correlated with BMD at various sites (P=0.011 to 0.023), whereas they were positively correlated with bone resorption markers (P=0.026 to 0.034).

Conclusions: Increased plasma S1P were associated with VFs among postmenopausal women with T2DM, suggesting that S1P may be involved in increased bone fragility in T2DM and could be potential markers of VF severity.

Does Diabetes Modify the Effect of FRAX Risk Factors for Major Osteoporotic and Hip Fracture Prediction? The Manitoba BMD Cohort. William Leslie*[1], Suzanne Morin[2], Lisa M. Lix[1], Sumit Majumdar[3]. [1]University of Manitoba, Canada, [2]McGill University, Canada, [3]University of Alberta, Canada

Background: Diabetes mellitus increases risk for major osteoporotic fractures (MOF) independent of factors that comprise the WHO Fracture Risk Assessment tool (FRAX). It is uncertain how best to consider the effect of diabetes in identifying high risk individuals. Therefore, we explored whether diabetes simply adds to, or modifies the effect of FRAX clinical risk factors on MOF and hip fracture risk.

Methods: Using a registry with all clinical DXA results for Manitoba, Canada, we identified women and men age >40 years undergoing baseline DXA in years 1996-2011. Population-based health services data were used to identify diabetes diagnosis, covariates required for FRAX, and incident MOFs. Since the effect of prior fracture is modified by anatomical site, prior fracture was stratified as clinical vertebral, hip, humerus, forearm, pelvis, and "other" (excluding head, neck, hands, feet). Cox proportional hazards models were used to test for interaction effects of diabetes with FRAX clinical risk factors (Model 1) and prior fracture site (Model 2).

Results: The study population included 62,413 individuals (age mean 64 years [SD 11], 91% women) of whom 6,455 (10%) had a diagnosis of diabetes. During mean follow-up 6 years, 492 (7.6%) with diabetes and 3726 (6.7%) without diabetes developed incident MOFs. Diabetes was a significant risk factor for fracture (adjusted hazard ratio [aHR] Model 1: 1.34 [95%CI 1.22-1.48]; Model 2: 1.16 [1.06-1.28]). FRAX risk factors showed significant associations with incident MOFs in one or more analyses. However, no significant interactions of diabetes with any FRAX risk factors were identified. Results were similar without BMD in the model except that higher BMI showed a stronger protective effect (aHR per 5 kg/m^2 0.83 with diabetes, 0.79 without diabetes; p-interaction 0.276). Prior fractures were risk factors for MOF, but again there were no significant interactions with diabetes diagnosis. For predicting hip fractures (1108 incident events), age was a significant modifier of diabetes-related risk (aHR age <60: 4.67 [95%CI 2.76-7.89], age 60-69: 2.68 [1.77-4.04], age 70-79: 1.57 [1.20-2.04], age >80: 1.42 [1.10-1.99]; p-interaction <.001).

Summary: Diabetes is an independent risk factor for MOFs but did not significantly modify the effect of FRAX risk factors or prior fracture site. However, diabetes exerted a stronger effect on hip fracture risk in younger versus older individuals. This has implications for fracture risk assessment in diabetes and for identifying high risk individuals.

Cortical Bone Laminar Analysis reveals Increased Midcortical Porosity in Type 2 Diabetics with History of Fragility Fractures. Ursula Heilmeier*[1], Karen Cheng[2], Robin Parrish[2], Jasmine Nirody[3], Janina Patsch[4], Thomas Baum[5], Andrew Burghardt[3], Gabby B. Joseph[3], Ann Schwartz[3], Thomas Link[3], Galateia Kazakia[3]. [1]University of California San Francisco, USA, [2]University of California, Berkeley, USA, [3]University of California, San Francisco, USA, [4]Medical University of Vienna, Austria, [5]Klinikum rechts der Isar, TU Muenchen, Germany

Diabetic bone disease is an increasingly recognized complication of Type 2 diabetes (T2D) characterized by paradoxically high fracture rates. Elevated cortical porosity was recently identified as a main factor contributing to this high fragility. However, the underlying mechanisms of diabetic cortical porosity remain elusive. Potential hypotheses include cortical trabecularization due to expansion of the bone marrow space, increased vascular infiltration, or both. The purpose of this study was to assess the nature and the spatial distribution of cortical porosity by determining pore number, size and radial distribution within endosteal, midcortical and periosteal layers of cortical bone in T2D women with fractures (DMFx) and compare them to fracture-free diabetics (DM), and non-diabetic controls with (Fx) and without (Co) fractures. 79 postmenopausal women (n=20 per group, DM: n=19) underwent high resolution peripheral quantitative computed tomography (HR-pQCT) of the distal tibia. HR-pQCT images were post-processed using our newly developed cortical bone laminar analysis (Fig. 1). Cortical bone contours and intracortical porosity were semi-automatically segmented, the cortex was divided into three layers of equal width, and each pore was assigned to a layer based on the location of its centroid. Total pore area (TPA), total pore number (TPN), and average pore area (APA) were calculated within each layer. Using ANOVA with post-hoc Tukey tests we found that DMFx subjects exhibited significantly elevated global porosity compared to DM subjects (+190%, p=0.001). Elevated porosity in DMFx vs DM patients was isolated to the midcortical layer (+271% TPA, p=0.030) (Fig. 2). High midcortical porosity in DMFx patients was associated with high TPN (DMFx: 21.2 vs. DM: 45.6; +126%; p=0.018) rather than APA (p>0.05). In all four groups, endosteal pores were generally larger (+135% APA p≤0.021) and more numerous (+319% TPN p≤0.001) than periosteal pores. We conclude that cortical pore laminar analysis is a helpful tool in investigating diabetic bone disease-related cortical porosity. Our finding of isolated high porosity in the midcortical layer suggests that this zone might be particularly susceptible to diabetic bone disease and that unique mechanisms may be acting within this midcortical region in T2D postmenopausal women with history of fragility fractures. However, longitudinal studies are needed to investigate the natural evolution of cortical porosity over time.

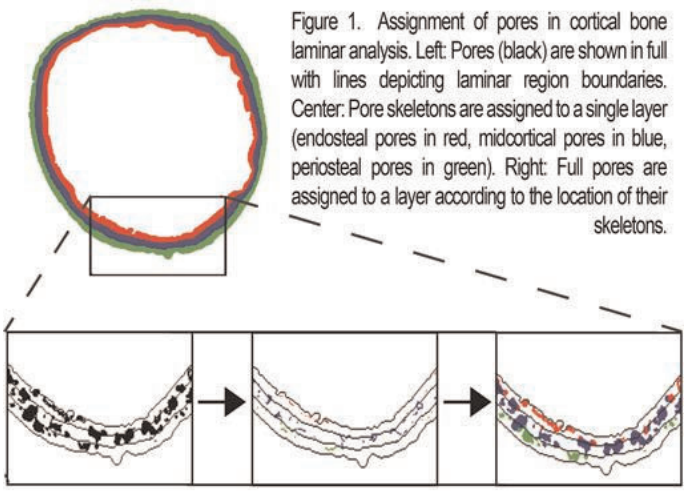

Figure 1. Assignment of pores in cortical bone laminar analysis. Left: Pores (black) are shown in full with lines depicting laminar region boundaries. Center: Pore skeletons are assigned to a single layer (endosteal pores in red, midcortical pores in blue, periosteal pores in green). Right: Full pores are assigned to a layer according to the location of their skeletons.

Figure 1

Figure 2 A-C. Results of cortical bone laminar analysis displayed by cortical layer and group (Co=Controls, Fx=women with history of fragility fractures, DM=type 2 diabetic women without fractures, DMFx= type 2 diabetic women with history of fragility fractures). ANOVA and post hoc Tukey tests revealed between-group differences as highlighted in white boxes. Elevated porosity in DMFx vs DM patients was isolated to the midcortical layer (+271% TPA, p=0.030), and driven by pore number rather than pore size (Fig.2 A and B). ** p≤ 0.001, * p≤ 0.05

Type 2 Diabetes and Obesity Each Contribute Separately to Adverse Skeletal Health: Adverse Effects on Cortical Bone Microarchitecture. Jessica Furst*[1], Laura Beth Anderson[2], Chiyuan Zhang[2], Kyle Nishiyama[2], Dorothy Fink[3], Shonni Silverberg[2], Mishaela Rubin[2]. [1]Columbia University Medical Center, USA, [2]Columbia University, USA, [3]NYP-Columbia, USA

Obesity and type 2 diabetes (T2D) are increasingly recognized to have adverse effects on skeletal health. Both disorders have a paradoxically elevated fracture risk despite the presence of normal to elevated bone mineral density (BMD) measurements. Although the two conditions often coexist, whether they have separate and specific contributions to bone fragility is unknown. To analyze the distinct effects of obesity and T2D on skeletal indices, we used dual energy X-ray absorptiometry (DXA; Hologic QDR4500, Waltham, Mass) and high resolution peripheral quantitative computed tomography (HRpQCT: Scanco, XtremeCT) with finite element analysis and cortical porosity assessment to examine 4 groups of postmenopausal women: normal weight, euglycemic controls (Cntrl n=6; BMI 22±1 kg/m2 and HbA1c 5.7%±1), obese euglycemic (Ob-NonDM n=5; BMI 36±2 kg/m2 and HbA1c 5.6%±1), nonobese type 2 diabetic (NonObDM n=8; BMI 24.4±1 kg/m2 and HbA1c 8.9%±1) and obese type 2 diabetic (ObDM n=9; BMI 35.6±1 kg/m2 and HbA1c 9.7%±1). The groups did not differ in age (mean overall age 59.4±1).

Generalized linear models were used with group status as the fixed effect to examine the difference in microarchitectural parameters.

We found that ObDM had higher BMD by DXA than Cntrl, Ob-NonDM and NonObDM at all sites. Similarly, by HRpQCT, trabecular bone volume and whole bone stiffness at the radius and tibia were greater in ObDM than in the other 3 groups. Cortical indices were worst in NonObDM (Table). Cortical BMD and thickness were lower and cortical porosity higher at both the radius and tibia and cortical area was lower at the tibia. Moreover, cortical porosity was highest in NonObDM at both the radius and tibia.

These data suggest that while the combination of T2D and obesity has a beneficial effect on densitometric indices, T2D in the absence of obesity has a deleterious effect on microarchitectural cortical parameters at both a weight-bearing and non-weight-bearing site. The cortical deficit is consistent with a decrease in volumetric bone density, and is likely due to increased cortical porosity, as well as a decrease in the overall amount of cortical bone. We conclude that T2D without obesity has a distinct adverse effect on cortical microarchitecture. This is the first study to provide insight into the separate contributions of diabetes mellitus and obesity to adverse skeletal health.

Group	Cortical BMD (Mg hydroxyapatite/cc)	Cortical Thickness (mm)	Cortical Area (mm^2)	Cortical Porosity (%)

Effect of Denosumab on Fasting Glucose Concentrations in Postmenopausal Women with Osteoporosis: Results From Subjects With Diabetes or Prediabetes From the FREEDOM Trial. Nicola Napoli*[1], Eric Vittinghoff[2], Nicola Pannacciulli[3], Daria Crittenden[3], Jang Yun[4], Andrea Wang[4], Rachel Wagman[5], Ann Schwartz[6]. [1]University Campus Bio-Medico di Roma, Italy, [2]UCSF, USA, [3]Amgen, Inc., USA, [4]Amgen, Inc., USA, [5]Amgen, Incorporated, USA, [6]University of California, San Francisco, USA

High serum RANKL concentration was a predictor of incident type 2 diabetes (T2DM) in a population-based study, and blockage of RANKL signaling improved glucose tolerance by enhancing hepatic insulin sensitivity in mouse T2DM models (Kiechl et al. *Nature Med* 2013;19(3):358-366). Denosumab (DMAb) is a fully human monoclonal antibody that binds with high affinity and specificity to RANKL and prevents the formation, function, and survival of osteoclasts, and is associated with vertebral and nonvertebral fracture risk reduction. In a prior post-hoc analysis of the FREEDOM trial, a 3-year, randomized, double-blind, placebo (PBO)-controlled study that enrolled 7808 postmenopausal women with osteoporosis, DMAb had no effect on incident diabetes or fasting serum glucose (FSG) in women without diabetes at baseline. Based on the favorable effect of blockage of RANKL on glucose tolerance in mouse T2DM models, we tested the hypothesis that DMAb decreases FSG in FREEDOM subjects with diabetes or prediabetes.

Baseline diabetes status was ascertained by self-report, use of anti-diabetic medication (ADM), or an FSG ⩾126 mg/dL. Prediabetes was defined as an FSG 100-125 mg/dL on no ADM. Average postbaseline FSG across visits was estimated using a repeated measures model and compared between DMAb and PBO. The model included treatment group; baseline FSG, body mass index, and age; visit; ADM use; treatment-by-visit interaction; and ADM use-by-visit interaction as fixed effects.

Baseline characteristics were similar between DMAb and PBO in both the subpopulations with diabetes and prediabetes. The estimated average postbaseline FSG across visits was not significantly different between DMAb and PBO in either women with diabetes or in women with prediabetes (p=0.20 and p=0.42, respectively); however, when censoring FSG values after ADM use in women with diabetes, estimated average postbaseline FSG across visits was lower with DMAb than PBO (p=0.02) (Table).

In this post-hoc analysis of postmenopausal women with osteoporosis, DMAb did not appear to affect FSG in the overall population with diabetes or prediabetes. There was evidence of FSG lowering with DMAb in women with diabetes who were not currently using any ADM. It remains to be determined whether blockage of RANKL has a clinically important effect on glucose metabolism.

Table

	Diabetes[1]		Prediabetes[2]		Diabetes (prior to ADM use)[3]

Effective Hexa-D-Arginine Therapy of X-Linked Hypophosphatemia Occurs Through Biochemical Targeting of MicroRNA335. Baozhi Yuan*[1], Abigail Radcliff[2], Michael Johnson[1], Robert Blank[3], Marc Drezner[1]. [1]University of Wisconsin, USA, [2]University of Wisconsin-Madison, USA, [3]Medical College of Wisconsin, USA

Previously, we found that decreased osteoblast *Signe1* (7B2) mRNA expression is a pivotal abnormality underlying the pathogenesis of X-Linked Hypophosphatemia (XLH), and that Hexa-D-Arginine (D6R) treatment rescues the *HYP* phenotype by increasing 7B2 mRNA. Recently, we observed that *Hyp*-mouse bone has increased miR335-3P and -5P expression, which reduce 7B2 mRNA by targeting the 7B2-3'UTR region. However, it remains unknown if miR335-3P and -5P serve as biochemical targets for D6R rescue of the *HYP* phenotype. Thus, we studied D6R effects on the miR335 mediated decrease in 7B2 production. Dose-dependent D6R treatment of TMOb osteoblasts resulted in a maximal decrement in expression of miR-3P (0.25 ± 0.2 vs 0.94 ± 0.1 [relative expression (re)]; $p<0.01$) and -5P (0.42 ± 0.02 vs 0.94 ± 0.1 [re]; $p<0.01$). In accord, D6R treated TMOb cells exhibited increased 7B2 mRNA (2.59 ± 0.40 vs 1.09 ± 0.3 [re]; $p<0.05$), as well as the anticipated down-stream effects. To confirm miR335-3P and 5P were biochemical targets for D6R treatment of XLH, we assessed D6R effects on TMOb cells transfected with *Phex* siRNA. Transfected cells exhibited a significant increase in miR335-3P (3.0 ± 0.20 vs 1.2 ± 0.08 [re]; $p<0.01$) and -5P (4.15 ± 0.80 vs 1.7 ± 0.08 [re]; $p<0.01$). However, D6R treatment abolished the stimulatory effects of *Phex* siRNA, restoring normal expression of miR335-3P (1.26 ± 0.10 vs 1.2 ± 0.08 [re]) and -5P (1.35 ± 0.30 vs 1.25 ± 0.10 [re]). Thereafter, we treated normal and *Hyp*-mice for 5 weeks with vehicle or D6R (1.5 µmole/kg/day). Bones from vehicle treated *Hyp*-mice showed a significant increase, compared to normal mice, in miR335-3P (4.76 ± 0.80 vs 1.03 ± 0.09 [re]; $p<0.001$) and -5P (6.29 ± 0.99 vs 1.01 ± 0.08 [re]; $p<0.001$). In contrast, bones from D6R treated *Hyp*-mice, exhibited a dramatic reduction, to levels similar to those in treated normal mice, in miR335-3P (1.78 ± 0.16 vs 1.65 ± 0.31 [re]) and -5P (2.25 ± 0.37 vs 1.86 ± 0.95 [re]). In concert, in *Hyp*- mouse bone, 7B2 mRNA increased, while FGF-23 and β-catenin mRNA decreased, to normal, thereby normalizing phosphate homeostasis and bone mineralization. The D6R effects on miR335-3P and -5P were specific, as no inhibitory effects were observed *in vitro* and/or *in vivo* on the expression of other miRNAs (e.g. miR214, let-7e, miR218, miR126), many of which affect bone metabolism. These data confirm increased miR335-3P and -5P expression play a central role in the pathogenesis of XLH and provide a target for effective drug treatment of this disease.

Aptamer-Functionalized Lipid Nanoparticles (LNPs) Targeting Osteoblasts as a Novel RNA Interference-Based Bone Anabolic Strategy. Liang Chao*[1], Ge Zhang[2], Baosheng Guo[3], Heng Wu[4], Liangqiang Zhang[5], Aiping Lu[3]. [1]Hong Kong, [2]Ge Zhang' S Lab, Hong Kong, [3]Hong Kong Baptist University, Hong Kong, [4]HKBU, Hong Kong, [5]Beijing Proteome Research Center, China

Objective: Our previously developed osteogenic siRNA delivery system $(AspSer-Ser)_6$-liposome has concerns on efficacy and safety mainly due to lack of osteoblast-specific delivery at cellular level (Zhang G, Nat Med 2012; Wang X, Nat Med 2013). The objective of this project is to develop novel aptamer-functionalized LNPs directly targeting osteoblasts at cellular level for RNAi-based bone anabolic therapy.

Methods: Aptamers were screened by cell-SELEX with osteoblasts as target cells and hepatocytes and PBMCs as non-target cells. Osteoblast-specific aptamer was

conjugated to LNPs that encapsulated osteogenic *Plekho1* siRNA (Lu K, Nat Cell Bio 2008), *i.e.*, Aptamer-LNPs-siRNA. *In vitro* evaluation of Aptamer-LNPs-siRNA was conducted by cyto-TEM, flow cytometry and confocal imaging in terms of physicochemical properties, biological characteristics and cellular uptake mechanisms. *In vivo* studies from biophotonic imaging, immunohistochemistry, FACS, real-time PCR, microCT, bone histomorphometry and mechanical testing were performed to examine the selectivity, efficacy and safety of Aptamer-LNPs-siRNA, including tissue/cell-selective delivery, gene knockdown efficiency, dose-response pattern, persistence of gene silencing, bone anabolic action and toxicity.

Results: We screened an aptamer (CH6) which could target osteoblasts but not hepatocytes and PBMCs (Fig. 1). Then, we developed CH6-functionalized LNPs encapsulating *Plekho1* siRNA, *i.e.*, CH6-LNPs-siRNA. *In vitro* data suggested that CH6 facilitated osteoblast-specific uptake of the encapsulated siRNA mainly *via* macropinocytosis (Fig. 2). Consistently, *in vivo* data further confirmed that CH6 facilitated skeleton/osteoblast-specific delivery of *Plekho1* siRNA (Fig. 3) and long persistence of gene knockdown (Fig 4), leading to promoted bone formation, improved bone micro-architecture (Fig. 5), increased bone mass and enhanced mechanical properties in osteopenic rats with no obvious toxicity.

Conclusion: CH6 aptamer-functionalized LNPs is a promising targeting system for directly delivering siRNA to osteoblasts, thus updates the targeted delivery systems from tissue level toward cellular level to facilitate clinical translation of RNAi-based bone anabolic strategy in efficiency and safety (N_HKBU435/12, NSFC 81272045, FRG2/12-13/027 and SCM-2013-SZTIC-001).

Efficacy of an Experimental small interfering RNA Therapy for Autosomal Dominant Osteopetrosis type 2 (ADO2). Mattia Capulli*[1], Antonio Maurizi[2], Nadia Rucci[2], Anna Teti[2]. [1]Department of experimental Medicine, University of L'Aquila, Italy, [2]University of L'Aquila, Italy

ADO2 patients experience high morbidity, including frequent fractures, osteomyelitis, hematological and neurological impairment. Reduced osteoclast activity is caused, in about 70% of cases, by heterozygous dominant negative mutations of the *CLCN7* gene, encoding the Cl^-/H^+ antiporter type 7 (ClC-7). Because of the dominant missense nature of the mutation, we hypothesized that small interfering (si)RNA could silence the mutant transcript without affecting the WT mRNA, thus mimicking a condition of aplosufficiency. The most frequent *CLCN7* gene mutation in humans is a ClC-7 p.G215R amino acid substitution. $CLCN7^{G215R}$-specific siRNA (100 nM) silenced by 85% transfected mutant mRNA/*EGFP* in HEK293 cells and in human osteoclasts generated from peripheral blood mononuclear cells (n=3; p=0.002; Student's t test). No change of $CLCN7^{WT}$ mRNA and no effect of scrambled siRNA on the mutant transcript were observed. Osteoclasts generated from the bone marrow of $Clcn7^{G213R}$ ADO2 mice, harboring the murine homolog of the human mutation, showed 70% reduced resorption pit formation (n=3; p=<0.0001 vs WT). This condition was 2.6-fold reverted by treatment with 100 nM $Clcn7^{G213R}$-specific siRNA (p=0.002 vs scrambled siRNA-treated ADO2 osteoclasts), rescuing bone resorption to 78% of WT osteoclasts. siRNAs were then made sticky by 3' dAdT overhangs and conjugated with the PolyPlus Transfection JetPEI® siRNA reagent, a linear polyethylenimine derivative providing effective and reproducible siRNA delivery *in vivo*, preventing inflammatory responses. Single i.p. injection in ADO2 mice of 2 and 4mg/Kg $Clcn7^{G213R}$-specific sticky siRNA/JetPEI conjugate induced 67% and 95% silencing of tibia mutant mRNA, respectively, with maximal effect at 48 hours. Treatment of ADO2 mice, 3 times a week for 2 weeks, with 4mg/Kg $Clcn7^{G213R}$-specific siRNA induced a 1.46-fold increase of serum CXT (n=3-5; p=0.036), 20% decrease of tibia trabecular BV/TV (n=6-8; p=0.02), 13% decrease of TbN (p=0.03) and 7% decrease of TbTh (p=0.05), with an overall improvement of the osteopetrotic bone phenotype. Similar mRNA silencing was obtained with siRNAs against *CLCN7* mutations causing ClC-7 p.R767W and p.R286W amino acid substitutions. These results demonstrate that a siRNA-based experimental treatment of ADO2 is feasible, and underscore a translational impact for future strategy to cure this therapeutically neglected form of osteopetrosis (patent RM2014A000272).

Therapeutic silencing intra-osseous *Ckip-1* for promoting bone formation in an aged rat model of male osteoporosis. Baosheng Guo*[1], Baoting Zhang[2], Ge Zhang[3]. [1]Hong Kong Baptist University, Hong Kong, [2]Price of Wales Hospital, The Chinese University of Hong Kong, Hong Kong, [3]Ge Zhang' S Lab, Hong Kong

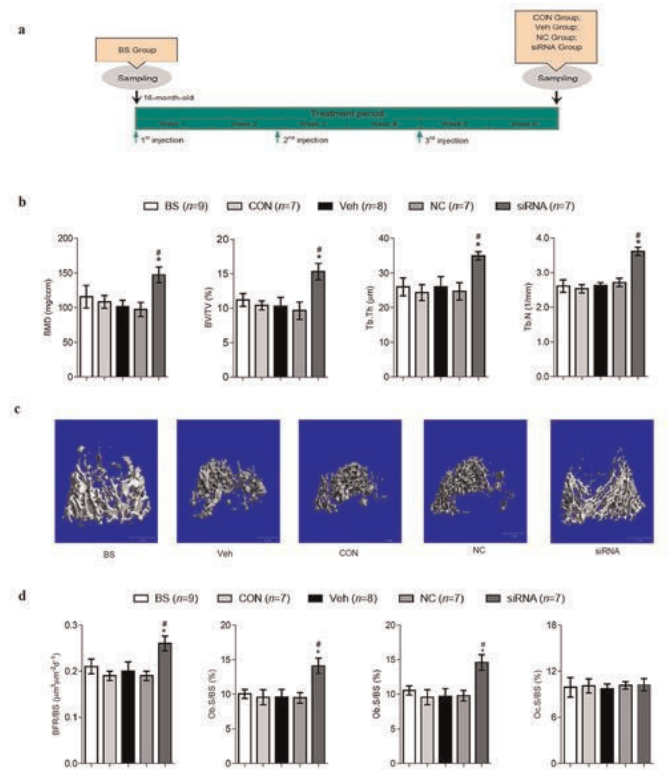
Introduction: *Ckip-1* is a newly discovered negative regulator gene of bone formation during bone development and bone maintenance without activating bone resorption (Lu K, et al, 2008). *Ckip-1* mRNA expression increased with age, whereas the bone formation decreased with age in the bone specimens from both the osteoporotic fracture patients and aged male rats (Guo B, et al, 2010. Thus, we hypothesized that *in vivo* administration of *Ckip-1* siRNA delivered by our previously developed $(Asp\text{-}Ser\text{-}Ser)_6$-liposome (Zhang G, et al, 2012) could promote bone formation and improve trabecular architecture in aged osteoporotic men.

Objectives: We aimed to investigate the effects of *Ckip-1* siRNA delivered by $(Asp\text{-}Ser\text{-}Ser)_6$-liposome on bone formation and trabecular architecture in the aged rat model of male osteoporosis.

Methodology: Ten 16-month-old male Sprague-Dawley rats were sacrificed at as baseline (BS group) before treatment. Thereafter, forty 16-month-old male rats were divided into siRNA treatment group (siRNA), Non-sense siRNA group (NC), vehicle control group (Veh) and age-matched control group (CON). The rats in above Group were given three periodic injections of *Ckip-1* siRNA (4 mg/kg), non-sense siRNA (4 mg/kg) encapsulated by osteoblast-specific delivery system, osteoblast-specific delivery system alone and PBS at an interval of two weeks, respectively. All the rats in each treatment group were sacrificed after six weeks of treatment (Figure a). After sacrifice, the bilateral distal femurs were subjected to microCT measurement and subsequent bone histomorphometric analysis.

Results: The microCT data revealed that the trabecular parameters in siRNA group were notably increased from baseline. The above microCT parameters were all obviously higher in siRNA Group than those in NC, Veh and CON groups (Figure b). Consistently, the better organized trabecular micro-architecture was also found in the rats from siRNA Group compared to the rats in BS, NC, Veh and CON groups (Figure c). The bone histomorphometric analysis data showed that the bone-formation-related parameters in siRNA Group were all significantly increased from baseline and higher than those in NC, Veh and CON groups, whereas the bone-resorption-related parameter (osteoclast surface) was unchanged among all the groups (Figure d).

Conclusion: Therapeutic gene silencing of *Ckip-1* in osteogenic cells could promote bone formation and improve trabecular architecture in aged rat model of male osteoporosis.



Promoted bone formation and increased bone mass by silencing *Ckip-1* within osteoblasts in aged male rats. A schematic diagram illustrating the experimental design (**a**), microCT parameters (**b**) and representative images of micro-architecture of trabecular bone at distal femur reconstructed by microCT (**c**), bone histomorphometric parameters (**d**) at distal femur in each group Note: * P<0.05 vs. BS Group; # P<0.05 vs. either NC or Veh Group. The actual sample size was indicated in the figures after excluding those accidently dead animals during experiment.

Decreased Optineurin Mediates MVNP Effects on Pagetic Osteoclast Formation. Quanhong Sun*[1], Juraj Adamik[1], Jolene Windle[2], G. David Roodman[3], Deborah Galson[1]. [1]University of Pittsburgh, USA, [2]Virginia Commonwealth University, USA, [3]Indiana University, USA

Paget's disease is characterized by abnormal osteoclasts (OCL) in pagetic lesions. Measles virus nucleocapsid protein (MVNP) has been reported to play a key role in the development of abnormal OCL in Paget's patients. In addition, MVNP expression targeted to OCL in transgenic mice induces pagetic-like lesions in vivo and aberrant OCL in vitro. MVNP induced upregulation of IL-6 is essential for the pagetic OCL phenotype. We have recently reported that MVNP activation of TBK1, an IKK family member, plays a critical role in mediating the effects of MVNP to generate aspects of the pagetic osteoclast phenotype, including elevated IL-6. Another IKK family member, optineurin (Optn), which is most closely related to IKKγ, has been shown to play a negative role in the innate immunity antiviral response by interacting with TBK1. Optn is a key player regulating various physiological processes including cell division and autophagy as well as the antiviral response. Interestingly, a non-coding SNP in the OPTN gene has recently been identified as a genetic risk factor for Paget's disease. We hypothesized that MVNP might prevent Optn repression of TBK1 function in OCL progenitors, thereby inducing a pagetic OCL phenotype. We have found that Optn mRNA and protein levels are decreased in OCL precursors from TRAP-MVNP mice as compared to wild-type OCL precursors. Similar results were observed in NIH3T3 cells stably or transiently transfected with MVNP cDNA compared to empty vector control cells. Optn over-expression inhibited IL-6-promoter luciferase reporter expression in HEK293 cells, and strikingly, even decreased endogenous IL-6 mRNA in the NIH3T3 cell line. Optn co-expression with MVNP blocked the MVNP stimulation of the IL-6 luciferase reporter in HEK293 cells and of endogenous IL-6 mRNA in NIH3T3 cells. Optn over-expression attenuated the p65 activation stimulated by MVNP or TBK1 in NIH3T3 cells. We found that TBK1 over-expression further decreased the Optn mRNA level in both TRAP-MVNP and wild-type OCL precursors, suggesting that there may be a positive feedback loop involved that potentiates the initial effects of MVNP activation of TBK1. Importantly, Optn over-expression in primary bone marrow monocytes decreased RANKL-stimulated OCL formation. These results suggest that the MVNP-induced decrease of Optn may mediate the effects of MVNP or TBK1 on the expression of IL-6, a key contributor to the pagetic OCL phenotype, and on OCL formation.

The Histone Deacetylase Sirtuin 1 is a Transcriptional Modulator of the Neuronal Control of Bone Mass. Na Luo*[1], Aruna Kode[1], Ioanna Mosialou[1], Mattia Capulli[2], Stavroula Kousteni[1]. [1]Columbia University Medical Center, USA, [2]University of L'Aquila, Italy

A well-established mode of neuronal regulation of bone mass favors bone mass accrual by inhibiting the activity of the sympathetic nervous system (SNS). In this regulatory loop the transcriptional mechanisms regulating catecholamine synthesis are still poorly understood. In addressing this question we focused on Sirtuin 1 (Sirt1), a histone deacetylase that integrates intracellular networks and intercellular signaling to facilitate multiple physiological functions. We show that a generalized but modest increase in *Sirt1* expression in transgenic mice (*TgSirt1* mice), compromised bone mass by suppressing bone formation and by promoting bone resorption. The opposite effects of Sirt1 on the two compartments of bone remodeling correlated with an increase in the activity of the SNS. Two observations further implicated the SNS as a mediator of the skeletal actions of Sirt1. First, expression of *Ucp1* in brown fat as well as levels of urinary epinephrine and norepinephrine increased in *TgSirt1* mice. Second, expression of *c-Myc*, *Creb* and their target genes *per1*, *per2*, *cry1*, *bmaI1 that* are upregulated by SNS signaling and contribute to the SNS regulation of bone mass, increased in osteoblasts of *TgSirt1* mice. Moreover, pharmacological inhibition of SNS .signaling by daily administration of the beta adrenergic receptor inhibitor propranolol to *TgSirt1* mice for 4 weeks fully restored osteoblast and osteoclast numbers and rescued the low bone mass phenotype of these animals. To determine if the high sympathetic tone in *TgSirt1* mice was due to a central effect of Sirt1, we examined *Sirt1* expression in the brain. Immunofluorescence analysis in coronal brain sections showed that *Sirt1* is expressed in the serotonergic neurons of the brainstem and the locus coeruleus, from where sympathetic activity emanates. Lastly, we inactivated *Sirt1* specifically in the brain by injecting 12-week-old mice carrying an allele of *Sirt1* in which exon 4 is floxed in the third ventricle with an adenovirus expressing recombinant Cre. We verified that Sirt1 was efficiently inactivated in the entire brain including the brainstem, hypothalamus, midbrain. Sirt1 inactivation in the brain decreased SNS activity and as a result, it increased bone mass by increasing bone formation and suppressing bone resorption. These observations suggest that, besides its cell autonomous effects in osteoblasts and osteoclasts, Sirt1 controls bone mass by a mechanism that involves upregulation of SNS signaling.

Convergence of transcriptional and epigenetic programs regulating osteogenic differentiation from mesenchymal stromal cells. Jonathan Gordon*[1], Hai Wu[1], Troy Whitfield[2], Coralee Tye[3], Andre Van Wijnen[4], Janet Stein[5], Gary Stein[6], Jane Lian[7]. [1]University of Vermont, USA, [2]Department of Cellular & Developmental Biology, University of Massachusetts Medical School, Worcester, MA, USA, [3]Vermont Cancer Center & Department of Biochemistry, University of Vermont, Burlington, VT., USA, [4]Mayo Clinic, USA, [5]Vermont Cancer Center & Department of Biochemistry, University of Vermont, Burlington, VT., USA, [6]University of VermontCollege of Medicine, USA, [7]University of Vermont College of Medicine, USA

Commitment to the osteoblast lineage is a complex process, utilizing a diverse cohort of DNA-binding regulatory molecules to initiate and sustain the stochastic progression of pluripotent mesenchymal cells to a tissue-specific terminally differentiated cell. These regulatory proteins may interact with chromatin directly through a DNA-binding domain, or through protein-protein interactions with DNA-bound proteins, functioning to modify gene expression and thereby providing a tissue-specific expression profile. To examine the mechanisms of osteoblast-related transcription factor regulation of lineage commitment, we have used a pure population of FACS-sorted vascular-associated aSMA+ MSCs to define genome-wide binding patterns of transcriptional regulators including Runx2, Dlx3 and several others during osteogenic differentiation. In addition we have compared these binding events with epigenetic modifications including H3K4me1, H3K4me3, H3K9me3, H3K9acetyl, H3K27me3, H3K27acetyl and H3K36me3. The patterns of transcription factor binding events present an overall picture as to regulation of gene expression during lineage specific commitment of MSC-derived osteoblasts. Using gene expression data derived from RNA-seq profiling, osteoblast-related transcription factor binding was correlated with differential gene expression and histone modification patterns to allow us to define gene regulatory networks contributing to osteogenesis. Using this analysis method, we have identified several gene regulatory pathways that include genes grouped by distinct functional roles such as: forkhead box family genes (FOX), chromatin regulators (e.g., Ezh2, Hdac10, Hdac2, Hdac3, Sirt1, Sirt6, Ncoa5, MLL3, DNMT1), nuclear co-receptors (e.g., VDR, Rarg, Nr1d2, Nr4a1, Rara, Nr2c1) and several zinc finger-related protein encoding genes. In addition, we have defined novel regulatory regions, denoted by histone modification marks and multiple transcription factor binding sites that may function as super enhancers critical for chromosomal organization leading to osteogenic differentiation. These data provide a global map of transcription factor binding and histone modifications during lineage commitment and define a comprehensive molecular signature of osteogenesis. This information can be further used to examine the role of specific transcriptional regulators and their involvement in osteoblast/bone development.

***Dnmt3b* is a Critical Target Gene during the Development of Osteoarthritis.** Jie Shen*[1], Cuicui Wang[2], Jason Meyers[1], John Ashton[1], Tzong-Jen Sheu[1], Jennifer Jonason[1], Regis O'Keefe[1]. [1]University of Rochester, USA, [2]University of Rochester Medical Center, USA

Osteoarthritis (OA) is a degenerative disease of articular cartilage that is projected to afflict >50 million people in the US by the year 2020. Predispositions include joint injury, heredity, obesity, aging and environment factors. Recent human studies revealed that DNA methylation signature was significantly shifted between healthy and OA patients, suggesting DNA methyltransferase (*Dnmt*) may play a critical role during OA pathogenesis. Despite extensive work over the past 20 years to delineate the epigenetic mechanism(s) of OA, a full understanding of the role of *Dnmt* is yet to be achieved. There are there major *Dnmts*. *Dnmt1* is ubiquitous and is involved in the whole genome methylation homeostasis. In contrast, two *de novo Dnmts*, 3a and 3b have tissue specific expression patterns and create unique methylation signatures. Our data showed that the expression of *Dnmt3b*, but not *Dnmt1* or *Dnmt3a* was significantly decreased in several well-established OA models, including an aging model, MLI model, and obesity model. Articular cartilage IHC array, including 70 human OA cartilage and 14 healthy cartilage samples, confirmed that DNMT3b expression was reduced in OA patients. *In vitro* experiments showed that mechanical loading and inflammatory factors significantly decreased *Dnmt3b* expression in ATDC5 chondrocytes. To examine the effect of *Dnmt3b* in chondrocytes, we treated primary articular chondrocytes with *Dnmt3b* siRNA and found that loss of *Dnmt3b* dramatically stimulated chondrocyte hypertrophy by reducing TGF signaling and increasing BMP signaling. To further investigate the role of *Dnmt3b* during OA development, we generated *Dnmt3b* conditional knockout mice ($Dnmt3b^{Agc1ER}$), which were administrated with tamoxifen at 2-month-old of age. In 3-month-old $Dnmt3b^{Agc1ER}$ mice, superficial zone articular chondrocytes had hypertrophy with high Type X Collagen expression. In 5-month-old $Dnmt3b^{Agc1ER}$ mice, a severe OA-like phenotype was observed, including cartilage tissue degradation, subchondral sclerosis and osteophyte formation. RNA-seq and Methyl-seq were performed and an integrated analysis performed; the data confirmed Dnmt3b targets expression and methylation of multiple TGF signaling targets and other genes involved chondrocyte

maturation and osteoarthritis. In summary, multiple known risk factors of OA change the homeostasis of articular chondrocytes via down-regulation of the *Dnmt3b* gene and target several OA-related pathways such as TGF-b and BMP signaling.

Histone Deacetylase 3 Suppresses Erk Phosphorylation and Subsequent Matrix Metalloproteinase (MMP)-13 Activity in Chondrocytes during Endochondral Ossification. Lomeli Carpio*, Elizabeth Bradley, Meghan McGee-Lawrence, Jennifer Westendorf. Mayo Clinic, USA

Histone deacetylase (Hdac) inhibitors are used extensively for treating cancer, arthritis, and epilepsy; however, these drugs inhibit multiple Hdacs, are teratogens, and have detrimental effects on the skeleton. Several Hdacs contribute to endochondral bone formation. In this study, we defined the cell autonomous role of Hdac3 in chondrocyte maturation by deleting it pre- and post-natally in type II collagen alpha 1 (Col2a1)-Cre expressing chondrocytes. Hdac3-CKO_{Col2} mice rarely survived embryogenesis. The few that did survive were hypomorphic for Hdac3 expression, runted, and had severely reduced cancellous and cortical bone density. Postnatal Hdac3 deficiency was induced with a tamoxifen-inducible Col2a1 Cre model (Hdac3-$CKO_{Col2ERT}$). At 4-weeks of age, these animals had residual hypertrophic cartilage and increased osteoclast activity in the primary spongiosa. By 8 weeks, these animals had compromised bone architecture, with significant decreases in cancellous bone but increases in cortical bone thickness, which is a compensation for disrupted growth plate maturation during development. Phosphorylation of Erk1/2, as well as its substrate Runx2, was elevated in Hdac3-depleted immature mouse articular chondrocyte (IMAC) micromass cultures. Activated Erk and Runx2 directly stimulate matrix metalloproteinase (MMP)-13 gene expression. MMP-13 mRNA and active enzymatic levels were higher in Hdac3-deficent IMAC cultures, as measured by QPCR and type I collagen zymography of conditioned media, respectively. U0126, an ERK inhibitor, returned MMP-13 expression to control levels in Hdac3-deficient IMAC cultures. In control mice, phosphorylated Erk and MMP-13 expression are restricted to the pre-hypertrophic zone of chondrocytes. With Hdac3 deficiency, phosphorylated Erk and MMP-13 are prematurely and prominently expressed in proliferative, pre-hypertrophic and hypertrophic chondrocytes. Together, these results indicate that Hdac3 controls the temporal and spatial regulation of Erk phosphorylation and subsequent MMP-13 expression to ensure proper chondrocyte maturation and ossification during long bone development.

MicroRNA-140 provides robustness to the regulation of hypertrophic chondrocyte differentiation by the PTHrP-HDAC4 pathway. Garyfallia Papaioannou*[1], Fatemeh Mirzamohammadi[2], Shigeki Nishimori[1], Marc Wein[1], Henry Kronenberg[1], Eric N. Olson[3], Tatsuya Kobayashi[1]. [1]Massachusetts General Hospital, USA, [2]Massachusetts General Hospital & Harvard Medical School, USA, [3]University of Texas Southwestern Medical Center, USA

Growth plate chondrocytes go through multiple differentiation steps and eventually become hypertrophic chondrocytes. The parathyroid hormone (PTH)-related peptide (PTHrP) signaling pathway plays a central role in the regulation of hypertrophic differentiation, at least in part, by enhancing histone deacetylase 4 (HDAC4), a negative regulator of Mef2 transcription factors that drives hypertrophy. We have previously shown that loss of the chondrocyte-specific microRNA (miRNA), miR-140, alters chondrocyte differentiation with a phenotype that includes mild acceleration of hypertrophic differentiation. However the mechanism by which miR-140-loss regulates chondrocyte differentiation is not clear. In this study, we investigated the interaction between the miR-140 pathway and the PTHrP-HDAC4 pathway. Homozygous deletion of the PTHrP or HDAC4 gene causes premature hypertrophic differentiation and reduces endochondral bone growth, whereas heterozygosity of PTHrP or HDAC4 has virtually no effect, suggesting that one allele of PTHrP or HDAC4 is sufficient to maintain normal skeletal growth. However, we found that the bone growth of heterozygous PTHrP or HDAC4 mutant mice was substantially impaired in miR-140-deficiency. This finding demonstrates that miR-140 plays an important role when the PTHrP-HDAC4 function is partially impaired, suggesting that these molecules are components of a common pathway. We found that miR-140-deficient chondrocytes showed increased Mef2c expression with normal levels of total and phosphorylated HDAC4. This finding indicates that the miR-140 pathway merges with the PTHrP-HDAC4 pathway at the level of Mef2c expression. Since Mef2c is not a predicted target of miR-140, the Mef2c upregulation is likely an indirect effect of miR-140-deficiency. We found that miR-140-deficient primary chondrocytes showed greater activation of p38 mitogen-activated protein kinase (MAPK) to serum stimulation when compared with control. Inhibition of p38 MAPK *in vitro* reduced Mef2c expression in miR-140-null chondrocytes, suggesting that miR-140 suppresses p38 MAPK signaling to inhibit hypertrophic differentiation. These results demonstrate that miR-140 ensures the robustness of the PTHrP/HDAC4 regulatory system by suppressing Mef2c-inducing stimuli.

Epigenetic control of skeletal development by the histone methyltransferase EZH2. Amel Dudakovic*[1], Fuhua Xu[2], Emily Camilleri[1], Meghan McGee-Lawrence[1], Eric Lewallen[1], Scott Riester[1], John R. Hawse[3], Gary Stein[4], Martin Montecino[5], Jennifer Westendorf[1], Andre Van Wijnen[1]. [1]Mayo Clinic, USA, [2]New Jersey Medical School, UMDNJ, USA, [3]Mayo Clinic College of Medicine, USA, [4]University of VermontCollege of Medicine, USA, [5]Universidad de Concepcion, Chile

Epigenetic control of gene expression is critical for normal development of fetal tissues including bone. Yet, chromatin related mechanisms that activate bone-specific programs have remained under-explored. Therefore, we investigated the expression profiles of a large cohort of epigenetic regulators (~400) during osteogenic differentiation of human mesenchymal stromal/stem cells (hMSCs) and mouse MC3T3 osteoblasts. We applied high-throughput RNA sequencing (RNASeq) analysis, robotic reverse-transcription quantitative polymerase chain reaction (RT-qPCR) analysis and western blotting. The molecular analyses establish that the polycomb group protein Enhancer of Zeste Homolog 2 (EZH2) is down-regulated during osteoblastic differentiation. EZH2 is the catalytic subunit of Polycomb Repressive Complex 2 (PRC2) and functions as a histone methyl-transferase. It suppresses gene transcription through modification of H3 lysine 27 by tri-methylation (H3K27Me3) and generates inaccessible chromatin. Knock-down (siRNA) of EZH2 protein levels or chemical inhibition of the enzymatic activity of EZH2 using a specific inhibitor (GSK126) during differentiation enhances the expression of osteoblast-specific histological and molecular biomarkers (e.g., Alizarin Red and AP staining, as well as ALPL, IBSP and BGLAP mRNAs). To understand the function of this epigenetic regulator during skeletal development, we examined a conditional knockout mouse (cKO) model for Ezh2. The Ezh2 gene was conditionally eliminated by Cre mediated excision in the mesenchymal lineage using the Prrx1 promoter. The resulting mice were examined for gross anatomy, radiology and μCT. Compared to wild type littermates, Ezh2 cKO mice exhibit stunted growth and malformation of forelimbs, paws, lumbar vertebrae and clavicles. Alterations are also observed in the epiphysis, the tibia-fibula junction and trabecular bone formation. Mutant mice have low bone mass as measured by DXA and μCT analysis. Several of these skeletal abnormalities resemble those observed in human patients with EZH2 mutations. Our data indicate that EZH2 is a critical epigenetic regulator for normal skeletal development and bone formation.

Formation of a Zinc finger protein 521-NuRD co-repressor complex is involved in osteoprogenitor commitment and Zebrafish skeletal development. Ken-ichi Takeyama*[1], Harikiran Nistala[2], William Addison[1], Satya Kota[1], Genri Kawahara[3], Louis Kunkel[3], Julian Mintseris[4], Steven Gygi[4], Francesca Gori[5], Roland Baron[6]. [1]Harvard School of Dental Medicine, USA, [2]Harvard University, USA, [3]Harvard Medical School, Boston Children's Hospital, USA, [4]Harvard Medical School, USA, [5]Harvard School of Dental Medicine, Massachusetts General Hospital, USA, [6]Harvard School of Medicine & of Dental Medicine, USA

The differentiation of mesenchymal stem cell (MSC) into osteoblast or chondrocyte is strictly controlled through gene regulation and epigenetic mechanisms with post-translational modifications on core histones. We have previously shown that the C2H2-type zinc finger protein 521 (Zfp521) plays important roles as a transcriptional repressor during osteoblastogenesis and chondrogenesis. Although HDAC-dependent repression of Runx2 or repression of Ebf1 are involved, the molecular mechanism(s) by which transcriptional repression by Zfp521 occurs still remains unclear.

To elucidate the transcriptional repressor function of Zfp521, we performed protein complex purification by stably expressing Zfp521 in HEK293A cells. We found all core components of the Nucleosome Remodeling and Deacetylase (NuRD) complex by mass spec analysis and validated the formation of a large complex (over 2 MDa) by glycerol gradient fractionation. Intriguingly, transglutaminase (TGase)3, which mediates protein-protein cross-linking, was also found in this complex. Endogeneous association of Zfp521 with NuRD and TGase3 was also observed in MEFs, W-20 and C3H10T1/2 cells, suggesting that Zfp521 regulates transcriptional repression through this complex during MSC differentiation. GST pull-down analysis demonstrated that RBBP4, a NuRD component that interacts with histone H4, binds directly to the N-terminal 13 amino acids (N13aa) of Zfp521 and to the catalytic region of TGase3. Furthermore, addition of N13aa peptides to the complex resulted in the disassembly of the Zfp521 and NuRD complex, whereas depletion of RBBP4 in HEK293A cells induced the dissociation of Zfp521 and TGase3.

To investigate the role of the Zfp521-NuRD complex in MSC differentiation in vivo, we depleted Zfp521 or RBBP4 homologs in Zebrafish and analyzed their skeletal phenotype. The mutant embryos (depleted Zfp521 or RBBP4) demonstrated similar developmental abnormalities including delayed cranial cartilage and bone development, and reduced expression of Sox9, Runx2 and Col II, suggesting that the Zfp521-NuRD complex plays a role in the suppression of genes involved in early skeletal development.

Taken together, our results suggest that 1) Zfp521 forms a large complex with NuRD and TGase3, and 2) the mechanisms by which Zfp521 exerts its transcriptional repression function to regulate MSC differentiation into osteoblast and chondrocyte involves epigenetic regulation via the recruitment of the NuRD complex.

The molecular chaperone FKBP51 regulates energy metabolism and bone mass by controlling PPARg and p38 MAPK activities in adipocytes and marrow mesenchymal stem cells. Lance Stechschulte*[1], Edwin Sanchez[1], Piotr Czernik[2], Beata Lecka-Czernik[2]. [1]University of Toledo Health Science Campus, USA, [2]University of Toledo College of Medicine, USA

Nuclear receptor PPARγ controls energy metabolism and promotes differentiation of mesenchymal stem cells (MSC) to adipocytes at the expense of osteoblasts. In contrast, p38 MAPK promotes MSC differentiation to osteoblasts at the expense of adipocytes. Phosphorylation of p38 MAPK at Thr180/Tyr182 is required for its kinase activity, which in turn phosphorylates and activates the pro-osteoblastic factors Runx2 and Wnt10b, and inhibits PPARγ pro-adipocytic transcriptional activity through Ser112 phosphorylation. Our recent evidence suggests that FK506-binding protein-51 (FKBP51) negatively regulates p38 and positively regulates PPARγ activity. Overexpression of FKBP51 in COS7 cells increases rosiglitazone-induced PPARγ activity at a PPRE-luciferase reporter, while deficiency of FKBP51 decreases PPARγ activity. The latter result correlated with a simultaneous increase of PPARγ phosphorylation at Ser112 and p38 MAPK phosphorylation at Thr180/Tyr182. Animals with whole-body FKBP51 ablation (p51-KO) are lean, insulin sensitive, and protected from obesity, with greatly reduced adipose tissue mass. These animals also exhibit high bone mass. Trabecular bone mass is 30% higher in p51-KO vs. WT mice, mainly due to increased number of trabeculae. This is accompanied by increased activity of osteoblasts, as reflected by 40% larger mineralized surface, 20% higher mineral apposition rate, and 60% higher bone formation rate. Osteocytes isolated from cortical bone of femurs showed decreased SOST expression by 2-fold in p51-KO animals. Consistently, osteoblasts isolated from the surface of the same bone are highly activated, as measured by increased expression of Runx2, osterix, collagen and osteocalcin. When tested for their differentiation potential, marrow MSCs derived from p51-KO mice develop fewer adipocytic colony forming units (CFU), but the same number of CFUs in the osteoblastic lineage. Interestingly, calcium content was 2-fold higher in osteoblasts formed from the marrow of p51-KO animals. These results indicate that the FKBP51 chaperone regulates energy metabolism and bone mass by controlling the balance between PPARγ and p38 MAPK activities. Thus, FKBP51 activity is evidence for a common mechanism regulating MSC differentiation and energy maintenance. Targeting this mechanism may serve as a new pharmacological means for simultaneous treatment of obesity, diabetes and osteoporosis.

Glucocorticoid Signaling in Osteoblasts Mediates Age-Associated Changes in Glucose Metabolism and Body Composition in Mice. Holger Henneicke*[1], Jingbao Li[2], Sylvia Jane Gasparini[3], Markus Seibel[4], Hong Zhou[4]. [1]ANZAC Research Institute, The University of Sydney, Australia, [2]Key Laboratory for Space Bioscience & Biotechnology, Institute of Special Environmental Biophysics, Faculty of Life Sciences, Northwestern Polytechnical University, China, [3]Bone Biology Program, ANZAC Research Institute, The University of Sydney, Australia, [4]Bone Research Program, ANZAC Research Institute, University of Sydney, Australia

The physiological aging process is associated with changes in body composition and metabolism, including central obesity, diabetes and osteoporosis. The osteoblast has recently been identified as a mediator of GC-induced metabolic dysfunction in mice.[1] We therefore hypothesized that a mechanistic link exists between increased GC signaling in the osteoblast and changes in body composition and fuel metabolism during aging.

To test this hypothesis, we investigated the aging phenotype of transgenic (tg) mice in which glucocorticoid signaling had been selectively disrupted in osteoblasts/osteocytes via targeted overexpression of the glucocorticoid-inactivating enzyme, 11ß-hydroxysteroid dehydrogenase type 2 ('11ßHSD2-tg' mice). Body weight and composition, insulin sensitivity and glucose tolerance, serum corticosterone (CS) and osteocalcin levels as well as hepatic gene expression patterns related to glucose and lipid metabolism were assessed in female 11ßHSD2-tg mice and litter-matched wild-type (WT) controls at 2 and 18 months of age.

From 2 to 18 months of age, female WT mice gained more in body weight (WT: +32g vs tg: +16g, $p<0.01$) and overall fat mass (WT: +20.7g vs tg: +6.3g, $p<0.01$, Fig 1A) than their tg littermates. 18 months-old WT mice exhibited reduced insulin sensitivity and hepatosteatosis, while insulin responsiveness and hepatic lipid deposition remained normal in their tg littermates (Fig. 1B). Hepatic mRNA expression of lipogenic and gluconeogenic genes was higher in aged WT compared to aged tg mice (acetyl-coA-carboxylase, WT: 12.8 vs tg: 5.6 fold increase on respective young control, $p=0.051$ & glucose-6-phosphatase, WT: 8.1 vs tg: 3.3 fold increase on respective young control, $p=0.09$). Serum CS concentrations were similar in 18-month-old WT and tg mice and ~3-fold higher than in 2-month-old mice ($p<0.05$). Serum osteocalcin concentrations declined during aging in both genotypes but remained significantly higher in tg mice at all time points ($p<0.05$).

Conclusion: Glucocorticoid signaling in osteoblasts is critically involved in the pathogenesis of age-related changes in glucose handling and body composition. Osteocalcin may act as a mediator of age-related metabolic dysfunction.

Brown adipocyte-like cells from the peripheral nerve functionally contribute to heterotopic bone formation in a multifaceted manner. Elizabeth Salisbury*[1], ZaWaunyka Lazard[2], Eric Beal II[2], Eleanor Davis[2], Alan Davis[1], Elizabeth Olmsted-Davis[1]. [1]Baylor College of Medicine, USA, [2]Baylor College of Medicine, USA

We have previously developed an animal model of heterotopic ossification (HO), whereby delivery of bone morphogenetic protein 2 (BMP2) to the skeletal muscle of mice initiates a crucial neuro-inflammatory response that ultimately results in endochondral bone formation within the muscle. One major outcome of neuro-inflammation is the degranulation of mast cells, which release proteases that remodel the epineurial matrix of the nerve. Mast cells also release serotonin locally, resulting in a significant increase in noradrenaline and activation of sympathetic signaling within 2 days after delivery of BMP2. Immunohistochemical and FACS analysis indicated the activation and replication of perineurial fibroblasts expressing the β_3-adrenergic receptor (ADRB3), through which noradrenaline is known to signal. This population of ADRB3$^+$ cells also expressed the neural migratory marker HNK1. By 4 days after exposure to BMP2, isolation and characterization of these ADRB3$^+$ cells revealed their presence within the soft tissues surrounding the site of BMP2 delivery and their absence from the nerves, suggesting the migration of this cell population. These cells also expressed the brown adipocyte marker uncoupling protein 1 (UCP1), which enables uncoupled aerobic respiration, as well as markers of glucose lactate fermentation, which provides these cells unique metabolic properties. Suppression of mast cell degranulation and the pursuant sympathetic signaling by administration of cromolyn inhibited the generation of these brown adipocyte-like cells, ablating both UCP1 gene and protein expression at the site. Cromolyn administration also significantly reduced heterotopic bone formation, as indicated by microCT, and appeared to suppress cartilage formation. Immunohistochemistry revealed multiple fates for these brown adipocyte-like cells, as one subset expressed the neural guidance molecule reelin and another expressed vascular endothelial growth factors (VEGF-D) for proper vascularization of the new bone. Furthermore, using tracking animals, a portion of these cells appear to differentiate directly into chondrocytes. The data collectively suggest that BMP2 activates a population of perineurial cells within the nerve to expand, migrate, and differentiate into brown adipocyte-like cells that have multiple functions in guiding the formation of heterotopic bone.

Leptin is crucial for ventral hypothalamic FosB-mediated regulation of glucose and energy homeostasis but not for bone homeostasis. Kazusa Sato*[1], Anna Idelevich[2], Glenn Rowe[3], Francesca Gori[4], Roland Baron[5]. [1]Harvard School of Dental Medicine, USA, [2]Harvard University, USA, [3]Harvard Medical School, USA, [4]Harvard School of Dental Medicine, Massachusetts General Hospital, USA, [5]Harvard School of Medicine & of Dental Medicine, USA

The ventral hypothalamus (VHT) plays a key role in bone homeostasis as well as in energy balance and glucose metabolism, through endocrine and neuronal pathways. Leptin, a key adipokine signaling via both the VHT and the periphery affects positively energy and glucose metabolism whereas it has been reported to also affect bone.

ΔFosB is a naturally truncated form of FosB that opposes AP-1 transcriptional activity. ENO2 (enolase 2)-ΔFosB mice, in which the expression of ΔFosB is driven in bone, adipose tissues, and the VHT, have increased bone mass and energy expenditure, decreased fat mass and increased glucose tolerance and insulin sensitivity, despite lower levels of leptin. Moreover, viral-mediated expression of ΔFosB in the VHT, where leptin receptors are highly expressed, phenocopies all the bone, glucose and energy phenotypes of ENO2-ΔFosB mice. We have generated a ΔFosB transgenic model in leptin deficient ob/ob mice (ob/ob-ENO2-ΔFosB) to determine whether the bone and energy phenotypes were linked and whether leptin could be that link. Surprisingly, in this model the ΔFosB-mediated metabolic improvement was lost whereas the increased bone mass remained, despite the absence of leptin.

The present study was therefore performed to evaluate the contribution of leptin to ΔFosB-mediated regulation specifically in the VHT. To this end, C57BL/6 and ob/ob mice were stereotaxically injected in the VHT with adeno-associated virus encoding ΔFosB (AAV-ΔFosB) or GFP (AAV-GFP) as control.

AAV-ΔFosB injection in the VHT did not improve the severe obesity and adiposity of ob/ob mice. Whereas C57-AAV-ΔFosB mice had increased energy expenditure, as expected, ob/ob-AAV-ΔFosB mice failed to respond. Similarly, ob/ob-AAV-ΔFosB mice failed to correct the exacerbated glucose intolerance and insulin resistance together with hyperinsulinemia and hypertrophic pancreatic islets observed in ob/ob-AAV-GFP mice. In contrast, μCT analysis of distal femur revealed that the ob/ob-AAV-ΔFosB mice still showed the significant increases in BV/TV and trabecular numbers and a significant decrease in trabecular spacing compared to ob/ob-AAV-GFP.

Taken together, these results demonstrate that signaling from the VHT downstream of ΔFosB affects separately bone homeostasis and energy/glucose metabolism: expression of the AP1 antagonist ΔFosB in the VHT increases bone in a leptin-independent manner whereas its regulation of energy and glucose metabolism is leptin-dependent.

DLK1 Exerts a Negative Feedback Regulation on The Osteocalcin-Insulin Loop. Basem Abdallah*[1], Nicholas Ditzel[2], Gerard Karsenty[3], Moustapha Kassem[2]. [1]Odense University Hospital, University of South Denmark, Denmark, [2]Odense University Hospital, Denmark, [3]Columbia University, USA

Several lines of evidence support the endocrine role of the skeleton in overall energy metabolism through the undercaboxylated form of osteocalcin (Glu-OCN) that acts on beta cells of the pancreas to increase their proliferation and the secretion of insulin. In turn insulin singals in osteoblasts favors in two-step pathways the decarboxylation and activation of osteocalcin. The nature of the negative regulatory signal of this loop remains unknown. DLK1/PREF-1/FA1 (Delta like 1/Pre-adipocyte factor-1/ fetal antigen-1), is a circulating factor produced by pancreatic β cells that co-localized with insulin in the secretory vesicles. Thus, we examined the role of DLK1 in insulin signaling in osteoblastic cells and its contribution to energy metabolism. Glu-OCN stimulated *Dlk1* gene expression by pancreatic islets. Insulin-induced osteoblast differentiation and osteocalcin expression were blocked in calvarial osteoblasts (OB) derived from osteoblast-specific *Dlk1* overexpressing mice (Col1-Dlk1) while it was significantly up-regulated in *Dlk1* null mice-derived OB (*Dlk1*$^{-/-}$OB). In addition, serum levels of Glu-OCN were reduced in Col1-Dlk1 mice by 43%, while it was elevated in *Dlk1*$^{-/-}$mice by 48% compared to WT controls. In vivo glucose metabolic studies revealed reduced insulin secretion and sensitivity in Col1-Dlk1 mice, while *Dlk1*$^{-/-}$mice showed increased insulin secretion and sensitivity. At the molecular levels, DLK1 antagonizes insulin signaling in OB by inhibiting the AKT phosphorylation of the forkhead transcription factor FoxO1 and also decreases osteocalcin expression. We propose that Glu-OCN-controlled production of DLK1 by pancreatic β cells acts as one negative feedback mechanism to counteract the stimulatory effects of insulin on osteoblast production of GLU-OCN, a mechanism preventing osteocalcin-induced hypoglycemia.

Mitochondrial Etiology of Osteoporosis. Roman Eliseev*, Jerry Madukwe, Regis O'Keefe. University of Rochester, USA

Current views on the pathogenesis of osteoporosis are primarily centered on aging-associated hormone depletion. However, the loss of bone starts before the decline in hormones and is, in large part, due to increased oxidative stress in aging bone. Mitochondria are both a major source and major sensor of oxidative stress. Therefore, mitochondria are in the center of research efforts in various fields including cardiovascular pathology; however their role in the pathogenesis of bone diseases, such as osteoporosis, is unknown. Bone forming osteoblasts originate from mesenchymal stem cells (MSC). Undifferentiated MSCs primarily use glycolysis for energy production and switch to mitochondrial oxidative phosphorylation during osteogenic differentiation. Active mitochondria are required for MSC osteogenic differentiation. We hypothesized that mitochondrial function is disrupted in aged bone marrow (BM) MSCs leading to their decreased osteogenicity and bone loss. Our data indicate that aged mice showing signs of bone loss as measured with micro-CT and histology (Fig. 1), have decreased oxidative metabolism in bone tissue as measured with metabolomics mass spectroscopy, and decreased BM MSC mitochondrial function as measured with oxygen consumption rate assay.

Mitochondrial permeability transition (MPT) is the major mechanism of mitochondrial dysfunction in aging. The MPT is a non-selective mitochondrial pore regulated by cyclophilin D (CypD). CypD knock-out (KO) mouse is an established MPT loss-of-function model which shows protection from aging-associated mitochondrial dysfunction in various tissues. We have evaluated the effect of CypD KO on aged bone and BM MSCs. Our data indicate improved bone quality (Fig. 1) and biomechanical properties, and increased BM MSC mitochondrial function and osteogenic potential in aged CypD KO mice when compared to aged wild type mice.

Our study presents evidence of disruption of oxidative metabolism and mitochondrial function in aged bone, and suggests that the MPT plays a significant role in such a disruption. Protecting mitochondrial function in BM MSCs via inhibition of the MPT is, therefore, a promising new approach to improve aging bone.

Identification of Gremlin1 as A Catabolic Factor Induced by Mechanical Stress Loading in Articular Chondrocytes. Song Ho Chang*[1], Hiroshi Kobayashi[2], Keita Okada[1], Shurei Sugita[3], Tomotake Okuma[1], Sakae Tanaka[1], Taku Saito[4]. [1]The University of Tokyo, Japan, [2]The University of Tokyo Hospital, Japan, [3]Japan, [4]University of Tokyo, Graduate School of Medicine, Japan

Excessive mechanical stress loading on articular cartilage is one of the major factors of osteoarthritis (OA); however, the molecular mechanisms of cartilage degradation by such loading remain unclear. To know target genes in this process, we first examined gene expression profiles of articular chondrocytes under mechanical stress loading using a cell stretcher system, STB-140 (STREX). We applied a uni-axial cyclic cell stretch (0.5 Hz, 10% stretch) to primary articular chondrocytes from 5-day-old mouse knee joints for 30 min, and cultured them for an additional 24 h. Among 2,076 upregulated genes in microarray analysis, we focused on Gremlin1 (Grem1), which is one of the most highly expressed genes. Grem1 is known to be a secretory protein that regulates limb development, although its function in articular cartilage is unknown. Immunocytochemistry confirmed that Grem1 expression was increased in cytoplasm of articular chondrocytes by cyclic cell stretch. Grem1 mRNA expression also increased under the cyclic hydrostatic pressure (0.1 Hz, 20 MPa) to femoral heads obtained from 3-week-old mouse in our original programmable system. Immunofluorescence further revealed that Grem1 protein was enhanced on the cell surface of articular chondrocytes during OA development of the experimental mouse model. In primary culture of mouse articular chondrocytes, recombinant human (rh) Grem1 treatment induced the expressions of catabolic factors including *Mmp13* and *Adamts5*, and suppressed those of anabolic factors including *Col2a1*, *Aggrecan* and *Sox9*. In the organ culture of mouse femoral heads, rhGrem1 treatment increased aggrecan release into the medium in a dose-dependent manner. In the experimental mouse OA model, intraarticular injection of rhGrem1 exacerbated cartilage degradation. To further

examine the mechanism underlying the catabolic effect of Grem1, we focused on the NF-κB signal which was identified as a candidate by pathway analyses and gene ontology analyses. In the organ culture of femoral heads from conditional knockout mice of Rela, a representative transcription factor of the NF-κB signal, rhGrem1 did not induce the aggrecan release. We additionally confirmed that an IKK inhibitor (BMS-345541) treatment also diminished the increase of aggrecan release. In conclusion, Grem1 is induced by mechanical stress loading and exerts catabolic effects to articular cartilage through the NF-κB signal. Gremlin1 may provide a novel therapeutic target of OA.

Cellular Tension Regulates TGFβ Receptor Spatial Organization and Induction of Chondrogenic Gene Expression. Joanna Rys*[1], Christopher DuFort[1], Michelle Baird[2], Michael Davidson[2], Tamara Alliston[1]. [1]University of California, San Francisco, USA, [2]National High Magnetic Field Laboratory & Department of Biological Science, Florida State University, USA

The extracellular microenvironment is rich in physical and biochemical cues that powerfully regulate cell behavior. Cells dynamically sense external physical cues through integrins and respond by modulating internal cellular tension and mechanotransduction pathways. Cell tension, generated in response to physical cues like substrate stiffness, calibrates the cellular response to biochemical signals through mechanisms that remain unclear. The growth factor TGFβ is a potent agonist of chondrocyte differentiation and is implicated in skeletal dysplasia and osteoarthritis. Previous work by our group demonstrated that substrate stiffness strongly enhances TGFβ-induced effector activity and chondrocyte gene expression (Allen 2012). To identify the molecular mechanisms by which physical cues modulate the cellular response to TGFβ, we are investigating the hypothesis that cellular tension regulates TGFβ receptor (TβRI and TβRII) spatial organization and function.

We utilized high-resolution quantitative imaging (total internal reflection fluorescence, TIRF) and novel fluorescently labeled TGFβ receptor subunits to visualize spatiotemporal regulation of signaling in mesenchymally-derived ATDC5 and NIH-3T3 cells. This innovative approach provided an unprecedented view of the cell surface and revealed that TβRII is excluded from focal adhesions, forming a peripheral ring that surrounds integrin α2 (Fig 1A-D). In contrast, both forms of TβRI (Alk1, Alk5) co-localize with integrin α2 at focal adhesion sites. This receptor organization pattern depends on cellular tension, as molecular inhibitors against both ROCK and myosin disrupt the exclusion of TβRII, and lead to co-localization with integrin α2 within 15 minutes of treatment (Fig 1E-H). To further elucidate the effect of cellular tension on TGFβ receptor dynamics, we created spatially resolved maps of individual receptors with single particle tracking photoactivation localization microscopy (sptPALM). These maps reveal distinct patterns of TβR localization with respect to focal adhesions. We utilized mass spectrometry coupled with co-immunoprecipitation to identify novel and specific protein-protein interactions with TβRI and TβRII, thus gaining insight into interactions that drive these mechanisms. This work elucidates the molecular mechanisms by which cells integrate physical and biochemical cues, insight that advances our understanding of development and disease progression in the skeleton and other tissues.

Muscle, Bone, and Nerve Differentially Interact to Achieve Trabecular and Cortical Bone Homeostasis. Steven Bain, Philippe Huber, Ronald Kwon, Laura Stoll, Ted Gross*. University of Washington, USA

Muscle atrophy precipitates rapid and frequently profound bone loss. The reduction in skeletal loading concomitant with sarcopenia has been presumed to be a primary mediator of bone catabolism. However, it is unclear whether diminished muscle function may modulate bone homeostasis independent of skeletal loading as *in vivo* models of muscle atrophy are invariably coupled with decreased skeletal loading. To address this question, we implemented three *in vivo* models of neuromuscular dysfunction intended to demonstrate differential gait dysfunction and muscle atrophy. We used gait kinetics and kinematics to quantify tibia mid-shaft normal strains and serial microCT imaging to quantify muscle, tibia trabecular and cortical bone atrophy in female C57 mice (16wk). Mice were randomly assigned to receive transient paralysis of the right calf (C) or quadriceps (Q) muscle groups (2U/100g Botulinum Toxin A, BTxA) or peripheral nerve injury (PNI) of the right sciatic nerve via a plastic sleeve (n=8/grp). Mice were assessed on d0, d5 and d12, with all measures normalized to d0 data. Gait-induced normal strains were more diminished by Q than C paralysis at d5 (-53.0 ± 4.9% vs -35.4 ± 3.1%; p=0.01), but were equivalently diminished by d12 (C: -37.0 ± 3.8%; Q: -40.6 ± 8.1%). PNI did not alter normal strains vs d0. By d12, calf muscle volume was diminished more by C (-32.2 ± 0.9%; $p<0.01$) than Q paralysis (-18.0 ± 2.4%), but not altered by PNI. C and Q paralysis significantly, but equivalently, degraded trabecular BV/TV at d5 (C:-21.4 ± 5.2%; Q:-33.8 ± 3.0%) and d12 (C:-69.1 ± 3.6%, Q:-72.0 ± 3.2%), while PNI induced less, but significant BV/TV loss at d12 (-26.5 ± 4.1%). C (8.4 ± 1.0%) and Q paralysis (11.7 ± 2.0%) induced significant (but equivalent) endocortical resorption at d12, while PNI did not. Diminished normal strains and decreased trabecular BV/TV were minimally correlated ($r^2<0.19$), but the relation between diminished normal strains and endocortical expansion was significant ($r^2=0.62$, $p<0.01$). In sum, these data suggest that cortical and trabecular bone are differentially regulated by muscle, bone and nerve interactions. For cortical homeostasis, muscle function was a potent modulator via gait-induced mechanical stimuli. However, the significant trabecular loss following PNI and the poor correlation between decreased gait-induced strains and BV/TV, suggest that neuronal pathways serve an essential role in trabecular homeostasis.

The nuclear envelope mechanosome regulates mechanical activation of βcatenin and its nuclear transport. Gunes Uzer*[1], Buer Sen[2], William Thompson[1], Zhihui Xie[3], Sherwin Yen[3], Guniz Bas[3], Maya Styner[4], Clinton Rubin[5], Janet Rubin[4]. [1]University of North Carolina, USA, [2]University of North Carolina At Chapel Hill, USA, [3]University of North Carolina, USA, [4]University of North Carolina, Chapel Hill, School of Medicine, USA, [5]State University of New York at Stony Brook, USA

Mechanical signals generated during functional loading promote osteoblastogenesis at load bearing sites and this mechanically-induced MSC phenotype is supported by nuclear shuttling of βcatenin to nucleus, a process that is poorly understood. Mimicking exercise, high magnitude strain (HMS, ~2%) augments pro-osteogenic and anti-adipogenic programs in MSC through proximal activation of FAK/mTORC2/Akt that regulates the active βcatenin pool. Low intensity vibration (LIV, 0.7G x 90Hz) induces a phenotypic response similar to HMS inducing FAK and Akt phosphorylation and preventing βcatenin degradation. However, application of LIV generates virtually no substrate strain (0.001%), which suggests that cellular mechanosensing and signal initiation must differ from that of HMS, even though both induce nuclear βcatenin translocation. We found that disruption of the nuclear envelope LINC complex (Linker of Nucleoskeleton and Cytoskeleton), through delivery of DNKASH or siSUN, prevented LIV but not HMS induction of pFAK and pAkt ($p<0.01$) supporting the idea that mechanosensing of LIV and HMS is dissimilar. Further, inhibition of FAK or FAK's co-regulator Fyn, both essential for strain-induced Akt recruitment focal adhesions (FAs), did not interfere with Akt activation by LIV ($p<0.05$). As Akt is required for the phenotypic LIV response, and its activation required LINC, we hypothesized that LIV might activate Akt at the nuclear envelope to facilitate inward βcatenin transport. First, immunoprecipitation (IP) of the FA protein Vinculin revealed that LIV-induced pAkt was not found in the FAs. We next found that IP of Nesprin, a LINC complex protein in the nuclear envelope showed a strong association with pAkt and βcatenin. Interestingly, βcatenin-Nesprin association decreased after LIV treatment followed by an increase in nuclear βcatenin, implicating Nesprin, and thus the LINC complex, in enabling the distal mechanical event of βcatenin nuclear entry. Indeed, disrupting LINC function (DNKASH, siSUN) prevented *both* LIV and HMS-induced nuclear accumulation of βcatenin. In summary, our data show that while proximal mechanical signals differ – the FAK and Akt response to substrate strain requires the substrate/membrane interface while response to LIV requires the cytoskeletal/nuclear interface – their distal signaling converges at the nuclear envelope where nuclear-cytoskeletal coupling is required for mechanically induced βcatenin transport into the nucleus.

Altered force sensing and cell-cell adhesion by mutant ACVR1/ALK2 FOP progenitor cells – implications for heterotopic ossification. Julia Haupt*, Brian Cosgrove, Claire McLeod, Andria Culbert, Robert L. Mauck, Eileen M. Shore. University of Pennsylvania, USA

In the rare genetic disease fibrodysplasia ossificans progressiva (FOP), progenitor cells are misregulated to differentiate to heterotopic bone in connective tissues. Rigidity of the microenvironment is a key modulator of lineage specification and

sufficient to direct cell fates. Soft substrates induce mesenchymal progenitors towards neuro-/adipogenic lineages while stiff substrates promote chondro-/osteogenesis. Pathologic stiffening of the microenvironment occurs in fibrotic diseases when damaged tissue aberrantly acquires increased rigidity during wound healing. Injury-induced early-to-intermediate stage FOP lesions similarly exhibit excessive fibroproliferation. Gain-of-function mutations in the BMP type I receptor ACVR1/ALK2 cause FOP, with R206H mutation most prevalent. Since BMP signaling regulates and is regulated by cell tensional force (with low signaling activity on soft vs. high activity on stiff substrates), altered ACVR1 signaling could influence mechanotransduction pathways. We hypothesized that the FOP mutation alters mechanical force sensing in progenitor cells, altering the perception of mechanical cues and lowering the threshold for bone formation. We used immortalized mouse embryonic fibroblasts (iMEFs) from an $ACVR1^{R206H}$ knock-in embryo and WT littermate on varied matrix elasticity (soft: 5kPa; moderate: 15kPa, stiff: 55kPa) and analyzed morphological parameters (cell size, aspect ratio (AR), circularity, solidity) at low cell density. WT cells responded to increasing stiffness as expected with increased cell size and AR, and decreased circularity and solidity. However, FOP iMEF response to soft substrates was similar to WT on stiff substrates, and FOP cells were less responsive to substrate rigidity. Increased cell polarity and membrane extensions in FOP iMEFs correlated with enhanced migration and proliferation. FOP iMEFs also showed a loss of contact inhibition, reduced cell-cell contacts with failure in adherens junction formation, and β-catenin loss at cell membranes. Increased β-catenin degradation in FOP iMEFs was facilitated by overexpression of the destruction complex component Axin2. These data support that the combination of increased BMP signaling, misinterpretation of soft substrates, and overall reduced sensitivity to mechanical stimuli in FOP cells lowers their threshold for commitment to chondro-/osteogenic lineages, resulting in an aberrant tissue repair response that leads to ectopic bone formation.

Inner ear vestibular signals contribute to bone loss through the sympathetic nervous system. Guillaume Vignaux*, Jean De La Croix Ndong, Florent Elefteriou. Vanderbilt University, USA

Elderly is a population highly affected by bone loss and with high risk of fracture. The vestibular system is degenerating with age and is known to influence autonomic outflow. Since sympathetic nerve activation induces bone loss, we hypothesized that microgravity-induced bone loss in space may be, at least in part, caused by disturbance in vestibular signals. To address this hypothesis, we used a mouse model of vestibular lesion (VBX).

VBX animals were subjected to a bilateral transtympanic injection of sodium arsenilate whereas Sham animals were injected with PBS. One hundred and twenty 2-month old mice were divided in 12 groups: 1) WT groups ± VBX ± propranolol 2) global beta2 adrenergic receptor (b2AR) deficient groups ± VBX 3) osteoblast specific b2AR deficient groups ± VBX.

Vestibular syndrome was evaluated 3, 15 and 30 days after lesions. One month after lesions, micro-CT and histomorphometry analyses were performed on the femoral epiphysis. UCP1 gene expression in the brown adipose tissue and serum TNFα were respectively measured as a marker of sympathetic nervous system (SNS) outflow and systemic inflammation.

During the entire month of study, all VBX animals expressed a significant vestibular syndrome. Micro-CT analyses revealed a significant reduction in trabecular Bone Volume/Tissue Volume in the WT VBX group versus WT Sham group. This phenotype was accompanied with both a significant decrease in osteoblast surface/bone surface and a significant increase in osteoclast surface/bone surface ratio. Additionally, UCP1 expression was increased 2-times after VBX whereas serum TNFα levels were not affected, suggesting an increase in SNS outflow and absence of chronic inflammation. Pharmacological treatment with propranolol (a non-selective beta blocker) or b2AR deficiency (global and specific) completely blunted the vestibular-induced bone loss and changes in bone microarchitecture and cellular parameters.

We conclude that vestibular signals, transmitted via sympathetic nerves, modulate bone remodeling, and that vestibular dysfunction may contribute to bone loss occurring with aging, along with the decrease in mobility and hormones changes. These results may also shed a new light on patients with vestibular disease.

Alternative NF-κB Controls Mitochondrial Biogenesis Independent of Osteoclast Differentiation. Rong Zeng*[1], Deborah Novack[2], Chang Yang[3]. [1]Washington University in St. Louis, USA, [2]Washington University in St. Louis School of Medicine, USA, [3]Washington University in St Louis School of Medicine, USA

The Osteoclast's (OC) role to resorb bone matrix is governed by many signaling pathways that control both differentiation and resorption, including the alternative NF-kB. Mitochondria are extremely abundant in OCs and likely provide ATP to ruffled membrane vATPases. During osteoclastogenesis (OCg) *in vitro*, mitochondria DNA copy number (mtCN) (a surrogate for mitochondria content) rises, but data are conflicting on whether it is obligate for differentiation. In this study we used mutations in the alternative NF-kB pathway proteins RelB and NIK to dissect the relationship between mitochondrial biogenesis (MB) and OCg. When OC precusors from relb-/-, nik-/-, and CatK.NT3 (constitutively active NIK transgene driven by the Cathepsin K promoter) mice were cultured under osteoclastogenic conditions (M-CSF+RANKL), we found mtCN to be reduced in relb-/- and nik-/-, and increased in CatK.NT3 cultures. Likewise, expression of oxidative phosphorylation subunits, assayed by qRT-PCR and immunoblotting, were significantly blunted in relb-/- and nik-/- but increased in CatK.NT3 cells. Importantly, there were parallel functional changes in basal and maximal oxygen consumption rates. By transmission EM, both relB-/- and CatK.NT3 OCs have abnormal mitochondrial morphology. Cells lacking classical pathway subunit p65 did not recapitulate these differences, indicating the distinct role of alternative NF-kB pathway for MB. To deduce the mechanism for MB defects, we examined expression of several genes known to control MB. PGC-1β (but not PGC-1α, PRC, or PPARγ) was significantly decreased in relb-/- and nik-/- cells during OCg, with ChIP data showing PGC-1β as a direct RelB transcriptional target. Because PGC-1β has been suggested to positively regulate both MB and OCg in OCs, we retrovirally overexpressed PGC-1β in relb-/- cells and evaluated both processes. Surprisingly, PGC-1β had no effect on differentiation or NFATc1 expression, and only partially restored MB. To investigate whether a lack of differentiation prevented MB, we overexpressed NFATc1 in relB-/- precursors, which fully restored OCg but had no effect on MB. Bone resorption was improved, but did not reach levels in similarly transduced WT cultures, indicating resorptive defects independent of differentiation. We conclude that one distinct arm of alternative NF-kB controls OCg (via NFATc1) while the other controls MB (via PGC-1β and other targets), acting in concert to contribute to OC's role in bone resorption.

The actin-binding protein Cofilin and its interaction with cortactin are required for podosome patterning in osteoclasts and bone resorption in vivo and in vitro. Detina Zalli*[1], Kenichi Nagano[2], Lynn Neff[3], Ken-ichi Takeyama[2], Walter Witke[4], Francesca Gori[5], Roland Baron[6]. [1]USA, [2]Harvard School of Dental Medicine, USA, [3] Harvard School of Dental Medicine 188 Longwood Ave Boston MA 02115, USA, [4]Prof. Dr. Walter Witke Institute of Genetics University Bonn Karlrobert Kreiten Str. 13 D - 53115 Bonn/Germany, Germany, [5]Harvard School of Dental Medicine, Massachusetts General Hospital, USA, [6]Harvard School of Medicine & of Dental Medicine, USA

Osteoclast (OC) adhesion to and migration along bone surfaces and thereby bone resorption requires expansion of specific F-actin adhesion structures, the podosomes, into a ring and their dense packing into the sealing zone, to define and seal off the resorption compartment. We and others have shown that the OC-specific transition from podosome clusters to belt is dependent on microtubules (MTs). Proteins enriched at MT +ends interact with proteins in podosomes, allowing the physical interaction of podosomes and MTs to control podosome behavior, with the interaction of cortactin (CTTN) and MTs EB1 playing a key a role in belt formation. MT +ends regulate CTTN phosphorylation by Src and CTTN phosphorylation and acetylation are inversely related. CTTN-deleted OCs are accordingly defective in sealing-zone formation and bone resorption. In the present study we explored further the link between MTs, podosomes and bone resorption by deleting cofilin, an actin-binding protein highly expressed in OCs, testing the hypothesis that it may act downstream of the MT-EB1-CTTN axis.First, we deleted cofilin in OCs in mice by crossing Ctsk-Cre mice with cofilin $(Cof)^{fl/fl}$ mice. Ctsk-Cre:$Cof^{fl/fl}$ mice displayed a markedly increased trabecular BV with normal BFR, indicating decreased resorption. Cofilin-depleted OCs showed impaired cell migration in vitro. In addition, Cof-depleted OCs presented defective targeting of microtubules to, and patterning of, the podosome belt. MT stability was decreased, with low levels of acetylated tubulin. Our results show that dephosphorylation of cofilin is required to stabilize MTs and allow podosome belt formation. Conversely, MT disruption leads to increased cofilin phosphorylation at Ser3. We then investigated whether cofilin interacts with CTTN in podosomes. We found that cofilin interacts with CTTN, and that phosphorylation of either cofilin or CTTN disrupts this interaction. In contrast, acetylated CTTN, induced by treatment of OCs with the HDAC inhibitor TSA, led to increased interaction with cofilin. Moreover, the localization of cofilin was altered in CTTN-null cells and conversely, CTTN localization was altered in cofilin-null OCs. These findings suggest that in OCs, the patterning of podosomes into a sealing zone involves the interaction between cofilin and CTTN downstream of the MTs plus-end protein EB1 and that this interaction is critical for the functional organization of OCs.

A Role for the Proprotein Convertase Furin in the Regulation of Osteoclastic Bone Resorption. Benjamin Ng*[1], Dian Teguh[2], Nathan Pavlos[3], Jennifer Tickner[4], Jiake Xu[3]. [1]The University of Western Australia, Australia, [2]Research personnel, Australia, [3]University of Western Australia, Australia, [4]University of Western Australia, Australia

Osteoporosis is a devastating disease, leading to bone fragility and fracture which has significant physical, psychosocial, and financial consequences. Increased

osteoclast (OC) formation and bone resorption is a major pathological hallmark of osteoporosis. Using comparative microarray analysis between OCs and macrophage-progenitors, we recently uncovered a cluster of genes encoding nine members of a convertase protein family that regulate proteolytic maturation of proproteins. Among these, furin, a regulator of the proteo-cleavage of the V-ATPase proton pump subunit Ac45, was identified as the major RANKL-responsive isoform expressed in OCs. To address the physiological importance of furin in OC-mediated bone resorption, we generated conditional knockout mice specifically lacking furin in OCs ($Furin^{\Delta OC}$). MicroCT analysis of 12 week old female mice demonstrated a significant increase in trabecular bone volume in the femora of $Furin^{\Delta OC}$ mice compared to floxed controls (by 62.0 $\pm$28.0%; p=0.003). Interestingly, histomorphometric analysis revealed that specific deletion of furin did not significantly alter the number or surface area of OCs in vivo. Consistently, OC formation and fusion was unaffected by furin deletion in vitro. By comparison, OC bone resorptive function was significantly impaired in OCs lacking furin as determined by reduced CTX (by 31.8 $\pm$11.5%; p=0.04) and reduced bone resorption pit depth (by 51.7 $\pm$7.2%; p=0.002). Consistent with the role of furin as the primary processing enzyme of Ac45, the expression levels of mature Ac45 protein were reduced in OCs from $Furin^{\Delta OC}$ mice compared to control littermates. In line with reduced Ac45 maturation, intracellular acidification was significantly reduced (by 20.3 $\pm$8.4%; p=0.01) in $Furin^{\Delta OC}$ OCs. Collectively, these data imply that furin functions as a positive regulator of osteoclastic bone resorption during bone homeostasis, in part through the proteolytic processing of the V-ATPase accessory subunit Ac45. Furin may therefore serve as a potential new therapeutic target for the treatment of OC-mediated bone diseases.

EBI2 guides osteoclast precursors to endosteal niches and regulates bone mass homeostasis. Erin Nevius*[1], Mark Horowitz[2], Masaru Ishii[3], Joao Pereira[2]. [1]Yale School of Medicine, USA, [2]Yale University School of Medicine, USA, [3]Graduate School of Medicine & Frontier Biosciences, Osaka University, Japan

Endosteal niches attract and regulate the activity of hematopoietic precursors, macrophages, osteoblasts, and osteoclasts. Osteoblasts and osteoclasts are essential regulators of skeletal integrity and are exclusively positioned in contact with endosteal surfaces. The purpose of this study was to characterize the mechanisms guiding these cells towards endosteal surfaces. The factors and mechanisms controlling this process are largely unknown. Here we show that the oxysterol 7α,25-dihydroxycholesterol (OHC) and its Gai protein coupled receptor EBI2, direct monocyte/osteoclast precursor migration towards endosteal niches, promote cell fusion, and regulate osteoclast differentiation. We show that the dynamic motile behavior of osteoclast precursors is restricted in the absence of EBI2-signaling, and this defect directly reduces osteoclast differentiation. Using a novel two-photon microscopy procedure to examine and quantify the 3-dimensional network of bone-associated osteoclasts, we demonstrate that EBI2 and cholesterol 25 dihydroxylase (CH25H) deficient mice have reduced osteoclast number and size. Consequently, EBI2-signaling deficient mice have increased bone mass and are protected from age-, and estrogen deficiency-induced osteoporosis. Using real-time intravital microscopy we visualized single monocytic cells with osteoclast precursor properties being attracted to and fusing with preformed bone-lining osteoclasts. These data suggest that osteoclast precursors migrate in a directed manner towards bone-lining osteoclasts. Osteoclast precursors, osteoclasts and osteoblasts express oxysterol-synthesizing enzymes and secrete 7α,25-OHC, indicating that EBI2 ligands are secreted in bone-proximal niches. Therefore, we assessed the role of EBI2 in guiding osteoclast precursors towards bone surfaces and promoting osteoclast differentiation in vivo. We show that EBI2 signaling is sufficient to direct monocyte/osteoclast precursors to endosteal surfaces and potentiates osteoclast differentiation in vivo. These studies identify a novel mechanism for bone mass homeostasis that involves ligand- directed cell migration towards endosteal niches. Therapeutic strategies targeting oxysterols and EBI2 signaling may have considerable clinical potential for the treatment of skeletal disorders, including menopause-induced bone loss.

Gain of function of Jagged1 stimulates osteoclastogenesis leading to low bone volume. Yangjin Bae*[1], Hanqiu Zheng[2], Yuqing Chen[3], Terry Bertin[3], Yibin Kang[4], Brendan Lee[1]. [1]Baylor College of Medicine, USA, [2]Department of Molecular Biology, Princeton University, USA, [3]1Departments of Molecular & Human Genetics, Baylor College of Medicine, USA, [4]Princeton University, USA

The Notch pathway is highly conserved signaling system involving cell fate determination, proliferation, differentiation, and tissue maintenance and/or renewal of stem cells in adults. Activation of Notch signaling requires a direct cell- cell interaction of Notch receptors and ligands. The importance of Notch signaling has been shown in human diseases that are caused by mutations in Notch receptors and ligands. Among these, mutations in the Notch ligand Jagged 1 (JAG1) results in Alagille syndrome (AGS). AGS patients can have skeletal defects including hemivertebrae and frequent fractures. Furthermore, genome wide association (GWA) studies have demonstrated an association between bone mineral density (BMD) and JAG1 polymorphisms. Hence, JAG1 is likely an essential Notch ligand for proper skeletal patterning and for postnatal skeletal homeostasis. Others have shown that JAG1 is highly induced ligand during fracture repair, suggesting the potential target to promote bone formation. Here, to understand the *in vivo* pathological consequence of gain of JAG1 function in bone, we generated *jag1* transgenic mouse driven by Col1a1 2.3kb promoter (*Col1a1-Jag1*). *Col1a1-Jag1* mice exhibit low bone mass. Interestingly, excessively trabecularized cortical bone was also observed suggesting the increased bone remodeling in cortex due to ectopic expression of *Jag1*. The osteoporotic phenotype was associated with increased osteoclast numbers that was confirmed with *in vitro* co-culture studies using transgenic osteoblasts. *In vivo*, mature osteoclast markers, *Trap* and *Ctsk,* were up-regulated. Overall, *Jag1* transgenic mouse share the osteoporotic phenotype of gain of function Notch1 in osteoblast. Our preliminary study of *Col1a1-Jag1* suggests that Jag1 plays an important role in bone homeostasis and remodeling.

ADAMTS 18 is important regulator of post-natal skeletal development and bone remodeling. Sardar Uddin*[1], Zong Dong Li[2], Yi-Xian Qin[3], Chuanju Liu[4]. [1]New York University Medical Center, USA, [2]Stony Brook University, USA, [3]State University of New York at Stony Brook, USA, [4]New York University, USA

ADAMTS 18 (a distintegrin and metalloproteinase with a thrombospondin type motif, AD18) is a member of a secreted Zn-metalloproteinase ADAMTS family. ADAMTS 18 was identified as bone mass determination factor and associated with hip bone fractures in major human ethnic groups in a genome-wide association study (GWAS). The purpose of this project is to *determine the role of ADAMTS 18 in skeletal development and remodeling.*

The growth and weight curve for AD18 $^{-/-}$ mice were recorded for 3 months and injected with calcein and alirzain red for histomophometry analysis. Mice were euthanized at age of 14 weeks, trabecular bone at proximal tibia was analyzed using microCT and mechanical properties were accessed with four-point bending at fermal mid-diaphysis. Microarray studies were conducted and confirmed using real time PCR. The over expression and miRNA studies are being conducted to further delineate the underlying mechanism of AD18 in bone remodeling.

The phenotypic analysis of $AD18^{-/-}$ confirmed smaller structure of KO mice relative to litter mates at 14 weeks but the difference was not apparent at 2 weeks suggest that AD18 plays important role in post natal skeletal development. The high expression of AD18 in metaphysis and diaphysis with little or no expression in physis and fetal cartilage further indicates that AD18 plays an important role in bone remodeling rather with limited or no role in bone modeling.

AD18 $^{-/-}$mice exhibit smaller tibia and growth plates with significantly compromised trabecular bone quality and quantity. Cortical bone does not show significant difference but mechanical testing show significant reduction in bone strength indicating potential disorientation of collagen fibers in bone matrix. AD18 expression and µCTdata collective suggest that AD 18 is important regulator of bone matrix classification as indicated by GWAS study.

AD18 deletion significantly inhibited genes associated with osteogenesis and activated genes associated osteoclastogensis. Over expression of AD18 in C2C12 confirmed increased Ssh1, Prrx 1, Runx 2 and Osterix and inhibited osteoclastogensis associated genes Lair 1 and Siglec-15 in RANK ligand treated RAW cells (figure 1).

In summary, the data from current study strongly implies that AD18 is an important and novel regulator of osteoclastogensis and osteogensis in bone remodeling with potential therapeutic implications for treatment of post natal dwarfish, osteopenia and osteoporosis.

Assessment and Intervention Thresholds for FRAX probabilities in the UK – An Evaluation of adjusting Thresholds in Older Postmenopausal Women.

Eugene McCloskey*[1], Helena Johansson[2], Anders Oden[3], Nicholas Harvey[4], Juliet Compston[5], John Kanis[6]. [1]University of Sheffield, United Kingdom, [2]Centre for Metabolic Bone Diseases, University of Sheffield Medical School, Sweden, [3]Consulting Statistician, Sweden, [4]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, [5]University of Cambridge School of Clinical Medicine, United Kingdom, [6]University of Sheffield, Belgium

In postmenopausal women, the UK National Osteoporosis Guideline Group (NOGG) intervention threshold is set at the 10-year probability of major osteoporotic fracture (OP) in a woman with a prior fracture, and reaches 33% at 85 years. This high threshold is avoided in many older women as the guidance also advocates treatment in those with a prior fracture without the need for DXA, especially at older ages (e.g. >70-75 years). However, women without prior fracture are required to achieve the intervention threshold, with or without a BMD measurement. We wished to compare the impact of current assessment and intervention thresholds to that of an alternative strategy at older ages.

Using a simulated population of over 56,000 women aged 50-90 years in the UK, with a distribution of risk factors similar to that in FRAX derivation cohorts and age distribution matched to the current UK population, the current NOGG strategy was compared to a strategy whereby the intervention and assessment thresholds were identical to those in the current NOGG strategy up until the age of 70 years (major OP probability intervention threshold 20%), but thereafter remained constant with increasing age.

Under current guidance, 38% of women aged 50-90 years would be recommended for therapy, comprising 30.1% with prior fracture, 1.4% with high risk in the absence of fracture and 6.4% at high risk after DXA scanning. Under the alternative strategy, the proportion recommended for therapy would only increase slightly (40.8%) but the impact at older ages was more marked. For example, in women aged 80-84 years (see Table), only a small proportion (9%) were eligible for therapy in the absence of fracture and the average probabilities of major osteoporotic fracture and particularly hip fracture were substantially higher in such patients than those qualifying on the basis of prior fracture. Under the alternative strategy, more elderly women with non-fracture risk factors would qualify for treatment (21%) and fewer would need a DXA scan. The average probabilities of major osteoporotic fracture and hip fracture are similar in all women indicated for therapy, with or without a fracture.

We conclude that the alternative threshold equilibrates fracture risk, particularly hip fracture risk, across treatment groups in older women with improved use of DXA resources.

Table 1. Comparison of the current and alternative strategies in women aged 80-84 years. The numbers in parentheses represent the average 10 year probability of major osteoporotic or hip fracture, respectively.

Strategy	Prior fracture (%)	High risk (%)	DXA referred (%)	Treat post DXA (%)	Total treated (%)
Current	39 (27,13)	3 (35, 26)	19 (22, 12)	6 (33, 22)	47 (29, 15)
Alternative	39 (27, 13)	14 (26, 16)	11 (18, 9)	7 (22, 12)	59 (27, 13)

Bone Mineral Density (BMD) at Multiple Sites and Risk of Multiple Types of Fracture: The Osteoporotic Fractures in Men (MrOS) Study.

Didier Chalhoub*[1], Eric Orwoll[2], Peggy Cawthon[3], Kristine Ensrud[4], Douglas Bauer[5], Steven Cummings[6], Jane Cauley[7]. [1]University of Pittsburgh, USA, [2]Oregon Health & Science University, USA, [3]California Pacific Medical Center Research Institute, USA, [4]University of Minnesota & Minneapolis VA Health Care System, USA, [5]University of California, San Francisco, USA, [6]San Francisco Coordinating Center, USA, [7]University of Pittsburgh Graduate School of Public Health, USA

Although many studies have examined the association between low bone mineral density (BMD) and fracture risk in older men, none have simultaneously studied the relationship between multiple sites of BMD and risk of multiple types of fractures or compared areal BMD (aBMD) with volumetric BMD (vBMD).

Using data from the Osteoporotic Fractures in Men (MrOS) study, we studied the association between multiple sites of aBMD and vBMD measurements, and risk of various fracture types during an average of 10.2 years of follow up. Hip and spine aBMD and vBMD were measured by dual-energy X-ray absorptiometry (DXA) and quantitative computed tomography (QCT), respectively. Information on fractures was obtained through our postcard follow-up system. Postcards are mailed every 4 months; >97% of these contacts are complete. All fractures were confirmed by radiographic report. Risk of clinical fractures was assessed at the hip, wrist, spine, arm, rib/chest/sternum, pelvis/tailbone, leg, hand/finger, skull/face, shoulder, ankle/foot/toe, and any non-spine fracture. After excluding participants with pathological fractures, Cox proportional-hazards modeling was used to assess the risk of fracture in 5990 older men per one standard deviation decrease in BMD; aBMD was available in 5989 and vBMD, in 3554 men. Except for a higher proportion of minorities, the characteristics of men in the vBMD subset were similar to the overall population of men.

Lower femoral neck aBMD and trabecular vBMD were associated with an increased risk of fracture at the hip, wrist, spine, arm, rib/chest/sternum, pelvis/tailbone, shoulder, ankle/foot/toe, and any non-spine fracture with HRs ranging between 1.12 and 2.79. There was no association between aBMD or vBMD with skull/face fractures (figure 1 and 2). In contrast, there was little association between femoral neck cortical vBMD and fracture (figure 3). Similar findings were found between lumbar spine aBMD and trabecular vBMD and fracture (data not shown).

In older men, the risk of various types of fractures is higher with lower areal and volumetric BMD. The stronger associations observed for trabecular vBMD than cortical vBMD may reflect the higher rate of bone turnover in the trabecular compartment.

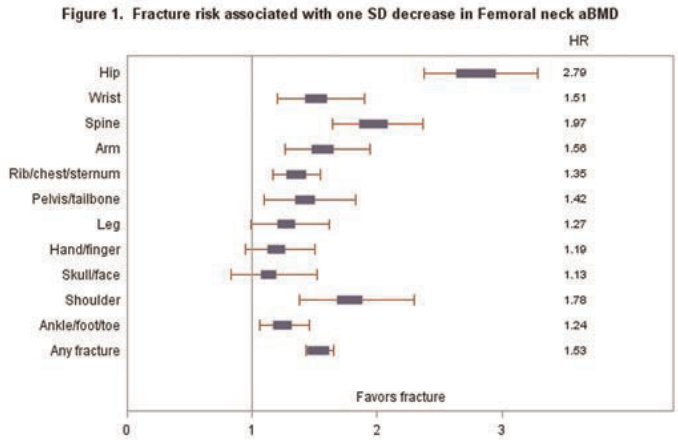

Figure 1. Fracture risk associated with one SD decrease in femoral neck aBMD

Risk and Cumulative Incidence of Subsequent Fractures Following an Initial Fracture: a Cohort Study with a Quarter Century Follow-up. Suzanne Morin*[1], Lin Yan[2], Lisa Lix[2], Sumit Majumdar[3], William Leslie[2]. [1]McGill University, Canada, [2]University of Manitoba, Canada, [3]University of Alberta, Canada

Background: Population-based data on long-term risk of subsequent fractures following an initial fracture are sparse.

Objective: To determine sex- and age-specific relative risk and cumulative incidence of hip (HF) and major osteoporotic fractures (MOF; hip, wrist, spine, humerus) over a 23-year period following any type of initial fracture.

Methods: Using comprehensive health care databases from Manitoba, Canada, we performed a retrospective matched cohort study of community-dwelling men and women aged 50 years and older with incident fracture 1986-2006 (n=62 491 fracture cases) with age and sex-matched controls (n=179 562). Annual crude and relative fracture rates to March 31st 2012 were determined according to initial fracture site and trauma intensity. Hazard ratios (HR) for subsequent fracture were estimated using relative survival analysis. Cumulative incidence rates for subsequent fractures were estimated after accounting for competing mortality. We performed a subgroup analysis in residents in long-term care (LTC) at the time of initial fracture (5600 cases and 14 180 controls, not matched on LTC status).

Results: We identified 11 694 wrist, 10 238 hip, 6211 humerus, 3793 spine, 28 718 other and 1837 traumatic fracture cases. The annual crude rates of subsequent of MOF or HF were highest during the first year, and following an initial fracture at the hip, humerus and spine in both men and women. The increased relative risk for subsequent MOF and HF was highest following initial humerus (HR 2.4; 95%CI: 2.2-2.5 and HR 2.2; 95% CI:2.0-2.4), spine (HR 2.4; 95% CI:2.2-2.7 and HR 2.1; 95% CI: 1.8-2.4) and hip fractures (HR 1.6; 95% CI:1.5-1.7 and HR 1.6; 95% CI 1.4 -1.7) and lowest following traumatic fractures. HRs were consistently higher in men than women, and in the younger age-groups (Table). Accounting for risk of competing mortality, the cumulative incidence of subsequent MOF and HF to 23 years was higher in fracture cases versus controls except in the oldest age category where this relationship reversed and was higher in controls than in cases (Figure). Controls also had a higher cumulative incidence of subsequent fracture than fracture cases who were LTC residents.

Conclusions: Long-term subsequent fracture risk following any type of initial fracture is considerable, particularly in the year post-fracture, though the risk is mitigated by competing mortality in the elderly. This suggests early interventions post-fracture are needed.

Persistence with Osteoporosis Therapies among Osteoporotic Women at High Risk for Fracture within a Commercially-Insured Population in the United States. Emily Durden[1], Lung-I Cheng*[2], Elnara Eynullayeva[1], Larry Radbill[1], Paul Juneau[1], Leslie Spangler[3], Faisal Mirza[3], Bradley Stolshek[2]. [1]Truven Health Analytics, USA, [2]Amgen, Inc., USA, [3]Amgen, USA

PURPOSE: Several medications are effective at reducing fracture risk in osteoporotic patients. However, persistence and compliance with osteoporosis therapy are generally poor. Recently, new therapies with less frequent administration have become available. This study evaluates persistence and compliance with osteoporosis therapies over 12 months after therapy initiation among osteoporotic women at high risk for fracture in the U.S.

Methods: Females ⩾ 50 years of age at high risk for fracture who newly initiated denosumab, raloxifene, teriparatide, or oral bisphosphonates (alendronate, ibandronate, or risedronate) between 1/1/2012 and 3/31/2012 were identified from the *MarketScan® Commercial* and *Medicare* databases (index date = qualifying claim date). High risk for fracture was indicated by one or more of the following: age ⩾ 70, a pre-index fracture, or pre-index use of osteoporosis therapy which was discontinued at least 3 months prior to index. Patients were required to have ⩾ 24 months of pre-index and ⩾ 12 months of post-index continuous enrollment. Propensity score weighting was used to adjust for differences in baseline clinical and demographic characteristics. Persistence, indicated by continuous use of index therapy with no gap > 60 days; medication coverage ratio (MCR), indicated by the proportion of days covered by therapy; and compliance, defined by an MCR ⩾ 0.80, were assessed during the 12-month follow-up. Logistic regression models were estimated to compare persistence and compliance between therapies.

Results: 6,187 women who newly initiated the index therapy (mean [SD] age: 71.9 [10.9] years) were identified. Propensity score weight-adjusted 12-month persistence with the index medication was highest among patients treated with denosumab (68.9%), followed by teriparatide (58.3%), raloxifene, (43.0%), alendronate (36.0%), ibandronate (33.4%), and risedronate (28.0%). The adjusted compliance varied from 70.3% for denosumab users, 51.1% for teriparatide users, 40.4% for raloxifene users, to 25.0 – 32.8% for oral bisphosphonate users. The odds of being persistent and compliant across treatments favored denosumab (odds ratios for persistence from 1.62 to 5.75, p<0.0001; for compliance from 2.36 to 7.25, p<0.0001).CONCLUSION: In this analysis of women with osteoporosis at high risk for fracture, persistence and compliance over 12 months were higher among patients who newly initiated denosumab compared to other osteoporosis therapies.

Table 1. Propensity Score Weight-Adjusted Persistence Rates, Medication Coverage Ratios (MCRs), and Compliance Rates with Index Therapy over 12 Months

	Persistence Rates		MCRs		Compliance Rates	
	n	%	Mean	SD	n	%
Denosumab (n=961)	662	68.9	0.83	0.21	676	70.3
Alendronate (n=2,820)	1,014	36.0	0.53	0.33	924	32.8
Ibandronate (n=1,062)	355	33.4	0.56	0.31	320	30.1
Risedronate (n=716)	200	28.0	0.47	0.32	179	25.0
Raloxifene (n=374)	161	43.0	0.59	0.33	151	40.4
Teriparatide (n=254)	148	58.3	0.65	0.32	130	51.1

Notes: Persistence is indicated by continuous use of index therapy with no gap > 60 days; medication coverage ratio (MCR) is indicated by the proportion of days covered by therapy; compliance is indicated by MCR ⩾ 0.80.

Table 1. Propensity Score Weight-Adjusted Persistence and Compliance Rates

Table 2. Propensity Score Weight-Adjusted Odds Ratios and Associated 95% Confidence Limits from Logistic Regression Model†, Persistence and Compliance with Index Therapy over 12 Months

	Persistence	95% CIs		Compliance	95% CIs	
	Odds Ratios	Lower	Upper	Odds Ratios	Lower	Upper
Denosumab vs. Alendronate	3.97	3.39	4.65	4.93	4.20	5.81
Denosumab vs. Ibandronate	4.48	3.72	5.43	5.65	4.65	6.85
Denosumab vs. Risedronate	5.75	4.65	7.14	7.25	5.81	9.00
Denosumab vs. Raloxifene	2.94	2.30	3.77	3.53	2.75	4.53
Denosumab vs. Teriparatide	1.62	1.22	2.16	2.36	1.78	3.15

† Models adjusted for age, health plan type, US Census region, urban residency, patient out-of-pocket expenditure for the index therapy, and the following baseline/pre-index clinical characteristics: Charlson Comorbidity Index score, number of unique medications prescribed, diagnosis of osteoporosis, osteopenia, renal insufficiency, gastrointestinal side effects, coronary heart disease, and osteoporosis-related fracture.

Diagnostic pathways for the detection of incomplete atypical femur fractures: An economic evaluation. Olga Gajic-Veljanoski*[1], R Bleakney[2], Linda Probyn[3], Angela M. Cheung[4]. [1]University Health Network, Canada, [2]Mount Sinai Hospital, Canada, [3]University of Toronto, Sunnybrook HSC, Dept. of Medical Imaging, Canada, [4]University Health Network-University of Toronto, Canada

Purpose: We conducted a cost-effectiveness analysis to determine which combination of diagnostic tests leads to the most accurate, the least costly and the safest detection of incomplete atypical femur fractures (AFFs) in patients on long-term bisphosphonates.

Methods: We developed a probabilistic decision tree model to compare 43 diagnostic pathways including single alternatives (SE-femur by densitometer [DXA], conventional radiograph X-ray [XR], CT, bone scintigraphy or MRI) and the combinations of DXA or XR with other alternatives in all or in selected patients (18 DXA, 15 XR and 5 DXA & XR combinations). The base case was a 65-year-old woman with osteoporosis and leg pain, treated with long-term bisphosphonates. We assumed a health care payer's perspective (2013 CAD). The incidence of incomplete AFFs and accuracy of DXA vs. XR were based on the data of our screening study and the published literature. We assumed that DXA and XR incur the same costs (base case). The diagnostic properties of other tests, their costs and all effective radiation exposures were based on the literature. Our outcomes included accurate diagnosis of AFF (true positives and true negatives), costs, effective radiation dose (mSV) and incremental cost-effectiveness ratio ($/accurate diagnosis). We estimated second-order uncertainty using Monte Carlo simulations.

Results: The mean accuracy of the 43 pathways ranged from 0.71 to 0.994, the mean costs from $40.4 to $496.9 and the cumulative effective dose from 0mSV to 7.1mSV. In base case analysis, comparing 43 alternative pathways, the three XR pathways ranked best (Table). After excluding XR-related pathways, DXA alone and DXA combined with either CT or MRI in test-positive patients ranked best (Table). At low incidence of incomplete AFFs (<1/1000 patient-years), addition of bone scan to XR or DXA in test-positive was more cost-effective than their combination with MRI. In sensitivity analyses, when the cost of DXA was at least $11 cheaper than the cost of XR (<=$29), XR alone pathway was eliminated by extended dominance and DXA plus CT in test positive ranked as the second best alternative (mean costs and mean accuracy: $48.92 and 0.9919, $299.6/accurate diagnosis).

Conclusions: For the detection of incomplete AFFs, combinations of XR or DXA with CT in initially test-positive patients may represent reasonable case finding pathways.

Table. Cost-effectiveness of best diagnostic pathways for the detection of incomplete AFFs

Diagnostic pathway	Mean Costs ($)§ (95% CrI)	Mean Accuracy (95% CrI)	Incremental Costs ($)	Incremental Accuracy	$/Accurate diagnosis
Analysis comparing all pathways (n=43)					
XR alone	40.37 (23.9-63.1)	0.9556 (0.89-0.99)			
XR plus CT in test positive	53.45 (33.1-83.2)	0.9936 (0.97-1.00)	13.08	0.0380	344.13
XR plus MRI in test positive	66.78 (38.6-110.2)	0.9942 (0.99-1.00)	13.33	0.0006	22 218.30
Analysis comparing pathways with SE-femur (DXA) as the initial test					
SE-femur (DXA) alone	40.37 (23.9-63.1)	0.9266 (0.88-0.96)			
SE-femur (DXA) plus CT in test positive	59.82 (38.2-88.1)	0.9914 (0.97-1.00)	19.41	0.0644	301.37
SE-femur (DXA) plus MRI in test positive	79.80 (48.9-121.6)	0.9925 (0.97-1.00)	19.98	0.0011	18 162.41

§Costs in 2013 CAD, discounted at 3% (t=1 year) ; 95% CrI denotes 95% credible interval; base case incidence of incomplete AFFs = 1/200.

Comparison of Fracture Risk Prediction by the U.S. Preventive Task Force Strategy and Two Alternative Strategies in Women 50-64 Years Old in the Women's Health Initiative. Carolyn Crandall*[1], Joseph Larson[2], Nelson Watts[3], Margaret Gourlay[4], Meghan Donaldson[5], Andrea Lacroix[6], Jane Cauley[7], Jean Wactawski-Wende[8], Margery L.S. Gass[9], John Robbins[10], Kristine Ensrud[11]. [1]University of California, Los Angeles, USA, [2]Fred Hutchinson Cancer Research Center, Seattle, WA, USA, [3]Mercy Health Osteoporosis & Bone Health Services, USA, [4]University of North Carolina, USA, [5]San Francisco Coordinating Center, USA, [6]Fred Hutchinson Cancer Research Center, USA, [7]University of Pittsburgh Graduate School of Public Health, USA, [8]University at Buffalo, USA, [9]The North American Menopause Society, USA, [10]University of California, Davis Medical Center, USA, [11]University of Minnesota & Minneapolis VA Health Care System, USA

Background: The United States Preventive Services Task Force (USPSTF) recommends osteoporosis screening for women younger than 65 years whose 10-year predicted risk of major osteoporotic fracture (MOF) is ⩾9.3% using the Fracture Risk Assessment Tool (FRAX). Among postmenopausal women aged 50-64 years old, it is uncertain how the USPSTF screening strategy compares with the Osteoporosis Self-Assessment Tool (OST) and the Simple Calculated Osteoporosis Risk Estimate (SCORE) in discriminating women who will and will not experience osteoporotic fracture.

Objective: To assess the sensitivity, specificity, and area under the receiver operating characteristic curve of the three strategies for discrimination of incident MOF over 10 years of follow-up among postmenopausal women aged 50-64 years.

Design: Prospective study, follow-up 1993-2008

Setting and participants: 62,492 participants of the Women's Health Initiative Observational Study and Clinical Trials, aged 50-64, not taking osteoporosis medication. We did not exclude data from women taking menopausal hormone therapy.

Measurements: 10-year FRAX-predicted probability of MOF (clinical spine, hip, forearm, shoulder), OST risk score, SCORE risk score, 10-year (observed) incidence of MOF.

Results: For identifying women with incident MOF, sensitivity of the strategies ranged from 25.8 to 39.8, specificity ranged from 60.7 to 65.8 and AUC for the ROC curves ranged from 0.52 to 0.56. Among women aged 50-54 years, the sensitivity of the USPSTF strategy for identifying incident MOF was 4.7% (3.3-6.0). Adjusting the thresholds to improve sensitivity resulted in decreased specificity.

Conclusions: The USPSTF strategy only identified about one-quarter of women aged 50-64 years who went on to experience incident MOF. Our findings do not support use of the USPSTF strategy, OST, or SCORE to identify younger postmenopausal women at risk of fracture.

Sensitivity, specificity, and area under the receiver operating characteristic curve (AUC) for identifying major osteoporotic fracture[1] after 10 years, stratified by baseline age.

All participants (n=62492)	**Osteoporotic Fracture**		
	Sensitivity (95% CI)	Specificity (95% CI)	AUC (95% CI)

MiR-17-92 Family MicroRNAs Play an Essential Role in Limb Development by Suppressing TGF-b Signaling. Fatemeh Mirzamohammadi*[1], Garyfallia Papaioannou[2], Elena Paltrinieri[3], Tatsuya Kobayashi[2]. [1]Massachusetts General Hospital & Harvard Medical School, USA, [2]Massachusetts General Hospital, USA, [3]Massachusetts General Hospital, USA

Small non-coding RNAs, microRNAs (miRNAs), regulate gene expression at the post-transcriptional level. Oncogenic miR-17-92 miRNAs promote cell proliferation by suppressing genes involved in specific signaling pathways including the transforming growth factor b (TGF-b) and phosphatidyl inositol 3 kinase (PI3K) pathways. Recent evidence suggests that miR-17-92 family miRNAs play an important role in skeletal development; hemizygous deletion of the miR-17-92 cluster miRNA gene causes Feingold syndrome type 2, whereas duplication of this gene has been found in patients with overgrowth and post-axial polydactyly type 2A. However, the mechanism by which miR-17-92 miRNAs regulate skeletal development is not known. In order to address this question, we conditionally deleted the miR17-92 gene and its paralogous miR106b-25 cluster miRNA gene in developing mouse limbs and the skull using Prx1-Cre transgenic mice. Conditional deletion of the miR-17-92 miRNA gene caused cutaneous syndactyly, brachydactyly, and delayed ossification of frontal bones in the skull. Additional deletion of the miR-106b-25 gene in miR-17-92 conditional knockout mice exacerbated the skeletal phenotype, suggesting that miR-17-92 and miR-106b-25 miRNAs play overlapping roles in limb development. In contrast, miR-17-92 overexpression caused limb overgrowth. miR-17-92 deficient limb bud and calvarial mesenchymal cells showed a dramatic reduction in proliferation. We found that miR-17-92 deficiency increased levels of TGF-b receptor II (Tgfbr2), a predicted miR-17 target gene, and phosphorylated Smad2, whereas there was no increase in the phosphorylated Akt level, indicating that miR-17-92 miRNAs suppress TGF-b but not PI3K signaling in skeletal mesenchymal cells. Treatment of miR-17-92 miRNA-deficient mesenchymal cells with the TGF-b receptor inhibitor, GW788388, ameliorated the proliferation defect. Furthermore, GW788388 treatment rescued the limb defects of miR-17-92/miR-106b-25 miRNA double conditional knockout mice. These data demonstrate that miR17-92 and miR106b-25 miRNAs promote proliferation of limb bud mesenchymal progenitor cells by suppressing cytostatic TGF-β signaling. In summary, we have shown that suppression of TGF-b signaling by miR-17-92 miRNAs is critical for mesenchymal cell proliferation and normal limb development. Our work provides a mechanistic insight into the pathoetiology of the Feingold syndrome.

Conditional ablation of MT1-MMP in SM22a-expressing cells identifies vascular- associated progenitors cells as essential for skeletal homeostasis. Joanne Shi*, Pamela Robey, Kenn Holmbeck. National Institute of Dental & Craniofacial Research, USA

Purpose: Extracellular matrix remodeling is essential in development. More so than in other tissues, the skeleton is extremely dependent on matrix turnover due to the continuous remodeling required for growth and mineral homeostasis. Membrane-type 1 matrix metalloproteinase (Mt1-Mmp) is a transmembrane molecule required for skeletal development and homeostasis. Accordingly, universal ablation of this enzyme leads to dramatic skeletal dysplasia with rampant bone erosion, arrested bone apposition and skeletal growth, which ultimately leads to early demise of mutant mice. To elucidate in greater detail from which cell and tissue specific compartment these defects emanate, we have performed selective ablation in a stage-specific manner to identify the temporal and spatial requirement for Mt1-Mmp activity in the skeleton

Methods: To selectively ablate the expression of *Mt1-Mmp* in vascular-associated cells, an *SM22a-Cre* expressing mouse strain was crossed to a mouse strain carrying a floxed allele of *Mt1-Mmp* to generate *SM22a-Cre; Mt1flf* mice. Additionally the *SM22a-Cre* strain was mated to *Rosa-26-LacZ* reporter mice to track expression of the Cre recombinase. The latter demonstrated predominant expression of *SM22a-Cre* in vascular-associated cells, but also in sutures, endostea, periostea and osteocytes.

Results: Selective loss of *Mt1-Mmp* in *SM22a*-positive cells leads to dwarfism with progressive skeletal dysplasia, rampant bone erosion and numerous osteoclasts in all bony segments, coinciding with disruption of Rankl attenuation by proteolysis. μCT analysis of whole skeleton and femora documented progressive loss of bone in all morphometric indices and dynamic bone apposition measurements were consistent with diminished bone formation. To validate this finding further, heterotopic ossification was induced, in vivo, using rhBMP-2 containing-Gelfoamäcarrier implanted subcutaneously. The resulting ossicles from *SM22a-Cre; Mt1flf mice* displayed extremely poor bone formation with absence of trabeculation and hematopoietic marrow.

Conclusion: Loss of *Mt1-Mmp* in *SM22a*-positive cells identifies vascular-associated cells as an essential progenitor pool required for basic skeletal growth, regulation of bone resorption and bone formation. In summary, we demonstrate that Mt1-Mmp-mediated proteolysis constitutes an indispensable skeletal progenitor function in vascular-associated cells, where it is required for normal skeletal development and homeostasis.

Characterization of aSMA Expressing Cells That Contribute To Muscle Heterotopic Ossification. Brya Matthews*[1], Elena Torreggiani[1], Danka Grcevic[2], Ivo Kalajzic[1]. [1]University of Connecticut Health Center, USA, [1]University of Connecticut Health Center, USA, [2]University of Zagreb, Croatia

Heterotopic ossification is formation of bone in atypical locations including muscle. Heterotopic ossification generally occurs as a result of aberrant BMP signaling. However, further studies are required to identify BMP-responsive cells in the muscle and understand how they contribute to heterotopic ossification. Alpha smooth muscle actin (αSMA) is a marker of perivascular cells and mesenchymal progenitors that contribute to bone growth and fracture healing. We aimed to evaluate whether αSMA+ cells can contribute to bone formation during heterotopic ossification.

To identify and trace cells we used αSMA promoter-driven inducible Cre (αSMACreERT2) combined with a Cre-activated tdTomato reporter Ai9 to generate SMA9 mice. Mature osteoblast/osteocytes were labeled with the Col2.3GFP reporter. To label muscle satellite cells we utilized Pax7CreERT2/Ai9 mice.

Pax7Cre/Ai9 labels cells below the basal lamina consistent with a satellite cell phenotype, while SMA9 labels similarly localized cells, in addition to perivascular cells. Pax7Cre/Ai9+ satellite cells are CD45/CD31-, Sca1- but SM/C2.6+. The SMA9+ cells are CD45/CD31- and ~60% express satellite cell marker SM/C2.6. 5% express MSC markers Sca1 and PDGFRα, and a larger proportion express PDGFRβ. During BMP2-induced heterotopic ossification, SMA9+ cells comprised 28% chondrocytes and 44% of Col2.3GFP+ osteoblasts, while Pax7Cre/Ai9+ satellite cells labeled only muscle fibers. Culture of sorted cells indicated that SMA9+ and Pax7Cre/Ai9+ cells differentiated into myotubes while the negative cells do not. SMA9+ cultured cells showed the highest upregulation of osteogenic gene expression after culture in the presence of BMP2. To clarify which subset of SMA9 cells possess osteogenic potential, we subdivided SMA9+ cells based on expression of SM/C2.6 and evaluated their ability to differentiate into osteoblasts after transplantation into muscle with BMP2. We observed osteogenic differentiation of SMA9/SM/C2.6+ cells suggesting that once the satellite cell population is removed from its niche they can exhibit osteogenic potential.

αSMA labels mesenchymal progenitor cells in the muscle that contribute to heterotopic ossification induced by BMP2. Our data indicate that the perivascular fraction of cells is responsible for heterotopic ossification, however, muscle satellite cells are capable of osteogenic differentiation after removal from their niche.

Interaction of RBP-J and Endogenous TGF-β Signaling Controls ITAM-Mediated Costimulation of Osteoclastogenesis and Bone Resorption. Christine Miller*, Susan Li, Xiaoyu Hu, Lionel Ivashkiv, Baohong Zhao. Hospital for Special Surgery, USA

Homeostatic osteoclastogenesis requires not only RANK signaling but also costimulatory signals from ITAM -containing receptors/adaptors, predominantly DAP12 and FcRγ in osteoclast precursors. The mechanisms by which costimulatory signals are regulated and integrated with RANK signaling are not well understood. In this study, we investigated whether RBP-J, a newly identified key inhibitory transcription factor for osteoclastogenesis, regulates ITAM-mediated co-stimulation and controls the crosstalk between ITAM and RANK signaling. To address these questions, we generated DAP12 and RBP-J double knockout (KO) mice ($Rbpj^{\Delta M/\Delta M}Dap12^{-/-}$) and DAP12, FcRγ and RBP-J triple KO mice (TKO). Strikingly, we found that RBP-J deficiency almost completely reversed the defects of osteoclast differentiation program and significantly rescued the osteopetrotic bone phenotype of *Dap12* KO or *Dap12/ Fcrg* double knockout (DKO) mice by bypassing the requirement for costimulation of osteoclastogenesis during bone homeostasis. In inflammatory settings, RBP-J deficiency enabled TNF-α to induce osteoclast formation and bone resorption in *Dap12* KO mice. Thus, RBP-J imposes a requirement for ITAM-mediated costimulation of RANKL or TNF-α induced osteoclastogenesis and bone resorption. Mechanistically, RBP-J suppressed induction of key osteoclastogenic factors NFATc1, Blimp1 and c-Fos by opposing ITAM-mediated expression and function of PLCγ2 and downstream calcium-CaMKK-Pyk2 signaling. Furthermore, we showed that the mechanism of PLCγ2 regulation is transcriptional, and then built upon the next generation high-throughput RNA sequencing experiments to identify a novel regulatory loop whereby RBP-J restrains the responsiveness of osteoclast precursors to endogenous TGF-β signaling, which in turn regulates transcription of PLCγ2 and downstream calcium oscillation. To the best of our knowledge, our results provide the first example of regulatory mechanisms of PLCγ2 expression and negative regulation of ITAM-signaling by RBP-J. These findings indicate that RBP-J plays an important role in suppressing ITAM-mediated costimulation, thereby limiting crosstalk between ITAM and RANK/TNFR signaling and fine tuning osteoclastogenesis during bone homeostasis and under inflammatory conditions. Environmental cues that regulate RBP-J expression/function would thus modulate the requirement for costimulatory signaling for osteoclast differentiation and bone remodeling.

Ensuing Osteopetrosis in TAK1-Null Mice Owing to Defective NF-B and NOTCH Signaling. Gaurav Swarnkar*[2], Yousef Abu-Amer[1], Kannan Karuppaiah[3], Gabriel Mbalaviele[1]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University School of Medicine, USA, [3]Washington University School of Medicine in St. Louis, USA

The protein kinase TGFβ activated kinase-1 (TAK1) is involved in activation of MAPK and NF-κB signaling pathways in response to inflammatory stimuli, and it has been reported to play a role in osteoclast (OC) survival. However, the physiological role and mechanism of TAK1 action in bone development has not been fully explored. In this study, TAK1 was conditionally deleted (cKO) in the myeloid lineage. TAK1cKO mice exhibited osteopetrosis, growth retardation and impaired tooth eruption, consistent with micro-CT and histological analysis parameters and with fewer osteoclasts compared with wild type mice. In vitro studies showed that bone marrow monocytes from TAK1cKO fail to differentiate into OC and expressed low levels of TRAP, Cathepsin-K, β3-integrin, and MMP9. This differentiation defect was corrected when WT-TAK1 was re-introduced retrovirally. We further found that activation of JNK, p38 and NF-κB in TAK1-deficient cells in response to RANKL was abrogated. To study the details of the mechanism underlying osteopetrosis in TAK1-null mice, we probed candidate pathways and found elevated levels of the transcription factor RBPjκ, a downstream target of NOTCH signaling, which has been reported to negatively regulate OC differentiation. Consistently, we observed significant reduction in the levels of NICD, a NOTCH cleaved peptide. More intriguingly, forced expression of exogenous NICD partially reversed the osteoclastogenic phenotype with concomitant changes in RBPjκ and NFATc1 levels. Surmising that activation of NF-κB is essential for complete rescue, expression of catalytically active IKK2, the immediate target of TAK1, restored NICD levels and completely recovered osteoclastogenesis. To further support this observation, we generated LysM-Cre-TAK1-RBPjκ for compound deletion of TAK1 and RBPjκ (DcKO) mice. In agreement with in vitro studies, we found that deletion of RBPjκ in the TAK1 null background significantly corrected the osteopetrotic phenotype. MicroCT and histology showed a complete rescue of the TAK1cKO phenotype as DcKO showed BV/TV, TB.Th, TB.N. and Tb.SP comparable to the WT mice with a significant increase in the OC numbers. In summary, our data establish that TAK1 is required for osteoclastogenesis and play an important role in bone development. We further provide evidence that the mechanism underlying the bone defect in TAK1-deficient condition is via coordinated regulation of NF-κB and NOTCH-RBPjκ signaling pathways.

Osteocalcin regulates muscle function and mass. Paula Mera*, Kathrin Laue, Gerard Karsenty. Columbia University, USA

A decrease in muscle function and mass or muscle wasting is a hallmark of the aging process and appears at the same time bone mass decreases. The fact that these two main manifestations of aging develop simultaneously has long raised the prospect that bone and muscle influence each other through means that need to be identified. To test the existence of the validity of this hypothesis from the bone point of view and since GPRC6A, a bona fide receptor for the bone-derived hormone osteocalcin, is expressed in fibers and satellite cells of the muscles; we asked if osteocalcin regulates muscle function and mass in the mouse. Here we show that, starting at 3 months of age *Osteocalcin null* mice (*Ocn-/-*) exhibit a decrease in muscle function as determined by either a gradual speed increase exercise or an endurance test performed in a treadmill apparatus designed to determine muscle fatigue. At the same time that this functional defect develops, muscle mass decreases in *Ocn-/-* mice. Conversely, in *Esp-/-* mice, a model of gain-of-function of osteocalcin, muscle function and mass are increased at 3 months of age. These functions of osteocalcin are mediated by GPRC6A, since mice lacking this receptor in all cells or in mycytes only display the same muscle phenotype than *Ocn-/-* mice. In searching for the molecular mode of action of osteocalcin in muscle we first demonstrated that, as previously seen in β-cells of the pancreas and Leydig cells of the testis, osteocalcin induces the activation of the cAMP/PKA pathway in mouse primary myotubes and that this activation is dependant on their expression of GPRC6A. We observed that osteocalcin, also in a GPRC6A-dependent manner, leads to the inhibition of the cellular energy sensor AMP-activated protein kinase (AMPK) in primary myotubes, this in turn promotes the activation of the mTOR complex, as demonstrated by the increase in the phosphorylation of its substrate S6K, a well-known activator of protein synthesis. Concomitantly, we found that osteocalcin promotes tyrosine incorporation into cellular proteins in wild type, but not in *Gprc6a-/-* primary myotubes. As expected given the nature of GPRC6A the effect of osteocalcin on AMPK-mTOR-S6K axis are dependant on the activity of PKA. Altogether, these data identify a novel function of osteocalcin as a regulator of muscle functions and mass and an additional signaling pathway affected by this hormone.

Inc., USA, [27]USA

Odanacatib (ODN), a selective oral inhibitor of cathepsin K, is in development for the treatment of osteoporosis. The randomized, double-blind, placebo-controlled, event-driven, Phase III Long-Term Odanacatib Fracture Trial (LOFT; NCT00529373) and its pre-planned blinded extension, in which patients continue on their originally assigned treatment, evaluated the efficacy and safety of ODN 50 mg once-weekly to reduce fracture risk in postmenopausal women with osteoporosis. Primary endpoints of the trial were new morphometric vertebral (VFx), hip, and clinical non-vertebral fractures. Secondary endpoints included safety and tolerability, clinical VFx, spine and hip BMD, and bone turnover markers. LOFT enrolled women ⩾65 years of age with a BMD T-score ⩽−2.5 at the total hip (TH) or femoral neck (FN) or with a prior radiographic VFx and a T-score ⩽−1.5 at the TH or FN. Participants were randomized to either ODN or placebo (1:1) and received weekly vitamin D_3 (5600IU) and daily calcium supplements to ensure a total daily calcium intake of ~1200 mg.

Overall, 16,713 participants were randomized at 387 centers in 40 countries, 16,071 were included in the analyses, and 642 excluded from all analyses due to study site closure (n=483), duplicate randomization (n=3), or failure to take any study drug (n=156). At baseline, mean (SD) age was 72.8 (5.3) years, 57% was Caucasian, 46.5% had a prior VFx, and mean BMD T-scores were: lumbar spine -2.7, TH -2.4, and FN -2.7. A total of 237 patients with hip fracture were estimated to provide statistical power. A prespecified interim analysis was performed when ~70% of targeted events had accrued. An external Data Monitoring Committee (DMC) reviewed these data and recommended that the base study be closed early due to robust efficacy and a favorable benefit-risk profile. The DMC noted that safety issues remained in certain selected areas. Both safety and efficacy continue to be monitored in the ongoing blinded extension trial. Data from an average follow-up of 40.8 months have been accrued from the base and extension studies, with 7081 patients completing at least 4 years of follow-up. At the time this abstract was written, final data analysis was not complete. This presentation will summarize the efficacy of ODN on fractures and BMD and general safety from the blinded, placebo-controlled base and extension study periods of LOFT. A separate presentation will discuss in depth the safety profile for ODN from this trial.

Odanacatib (ODN), a selective oral inhibitor of cathepsin K, is in development for the treatment of osteoporosis. The randomized, double-blind, placebo-controlled, event-driven, Phase III Long-Term Odanacatib Fracture Trial (LOFT; NCT00529373) and its pre-planned blinded extension, in which patients continued on their originally assigned treatment, evaluated the efficacy and safety of ODN 50 mg once-weekly in reducing the risk of fractures in postmenopausal women with osteoporosis.

Women ⩾65 years with a BMD T-score ⩽-2.5 at the total hip (TH) or femoral neck (FN), or with a radiographic vertebral fracture and T-score ⩽-1.5 at the TH or FN were randomized (1:1) to ODN or placebo. Participants also received weekly vitamin D_3 (5600 IU) and daily calcium supplements to ensure a total daily intake of ~1200 mg. Primary endpoints were new morphometric vertebral, hip, and clinical non-vertebral fractures. Safety analysis used a multi-tiered approach on the All-Patients-as-Treated population. External Clinical Adjudication Committees evaluated the following adverse event (AE) categories: select dental, select skin, serious respiratory, delayed fracture union, atypical femoral fractures, atrial fibrillation/flutter, cardiovascular and cerebrovascular.

Overall, 16,713 participants were randomized at 387 centers in 40 countries, 16,071 were included in the analyses, and 642 excluded from all analyses due to study site closure (n=483), duplicate randomization (n=3), or failure to take any study medication (n=156). Baseline mean (SD) age was 72.8 (5.3) years, 57% were Caucasian, and 46.5% had a prior vertebral fracture. Mean baseline BMD T-scores were: lumbar spine -2.7, TH -2.4, and FN -2.7.

The base study was closed early based on the recommendation of the independent Data Monitoring Committee (DMC) who reviewed a prespecified interim analysis and noted robust efficacy and a favorable benefit/risk profile. The DMC also noted that safety issues remained in certain selected areas. Both safety and efficacy continue to be monitored in the ongoing blinded extension.

Safety data from this large, long-term study will be presented, including the incidence of AEs in the ODN and placebo groups in the base study and its ongoing blinded extension. At the time this abstract was written, final data analysis was not complete. The results will be available for presentation at the ASBMR meeting.

Randomized Controlled Trial to Assess the Safety and Efficacy of Odanacatib in the Treatment of Men with Osteoporosis. Eric Orwoll*[1], Silvano Adami[2], Neil Binkley[3], Roland Chapurlat[4], Bente Langdahl[5], Steven Doleckyj[6], Hilde Giezek[7], Boyd Scott[6], Arthur Santora[6]. [1]Oregon Health & Science University, USA, [2]University of Verona, Italy, [3]University of Wisconsin, Madison, USA, [4]E. Herriot Hospital, France, [5]Aarhus University Hospital, Dnk, [6]Merck & Co., Inc., USA, [7]MSD Europe Inc., Brussels, Belgium

Background

Osteoporosis in men is an important clinical problem, associated with significant morbidity, mortality, and societal expense. Odanacatib (ODN), a selective inhibitor of cathepsin K, is currently being investigated as a treatment for osteoporosis. In a Phase II study in postmenopausal women, treatment with ODN 50mg once-weekly resulted in increases in bone mineral density (BMD) at the lumbar spine (LS) (11.9%) and total hip (TH) (9.8%) over 5 years. This Phase III study investigated safety and efficacy of ODN in the treatment of men with osteoporosis.

Methods

This was a double-blind, randomized; placebo controlled 24-month trial. We enrolled men ⩾40 and ⩽95 years of age with idiopathic osteoporosis or osteoporosis due to hypogonadism. A LS or hip (TH, femoral neck (FN) or trochanter) T-score of ⩽-2.5 to ⩾-4.0 without prior vertebral fracture or ⩽-1.5 to ⩾-4.0 with one prior vertebral fracture was required. Participants were randomized (1:1) to 50mg of ODN or PBO orally once-weekly, and received weekly vitamin D_3 (5600IU) and daily calcium supplements (total including food ~1200mg daily). The primary outcome was the effect of ODN versus PBO on LS BMD assessed by DXA versus PBO at 24 months. Secondary outcomes included safety and tolerability and changes in BMD at the TH, FN, trochanter sites, and bone turnover markers.

Results

A total of 292 men were randomized and received at least one dose of study medication. The average age was 68.8 years, and 5.8% had total testosterone levels below 250ng/dL. BMD increases from baseline at 24 months in the ODN group at the LS and all 3 hip sites (TH, FN and trochanter) were 6.9%, 1.9%, 1.7% and 2.8% respectively, and all were greater vs. PBO (all $p<0.01$). Compared to PBO at 24-months, ODN significantly decreased the bone resorption markers u-NTx/Cr and s-CTx (68% and 77%, both $p<0.001$), and also decreased bone formation markers, s-P1NP and s-BSAP (16 and 8%, $p=0.001$ and $p=0.019$ respectively). The between group decrease of bone formation markers was maximal at 3 months, after which levels returned towards baseline by 24 months. The adverse events and overall safety profile were similar between ODN and PBO.

Conclusion

In this study, ODN increased spine and hip BMD in osteoporotic men. Changes in bone turnover markers suggest that ODN treatment decreases bone resorption while producing relatively small decreases in bone formation. ODN is a promising potential therapy for treatment of osteoporosis in men.

The Transition from Denosumab to Teriparatide or from Teriparatide to Denosumab in Postmenopausal Women with Osteoporosis: The DATA-Switch Study. Benjamin Leder*[1], Joy Tsai[2], Alexander Uihlein[3], Yuli Zhu[4], Katelyn Foley[4], Robert Neer[2], Sherri-Ann Burnett-Bowie[2]. [1]Massachusetts General Hospital Harvard Medical School, USA, [2]Massachusetts General Hospital, USA, [3]Northwestern Memorial Faculty Foundation, USA, [4]Massachusetts General Hospital, USA

Introduction: Bisphosphonates (BPs) preserve and extend BMD increases achieved during a 2-year course of teriparatide (TPTD) and TPTD preserves and extends BP-induced BMD gains as well. This allows patients to transition from one treatment to another as clinically indicated. The effects of TPTD when used after denosumab (DMAB), however, and the effects of DMAB when used after TPTD are unknown. Defining the clinical consequences of these drug transitions is essential in guiding the management of osteoporosis over time.

Methods: Postmenopausal osteoporotic women completing the DATA study that assessed the effects of 2-years of DMAB (60-mg every 6-months), TPTD (20-μg daily), or both, were enrolled in DATA-Switch. In DATA-Switch, women who received DMAB for the first 2-years were switched to TPTD and women who received either TPTD or TPTD+DMAB were switched to DMAB alone. BMD was measured 6 and 12 months after switching treatments.

Results (Fig): In women switched from TPTD to DMAB (n=27), 12-months of DMAB increased spine BMD by an additional 5.7%, femoral neck (FN) BMD by an additional 3.5%, and total hip (TH) BMD by 3.1%, resulting in net 3-year BMD increases of 15.1% at the spine, 5.7% at the FN, and 5.3% at the TH. In women switched from DMAB to TPTD (n=24), spine BMD decreased by -1.5% after 6-months of TPTD but then rebounded, resulting in a 12-month change of +1.6% and a net 3-year change of 10.4%. One year of TPTD given after DMAB, however, decreased FN BMD by -1.6% and TH BMD by -2.7%, resulting in net 3-year BMD increases of 1.6% at the FN and 0.7% at the TH. In women switching from combination therapy to DMAB alone (n=21), spine BMD increased by an additional 2.7% while FN and TH increased only slightly, resulting in net 3-year increases of 15.0% at the spine, 7.2% at the FN, and 7.1% at the TH. After a total of 3-years of therapy, the increase in TH BMD remained greater in women who received combination therapy followed by DMAB than in either other groups (P=0.047).

Conclusions: DMAB prevents bone loss and increases BMD in women treated with TPTD. TPTD, however, does not fully prevent the bone loss that occurs after DMAB discontinuation, particularly at the hip. Thus, the use of TPTD immediately after DMAB may not be advisable, especially in women at very high fracture risk. Two years of combined TPTD and DMAB followed by DMAB alone results in the most favorable effects on hip BMD and may be a useful treatment approach in high-risk patients.

Effect of Blosozumab on Bone Mineral Density: 52-Week Follow-up of a Phase 2 Study of Postmenopausal Women with Low Bone Mineral Density. Charles Benson*[1], Alan Chiang[1], Leijun Hu[1], Alam Jahangir[1], Bruce Mitlak[1], Robert Recker[2], Deborah Robins[1], Hideaki Sowa[3], Adrien Sipos[1]. [1]Eli Lilly & Company, USA, [2]Creighton University, USA, [3]Lilly Research Laboratories Japan, Eli Lilly Japan K.K., Japan

Purpose: Blosozumab (bmab) is a humanized anti-sclerostin monoclonal antibody being developed for the treatment of severe osteoporosis. A randomized, parallel-design, double-blind, placebo-controlled, Phase 2 study that assessed the safety and efficacy of different bmab doses found that 52 weeks of bmab treatment significantly increased lumbar spine bone mineral density (BMD) and was generally well tolerated. Based on bone biomarker data, the BMD increases seen in the Phase 2 study likely resulted from elevated bone formation not associated with increased resorption. Here, we report the 52-week follow-up data from the Phase 2 study. Methods: Postmenopausal women with low BMD (lumbar spine T-score -3.5 to -2.0) were randomized to 1 of 3 subcutaneous bmab treatments (180 mg every 4 weeks [Q4W] [n=31]; 180 mg every 2 weeks [Q2W] [n=30]; 270 mg Q2W [n=30]) or placebo (n=29) for 52 weeks followed by a 52-week follow-up period during which patients did not receive bmab. Efficacy was assessed as BMD changes from baseline through Week 104 in lumbar spine, total hip, and femoral neck. BMD was measured by dual energy x-ray absorptiometry. Safety was also assessed. Results: Of the 120 women enrolled (mean baseline age 66 years; mean lumbar spine T-score -2.75), 106 completed the 52-week treatment and entered the 52-week follow-up; 88 completed the follow up. In general, bmab resulted in significantly greater increases in BMD for lumbar spine, total hip, and femoral neck at 52 weeks of treatment compared with placebo (Figure). Upon treatment discontinuation, a reduction in BMD was seen in all bmab groups. However, at the end of the follow-up period, lumbar spine, total hip, and femoral neck BMD for bmab 270-mg Q2W and lumbar spine and total hip BMD for bmab 180-mg Q2W remained significantly greater than placebo. Treatment-emergent adverse events (TEAEs) during the 52-week follow-up period were similar across treatment groups, with most due to infections and infestations (n=39). TEAEs reported during the 52-week follow-up did not appear to be due to bmab treatment. Conclusion: After 52-weeks of bmab treatment, lumbar spine, total hip, and femoral neck BMD increased significantly compared with placebo, as reported previously. During 52 weeks of post-treatment follow-up, BMD declined, but generally remained significantly greater than placebo for the 2 highest doses. These findings support the continued study of bmab to treat osteoporosis.

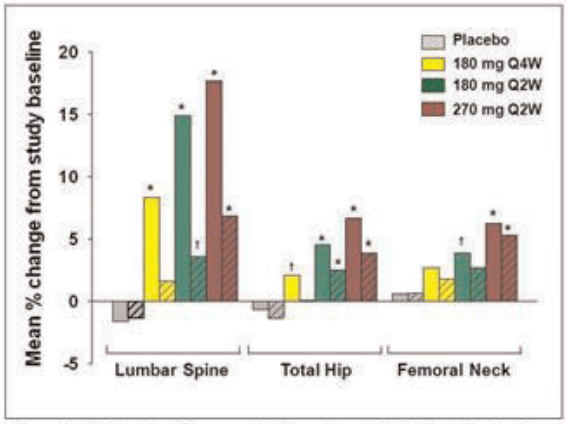

Figure legend: Open bars indicate mean % change from study baseline at 52 weeks of bmab treatment. Striped hatching indicates mean % change from study baseline through Week 104. *p<0.001, †p<0.05 compared with placebo. Abbreviations: Q4W= bmab every 4 weeks; Q2W= bmab every 2 weeks. P-values are corrected Dunnett's adjusted p-values

Effects of 2 Years of Treatment With Romosozumab Followed by 1 Year of Denosumab or Placebo in Postmenopausal Women With Low Bone Mineral Density.

MR McClung*[1], A Chines[2], JP Brown[3], A Diez-Perez[4], H Resch[5], J Caminis[6], Ma Bolognese[7], S Goemaere[8], HG Bone[9], JR Zanchetta[10], J Maddox[2], O Rosen[2], S Bray[11], A Grauer[2]. [1]Oregon Osteoporosis Center, USA, [2]Amgen Inc., USA, [3]Laval University & CHU de Québec Research Centre, Canada, [4]Autonomous University of Spain, Spain, [5]St. Vincent Hospital, Austria, [6]UCB, USA, [7]Bethesda Health Research Center, USA, [8]Ghent University Hospital, Belgium, [9]Michigan Bone & Mineral Clinic, USA, [10]Instituto de Investigaciones Metabólicas, Argentina, [11]Amgen Ltd., United Kingdom

Purpose: We previously reported that 1 year of treatment with the sclerostin antibody romosozumab (Romo) was associated with increased bone mineral density (BMD) and bone formation and with decreased bone resorption in postmenopausal women with low BMD (McClung *NEJM* 2014). Here, we report the results of 2 years of treatment with Romo followed by 1 year of denosumab (DMAb) or placebo.

Methods: This phase 2 study enrolled 419 postmenopausal women age 55 to 85 years with a lumbar spine, total hip, or femoral neck T-score ≤–2.0 and ≥–3.5. Women received 1 of 5 regimens of Romo (70 mg QM, 140 mg QM, 210 mg QM, 140 mg Q3M, 210 mg Q3M; data for the 210 mg QM group are shown in the figures) or placebo for 2 years. At the end of 2 years, eligible subjects entered a 1-year extension phase and were re-randomized 1:1 within their original treatment group to placebo or DMAb 60 mg Q6M. Only women who entered the extension were included in these analyses.

Results: Romo led to rapid and marked increases in lumbar spine and total hip BMD during year 1 and continued increases through year 2. The largest gains were observed with Romo 210 mg QM, with BMD increases of 15.7% (lumbar spine) and 6.0% (total hip) (Figures). Women receiving Romo 210 mg QM who transitioned to DMAb continued to accrue BMD at a rate similar to that in the second year of Romo; in those who transitioned to placebo, BMD returned towards pretreatment levels.

Romo induced rapid stimulation of bone formation (P1NP) and decreased bone resorption (CTX). Increases of P1NP were transitory, returning towards baseline within 6 to 12 months and remaining below baseline through year 2. CTX remained below baseline through year 2. In subjects receiving Romo 210 mg QM who transitioned to DMAb: P1NP and CTX decreased; for those who transitioned to placebo: P1NP gradually returned to pretreatment levels, while CTX initially increased above baseline and gradually returned towards baseline.

Adverse events were balanced between the placebo and Romo groups during the first 2 years of the study (with the exception of injection site reactions, most reported as mild) and in the placebo and DMAb groups during year 3.

Conclusion: Romo led to rapid and marked increases in lumbar spine and total hip BMD over 2 years, which continued with DMAb and resolved after transition to placebo. These data suggest that the treatment effects observed with Romo are further augmented by follow-on treatments like DMAb.

FR0002

Sclerostin and FGF-23 Protein Expression in Bone of Patients with Chronic Kidney Disease. Florence Lima*[1], Valentin David[2], Hanna Mawad[1], Hartmut Malluche[4]. [1]University of Kentucky, USA, [2]University of Miami, Miller School of Medicine, USA, [4]University of Kentucky Medical Center, USA

Purpose: Chronic kidney disease-mineral and bone disorder (CKD-MBD) develops early and progresses inexorably during loss of kidney function. Sclerostin and FGF23, both produced by osteocytes, are increased in blood in CKD-MBD. The aim of this study was to explore expression of sclerostin and FGF23 in bone and to establish correlations with blood levels and bone turnover.

Methods: In this IRB approved cross-sectional study, 45 patients with CKD stage 5 on dialysis underwent anterior iliac crest biopsies after double-tetracycline labeling. Undecalcified bone samples were evaluated by histomorphometry to assess turnover and for quantifying FGF23 and sclerostin expression by immunostaining. Serum sclerostin and FGF23 levels were measured by ELISA.

Results: Patients with low bone turnover had higher serum sclerostin levels than patients with high bone turnover (3.7 ng/mL ± 1.3 vs. 1.9 ng/mL ± 1.3, $P<0.001$). Serum FGF23 levels were lower in patients with low bone turnover (2475 pg/mL ± 4720 vs. 16169 pg/mL ± 13426, $P<0.01$). Expression of sclerostin in osteocytes was higher in patients with low bone turnover ($P<0.01$) and expression of FGF23 was higher in patients with high bone turnover ($P<0.05$; Table 1). Sclerostin positive osteocytes were more present in cortical bone ($P<0.001$) while FGF23 positive osteocytes were more present in trabecular bone ($P<0.05$) in both turnover groups. Sclerostin and FGF23 expression in trabecular and cortical bone correlated with serum levels (sclerostin: rho = 0.49 and 0.44, $P<0.05$; FGF23: rho = 0.69 and 0.68, $P<0.001$). Correlations between sclerostin and FGF23 blood levels as well as their expression in bone with histomorphometric bone parameters are shown in the Table 2. Serum sclerostin and its expression in bone were negatively correlated with bone formation rate and osteoid thickness. Serum FGF23 and its expression in bone were negatively correlated with mineralization lag time.

Conclusion: These results show different patterns of sclerostin and FGF23 expression in low and high bone turnover suggesting a role in the turnover abnormalities of patients with CKD stage 5 on dialysis.

	% scl+ocy		% FGF23+ocy

Gfi1 Inhibits Osteoblast Differentiation in Multiple Myeloma by Inducing Epigenetic Repression of *Runx2* in Bone Marrow Stromal Cells. Juraj Adamik*[1], Quanhong Sun[1], G. David Roodman[2], Deborah Galson[1]. [1]University of Pittsburgh, USA, [2]Indiana University, USA

Multiple myeloma (MM), the most frequent cancer to impact the skeletal system, induces osteolytic bone lesions that rarely heal even after therapeutic remission. MM-induced alteration of the bone marrow microenvironment causes suppression of bone marrow stromal cell (BMSC) differentiation into functional bone-forming osteoblasts (OB) by repressing the key OB differentiation factor Runx2. We reported that MM cells upregulate the transcriptional repressor Gfi1 in BMSC, which can repress the *Runx2* gene. We examined if direct Gfi1 binding and recruitment of chromatin co-repressors alters the epigenetic state of the *Runx2* gene resulting in long term OB suppression. Co-culture experiments revealed that MM repression of *Runx2* mRNA is a direct result of inhibition of pre-loaded, promoter-bound paused and elongating (Ser2-phospho CTD) RNA Pol II. Kinetic ChIP analyses of MM-exposed preosteoblast MC4 cells revealed that Gfi1 is recruited to the *Runx2* gene only after 24 h of MM treatment with increased occupancy at 36 and 48 h. Concomitantly, we observed recruitment to the *Runx2* gene of histone modifiers HDAC1, Co-REST, LSD1, and G9a along with reduction of the transcriptionally permissive euchromatin marks H3K4me3, H3K9ac, H3K12ac, H3K27ac, and H3K36me3. These changes persisted even after removal of MM cells making *Runx2* transcription refractory to OB differentiation signals. The opposite changes were found on the *Il6* gene, which is upregulated in MM-exposed BMSC. Gfi1 over-expression studies demonstrated that full length Gfi1 binds to the endogenous *Runx2* promoter and recruits HDAC1 and G9a, repressing *Runx2*. However, the 239-423 Gfi1 DNA binding domain binds *Runx2* and recruits HDAC1, but not G9a, and does not repress *Runx2*, indicating that HDAC1 recruitment is not sufficient to repress *Runx2*. Additionally we showed that although Gfi1 knockdown in MC4 cells did not block the MM-induced rapid decrease of *Runx2* mRNA (within 3 h), it did prevent the sustained repression of *Runx2* following induction of OB differentiation for 2-4 d. This result fits with the observed delayed arrival of Gfi1 at *Runx2* and suggests that Gfi1 is a critical mediator of long term epigenetic suppression of the *Runx2* gene in the myeloma distorted BMSC microenvironment. The understanding of the mechanisms associated with the suppressive effects of Gfi1 may lead to development of therapeutics for various inflammatory diseases causing homeostatic imbalance in the bone microenvironment such as MM.

Atypical Femoral Fractures: Radiographic and Histomorphometric Features in 19 Patients. Aliya Khan*[1], Angela M. Cheung[2], Osama Ahmed Khan[3], Mohammed Zohair Rahman[1], Ken Pritzker[4], Brian Lentle[5]. [1]McMaster University, Canada, [2]University Health Network-University of Toronto, Canada, [3]McMaster University, Canada, [4]University of Toronto, Canada, [5]University of British Columbia, Canada

Purpose

This study describes characteristics and histomorphometric and radiographic features of atypical femoral fractures (AFF) as seen in 19 cases referred for evaluation.

Methods

All patients referred for evaluation of AFF were reviewed.

Patients meeting the ASBMR criteria for AFF were further evaluated and tetracycline labeled bone biopsies were completed. Radiographs were reviewed by a musculoskeletal radiologist.

Results

All fracture lines were transverse or short oblique and 15 of 19 patients demonstrated thickened cortices on x-ray. We report 19 cases of AFF in patients on long term bisphosphonate (BP) therapy. 14 of 19 fractures occurred without a fall or direct trauma to the femur with 5 cases occurring after a fall from standing height. All patients were female; average age was 65 years (range 23-80 years). 4 of the 19 cases were of Chinese descent, 4 were East Indian, with 11 being Caucasian. Average BP durations of use was 9.8 years (range 6-15 years). 9 of 19 patients were on alendronate alone, 2 patients were on risedronate alone, 6 patients on a combination and 1 patient on a combination of pamidronate and alendronate. 1 patient was on a combination of alendronate and denosumab. Prodromal thigh or groin pain was seen in 12 of the 19 patients for 1 to 15 months prior to fracture. Proton pump inhibitor use was present in 6 patients. 2 patients were on prednisone for rheumatoid arthritis and 2 patients on prednisone for asthma. 1 patient had a diagnosis of osteogenesis imperfecta type IV with a history of multiple fragility fractures and had experienced a femoral fracture after 12 years of IV pamidronate with features consistent with an AFF. All patients had 25OH Vit D levels > 50nmol/L. 18 of the patients with radiographic features of AFF had been on a bisphosphonate for > than 6 years. 1 patient had been on alendronate for 5 months. 8 of 19 patients had bilateral femoral fractures.

Bone Biopsy Results

A large number of patients with radiographic features of an AFF had evidence of mineralization abnormalities on tetracycline labeled bone biopsy. Decreased osteoid surface and mean mineralized trabecular width was seen in 6 of 11 biopsies. Diffuse label was noted in 5 of 11 biopsies. Mineralization abnormalities were noted in a significant number of patients with radiographic features of AFF. All of the women had normal or mildly reduced serum vitamin D levels.

Conclusion

Histomorphometric features seen on bone biopsy in women sustaining an AFF in association with long term bisphosphonate use included evidence of mineralization abnormalities and decreased bone formation. 1 patient had features of decreased bone formation and mineralization abnormalities with only 5 months of bisphosphonate exposure. Improved understanding of the pathophysiology leading to these fractures may be gained with further histomorphometric data in larger numbers of patients.

A Novel *VCP* Mutation in a Patient with Paget's Disease of Bone without Myopathy and Neurological Involvement. Omar Albagha*[1], Ranganath Lakshminarayan[2], Stuart Ralston[1]. [1]University of Edinburgh, United Kingdom, [2]University of Liverpool, United Kingdom

Missense mutations in *VCP* cause the rare disorder of Inclusion body myopathy, Paget's disease of the bone and frontotemporal dementia (IBMPFD) and some cases of amyotrophic lateral sclerosis. Mutations of VCP have not previously been reported in classical PDB in the absence of other features of IBMPFD. Here we describe a novel missense mutation in the *VCP* gene in a patient with classical PDB. The patient was diagnosed with polyostotic PDB at age 52 years affecting the pelvis, humerus, spine and skull and there was no family history of PDB, muscle or neurological disease. He died at age 92 and there were no signs of myopathy or dementia. The *VCP* mutation was detected as part of an exome sequencing effort to identify novel PDB-associated mutations. Exome capture was performed using Agilent SureSelectXT V5 target enrichment kit followed by DNA sequencing using the illumina Hiseq2000 platform with a 36X mean coverage. Sequence mapping, alignment and variant calling were performed using the Picard/BWA/GATK pipeline. Analysis of known PDB susceptibility genes identified a heterozygous mutation c.697A>G (p.I233V) in *VCP* which was not detected in the publicly available databases including 1000 Genome and NHLBI exome data. This mutation is located next to the previously reported p.A232E which causes severe IBMPFD and affects the D1 domain that provides the protein's main catalytic activity. This study illustrates that classical PDB may occur as the result of mutations in *VCP* and extends further the phenotypic spectrum of diseases caused by missense mutations in this gene

NFAM1 Modulates Calcineurin-NFATc1 Signaling during Osteoclast Differentiation in Paget's Disease of Bone. Yuvaraj Sambandam*[1], Kumaran Sundaram[2], Takamitsu Saigusa[1], Sudhaker Rao[3], William Ries[1], Sakamuri Reddy[2]. [1]Medical University of South Carolina, USA, [2]Charles P. Darby Children's Research Institute, USA, [3]Henry Ford Hospital, USA

Paget's disease of bone (PDB) is a chronic focal skeletal disorder that affects 2-3% of the population over 55 years of age. The disease is characterized by abnormal osteoclasts with excess bone resorption activity and abundant poor quality new bone formation.We previously detected measles virus nucleocapsid protein (MVNP) transcripts in osteoclasts from patients with PDB. Also, MVNP stimulates pagetic osteoclast formation in vitro and in vivo. We identified that microarray analysis of human bone marrow derived preosteoclast cells transduced with MVNP increased (7-fold) NFAT activating protein with ITAM motif 1 (NFAM1) expression. NFAM1(also known as CNAIP) is a ~30 kDa transmembrane glycoprotein that contains an extracellular Ig domain and an intracellular immunoreceptor tyrosine-based activation motif (ITAM) bearing region, however, a functional role for NFAM1 in PDB is unknown. Therefore, we hypothesize that NFAM1 modulates MVNP induced pagetic osteoclast differentiation. We demonstrate that MVNP expression in normal human peripheral blood monocytes (PBMC) significantly increased (10-fold) NFAM1 mRNA expression without RANK ligand (RANKL) treatment. Western blot analysis further confirmed that MVNP increased (4.8-fold) NFAM1 expression in these cells. Also, bone marrow cells derived from patients with Paget's disease demonstrated elevated levels of NFAM1 mRNA expression. NFAM1 has been shown to induce ITAM phosphorylation and Syk recruitment. We showed that MVNP transduction into preosteoclast cells increased ITAM phosphotyrosine activation (4.0-fold) and p-Syk (5.5-fold) levels without RANKL stimulation. Furthermore, MVNP expression upregulates calcineurin, a calcium-dependent serine-threonine phosphatase (8-fold) and NFATc1 (5-fold) transcription factor expression. We then measured intracellular Ca^{2+} concentrations in fura-2/AM loaded preosteoclast cells with dual-excitation wavelength fluorescence microscopy. MVNP transduced cells stimulated with RANKL showed elevated Ca^{2+} oscillations and intracellular levels. Interestingly, shRNA knock-down of NFAM1 expression significantly decreased MVNP induced calcineurin, p-Syk, NFATc1 expression and intracellular Ca^{2+} levels in preosteoclast cells. Furthermore, NFAM1 suppression inhibits MVNP induced osteoclast differentiation in mouse bone marrow cultures. Thus, our results suggest that NFAM1 modulation of calcineurin-NFATc1 signaling axis plays a critical role in pagetic osteoclast differentiation.

Long-Term Effect of Recombinant Human Parathyroid Hormone, rhPTH(1-84), on Skeletal Dynamics in Patients With Hypoparathyroidism: One-Year Data From the Open-Label RACE Study. Bart L. Clarke*[1], Michael Mannstadt[2], Dolores M. Shoback[3], Tamara J. Vokes[4], Mark L. Warren[5], Michael A. Levine[6], Hjalmar Lagast[7], John P. Bilezikian[8]. [1]Mayo Clinic Division of Endocrinology, Diabetes, Metabolism, & Nutrition, USA, [2]Massachusetts General Hospital & Harvard Medical School, USA, [3]SF Department of Veterans Affairs Medical Center, University of California, USA, [4]University of Chicago Medicine, USA, [5]Endocrinology & Metabolism, Physicians East, USA, [6]Children's Hospital of Philadelphia, USA, [7]NPS Pharmaceuticals, Inc, USA, [8]College of Physicians & Surgeons, Columbia University, USA

Patients with hypoparathyroidism have reduced bone turnover, abnormally increased bone mineral density (BMD), and abnormal bone microarchitecture. Conventional therapy with oral calcium (Ca) and activated vitamin (Vit) D does not normalize skeletal metabolism and can cause hypercalcemia and hypercalciuria. The phase III, placebo-controlled REPLACE study demonstrated the safety and efficacy of 50, 75, or 100 μg rhPTH(1-84) in patients with hypoparathyroidism.[1] In REPLACE, treatment with rhPTH(1-84) improved mineral homeostasis, increased bone turnover markers (BTMs), and reduced BMD. The RELAY study showed that a lower dose (25 μg) of rhPTH(1-84) may be sufficient for some patients. A hypothesis of RACE, a study of patients previously treated in REPLACE and/or RELAY, is that long-term treatment with rhPTH(1-84) provides prolonged effects on skeletal turnover and maintains serum and urine mineral parameters.

Patients were started on 25 or 50 μg/d rhPTH(1-84) with titration up to 50, 75, or 100 μg/d if active Vit D and oral Ca could be reduced further. Bone turnover was assessed by: serum levels of bone-specific alkaline phosphatase, cross-linked C-telopeptide of type 1 collagen, aminoterminal propeptide of type 1 collagen, and osteocalcin. BMD was determined by DXA.

Of the 53 patients enrolled at 13 centers (83% female; mean ± SD age 48±10 y; BMI 31±7 kg/m^2; mean duration of hypoparathyroidism 16±13 y), 49 are included in this interim analysis. 74% (95% CI, 59–85) met the efficacy endpoint (≥50% reduction in oral Ca [or ≤500 mg/d] and ≥50% reduction in active Vit D [or ≤0.25 μg/d] at Week 52 while maintaining a serum Ca level ≥7.5 mg/dL). By Week 52, mean baseline Ca and active Vit D doses were reduced by 67%±34% and 73%±44%, respectively. At Week 52, all BTMs had increased from low normal baseline levels (Table). BMD Z-scores at lumbar spine (LS), total hip (TH), femoral neck (FN), and distal one-third radius (DR) decreased toward normal at Week 52 (baseline mean ± SD): LS −0.05 (2.02±1.49), TH −0.08 (1.44±1.14), FN −0.12 (1.27±1.28) and DR −0.20 (0.94±0.81). Adverse event profile was similar to the REPLACE trial.[1]

Extended treatment with rhPTH(1-84) is associated with increases in BTMs, even when re-treated with rhPTH, and beneficial reductions in BMD. These findings also demonstrate that bone turnover remains stimulated with rhPTH(1-84) over 1 year, confirming results in shorter-term studies.

Low Vitamin D Levels in Primary Hyperparathyroidism Affect Cortical Bone Density and Porosity but not Estimated Bone Stiffness. Marcella Walker*[1], Kyle Nishiyama[1], Elaine Cong[2], James Lee[3], Anna Kepley[1], Chiyuan Zhang[1], X Guo[1], Shonni Silverberg[1]. [1]Columbia University, USA, [2]Columbia Presbyterian Medical Center, USA, [3]Columbia University College of Physicians & Surgeons, USA

Data regarding the skeletal effects of vitamin D (25OHD) deficiency and insufficiency in primary hyperparathyroidism (PHPT) are limited. Patients with mild PHPT (n=100; 78% women, mean age ± SD 62±12 years, calcium 10.7±0.6mg/dl, PTH 83±41pg/ml; 25OHD 30±10ng/ml) were studied with bone markers, dual x-ray absorptiometry (DXA), high-resolution peripheral quantitative computed tomography (HRpQCT) and microfinite element analysis (μFEA). Low 25OHD levels were common (54%<30ng/ml, mean 21±6 ng/ml; 20%≤20ng/ml, mean 14±4ng/ml). Those with 25OHD<30 vs. ⩾30ng/ml (mean 38±6ng/ml) did not differ by PHPT duration, history of nephrolithiasis or fractures, renal function or race, but they were younger (58±13 vs. 67±9yrs, p=0.0001), more likely to be male (31 vs. 13%, p=0.06) and tended to have higher BMI (29.0±6 vs. 26.8±6kg/m^2, p=0.06). Before and after adjusting for age and BMI, those with 25OHD<30ng/ml had higher PTH (94±42 vs. 70±42pg/ml, p=0.01) but lower PO_4 (2.9±0.5 vs. 3.2±0.5mg/dl, p<0.01) and FGF-23 (98±114 vs. 146±114RU/ml, p=0.06) levels but serum calcium, 1,25-dihydroxyvitamin D, and bone turnover (CTX and BSAP) did not differ. Those with 25OHD<30ng/ml had lower age- and BMI-adjusted DXA T-scores at the 1/3 radius (-1.6±1.4 vs. -0.9±1.4; p=0.02) but not at other sites (spine: 1.0±0.2 vs. 0.9±0.2, p=0.73; FN: -1.1±1.0 vs. -1.3±1.0, p=0.66; total hip: -0.7±1.0 vs. -1.1±1.6, p=0.29). By HRpQCT, those with 25OHD<30ng/ml had 15% higher cortical porosity at the tibia (7.5±2.3 vs. 6.5±2.3%, p=0.05) but not the radius, and tended to have lower cortical density (radius: 801±83 vs. 832±83mgHA/cm^3 p=0.07; tibia: 756±67 vs. 783±68mgHA/cm^3 p=0.06). These differences did not affect μFEA-estimated whole bone stiffness (radius: 31.0±9.6 vs. 32.4±9.6kN/mm, p=0.51; tibia: 102.7±23.0 vs. 98.9±23.0kN/mm, p=0.45) or failure load. Trabecular indices did not differ by vitamin D status. Those with 25OHD≤20ng/ml also had higher PTH (≤ 20 vs. ⩾30ng/ml: 113±40 vs. 70±42pg/ml, p<0.001; vs. >20ng/ml: 75±39pg/ml, p<0.001). Similar cortical trends were apparent in those with 25OHD≤ 20 vs. ⩾30, but these were less marked in those with 25OHD ≤ 20 vs. >20ng/ml. Results were similar in women only. In mild PHPT low 25OHD is associated with higher PTH levels, higher cortical porosity and modestly lower cortical BMD. These differences did not result in lower mechanical competence, suggesting that the current 25OHD thresholds do not have a major effect upon skeletal health in mild PHPT.

PTH(1-84) Treatment is Safe and Effective in Hypoparathyroidism for Six Years. Mishaela Rubin*[1], Natalie Cusano[2], Laura Beth Anderson[1], Dinaz Irani[3], James Sliney[1], Elizabeth Levy[1], Wen-wei Fan[1], Donald McMahon[2], John Bilezikian[2]. [1]Columbia University, USA, [2]Columbia University College of Physicians & Surgeons, USA, [3]Columbia University Medical Center, USA

Hypoparathyroidism (HypoPT) is a rare disorder in which PTH is absent. We found that 4 years of PTH(1-84) reverses the associated hypocalcemia, hyperphosphatemia, hypercalciuria and elevated bone mineral density (BMD). Yet the lifelong nature of HypoPT necessitates an extension of those findings. 27 HypoPT (47.7 ± 2 yrs; 20 female; 25 Caucasian) were studied (postsurgical: n=16; autoimmune: n=10; DiGeorge: n=1). Medications included calcium: 2858 ± 240 mg/d; calcitriol: 0.66 ± 0.1 μg/d; vitamin D: 13,389 ± 3,247 IU/d and HCTZ: 9 ± 3 mg/d. Serum calcium was 8.5 ± 1 mg/dL with undetectable PTH; BMD (g/cm^2) was lumbar spine 1.227 ±0.05; femoral neck 0.968 ±0.04, total hip 1.085 ± 0.04 and distal 1/3 radius 0.733 ±0.01. PTH(1-84) was started at 100 μg qod and changed after 2-3 years to 50 μg/d (n=15); other doses ranged from to 25-100 μg/d. Decreases occurred in supplemental calcium (2858 ± 240 to 1250 ± 267 mg/d; p<0.001), calcitriol (0.66 ± 0.1 to 0.27 ± 0.1 μg/d; p<0.001) and vitamin D (13,389 ±3,247 to 2045 ±3,633 p=0.04); HCTZ did not change. Serum calcium was stable (8.5 ±0.2 to 8.6 ±0.2 mg/dl) while 24 hr urinary calcium decreased (273.0 ± 25 to 193.3 ± 27 mg; p=0.007). Serum phosphate (4.3±0.2 to 4.2 ±0.2 mg/dl), creatinine (0.96 ± 0.1 to 0.96 ± 0.1 mg/dl), and 1,25(OH)2D (39.0 ± 4 to 33.8 ± 10) did not change, but 25(OH)D (79.7 ±7 to 40.9 ± 19 ng, p=0.04) and Mg decreased (1.8 ±0.1 to 1.7 ±0.1 mg/dl; p=0.02), while alkaline phosphatase increased (65.3 ± 3 to 77.3 ± 4 IU/l; p=0.007). BMD (g/cm^2) increased 4% at the spine (1.22 ± 0.1 to 1.26 ± 0.1; p=0.004), 3% at the total hip (1.08 ± 0.1 to 1.10 ± 0.1; p=0.03), did not change at the femoral neck (0.97 ±0.1 to 0.97 ±0.1) and decreased 4% at the 1/3 radius (0.73 ± 0.1 to 0.71 ± 0.1; p<0.001). One kidney stone and 2 fractures (stress and toe) occurred. Hypercalcemia occurred 13 times out of 407 serum calcium measurements (6%). These data suggest that 6 years of PTH(1-84) treatment in HypoPT leads to sustained normalization in calcium metabolism. Urinary calcium excretion, calcium and calcitirol supplemental requirements persisted in being lower than baseline values, along with maintenance of normal serum calcium levels. BMD changes were site-specific, with a proclivity to increase at trabecular and decrease at cortical sites. These data, the longest-term clinical experience with PTH treatment available to date, suggest that PTH(1-84) treatment is a safe and effective long-term option in HypoPT.

FR0016

Skeletal Microstructure Continues to Improve Markedly Two Years After Parathyroidectomy in Primary Hyperparathyroidism. Natalie Cusano*[1], Chiyuan Zhang[2], Wen-Wei Fan[1], Aline Costa[2], Elizabeth Levy[1], John Bilezikian[1]. [1]Columbia University College of Physicians & Surgeons, USA, [2]Columbia University, USA

It is well known that BMD improves after parathyroidectomy in primary hyperparathyroidism but little is known about post-parathyroidectomy changes in skeletal microstructure. We previously reported our results in a cohort of subjects through 18 months and we now extend our findings through 2 years post-parathyroidectomy. We studied 28 subjects [age: 63 ± 14 years, duration: 7 ± 9 years, 19 women (17 postmenopausal), 93% Caucasian] with baseline and at least 6 month data. Of these participants, 19 were also assessed at 12 months, 15 at 18 months, and 9 at 24 months (5 women). Measurements were made at the distal radius and tibia using high resolution peripheral quantitative computed tomography (HRpQCT, Scanco Medical AG) to assess volumetric bone mineral density (vBMD) and bone microstructure. To evaluate changes after parathyroidectomy, we used a linear mixed model for repeated measures. At both the radius and tibia, there were significant increases in total vBMD; total, cortical, and trabecular area; and cortical thickness (Table). Additionally, there was a significant increase in cortical density at the tibia alone. The tibia experienced greater numerical improvements than the radius.

We also investigated sex-specific differences using sex as a covariate in the model. Age was similar (men: 57 ± 19 vs. women: 66 ± 10 years; p=0.13). Men demonstrated a trend towards shorter duration of disease (2 ± 5 vs. 9 ± 7 years; p=0.06). We found gender-specific differences at the tibia that remained significant after adjustment for age and disease duration in trabecular density (men: +3.4 ± 10% vs. women -0.3 ± 9%; p=0.006) and trabecular bone volume fraction (men: +3.2 ± 10% vs. women -0.3 ± 9%; p=0.009).

This report provides the longest post-parathyroidectomy results for HRpQCT to date, demonstrating clear improvement in geometric properties and vBMD at both the radius and tibia. Our results continue to demonstrate site-specific differences, with greater improvements at the tibia, a weight-bearing site. We also report gender-specific differences in trabecular microstructure at the tibia. The etiology for sex-specific differences in response to parathyroidectomy is unclear. The results help to establish that bone quality improves after parathyroidectomy and that there ar0e differences between men and women.

Accurate Quantification of Bone Fragility Requires Inclusion of Pores of all Sizes. Afrodite Zendeli*[1], Yohann Bala[2], Mariana Kersh[3], Ali Ghasem-Zadeh[4], Ego Seeman[4], Roger Zebaze[5]. [1]Endocrine Centre, Austin Health, University of Melbourne, Australia, Australia, [2]University of Melbourne, Dept. of Medicine, Australia, [3]Department of Mechanical Engineering, Melbourne School of Engineering, University of Melbourne, Australia, Australia, [4]Austin Health, University of Melbourne, Australia, [5]Austin Health, University of Melbourne, Australia

Introduction: Intracortical remodeling during growth forms osteons with Haversian and Volkmann canals responsible for most cortical voids which are seen as 'pores' of ~50-80 μm. With age, unbalanced and accelerated remodeling upon canal surfaces enlarges them focally, some coalesce form large pores, while new canals may be excavated increasing canal density (number per unit volume). This increase in porosity causes 70% of all age-related bone loss and increases fragility exponentially. As porosity may generate stress concentrators and influence crack initiation, large numbers of small pores may reduce strength more than fewer large pores independently of the total void volume. As *in vivo* imaging devices like HRpQCT have a resolution of ~125 μm, we proposed that failure to include pores <125 μm

underestimates bone fragility by underestimating porosity and disregarding the stress risers so produced by small pores.

Methods: In scanning electron microscopy images of the anterior subtrochanteric region in 16 Caucasian women (age 29 – 87 years), we assessed pore number and diameter to determine the contribution of pores < 125 μm to total porosity. Finite element (FE) models were used to simulate loading the subtrochanteric cortex. Total porosity was kept constant at 25% varying pore size from 53 to 300 μm while applying a 250KN bending force along one edge of the cortex to quantify strain distribution.

Results: Limiting quantification of porosity to pores > 125μm excluded 77.2 ± 9.4% of all pores in the total cortex; 88.1 ± 9.22% of pores were missed in the compact-appearing cortex (CC), and 58.6 ± 14.3% were missed in the transitional zone (TZ) ($p < 0.001$). Thus, porosity was underestimated by 41.9 ± 17.4 % in the total cortex. The underestimation was almost three-fold greater in the CC than in the TZ (56.6 ± 20.2 % vs 18.1 ± 16.6 %; $p < 0.001$).

For a given level of porosity, although total strain was relatively constant, areas with highest strain increased with decreasing pore diameter ($R^2=0.72$; $p<0.001$). When pore size was < 125 μm, the areas subjected to >2600 μstrain increased by 135% compared to models with pores > 125 μm.

Conclusion: Confining quantification of porosity to pores above the resolution of HRpQCT underestimates porosity by 50% and ignores the contribution of ~80% of all pores to fragility. Accurate quantification in the effects of ageing, diseases and therapies in bone fragility requires inclusion of all pores regardless of their size.

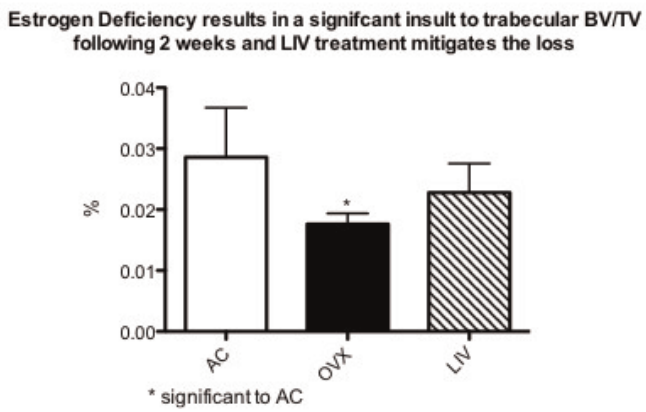
Consequences of acute estrogen deficiency on bone quality and biology and the effects of Low Intensity Vibrations for mitigating bone loss. Divya Krishnamoorthy*[1], Clinton Rubin[2], Danielle Frechette[3]. [1]SUNY Stony Brook University, USA, [2]State University of New York at Stony Brook, USA, [3]Stony Brook University, USA

Current drug and non-drug treatments for post-menopausal osteoporosis are not particularly effective at reversing the severe insult to bone quantity. This study investigates the responsiveness of skeletal remodeling in ovariectomized (OVX'd) mice to low intensity mechanical vibrations (LIV), which has been shown to be anabolic to bone. We aimed to identify the most effective period, either in the acute or chronic phases of OVX-induced bone loss, for the application of mechanical intervention. In just 2w following the cessation of estrogen, C57BL/6 female mice OVX'd at the age of 8w (n=5, OVX) revealed a significant 38% ($p<0.05$) reduction in trabecular BV/TV compared to sham controls (n=6, AC), along with a 19% increase and 18% decrease in trabecular spacing and number, respectively (both $p>0.05$). In addition to the immediate defect in bone quality, bone marrow cell populations also exhibited shifts within just 2w following OVX. The percent of B cells, T cells and myeloids show 44% increase ($p>0.05$) and 14% & 17% decrease ($p>0.05$) with respect to controls. Mice receiving just 2w of LIV (n=8, LIV) treatment (0.3g, 90Hz, 15min/day) immediately following cessation of estrogen exhibited only about half the decrease in BV/TV compared to shams as that of OVX (-20% in LIV ($p>0.05$) vs. -38% in OVX ($p<0.05$)). Bone marrow leukocyte populations showed no significant differences with LIV suggesting that, the partial mitigation of bone by LIV might actually be a protection of resident bone cells rather than an effect on the bone marrow cell populations. The application of LIV for 6w following the significant insult to bone that occurs in 2wks was in fact unsuccessful at both restoring trabecular bone and normalizing bone marrow leukocyte populations. These data not only reveal that the insult to the skeletal quality and biology is defected immediately upon estrogen deficiency but that the application of interventions would be more effective during menopause when bone remodeling is at its peak rather than post-menopause when bone loss it too severe to overcome.



Estrogen Deficiency results in insult to BV/TV following 2w & LIV treatment mitigates the loss

Cortical Tissue from Postmenopausal Women with Atypical Fractures Shows Reduced Heterogeneity in Nanomechanical Properties. Ashley Lloyd*, Eve Donnelly. Cornell University, USA

Bisphosphonates are the primary pharmacologic treatment for osteoporosis and reduce fracture risk by 30-50% in postmenopausal women. However, atypical femoral fractures, characterized by a transverse brittle morphology, have been associated with prolonged bisphosphonate treatment. Because bisphosphonates reduce bone remodeling, they have the potential to alter bone tissue material properties. However, the tissue material properties of atypical fractures are unknown.

Thus, the objectives of this study were (1) to compare the nanomechanical properties of bone tissue from patients with atypical femoral fractures to that of patients with typical fragility fractures, and (2) to correlate the nanomechanical properties with compositional properties.

Specimens of proximal femoral cortical bone adjacent to the fracture site were obtained from postmenopausal osteoporotic women during fracture repair surgery. The patients were allocated into three study groups: patients with atypical fractures, all of whom had a history of bisphosphonate use (+BIS Atypical: n=7, age 73+/-12y, bis 9.3+/-4y); and patients with typical fragility fractures with and without bisphosphonate use (+BIS Typical: n=4, age 88+/-6y, bis 9.5+/-6y; -BIS Typical: n=4, age 85+/-3y).

Raman microscopy was used to assess the mineral:matrix ratio, carbonate:phosphate ratio, and mineral crystallinity. Nanoindentation was used to assess the reduced modulus and hardness. The compositional properties were correlated with nanomechanical properties. Compositional heterogeneity was assessed through the full width at half maximum of parameter histograms.

Mean mineral:matrix ratio was 7.5% greater in atypical samples compared to pooled controls (+BIS Atypical: 1.57 vs. +BIS Typical: 1.33, p=.016; vs. –BIS Typical: 1.41, p=.086) (Fig. 1a). The distributions of tissue mechanical properties were narrower in atypical samples compared to pooled controls, with reduced modulus 15.9% narrower (p=.053) and hardness 12.4% narrower (p=.033) (Fig. 1b). Crystallinity was the best predictor of both hardness and reduced modulus across all groups.

The elevated tissue mineralization in atypical samples suggests increased tissue age and increased brittleness. The decrease in heterogeneity of mechanical properties is consistent with a reduction in overall bone toughness due to a loss of intrinsic toughening behavior and the transverse fracture morphology observed radiographically.

Sequential Impact Loading and Zoledronic Acid Pre-Treatments Protect Against Disuse-Induced Bone Strength Loss in the Rat Femoral Neck. Ray Boudreaux*, Jessica Brezicha, Scott Lenfest, Anand Narayanan, Susan Bloomfield, Harry Hogan. Texas A&M University, USA

Disuse is a potent down-regulator of bone mass. Recent data demonstrate that bisphosphonates (BP) and exercise can mitigate bone loss, yet interactive effects when the two are combined are unclear. Zoledronic Acid (ZA) given as a yearly injection avoids the GI side effects of other BPs. This study used high impact loading (IL) to simulate exercise, followed by ZA just before a period of disuse. We hypothesized that this novel sequential pre-treatment would protect against disuse-induced losses in strength and densitometric properties at the femoral neck (FN). We further

hypothesized that the sequential combination of IL and ZA pre-treatment would be superior to either treatment alone.

Male Sprague-Dawley rats (6-mo) were block assigned by initial body weight to 1 of 6 groups (n=12/group): BC (baseline control), CC (cage control), HU (hindlimb unloaded), IL+HU (impact loading prior to HU), ZA+HU (ZA prior to HU), and IL+ZA+HU (IL followed by ZA prior to HU). IL took place 3x/wk, consisting of 25 free-fall drops per session from a height of 60 cm for 5 weeks. A single dose of ZA (60 μg/kg) was administered the day before the start of 28d of HU, achieved via the traditional tail suspension method. Femurs were collected at the end of HU, and *ex vivo* pQCT scans were conducted followed by standard mechanical tests of the FN. For untreated HU rats, disuse caused significantly lower ultimate force (-20%) and absorbed energy (-35%) vs. CC, but all 3 treatments were effective countermeasures. At the end of HU, ultimate force was 21% higher than HU for IL+HU, 17% higher for ZA+HU, and 31% higher for the combination (IL+ZA+HU). Absorbed energy was also higher (by 34%, 30%, 49%, respectively). HU lowered total BMC (-11%) and vBMD (-6%) vs. CC. All 3 treatments had significantly higher vBMD than HU (by 5.8%, 6.9%, 8.3%, respectively). For BMC and bending strength index, however, only IL+ZA+HU led to significantly higher values vs. HU (by 14% and 15%, resp.).Our study demonstrated that monotherapy of IL or ZA was capable of mitigating HU-induced bone loss in the FN of skeletally mature rats, but the sequential combination of IL+ZA was better than either treatment alone for mechanical properties and selected densitometric variables. To our knowledge, this is the first study to document protection from disuse bone loss in rats via ZA and/or impact loading. The results provide encouraging support for the potential advantages to be gained from combination therapies.

Microdamage Formation In Osteocalcin and Osteopontin Deficient Mice. Stacyann Morgan*[1], Ondrej Nikel[1], Atharva Poundarik[2], Caren Gundberg[3], Deepak Vashishth[1]. [1]Rensselaer Polytechnic Institute, USA, [2]Rensselaer Polytechnic University, USA, [3]Yale University School of Medicine, USA

Fatigue-induced microdamage leads to bone resistance against stress and fragility fractures. We have recently shown that osteocalcin (OC) and osteopontin (OPN) acts as link proteins and enhances bone toughness[1]. However, the role of these proteins in energy dissipation during physiological cyclic loading is unknown. To address this question, here we studied microdamage formation in wild type (WT) and OC-OPN$^{-/-;-/-}$ mice subjected to cyclic loading.

Tibias from male 6 months old C57/BL6 mice (n=6) and their OC-OPN$^{-/-;-/-}$ littermates were obtained and stored in saline soaked gauze at -80C until use. The soft tissue was removed and a strain gauze (EA-13-015DJ-120, Vishay) was bonded on to the lateral surface. Each bone was loaded by a linear ramp in four point bending at 40N/sec until 5000μ? was achieved. The bones were subsequently loaded in fatigue between 1N and the predetermined maximum load at 2Hz. Cyclic loading was interrupted in the tertiary phase of the fatigue life at 70% stiffness loss. Samples were stained in 1% basic fuchsin and embedded in polymethyl methacrylate (PMMA). Transverse sections through the region of the gauge were created at 100 μm thickness. Diffuse damage and linear microcracks were observed using a confocal microscopy at 10x (Zeiss LSM 510Meta, Carl Zeiss,Germany). Linear microcrack density and diffuse damage area were assessed for each sample. Mann-Whitney Rank Sum test was used to determine differences between the groups.

Linear microcracks and diffuse damage was observed in both groups. However, diffuse damage was significantly higher in WTs (p=0.002) than OC-OPN$^{-/-;-/-}$ (WT=0.072±0.06 mm^2/ mm^2, OC-OPN$^{-/-;-/-}$ =0.003±0.07 mm^2/ mm^2). While OC-OPN$^{-/-;-/-}$ had higher number of linear microcracks (4.33±3.5 #LMC/ mm^2) compared to WTs (3.0±2.7 #LMC/ mm^2), the result was not significantly different (p=0.30). Differences in fatigue behavior between the two groups was consistent with microdamage data and also showed differences in post fatigue creep behavior. In summary, our study shows that the loss of OC and OPN from bone matrix, significantly reduces diffuse damage formation and affects fatigue behavior of bone. The results indicate that energy dissipation is largely governed by diffuse damage formation, as opposed to linear microcracks, and its absence decreases the resistance of bone to fatigue failure.

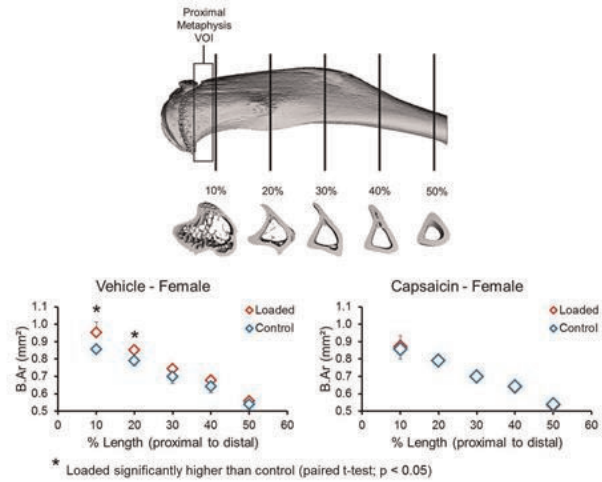
Lack of Adaptive Bone Response to Increased Mechanical Loading in a Mouse Model of Reduced Peripheral Sensory Nerve Function. Mollie Heffner*[1], Blaine Christiansen[2]. [1]UC Davis Medical Center, USA, [2]University of California - Davis Medical Center, USA

Sensory nerves in bone have traditionally been assigned the role of pain transmission, but recent insights into the interaction between neuropeptides and bone cells suggest a more direct role for nerves in bone. However, the role of sensory nerves in bone, especially under adaptive conditions such as increased mechanical loading, remains largely undefined. In this study, we used capsaicin-treated mice as a model of decreased peripheral sensory nerve function to study the role of sensory nerves during adaptation of bone to anabolic mechanical loading. Mice were injected subcutaneously with capsaicin (50 mg/kg) on days 2 and 5 after birth; decreased sensory nerve function was confirmed in skeletally mature mice (12 weeks old) with a thermal stimulus sensitivity test. Capsaicin- (n = 10 male, 10 female) and vehicle-treated mice (n = 10 male, 8 female) were subjected to mechanical loading via tibial compression. The right lower leg of each mouse was compressed to a target compressive load of 3 N at 4 cycles/sec, 1200 cycles/day, 5 days/week for 2 weeks. Left tibiae served as internal controls. Bilateral tibiae were scanned using micro-computed tomography (SCANCO μCT 35). Trabecular bone was analyzed at lateral and medial compartments of the proximal tibial metaphysis. Cortical bone was analyzed at 10, 20, 30, 40 and 50% of the tibia length from the proximal end. Tibial compression resulted in increased bone structure in the loaded tibiae of vehicle-treated mice, particularly at the lateral metaphysis trabecular bone, and at proximal sites along the tibial length (10% and 20%). In contrast, we observed no differences in bone structure between the loaded and contralateral tibiae of capsaicin-treated mice. For example, male vehicle-treated mice had 5.5% greater trabecular thickness at the lateral region of the tibial metaphysis (p = 0.028), while male capsaicin-treated mice showed no significant change. Similarly, female vehicle-treated mice had 2.7-5.8% greater bone area in the loaded tibia compared to the contralateral tibia at 10% and 20% of the tibia length, while female capsaicin-treated mice showed no differences at these locations (Fig. 1). These findings suggest that bones of mice with reduced peripheral sensory nerve function are less sensitive to increased mechanical loading than sensory intact mice. These observations are potentially important when considering treatment options for bone disease in subjects with diminished sensory nerve activity.



Cross-sectional bone area of loaded and control tibiae of vehicle and capsaicin-treated female mice.

A School-based Seven Year Exercise Intervention Program in 6-9 Year Old Children Improve Skeletal Traits without Increasing the Fracture Risk – A Population-Based Prospective Controlled Study in 3534 Children. Jesper Fritz*[1], Magnus Karlsson[2], Bjorn Rosengren[2], Magnus Dencker[2], Caroline Karlsson[2]. [1]Sweden, [2]Skåne University Hospital Malmö, Lund University, Sweden

Purpose: Most prospective physical activity (PA) intervention studies in children are short-term and concerns for an increased fracture risk.

Method: We conducted a population based long-term prospective controlled exercise intervention study with 40 minutes of scheduled PA in school per day for 7 years in 619 girls and 720 boys aged 6-9 years at study start. An age matched control cohort of 1069 girls and 1126 boys continued with the Swedish standard of 60 minutes PA per school week. We registered incident fractures and calculated rate ratio (RR) with 95% confidence interval (95% CI). In a sub-sample of 63 girls and 91 boys in the intervention and 38 girls and 36 boys in the control group, we followed skeletal traits annually by dual X-ray absorptiometry (DXA) and at last follow-up also by peripheral quantitative computed tomography (pQCT). We calculated individual slopes and annual changes in bone mineral density (BMD; g/cm2), bone mineral content (BMC; g) and femoral neck area (cm2) and we also compared volumetric BMD (vBMD; mg/cm3) between groups. Data are reported as mean gender-specific group differences with 95% CI within brackets.

Results: There were 25.2 fractures/1000 person-years in the intervention group and 23.4 fractures/1000 person-years in the control group, resulting in a RR of 1.08 (0.88, 1.31). Furthermore, there were no group differences in the gender specific fracture risk evaluations (data not shown). For girls the annual gain in spine BMD was 0.01g/cm2 (0.00, 0.01), in femoral neck BMC 0.07g (0.02, 0.11) and in femoral neck area 0.03cm2 (0.00, 0.06) greater in the intervention than in the control group. With DXA at last follow up, the intervention girls had 0.4g (0.0, 0.8) higher femoral neck BMC than the control girls. With pQCT at last follow up, the intervention girls had 13.7mm2 (0.4, 27.0) larger tibial cortical area, 16.4g (1.3, 31.4) higher tibial cortical BMC and

22.6mg/cm3 (4.1, 41.0) higher tibial trabecular vBMD than the control girls. The intervention boys had at last follow-up 18.5mg/cm3 (4.1, 32.9) higher radius cortical vBMD than the control boys while the other traits and annual gains were similar.

Conclusions: PA intervention for 7 years in school in at study start 6-9 year old children, improves in girls the gain in bone mass and bone structure and is in boys associated with higher bone mass without in neither of the genders increasing the fracture risk.

Effects of History of Amenorrhea on Marrow Adiposity, Cortical Bone Mass and Distribution in Retired Elite Gymnasts. Rachel Duckham*[1], Timo Rantalainen[2], Gaele Ducher[3], Prisca Eser[3], Robin Daly[4]. [1]Deakin University, Aus, [2]University of Jyväskylä, Finland, [3]Deakin University, Australia, [4]Centre for Physical Activity & Nutrition Research, Deakin University, Australia

Purpose: Bones adapt to prevalent loading in a site-specific manner, which may be related to the preferential differentiation of bone marrow mesenchymal stem cells into osteoblasts rather than adipocytes. Given that amenorrhea (AME) can adversely affect bone health, the aims of this study were to examine: 1) the effects of history of athletic AME on exercise-induced changes in bone strength, geometry, cortical vBMD and its distribution in retired gymnasts; 2) examine whether bone marrow density, as an estimate of marrow adiposity, differs between retired gymnasts with contrasting menstrual histories, and 3) whether marrow density is an independent predictor of cortical bone mass, structure and strength.

Methods: 28 female retired gymnasts (mean $\pm$ SD: age 23 ± 5 years; years retired 6 ± 4) reporting a history of AME (primary or secondary AG, n=10) were compared with former eumenorrhoeic gymnasts (EG, n=15) and controls (C, n=30, aged 26 ± 8 years). pQCT was used to assess marrow density, muscle CSA, total (ToA), cortical (CoA) and medullary area (MeA), strength strain index (SSIp) and total cortical and regional (endo-, mid- and peri-cortical) vBMD at the mid (66%) radius and tibia.

Results: Menarcheal age was delayed in AG compared to EG and C (17 vs 13 and 12 years, $P<0.001$). At the radius, SSIp was 22-29% ($P<0.001$) higher in AG and EG versus C, which was accompanied by 19-25% ($P<0.001$) greater ToA. CoA was not different between AG and C because of medullary expansion in AG. Radial cortical vBMD was 9-18% ($P<0.05$) lower at the endo- and mid-cortical regions in AG compared to C. At the tibia, AG had 18% ($P<0.05$) higher SSIp compared to C, which was accompanied by enhanced bone structure (12-13% greater ToA and CoA, $P<0.05$) but not cortical vBMD. Marrow density did not differ significantly between AG (tibia 0.967+0.006; radius 0.946 ± 0.008), EG (tibia 0.959 ± 0.006; radius 0.957 ± 0.007) and C (tibia 0.954 ± 0.004; radius 0.960 ± 0.005). Moreover, there was no associations between marrow density and bone strength and its determinants in the subgroups or all women combined, even after adjusting for bone length, MeA and muscle CSA.

Conclusion: Former female gymnasts, irrespective of menstrual history, had greater cortical bone size and strength, but normal or lower vBMD, at peripheral sites compared to the non-active women. In contrast, there were no differences in marrow adiposity which suggests that it did not contribute to the observed differences in bone strength.

Increased Physical Activity during Growth Improves Muscular Development without Affecting Fracture Risk – a Four-Year Prospective Controlled Exercise Intervention Study in 2 525 Children. Marcus Coster*[1], Jesper Fritz[1], Magnus Dencker[2], Susanna Stenevi-Lundgren[2], Jan-Ake Nilsson[2], Bjorn Rosengren[2], Magnus Karlsson[2]. [1]Sweden, [2]Skåne University Hospital Malmö, Lund University, Sweden

Short-term pediatric exercise intervention programs improve muscle strength. It is unknown whether these benefits remain with extended duration of intervention, and some concerns for higher fracture risk have been raised. We therefore evaluated the effects of a four-year exercise intervention on fracture risk and muscle strength.

We registered incident fractures in an intervention group of 391 girls and 468 boys, aged 6–9 years at study start, who received 40 minutes of physical activity (PA) per school day (200 minutes per week) during a four-year period, and in a control group of 815 girls and 851 boys who continued with the standard of 60 minutes of PA per week. In a sub-cohort of 236 children we annually estimated muscle strength as isokinetic Peak Torque (PT) of the knee extensors and flexors in the right leg at speeds of 60o/second and 180o/second by a computerized dynamometer. We also measured lean body mass by dual energy X-ray absorptiometry (DXA). We calculated the rate ratio (RR) for fracture risk and estimated annual change in muscle strength and lean body mass by linear regression in each individual. We adjusted group comparisons for baseline age, baseline value for the measured parameter, annual changes in height and Tanner stage at follow-up.

The fracture risk was similar in the intervention and control group [RR 1.10 (0.82, 1.47)]. The annual gain in PT flexion strength was greater in girls ($p<0.05$) and boys ($p<0.01$) in the intervention than in the respective control group, while the gain in lean body mass was similar. Girls in the intervention group also had greater gain in PT extension strength at 180 ^{o}/sec ($p<0.05$).

Our four-year exercise intervention program initiated in the prepubertal period improves the gain in leg muscle strength in both girls and boys without affecting the fracture risk.

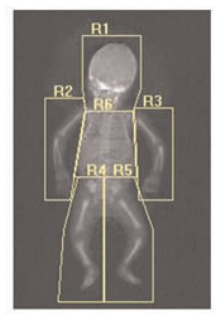
Novel "3-6" infant DXA scanning and analysis protocols to isolate movement and other artifacts. John Shepherd*[1], Bo Fan[1], Cassidy Powers[2], Lynda Stranix-Chibanda[3], Mary Glenn Fowler[4], Linda Dimeglio[5], Cynthia Mukwasi[6], Kathy George[7], George K Siberry[8]. [1]University of California, San Francisco, USA, [2]UCSF, USA, [3]Department of Paediatrics & Child Health College of Health Sciences University of Zimbabwe, Zimbabwe, [4]Makerere University(MU)-Johns Hopkins University(JHU) Research Collaboration, Uganda, [5]Indiana University School of Medicine, USA, [6]University of Zimbabwe, Zimbabwe, [7]FHI 360, USA, [8]NICHD/NIH, USA

Much progress has been made in prevention of mother to child transmission (PMTCT) of HIV by use of combination antiretroviral drugs (ARVs) given to the mother and infant during pregnancy and breastfeeding. However, some ARVs have been linked to decreased bone mineral density. Movement and artifacts in infant DXA scans are common, and may lead to scan invalidation. To date, standardized acquisition and analysis methods for infant spine and whole body DXA scans do not exist. We developed a "3-6" infant DXA protocol for up to 3 scan attempts and 6 analysis regions for whole body scans. The 3-6 protocol is designed to improve the odds of acquiring a motion-free scan, and a correction method using either reflection or multiscan imputation. We characterized the effectiveness of this protocol by measuring the precision and accuracy of the bone and soft tissue measures. Newborns received spine and whole body DXA scans with up to 3 attempts to acquire a motion free scan. All attempts were saved. A 6-region whole body analysis was used to allow for reflection analysis of arms and legs, and to isolate the head. We evaluated the difference in BMC for head and arm positioning. Regional precisions were estimated as root mean square errors (RMSE) or percent coefficients of variation (%CV) for scans with multiple valid results. Results from scans without movement were compared to estimated results from either reflection (whole body) or multiscan imputation (spine). To date, 533 infants have been sequentially recruited (198 male) with at least one valid whole body scan (82%) and spine scan (91%). An additional 11% of whole body and 7% of spine scans were recovered using reflection and multiscan imputation. Spine precision for paired scans was 3.2% (BMD) and 4.1% BMC (n=30 pairs). Whole body precision was 6.6% for BMC and 5.0% for BMD (n=5 pairs), and 1.9%, 3.2%, 2.7%, and 1.4% for lean, fat, % fat, and total mass respectively. Omitting one vertebrae did not significantly impact the total BMD. One-vertebra imputation resulted in $<$ 1% total BMD change. The RMSE of total body measures using reflection was in all cases less than the precision for any single region. After adjusting for subtotal BMC, head turning caused an apparent increase in total BMC by 3.6%. Arm and leg bending showed no difference in the total BMC ($p>0.3$). We conclude that the 3-6 protocol is effective in improving the accuracy of infant DXA scans and provides good spine and whole body DXA precision.



Ideal positioning for an infant whole body scan with six regions of interest. Notice that there are no motion artifacts and no overlapping regions.

Infant whole body example of 3-6 protocol

Determining Peak Bone Mineral Density in 16 to 24 year olds: A Longitudinal HR-pQCT Study. Lauren Burt*, Sarah Manske, Jenn Bhatla, David Hanley, Steven Boyd. University of Calgary, Canada

Peak bone mineral density (PBMD) occurs by late adolescence or early adulthood, and its timing has mainly been assessed using dual x-ray absorptiometry (DXA). PBMD measured with high-resolution peripheral quantitative computed tomography (HR-pQCT) may differ due to resolution or skeletal site differences. If HR-pQCT can be used as a clinical assessment tool, identifying individuals with osteoporosis and increased fracture risk, normative data illustrating PBMD is important to implement a T-Score classification system. In our population-based cohort we aimed to assess differences in PBMD between females and males by HR-pQCT compared with DXA.

Females (n=42, 21.5 yrs) and males (n=33, 21.6 yrs) from the Calgary youth cohort of the Canadian Multicentre Osteoporosis Study (CaMos) participated in a 2-year follow-up study. DXA (Hologic, USA) scans of the left hip provided areal bone mineral density (aBMD) of femoral neck (FN) and total hip (TH). Non-dominant radius and left tibia were scanned using HR-pQCT (Scanco Medical, Switzerland). To compare repeat scans, automated 3D image registration was conducted (IPL software) and masks of the common region were applied for data analysis. Total volumetric BMD (Tt.BMD), cortical BMD (Ct.BMD), trabecular BMD (Tb.BMD) and cortical porosity (Ct.Po) were assessed, and finite element analysis estimated apparent bone strength. A repeated measures ANOVA assessed age-related bone change over time.

Over 2-years, DXA-derived aBMD decreased at the FN and TH for females and males by -0.5 to -1% per year ($p<0.01$). At the radius, Tt.BMD increased by 1% per year for both females and males ($p<0.01$), Tb.BMD increased 0.8% per year for males ($p<0.01$) but did not increase for females. Ct.BMD increased by 0.7% for females and 1% per year for males ($p<0.01$). There were no significant changes in Ct.Po or apparent bone strength for females or males at the radius ($p>0.05$). At the tibia, there were no significant increases in BMD for females or males; however, Ct.Po increased 7% for females and 10% per year for males ($p<0.01$). Apparent bone strength did not change for females or males at the tibia ($p>0.05$).Our 2-year longitudinal study is consistent with known DXA peaks in aBMD occuring before 20 years at the FN and TH. Our 3D measures reflected an increase in HR-pQCT-derived BMD parameters at the radius, suggesting PBMD at the radius occurs at an age greater than 22 years in both females and males. At the tibia, all HR-pQCT-derived BMD parameters remained stable suggesting PBMD at this skeletal site may occur before 22 years in both females and males, similar to hip aBMD. Like DXA (hip vs. spine), timing of PBMD differs according to skeletal site (radius vs. tibia). Peak normative data for HR-pQCT should comprise of <22 year olds to capture PBMD at the tibia and ⩾ 22 year olds to capture PBMD at the radius.

FR0058

Does up to three years of exposure to recreational gymnastics between 4 and 12 years of age influence bone strength development at the radius and tibia?. Marta Erlandson*[1], Stefan Jackowski[1], Rita Gruodyte-Raciene[2], Saija Kontulainen[1], Adam Baxter-Jones[1]. [1]University of Saskatchewan, Canada, [2]Lithuanian Sports University, Lithuania

Introduction: Gymnastics training results in unique high mechanical loading to the skeleton. It therefore, provides an excellent model for assessing the effects of weight-bearing physical activity on bone development. Elite gymnasts have been found to display higher aBMD, BMC, and bone structrual strength both during active sports participation and after retirement. Recreational gymnasts have also been found to have greater bone parameters in cross-sectional studies compared to peers not exposed to gymnastics. What is unknown is the long-term consequence of early exposure to recreational, low-level, gymnastics on the subsequent development of bone strength. The purpose of this study was to investigate the influence of exposure to recreational gymnastics during childhood on bone properties and estimated strength development at the radius and tibia.

Methods: One hundred and twenty seven children (59 males, 68 females) between 4 and 9 years of age, involved in either recreational gymnastics (gymnasts) or other recreational sports (non-gymnasts) were recruited and followed for three consecutive years. Measures included demographics, anthropometrics, gymnastics participation, physical activity and peripheral quantitative computed tomography (pQCT) scans of the distal and shaft sites of forearm and lower leg. Multilevel random effects models were constructed to assess development of bone strength measures, controlling for age, limb length, weight, physical activity, muscle area, sex, and gymnastics exposure.

Results: Once age, limb length, weight, muscle area, physical activity and sex were accounted, it was observed that individuals exposed to recreational level gymnastics had significantly greater total bone area (18.0 $\pm$ 7.5 mm^2) and total bone content (6.0 $\pm$ 3.0 mg/mm) at the distal radius than individuals not exposed to recreational gymnastics ($p<0.05$). Gymnastics exposure was not a significant independent predictor for any bone measures at the radial shaft or at the tibia ($p>0.05$).

Conclusions: Exposure to recreational gymnastics provides skeletal benefits at the distal radius at all ages, suggesting that childhood recreational gymnastics exposure is advantageous to bone development at the wrist. As recreational gymnastics skills can be implemented into physical education programs, this type of training could potentially impact primary wrist fracture prevention. However, randomized controlled trials of recreational gymnastic exposure are required to further support these findings.

The Association of Child Bone Measures Across Ages with Parent Bone Measures. Steven Levy*[1], Elena Letuchy[2], Julie Eichenberger Gilmore[3], Kathleen Janz[1], Trudy Burns[4], James Torner[5]. [1]University of Iowa, USA, [2]Univ. of Iowa Dept. of Epidemiology, USA, [3]Univ. of Iowa College of Medicine, USA, [4]Univ of Iowa College of Epidemiology, USA, [5]Univ. of Iowa Department of Epidemiology, USA

Purpose: This analysis characterized associations between parental bone and growth measures and those of their children from early childhood to late adolescence. These associations can indicate propensity for growth and bone accrual determined by familial influences. Methods: Iowa Bone Development Study examinations conducted every 2 to 3 years from age 5 to 17 years (6 waves) in boys and girls obtained measures of bone mineral content (BMC) and density (BMD) for hip, spine, and whole body from DXA (Hologic); and growth measures of height and weight. Parental measures were assessed once at the age 8 examinations. Parent-child correlations were estimated for: 1) ''raw'' bone and growth outcomes; 2) minimally adjusted outcomes (residuals and predicted values from gender- and wave-stratified linear regression models for children with height and weight (for bone) as predictors; parental models also included age); and 3) fully adjusted outcomes (models also included, e.g., physical activity). Analyses were done for children using all available data from each wave (n=120-240 per wave, varied by wave and parent/child gender) and again for those with measures at each examination (n=218). Results: The parent-child height association was stronger for maternal measures, and increased with child age (r=0.46 to 0.59 for daughters; r=0.40 to 0.59 for sons). Weight correlations showed a slight positive age trend for daughters, but not sons, and the strength of the association was not different for mothers vs. fathers. Spine BMC showed stronger maternal associations. The hip BMC and whole body (without head) BMC maternal associations were also stronger for daughters (r=0.5). For sons, there was no difference mothers vs. fathers (r=0.45). The strongest associations were for maternal-child spine BMC (r?0.6 for sons and daughters) at age 17. In general, there appear to be stronger maternal influences on bone measures; the strength is modified by covariate adjustment. Father-daughter associations are strongest for covariate-adjusted spine BMD and BMC; father-son associations are strongest for hip BMC and BMD. Analyses limited to children measured at all waves showed similar patterns. Conclusion: The strength of parent-child height, but not weight, associations was dependent on child age. Only spine measures showed stronger associations at older ages when adjusted for growth measures and other covariates, reflecting stronger parental influences.

The Longitudinal Relationship Between Visceral Fat and Bone Development: The Iowa Bone Development Study. Natalie Glass*[1], James Torner[1], Elena Letuchy[1], Trudy Burns[1], Kathleen Janz[1], Janet Schlechte[2], Julie Eichenberger Gilmore[1], Steven Levy[1]. [1]University of Iowa, USA, [2]University of Iowa Hospital, USA

Purpose: Greater visceral fat (VF) has been associated with with lower bone measurements in youth, though this relationship has not been evaluated longitudinally. The purpose of this study was to determine if VF is negatively associated with bone parameters in overweight and obese adolescents from age 11-17.

Methods: Iowa Bone Development Study participants underwent peripheral quantitative computed tomography (pQCT) scans of the radius and tibia and whole body dual energy x-ray absorptiometry (DXA) scans every 2 years from age 11-17. Eligible participants were overweight or obese at age 11 according to CDC BMI

percentiles and had age 11 baseline scans and age 15 or 17 follow-up. VF area (cm^2) was estimated from whole body DXA scans using Apex 4.0.2 software (Hologic, Inc). Gender specific analyses evaluated the relationship between VF and bone development with growth models using biological age (visit age – age of peak height velocity) as the time variable adjusted for limb length and lean mass. Results are presented as standardized parameter estimates.

Results: Eligible participants included 42 girls(45% obese) and 52 boys (35% obese) with a mean age at baseline of 11.2±0.3 years. In girls, greater VF was associated with thinner cortical bone and lower strength-strain index (SSI) at the radius (20% site), but not tibia (Table). In boys, greater VF was associated with lower density and strength at the trabecular bone site (4%) at the tibia but not radius. At the cortical site in boys (20%), greater VF was associated with thinner bones at the radius with no significant associations at the tibia. In sensitivity analyses restricted to obese participants, results remained relatively unchanged in girls. In boys, the relationship between VF and SSI (20% site) became significant (-0.12±0.05, p=0.0260) while parameter estimates for associations at the 4% tibial site were attenuated and no longer reached significance (BMD: -0.14±0.08, p=0.11; BSI: -0.17±0.09, p=0.07).

Conclusions: Greater VF is associated with lower cortical bone strength at the non-weight-bearing radius but not at the tibia where greater mechanical loading may attenuate the negative relationship. Lower trabecular bone strength at the tibia with greater VF in boys may be a reflection of more rapid growth at that site. These results suggest the bone-fat relationship may vary depending on adiposity and bone site and explain previous, conflicting reports on this relationship.

CCL3 demonstrates sexually dimorphic regulation of skeletal homeostasis and the hematopoietic stem cell pool in the bone marrow. Benjamin Frisch*[1], Alexandra Goodman[1], Mary Georger[1], Michael Becker[1], Laura Calvi[2]. [1]University of Rochester School of Medicine & Dentistry, USA, [2]University of Rochester School of Medicine, USA

Hematologic malignancies are known to remodel the bone marrow microenvironment reducing support for normal hematopoiesis and increasing support for malignant hematopoiesis. One molecular mechanism that has been demonstrated to play a role in this microenvironmental remodeling is the chemokine CCL3. However under normal physiologic conditions the role of CCL3 in the maintenance of the skeleton and hematopoiesis is poorly understood. To study this we utilized mice that lack CCL3 (CCL3KO). CCL3KO mice demonstrate a marked increase in the frequency and number of phenotypic long-term hematopoietic stem cells (LT-HSCs) in the marrow by flow cytometric analysis (0.0053 ± 0.0005 vs. 0.0106 ± 0.0007 % of cells, WT vs. CCL3KO p≤0.0001 n=8 mice/group). A significant increase was also seen in short-term HSCs (ST-HSCs), but not in multipotent progenitors (MPPs) (data not shown), suggesting that in the HSC compartment CCL3 regulates the most immature hematopoietic cells. When separated by gender we observed that the LT-HSC phenotype, when compared to WT controls, was most severe in female CCL3KO mice with a 2.8 fold increase in LT-HSC frequency while male mice had a 1.5 fold increase in LT-HSC frequency, both were statistically significant. In the peripheral blood, monocytes, granulocytes, and red blood cells were all significantly decreased in CCL3KO mice (9.78 ± 0.3 vs. 8.06 ± 0.2 RBCs*10^6/µl, WT vs. CCL3KO p≤0.001 n=8 mice/group). This suggests that CCL3 not only regulates the most immature hematopoietic cells, but also the production of mature hematopoietic cells. When the skeleton was analyzed we found that male mice had no change in femoral trabecular (Tb) architecture, while female mice showed decreased Tb number (0.79 fold, p≤0.05 n=4 mice/group), decreased Tb connectivity density (0.62 fold, p≤0.05 n=4 mice/group), increased Tb thickness (1.17 fold, p≤0.01 n=4 mice/group), and increased Tb spacing (1.29 fold, p≤0.05 n=4 mice/group) in the femur when compared to WT controls measured by µCT. In femoral cortical bone male and female CCL3KO mice had opposite phenotypes when compared to WT controls measured by µCT. Males had decreased cortical thickness (0.87 fold, p≤0.01 n=4 mice/group) while females had increased cortical thickness (1.17 fold, p≤0.05 n=4 mice/group). These data support a gender specific role for CCL3 in the maintenance of the bone marrow microenvironment with sexually dimorphic effects on both the skeletal and hematopoietic systems.

Fibrillin-1 Regulates Marrow Stem Cell Lineage Commitment and Differentiation. Silvia Smaldone*[1], Francesco Ramirez[2]. [1]USA, [2]Icahn School of Medicine at Mount Sinia, USA

Previous characterization of osteopenia in mice with Marfan syndrome has implied that the extracellular protein fibrillin-1 restricts osteoblast maturation and osteoblast-dependent osteoclastogenesis. Here osteopenia progression was studied in mice with conditional inactivation of Fbn1 gene in the developing limbs ($Fbn1^{Prx1-/-}$ mice). Micro-computed tomography (µCT) analyses of $Fbn1^{Prx1-/-}$ mice revealed progressive decline of bone mass after the animals reached 1-month of age. Progressive osteopenia was associated with persistent bone resorption, due to elevated number of osteoclasts, and reduced bone formation rate (BFR) in spite of proper mineralization ability of bone marrow derived osteoblasts. Interestingly, a transient increase in the number of skeletal progenitor cells (SkP) concomitant with reduced number of mesenchymal stem cells (MSC) was observed in 3 months-old mice and it was followed by a dramatic decline in SkP frequency and mature osteoblasts number in 6-month-old $Fbn1^{Prx1-/-}$ mice. These results suggested that lack of functional fibrillin-1 in the bone marrow microenvironment accelerate MSC's rate of commitment leading to a premature, age-dependent, depletion of the stem pool and eventually bone forming cells. These changes were also accompanied by loss of marrow fat cells resulting from impaired plasticity of bone marrow progenitor cells towards adipogenesis. Consistent with enhanced TGFβ activity of bone marrow cell cultures, systemic treatment of $Fbn1^{Prx1-/-}$ mice with pan-TGFβ neutralizing antibody 1D11 mitigated both bone and MSC loss. Altogether, our data indicate that fibrillin-1 is a structural component of the bone marrow niche that regulates lineage commitment and differentiation of MSCs by modulating local TGFβ activity.

BMP-2 Exerts a Tight Control of CXCL12 Cellular, Temporal and Spatial Expression that is Essential in Fracture Repair. Helen Willcockson*[1], Timothy Myers[1], Lara Longobardi[2], Ping Ye[2], Tieshi Li[2], Joseph Temple[1], Alessandra Esposito[1], Billie Moats-Staats[3], Anna Spagnoli[2]. [1]University of North Carolina, USA, [2]University of North Carolina at Chapel Hill, USA, [3]University of North Carolina- Chapel Hill, USA

The molecular mechanisms through which bone morphogenic protein-2 (BMP2) exerts its essential role in fracture repair still need to be determined. Although there is compelling evidence that CXCL12 is involved in the regenerative response to injuries, its function in fracture repair has been scarcely investigated. Here, we report a functional interplay between BMP2 and CXCL12 during fracture repair. Using BMP2-LacZ reporter mice, we found that during the first 10 days after fracture, cellular expression of BMP2 and CXCL12 co-localize along the endosteum adjacent to the fracture site. To determine the possible regulation of CXCL12 by BMP2, we used control ($BMP2^{flox/flox}$) and Prx1Cre conditional BMP2 haploinsufficient fractured mice ($BMP2^{cKO/+}$) that have abnormal fracture healing. Fractured wild-type mice showed CXCL12 expressing cells (detected by immunohistochemistry and immunofluorescence) within the endosteum close to the fracture site and within the fractured bones that lasted up to 14 days post-fracture. This immunodetection was fracture-induced since CXCL12 signal within the endosteum was almost undetectable in unfractured mice. Compared to control ($BMP2^{flox/flox}$) fractured mice, we found higher levels of CXCL12 expression in $BMP2^{cKO/+}$ fractured mice that were maintained through day 21 after fracture. Remarkably, $BMP2^{cKO/+}$ showed a disorganized pattern of CXCL12 expression at the endosteal site as well as within the fractured bones, with an increase in endothelial-containing vascular formations that were PECAM positive. In apposition to these vascular structures, supportive pericytes expressing NG2 were associated with CXCL12 positive cells. Stem cell factor expression showed a similar distribution with CXCL12. To determine a functional relationship between CXCL12 and BMP2, we treated $BMP2^{cKO/+}$ and control mice with AMD3100, an antagonist of CXCL12 receptor(s) given IP (2.5 mcg/gm of body weight/2x/day) 2 days before and from day 2 to day 7 after fracture. We found that AMD3100 induced callus formation in $BMP2^{cKO/+}$ mice as determined by microCT, histological and in-situ hybridization analyses for bone/cartilage markers. Taken together our studies show that BMP2 exercises controlled regulation of CXCL12 expression in time, pattern and localization that is essential for fracture repair. This has far-reaching implications for our understanding of the fracture repair process and to promote healing by modulating these mechanisms.

Bone Marrow Adipocytes are Distinct from White or Brown Adipocytes. Mark Horowitz*[1], Ryan Berry[2], Rose Webb[2], Tracy Nelson[2], Yougen Xi[2], Casey R. Doucette[3], Jackie A Fretz[2], Chris D. Church[2], Clifford J. Rosen[3], Matthew S. Rodeheffer[2]. [1]Yale University School of Medicine, USA, [2]Yale School of Medicine, USA, [3]Maine Medical Center Research Institute, USA

It has become evident that bone marrow (BM) adipocytes are more than " filler" in the BM. We have developed new techniques to quantitatively assess BM adipogenesis and lineage trace BM adipocyte progenitors (MAP) in mice. Using these techniques we have found that different mouse strains have different endogenous levels of marrow fat and BM adipogenesis. While increased marrow adipose tissue (MAT) has divergent affects on bone density, much remains to be discovered about the origin, ontology and function of BM adipocytes and their relationship to adipocytes in other depots.

We have found that C57BL/6 mice have very low constitutive marrow adipocytes that can be induced by feeding with rosiglitazone-containing diet, high-fat diet or irradiation. To determine the origin of BM adipocytes, we have performed lineage tracing using the fluorescent *mT/mG* reporter mouse in concert with various mouse models driving cre-recombinase from lineage specific promoters. In *mT/mG* mice, expression of cre-recombinase results in permanent removal of the targeted dTomato (mT) cassette and expression of the membrane targeted eGFP (mG) cassette, resulting in "flipping" from dTomato+ to eGFP+ cells. BM adipocytes within either the BM plug or decalcified frozen sections of long bones from cre:mT/mG mice can be visualized through fluorescent confocal microscopy.

All preformed brown adipocytes are traced in *Myf5-cre:reporter* mice. We have found that BM adipocytes are not lineage related to brown adipocytes as they are uniformly dTomato+ in *Myf5-cre:mT/mG* mice. In addition, all BM adipocytes are uni-locular, while brown adipocytes are multi-locular. WAT-APs have recently been shown to express PdgfRα leading to tracing all white adipocytes in *Pdgfra-cre:mT/mG* mice. However, only a subset of BM adipocytes is traced by *PdgfRα-cre*, regardless of the induction method, suggesting that MAPs and WAT-APs may be distinct. Consistent with this data, recent reports have shown that BM adipocytes are traced in *Osx1-cre:mT/mG* mice. We observe uniform dTomato+ vWAT, sWAT, BAT adipocytes and APs, while tracing a subset of cells on bone surfaces and osteocytes in this same model.

These experiments indicate that MAT is dynamic and changes in response to stress and that BM adipocytes/MAPs are distinct from white or brown adipocytes/APs. These data are some of the first to define the ontogeny of BM adipocytes/MAPs *in vivo* and indicate that BM contains a distinct fat depot.

Elucidating the Osteoimmunology of Critical Defects with Longitudinal Intravital Microscopy in the Murine Cranial Window Model. Longze Zhang*[1], Jason Inzana[2], Hani Awad[3], Regis J. O'Keefe[1], Xinping Zhang[3], Edward Schwarz[1]. [1]University of Rochester, USA, [2]USA, [3]University of Rochester Medical Center, USA

Background: Reconstruction of critical defects remains a major challenge due to the host inflammatory and fibrotic response. Thus, elucidating the osteoimmunology responsible is essential towards a solution. Previously we found that intermittent teriparatide (rPTH) therapy facilitates structural femoral and calvarial allograft healing in mice via increased osteogenesis and host-allograft bony union, and significantly decreased fibrosis. We also discovered that it significantly decreased large vessel arteriogenesis and the accumulation of mast cells in the interfacial tissue between the host and allograft bone. As the functional significance of this finding is unknown, we utilized in vivo multiphoton laser scanning microscopy (MPLSM) in the murine chronic cranial defect window chamber model to test the hypotheses that: 1) mast cell appearance in a critical bone defect coincides with arteriogenesis; and 2) mast cells specifically accumulated proximal to large (>30 μm in diameter) vessels.

Methods: Chronic cranial defect windows were produced in 8-week-old C57B/6 mice, which were randomized to rPTH and placebo. FITC-conjugated anti-Mcpt-5 or anti-CD11b antibody, was administered i.v. with Texas Red-Dextran to image mast cells or monocytes/macrophages respectively, with the vasculature. Weekly MPLSM imaging was performed, and 3D-reconstruction of the z-stack images with Amira was used to quantify vessel thickness, vascular volume, total volume, and vascular volume fraction. We also quantified Mcpt-5+ and CD11b+ cell numbers and determined their mean distance from large vessels (>30μm) vs. small (<30μm) blood vessels.

Results & Discussion: rPTH significantly increased angiogenesis and decreased arteriogenesis, consistent with prior studies. While CD11b+ cells were present in the middle of the defect in large numbers (60+/- 20/field, 10X) as early as day 14, Mcpt-5+ cells first appeared in the ROI on day 28 with much fewer number (12 +/- 6/field, 10X). Moreover, while CD11b+ cells were significantly closer to small vs. large vessels (14.1+/- 4.1 μm vs. 98.9 +/- 19.0 μm; $p < 0.05$), the opposite was true for Mcpt-5+ cells (61 +/- 3.7 μm vs. 26.9 +/- 14.6 μm; $p < 0.05$). These novel findings suggest that coupled osteogenesis and angiogenesis at the healing edge of a critical defect is opposed by arteriogenesis and fibrosis within the defect, and that rPTH efficacy includes inhibitory effects on arteriogenesis and mast cell-induced fibrosis.

Roquin Is A Novel Regulator of Bone Homeostasis. Bay Sie Lim*, Euphemie Landao, Shek Man (Jacky) Chim, Jennifer Tickner, Nathan Pavlos, Jiake Xu. University of Western Australia, Australia

Many osteolytic diseases have highlighted the intimate relationship between the immune and skeletal system. However, the underlying mechanism of osteoimmunology remains poorly understood. To gain insights into the molecular genetics and mechanisms of osteoimmunology, we have employed a chemical (ENU) mutagenesis screen and identified a mouse line, San Roque (*san/san*), which carries a M199R mutation in the Roquin (Rc3h1) gene. *San/san* mice display an autoimmune disease consistent with Systemic Lupus Erythematosus with dysregulation of follicular helper T cells [1]. Preliminary X-ray analysis revealed that *san/san* mice exhibit a lower bone density in comparison to WT littermates. MicroCT and histological analyses confirmed a low bone mass phenotype in *san/san* mice with a significant reduced bone volume (BV/TV) as compared to WT littermates (Figure 1). Real-time PCR showed elevated RANKL expression in whole bone isolated from *san/san* mice relative to WT mice. Flow cytometry analysis revealed that the increased RANKL expression was accompanied by a significant expansion of putative osteoclast progenitor populations in the *san/san* mice relative to WT mice. Consistent with the observed increased in progenitors, we also observed enhanced osteoclastogenesis and osteoclast activity from bone marrow macrophages (BMMs) derived from *san/san* mice, accompanied by enhanced RANKL-mediated MAPK signaling. *In vivo* bone calcein labeling showed a reduction in bone mineral apposition rate in the *san/san* mice indicating that osteoblast activity was also affected. In keeping with this phenotype, *san/san* calvarial-derived osteoblast culture showed a reduction in bone nodule formation. Furthermore, co-culture experiments revealed that calvarial osteoblasts of *san/san* mice have a reduced ability to support osteoclastogenesis, suggesting an extrinsic contribution to the pre-priming effect of osteoclast progenitors within the bone marrow niche in *san/san* mice. Taken together, our data demonstrates that Roquin is an important regulator of bone homeostasis and osteoimmunology.R-eference

FR0069

Specificity protein-1 mediated SDF-1/CXCL12 synthesis is inhibited by Cbl-PI3K interaction in bone marrow reticular cells. Naga Suresh Adapala[1], Vanessa Piccullio[2], Hector Aguila[2], Joseph Lorenzo[2], Archana Sanjay*[3]. [1]Texas Scottish Rite Hospital for Children, USA, [2]University of Connecticut Health Center, USA, [3]UCHC, USA

The chemokine SDF-1/CXCL12 plays an important role in bone remodeling by influencing osteoclast precursor migration and osteoblast formation. However, the molecular mechanism(s) regulating SDF-1 synthesis are not well understood. The E3 ubiquitin ligase and adaptor protein Cbl, influences bone remodeling by regulating the cellular distribution and activity of phosphoinositide 3-kinase (PI3K). We previously reported that mice with a loss of Cbl-PI3K interaction, due to a tyrosine to phenylalanine mutation at the PI3K binding site of Cbl protein (CblY737F, YF knock-in mice) had uncoupling of bone resorption from bone formation. Loss of Cbl-PI3K complex formation also resulted in increased PI3K/AKT signaling and SDF-1 expression, which altered the cellular composition of the bone marrow. SDF-1 is predominantly produced by CXCL12 abundant reticular (CAR) cells and flow

cytometric analysis revealed that both numbers of CAR cells and their SDF-1 production were increased in the bone marrow of YF mice. We found that SDF-1 promoter activity in WT cells was attenuated by a PI3K inhibitor. Next, to understand the molecular mechanism of increased production of SDF-1 in YF mice, bone marrow reticular cells ($CD45^-Ter119^-CD31^-Sca1^-$) were treated with increasing concentrations of PI3K and AKT inhibitors. Basal SDF-1 gene expression was 2-fold higher in YF cells compared to WT cells. The degree of inhibition observed with 1μM concentrations of either inhibitor in WT cells was only seen with 10μM concentration in YF cells. There are several Specificity protein 1 (Sp1) transcription factor-binding sites in SDF-1 promoter. Compared to WT, higher Sp1 protein levels were detected in the nucleus of YF cells. Furthermore, treatments of WT cell with the PI3K inhibitor LY294002 at either 1 and 10μM markedly decreased Sp1 localization in the nucleus. However, decreased nuclear Sp1 levels were only detected in YF cells at higher concentrations of LY294002. Treatment of cells with Mithramycin A, which blocks Sp1 binding to GC-rich regions of the SDF-1 promoter, markedly reduced SDF-1 mRNA levels in WT cells. However, significantly less inhibition was seen in YF cells. Taken together, these data suggest that the YF mutation of Cbl results in increased-PI3K/AKT signaling which, in turn, increases SP-1-regulated SDF-1 expression in the bone marrow reticular cells. We conclude that Cbl-PI3K interaction in WT bone marrow reticular cells negatively regulates SP1-mediated SDF-1 synthesis.

CTLA4-Ig Protects Against PTH Induced Bone Loss by Inhibiting T Cell Production of TNFα. Abdul Malik*[1], Jerid Robinson[2], Jau-Yi Li[1], Michael Reott[3], Jonathan Adams[4], M. Neale Weitzmann[1], Roberto Pacifici[1]. [1]Emory University School of Medicine, USA, [2]Emory University, USA, [3]Emory University School of Medicine, USA, [4]Emory University, USA

Continuous PTH (cPTH) treatment, a model of primary hyperparathyroidism, induces bone loss by stimulating the production of the osteoclastogenic cytokine TNFα (TNF) by bone marrow (BM) T cells. CTLA4-Ig (Abatacept) is an inhibitor of costimulation approved for rheumatoid arthritis that inhibits T cell activation and T cell cytokine production. In this study we investigated whether CTLA4-Ig prevents cPTH induced bone loss. 16 weeks old C57BL/6 female mice were infused with vehicle or cPTH (hPTH 1-34 at 80μg/kg/day) for four weeks using osmotic mini pumps. Mice were also treated with CTLA4-Ig or irrelevant-Ig (Irr.Ig) 100μg/mice IP, three times a week. cPTH induced a significant loss of trabecular bone in mice treated with Irr. Ig but not in those injected with CTLA4-Ig, demonstrating that CTLA4-Ig inhibits cPTH induced bone loss. CTLA4-Ig completely prevented the increase in serum levels of CTX (a marker of bone resorption) and osteocalcin (a marker of bone formation) induced by cPTH. Cultures of BM from mice treated with cPTH produced more osteoclasts (OCs), colony forming unit-alkaline phosphate (CFU-ALP) and mineralization nodules than those from control mice. These changes were prevented CTLA4-Ig treatment. We also found that CTLA4-Ig inhibited the capacity of cPTH to increase T cell TNF production. In summary, we found that CTLA4-Ig protects against the bone loss and the increase in bone resorption induced by cPTH by blocking the production of TNF by T cells. These findings provide a proof of principle for utilizing CTLA4-Ig as a novel treatment for primary hyperparathyroidism.

A Novel Sequestosome-1 / p622 ZZ Domain Inhibitor Blocks TNFα Induced Suppression of OBL Differentiation in MM. Rebecca Silbermann*[1], Jumpei Teramachi[1], Khalid Mohammad[1], Wei Zhao[1], Dan Zhou[1], Peng Yang[2], Julie L. Eiseman[2], Xiang-Qun Xie[2], G. David Roodman[1], Noriyoshi Kurihara[1]. [1]Indiana University, USA, [2]University of Pittsburgh, USA

Multiple myeloma (MM) bone disease is marked by irreversible osteoblast (OBL) suppression and uncoupling of the bone resorption – formation process. We previously reported that the ZZ domain of sequestosome-1 (p62) is required for bone marrow stromal cell (BMSC) support of MM cell growth and serves as a platform for the formation of signaling complexes that result in NF-κB, p38 MAPK, and PI3K activation in MM patient BMSC. We developed a small molecule inhibitor, (XRK3F2), that blocks p62-ZZ domain mediated protein interactions, including TNFα mediated signaling in BMSC, and recently reported that intraperitoneal XRK3F2 treatment induced new cortical bone formation by μCT in C57BL/KaLwRij mice intratibially inoculated with the murine MM cell line 5TGM1-gfp, as compared with vehicle treated animals bearing MM. Histology confirmed the presence of new bone formation along the periosteal surface of the tibia, and animals that developed new bone formation had high-grade extra-tibial tumors without evidence of new bone formation in bones that had not been inoculated with MM cells.

We now report that XRK3F2 induces new cortical bone formation only in the presence of significant systemic MM tumor burden (defined by high IgG2b levels), and that in all cases new bone formation developed adjacent to tumor, as demonstrated by anti-GFP immunohistochemistry, suggesting that XRK3F2 modulates local MM cell and bone cell interactions. To evaluate if XRK3F2 alters MM production of OBL inhibitors or stromal cell differentiation under osteoblastogenic conditions, we treated 5TGM1 cells, murine stromal cells (MC4), and 5TGM1 – MC4 co-cultures with doses of XRK3F2. XRK3F2 did not alter 5TGM1 production of MC4 derived IL-7 or TNFα when MM cells were cultured alone, and did not affect MC4 differentiation in the absence of MM. Interestingly, XRK3F2 treatment of 5TGM1-MC4 co-cultures under osteogenic conditions resulted in significantly higher levels of RUNX2 than vehicle treated co-cultures. This effect was most pronounced at XRK3F2 doses similar to the IC_{50} reached in vivo in our prior studies. XRK3F2 treatment in our co-culture system also blocked the over-expression of GFI-1, a transcriptional repressor of RUNX2 induced in MM cells by BMSC or TNFα. These results suggest that XRK3F2 may block GFI-1 or the TNFα induced suppression of OBL differentiation observed in MM cell-BMSC co-cultures, and that p62-zz domain blockade may serve as an anabolic agent in MM bone disease.

Alternatively Activated Monocyte and Macrophage Efferocytosis Support Prostate Cancer Skeletal Metastasis. Jacqueline Jones*[1], Fabiana Soki[2], Hernan Roca[1], Stefanie Thiele[3], Yusuke Shiozawa[1], Yugang Wang[1], Todd Morgan[1], Lorenz Hofbauer[3], Kenneth Pienta[4], Laurie McCauley[2]. [1]University of Michigan, USA, [2]University of Michigan School of dentistry, USA, [3]Dresden University Medical Center, Germany, [5]Dresden University Medical Center, Germany, [4]John Hopkins University, USA

Macrophages play a vital role in maintaining tissue homeostasis by clearing foreign pathogens and apoptotic tumor cells through phagocytosis (termed efferocytosis). However, their functional role and pathophysiological contribution to the tumor microenvironment in skeletal metastases is unclear. The purpose of this study was to determine the efferocytic monocyte/macrophage type and its potential in supporting prostate cancer (PCa) skeletal metastasis through efferocytosis. FACS analysis of peripheral blood mononuclear cells isolated from patients with PCa skeletal metastasis showed significantly higher (20% increase) triple positive CD68+/CD14+/CD16+ (alternatively activated, M2) monocyte populations as compared with non-cancer controls ($p<0.05$), and significantly correlated with their PSA levels ($p<0.05$). Moreover, monocytes isolated from PCa skeletal metastasis patients presented a 2.5 fold increase in efferocytosis versus patients without cancer. To further confirm these findings, we analyzed tissue microarrays, which revealed malignant PCa tissue expressed significantly higher levels of MFG-E8, a known facilitator of efferocytosis, in invasive versus benign tissues (31.9 ± 1.3 and 4.9 ± 0.7 respectively). Co-localization of CD68+ phagocytic cells and MFG-E8 was significantly increased in malignant PCa tissue ($p<0.05$). To determine the molecular mechanisms, several *ex vivo* assays were performed. *Ex vivo* analysis of efferocytosis using murine bone marrow macrophages revealed that $MHCII^{low}$ CD36+ and F4/80+ positive cells (M2 macrophages) are proficient at efferocytosis of apoptotic tumor cells and phosphatidylserine coated apoptotic mimicry beads. Modulation of macrophage efferocytosis with resolvin D (stimulator), cytochalasin D (inhibitor) or placement at 4° (blunt inhibition) resulted in differential expression of pro-efferocytic and tumorigenic genes (TGF-β, MFG-E8, MERTK, and PPAR-γ). Cytokine stimulation using IL4 and M-CSF increased macrophage efferocytosis, which correlated with increased pro-tumorigenic, M2-like gene expression (YM1, TGF- β). More importantly, soluble factors released from macrophages during efferocytosis resulted in a 30% increase of PC-3 cell numbers in a transwell assay, compared to macrophages alone. Together, these studies suggest that M2 macrophages display an efferocytic behavior that promotes PCa growth. Targeting these subpopulations shows promise as a therapeutic approach for skeletal metastasis.

Critical role of Pim-2 in NF-κB-mediated suppression of osteoblastogenesis and stimulation of osteoclastogenesis: Therapeutic impact of Pim inhibition on myeloma bone disease. Jumpei Teramachi*[1], Masahiro Hiasa[2], Asuka Oda[3], Ryota Amachi[3], Takeshi Harada[3], Shingen Nakamura[3], Kumiko Kagawa[3], Hirokazu Miki[3], Shiro Fujii[3], Keiichiro Watanabe[4], Itsuro Endo[5], Toshio Matsumoto[5], Masahiro Abe[6]. [1]The University of Tokushima, Japan, [2]Indiana University School of Medicine, USA, [3]Department of Medicine & Bioregulatory Sciences, Institute of Health Biosciences, The University of Tokushima Graduate School, Japan, [4]Tokushima University Hospital, Japan, [5]University of Tokushima Graduate School of Medical Sciences, Japan, [6]University of Tokushima, Japan

Myeloma (MM) cells enhance osteoclastogenesis and suppress osteoblastogenesis to cause devastating bone destruction with rapid loss of bone. The NF-κB pathway is critically involved in tumor expansion and bone destruction in MM. The activation of the NF-κB pathway suppresses osteoblastogenesis while enhancing osteoclastogenesis. We demonstrated that the activation of the NF-kB pathway up-regulated Pim-2 kinase levels in MM cells, and that blockade of Pim-2 induced MM cell death and ameliorated MM bone disease. However, the precise role of Pim-2 in bone metabolism still remains unknown. Therefore, the present study was undertaken to clarify the relationship between the Pim-2 and NF-κB pathways in bone metabolism on MM bone disease. TNF-α potently induced Pim-2 expression in bone marrow stromal cells

(BMSC) and MC3T3-E1, and also in monocytes and RAW264.7. The TNF-α-induced up-regulation of Pim-2 in these cells was mostly abolished by inhibitors of NF-κB. However, Pim inhibition did not affect the the activation of the NF-κB pathway in MC3T3-E1 induced by TNF-a, suggesting Pim-2 induction downstream of the NF-κB pathway. TNF-α potently suppressed mineralized nodule formation by BMP-2 in MC3T3-E1 and BMSC along with the activation of the NF-κB pathway; however, addition of the Pim-2 inhibitor SMI-16a as well as Pim-2 siRNA restored their mineralization. The Pim-2 inhibition enhanced the phosphorylation of Smad1/5 by BMP-2 while suppressing Smad2/3 phosphorylation by TGF-b in MC3T3-E1. The Pim-2 inhibition also suppressed the induction of NFATc1 and c-fos, critical factors for osteoclast differentiation, as well as osteoclastogenesis by TNF-α or RANKL. Histomorphometric analysis in bone lesions in mouse MM models showed that treatment with SMI-16a restored bone formation with mild amelioration of osteoclastogenesis. Consistently, the suppression of osteoclastogenesis *in vitro* required SMI-16a at doses over 10 μM, while 0.2 μM was enough to induce osteoblastogenesis, suggesting preferential induction of bone formation. Collectively, these results demonstrated that Pim-2 is a major downstream target of NF-κB signaling in both osteoblastic and osteoclastic lineage cells in addition to MM cells to cause the skewed bone metabolism in MM. Because different signaling pathways besides the NF-κB pathway also up-regulate Pim-2 expression in these cells, Pim-2 is suggested to be a pivotal therapeutic target for bone destruction and tumor progression in MM.

Ubiquitin-specific peptidase 45 (USP45), a family member of de-ubiquitinating enzyme, controls epithelial-mesenchymal transition of breast cancer in bone. Yuki Nagata*[1], Soichi Tanaka[2], Kenji Hata[3], Masahiro Hiasa[4], Riko Nishimura[3], Toshiyuki Yoneda[4]. [1]Indiana University-Purdue University Indianapolis, USA, [2]Osaka University, Japan, [3]Osaka University Graduate School of Dentistry, Japan, [4]Indiana University School of Medicine, USA

Aggressive cancer cells undergo epithelial-mesenchymal transition (EMT) in which epithelial cancer cells trans-differentiate into mesenchymal fibroid cells and acquire increased invasiveness and metastasis. EMT is regulated by a variety of extracellular and intracellular molecules. TGFb is one of the most potent stimulators of EMT and Snail is a well-recognized transcription factor that promotes EMT by repressing the expression of the epithelial marker, E-cadherin. We found MCF-7 human breast cancer cells expressing GFP (MCF-7/GFP) underwent EMT with up-regulation of Snail and down-regulation of E-cadherin when inoculated in the tibial bone marrow in which TGFb is continuously released via bone resorption. Inhibition of bone resorption by zoledronic acid (ZA) inhibited osteolytic colonization of MCF-7/GFP cells with decreased Snail expression. To our surprise, Snail expression in MCF-7/GFP cells was decreased by ZA treatment of MCF7 cells *in vitro*, suggesting that ZA decreased Snail expression independent of bone resorption. The decrease of Snail by ZA was restored by the proteasome inhibitor lactacystin, suggesting that ZA decreases Snail expression via ubiquitin/proteasome degradation. Differential microarray analysis of untreated and ZA-treated mammary tumors identified the de-ubiquitinating enzyme, ubiquitin-specific peptidase 45 (USP45), as a candidate involved in proteasomal degradation of Snail. USP45 expression was increased in MCF-7/GFP tumors in bone compared with the tumor in the mammary fat pad. TGFb increased USP-45 as well as Snail. Overexpression of USP45 in MCF-7/GFP cells induced Snail expression and other mesenchymal markers including N-cadherin and vimentin, while E-cadherin expression was abolished. USP45 physically bound to Snail and specifically de-ubiquitinated Snail. *In vitro* de-ubiquitination assays showed Snail ubiquitination was inhibited by USP45. ZA inhibited USP-45 expression and its de-ubiquitinating activity, thereby promoting Snail degradation. Importantly, ZA prevented metastasis of breast cancer from bone to lung and liver, presumably by promoting Snail degradation via inhibition of USP 45. Thus, our results suggest that the bone microenvironment rich in TGFb stimulates EMT in breast cancer by preventing proteasomal degradation of Snail via up-regulation of the de-ubiquitinating enzyme USP45. USP45 may be a potential target for development of a novel therapeutic agent for bone metastasis of breast cancer.

Targeting Dickkopf-related protein 1 (Dkk1) reduces extraskeletal tumor growth by novel immunomodulatory effects. Lucia D'Amico*[1], Ali Zamani[2], Aude-Helene Capietto[1], Roberta Faccio[3]. [1]Washington University School of Medicine, USA, [2]Department of Orthopedics, Washington University, St. Louis, Missouri, USA, [3]Washington University in St Louis School of Medicine, USA

Myeloid derived Suppressor Cells (MDSC) are potent inhibitors of anti-tumor T-cell responses involved in tumor progression. Downregulation of PLCγ2/β-catenin pathway occurs in MDSC from cancer patients and tumor-bearing mice and enhances their ability to suppress T cell activation and promote tumor growth. However, how β-catenin is reduced in MDSC during tumor progression is unknown. Dkk1 is an inhibitor of the Wnt/β-catenin pathway and is highly expressed in multiple myeloma patients with lytic bone disease. Although Dkk1 is known to modulate tumor growth in bone by suppressing osteoblast differentiation, we propose the novel hypothesis that Dkk1 favors tumor progression via downregulation of β-catenin in MDSC. To avoid possible confounding results due to the function of Dkk1 on bone cells, we chose to study the immunomodulatory effects of Dkk1 using an extraskeletal tumor model consisting of mice bearing subcutaneous (s.c) Lewis Lung Carcinomas (LLC). While Dkk1 expression is barely detectable in LLC cells in vitro, Dkk1 level in the tumor is significantly upregulated 14 days after inoculation. Dissection of the tumor mass reveals that the Wnt inhibitor is mainly expressed by the tumor-associated fibroblasts but not by LLC cells. To investigate the effects of Dkk1 on extraskeletal tumor growth, α-Dkk1 or IgG control Abs (20 mg/kg) were administered 3x/week to WT mice at time of LLC s.c. inoculation. Strikingly, tumor growth is significantly decreased in mice treated with α-Dkk1Ab compared to controls ($p = 0.019$). While α-Dkk1Ab does not directly affect LLC proliferation or survival in vitro, Dkk1 neutralization significantly reduces % of MDSC in vivo. This finding suggests that Dkk1 promotes tumor growth by favoring MDSC expansion. To further investigate the effects of Dkk1 on MDSC accumulation, we turned to the PLCγ2-/- mice since PLCγ2 null MDSC display reduced β-catenin level and stronger immune-suppressive functions compared to WT. α-Dkk1Ab significantly reduces tumor growth in null mice compared to IgG ($p = 0.006$). % of MDSC in bone marrow, spleen and tumor site is reduced while % of CD4 and CD8 T cells are restored by α-Dkk1Ab. Importantly, Dkk1 neutralization rescues β–catenin expression in PLCγ2-/- MDSC. Taken together, we demonstrate that α-Dkk1 treatment reduces extraskeletal tumor growth by targeting MDSC. The novelty of this work consists in having identified an immunomodulatory role for Dkk1 independent of its effects on bone cells.

The unexpected role of Hemoglobin beta (HBB) in breast cancer. Nadia Rucci*[1], Mattia Capulli[1], Luca Ventura[2], Patrizia Sanità[3], Simona Delle Monache[3], Adriano Angelucci[3], Anna Teti[1]. [1]University of L'Aquila, Italy, [2]San Salvatore Hospital, Italy, [3]University of L'Aquila, Italy

Breast cancer (BrCa) patients with metastases restricted to bone (BO) show a longer overall survival compared to BrCa patients developing bone and visceral metastases (BV). Gene expression analyses revealed few genes whose expression was significantly different between the two groups of bone metastases. Among them, we found the hemoglobin beta (HBB) to be one of the most upregulated in BV vs. BO. We confirmed the HBB expression in 34 out of 57 human primary tumors analyzed. Moreover, the percentage of HBB positive cancer cells (HBB score) in ductal and lobular breast carcinomas was significantly higher in the invasive lesions than in the in situ counterpart (6-fold, $P<0.05$). Higher expression of HBB was also observed in ductal infiltrating carcinoma *vs.* the lobular invasive histotype (2.2-fold, $P<0.05$), while benign lesions, the in situ counterpart of lobular carcinoma and normal tissue were negative. Interestingly, a positive correlation ($P<0.05$) was observed between HBB and the score of the proliferation marker Ki67. In vitro, we evaluated HBB expression between poorly aggressive (MCF7, HCC1954) and highly aggressive (MDA-MB231) BrCa cells, finding a higher mRNA and protein expression in the latter (11-fold $P<0.05$). Forced HBB overexpression in MDA-MB231 cells (MDA-HBB) induced an increased ability to migrate and invade in vitro vs. control cells (MDA-Empty), accompanied by increased transcriptional and protein expression of MMP9, and by increased expression of several oxidative stress associated mRNAs, including NOS2, NOX5, DUSP1, PREX1 and LPO. In an in vitro tube formation assay, MDA-HBB conditioned medium induced tube formation better than MDA-Empty (1.5-fold increase $P<0.05$). In agreement, the in vivo growth rate of orthotopically implanted MDA-HBB was significantly higher ($P<0.005$) compared to MDA-Empty. Tumor weight was increased too (1.9 fold, $P=0.002$), while histology showed less fibrosis in MDA-HBB tumor sections (0.4 fold, $P<0.001$). Moreover, local recurrence and visceral metastases were observed in 60% of MDA-HBB implanted mice, while MDA-Empty tumor recurrence and relapse did not occur over the same timeframe. Intriguingly, primary human prostate cancers as well as the prostate cancer cell line PC3 did not express HBB, suggesting specificity for BrCa. In conclusion, the expression of HBB in BrCa is positively correlated with aggressiveness, implying that HBB expression in BrCa cells could represent a specific pivotal pro-tumoral event.

CXCL14, an inhibitor of CXCL12/CXCR4 signaling, is upregulated in prostate cancer bone metastasis. Alexander Dowell[1], Katrina Clines[2], Colm Morrissey[3], Shi Wei[1], Gregory Clines*[4]. [1]University of Alabama at Birmingham, USA, [2]University of Michigan, USA, [3]University of Washington, USA, [4]University of Michigan, USA

Prostate cancer bone metastasis is present in 90% of men with advanced stage disease and is the principal source of morbidity and death. The discovery of novel drugs that target bone metastasis and biomarkers that identify men with early stage prostate cancer who are at risk for bone metastasis is of critical importance. An investigation by our group to uncover targets of endothelin-1, a factor involved in the osteosclerotic response of prostate cancer in bone, led to the identification of CXCL14. This 77 amino acid secreted protein is a member of the CXC chemokine

family. Chemokines play a pivotal role in prostate cancer cell homing to bone. CXCL14 represented an ideal target of interest due to its close homology with CXCL12 (also known as SDF-1). CXCL12 originating from bone promotes epithelial-mesenchymal transition and directs the migration of CXCR4-expressing circulating prostate cancer cells to bone. We hypothesized that CXCL14 modifies the action of CXCL12 during the metastasis of prostate cancer to the skeleton. In a human prostate cancer tissue microarray, the expression of CXCL14 was significantly upregulated in prostate cancer bone metastasis (H-Score mean 172.5, n=113) as compared to soft tissue metastasis (H-score mean 99.5, n=57, $p<0.001$), primary prostate cancer and normal prostate. CXCL14 expression in the prostate cancer xenograft line LuCaP 23.1 was increased in mouse tibia compared to subcutaneous implanted tumor. Similarly, CXCL14 was absent from the $ARCaP_M$ prostate cancer cell line, but was readily detected after intratibial inoculation. These data suggest that bone, but not other tissues, supplies prostate cancer cells with a unique signature of factors that increase CXCL14 expression. We next performed functional studies to uncover CXCL14 action in prostate cancer. CXCL14 blocked CXCL12-mediated *in vitro* chemotaxis of the $ARCaP_M$ prostate cancer cell line and is consistent with recent published data that CXCL14 binds to CXCR4 to block CXCL12-mediated activation of CXCR4. CXCL14 therefore opposes CXCL12 action and may be a critical factor in colonization of prostate cancer cells after CXCL12-mediated arrival to bone. Our model supports that bone-derived CXCL12 directs CXCR4-expressing prostate cancer cells to bone, and the bone microenvironment activates prostate cancer CXCL14 expression that reverses CXCL12 to halt further migration and promote colonization in bone.

Lysyl oxidase promotes survival and outgrowth of colon cancer cells in the bone marrow, enabling bone metastasis formation. Caroline Reynaud*[1], Laura Ferreras[2], Delphine Goerhig[2], Marie Brevet[3], Philippe A.R. Clezardin[4]. [1]INSERM Unité 1033UFR de Médecine Lyon-Est (domaine Laënnec), Fra, [2]INSERM U1033, France, [3]Hospices Civils de Lyon, France, [4]INSERM & University of Lyon, France

Lysyl oxidase (LOX) catalyzes the cross-linking of collagens and elastin in the extracellular matrix, thereby regulating the tensile strength of many tissues, such as in the bone. In cancer, LOX plays a critical role in facilitating tumor growth and metastasis formation in soft tissues. Whether tumor-derived LOX also enables bone metastasis is unknown. In this study, we first showed by immunohistochemistry using patient's tumor specimens, that *LOX* was expressed in the desmoplastic tumor stroma of pairs of colorectal carcinomas and their matching bone metastases. Preclinical experiments showed that *LOX* overexpression in different colon carcinoma cell lines enhanced the formation of osteolytic lesions in animals by promoting both skeletal tumor burden and osteoclast-mediated bone resorption. Additionally, exogenous LOX treatment of animals enhanced bone metastasis formation caused by parental colorectal carcinoma cells. Conversely, the pretreatment of animals with the LOX inhibitor b-aminopropionitrile or the silencing of *LOX* in colorectal carcinoma cells drastically reduced the formation of osteolytic lesions. *In vitro*, tumor-derived LOX indirectly promoted osteoclast differentiation by enhancing the secretion of osteolytic factors from colon cancer cells. LOX also directly enhanced the attachment of colon cancer cells to collagen (but not to fibronectin) and promoted cancer cell survival by activating interleukin-6 autocrine signaling pathways. In conclusion, our findings provide novel evidence that LOX endows colon cancer cells with the ability to thrive in the bone marrow microenvironment and stimulate osteoclast-mediated bone destruction.

Tumour-derived alkaline phosphatase promotes Epithelial-Mesenchymal Transition (EMT) and cell survival in bone metastatic prostate cancer; regulation by miR-373. Srinivasa Rao*, Ann Snaith, Patrick Kratschmer, Freddie Hamdy, Claire Edwards. University of Oxford, United Kingdom

Prostate cancer (PCa) bone metastases are often associated with mixed osteolytic/osteoblastic lesions. Identifying novel mechanisms that underlie this debilitating bone disease will ultimately reveal new therapeutic targets. We have identified differential expression of the key osteoblastic enzyme alkaline phosphatase (ALP) in a panel of PCa cell lines with increasing metastatic potential. Using a high-throughput screening approach, in vivo models of disease and pharmacological and molecular manipulation of ALP, the function and regulation of tumour-derived ALP in PCa bone metastasis was explored. ALP activity and mRNA expression were higher in osteoblastic ARCaPM cells than non-metastatic ARCaPE ($p<0.001$). ALP expression was lower in osteolytic PC3 cells, and undetectable in the majority of non-bone metastatic cell lines. Inoculation of ARCaPM cells into nude mice resulted in both osteolytic and osteoblastic lesions following microCT analysis, whereas PC3 cells resulted in purely osteolytic lesions. Lentiviral-mediated knockdown of ALP in ARCaPM cells resulted in ~50% decrease in cell viability and Mesenchymal-Epithelial Transition, evidenced by a change in morphology, increase in E-cadherin ($p<0.001$) and decreased migration. ALP knockdown in PC3 cells decreased cell viability ($p<0.01$). Inhibition of ALP by levamisole dose-dependently inhibited cell viability in a panel of bone metastatic PCa cells. ALP activity also correlated with the ability of PCa cells to mineralize in vitro. We have undertaken two complementary approaches to study ALP regulation in PCa bone disease. RNA-seq identified microRNAs that were differentially expressed in ARCaPM cells as compared to ARCaPE cells. Transfection of ARCaPM cells with a microRNA mimic library followed by a high-throughput functional screen identified microRNAs that regulate ALP activity. From these data, we focused on miR-373, which has a 22-fold lower expression in ARCaPM cells compared to ARCaPE cells ($p<0.05$). Overexpression of miR-373 in ARCaPM cells resulted in a 60% reduction in ALP gene expression ($p<0.05$), a reduction in Runx2 expression, a 20% reduction in ALP activity ($p<0.01$), and a 60% reduction in mineralization of ARCaPM prostate cancer cells ($p<0.01$). Our study defines a novel mechanism whereby tumour-derived ALP induces EMT and survival of PCa cells, with ALP expression regulated by miR-373, so identifying ALP and miR-373 as mediators of PCa bone metastasis.

FR0084

Integrin Alpha5beta1 is a Potential Therapeutic Target to Treat Experimental Breast Cancer Bone Metastasis. Francesco Pantano[1], Martine Croset[2], Keltouma Driouch[3], Edith Bonnelye[4], Michele Iuliani[1], Marco Fioramonti[1], Daniele santini[1], Giuseppe Tonini[1], Philippe A.R. Clezardin*[5]. [1]Medical Oncology Division, University Campus-Bio-Medico, Italy, [2]INSERM Research Unit U1033, University of Lyon1, France, [3]Institute Curie, France, [4]Faculte de Medecine RTH Laennec, France, [5]INSERM & University of Lyon, France

The fibronectin receptor, α5β1 integrin, is highly expressed in breast cancer cell lines and disseminated tumor cells (DTC) from bone marrow (BM) of breast cancer patients. The binding of α5β1 to fibronectin sustains tumor growth and contributes to the survival of breast cancer cells in BM. We have shown by *in-silico* analysis, using public microarray data sets, that high levels of α5 expression correlates with a short onset of bone metastasis (BonMet) in resected breast cancer patients. Quantitative real-time PCR analysis performed on primary tumors from 427 breast cancer patients showed that (1) high α5 levels correlated with metastatic status and clinical parameters and (2) α5 was an independent negative prognostic factor for BonMet relapse. Therefore, we studied the role of α5β1 in a mouse model of BonMet. We choose the breast cancer cell line B02, which highly expresses α5β1 and specifically metastases to bone, that we injected intra-arterially to mice in combinaison with the anti-human-α5β1 chimeric antibody (M200). *In vitro*, M200 blocked the adhesion and migration of B02 to fibronectin. To assess the role of α5β1 in early BM colonization by tumor cells, mice were treated with M200 (3 injections at 15mg/kg, starting the day prior to B02 inoculation to mice) or with vehicle. Seven days after tumor cell injection, the DTC number in the BM was significantly decreased in M200-treated mice, highlighting the anti-invasive properties of M200. Then, B02 tumor-bearing mice were treated with vehicle or M200 at 15mg/kg, 3 times a week during 28 days at which time, animals develop overt BonMet. M200 treatment delayed the onset of metastasis and decreased the extent of osteolytic lesions and tumor burden in metastatic mice. Additionally, M200 decreased human osteoclast differentiation *in vitro*, suggesting that α5β1 may also inhibit bone resorption *in vivo*. The lentiviral mediated-silencing of α5 expression in B02 reproduced the inhibitory effects obtained with M200 treatment of mice bearing BonMet. However, α5 silencing in MDA-MB-231 cells, which form metastases to BM and lungs, affected only DTC number in bone but not in lungs, indicating that the activity of α5β1 may be tissue-specific. Overall, we have shown that α5β1 mediates colonization of tumor cells in the BM and promotes the progression of bone metastasis *in vivo*, suggesting that the therapeutic targeting of α5β1 may be an effective strategy to treat bone metastasis.

Roundabout receptors mediate breast cancer bone metastasis formation and progression. Lise Clement-Demange*[1], Bénédicte Eckel[2], Vincent Gonin[2], Delphine Goehrig[2], Chantal Diaz-Latoud[2], Philippe A.R. Clezardin[3]. [1]France, [2]INSERM U1033, France, [3]INSERM & University of Lyon, France

Roundabount (ROBO) receptors regulate axon guidance. We did a comparative transcriptomic analysis of human MDA-MB-231 breast cancer cells with that of a cell subpopulation that only metastasizes to bone (referred to as B02) and demonstrated that Robo1 and Robo4 receptors were overexpressed in B02 cells. Interestingly, a high Robo4 expression in primary tumors from patients with breast cancer (n=254) correlated with poor prognosis and increased risk of relapse to bone. We therefore examined the functions of Robo1 and Robo4 in tumor outgrowth and bone metastasis formation.

Inoculation of Robo4-depleted cells in the mammary fat pad of mice led to a 50% reduction in tumor burden, whereas the outgrowth of Robo1-depleted tumors was substantially increased, compared with animals injected with mock-transfected B02 cells. Bone metastasis experiments were realized by injection of tumor cells into the caudal artery of mice and animals were analyzed by radiography on day 25 after tumor cell inoculation. The extent of osteolytic lesions was dramatically increased in

animals bearing Robo1-depleted tumors, when compared with animals bearing Robo4-depleted tumors.*In vitro*, the treatment of parental B02 breast cancer cells with anti-Robo1 antibody promoted invasiveness, whereas anti-Robo4 antibody dose-dependently inhibited B02 cell invasion. Altogether these results let us hypothesize that Robo4 might facilitate the engraftment of tumor cells in the bone marrow. To address this question, two experiments were set up. First, the bone marrow was flushed from the hind limbs of animals 7 days after tumor cell inoculation and cells cultured under antibiotic selection, enabling the selective growth of tumor cells. The number of colonies from the bone marrow of mice inoculated with Robo4-depleted cells was reduced by 75 to 80% when compared with Robo1-depleted cells. In the second experiment, B02 cells were first incubated with an anti-Robo4 antibody, one hour before intra-tibial inoculation. The incidence of colony appearance after bone marrow flush was reduced by 50% when B02 cells were incubated with the anti-Robo4 antibody and the number of colonies was dramatically reduced from 792 to 33 / mouse. These results provide strong evidence that axon guidance receptors Robo1 and Robo4 are involved in bone metastasis formation and that the use of an antibody directed against Robo4 receptor could lead to the development of innovative therapies to prevent bone metastasis.

Superoxide dismutase 2 (SOD2) is a major antioxidant enzyme localized mitochondria to diminish mitochondrial superoxide. Human studies have reported that SOD2 protein and *SOD2* gene expression were significantly decreased in osteoarthritic cartilage. However, pathophysiological role of SOD2 in chondrocytes has not been fully elucidated yet. Here, we generated a novel chondrocyte-specific *Sod2*-deficient (cKO) mouse using a Cre-loxp system to conclude whether SOD2 loss in chondrocytes enhances osteoarthritis (OA) progression. Dehydroethidium, a specific dye for superoxide detection, staining revealed that *Sod2* ablation significantly enhanced superoxide generation by 400% in isolated chondrocytes from the cKO mice. *Sod2* loss in chondrocytes of knee joint developed no obvious skeletal abnormalities during growth term, while the cKO mice significantly accelerated cartilage loss in the depth of tidemark at eight weeks after surgery. Moreover, *Sod2* deficiency spontaneously exacerbated OA pathologies at 12 months of age. *In vitro* experiments also revealed that *Sod2* depletion caused impaired mitochondrial membrane potential using JC-1 staining as well as swollen mitochondrial morphology associated with disrupted cristae using an electron microscope. Furthermore, gene expression analyses clarified that anabolic genes, including *Col2a1* and *Acan*, were significantly down-regulated, while catabolic genes, including *Mmp13* and *Adamts5*, were significantly up-regulated. Alcian blue staining confirmed a significant 80% decrease of proteoglycan in cKO chondrocytes. Taken together, these results demonstrated that *Sod2* deficiency in chondrocytes induced mitochondrial superoxide generation and mitochondrial dysfunction associated with decreased membrane potential resulted in cartilage degeneration and loss via impaired proteoglycan metabolism. Our findings revealed that SOD2 plays a protective role in OA pathogenesis regulating mitochondrial function in mice.

[1]The University of Tokyo, Japan, [2]University of Tokyo, Graduate School of Medicine, Japan, [3]The University of Tokyo Hospital, Japan, [4], Japan, [5]Gifu University, Japan, [6]University of Tokyo Schools of Engineering & Medicine, Japan, [7]JCHO Tokyo Shinjuku Medical Center, Japan

Hypoxia-inducible factor-1α (HIF-1α) plays a crucial role in hypoxic conditions for cell survival in various tissues. In chondrocytes, previous studies have shown that HIF-1α is essential in endochondral ossification and for interzone formation in joint development; however, the underlying molecular mechanisms remain unclear. Moreover, while HIF-2α regulates expression of various catabolic factors and osteoarthritis (OA), physiological and pathological functions of HIF-1α in articular cartilage are yet to be revealed. Here, we investigated the HIF-1α function in articular cartilage by analyzing surgical OA models and cartilage development using conditional knockout mice. When we created the experimental OA model one week after tamoxifen injection to *Col2a1-Cre^{ERT2};Hif1a$^{f/f}$* mice, we found that OA development was markedly accelerated as compared to the control *Hif1a$^{f/f}$* joints. We then examined articular cartilage formation in *Sox9-Cre;Hif1a$^{f/f}$* embryos, and found a massive cavity continuing from the joint surface forming a trumpet-shaped epiphysis. Notably, apoptosis and Mmp13 expression were upregulated in both of these cKO mice. In addition, aggrecan release was increased when femoral heads from 3 week old cKO mice were cultured in IL-1β and decreased when WT mice were cultured with $CoCl_2$, a stabilizer of Hif-1α. To determine altered gene expression by HIF-1α deficiency, we carried out a microarray with cartilage samples from cKO mice. The catabolic factors Mmp13 and Mmp9, anabolic factors Sox9 and Col2a1 and the apoptosis related genes Bnip3 and Bnip3l showed marked fold changes. To confirm these results, we obtained articular chondrocytes from *Hif1a$^{f/f}$* mice and introduced adenoviral vector expressing Cre recombinase or GFP. Real-time RT-PCR revealed increases of catabolic factors including *Hif2a, Mmp13* and *Mmp9*, and decreases of anabolic factors including *Col2a1* and *Sox9* by the deletion of HIF-1α under both normoxic and hypoxic (1% O_2) conditions. Similar results were also obtained by HIF-1α silencing in primary articular chondrocytes from WT mice using siRNA. When HIF-1α was lentivirally overexpressed in ATDC5 cells, the opposite results were obtained. In conclusion, HIF-1α is essential for articular cartilage homeostasis through its induction of anabolic factors and suppression of catabolic factors and HIF-2α. Elucidation of the molecular network related to HIF-1α may lead to an understanding of cartilage regeneration and subsequent OA treatment.

***PTHrP* is a candidate marker of slowly replicating "resting" chondrocytes in the postnatal growth plate cartilage.** Noriaki Ono*[1], Wanida Ono[2], Henry Kronenberg[2]. [1]University of Michigan School of Dentistry, USA, [2]Massachusetts General Hospital, USA

In endochondral bone development, chondrocytes in growth plate cartilage continue to proliferate postnatally, providing engines for bone lengthening. We hypothesize that slowly replicating cells of the growth plate are the sources of all other chondrocytes and show characteristics of postnatal stem cells. To isolate label-retaining cells (LRCs) (and therefore slowly replicating cells) from the growth plate, we generated mice harboring a Tet-Off system regulating expression of GFP linked to a histone (H2B-GFP) driven by type II collagen (Col2) promoter. In order to preferentially mark growth plate chondrocytes with tdTomato, we also included a *Col2-creER* transgene activating a *Rosa26*-tomato reporter (*Col2-tTA*; *TRE*-H2B-EGFP; *Col2-creER*; *R26R*-tomato). These mice were fed with doxycycline from 3 weeks of age for various periods to shut off GFP expression (chase), and injected twice with tamoxifen during 72 hours before being sacrificed. Dissected epiphyses were digested with collagenase to harvest chondrocytes for FACS analysis. Tomato$^+$ chondrocytes near the top of the growth plate retained a higher level of H2B-GFP expression. The fraction of a label-retaining population with $>10^4$ unit of GFP (GFP^{high}) within the Tomato$^+$ population gradually decreased as the chase period lengthened. LRCs and non-LRCs were FACS-sorted after 4 weeks of chase, when GFP^{high} represented ~10% of total Tomato$^+$ cells. RNA of both populations was amplified and subjected to Affymetrix cDNA microarray analysis. Upregulated genes in LRCs were listed and confirmed by qPCR using independent samples. Of these genes, we found that *PTHrP* mRNA was enriched in LRCs (x3.8). Analysis of *PTHrP-LacZ* knock-in mice revealed that PTHrP$^+$ chondrocytes were localized at the top of the postnatal growth plate. To ask whether these cells are slowly replicating, *PTHrP-LacZ* mice were pulsed with 9 serial injections of EdU from postnatal day 4 to 6 and chased thereafter for 3 weeks. While 17.9±2.7% of EdU$^+$ cells were LacZ$^+$ shortly after the pulse at day 7, the fraction increased to 77.6±9.6% after the chase at day 28, suggesting that LRCs were enriched among PTHrP$^+$ cells. Therefore, our data indicate that *PTHrP* is a candidate marker for slowly replicating ''resting'' chondrocytes of the postnatal growth plate, and will be instrumental in identifying characteristics of putative chondrocyte stem/progenitor cells. We are currently generating *PTHrP-creER* BAC transgenic mice to study the fate of these chondrocytes.

Ablation of CypA Leads to Impaired Chondrogenesis by Inhibiting NF-κB-Sox9 Pathway. Mian Guo*[1], Jia Shen[2], Jinny Kwak[2], Xinli Zhang[2], Aaron James[3], Kevork Khadarian[2], Kang Ting[2], Chia Soo[4], Robert Chiu[5]. [1]Dental & Craniofacial Research Institute & Division of Oral Biology, School of Dentistry, University of California, Los Angeles; Department of Neurosurgery, the Second Affiliated Hospital of Harbin Medical University, USA, [2]Dental & Craniofacial Research Institute & Section of Orthodontics, School of Dentistry, University of California, Los Angeles, USA, [3]Department of Pathology & Laboratory Medicine, David Geffen School of Medicine, University of California, Los Angeles, USA, [4]Division of Plastic & Reconstructive Surgery, School of Medicine, University of California, Los Angeles; Department of Orthopedic Surgery, School of Medicine, University of California, Los Angeles, USA, [5]Dental & Craniofacial Research Institute & Division of Oral Biology, School of Dentistry, University of California, Los Angeles; Jonsson Comprehensive Cancer Center & Division of Surgical Oncology, University of California, Los Angeles, USA

Cyclophilin A (CypA) is a PPIase (peptidyl-prolyl cis-trans isomerase) that regulates protein folding, stability and translocation in diverse cellular processes. Recent studies have demonstrated skeletal malformations in mice with PPIase deficiency. This study aims to investigate the role of CypA in chondrogenesis and the potential involvement of the NF-κB-Sox9 signaling pathway.

First, the skeletal phenotypes of CypA wildtype (wt) and knockout (ko) mice were assessed by Alcian Blue/Alizarin Red whole mount staining, microCT, and immunohistochemistry. Next, we cultured E12.5 mouse limb bud cells (wt vs ko) and ATDC5 prechondroblastic cells (control vs stable knockdown) in 3D systems. The chondrogenic capacity of these cells was compared by immunostaining and RT-PCR of chondrogenic markers expression. Finally, the direct interaction between CypA and NF-κB/p65 was determined using co-immunoprecipitation. In addition, CypA regulation of NF-κB/p65-Sox9 signaling was analyzed by western blot, luciferase reporter assay and immunohistochemical staining.

Results showed that CypA ko mice were 10% shorter in body length at birth, and exhibited endochondral ossification defects in the skull, long bones and vertebrae. MicroCT analyses and Alcian Blue staining of femur and lumbar vertebrae revealed significantly decreased bone formation and cartilaginous matrix deposition in CypA ko mice. When assessing the long bone growth plate in developing mice, we observed a thinner growth plate, shorter chondrocyte columns, and reduced expressions of Col2 & Col10 in CypA null mice (Fig.1). The inhibition of chondrogenesis by down-regulating CypA was confirmed *in vitro* in mouse limb bud cells and ATDC5 cells. Alcian Blue staining for chondrocytes and the expression of several chondrogenic differentiation markers (Col2, Col10, Runx2 and Sox9) were all decreased in CypA ko or kd cells (Fig.2). Next, the involvement of NF-κB/p65-regulated Sox9 expression in CypA-mediated chondrogenesis was assessed. Results showed that CypA affects p65 stability by directly binding its N-terminal 170-176 amino acids. p65 levels and activity were significantly inhibited in CypA knockdown cells, which in turn led to the downregulation of Sox9 expression (Fig.3).

These findings suggest that CypA plays an important role in chondrogenic development via the regulation of the NF-κB/p65-Sox9 signaling pathway. Further study will focus on the mechanisms of CypA regulated endochondral ossification.

Notch Inhibits Chondrogenic Differentiation of Mesenchymal Progenitor cells by Targeting Twist1. Martin Chang*[1], Ye Tian[2], Edward Schwarz[3], Matthew Hilton[4], Yufeng Dong[3]. [1]University of Rochester Medical Center, USA, [2]Shengjing Hospital, China Medical University, China, [3]University of Rochester, USA, [4]Duke University Musculoskeletal Research Center, USA

Recently we have demonstrated the importance of RBPjk-dependent Notch signaling in the regulation of mesenchymal progenitor cell (MPC) differentiation during chondrogenesis both *in vivo* and *in vitro*, although the exact molecular mechanisms remain unknown. Here we have performed Notch gain- and loss-of-function experiments to demonstrate for the first time that Notch suppression of MPC differentiation and chondrogenesis acts via up-regulation of the transcription factor *Twist1*. Notch activation, via Notch intracellular domain (NIDC1) over-expression, in micromass cultures of murine limb-bud MPCs displayed an inhibition of chondrogenesis. This was evidenced by significant decreases in the expression of chondrogenic marker genes, including *Col2a1* and *Acan1*, as well as decreased alcian blue staining. We further demonstrated that *Twist1* is exclusively expressed in MPCs at early stages of chondrogenesis during Notch activation and that inhibition of Notch signaling in these cells significantly reduced TWIST1 protein levels. In contrast, over-expression of NICD1 induced rapid TWIST1 expression in the nucleus and the effects of Notch on MPC differentiation was markedly reduced by knocking down of *Twist1* in MPC

micromass cultures (Fig. 1). Furthermore, luciferase assays demonstrate that constitutively active Notch signaling significantly enhanced *Twist1* promoter activity. Interestingly, mutation studies indicate that a putative NICD/RBPjk binding element TGGGAA (-1432/-1426) in the promoter region is required for the Notch-responsiveness of the *Twist1* promoter. Finally, chromatin immunoprecipitation assays using limb-bud MPCs further confirmed that the NICD influences *Twist1* transcription by directly binding to the *Twist1* promoter *in vivo* via the RBPjk binding site (Fig. 2). Taken together, our results indicate that RBPjk-dependent Notch signaling directly activates *Twist*1, and this likely contributes to the Notch-mediated repression of chondrogenesis and chondrocyte gene expression. These data provide novel insights into our understanding of the molecular mechanisms underlying Notch inhibition of chondrogenesis.

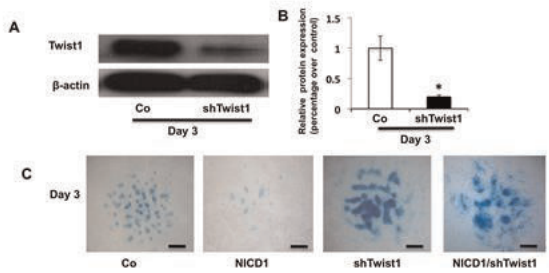

Fig. 1: Limb bud cells in micromass were infected with NICD1 or/and shTwist1 lentivirus for 3 days before being harvested for Western Blot and Alcian blue staining (A) Twist1 protein levels were significantly reduced by Twist1 shRNA lentiviral infection. (B) Quantification of Twist1 protein expression in Western blots. (C) A significant increase in chondrocyte nodule formation was observed in both shTwist1 infected cells with or without co-infection with NICD1, and a drastic reduction in chondrocyte nodule formation was seen in NICD1-expressing cells. Scale bars, 100 μm.

Fig. 1

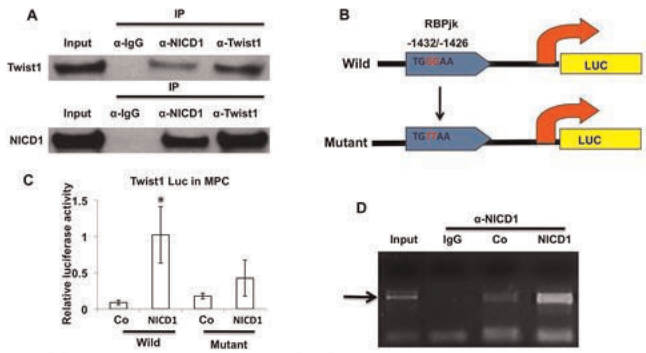

Fig. 2: (A) Immunoprecipitation assays (n=3) show that Twist1 protein interacts with NICD1. (B) RBPJK binding site-mutated promoter construct. Nucleotides that mutate from established consensus sequences are highlighted in red. (C) Twist1 promoter Luciferase assays. (D) Chromatin immunoprecipitation showed a specific fragment was detected between the RBPJK response element and Twist1 in control (Co) MPCs, and this fragment formation was enhanced by overexpression of NICD1 in MPCs.

Smad2/3 Mediated TGFbeta Signaling Controls Postnatal Chondrocyte Proliferation and Differentiation by Inhibiting *Ihh* Transcription. Weiguang Wang*, Karen Lyons, Teni Anbarchian. University of California, Los Angeles, USA

TGF-β signaling exhibits important roles in joint development and articular cartilage (Ref1). However, it is not clear to what extent TGF-β mediates its effects through canonical Smad2/3 pathways vs. non-canonical pathways. To address this question, we generated mice with a conditional deletion of *Smad2* in chondrocytes using Col2cre (*Smad2^{cko}*), mice with *Smad3* globally deleted (*Smad3$^{-/-}$*), and the cross of these two strains to obtain mice with both *Smad2* & *3* deleted in chondrocytes (Double mutant mice). At P0, *Smad2^{cko}, Smad3$^{-/-}$* and double mutant mice exhibited an expansion of both non-hypertrophic and hypertrophic zones in growth plate. PCNA staining showed that there is an increase of proliferation in resting chondrocytes in all 3 types of mutant mice. These defects were much more severe in *Smad2/3* double mutant and *Smad2^{cko}* than in *Smad3$^{-/-}$* mice. *In situ* hybridization results demonstrated an increase of *Ihh* mRNA expression in prehypertrophic chondrocytes in all 3 types of mutant mice, when compared with the WT(Fig). In addition, qPCR showed that TGF-β treatment inhibits *Ihh* transcription in rib primary chondrocytes of WT mice, but this inhibition is diminished in cells from all 3 types of mutant mice, and that this defect is more severe in double mutant and *Smad2^{cko}* than in *Smad3$^{-/-}$* cells. Moreover, luciferase reporter assay showed that Smad2 and Smad3 are required for inhibition of the 742bp *Ihh* promoter by TGF-β. Further examination of this *Ihh* promoter revealed 4 putative Smad2&3 binding elements (SBEs). Chip analysis using ATDC5 cells revealed that Smad2 only associates with SBE2, and Smad3 has high affinity with both SBE1 and SBE2, suggesting that Smad2 and Smad3 may have different functions in regulating expression of *Ihh*. Enhanced *Ihh* signaling is highly associated with osteoarthritis phenotype (Ref2). By 1 month, the double mutant mice developed early onset of osteoarthritis-like phenotypes. By 4 months, there was severe degeneration of articular cartilage, associated with elevated expression of Ihh, ColX and MMP13 in all these mutant mice. These observations suggest that TGF-β signaling mediated by both Smad2 and Smad3 is important for the regulation of postnatal growth plate chondrocyte proliferation, differentiation and maintenance of articular cartilage, and that Smads 2 & 3 may control these processes via inhibiting *Ihh* transcription.

The novel transcription factor Zinc Finger Homeobox 4 (Zfhx4) is critical to late stage of endochondral ossification. Eriko Nakamura*[1], Kenji Hata[2], Maokoto Wakabayashi[3], Yoshiaki Yura[1], Toshiyuki Yoneda[4], Riko Nishimura[2]. [1]Osaka University Graduate School of Dentistry, Japan, [2]Osaka University Graduate School of Dentistry, Japan, [3]Asahi Kasei Pharma, Japan, [4]Indiana University School of Medicine, USA

Endochondral ossification is a unique and important biological event, temporally and spatially regulated by transcription factors, including Sox9, Runx2, and Osterix. Although our understanding of the transcriptional regulation of endochondral ossification is in progress, the precise regulatory mechanism still remains elusive. We examined whether yet-unidentified transcription factors contribute to endochondral ossification. To address this, we performed microarray analyses using mouse limb bud cells. Mcroarray analyses showed high expression level of Zfhx4, a gene putatively proposed to be responsible for 8q21.11 Microdeletion Syndrome., The syndrome is characterized by micrognathia, camptodactyly, and syndactyly. Consistent with the microarray, RT-qPCR showed that Zfhx4 was highly expressed in chondrocytes, long bones, and calvariae. To investigate the role of Zfhx4 in endochondral ossification, we generated the Zfhx4 floxed mice and subsequently mated them with CAG-Cre transgenic mice. The Zfhx4 conditional knockout (KO) mice died of respiratory failure within a day after birth. The skeletal preparation of the Zfhx4 KO mice at E15.5 exhibited trivialized thoracic cavity, malformation of skull, and dysplasia of femur, scapula, mandible and rib. Histological analyses indicated that endochondral ossification was arrested at hypertrophic zone in the femur of Zfhx4 KO mice at E15.5. We next examined expression of chondrogenic markers by performing immunohistochemical staining of femur of Zfhx4 KO and wild-type (WT) littermates at E15.5. Col2 and Col10 expression levels were equivalent in Zfhx4 KO and WT. In contrast, MMP13 expression was dramatically down-regulated in Zfhx4 KO mice compared with WT mice. Of note, calcification of cartilage matrices was markedly suppressed in Zfhx4 KO at E15.5 as demonstrated by von Kossa staining. Because the phenotype observed in Zfhx4 KO resembled Osterix KO, we examined interaction between Zfhx4 and Osterix. Fluorescent imaging analyses showed co-localization of Zfhx4 with Osterix, but not with Runx2. These results suggest that Zfhx4 is an important transcription factor, playing a role in degradation and calcification of cartilage matrices, presumably through interaction of Zfhx4 with Osterix. In conclusion, we identified Zfhx4 as a novel transcription factor that might be critical to the late stage of endochondral ossification.

The transcription factor Foxc1 regulates chondrocyte hypertrophy in a synergistic cooperation with Runx2. Michiko Yoshida*[1], Kenji Hata[2], Sachiko Iseki[3], Teruko Takano-Yamamoto[4], Riko Nishimura[2], Toshiyuki Yoneda[5]. [1]Osaka University Graduate School of Dentistry, Japan, [2]Osaka University Graduate School of Dentistry, Japan, [3]Tokyo Medical & Dental University, Japan, [4]Tohoku University Graduate School of Dentistry, Japan, [5]Indiana University School of Medicine, USA

Endochondral ossification is spatially and temporally controlled by chondrogenic transcription factors. Given complexity and diversity of endochondral ossification, we attempted to identify an additional yet-unexplored transcription factor that contributes to the regulation of endochondral ossification. To this end, we performed FACS-assisted microarray profiling of transgenic mice overexpressing an improved-YFP, Venus, under the control of the *Col2a1* gene promoter and identified Forkhead Box c1 (Foxc1) that was selectively expressed in cartilage. Immunohistochemistry showed the evident expression of Foxc1 in proliferating and hypertrophic chondrocytes, suggesting a potential role of Foxc1 in endochondral ossification. Consistent with this notion, overexpression of Foxc1 strikingly increased *Col10a1* mRNA expression. DNA pull-down assay showed the direct binding of Foxc1 to a Foxc1-binding element in the *Col10a1* gene promoter. Of note, overexpression of Foxc1 together with Runx2, an essential transcription factor for chondrocyte hypertrophy, synergistically increased the expression of *Col10a1* and *MMP13*, both of which are well-known target gene of Runx2 in hypertrophic chondrocytes. Moreover, IP-western analysis demonstrated a physical associationbetween Foxc1 and Runx2. These data collectively suggest that the interactions between Foxc1 and Runx2 play an important role in the regulation of chondrogenic gene expression associated with hypertrophy. Finally, we investigated the role of Foxc1 in vivo using spontaneous *Foxc1*-inactivated mutant mice (*Foxc1*^{ch}). *Foxc1*$^{ch/ch}$ mice showed diverse skeletal abnormalities including dwarf phenotype and complete absence of the ossification center in the sternum. Histological analysis showed that there are reduced areas positive for Col10a1 and MMP13 in tibia of *Foxc1*$^{ch/ch}$ mice compared to that of WT mice at E15.5 days. Remarkably, Col10-positive hypertrophic chondrocytes were not detected in the sternum of *Foxc1*$^{ch/ch}$. *Col10a1* mRNA expression was decreased in primary chondrocytes isolated from *Foxc1*$^{ch/ch}$. However, Runx2 mRNA expression was not affected and overexpression of Foxc1 restored the expression of *Col10a1* in *Foxc1*$^{ch/ch}$ chondrocytes.

In conclusion, we identified the transcription factor Foxc1 that is selectively expressed in cartilage. Our results suggest that synergistic interactions of Foxc1 with Runx2 may regulate chondrocyte hypertrophy via the control of Col10a1 and MMP13 expression.

Absence of Cx37 leads to bone matrix modifications in mice: a potential explanation for why reduced cortical thickness is not followed by decreased mechanical strength. Rafael Pacheco Da Costa*[1], Eduardo Katchburian[2], Hannan Davis[3], Lilian Plotkin[4], Rejane Reginato[5]. [1]Indiana University/ Universidade Federal de Sao Paulo - Brazil, Brazil, [2]Federal University of São Paulo, Brazil, [3]Indiana University School of Medicine, USA, [4]Indiana University School of Medicine, USA, [5]UNIFESP - Federal University of São Paulo, Brazil

Connexin (Cx) 37 is a gap junction protein expressed in all bone cell types, and its deletion leads to increased cancellous bone mass due to defective osteoclast maturation. In spite of reduced cortical thickness, Cx37-deficient mice (Cx37$^{-/-}$) exhibit higher mechanical strength in the femoral midshaft than Cx37$^{+/+}$ littermates, suggesting changes in bone composition. We investigated here whether global deletion of Cx37 alters the composition of bone extracellular matrix. For this, mRNA isolated from vertebrae of 5-month-old Cx37$^{-/-}$ mice and littermate Cx37$^{+/+}$ wild type controls (N=7-10) was analyzed by qPCR. Cx37$^{-/-}$ mice exhibited increased expression of Col3a1 (a gene involved in collagen formation), and Loxl2, Loxl3 and Loxl4 (genes that encode for enzymes associated with collagen maturation) compared to Cx37$^{+/+}$ mice. Consistent with this, collagen fiber in the femoral midshaft analyzed in bone sections stained with picrosirius red and evaluated under polarization microscopy, showed that Cx37$^{-/-}$ mice exhibit predominance of reddish birefringence, suggesting the presence of thicker fibrils and reduced bone remodeling. In addition, these mice showed more intense type II collagen immunostaining, which could explain the improved bone strength, and a slight decrease in biglycan, an indication of increased collagen maturation. On the other hand, decorin did not change. Sulfated glycosaminoglycans were slightly decreased in Cx37$^{-/-}$ mice, as evidenced by alcian blue staining. On the other hand, expression of biglycan proteoglycan, Chsy1 and Chpf glycosaminoglycans, and of Has3, a gene associated with synthesis of low molecular weight hyaluronan, was increased in Cx37$^{-/-}$ mice. MLO-Y4 osteocytic cells silenced for Cx37, using shRNA, which reduced Cx37 mRNA levels by 82% (N=6-9) and protein by 40% (N=3), exhibited increased Chsy1 and Chpf and decreased Has2 and Chsy3 mRNA expression. In addition, luminican and decorin mRNA levels were decreased in MLO-Y4 osteocytic cells lacking Cx37. Consistent with the *in vivo* results, Col1a1, Col3a1, Lox, Loxl1 and Loxl2 were increased in Cx37-silenced MLO-Y4 cells, suggesting that modifications in the bone matrix originate, at least in part, from changes in osteocytic gene expression. Our findings suggest that deletion of Cx37 increases bone strength through modification of extracellular bone matrix protein synthesis by osteocytes.

ASXL2 Regulates Skeletal, Glucose and Lipid Homeostasis. Nidhi Rohatgi*[1], Takashi Izawa[2], Tomohiro Fukunaga[3], Qun-Tian Wang[4], Matthew Silva[5], Michael Gardner[6], Michael McDaniel[7], Clay Semenkovich[6], Wei Zou[5], Steven Teitelbaum[5]. [1]Washington University in St. Louis, USA, [2]University of Tokushima Grad Sch, Japan, [3]Washington University in St. Louis School of Medicine, USA, [4]UIC Biological Sciences, USA, [5]Washington University in St. Louis School of Medicine, USA, [6]Washington University School of Medicine, USA, [7]Washington Univerity School of Medicine, USA

ASXL2 is an ETP, transcription-regulating protein which is highly associated with bone mineral density in mouse and man. We find by cluster analysis that ASXL2 is expressed conjointly with genes governing myeloid differentiation suggesting it may participate in osteoclast differentiation. In fact, osteoclastogenesis of ASXL2-/- mice is arrested eventuating in a 400% increase in trabecular bone mass. Interestingly, ASXL2 regulates the osteoclast via two distinct but related signaling pathways. First, it induces osteoclast formation in a PPARγ /c-Fos-dependent manner. Thus, it is required for RANK ligand- and PPARγ agonist (thiazolidinedione)-induced bone resorption. Second, ASXL2 promotes osteoclast mitochondrial biogenesis and thus function in a c-Fos independent manner which is mediated by PGC-1β. Because PPARγ is a nuclear receptor and transcription factor which not only governs osteoclast formation but is key to maintaining whole body insulin sensitivity and glucose metabolism, we asked if ASXL2 impacts these metabolic events. Establishing such is the case ASXL2-deficient mice have type 2 diabetes (T2D) with impaired glucose homeostasis and global insulin resistance. As occurs in diabetic patients, fracture repair of ASXL2-/- mice is delayed. Similar to that attending PPARγ deficiency, Asxl2-/- mice are also lipoatrophic with significantly smaller subcutaneous and epididymal fat pads. The white adipose tissue of ASXL2-/- mice contains immature adipocytes and defects both in lipogenic and lipolytic markers. Our studies establish a link between skeletal biology and the metabolic syndrome and may provide insights into the reason thiazolidinedione-treated T2D patients are predisposed to poorly healing fractures.

FR0103

Protein Phosphatase 5 (PP5) regulates both energy metabolism and bone mass by reciprocal regulation of PPARγ and Runx2 activities. Lance Stechschulte*[1], Chunxi Ge[2], Piotr Czernik[3], Edwin Sanchez[1], Renny Franceschi[4], Beata Lecka-Czernik[3]. [1]University of Toledo Health Science Campus, USA, [2]Pom Univ of Michigan School of Dentistry, USA, [3]University of Toledo College of Medicine, USA, [4]University of Michigan, USA

Nuclear receptor PPARγ represents a ligand-regulated transcription factor that translates metabolic, nutritional, and pathophysiological signals into adipocyte activities maintaining energy metabolism. PPARγ is also expressed in marrow mesenchymal stem cells (MSCs) and controls development of both osteoblasts (OB) and adipocytes (AD). PPARγ is subjected to posttranslational phosphorylation which determines its specific activities, including promotion of AD differentiation into white or beige phenotypes, and anti-OB activity. Upon PPARγ activation, Ser112 phosphorylation is decreased, promoting marrow MSCs commitment toward white-type AD and away from the OB lineage. The Runx2 transcription factor, a major regulator of MSC commitment to the OB lineage, is also controlled by phosphorylation. Increased phosphorylation at Ser319 is essential for its pro-OB effect. Because of their reciprocal effects on MSC differentiation toward OB and AD lineages, we hypothesized PPARγ and Runx2 activities are regulated by the same mechanism. PP5 phosphatase binds to both transcription factors and dephosphorylates Ser112 of PPARγ leading to increased pro-AD and anti-OB activity, and dephosphorylates Ser319 of Runx2 leading to decreased pro-OB activity. PP5 overexpression reduced Runx2 basal and MAPK-stimulated transcriptional activity, along with Ser319 phosphorylation. Interestingly, PP5 did not affect pERK levels, neither basal nor induced, indicating that Runx2 is a direct target for PP5. PP5-KO mice are characterized with reduced weight gain, reduced body fat, lower fasting glycaemia, improved glucose and insulin tolerance, augmented spontaneous locomotor activity and energy expenditure, and augmented bone mass with reduced marrow adiposity. Epididymal fat of PP5-KO mice is converted to beige fat characterized by increased expression of UCP1 and beige AD-specific markers. Marrow MSCs derived from PP5-KO mice have higher potential to develop colony forming units (CFU) of OB lineage, but lower potential to develop fat-laden CFUs of AD lineage. PP5 deficiency in marrow MSCs results in increased expression of pro-OB markers and markers of beige AD, including Wnt10b and IGFBP2. These results identify PP5 as a common regulator of PPARγ and Runx2 activities and implicate that improved energy metabolism synergizes with increased bone mass. Our observation may now form the basis for novel therapies that simultaneously target bone and fat metabolism.

FR0104

Gsα-deficient osteoblasts and osteocytes induce beige adipogenesis and a lean phenotype via interactions with skeletal muscle. Keertik Fulzele*[1], Vaibhav Saini[2], Padrig Tuck[3], Xiaolong Liu[3], Christopher Dedic[3], Jenna Garr[3], Vladimir Zoubine[3], Pankaj Shah[3], Evan Rosen[4], Paola Divieti Pajevic[5]. [1]Massachusetts General Hospital; Harvard Medical School, USA, [2]MGH, Harvard Medical School, USA, [3]Endocrine Unit, Massachusetts General Hospital, Harvard Medical School, USA, [4]Division of Endocrinology, Diabetes, & Metabolism, Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [5]Massachusetts General Hospital & Harvard Medical School, USA

Mice with induced osteocyte or osteoblast deficiency are significantly lean indicating a role of osteolineage cells in regulating body fat accumulation It has been reported that undercarboxylated osteocalcin (ucOC) secreted by mature osteoblasts, regulates glucose homeostasis; however, it could not rescue the lean phenotypes of osteoblast deficient mice suggesting other mechanism(s) for regulation of body adiposity. We found that mice lacking the stimulatory subunit of G-proteins, Gsα, in osteoblasts and/or osteocytes are lean similar to the osteoblast or osteocyte-deficient mice. DMP1-Cre or osteocalcin-Cre (OC-Cre) mice were mated with Gsα floxed mice to generate mice lacking Gsa only in osteocytes (DMP1-GsαKO) or both osteoblasts and osteocytes (OC-GsαKO). DMP1-GsαKO and OC-GsαKO mice had significantly decreased body weights by 9-weeks of age and continued to be leaner as compared to control littermates. DXA analysis revealed that the decreased body weight was due to significant decrease in body adiposity in DMP1-GsαKO (36%), and OC-GsαKO (10%) mice whereas the lean mass not changed. Gonadal and inguinal fat pads (GWAT and InWAT) were significantly decreased in DMP1-GsαKO (77%) and OC-GsαKO (35%) mice whereas brown adipose tissue (BAT), and pancreas were not changed. The lean phenotype of these mice was not dependent on ucOC, because serum insulin levels were not altered during fasting as well as in fed state and osteocalcin levels were reduced. Histological examination of GWAT and InWAT showed a significantly decreased adipocyte cell surface area and numerous multi-locular adipocytes suggesting brown-adipocyte-like adipogenesis in these WAT, called beige adipocytes. Immunostaining for uncoupling protein 1 (UCP1) revealed extensive beige adipogenesis in GWAT and InWAT of these mice along with increase in beige adipogenesis markers (PRDM16, Dio2, Cox5b, and Elvol3) as assessed by qPCR. Among the circulating factors that induce beige adipogenesis, we found that serum levels of irisin were significantly increased in DMP1-GsαKO, and OC-GsαKO mice. Moreover, we found that osteoblasts and osteocytes also expressed irisin and these levels were increased in Gsα-deficient osteoblasts and osteocytes as assessed by immunohistochemistry and qPCR. Taken together, our data show that Gsα-deficient osteoblasts and osteocytes leads to a lean phenotype primarily by increasing beige-adipogenesis, at least in part, via increased irisin from skeletal muscle.

Systematic integration of computational approaches and validation experiments reveals functionality beyond GWAS signals and identifies *ADCY5* as having genetic pleiotropy for Bone Mineral Density and Type 2 Diabetes. Melina Claussnitzer*[1], Luke D Ward[2], Xing Chen[3], David Karasik[4], Adrienne L Cupples[5], Hans Hauner[6], Douglas Kiel[7], Manolis Kellis[2], Yi-Hsiang Hsu[8]. [1]Hebrew SeniorLife, Institute for Aging Research & Harvard Medical School, USA, [2]Computer Science & Artificial Intelligence Laboratory, Massachusetts Institute of Technology (MIT), USA, [3]Harvard University, USA, [4]Hebrew SeniorLife; Bar Ilan University, USA, [5]Department of Biostatistics, Boston University School of Public Health, USA, [6]Else Kröner-Fresenius-Zentrum for Nutritional Medicine, Technical University Munich, Germany, [7]Hebrew SeniorLife, USA, [8]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA

Recent studies suggest genetic pleiotropy of bone mineral density (BMD) and metabolic syndrome risk factors, but the underlying genetic factors remain unknown. Genetic signals emerging from genome-wide association studies (GWAS) are frequently located in non-coding regions and have rarely been traced to the disease-causing variants. We recently developed Phylogenetic Module Complexity Analysis (PMCA), to infer regulatory variants in a region of disease association. PMCA tests variants by analyzing the flanking region for cross-species conserved motif modules, exploiting evolutionary information while allowing for transcription factor binding site turnover.

To systematically study pleiotropy, and to identify the underlying causal variants, we conducted the first multivariate GWAS of femoral neck BMD and metabolic risk factors in ~35,000 Caucasians, and identified 140 bivariate loci that achieved genome-wide significance or genome-wide suggestive significance. We then applied PMCA to the 140 bivariate signals and identified several potential pleiotropic causal variants. Among them, the intronic variant rs56371916 at the *ADCY5* locus (bivariate GWAS p-value = 1.9×10^{-9} for BMD with glucose levels). We report multiple lines of evidence supporting rs56371916 (C/T, MAF=0.14) to be causal for the genetic correlation: (1) it harbors a functional regulatory SREBP motif based on conservation of a AP1-NKXH-SREBP-EVI motif cluster across species; (2) chromatin segmentations on the Roadmap reference epigenomes revealed rs56371916 to be located in an enhancer chromatin state; (3) using EMSA, we found allele-specific SREBP binding for adipocytes (2.3-fold, $p<0.05$) and osteoblasts (3.1-fold, $p<0.05$) nuclear extract; (4) luciferase assays show cell type-specific enhancer effects for osteoblasts (2.8-fold, $p<0.05$) and adipocytes (3.5-fold, $p<0.05$); (5) Lastly, we use SREBP-1 knockdown by siRNA to show that increase in *ADCY5* mRNA is dependent on rs56371916 (1.9-fold, $p<0.05$) and regulation by SREBP-1. We are currently undertaking CRISPR/Cas9 genome engineering in patient samples to assess osteoblast function and insulin sensitivity.

Our general approach for the computational discovery and experimental dissection of disease variants has important implications on the study of pleiotropy in particular, and complex traits more generally, which can help bridge the genotype-to-phenotype gap between genetic variants, molecular mechanisms, and cellular and organismal phenotypes.

The Transient Receptor Potential Channel M8 (TRPM8) Regulates Mesenchymal Stromal Cell Lineage Allocation, Cortical Expansion and the Skeletal Response to Acute Cold Exposure in Mice. Katherine Motyl*[1], Phuong Le[1], Daniel Brooks[2], Casey Doucette[1], Mary Bouxsein[3], Clifford Rosen[4]. [1]Maine Medical Center Research Institute, USA, [2]Beth Israel Deaconess Medical Center, USA, [3]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [4]Maine Medical Center, USA

Recent data indicate a role for thermogenic brown adipose tissue (BAT) in regulating bone remodeling in humans and rodents. In particular, we have found that activation of BAT is associated with SNS-mediated trabecular bone loss. Deletion of TRPM8 causes reduced thermogenesis in response to the TRPM8 agonist icilin, which mimics cold-exposure. We sought to determine if TRPM8 plays a role in bone homeostasis and if *Trpm8*-/- mice would have altered thermogenesis and bone remodeling in response to cold. Utilizing mice with GFP-tagged TRPM8 expression, we found TRPM8 positive cells within bone marrow *in vivo* and *ex vivo*. BMSCs from -/- mice had reduced fibroblast colony forming units, alkaline phosphatase and Von Kossa staining during osteoblast differentiation compared to littermate controls. Interestingly, BMSCs from -/- mice also had reduced adipocyte differentiation (Oil Red O). This finding was further confirmed with ear mesenchymal stem cells (eMSCs) differentiated to adipocytes. Despite striking differences *in vitro*, -/- mice at 22℃ have only subtle differences in trabecular micro-architecture of the femur. However, -/- mice have significantly lower total area and medullary area of the femur diaphysis (at 52 wks of age), suggesting impaired periosteal expansion and endosteal resorption. We next used cold-exposure to examine the effect of thermogenesis on bone. After 6 hr at 4℃, +/+ tibiae (including marrow) had reduced *Runx2*, increased *Rankl*, and increased *Ucp1* (thermogenic marker) expression compared to room temperature (RT) controls, a change which was prevented in -/- tibiae. When exposed to 4℃ for 3 weeks (after 1 week acclimatization at 18℃), both +/+ and -/- mice lost trabecular bone compared to RT similarly, despite lower core temperature (T) of the -/- mice during the first 2 weeks. Core T then normalized in -/- mice, suggesting novel, undefined mechanisms are present to sense cold and activate thermogenesis. In summary, TRPM8 may be important for BMSC lineage allocation, which could explain why cooler extremities (i.e. long bones) have more marrow adiposity relative to axial bones. Further quantitation of marrow adiposity in the -/- mice by osmium μCT, and experiments examining the differential role of TRPM8 in acute vs. long-term cold exposure are underway. These studies will enhance our understanding of thermogenesis and the communication between adipose tissue and bone, and have implications for osteoporosis and obesity therapeutics.

Effect of Prolonged Caloric Restriction on Bone Metabolism and Bone Mineral Density in Non-obese Younger Adults. Dennis Villareal*[1], Lugi Fontana[2], Sai Krupa Das[3], Leanne Redman[4], Steven Smith[5], Edward Saltzman[3], Connie Bales[6], James Rochon[7], Carl Pieper[6], Megan Huang[8], Michael Lewis[9], Ann V Schwartz[10]. [1]University of New Mexico School of Medicine, USA, [2]Washington University School of Medicine, USA, [3]5Jean Mayer USDA Human Nutrition Research Center on Aging at Tufts University, USA, [4]Pennington Biomedical Research Center, USA, [5]Florida Hospital & Sanford Burnham Medical Research Institute, USA, [6]Duke Universtiy School of Medicine, USA, [7]Rho Federal Systems, USA, [8]Duke Clinical Research Institute, USA, [9]University of Vermont College of Medicine, USA, [10]University of California San Francisco, USA

Importance: Although caloric restriction (CR) could delay biological aging in humans, it is unclear if this would occur at the cost of significant bone loss.

Objective: To evaluate the effect of prolonged CR on bone metabolism and bone mineral density (BMD) in young healthy adults.

Design: We conducted a two-year multicenter randomized, controlled trial.

Participants: Two-hundred eighteen normal weight or slightly overweight (body mass index: 25.1±1.7 kg/m^2), young (age: 37.9±7.2 yr) adults participated in the study.

Interventions: Participants were randomly assigned to 25% CR (CR group; n=143) or ad libitum (AL group; n=75).

Main outcomes and measures: Main outcomes for this study were BMD and markers of bone turnover. Other outcomes included body weight and composition, bone-active hormones, nutrient intake, physical activity (PA), and strength.

Results: Body weight (-7.5±0.4 vs. 0.1±0.5 kg), fat mass (-5.3±0.3 vs. 0.4±0.4 kg), and fat-free mass (-2.2±0.2 vs. -0.2±0.2 kg) decreased in the CR group, not in the AL group (all $p<0.001$). Compared with AL, the CR group had greater losses in BMD at 24 months: at the lumbar spine (-0.013±0.003 vs. 0.007±0.004 g/cm^2), total hip (-0.017±0.002 vs. 0.001±0.003 vs g/cm^2), and femoral neck vs. (-0.015±0.003 vs. -0.005±0.004 g/cm^2). Changes in bone turnover markers were greater at 12 months for C-telopeptide (0.098±0.012 vs. 0.025±0.015 µg/L), tartrate-resistant acid phosphatase (0.4±0.1 vs. 0.2±0.1 U/L), and bone-specific alkaline phosphatase (BSAP) (-1.4±0.4 vs. -0.3±0.1 vs. U/L) but not P1NP; at 24 months only BSAP differed between groups (-1.5±0.4 vs. 0.9±0.6). In addition to lower weight, the CR group had larger increases in cortisol and adiponectin and decreases in leptin and insulin, hormones associated with bone loss, compared with AL. However, 25-hydroxyvitamin D and IGF-1 changes did not differ between CR and AL groups. The CR group also had a larger reduction in PA. Multiple regression analyses revealed that the combination of changes in body composition, hormones, nutrient intake, and PA explained 10-31% of the variance in changes in BMD and bone markers in the CR group.

Conclusions and relevance: Bone loss at clinically important sites of osteoporotic fractures represents a potential limitation of prolonged CR. Further long-term studies are needed to determine the clinical significance of bone loss in healthy young adults with CR-induced weight loss.

Sclerostin is associated with metabolic syndrome in older men from the MINOS cohort. Cyrille Confavreux*[1], Pawel Szulc[2], Olivier Borel[3], Annie Varennes[4], Joelle Goudable[5], Roland Chapurlat[6]. [1]INSERM UMR1033 - Universite de Lyon, France, [2]INSERM UMR 1033, University of Lyon, Hopital E. Herriot, Pavillon F, France, [3]INSERM U1033 - Université de Lyon, France, [4]Laboratoire Central de Biochimie, Hospices Civils de Lyon, France, [5]INSERM UMR1060 - Université de Lyon, Hospices Civils de Lyon, France, [6]E. Herriot Hospital, France

Rationale.Bone is an endocrine organ regulating energy metabolism. In mice, the metabolic syndrome (MetS) phenotype induced by the destruction of half osteoblasts was partially rescued by osteocalcin (OC) treatment suggesting that bone may secrete other metabolically active factors. Preliminary data show that serum sclerostin is increased in type 2 diabetic patients and is correlated positively with abdominal fat and weakly negatively with HDL-cholesterol level. Therefore, our aim was to study the association between serum sclerostin level and MetS in older men.

Materials and methods.Serum levels of sclerostin and OC were measured in 694 men aged 50 to 85 years. MetS was diagnosed according to the harmonized definition (Alberti. Circulation 2009). Serum sclerostin was measured using Teco® ELISA kit. We assessed the association between sclerostin level and MetS using logistic regression.

Results.Serum sclerostin was higher in 216 men with MetS than in the 478 without MetS (0.66±0.21 vs 0.61±0.19 ng/ml; $p<0.005$). In a logistic regression model adjusted for age, smoking, alcohol intake, physical activity and serum levels of 25OHD, OC and apparent free testosterone, higher sclerostin serum level was associated with higher prevalence of MetS (OR [95%CI]=1.28 per 1 SD increase [1.05-1.57]; $p<0.05$). Average serum sclerostin level increased across the increasing number of MetS components (p for trend <0.001) and was 15% (0.5 SD) higher in men with 4-5 MetS components compared with men without any MetS component. In contrast to OC, the strength of the relationship of sclerostin with mild (3 components) and moderate/severe (4/5 components) MetS was similar (OR=1.25 [1.01-1.55] and 1.33 [1.001-1.76] per 1 SD increase, respectively). After adjustment for confounders, MetS prevalence was two-fold higher in the highest sclerostin quartile (vs the lowest) and in the lowest OC quartile (vs the highest), respectively. After further adjustment for urinary total deoxypyridinoline, men who were simultaneously in the highest sclerostin quartile and the lowest OC quartile had higher MetS prevalence (OR=2.90 [1.51-5.55]; $p<0.001$) compared with men who were simultaneously in the three lower sclerostin quartiles and three upper OC quartiles.

Conclusion.In older Caucasian men, higher serum sclerostin was associated with MetS independently of OC, bone resorption rate and other confounders. Men with the "high sclerostin-low osteocalcin" profile had the highest MetS prevalence.

The relationships between bone-derived proteins, osteocalcin and sclerostin, and atherosclerosis in subjects with coronary artery bypass grafting. Kyoung Min Kim*, Soo Lim, Jae Hoon Moon, A Ram Hong, Hak Chul Jang, Sung Hee Choi. Seoul National University Bundang Hospital, South Korea

Accumulating evidence recently suggests the systemic roles of bone-derived proteins, and severe human studies reported the relationships between osteocalcin (OCN) or sclerostin, and the atherosclerotic parameters. The aims of this study were to evaluate sclerostin and osteocalcin levels in subjects who underwent coronary artery bypass graft (CABG) surgery and to analyze its relationships with atherosclerosis.

This was an age- and sex- matched case-control study that included 61 male subjects who underwent CABG and identical number of controls. Forty-six subjects (37.7%) were diabetes and 62 hypertensive subjects (50.8%) were included. Serum sclerostin, uncarboxylated-osteocalcin (ucOCN) and carboxylated-osteocalcin (cOCN) were measured using a commercially available ELISA and were transformed logmatically for statistical analysis.

Serum sclerostin concentrations in CABG group were significantly higher than in the controls, whereas the levels of serum ucOCN in CABG group were significantly lower than in the controls ($p<0.05$, respectively). These statistical significances were maintained even after adjusting for confounding atherosclerotic risk factors. However, there was no difference in cOCN levels between CABG group and controls. When subjects were further divided according to the presence of diabetes, serum ucOCN concentrations in CABG group were significantly lower regardless of diabetic status ($p<0.05$ in both groups). In multiple logistic regression analysis, both higher sclerostin and lower ucOCN levels were independent predictors for atherosclerosis (OR 2.46, 95% CI 1.02-7.51, $p<0.05$ for sclerostin, OR 0.34, 95% CI 0.15-0.75, $p<0.05$ for ucOCN).In subjects who underwent CABG, serum sclerostin level was increased and ucOCN level was decreased compared to controls. Further studies are warranted to establish the precise roles of sclerostin or ucOCN in the pathogenesis of atherosclerosis.

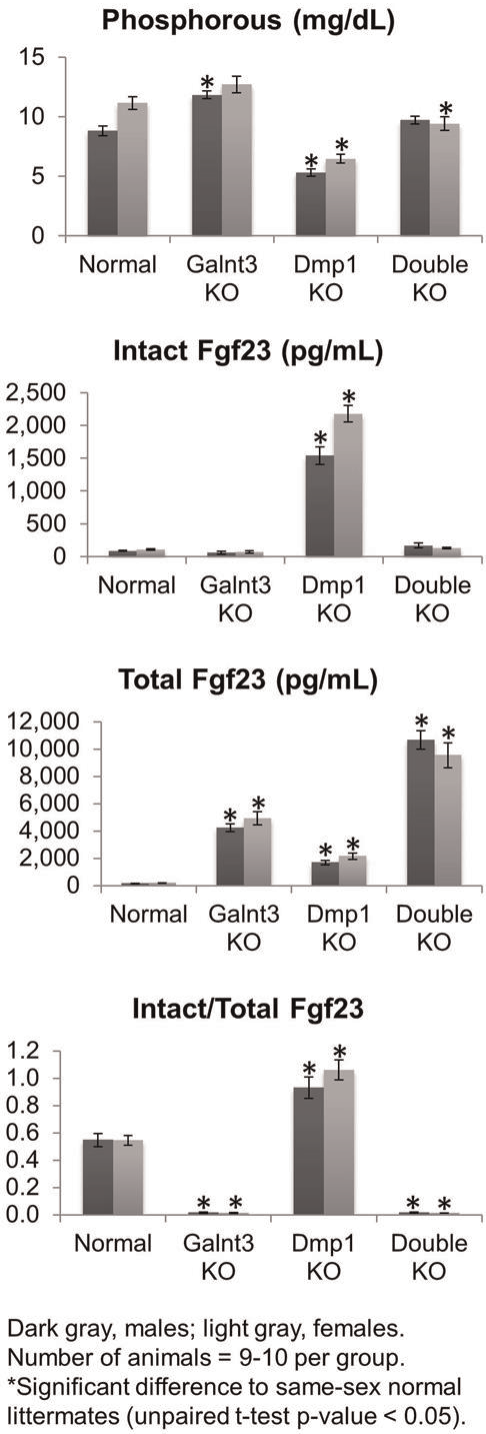
Phosphate Set Point Defect in *Dmp1* Knockout Mice. Shoji Ichikawa*[1], Rita Gerard-O'Riley[1], Amie Gray[1], Dena Acton[1], Jian Feng[2], Michael Econs[1]. [1]Indiana University School of Medicine, USA, [2]Texas A&M Health Science Center, USA

Inactivating mutations in the dentix matrix protein 1 (*DMP1*) gene cause an autosomal recessive form of hypophosphatemic rickets (ARHR). Hypophosphatemia in ARHR results from increased circulating levels of a phosphaturic hormone, fibroblast growth factor 23 (FGF23), which inhibits renal phosphate reabsorption and 1,25-dihydroxyvitamin D synthesis. Similarly, elevated FGF23 is responsible for X-linked hypophosphatemic rickets (XLH). Recently, we demonstrated that *Phex* mutations in a murine model of XLH create a lower set point for extracellular phosphate, where increased phosphorus further stimulates Fgf23 production to maintain low serum phosphorus levels. In this study, we tested the presence of the altered response to extracellular phosphate in a murine model of ARHR, *Dmp1* knockout mice. *Dmp1* knockout mice were crossed to *Galnt3* knockout mice, a murine model of familial tumoral calcinosis, to generate *Dmp1*/*Galnt3* double knockout mice. We then compared serum biochemistries of 12-week-old double knockout mice to those of controls, including *Dmp1* knockout mice, *Galnt3* knockout mice, and phenotypically normal double heterozygous mice. *Dmp1* knockout mice had 19 fold increase in intact Fgf23 levels, resulting in hypophosphatemia. In contrast, *Galnt3* knockout mice had 33% reduction in intact Fgf23 with consequent hyperphosphatemia. *Dmp1* knockout mice in the *Galnt3*-null background had almost complete correction of serum phosphorus with normal intact Fgf23 levels, but a 57 fold elevation in total Fgf23 concentrations. We also determined how loss of the Dmp1 function affects processing of Fgf23 protein. In normal mice, approximately 55% of Fgf23 existed as intact protein. Due to the lack of *O*-glycosylation to protect from proteolytic cleavage, only 1.5% of intact Fgf23 was secreted in *Galnt3* knockout mice. Interestingly, there was little proteolytic cleavage of Fgf23 in *Dmp1* knockout mice, while *Dmp1* knockout mice lacking normal *Galnt3* alleles had the same level of cleavage as in *Galnt3* knockout mice. In summary, *Dmp1* knockout mice had markedly elevated Fgf23 levels in part due to decreased proteolytic processing of Fgf23. Lack of *O*-glycosylation by *Galnt3* was able to normalize intact Fgf23, and thus, serum phosphorus, in *Dmp1* knockout mice. However, the increased Fgf23 production in the double knockouts suggests that similar to *Phex* mutant mice, *Dmp1* knockout mice may have a lower set point for extracellular phosphate.



Serum biochemistries of Dmp1/Galnt3 double knockout mice and controls.

SNORD116, a Non-translated, Imprinted Central Regulator of Bone Mass: Possible Role in Skeletal Abnormalities in Prader-Willi Syndrome. Ee-Cheng Khor[1], Bruce Fanashawe[1], Yue Qi[2], Peter Croucher[1], Herbert Herzog[2], Paul Baldock*[3]. [1]Osteoporosis & Bone Biology Division, Garvan Institute of Medical Research, Australia, [2]Neuroscience Division, Garvan Institute of Medical Research, Australia, [3]Garvan Institute of Medical Research, Australia

Our understanding of the central control of bone mass has increased markedly; however, much remains to be determined. Here we describe the first non-translated, imprinted pathway from the brain to bone, and its potential role in disease.SNORD116 exists as a 29 copy cluster of unknown function; it is not translated but produces small non-translated nucleolar RNA's (snoRNA). SNORD116 is widely expressed in the brain in humans and is exclusively expressed in the brain of mice.SNORD116 resides within the Prader-Willi Critical Region, and is therefore imprinted, with the maternal copy silenced. Prader-Willi Syndrome (PWS) individuals display additional dysfunction and/or deletion of the non-silenced paternal allele. Loss of SNORD116 has recently been associated with PWS, which involves obesity, insatiable appetite, cognitive impairment, hormonal imbalance, short stature and osteoporosis.Snord116 KO mice were studied to determine whether SNORD116 may regulate bone mass and potentially the skeletal changes in PWS. Consistent with reduced stature in PWS, Snord116 KO mice showed delayed skeletal development, with reduced bone size and mass in femurs and vertebrae of both sexes. The osteopenia in Snord116 KO was due to reduced cortical bone volume and cortical mineral apposition rate, with no change in cancellous bone. Importantly, the reduced cortical bone formation was evident in skeletally mature mice, indicating ongoing suppression of osteoblast activity by loss of Snord116 expression in the brain, beyond developmental processes.These skeletal changes were consistent diminished somatotropic axis activity; with reduced serum IGF-1 levels in Snord116 KO mice.The site of Snord116 activity in bone was isolated to the hypothalamus, with viral-mediated over supply of Snord116 in this region further reducing bone mass in Snord116 KO mice. Moreover, this response indicates that normal skeletal homeostasis requires a physiological range of Snord116 expression.In conclusion, SNORD116 deletion in mice recapitulates the short stature and low BMD and aspects of the hormonal imbalance of PWS individuals. Moreover, it demonstrates for the first time, that non-translated RNA, expressed solely within the brain can regulate bone mass in health and disease. Moreover, it illustrates the potential complexity of central regulation of bone mass.

The anti-osteoanabolic function of Sost is blunted in mice carrying the high bone mass mutation of Lrp5. Timur Yorgan*[1], Stephanie Boerms[2], Peggy Benisch[3], Franz Jakob[4], Michael Amling[5], Thorsten Schinke[6]. [1]University of Hamburg, University Medical Center Hamburg-Eppendorf, Germany, [2]Department of Osteology & Biomechanics, University Medical Center Hamburg-Eppendorf, Germany, [3]University of Wuerzburg, Germany, [4]Orthopedic Center for Musculoskeletal Research, University of Wuerzburg, Germany, [5]University Medical Center Hamburg-Eppendorf, Germany, [6]Department of Osteology & Biomechanics, University Medical Center Hamburg Eppe, Germany

Activating mutations of the putative Wnt co-receptor Lrp5 or inactivating mutations of the secreted molecule Sclerostin cause excessive bone formation in mice and humans. Previous studies have suggested that Sclerostin functions as an Lrp5 antagonist, yet clear *in vivo* evidence was still missing, and alternative mechanisms have been discussed. To address the question, if the anti-osteoanabolic function of Sclerostin, at least in mice, depends on Lrp5 interaction, we took advantage of two previously established mouse lines carrying different high bone mass alleles of Lrp5 (Lrp^{A123V} and Lrp^{G170V}). We additionally generated transgenic mice over-expressing *Sost* specifically in osteoblasts and crossed them into the Lrp^{A123V} and Lrp^{G170V} background. Using µCT-scanning and histomorphometry we found that transgenic over-expression of *Sost* under the control of a 2.3 kb *Col1a1* promoter fragment causes reduced bone formation and osteoporosis in the presence of intact Lrp5. Importantly however, this anti-osteoanabolic influence of *Sost* over-expression was fully abolished in mice homozygous for the Lrp^{A123V} or the Lrp^{G170V} allele, respectively. In contrast, osteoblast-specific over-expression of *Krm2*, encoding a transmembrane Wnt signaling antagonist, dramatically reduced bone mass on both, the wildtype and the mutant Lrp5 background. These data show that Krm2, a putative receptor for Dkk proteins, influences bone remodeling in an Lrp5-independent manner. Most importantly however, we were able to provide *in vivo* evidence showing that Sclerostin controls bone formation through interacting with the extracellular region of Lrp5.

The Effects of Activin Receptor Type IIB Fusion Protein (ActRIIB-Fc) on Hindlimb Skeletal Muscles and Femoral Properties of Osteogenesis Imperfecta Model (*oim*) Mouse. Young Jeong*[1], Marybeth Brown[2], R. Scott Pearsall[3], Charlotte Phillips[4]. [1]University of Missouri, USA, [2]University of Missouri, USA, [3]Acceleron Pharma, USA, [4]University of Missouri-Columbia, USA

Osteogenesis imperfecta (OI) is a heritable connective tissue disorder primarily due to defects in the type I collagen genes. The clinical features of OI include low bone mass with reduced biomechanical strength, and frequent fractures in patients. Myostatin, a member of transforming growth factor- β (TGF-β) superfamily, is known to regulate muscle differentiation and growth by signaling through activin receptor type IIB (ActRIIB). Myostatin deficiency can lead to increased muscle mass,

which has been associated with increased bone mass and strength. In addition, Activin A, another member of TGF-β superfamily, is highly expressed in bone cells and known to promote osteoclastogenesis by signaling through the activin receptors. Recent studies using soluble activin receptor type IIB fusion protein [ActRIIB-Fc (RAP-031), Acceleron Pharma] were shown to prevent the effects of androgen deprivation and aging on bone quality; increasing muscle force production and bone mineral density. The ActRIIB-Fc functions as a molecular decoy receptor and binds to myostatin and activin A, preventing endogenous ActRIIB activation, leading to increased muscle and bone mass, respectively. In the following study, we investigated whether the use of ActRIIB-Fc would increase bone and muscle mass in the osteogenesis imperfecta mouse (*oim*) model. Bi-weekly injections (10mg/kg) of ActRIIB-Fc were given to Wt and *oim*/*oim* mice, beginning at 2 months of age. At 4 months, the mice were weighed, and the hindlimb skeletal muscles and bones were harvested. In treated mice, the overall body weights and the soleus, plantaris, tibialis anterior, and quadriceps muscle weights were increased compared to vehicle treated control mice regardless of gender and genotype. By μCT analysis, female Wt and *oim*/*oim* mice femora exhibited increased cortical bone width with ActRIIB-Fc treatment, as well as Wt female femora exhibited gains in polar moment of area with ActRIIB-Fc treatment. Our findings suggest that systemic administration of ActRIIB-Fc induced gains in hindlimb skeletal muscle weights in both genders of Wt and *oim*/*oim* mice, with improved femoral bone geometry in female Wt and *oim*/*oim* mice.

The F508DEL-CFTR Mutation Inhibits Osteoblast Differentiation and Function Through Constitutive Activation of Nf-Kb Signaling. Carole Le Henaff*, Rafik Mansouri, Dominique Modrowski, Pierre J. Marie. UMR-1132 Inserm, Paris, France & b Université Paris Diderot, Sorbonne Paris Cité, France

Cystic fibrosis (CF) is often associated with bone loss with significant clinical implications. The mechanisms underlying bone pathology in CF are poorly known. We recently showed that mice with the prevalent human F508del mutation in the CF transmembrane conductance regulator (CFTR) display vertebral osteopenia resulting from decreased bone formation and altered osteoblast activity in vivo. To identify the molecular mechanisms underlying the altered bone formation in CF, we characterized the osteoblast phenotype in F508del-CFTR mice and we determined the mechanisms involved in this phenotype. The analysis of bone marrow stromal cells (BMSCs) isolated from long bones in F508del-CFTR mice revealed a marked decrease in the expression of osteoblast genes (RUNX2, ALP, COL1A1, OC) associated with decreased in vitro matrix mineralization compared to WT mice. Mutant trabecular osteoblasts also displayed decreased ALP and COL1A1 mRNA levels compared to WT mice, indicating that the F508del-CFTR mutation mostly impacts osteoblast differentiation and function. In contrast, cell proliferation was not affected in BMSCs or in trabecular osteoblasts. The alteration in osteoblast function was related to the F508del-CFTR mutation since a CFTR corrector (miglustat) improved osteoblast gene expression in mutant osteoblasts. Mechanistically, we found that trabecular osteoblasts from F508del-CFTR mice had constitutively active NF-kB transcriptional activity compared to WT osteoblasts, as shown in a NF-kB reporter assay. Consistent with the increased NF-kB signaling, we found that both BMSCs and trabecular osteoblasts isolated from F508del-CFTR mice showed increased RANKL/OPG ratio compared to WT mice. Importantly, inhibition of NF-kB signalling by a specific pharmacological inhibitor improved osteoblast gene expression and reduced the RANKL/OPG ratio in F508del-CFTR osteoblasts. The data indicate that NF-kB signaling is exacerbated in F508del osteoblasts, which results in a marked alteration of osteoblast differentiation and function and increased expression of key modulators of osteoclastogenesis. This reveals a novel molecular mechanism underlying the osteoblast dysfunction induced by the F508del-CFTR mutation in mice, and suggests a molecular target to attenuate the abnormal osteoblast activity and decreased bone formation in this genetic disorder.

WNT1 is one of the major WNT ligands regulating bone homeostasis. Kyu Sang Joeng*[1], Yi-Chien Lee[2], Ming-Ming Jiang[2], Terry Bertin[2], Yuqing Chen[2], Annie Mary Abraham[3], Hao Ding[3], Xiaohong Bi[4], Catherine Ambrose[5], Brendan Lee[1]. [1]Baylor College of Medicine, USA, [2]Baylor College of Medicine, USA, [3]University of Texas Health Science Center at Houston, USA, [4]University of Texas Health Science Center at Houst, USA, [5]University of Texas Health Science Center at Houston, USA

We and other groups recently identified that various mutations in *WNT1* cause a recessive form of Osteogenesis Imperfecta (OI), characterized by brittle bones. To understand the function of WNT1 in bone homeostasis as well as the pathogenic mechanism of OI caused by *WNT1* mutations, we studied two mouse models; *swaying* mice carrying a spontaneous mutation in *Wnt1* (as a loss of function study) and *DMP1-Cre; Rosa26-Wnt1* mice (as a gain of function study). Interestingly, the swaying mice recapitulate the major features of OI patients, exhibiting spontaneous fractures (65% fracture rate) with severe osteopenia. Subsequent histomorphometric analyses showed that osteoblast activity was significantly decreased in *swaying* mice without any changes in osteoclasts. The specific defects in osteoblasts prompted us to test the osteogenic potential of WNT1 using the gain of function mouse model. We overexpressed WNT1 in late osteoblasts/osteocytes by crossing *DMP1-Cre* transgenic mice with *Rosa26-Wnt1* knock-in mice. As we expected, the *DMP1-Cre; Rosa26-Wnt1* mice showed a dramatic increase in bone mass. Our *in vitro* study confirmed that WNT1 enhances osteoblast differentiation and mineralization. To understand the biomechanical and biochemical mechanism of the fracture incidence in *swaying* mice, we performed 3-point bending and Raman spectroscopy. *Swaying* mice exhibited reduced bone strength with decreased mineral composition in the bone matrix, which is different from other OI models that exhibit increased mineral composition in the bone matrix. Finally, we tested the therapeutic potential of sclerostin antibody (Scl-Ab) in OI caused by *WNT1* mutations by using swaying mouse. Interestingly, *swaying* mice treated with Scl-Ab from 2 to 8 weeks of age showed improved fracture incidence (10% fracture rate when compared to vehicle treated *swaying* mice (80% fracture rate). Subsequent analyses showed significantly increased bone mass in the Scl-Ab treated *swaying* mice. Based on these data, we conclude that 1) WNT1 is a major WNT ligand regulating bone homeostasis in both mice and humans, 2) the *swaying* mouse is a model of OI caused by WNT1 mutations, 3) the low bone mass phenotype in *swaying* mice is due to decreased osteoblast activity, 4) the biomechanical and Raman spectroscopic analyses suggest that the mechanism of bone fragility in OI due to *WNT1* mutations is distinct from other types of OI, and 5) Acl-Ab may be an effective treatment for OI patients with *WNT1* mutations.

***Disclosures: Kyu Sang Joeng**, Amgen provided Scl-Ab for this study, 10*

Discovery of Novel Models of Bone Disease using an Unbiased High-Throughput Phenotyping Screen of Transgenic Mice. Douglas Adams[1], Renata Rydzik[1], Li Chen[1], Seung-Hyun Hong[2], Dana Godfrey[3], Xi Jiang[1], Zhihua Wu[1], Vilmaris Diaz-Doran[1], Caibin Zhang[1], Dong-Guk Shin[4], David Rowe[1], Cheryl Ackert-Bicknell*[5]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut, USA, [3]The Jackson Laboratory, USA, [4]University of Connecticut, USA, [5]University of Rochester, USA

Work is underway via the Knockout Mouse Program (KOMP) to generate knockout mice for all known genes and to conduct cursory phenotyping to identify the physiologic role(s) of these genes. However, for bone, this phenotyping includes only whole body areal bone mineral density (aBMD), a low-resolution measure lacking mechanistic dimension. A more comprehensive examination of bone is needed to capture the bone physiologic role of any gene; thus, we have developed a high-throughput pipeline to conduct such phenotyping. We will phenotype males and females of 80 KOMP lines per year over 4 years, plus controls. Our high-resolution μCT analysis is automated to provide rapid morphometric measurements of femora and vertebrae, and when this analysis identifies a bone phenotype, we conduct additional dynamic bone histomorphometry. We are using an automated cryosectioning method and a uniquely objective computational image analysis protocol to achieve precise, high-throughput measures indicative of bone formation and resorption. All skeletal phenotype data generated will be publically available via a devoted website. Our goal is to identify new genes with key roles in regulating bone physiology. One such example is cerebellin 3 precursor protein (*Cbln3*), a gene primarily studied for its role in neuronal synapses. By μCT we determined that female *Cbln3*$^{-/-}$ mice present with no phenotype in femoral bone mass or geometry, whereas male mice exhibited 33% higher femoral trabecular bone mass ($p=0.007$) and 6% higher cortical mass ($p=0.03$), with no difference in femur length. Histomorphometry confirmed this sexual dimorphism in trabecular mass, as well as a characteristically higher BFR in females. Measurement of femoral aBMD confirmed a 7% increase in male *Cbln3*$^{-/-}$ mice, whereas in females both BMC and bone area increased, resulting in a trend towards a net decrease in aBMD which complicates interpretation of bone phenotype if screened by aBMD alone. From these data, we conclude that *Cbln3* is a novel regulator of bone physiology. Our pipeline is poised to identify a number of such novel models as we are purposely choosing genes that are understudied in the context of bone biology. As we move towards personalized medicine, there is genuine need to define the genetic landscape of disease. This requires understanding the number of genes that impact skeletal disease and the degree and manner in which they do so, current gaps in knowledge that our study seeks to fill.

Novel Causes of Bone Dysplasias Identified through Whole Exome Sequencing. Emily Farrow*[1], Serdar Ceylaner[2], Zafer Bicakci[3], Ergun Cetinkaya[4], Melanie Patterson[5], Lisa Krivohlavek[5], Margaret Gibson[5], Katie Barger[5], Carol Saunders[5], Neil Miller[5], Neil Mardis[5], Stephen Kingsmore[5]. [1]Children's Mercy Hospital, USA, [2]Intergen Genetics Diagnosis & Research Centre, Turkey, [3]Pediatrics, Kafkas University, Turkey, [4]Pediatrics of Endomer, Turkey, [5]Children's Mercy Hospital, USA

Inherited bone dysplasias occur in approximately 1/5000 births. Often a molecular diagnosis, important not only for establishing recurrent risks but also for clinical treatment, is not made due to genetic heterogeneity. While individual inherited bone dysplasias are rare, their collective study has been important in identifying novel therapeutic targets for common multifactorial bone disorders, such as osteoporosis, which affects 30% of postmenopausal women.

Whole exome sequencing was performed on two patients with undiagnosed bone dysplasias. Previously, both patients had undergone extensive clinical testing that was negative. Exome sequencing of the probands identified likely causative mutations in two biologically plausible, novel candidate genes. The first patient, who died of osteopetrosis at 5 months of age, had a homozygous, premature stop variant in the gene encoding TNF receptor-associated factor 6 (TRAF6). The second patient had cleft palate, severe pectus excavatum, and mesomelic dysplasia and was found to have a homozygous frameshift variant in hyaluronan and proteoglycan link protein 1 (HAPLN1). Each variant is unique in the Center for Pediatric Genomic Medicine's warehouse of 1400 individuals tested, 1000 Genomes, and the Exome Variant Server. Clinical sequencing confirmed disease segregation with variant homozygosity in the two consanguineous families. In both patients, the bone dysplasia recapitulated the features of mice with null mutations of these loci. Taken together, these results demonstrate that next generation sequencing of probands is an effective diagnostic tool for the identification of novel genes for mendelian causes of bone dysplasia.

Tissue Non-specific Alkaline Phosphatase Enzyme Therapy Prevents Abnormal Craniofacial Endochondral and Intramembraneous Bone Development in the *Alpl*$^{-/-}$ Mouse Model of Infantile Hypophosphatasia. Jin Liu[1], Hwa Kyung Nam[1], Cassandra Campbell[1], Kellen Da Silva Gasque[2], Jose Luis Millan[2], Nan Hatch*[1]. [1]University of Michigan, USA, [2]Sanford-Burnham Medical Research Institute, USA

Hypophosphatasia (HPP) is a rare metabolic disorder that features osteomalacia due to loss-of function mutations in the gene (Alpl) encoding tissue-nonspecific alkaline phosphatase (TNAP). Recent reports demonstrated that injection of a mineral-targeted form of TNAP in infants and children with debilitating HPP dramatically improves skeletal mineralization, yet a high incidence of craniosynostosis (the premature fusion of cranial bones) remains in these patients. Significantly, as more children with HPP survive due to enzyme replacement therapy, craniosynostosis has become a more pressing medical concern in this patient population. TNAP enzyme replacement has thus far been initiated weeks to years after birth in HPP patients. We hypothesize that the therapy must be initiated at an earlier developmental time point to prevent craniosynostosis and craniofacial skeletal abnormalities in HPP patients. We are utilizing the Alpl-/- mouse model of infantile HPP to establish mechanisms by which TNAP regulates craniofacial skeletal development and determine if earlier TNAP enzyme replacement can prevent craniofacial skeletal abnormalities. Results show that juvenile Alpl-/- mice exhibit histologic abnormalities of calvarial bones and the cranial base involving growth plates, cortical and trabecular bone that include poorly demarcated cortices, diminished marrow space and hypertrophic chondrocyte zone expansion. Craniosynostosis in the form of coronal suture fusion is present by three weeks after birth. Alpl-/- mice also feature significantly diminished cranial and cranial base bone mineralization, and an abnormal craniofacial shape. Here we also report for the first time that TNAP enzyme replacement starting in neonates rescues all craniofacial skeletal abnormalities seen in Alpl-/- mice. Micro-CT, histologic and digital caliper based analyses show that the skulls of treated P15 Alpl-/- mice (n=44) are significantly different than those of untreated Alpl-/- mice (n=44), but not significantly different than those of wild type mice (n=45). These findings demonstrate that post-natal TNAP enzyme replacement therapy is efficacious for preventing HPP-associated craniofacial skeletal abnormalities when initiated shortly after birth. Results presented here also indicate that the influence of TNAP on craniofacial skeletal development extends beyond that of promoting hydroxyapatite crystal growth, and includes both osteoblastic and chondrocytic differentiation mechanisms.

A number of novel loci are implicated for height and bone density determination through integration of ESR1 DNA occupancy and SNP association data. Matthew Johnson*[1], Perry Evans[2], Mahdi Sarmady[2], Kurt Hankenson[3], Andrew Wells[4], Struan Grant[5]. [1]Children's Hospital of Philadelphia, USA, [2]The Children's Hospital of Philadelphia, USA, [3]University of Pennsylvania, USA, [4]Children's Hospital of Philadelphia, USA, [5]Children's Hospital of Philadelphia / University of Pennsylvania, USA

Genome-wide association studies (GWAS) have demonstrated that genetic variation at the *ESR1* (Estrogen Nuclear Receptor Alpha) locus is associated with BMD. ESR1 is a transcription factor known to regulate osteoclastogenesis. Given these observations, we hypothesized that ESR1 regulates the expression of a set of molecular pathways critical to skeletal function. Drawing on our laboratory and bioinformatic experience, we analyzed ChIP-seq data for ESR1 available via the ENCODE project to determine its global genomic binding and pathway pattern in order to gain clearer understanding of its role in bone homeostasis.

We aligned the ChIP-seq data generated for two different cell lines i.e. T-47D (derived from mammary ductal carcinoma) and ECC-1 (derived from endometrium adenocarcinoma). Using HOMER set at an FDR of 1%, a comparable total of 5,729 and 5,530 binding sites were observed for T-47D and ECC-1, respectively, corresponding to 3,726 and 4,194 known genes, respectively.We then performed pathway analyses using Ingenuity. The category entitled 'Connective Tissue Development and Function, Tissue Development, Cancer' and 'Cardiovascular System Development and Function, Organ Morphology, Skeletal and Muscular System Development and Function' were ranked among the most significantly enriched for 'Associated Network Functions'. Furthermore, when considering 'Canonical Pathways', ''Wnt/β-catenin Signaling'' (P= 2.84x10^{-4}; T-47D) and ''ERK/MAPK Signaling'' (P= 2.09x10^{-4}; ECC-1) were significantly enriched. We also observed that ESR1 binding sites in T-47D were significantly enriched for GWAS-implicated loci for both endocrine and cancer traits, whereas for ECC-1 this significant enrichment was limited to just endocrine. Given these observations, we investigated if we could reveal novel BMD and height loci through a meaningful reduction of constraints of multiple testing by restricting association analyses of available genome wide genotyping data to just the genes yielded from this approach. To that end, we observed significant association with a number of loci, including *ITCH* (P=5.37x10^{-6}) and *MAP1LC3A* (P=7.24x10^{-6}), which survived correction for the number of multiple tests applied.

In conclusion, ChIP-seq data generated leveraging this GWAS-implicated transcription factor provided a biologically plausible method in which to limit multiple testing in assessment of genome-wide genotyping data to implicate novel trait-associated loci.

Strong Correlation Between BMD Associated Transcripts in Postmenopausal Iliac Bone Biopsies and DNA Methylation Levels at Specific CpGs. Sjur Reppe*[1], Runa M. Grimholt[2], Robert Lyle[2], Ole K. Olstad[2], Vigdis T. Gautvik[3], Kaare M. Gautvik[4]. [1]Oslo University Hospital, Ullevaal, Norway, [2]Oslo University Hospital, Ullevaal, Norway, [3]University of Oslo, IMB, Norway, [4]Oslo University Hospital, Oslo Deacon Hospital, University of Oslo, Norway

Background DNA methylation affects expression of associated genes and may explain part of the ''missing heritability'' from GWAS studies in post-menopausal osteoporosis which is a multigenetic disorder. In spite of large population studies, single nucleotide polymorphisms (SNPs) can only account for ~6 % of the BMD variation. In bone biopsies from a well described cohort of post-menopausal women (50-85 years) presenting with a marked variation in T-score, we analyzed global mRNA expression and CpG DNA methylation data aiming to identify methylation patterns affecting transcript levels and thereby bone metabolism.

Methods We obtained global mRNA expression data from postmenopausal iliac bone biopsies through analysis on Affymetrix microchips. DNA was isolated from the same 80 bone biopsies, and global DNA methylation data on ~450 000 CpGs were obtained using Illumina 450 k beads. In this study we analyzed CpG methylation levels in the genes that represent the mRNAs most significantly correlated to BMD.

Results We initially looked for CpGs in the 10 genes whose mRNA levels showed the highest correlation to BMD and detected that *SOST* and *MEPE* contained several CpGs correlating to their mRNA levels as well as to BMD and the osteoporotic phenotype. Next, we correlated transcript levels of the 100 genes most significantly associated with BMD with in all 2600 CpG methylation sites present in these genes. We found 4 transcripts (MEPE, SOST, WIF1 and DKK1) highly correlated ($r > |0.4|$, $p<0.0002$) to >100 CpG methylation levels, while on average each of the 100 transcripts correlated only to 15 CpGs. We also identified 10 CpGs in which the methylation level correlated strongly with the osteoporotic phenotype.

Conclusions Our results suggest that in bone a relationship exists between DNA methylation and level of transcription in genes highly associated with BMD. Wnt associated genes which are known to affect bone metabolism, appear to especially lend themselves to regulation by CpG methylatio

FGF23 Neutralizing Antibody Improves Bone Phenotype of HMWFGF2 Isoforms Transgenic Mice. Liping Xiao*[1], Collin Homer-Bouthiette[1], Erxia Du[1], Marja Marie Hurley[2]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut Health Center School of Medicine, USA

Overexpression of nuclear high molecular weight isoforms of FGF2 (HMWTg) in osteoblastic lineage cells induces dwarfism, hypophosphatemia and osteomalacia in HMWTg mice via modulation of FGF23, FGF receptors (FGFR) and Klotho (Xiao & Hurley, 2010). HMW also has phosphate independent effects on bone formation in vitro mediated in part via FGF23. HMW inhibits bone marrow stromal cell (BMSC) mineralization through FGF23/FGFR/MAPK in vitro (Xiao & Hurley, 2013).

To determine the impact of FGF23 neutralization on bone homeostasis in HMWTg mice, 2-month old HMWTg or Vector control male mice were intraperitoneally injected with 10mg/kg FGF23-Ab or an isotype control antibody (IgG), 2 days/week, for 6 weeks. Bone mineral density (BMD) and bone mineral content (BMC) were monitored at 0, 2, 4, and 6 weeks post injection using a Piximus Mouse 11 densitometer. At 4 and 6 weeks post injection, serum and 24 hour urine

were collected to measure calcium (Ca++) and phosphorous (Pi). Urine creatinine was measured for normalization of urine Pi excretion. To assess femur length, Digital x-rays of the isolated femurs were obtained post sacrifice..

As previously reported, HMW mice were smaller than Vector mice. This decreased body size was not rescued by FGF23AB injection (Table 1). Serum phosphate was significantly decreased in HMWTg-IgG mice compared with Vector-IgG mice (Table 1). Six-week injection of the FGF23 antibody corrected the hypophosphatemia in HMWTg mice, accompanied by reduced urine phosphate wasting (Table 1). Serum Ca++ level was similar among the three groups of mice. As shown in Table 1, six-weeks of injection of the FGF23-Ab rescued the decreased vertebral BMD and BMC observed in HMWTg mice. Similar rescue was observed on femoral BMD and BMC. FGF23-Ab injection also partially corrected the shortened femur length observed in HMWTg mice (Table 1 and Figure 1). Widened growth plate in HMWTg mice was also partially normalized by FGF23-Ab injection. However, the dwarf phenotype was not corrected.

We conclude that excess actions of FGF23 underlie some of the phenotypic abnormalities such as hypophosphatemic rickets in HMWTg mice.

Table 1	Vector IgG	HMW IgG	HMW FGF23AB

FR0139

Role of XLαs in phosphate and vitamin D metabolism during early postnatal development. Qing He*[1], Cumhur Aydin[2], Braden Corbin[3], Regina Goetz[4], Moosa Mohammadi[4], Antonius Plagge[5], Murat Bastepe[3]. [1]Endocrine Unit, Department of Medicine, Massachusetts General Hospital & Harvard Medical School, USA, [2]Gulhane School of MedicineAnkara, TURKEY, Turkey, [3]Massachusetts General Hospital, Harvard Medical School, USA, [4]Department of Biochemistry & Molecular Pharmacology, New York University School of Medicine, USA, [5]Department of Cellular & Molecular Physiology, Institute of Translational Medicine, University of Liverpool, United Kingdom

The imprinted *GNAS* complex locus encodes several products including the alpha subunit of the stimulatory G protein (Gsα) and its extra-long variant XLαs. XLαs can mimic Gsα, which mediates the actions of PTH and plays important roles in skeletal development and mineral ion homeostasis. Since XLαs is expressed in bone and kidney, we aimed to investigate its role in the regulation of serum phosphate and calcium. In XLαs knockout mice (XLKO), we observed hyperphosphatemia (WT 10.3 ± 0.2 mg/dl; KO 11.4 ± 0.4 mg/dl; $p<0.05$) and hypocalcemia (WT 1.48 ± 0.01 mmol/l; KO 1.42 ± 0.02 mmol/l; $p<0.05$) at postnatal day 2 (P2). These mice showed 2-fold elevated serum PTH (WT 65.25 ± 1.34 pg/mL; KO 138.10 ± 4.99 pg/mL; $p<0.01$), as well as significantly increased 1,25-dihydroxyvitamin D levels (WT 183.42 ± 4.64 pmol/L; KO 378.02 ± 6.86 pmol/L; $p<0.001$). Quantitative RT-PCR analysis of whole kidneys revealed about 5-fold and 2-fold increases of 25-hydroxyvitamin D 1-alpha hydroxylase (Cyp27b1) and vitamin D-24 hydroxylase (Cyp24a1) mRNA levels, respectively. P10 XLKO mice displayed a similar but milder phenotype than P2 XLKO mice. Western blot analysis and immunofluorescence staining of kidneys from P10 XLKO mice demonstrated increased levels of sodium-phosphate co-transporter Npt2a in brush border membranes of the proximal tubules. In response to PTH injection, the brush border levels of Npt2a decreased in both WT and XLKO kidneys, but the induction of Cyp27b1 was modestly blunted in XLKO. In addition, serum FGF23 levels were significantly reduced in XLKO mice (WT 524.11 ± 11.64 pg/mL; KO 158.86 ± 9.29 pg/mL; $p<0.001$ at P2; and WT 398.68 ± 10.14 pg/mL; KO 234.40 ± 10.50 pg/mL; $p<0.01$ at P10). FGF23 mRNA levels in XLKO femurs were also significantly reduced (38.86 ± 4.37%; $p<0.05$ at P10). Moreover, injection of a stable recombinant FGF23 mutant (FGF23R176Q) for 4 days from P6 to P10 into XLKO mice normalized the serum phosphorus levels (saline-injected WT 12.07 ± 0.10 mg/mL; saline-injected KO 13.64 ± 0.16 mg/mL; FGF23-injected WT 10.53 ± 0.17 mg/mL; FGF23-injected KO 11.62 ± 0.23 mg/mL), and significantly decreased renal Cyp27b1 mRNA levels. These results indicate that XLαs is essential for normal phosphate and vitamin D metabolism and plays a critical role in regulating FGF23 expression during early postnatal development.

Effect of a Calcilytic Compound in Autosomal Dominant Hypocalcemia Model Mice. Bingzi Dong*[1], Itsuro Endo[1], Takeshi Kondo[2], Yukiyo Ohnishi[2], Masahiro Abe[2], Seiji Fukumoto[3], Tomoka Hasegawa[4], Norio Amizuka[5], Shin-ichi Aizawa[6], Toshio Matsumoto[1]. [1]University of Tokushima Graduate School of Medical Sciences, Japan, [2]University of Tokushima, Japan, [3]University of Tokyo Hospital, Japan, [4]Hokkaido University, Japan, [5]Hokkaido University School of Dentistry, Japan, [6]RINKEN Center for developmental biology, Japan

Background: Activating mutations of calcium sensing receptor (CaSR) gene cause autosomal dominant hypocalcemia (ADH). ADH develops hypocalcemia, hyperphosphatemia, and hypercalciuria, similar to hypoparathyroidism. Treatment of ADH with active vitamin D_3 aggravates urinary Ca excretion and renal insufficiency. PTH replacement cannot reverse all the abnormalities especially renal calcification and deranged bone mineralization. Thus, new therapeutic strategy is needed for ADH. Calcilytics are allosteric inhibitors of CaSR, and can stimulate PTH secretion and renal Ca reabsorption. Thus, calcilytics can become a specific therapeutic agent for ADH. Previously, we demonstrated that a calcilytic, JTT-305, suppressed the exaggerated response to extracellular Ca^{2+} in HEK cells transfected with CaSR genes bearing activating mutations. The present study was aimed to clarify whether JTT-305 can reverse the phenotypes of ADH in mutated CaSR gene knock-in mice in vivo.

Methods: We generated two strains of ADH model mice with activating mutations of human CaSR (C129S in the extracellular domain, A843E in the transmembrane domain) knocked-in (KI). A843E mutation has more severe phenotype in human. We treated these mice with JTT-305 or PTH, and investigated their effect on Ca and Pi metabolism.

Results: Both C129S and A843E KI mice exhibited hypocalcemia, hyperphosphatemia, hypercalciurea, renal calcification, and reduced serum $1,25(OH)_2D$, urinary cAMP, and renal CYP27b1 mRNA encoding 1α-hydroxylase, mimicking almost all the features of human ADH. A843E KI mice exhibited more prominent phenotypes as in humans. Mutated CaSR KI mice showed increased BMD but low bone turnover with low serum PTH. JTT-305 treatment rapidly increased serum PTH, improved serum and urine Ca and Pi levels, and increased urinary cAMP and renal CYP27b1 mRNA expression in a dose-dependent manner. After long-term treatment with JTT-305, serum Ca recovered to normal range, and urinary Ca excretion decreased with no renal calcification. JTT-305 also increased BMD in both wild type and KI mice with higher bone remodeling. In contrast, PTH replacement improved serum Ca and Pi in KI mice, but urinary Ca remained elevated and renal calcification remained.

Conclusion: Mutated CaSR gene KI mice mimicked almost all the features of human ADH, and JTT-305 can reverse all the abnormalities in Ca and Pi parameters in these mice. JTT-305 can become a new therapeutic agent for ADH.

Regulation of PTH-induced Bone Loss: A Role for Monocyte Chemoattractant Protein-1. Jawed Siddiqui*[1], Joshua Johnson[1], Joseph Tamasi[2], Nicola Partridge[3]. [1]New York University, USA, [2]Bristol-Myers Squibb, USA, [3]New York University College of Dentistry, USA

Parathyroid hormone (PTH) stimulates bone resorption as well as bone formation *in vivo*. The catabolic actions of PTH have been recognized in patients with hyperparathyroidism, or with acute infusion of hPTH(1-34). Our microarrays of

bone from rats injected with hPTH-(1-34) daily for 14 days showed a number of cytokines and chemokines were highly induced, in particular, RANKL, IL-6, and CCL2 (Monocyte Chemoattractant Protein-1, MCP-1). We also found that transient MCP-1 is essential for the anabolic effects of hPTH(1-34) on bone. To determine the role of MCP-1 in prolonged continuous PTH, as seen in hyperparathyroidism, we treated 8-week-old female WT and MCP-1$^{-/-}$ mice with continuous infusion of hPTH(1–34) or vehicle for 14 days, using Alzet osmotic pumps. To assess the differential effects of hPTH-(1-34) on cortical and trabecular bone, microcomputed tomography was utilized to analyze femurs harvested at death. Cortical bone showed that infusion with hPTH induced significant bone loss in WT mice with decreased bone volume/total volume (BV/TV), bone mineral density (BMD), mean cross-sectional area (B.Ar) and mean polar moment of inertia (MMI) when compared with the saline treated group. In addition, cortical thickness (Cs.Th) and total cross sectional area (T.Ar) were also found to be significantly lower in PTH-infused WT mice. In contrast, hPTH did not cause significant cortical bone loss in MCP-1$^{-/-}$ mice. Further, μCT analysis of trabecular bone showed that compared with the saline group, the hPTH group had reduced trabecular thickness (Tb.Th), and structure model index in WT mice. Again, the MCP-1$^{-/-}$ mice were protected against PTH-induced bone loss. To establish whether MCP-1 is required for PTH to induce osteoclast formation in vitro, bone marrow macrophages (BMMs) from MCP-1$^{-/-}$ and WT mice were cultured with M-CSF and RANKL for 7 days and osteoclasts were counted. Data revealed that BMMs from MCP-1$^{-/-}$ mice showed decreased multinucleated osteoclast formation compared to WT mice. Further, mRNA analysis of the distal femurs of hPTH(1-34) infused mice showed that PTH induced the expression of NFAT, TRAP, carbonic anhydrase and cathepsin/K in WT mice but failed to demonstrate such changes in MCP-1$^{-/-}$ mice, indicating that MCP-1 is necessary for the recruitment of monocytes and pre-osteoclastic cells and assists in the formation of mature osteoclasts. Together these are the first data to show that MCP-1 is required for the catabolic response to PTH.

Role of Interleukin-32 Gamma in Bone Formation in Ankylosing Spondylitis. Chang Keun Lee*[1], Eun-Ju Lee[2], Eun-Jin Lee[3], Seokchan Hong[2], Bin Yoo[2], Tae-Hwan Kim[4], Soo-Hyun Kim[5], Eun-Ju Chang[3], Yong-Gil Kim[2]. [1]University of Ulsan College of Medicine, South Korea, [2]Department of Rheumatology, University of Ulsan College of Medicine, Asan Medical Center, South Korea, [3]Department of Biomedical Sciences, Cell Dysfunction Research Center & BMIT, University of Ulsan College of Medicine, Asan Medical Center, South Korea, [4]Hanyang University Hospital for Rheumatic Diseases, South Korea, [5]Department of Biomedical Science & Technology, Konkuk University, South Korea

Objective. To investigate the role of IL-32γ in osteoblast differentiation and its association with the pathogenesis of ankylosing spondylitis (AS).

Methods. The concentration and expression of IL-32γ were evaluated in synovial fluid and synovial tissue from patients with AS, rheumatoid arthritis (RA) and osteoarthritis (OA), using ELISA and immunohistochemistry. To establish whether IL-32γ affects bone formation in vivo, we used micro-CT to examine osteoblast differentiation from calvarial cells of IL-32γ transgenic (TG) mice and bone volume in these animals. To elucidate the mechanism of osteoblastogenesis, levels of regulators were assayed in IL-32γ TG mice and in human osteoblasts after IL-32γ stimulation.

Results. The IL-32γ levels were higher in the synovial fluid of AS patients compared with RA or OA patients. Expression of IL-32 was higher in AS synovia than in RA or OA synovia. IL-32γ TG mice showed higher rates of osteoblast differentiation than wild-type (WT) mice. Micro-CT analysis revealed that IL-32γ TG mice, particularly males, have a higher bone volume than WT mice. The constitutive expression of DKK-1, a negative regulator, was suppressed in calvarial cells from IL-32γ TG mice, and IL-32γ reduced DKK-1 expression in both WT precursor cells and human osteoblasts. IL-32γ increased the expression of receptor activator of nuclear factor kappa-B ligand (RANKL), but not osteoprotegerin (OPG), leading to a high RANKL/OPG ratio.

Conclusions. The elevated expression of IL-32γ in AS enhances osteoblast differentiation and increases bone volume in mice. Therefore, IL-32γ is a potential molecular target to prevent the progression of AS.

Pro-Resorptive Therapy for Heterotopic Ossification. Song Xue*[1], Roberto Fajardo[2], Kevin McHugh[1]. [1]University of Florida, USA, [2]UT Health Science Center, San Antonio, USA

Heterotopic ossification (HO) is the formation of bone in non-osseous tissues. HO is a frequent complication of orthopaedic surgery, especially following blast-trauma, with two thirds of patients developing painful and debilitating HO. There are currently no effective treatments for HO other than surgical excision of the ossified tissue which is an extremely difficult and involved procedure. Therefore, there is a significant unmet need for effective and non-invasive treatments of HO.

Bone metabolism is regulated by the local expression and ratio of the osteoclast (OC) inducer RANKL to the native OC inhibitor osteoprotegerin (OPG). We show that OPG expression is higher and OC numbers are much lower in HO bone, relative to native skeletal sites. We hypothesize that high OPG expression is required for HO, blocking OC formation and favoring maintenance of heterotopic bone. We propose that releasing the OPG blockade of OC formation, with function-blocking anti-OPG antibodies, will allow OC formation and prevent the development of HO. Importantly, due to the high OPG expression, HO will be a selective target of this pro-resorptive approach.

We employed a mouse model of HO in which transgenic mice harbor a Cre-inducible constitutively-active ALK2 receptor construct (caALK2)(a R220A mutant of the BMP receptor ALK2). Expression of the caALK2 gene is induced by intramuscular injection of adenoviral Cre (Ad-Cre). Following injection of Ad-Cre, animals reproducibly develop significant ectopic bone at the site of injection over a rapid 14 day time course. Systemic treatment is by intraperitoneal injection of anti-OPG antibody. HO production was demonstrated over time by a range-of-motion (ROM). MicroCT was used to quantify HO formation and contralateral native bone volume. Histology was used to characterize the HO and to identify TRAP positive OCs.

Systemic treatment with an inhibitory antibody against OPG results in an increase in OCs in ectopic bone. Statistically significant reduction of mineralized tissue in HO was seen with a concomitant and statistically significant improvement in ROM, compared to IgG treated controls. Notably, bone loss seen at ectopic sites was greater than loss at native skeletal sites in the same animal.

These studies indicate that osteoclastic resorption is likely inhibited in HO by OPG expression and if OPG function is blocked, HO is reduced. Therefore, novel pro-resorptive therapies for HO may have a significant impact on the treatment of HO.

Role of *sarA* in osteomyelitis pathogenesis in UAMS-1 and LAC clinical strains of *Staphylococcus aureus* . Dana Gaddy*, Nisreen Akel, Karen Beenken, Mark Smeltzer, Larry Suva. University of Arkansas for Medical Sciences, USA

Osteomyelitis is a serious bone infection typically caused by *Staphylococcus aureus*, the pathogenesis of which is poorly understood. The details of the cellular host responses of bone to the infection are specifically lacking. Biofilms play a clinically defining role in many forms of *S. aureus* infection, and can confer an intrinsic resistance to both conventional antibiotics and host defenses. Biofilm formation requires the staphylococcal accessory regulator (*sarA*), and its mutation limits the capacity of wildtype *S. aureus* to form a biofilm. Indeed, *sarA* mutations are correlated with an increased susceptibility to multiple antibiotics and a reduced capacity to cause bone and joint infections *in vivo*. We sought to determine the impact of *sarA* in a murine model of osteomyelitis, and determined the host bone response to infection using two contemporary genetically diverse clinical *S. aureus* isolates (UAMS-1) and a community-acquired strain (LAC), along with their isogenic *sarA* mutants. Mice were injected unicortically with vehicle control or *S. aureus* into the femoral diaphysis of adult mice. On day 14, serum was collected and injected limbs harvested and fixed in formalin. Serum inflammatory cytokine profiles demonstrated that wildtype *S. aureus* infection selectively diminished IL-1 receptor antagonist levels while increasing IP10/CXCL10. In contrast, injection of the *sarA* mutants resulted in lower IP10 induction. MicroCT analysis of all injected bones revealed extensive reactive periosteal new bone surface that extended proximally, distally and circumferentially. Non-infected bones healed within 14 days, whereas UAMS-1 and LAC infection caused extensive injection site osteolysis, and significant increases in new periosteal bone forming surfaces and reactive bone volume. Histomorphometry demonstrated that the increased new bone area/total area extended well beyond the localization of Gram+ bacteria. Injection of the biofilm-compromising *sarA* mutants, resulted in less injection site bone erosion and significantly decreased reactive new bone formation. Collectively, these data demonstrate the importance of *sarA* (and possibly biofilm formation) in the etiology and pathophysiology of osteomyelitis in *S. aureus* infections *in vivo,* and suggest that targeting this molecule for therapeutic inhibition may limit biofilm formation as well as the host bone response, thereby enhancing the efficacy of antibiotic therapy.

Sparsely ionizing radiation exacerbates the effects of rat hindlimb suspension on the musculoskeletal system. Nisreen Akel*, Robert Griffin, Howard Hendrickson, Parimal Chowdhury, Maxim Dobretsov, Larry Suva, Dana Gaddy. University of Arkansas for Medical Sciences, USA

It is well known that spaceflight and disuse have deleterious effects on the musculoskeletal system. Since these effects could be attributed to either the microgravity (disuse) and/or radiation components, we determined the extent to which irradiation affects the well-characterized disuse-associated effects on muscle and bone loss. Having previously demonstrated that 2 weeks of hindlimb suspension (HLS) in adult 6 month old rats caused dramatic loss in both trabecular and cortical bone mineral density, as well as compromised soleus muscle mass and protein synthesis, we next determined if ionizing radiation exacerbated HLS. We compared the

musculoskeletal response in 4 groups of rats: control (CON), irradiated (IR), HLS, and irradiated plus suspended (IR+HLS) for 2 weeks. IR and IR+HLS groups were exposed to a 2Gy radiation per exposure every third day for a total radiation dose of 10Gy over 2 weeks. HLS, but not IR, resulted in soleus muscle atrophy. Although the proximal tibial trabecular bone mineral density (BMD) was not affected by IR, BMD was significantly diminished by HLS, and further significantly decreased by IR+HLS. Similarly, cortical midshaft BMD was unaffected by IR alone, but was compromised by HLS, an effect significantly exacerbated by IR. To address the mechanisms involved in the HLS+IR-dependent effects of the MSK system, a series of metabolomics analyses were performed. IR significantly increased soleus muscle Citrulline/Arginine (Cyt / Arg) ratio over CON. HLS+IR together further increased the soleus muscle Cyt / Arg ratio. Alterations in the bioavailability of citrulline are proposed to result in a compromised microvasculature. These effects lead to detrimental changes in nitric oxide (NO) production, thereby implicating the NO pathway in mediation of the observed MSK effects of both HLS and IR. The metabolomics approach revealed a significant decrease in the serum concentration for eleven amino acids following HLS, many of which are involved in NO synthesis. Collectively, these data demonstrate that HLS induces major physiological changes in the MSK system, some of which involve the NO pathway, and that these changes are exacerbated by exposure to irradiation. Such a scenario experienced in spaceflight and/or onboard ISS will require novel countermeasures that protect and/or reverse the effects.

Tensile Force Induces Vascular Formation during the Ealy Biomechanical Response of Cranial Sutures via ROCK2, CTGF, and ERK1/2 Dependent Mechanisms. Nobuo Takeshita*[1], Masakazu Hasegawa[2], Kiyo Sasaki[2], Daisuke Seki[2], Shunrou Miyashita[2], Ikuko Takano[2], Yuuki Miyajima[2], Teruko Takano-Yamamoto[1]. [1]Tohoku University, Japan, [2]Division of Orthodontics & Dentofacial Orthopedics, Department of Oral Health & Development, Tohoku University Graduate School of Dentistry, Japan

Sutures are fibrous tissues that connect bones in craniofacial skeletal complexes. Sutures are not only sites of craniofacial skeletal growth, but also transmit mechanical stresses that are loaded to the craniofacial skeleton. Tensile force induces vascular formation in sutures, and vascular formation may be one principal biological process that directs subsequent bone formation. However, the molecular regulatory mechanisms of this tensile force-induced vascular formation in sutures are not fully understood. In the present study, an *in vivo* analysis was performed to elucidate the molecular mechanisms of vascular formation during the early biomechanical response of sutures. We established a murine model to apply tensile force to cranial sagittal sutures. The expression of osteoblast markers decreased in a time-dependent manner in the early response of sutures. In contrast, tensile force upregulated the mRNA expressions of vascular factors, including VEGF and Hif-1α, endothelial cell markers, and MMPs in sutures. The expressions of ROCK2 and CTGF mRNA were also upregulated by tensile force, and administration of ROCK inhibitor Y-27632 and a CTGF neutralizing antibody abolished the tensile force-induced VEGF expression. The inactivation of CTGF also partially inhibited Hif-1α expression induced by tensile force. Moreover, tensile force activated ERK1/2 signaling in sagittal sutures, and ERK1/2 inhibitor U0126 partially inhibited the tensile force-induced CTGF expression. In conclusion, we demonstrate for the first time the gene expression dynamics that indicate induction of vascular formation during the early response of sutures to tensile force. Moreover, these data suggest that tensile force-induced vascular formation is regulated by complex molecular mechanisms orchestrated by ROCK2, CTGF, and, at least in part, by ERK1/2.

Mechanotransduction from Dendritic Processes to Cell Body of Osteocytes through the Functional Interplay of Integrin Activation, PI3K Signaling and Connexin Hemichannels. Manuel Riquelme*[1], Nidhi Batra[2], Jean Jiang[3]. [1]University of Texas Science Center, San Antonio, USA, [2]University of Texas Health Science Center at San Antonio (UTHSCSA), USA, [3]University of Texas Health Science Center at San Antonio, USA

Connexin 43 (Cx43) hemichannel in osteocytes is a major portal for release of factors important for the anabolic effects of mechanical loading on bone. Mechanical stimulation in the form of fluid flow shear stress induces the opening of Cx43 hemichannels in MLO-Y4 osteocyte releasing prostaglandins, ATP and potentially other signaling molecules. We and others have previously shown that dendritic processes serve as a mechanical sensory part of the osteocyte. We also demonstrated that the interaction between integrin α5 and Cx43 on the cell body is essential for the opening of hemichannels by mechanical stress. However, how mechanical signals are transmitted from dendritic processes to cell body leading to the opening of Cx43 hemichannels remained unknown. Here, we show that integrin αVβ3 located at the dendritic processes is a primary mechanosensor that activates intracellular PI3K/AKT signaling, and integrin α5β1 and Cx43 hemichannels on the cell body. Integrin αV co-localized with integrin β3, but not Cx43 at the osteocytic dendritic processes. Upon flow shear stress, both integrin α5β1 and αV were activated. Inhibition of integrin αV activation prevented the Cx43 hemichannel opening on the cell body. Ablation of integrin α5 by siRNA attenuated the hemichannel opening when dendrites were mechanically stimulated, suggesting the mechanical transmission from integrin αV to α5 in the opening of hemichannels. Moreover, the inhibition of flow shear stress-induced PI3K/AKT activation blocked integrin α5β1 activation and hemichannel opening. Interestingly, inhibition of the activation integrin αV, but not α5, attenuated the activation of PI3K-AKT upon mechanical loading. Under rest condition, the activation of PI3K/AKT pathway induced by insulin growth factor 1 increased the activity of Cx43 hemichannels; however it did not induce the activation of α5β1, suggesting that the phosphorylation by AKT is sufficient for the opening of Cx43 hemichannels. Moreover, hemichannel opening was only blocked by anti-integrin αV antibody at low, but not high FSS, suggesting that αV is a more sensitive mechanosensor than α5 in opening HC. Taken together, these results suggest that dendritic integrin αVβ3 senses mechanical stimulation that activates PI3K/AKT leading to the activation of integrin α5β1 and subsequently the opening of Cx43 HC with a release of important bone anabolic factors.

FR0166

MiR-103a: a novel mechano-sensitive microRNA inhibits bone formation through targeting Runx2. Bin Zuo*[1], JunFeng Zhu[1], Jiao Li[2], XiaoDong Chen[1], Xiaoling Zhang[3]. [1]Department of Orthopedic Surgery, Xinhua Hospital, Shanghai JiaoTong University School of Medicine (SJTUSM), China, [2]The Key Laboratory of Stem Cell Biology, Institute of Health Sciences, Shanghai Institutes for Biological Sciences (SIBS), Chinese Academy of Sciences (CAS) & Shanghai Jiao Tong University School of Medicine (SJTUSM), China, [3]Institute of Health Sciences, Peoples Republic of China

Emerging evidence indicates that microRNAs (miRNAs) play essential roles in regulating osteoblastogenesis and bone formation. However, the role of miRNA in osteoblast mechanotransduction remains to be defined. In this study, we aimed to investigate if miRNAs regulate mechanical stimulation-triggered osteoblast differentiation and bone formation through modulation of Runx2, the master transcription factor for osteogenesis. We first investigated the role of mechanical loading both in a mouse model and in osteoblasts culture system and the outcomes clearly demonstrated that mechanical stimuli can regulate osteogenesis and bone formation both *in vivo* and *in vitro*. Using bioinformatic analyses and subsequently confirmed by quantitative Real-Time PCR (qRT-PCR), we identified miR-103a as a novel mechano-sensitive miRNA in human preosteoblast cell lines. Both miR-103a and its host gene PANK3 were downregulated during cyclic mechanical stretch-induced (CMS, 8% elongation, 0.5 Hz) osteoblast differentiation, whereas Runx2 protein expression was upregulated. Overexpression of miR-103a significantly decreased Runx2 protein level and inhibition of miR-103a increased Runx2 protein level, suggesting that miR-103a acts as an endogenous attenuator of Runx2 in osteoblasts. Mutation of putative miR-103a binding sites in Runx2 mRNA abolishes miR-103a-mediated repression of the Runx2 3'UTR luciferase reporter activity, suggesting that miR-103a binds to Runx2 3'UTR. Osteoblast marker genes profiling and osteogenic phenotype assays demonstrated that miR-103a negatively correlates with CMS-induced osteogenesis. Further, the perturbation of miR-103a also has a significant effect on osteoblast activity and matrix mineralization. More importantly, we found an inhibitory role of miR-103a in regulating bone formation in hindlimb unloading mice, and pretreatment with antagomir-103a partly rescued the osteoporosis caused by mechanical unloading. Taken together, our data suggest that miR-103a is the first identified mechano-sensitive miRNA that regulates osteoblast differentiation via directly targeting Runx2, and therapeutic inhibition of miR-103a may be an efficient anabolic strategy for skeletal disorders caused by pathological mechanical loading.

FR0167

Osteoblast mechanoresponse: the role of Lipocalin 2. Mattia Capulli*[1], Sara Gemini Piperni[1], Patrick Lau[2], Petra Frings-Meuthen[2], Martina Heer[3], Anna Teti[1], Nadia Rucci[1]. [1]University of L'Aquila, Italy, [2]German Aerospace Center (DLR), Germany, [3]PROFIL - Institute for Metabolic Research GmbH, Germany

A global transcriptome analysis of mouse calvarial osteoblasts, subjected to simulated microgravity (0.008*g*), revealed Lipocalin2 (LCN2) to be the most upregulated gene in low loading condition. In this study we demonstrated that upregulation of LCN2 in mechanical unloading occurs in humans and mice. We evaluated LCN2 serum levels in 8 healthy male volunteers, subjected to head-down tilt bed rest and observed a progressive increase of LCN2 that achieved statistical significance after 12 days (R=0.31, P=0.01). Results obtained in humans were confirmed in three different mouse models of mechanical unloading: tail suspension, treatment with the muscle paralysis inducer Botox, and dystrophic MDX mice. In all these models, the unloading condition reduced the bone volume/tissue volume ratio and significantly increased the transcriptional expression of LCN2 in bone compared to control mice. A significant increase or LCN2 protein expression was also confirmed

in the femurs of Botox-treated mice. Moreover, increase of mechanical loading in MDX mice, obtained by treadmill physical exercise, reduced the LCN2 expression to 18% of untrained MDX ($P<0.05$), returning its level to that of WT (90% of WT, $P=0.52$). Interestingly, mouse osteoblasts expressed the LCN2 receptors megalin and 24p3r, thus indicating an autocrine-paracrine effect of LCN2 in this cell type. In agreement with our hypothesis, primary mouse osteoblasts transduced with LCN2-expression-vector (LCN2OBs) showed reduced Runx2, Osterix and Alp transcriptional expression compared to empty-vector transduced osteoblasts (emptyOBs) (28, 20 and 17% of control, respectively, $P<0.04$). Consistently, ALP activity was less prominent in LCN2OBs (54% of control, $P=0.003$). LCN2OBs also exhibited an increase of the Rankl/Opg ratio and IL-6 mRNA expression (8- and 5.3-fold, respectively, $P<0.02$), suggesting that LCN2 up-regulation could link osteoblast poor differentiation with enhanced osteoclastogenesis. Reliably, incubation of purified mouse bone marrow mononuclear cells with conditioned media from LCN2OBs, or their co-culture with LCN2OBs, enhanced osteoclast formation (5- and 2-fold, respectively, $P<0.05$). In conclusion, our in vivo and in vitro data indicate that LCN2 is involved in the osteoblast mechanoresponse and that its upregulation appears central to the loss of bone induced by low mechanical forces, contributing to both poor osteoblast differentiation and increased osteoblast-mediated osteoclastogenesis.

PDGF Secreted by TRAP$^+$ Preosteoclasts Induces Angiogenesis for Bone Formation. Hui Xie*[1], Zhuang Cui[2], Long Wang[3], Lingling Xian[4], Zhuying Xia[5], Yin Hu[5], Changjun Li[1], Liang Xie[1], Janet Crane[6], Mei Wan[4], Gehua Zhen[7], Tao Qiu[4], Weizhong Chang[6], Maureen Pickarski[8], Le Duong[9], Xu Cao[6]. [1]Johns Hopkins Medical Institution, USA, [2]Department of Orthopaedic Surgery, Johns Hopkins University School of Medicine, USA, [3]Department of Orthopaedic Surgery, Johns Hopkins University School of Medicine, USA, [4]Johns Hopkins University School of Medicine, USA, [5]Institute of Endocrinology & Metabolism, Second Xiangya Hospital of Central South University, China, [6]Johns Hopkins University, USA, [7]The Johns Hopkins Hospital, USA, [8]Merck & Co., Inc., USA, [9]Merck Research Laboratories, USA

Angiogenesis is essential for new bone formation during bone modeling, remodeling and growth. Osteoblast bone formation requires transport of minerals, nutrients, oxygen and metabolic wastes through blood vessels, but regulation of angiogenesis for bone formation remains elusive. Here we report that TRAP$^+$ preosteoclasts secrete PDGF-BB to induce angiogenesis for the new bone formation. In brief, conditioned medium (CM) of TRAP$^+$ preosteoclasts significantly increased migration of epithelial progenitor cells (EPC) and MSCs and the neutralizing antibody for PDGF-BB abolished the migration. TRAP$^+$ preosteoclasts secrete PDGF-BB, but not mature bone resorptive osteoclasts. TRAP$^+$ lineage-specific PDGF-BB knockout mice ($Pdgfb^{-/-}$) show that bone mass of both trabecular and cortical bone were significantly decreased. Importantly, PDGF-BB levels in both bone marrow and peripheral blood were significantly decreased, and bone marrow VEGF level was also decreased, suggesting that angiogenesis in the bone marrow was affected. We found that vessel volume and surface in both bone marrow and periosteum were significantly decreased in $Pdgfb^{-/-}$ mice and the CD31$^+$ EPCs were also decreased. Moreover, the osteoblast size was much smaller in $Pdgfb^{-/-}$ mice relative to their WT littermates, suggesting that PDGF-BB secreted by TRAP$^+$ preosteoclasts stimulates angiogenesis for osteoblast maturation and bone formation. Furthermore, phosphorylation of PDGFRβ and its downstream components PI3K, Akt and FAK was induced by preosteoclast CM. Notably, EPC and MSC migration induced by preosteoclast CM was abolished by each of the inhibitors for PDGFR, PI3K, Akt and PAK, indicating that PI3K/Akt/FAK signaling mediates the cell migration. Cathepsin K inhibitor (CatK), as a novel anti-osteoporosis drug for inhibition of osteoclast bone resorption, stimulates bone formation and increases TRAP$^+$ cells. We found that PDGF-BB levels were increased significantly in both bone marrow and peripheral blood, and VEGF level was also increased in bone marrow. Blood vessel volume and surface in both bone marrow and periosteum were significantly increased in CatK KO mice and WT mice treated with CatK inhibitor L-235, and CD31$^+$ EPCs were also increased. Taken together, PDGF-BB secreted by TRAP$^+$ preosteoclasts stimulates angiogenesis to prepare transport minerals, nutrients, oxygen and other factors for osteoblastic bone formation during bone remodeling and cortical bone formation.

Role of the STING cytosolic DNA sensor pathway in bone remodeling. Rebecca Baum*[1], Shruti Sharma[1], Yukiko Maeda[1], Catherine Manning[1], Jason Organ[2], David Burr[2], Ann Rothstein[1], Kate Fitzgerald[1], Ellen Gravallese[1]. [1]University of Massachusetts Medical School, USA, [2]Indiana University School of Medicine, USA

Innate immune sensors such as cytosolic DNA sensors and toll-like receptors detect nucleic acid from viral and bacterial pathogens to clear infection, as well as endogenous nucleic acid from stressed or dying cells, contributing to the pathogenesis of autoimmune disease. Upon detection of DNA, cytosolic sensors trigger a signaling cascade that results in the production of proinflammatory cytokines and type I interferons. We have identified a potentially important role for cytosolic DNA sensor pathways in bone by studying a mouse lacking the lysosomal endonuclease DNaseII. In this model, DNA accumulates in lysosomes and in the cytosol, leading to polyarthritis and articular bone erosions, resembling that seen in human rheumatoid arthritis. Given the production of proinflammatory cytokines in this model, bone loss would also be expected in the axial and appendicular skeleton. Paradoxically, bone accumulates, resulting in almost complete replacement of the marrow cavity by bone at 16 mo. Total trabecular volume (femur) is significantly increased by 6 mo. in DNaseII deficient mice compared to controls (5.58 vs 4.51 mm^3; $p=0.0018$). CFU assays demonstrate the presence of increased numbers of osteoblast precursors, and osteoid production is also significantly increased. Furthermore, ectopic bone forms throughout the spleen, a site of extramedullary hematopoesis and probable DNA accrual. To understand mechanism, we sought to define the contribution of cytosolic DNA sensors in this model of bone accrual. Several cytosolic sensors signal through an ER-associated protein, stimulator of interferon genes (STING). Therefore, we generated mice deficient in both DNaseII and STING. As previously reported, arthritis is completely abrogated in these mice. We now show that STING deficiency also prevents the accrual of bone seen in the long bones and spleens of DNaseII deficient mice (bone density: 813.7 vs 846.9 mg HA/cm^3; $p=0.002$). To determine the contribution of STING in bone turnover, independent of DNaseII deficiency, we evaluated the bone phenotype in STING deficient mice. By 6 mo. of age, a significant decrease is seen in bone density (1059.8 vs 1088.9 mg HA/cm^3; $p=0.0072$) and BV/TV (0.46 vs 1.03%; $p=0.0156$) in STING deficient mice compared with controls. The discovery of a role for DNA sensor pathways in bone may provide insights into mechanisms of bone remodeling as well as new targets for the treatment of bone disorders.

TIEG suppresses SOST expression and mediates the skeletal response to sclerostin antibody therapy. Anne Gingery*[1], Kevin S. Pitel[2], Gino W. Gaddini[3], Xiaodong Li[4], Hua Zhu Ke[5], Russell T. Turner[6], Nalini M. Rajamannan[7], Urszula T. Iwaniec[6], Thomas C. Spelsberg[8], Malayannan Subramaniam[8], John R. Hawse[9]. [1]Mayo Clinic School of Medicine, USA, [2]Mayo Clinic, USA, [3]Oregon State University, USA, [4]Amgen, Inc., USA, [5]Amgen, USA, [6]Oregon State University, USA, [7]Mayo Clinic, Rochester MN, USA, [8]Mayo Clinic, USA, [9]Mayo Clinic College of Medicine, USA

TGFβ Inducible Early Gene-1 (TIEG) is known to play important roles in skeletal development and its misregulation and mutation is associated with osteoporosis in humans. Furthermore, TIEG has recently been shown to be critical for optimal TGFβ, BMP and estrogen signaling in bone. Finally, TIEG knockout (KO) mice exhibit a female-specific osteopenic phenotype. In order to better understand the molecular basis for this phenotype, we determined gene expression changes in the cortical shells of long bones isolated from wildtype (WT) and TIEG KO mice. One of the most up-regulated genes in KO bone was sclerostin (Scl) which exhibited approximately a 12-fold increase relative to WT animals. Serum levels of Scl were also significantly elevated in KO mice and TIEG was shown to suppress Scl promoter activity in transient transfection assays. The use of TOPGAL reporter mice demonstrated that loss of TIEG expression resulted in a 3-fold decrease in canonical Wnt pathway activity in the skeleton relative to WT mice potentially due to elevated Scl levels. In order to determine the contribution of elevated Scl levels in the observed osteopenic phenotype of TIEG KO mice, we treated WT-TOPGAL and KO-TOPGAL animals with either vehicle control or a Scl neutralizing antibody (25 mg/kg, 1x/wk, s.c.) for 6 weeks (10 animals/treatment group). DXA, pQCT and microCT analyses revealed that deactivation of Scl resulted in significant increases in numerous cancellous and cortical bone parameters throughout the skeleton in both WT and KO mice. Overall, a more robust skeletal response was observed in TIEG KO mice following antibody administration. To understand potential differences in the response of WT and KO mice to Scl antibody administration, a Wnt signaling pathway PCR array was employed to monitor gene expression changes in the cortical shells of long bones. These data revealed that 15 and 17 genes were significantly up- or down-regulated following antibody exposure in WT and KO animals respectively, of which only 3 were commonly regulated in both genotypes. A number of positive regulators of Wnt signaling, such as Wnt1, Lef1, Wnt4 and Frzd6 were induced in TIEG KO mice but not WT animals following antibody treatment. These data demonstrate that elevated sclerostin levels in TIEG KO mice substantially contribute to the observed osteopenic phenotype and reveal that TIEG imparts significant effects on the response of the skeleton to Scl antibody therapy.

CHIP Is a Critical Regulator of Bone Remodeling. Shan Li*[1], Wanqing Xie[2], Guozhi Xiao[1], Di Chen[1]. [1]Rush University Medical Center, USA, [2]Rush University Medical Center, USA

The regulatory mechanism of bone remodeling is not fully understood. CHIP is an E3 ligase and regulates protein stability in immune and tumor cells. The role of CHIP in bone remodeling has not been reported. In this study, we found that *Chip*$^{-/-}$ mice had osteopenic phenotype. μCT analysis showed that bone volume, bone mineral density, trabecular numbers, trabecular thickness and connectivity density were significantly reduced (66, 59, 44, 33 and 75% decreases); while trabecular separation and structure model index were significantly increased (1.7- and 1.4-fold) in 1-month-old *Chip*$^{-/-}$ mice, indicating lower trabecular bone mass and more fragile bone in *Chip*$^{-/-}$ mice. Histology analyses showed that TRAP+ osteoclast numbers and osteoclast surface were significantly increased (1.6- and 1.5-fold) in *Chip*$^{-/-}$ mice. *In vitro* assays showed that osteoclast numbers (3.5-fold) and bone resorption area were significantly increased in osteoclast cultures derived from *Chip*$^{-/-}$ mice. Expression of *Cathepsin K*, *Mmp9,* and *Nfatc1* was increased (7-, 16-, and 5-fold) after RANKL treatment in *Chip*$^{-/-}$ bone marrow cells. A significant increase in TRAF6 protein, but not mRNA, levels were observed in *Chip*$^{-/-}$ bone marrow cells, suggesting that CHIP regulates TRAF6 protein stability. In a series of *in vitro* studies we found that: 1) Interaction of endogenous CHIP with TRAF6 was detected in RAW264.7 cells. 2) The ubiquitination and proteosome degradation of endogenous TRAF6 protein was significantly reduced in *Chip*$^{-/-}$ bone marrow cells. 3) Mutation of CHIP in the site which is required for its E3 ligase activity completely abolished CHIP-induced TRAF6 degradation in 293 cells. 4) The phosphorylation of IKKα/β and IκBα was significantly increased in *Chip*$^{-/-}$ bone marrow cells treated with RANKL. 5) p65 nuclear translocation was enhanced in *Chip*$^{-/-}$ bone marrow cells treated with RANKL. 6) RANKL- or TRAF6-induced NF-κB activity was suppressed by CHIP in RAW264.7 cells. In addition to changes in osteoclast formation, we also found that bone formation rates were significantly reduced in 1-month-old *Chip*$^{-/-}$ mice. β-catenin protein levels, ALP activity and mineralized bone nodule formation were significantly decreased and expression of osteoblast marker genes, including *Runx2*, *Osx*, *Col1*, *Opn*, *Bsp* and *OC*, was down-regulated (43, 37, 67, 30, 60, and 45% decreases) in *Chip*$^{-/-}$ bone marrow stromal cells. Our studies demonstrated that CHIP is a critical regulator for bone remodeling.

Is MMP-13 the critical mediator for the effects of HDAC4 deletion in mice?. Teruyo Nakatani*[1], Tiiffany Chen[2], Shoshana Yakar[3], Nicola Partridge[4]. [1]New York University College of Dentistry, USA, USA, [2]New York University, USA, [3]New York University College of Dentistry, David B. Kriser Dental Center, USA, [4]New York University College of Dentistry, USA

Histone deacetylase 4 (HDAC4), which is expressed in prehypertrophic chondrocytes, regulates chondrocyte hypertrophy. *Hdac4*$^{-/-}$ mice are runted in size at birth and do not survive to weaning. Previously, we reported that HDAC4 is a repressor of MMP-13 transcription, and the absence of HDAC4 leads to increased expression of MMP-13 both *in vitro* (osteoblastic cells) and *in vivo* (hypertrophic chondrocytes and osteoblasts). MMP-13 is expressed in both these cells and is thought to be involved in endochondral ossification and bone remodeling. To identify whether the phenotype of *Hdac4*$^{-/-}$ mice is due to MMP-13 up-regulation, we generated *Hdac4*$^{-/-}$/*Mmp13*$^{-/-}$ double mutants. The *Mmp13*$^{-/-}$ mice have a similar body mass compared to wild type mice. The *Hdac4*$^{-/-}$/*Mmp13*$^{-/-}$ mice are significantly heavier and larger than the *Hdac4*$^{-/-}$ mice and their mean survival is longer (*Hdac4*$^{-/-}$: 7.3, *Hdac4*$^{-/-}$/*Mmp13*$^{-/-}$:16days). Histological examination showed that the double mutants recover the heights of their growth plate. Immunohistochemistry showed that the expression of osteocalcin and alkaline phosphatase increased in *Hdac4*$^{-/-}$/*Mmp13*$^{-/-}$ mice compared with *Hdac4*$^{-/-}$ mice. TRAP staining was decreased in *Hdac4*$^{-/-}$ mice but rescued in *Hdac4*$^{-/-}$/*Mmp13*$^{-/-}$ mice. Tibiae of 8 day old animals were subjected to microCT analysis. We found that *Hdac4*$^{-/-}$ mice have significantly decreased cortical bone mass compared with the wild type mice. In *Hdac4*$^{-/-}$/*Mmp-13*$^{-/-}$ mice, all these parameters recovered. In trabecular bone, ablation of HDAC4 caused an increase in BMD and Tb.Th. which normalized in the *Hdac4*$^{-/-}$/*Mmp13*$^{-/-}$. Taken together, our findings indicate that the premature phenotype seen in the *Hdac4*$^{-/-}$ mice is partially derived from MMP-13 elevation and may be due to a bone remodeling disorder that influences tibial cortical bone mass, mineralization, trabecular thickness, BMD and connectivity.

Testosterone supplementation increases skeletal muscle mass and maximal voluntary strength in healthy, androgen-deficient and eugonadal young and older men. However, administration of steroidal androgens is associated with a high frequency of dose-limiting adverse effects, such as erythrocytosis and prostate events. We developed a SARM with minimal androgenic activity in the prostate and no observable risk of erythrocytosis while maintaining muscle and bone anabolic activity. Daily oral treatment of LY2452473 resulted in a dose-dependent increase (ED_{90} 2.5 mg/Kg-d) in vertebral bone mineral content (BMC), cross-sectional area and bone mineral density (BMD) in the delayed rat ORX model accompanied by gains in cortical area (associated with increases in periosteal alkaline phosphatase activity) and recovery of mid-shaft and femoral neck biomechanical properties to the sham control animal levels. A significant but modest increase in levator ani muscle mass is seen with oral administration of LY2452473 in the delayed rat orchidectomy (ORX) model. No treatment related effects in the prostate or uterine endometrium were noted in the 8 week pharmacology model when using female or male gonadectomized rats up to 10 mg/kg/day (uterus) or 30 mg/kg/day (prostate). A significant gain in whole body muscle mass as measured by DEXA was seen in phase I studies in healthy volunteers at the 5 mg dose. A dose dependent increases in procollagen type 1 N-terminal (P1NP) and decreases in resorption markers were also observed in these trials. In addition using peripheral QCT we show a gain in calf muscle area in 4 weeks in both males and females. In contrast, LY treatment did not show changes in PSA in men and signs of virilization in females or changes in hematocrit at any of the doses. However, SARM treatment resulted in a dose dependent decrease in HDL (>20%) which was completely reversible after cessation of treatment. Collectively, the SARM molecule represents an oral agent with bone and muscle anabolic activities that is devoid of some of the classic risks associated with testosterone replacement.

Activation of Prostaglandin E_2 EP4 signaling promotes primary myoblast proliferation via regulation of cell cycle progression and MyoD expression. Chenglin Mo*[1], Lori Wetmore[2], Julian Vallejo[3], Leticia Brotto[3], Lynda Bonewald[4], Marco Brotto[4]. [1]University of Missouri-Kansas City, USA, [2]William Jewell College, USA, [3]Muscle Biology Research Group, School of Nursing & Health Studies, University of Missouri-Kansas City, USA, [4]University of Missouri - Kansas City, USA

PGE_2 is produced by osteocytes and elevated in response to mechanical loading. Our previous studies showed the MLO-Y4 osteocyte-like cell conditioned media and a major component of this media, PGE_2, stimulated C2C12 myogenesis. To validate and extend these previous studies using cell lines, primary myoblasts isolated from mouse hindlimb muscles were used. All four PGE_2 receptors, EP1 to EP4, were detectable in primary myoblasts by real-time PCR. To identify the functional receptor, cells were treated with 50nM of PGE_2, 17-phenyl trinor PGE_2 (EP1/EP3 agonist), butaprost (EP2 agonist), or CAY 10598 (EP4 agonist). After 48h, cells were collected and counted. Treatment with PGE_2 or EP4 agonist CAY 10598 significantly increased myoblast number by $23.3 \pm 6.4\%$ and $17.6 \pm 6.2\%$ ($p<0.05$), respectively. However, EP1/EP3 or EP2 agonists did not have any significant effects. To confirm that EP4 signaling is important for primary myoblast proliferation, cells were then treated with 30μM of the EP4 antagonist L161,982 for 48h, which resulted in a $27.3 \pm 4.3\%$ ($p<0.05$) decrease in proliferation. To study the molecular mechanisms behind the effect of PGE_2 signaling on primary myoblast proliferation, cell cycle analysis was conducted. Primary myoblasts were synchronized in G0/G1 phase by serum starvation with Ham's F-10 medium containing 1% fetal bovine serum (FBS) for 10h, then the medium was switched to complete growth medium (Ham's F-10 with 20% FBS) along with the addition of PGE_2, CAY 10598, or L161,982 for 12h. Cell cycle analysis showed that although no significant difference was observed between control and PGE_2 or CAY 10598 treated cells, L161,982 increased the number of cells in G0/G1 phase by $19.4 \pm 3.7\%$ ($p<0.05$), suggesting that EP4 signaling could be important for G1-S phase transition. Next, MyoD protein expression, a muscle regulatory factor that plays a role in satellite cells activation and myoblast proliferation was measured using Western blot analysis. Compared with control, MyoD did not change after treatment with of PGE_2, CAY 10598, or L161,982 at 12h. However at 36 hrs, MyoD increased by 55.7% and 48.5% following PGE_2 and CAY 10598 treatments, whereas L161,982 reduced MyoD level to 43.1%. Taken together, these data suggest that PGE_2 signaling via EP4 receptor is important for the regulation of cell cycle progression and MyoD expression in primary myoblast proliferation.

Fibrodysplasia ossificans progressiva (FOP) is a rare hereditary disease, which is characterized by postnatal progressive heterotopic endochondral ossification in skeletal muscle. Gain-of-function mutations of ALK2, one of type I BMP receptors, have been identified in patients with typical and atypical FOP. In the present study, we established and characterized murine embryonic stem (ES) cell lines, which express V5-tagged wild-type (WT) or mutant (R206H) ALK2 from the ROSA26 locus in a Tet-Off system. These cell lines did not express the V5-tagged exogenous ALK2 in the presence of Dox (Dox+). In contrast, the expression of WT or mutant ALK2 was turned on by removing Dox (Dox-) from the culture media. The mRNA and protein levels of WT and mutant ALK2 were confirmed in the Dox- cultures by quantitative real-time RT-PCR and Western blotting, respectively. In FACS analysis, both WT and mutant ALK2 were expressed on the cell surface in the Dox- cultures. The BMP-specific luciferase reporter activity was induced in both WT and mutant ALK2-carrying cells in response to BMP stimulation in the Dox+ cultures, although the reporter was induced without adding BMP in the Dox- cultures of mutant ALK2-carrying cells. The cells were maintained in Dox+, and then they were cultured in pellets in Dox+ or Dox- with or without adding TGF-β/BMP to induce chondrogenic differentiation. Simultaneous stimulation with TGF-β and BMP induced the mRNA expression of type II and type X collagens in both WT and mutant ALK2-carrying cells even in the Dox+ cultures. In contrast to WT ALK2-carrying cells, the mutant ALK2-carrying cells differentiated into chondrocytes in the Dox- cultures in the presence of TGF-β alone. Taken together, these findings suggested that mutant ALK2 found in FOP stimulates the capacity of chondrogenic differentiation in stem cells. This Tet-Off ES cells may be a useful model to examine molecular mechanisms of heterotopic ossification in patients with FOP.

The Age-Associated Rise in miRNAs from Muscle Target SDF-1 and Musculoskeletal Regulatory Genes is Reversed with Caloric Restriction and Leptin. Sudharsan Periyasamy-Thandavan[1], Samuel Herberg[2], Phonepasong Arounleut[3], Sunil Upadhyay[4], Galina Kondrikova[4], Amy Dukes[4], Colleen Davis[4], Maribeth Johnson[4], Xing-Ming Shi[4], Carlos Isales[4], Mark Hamrick[5], William Hill*[6]. [1]Georgia Regents University & Charlie Norwood VAMC, USA, [2]Case Western Reserve University, USA, [3]Georgia Regents University (formally Georgia Health Sciences University), USA, [4]Georgia Regents University, USA, [5]Georgia Health Sciences University, USA, [6]Georgia Regents University & Charlie Norwood VAMC, USA

MicroRNAs (miRNAs) have the potential to regulate broad changes in connected systems and pathways altering homeostatic gene expression. We have previously identified age-related changes in the expression profiles of miRNAs isolated from human bone marrow mesenchymal stem cells (BMSCs). These miRNAs targeted numerous genes associated with musculoskeletal development, maintenance, aging and osteoporosis. As well as, the chemokine SDF-1 (CXCL12), and its receptor CXCR4. The SDF-1 axis is critical in the migration, survival, and engraftment of stem cells, including BMSCs and muscle satellite cells (SCs). We have noted leptin can alter systemic and muscle SDF-1 levels in an age-related manner suggesting nutrient signaling may effect systemic, or tissue SDF-1 expression. We hypothesized that changes in nutrient signaling pathways may modulate specific miRNA in an age specific manner. In turn these miRNAs may alter SDF-1 and key osteogenic, or myogenic pathway genes. We tested this hypothesis by examining changes in miRNAs, we had previously identified as linked to aging in BMSCs, in muscles of mice aged 12 months and 20 months fed ad-libitum (AL) and mice 20 months on caloric restriction (CR). We also treated other mice aged 20 months on caloric restriction with recombinant mouse leptin for 10 days at 10 mg/kg body weight. Age-associated patterns of expression of miR-29b-1-3p, miR-29b-1-5p, miR-1244 & miR-141 in murine muscle (12 vs 20 months) mirrors that seen in human BMSCs between young (under 45 years of age) and older (over 65 years of age) subjects. In both cases the miRs 29b-1-5p, 1244 and 141 increased, while miR-29b-1-p3 did not change. Of interest the miR-29 family is well known to target muscluloskeletal and extracellular matrix genes. CR reduced the miRs 29b-1-5p, 1244 and 141 in 20 month old mice to levels equal to that of 12 month mice while miR-29b-1-3p was not altered. Of interest CR with leptin treatment further reduced expression of miRs 29b-1-5p, 1244 & 141 well below that seen in the 12 month mice and surprisingly the amount of miR-29b-1-3p rose significantly. Therefore, it appears that food restriction is a potent regulator of miRNAs, and suppresses miRNAs that target muscluloskeletal gene systems in aged muscle. Leptin further drives this effect significantly below what is seen in younger muscle, which may induce an inbalance in gene expression that might itself impair the potential for muscle regeneration.

The Effects of Combined Use of Glucocorticoids and Bisphosphonates on Musculoskeletal System in a Mouse Model of Duchenne Muscular Dystrophy. Jane Mitchell[1], Sung-Hee Yoon*[2], Jinghan Chen[3], Ariana delaCruz[2], Kim Sugamori[3], Marc Grynpas[4]. [1]University of Toronto, Canada, [2]University of Toronto, Canada, [3]Univeristy of Toronto, Canada, [4]Lunenfeld-Tanenbaum Research Institute of Mount Sinai Hospital, Canada

Duchenne Muscular Dystrophy (DMD) is an X-linked recessive genetic disorder occurring in 1 in 3500 boys. Due to mutations in the gene encoding dystrophin, a sarcolemmal protein critical in stabilizing the link between muscle fibers and dystrophin-associated glycoprotein complex in surrounding extracellular matrix, DMD patients show progressive muscle membrane fragility and muscle necrosis. Glucocorticoids (GC) are the only available treatment, having anti-inflammatory effects on muscles thus prolonging ambulation in patients with DMD. GC-induced osteoporosis (GIO) resulting in increased bone fragility and high prevalence of vertebral bone fractures is common in DMD patients. We hypothesized that the use of bisphosphonates (BP) at the initiation of GC treatment will ameliorate GIO development during growth, without harmful effects on dystrophic muscle. In this study, C57BL10ScSn-Mdx mice (Mdx), the a commonly used animal model for DMD, received continuous GC (prednisone) or placebo treatment from 5 to 13 weeks of age. Bisphosphonates (pamidronate) were given for the first two weeks of GC therapy in some mice and the effects of GC and combination therapy of GC and BP (GCB), on bones and muscles were examined. GC treatment significantly decreased femur length ($p<0.001$) compared to PL treated WT and Mdx mice. Areal bone mineral density (BMD) determined by dual energy X ray absorptiometry (DEXA) was significantly decreased in GC-Mdx ($p<0.001$) and this was ameliorated in mice treated with GC and bisphosphonate. MicroCT analysis of cortical bone in mid-diaphysis showed that GC treatment resulted in significantly decreased cortical thickness ($p<0.001$), and bone area ($p<0.001$) compared to PL treated mice. GCB-Mdx mice had significantly greater cortical thickness and bone area compared to GC-Mdx. GC therapy significantly improved muscle function as measured by fore-limb grip strength test, histological analysis of diaphragm, and serum creatine kinase (CK), and these improvements were also seen in mice treated with GC and bisphosphonate. Thus, early BP treatment at the initiation of long-term GC therapy is demonstrated to ameliorate GC-induced loss of cortical bone without any negative effects on dystrophic muscles in growing mice.

Effects of eldecalcitol on body weight, bone mineral density and skeletal muscle in glucocorticoid-treated rats. Hayato Kinoshita*[1], Naohisa Miyakoshi[2], Michio Hongo[2], Yuji Kasukawa[2], Koji Nozaka[2], Yoichi Shimada[3]. [1]Akita University, Japan, [2]Akita University Graduate School of Medicine, Japan, [3]Akita University Graduate School of Medicine Department of Orthopedics Surgery, Japan

Purpose: Prednisolone (PSL) causes secondary osteoporosis (OP) and myopathy, which is a risk factor for falls. It is reported that vitamin D prevents falls and fractures. However, the effects of a new vitamin D_3 analogue, eldecalcitol, on steroid-induced myopathy are still unclear. In this study, we examined whether eldecalcitol could inhibit PSL-induced myopathy or OP in rats.

Methods: Six-month-old female Wistar rats were randomized into the following four groups (n=14?16/group): 1) control group, administered eldecalcitol vehicle and PSL vehicle; 2) PSL group, administered PSL (10 mg/kg) and eldecalcitol vehicle; 3) E group, administered eldecalcitol (0.05 μg/kg) and PSL vehicle; and 4) PSL+E group, administered PSL and eldecalcitol. PSL, eldecalcitol and their vehicles were administered every day for 2 or 4 weeks. Body weight loss during the experiment was measured. Right calf muscle strength and fatigue were measured at the end of administration. Muscle strength and fatigue were obtained by electrically stimulating the right sciatic nerve. Sections from the left tibialis anterior (TA) muscle were stained by adenosine triphosphatase and the cross-sectional areas (CSAs) of the muscle fibers were measured. Bone mineral density (BMD) of the right femur was measured by dual-energy X-ray absorptiometry.

Results: Only after 4 weeks of treatment, weight loss in the PSL+E group was significantly higher than that in the control group ($p<0.01$) and muscle strength of the PSL+E group was significantly higher than that of the PSL group ($p<0.05$). Furthermore, CSAs in the E group and PSL+E group were significantly larger than those in the PSL group ($p=0.0026$ and $p=0.0115$). After 2 weeks of treatment, the distal femoral BMD of the E group was significantly higher than that of the PSL group ($p=0.0261$). After 4 weeks of treatment, the total, proximal, middle and distal femoral BMD of the PSL group was significantly lower than those of the control and

E groups (p=0.0005 and p<0.0001, respectively). Eldecalcitol significantly increased the total, proximal and distal BMD after treatment with PSL compared with the PSL group (p=0.0002, p=0.0069, and p<0.0001) after 4 weeks of treatment.

Conclusions: In the 4-week-treated rats, eldecalcitol prevented muscle atrophy of the TA and loss of femoral BMD, and increased calf muscle strength. Based on these results, we hypothesize eldecalcitol will inhibit steroid-induced OP and myopathy after 4 weeks administration.

Mediation of SDF-1/CXCR4 signaling in aged skeletal muscle by the adipokine leptin. Samuel Herberg*[1], Sudharsan Periyasamy-Thandavan[2], Phonepasong Arounleut[3], Sunil Upadhyay[4], Amy Dukes[5], Colleen Davis[4], Galina Kondrikova[5], Maribeth Johnson[5], Carlos Isales[4], William Hill[2], Mark Hamrick[6]. [1]Case Western Reserve University, USA, [2]Georgia Regents University & Charlie Norwood VAMC, USA, [3]Georgia Regents University (formally Georgia Health Sciences University), USA, [4]Georgia Regents University, USA, [5]Georgia Regents University, USA, [6]Georgia Health Sciences University, USA

Aging is associated with a decline in both muscle and bone mass, which is thought to involve dysfunction in bone- and muscle-derived stem cells. The chemokine SDF-1 (CXCL12) and its receptor CXCR4 play important roles in the migration, survival, and engraftment of stem cells, including bone marrow stromal cells (BMSCs) and muscle satellite cells (SCs). Adult muscle constitutively expresses SDF-1, and CXCR4 expression in muscle is elevated during muscle regeneration. Previous work in mice has shown that, with food restriction, leptin levels are decreased while SDF-1 levels are increased, and the reverse is observed with diet-induced obesity. We therefore speculated that leptin and the SDF-1/CXCR4 axis may interact throughout adulthood to mediate musculoskeletal tissue repair and regeneration. We tested this hypothesis by examining SDF-1 and CXCR4 expression in muscles of mice aged 12 months and 20 months fed ad-libitum (AL) and mice 20 months on caloric restriction (CR). We also treated mice aged 20 months on caloric restriction with recombinant mouse leptin for 10 days at 10 mg/kg body weight. Serum SDF-1 was increased in the aged mice, but leptin treatment reduced serum SDF-1 to levels seen in the younger (12 month) animals. SDF-1alpha expression in muscle decreased with age, but was increased with caloric restriction, and leptin treatment reversed this increase. CXCR4 expression in muscle decreased slightly with age, but was increased almost four-fold with caloric restriction, and this increase was attenuated by leptin treatment. Together these data suggest that food restriction is a potent stimulus for SDF-1 and CXCR4 activation in aged muscle, and that leptin can antagonize this effect. Thus, while we have previously demonstrated that leptin can increase muscle mass and IGF-1 in leptin-deficient rodents, leptin may also impair the potential for muscle regeneration and satellite cell migration via its effects on SDF-1/CXCR4 interactions.

Elevated TGF-β in Subchondral Bone Causes Joint Degeneration of Rheumatoid Arthritis and Osteoarthris. Xin Xu*[1], Liwei Zheng[2], Qin Bian[3], Xuedong Zhou[4], Xu Cao[5]. [1]Johns Hopkins University, Medical Institute, USA, [2]West China School of Stomatology, Sichuan University, Peoples Republic of China, [3]USA, [4]West China School of Stomatology, Sichuan University, China, [5]Johns Hopkins University, USA

Rheumatoid arthritis (RA) is an autoimmune disease that affects many tissues/organs including synovial joints, skin, lung, kidneys, vasculatures, etc. However, inadequate understanding of the pathogenesis of articular cartilage degeneration leads to insufficient treatment/prevention of this disease. Our previous study has shown that TGF-β-mediated subchondral bone alterations play an essential role in initiating cartilage degeneration of osteoarthritis (OA). Although rheumatoid arthritis and osteoarthritis have distinct clinical manifestations, both diseases are associated with bone marrow edema/lesions in the subchondral/subcortical bone. The current study was to delineate the mechanisms of TGF-β-mediated subchondral bone pathologies in the initiation of cartilage degeneration of RA-affected joint. By using both collagen-induced arthritis (CIA) mice model and spontaneous arthritis mice (TNF-α transgenic mice) model, we detected uncoupled bone remodeling phenotypes in the tibial subchondral bone of RA affected joint, accompanying with an excessive activation of TGF-β ligand and its down-stream signaling chronologically sequential to the increased osteoclastic bone resorption. Cellular clusters of osteoprogenitors and increased level of nestin positive Mesenchymal Stem Cells (MSCs) were also observed in the RA-affected subchondral bone marrow. By inhibition of TGF-β signaling with intraperitoneal administration of TβRI inhibitor (SB-505124), the abnormal bone phenotypes of CIA mice were rescued paralleled to the subsidence of MSCs/osteoprogenitors aggregation in the subchondral bone marrow, and the articular cartilage was protected. The cartilage protective effect of TGF-β blockade was also reproduced by local neutralization of TGF-β with pan-specific antibody (1D11) in the tibial subchondral bone of CIA rat. Further conditional deletion of the gene encoding TGF-β receptor II (Tgfbr2) in nestin-positive MSCs also rescued the uncoupled bone remodeling phenotypes in the subchondral bone of CIA mice (Nestin-cre^{T-M}Er::Tgfbr2flox/flox mice), and consequently protected the cartilage of RA. Hence, our data clearly demonstrate that excessive activation of TGF-β in subchondral bone initiates cartilage degeneration in RA, and the pathogenesis of OA and RA joint destruction converges on the TGF-β-mediated subchondral bone pathologies.

Elucidating Molecular Mechanisms leading to Post Traumatic Osteoarthritis in Sost KO Mice. Jiun Chiun Chang*[1], Blaine Christiansen[2], Nicole Collette[3], Aimy Sebastian[4], Deepa Murugesh[5], Sarah Hatsell[6], Aris Economides[7], Craig Blanchette[8], Gabriela Loots[9]. [1]University of California, Merced, USA, [2]University of California - Davis Medical Center, USA, [3]Lawrence Livermore National Laboratory, USA, [4]University of California, Merced, USA, [5]Lawrence Livermore National Laboratories, USA, [6]Regeneron Pharmaceuticals, USA, [7]Regeneron Pharmaceuticals, Inc., USA, [8]Lawrence Livermore National Laboratories, USA, [9]Lawrence Livermore National Laboratory, UC Merced, USA

Sost was recently implicated in regulating chondrocyte function in osteoarthritis (OA). Sost levels were found to be elevated in regions of osteoarthritic cartilage in surgical models of OA. However, the role of *Sost* in OA and its involvement in regulating biomarkers such as MMPs, interleukins and collagens is unclear. We examined the progression of OA using a noninvasive tibial compression overload model of post traumatic osteoarthritis (PTOA) in mice overexpressing (*TG*) or lacking *Sost* (*KO*). OA development was examined histologically and by μCT at 6-, 12-, and 16- weeks post injury. KOs displayed a more severe cartilage loss relative to the wildtype (*WT*) littermates, while a less severe OA phenotype was observed in TGs. We also quantified subchondral trabecular bone in the femoral epiphysis and osteophyte formation by μCT. Injured knees of *WT* mice lost a significant amount of trabecular bone (~24%), while *KOs* exhibited no significant bone loss. Moreover, ~28% greater osteophyte volume was observed in the *KOs* and ~49% less in the *TGs* relative to *WT*s at 16 weeks post injury. Fluorescent MMPSense substrate was administered intravenously immediately post injury and MMP activity was quantified 3 days post injury. *KO* injured joints showed similar MMP activity levels as controls while *TG* had ~2-fold less MMP activity, suggesting that *SOST* overexpression inhibits the activity of proteolytic enzymes known to degrade articular cartilage matrix. Next we quantified gene expression using RNA sequencing (RNASeq) at 1 day post injury and compared injured and uninjured *KO* joints to injured and uninjured littermate controls. In this analysis, 84 and 78 transcripts were found to be up-regulated by more than 2-fold in *WT* and *KO* injured joints, respectively. Consistent with the MMPSense data, MMPs 2/3/13 transcripts were significantly up-regulated in both *KO* and control injured joints. Among the transcripts that were differentially expressed between *KO* and control injured joints we found CRABP-II 6-fold up-regulated exclusively in *WT* injured joints only, while RRAD was up-regulated 14-fold in *KO* injured joints and only 2-fold in injured controls, suggesting that these genes may play a role in the phenotypic differences observed between *WT* and *KO* injured joints. These results show that in mice which have developed in the absence of Sost, the response to traumatic joint injury is accentuated; in contrast, chronic overexpression of SOST appears to have a protective role.

Genetic Inhibition of FGFR1 in Cartilage at Adult stage Attenuates the Degeneration of Articular Cartilage in FGFR3 disruption mice. Yangli Xie*[1], Wei Xu[2], Junlan Huang[2], Xiaolan Du[2], Siru Zhou[2], Lin Chen[3], Zuqiang Wang[2]. [1]Center of Bone Metabolism & Repair,State Key Laboratory of Trauma, Burns & Combined Injury, Trauma Center, Institute of Surgery Research, Daping Hospital, Third Military Medical University, Chn, [2]Center of Bone Metabolism & Repair, State Key Laboratory of Trauma, Burns & Combined Injury, Trauma Center, Institute of Surgery Research, Daping Hospital, Third Military Medical University, China, [3]Daping Hospital, Peoples Republic of China

Study has shown that deletion of fibroblast growth factor receptor 3 (FGFR3) lead to spontaneous osteoarthritis (OA) in mice. We previously demonstrated that inducible disruption of FGFR1 in cartilage delays the progression of cartilage degeneration in spontaneous OA and destabilization of the medial meniscus (DMM) models. Previous work has suggested thatthe ratio of FGFR1 to FGFR3 in articular cartilage may infulence the maintenance of cartilage and development of OA. To study the relative role of FGFR1 and FGFR3 in the process of cartilage maintenance, we inducibly inactivated FGFR3 and FGFR1 in chondrocytes by injecting tamoxifen

(TM) into mice with floxed *Fgfr*1 alleles, floxed *Fgfr*3 alleles and Col2a1-CreERT2 allele (hereafter referred to as Fgfr1/3^{Col2ER}) and compared them with Fgfr1^{Col2ER}, Fgfr3^{Col2ER} and Cre-negative mice. All mice mentioned above were intraperitoneally injected with TM (1 mg/10 g body weight, × 5 days) at age of 8 weeks. DMM surgery was performed on the right knee joints of 10-week-old male mice, and sham surgery was performed with medial capsulotomy only. All knee joint specimens were analyzed by micro-computed tomography, histologic analysis, and real-time PCR at 8 weeks postoperatively or at 12 months.

Compared to Fgfr1^{Col2ER}, Fgfr3^{Col2ER} and Cre-negative mice, Fgfr1/3^{Col2ER} mice showed no significant gross phenotype. The length of tibia and femurs showed no remarkable changes. Histologically, Fgfr3Col2ER mice developed early-onset of DMM induced and age-related cartilage matrix loss and abnormal hypertrophy of chondrocytes in the knee cartilage compared with Cre-negative mice, while, Fgfr1/3^{Col2ER} mice showed the similar process with Cre-negative mice. Immunohistochemical analysis demonstrated a significant reduction in matrix metalloproteinase 13 (MMP13) and Collagen 10 expression in the superficial chondrocytes above the tidemarks of Fgfr1/3^{Col2ER} mice compared with that of Fgfr3Col2ER mice. Gene expression analysis demonstrated that inactivation of FGFR3 led to enhanced Collagen10,Mmp13 and Adamts5 expressions and depressed Col2, aggrecan expressions in knee cartilage, while inactivation of FGFR1 in FGFR3 ^{Col2ER} mice can alleviate these phenotype.

Our results indicate that deletion of FGFR3 in chondrocytes leads to early-onset degeneration of knee cartilage which can be partially rescued by deletion of FGFR1. These findings about the role of FGFR1 and FGFR3 in articular cartilage degeneration may provide experimental data for further mechanism studies, and for screening of therapeutic approaches for human OA.

3D Bone Microarchitectural Assessment in the Human Knee by Second Generation HR-pQCT – A New Tool for Early Osteoarthritis Detection?.

Sarah Manske*, Ying Zhu, Britta Jorgenson, Steven Boyd. University of Calgary, Canada

The sequence of events leading to osteoarthritis (OA) after joint injury such as anterior cruciate ligament (ACL) tears is poorly understood. Increasing evidence suggests that subchondral bone changes may precede cartilage loss. However, the nature of the bone changes that may be linked to OA progression is unclear as both high and low BMDs have been associated with radiographic OA.

High resolution peripheral quantitative computed tomography (HR-pQCT) scanners have become standard tools to assess bone microarchitecture *in vivo*, however, until recently, gantry size limited scan sites to distal peripheral limbs. The development of the second generation scanner (HR-pQCT2; XtremeCTII, Scanco Medical) with a larger field of view (FOV, 14 cm), longer gantry (115 cm), and increased scan length (20 cm) will permit examination of sites such as the knee and elbow. We sought to explore the capability of this cutting edge technology to examine bone microarchitecture in the knee.

We scanned two human cadaveric knees, and one participant (height = 178 cm, weight = 78 kg) *in vivo* five months following an ACL reconstruction in the HR-pQCT2. For the participant, we acquired a 6 cm long region of interest using the patient protocol (61 μm, 43 ms integration time (IT), 900 projections/180˚). In the cadaveric samples, we tested several protocols by varying spatial resolution, IT, and number of projections to optimize image quality and acquisition time. For 3D visualization, we filtered the images and applied a threshold to segment bone from soft tissue.

Qualitatively, we found that in the cadaveric scans we obtained sufficient image quality for microarchitectural analysis with a practical scan acquisition time using 61 μm, 100 ms IT and 900 projections/180˚ (Figure 1). In the participant scan, the knee and surrounding soft tissue fit in the gantry, although positioning in the centred FOV was a challenge. These initial *in vivo* data resulted in images that were noisier than radius scans using the same protocol. However, we could clearly visualize individual trabeculae, as well as the tunnels drilled during the ACL reconstruction.

Protocol optimization for participant scans is ongoing. Future work will involve defining subregions of analysis at various depths from the cartilage surface. We plan to use this new technology examine individuals at risk for developing knee OA to determine whether microarchitectural deterioration can be used as an early OA detection tool.

Figure 1. Sagittal view of cadaveric knee acquired at 61 μm, 100 ms integration time, and 900 projections/180° using HR-pQCT2.

FR0207

The influence of osteophytes on femoral neck microcracks in osteoarthritis.

Gustavo Davi Rabelo[1], Jean-Paul Roux*[2], Nathalie Portero-Muzy[1], Stephanie Boutroy[3], Roland Chapurlat[4], Pascale Chavassieux[5]. [1]INSERM UMR1033, Université de Lyon, France, [2]INSERM, UMR 1033, Université de Lyon, France, [3]INSERM U1033 & Université de Lyon, France, [4]E. Herriot Hospital, France, [5]INSERM UMR1033, Université De Lyon, France

Structural changes of the femoral neck (FN) contribute to the risk of fracture. Patients with osteoarthritis (OA) seem protected against FN fracture, mostly related to cortical thickening. In relation to osteophytes, patients with osteophytic hip OA had higher BMD, wider femoral necks, and greater bone strength than those with atrophic OA or without OA. The aim of this study was to evaluate the microcrack density (Cr.N/BV) and length (Cr.Le) in hip OA and its relation with cancellous and cortical characteristics in the osteophyte region.

Samples were obtained during arthroplasty for hip OA in 18 women (66±8 yrs). Calcein bulk-staining was performed to identify microcracks and Goldner staining for the histomorphometric analysis. 3D measurements were assessed by HR-pQCT (Scanco). The presence of microcracks was analyzed in the osteophyte area and in the remaining part. The texture analysis of the cortex was made separately in the quadrants of the osteophyte and the opposite part. Both a thresholded and an unthresholded methods were used in order to improve the 3D analysis obtained with the low resolution of the CT images (82 μm). From thresholded images, we measured cortical thickness (Ct.Th) and its heterogeneity (Ct.ThSD), porosity (Ct.Po) and Fractal Dimension (Ct.FDbin). From unthresholded images, we measured the Fractal Dimension (Ct.FDgray) and lacunarity.

Osteophytes were present in all samples, but microcracks were observed in only 3 of them. Cr.N/BV was significantly higher in cancellous than cortical bone ($p<0.001$) but Cr.Le tended to be higher in cortical than cancellous bone ($p=0.07$). Cr.N/BV was significantly lower in osteophytes than in the other part ($p=0.02$). The bone mass of the osteophytes was significantly higher than the other part ($p<0.0005$) but the microarchitecture was not better. Cortical fractal dimension was significantly higher in the osteophyte quadrant than the opposite quadrant (Ct.FDbin $p<0.005$, Ct.FDgray $p=0.002$), with higher Ct.Th ($p<0.0001$) and Ct.ThSD ($p\leq0.01$). The lacunarity and Ct.Po were not significantly different.

In conclusion, these results showed that in hip OA, the microcrack formation was lower in the osteophytes. The osteophyte region presents a higher complexity (Fractal dimension) in bone structure when compared with the opposite part. These results suggest that the different organization of osteophyte bone may explain lower microdamage frequency, which is useful to understand microdamage occurrence in bone.

Nuclear Factor of Activated T-Cells (Nfatc)2 Inhibits Osteoblast Function and Causes Osteopenia. Stefano Zanotti*, Ernesto Canalis. University of Connecticut Health Center, USA

Nuclear factor of activated T-cells (Nfat)c1 to c4 are transcription factors that regulate critical cellular events. Whereas Nfat proteins play an undisputable role in osteoclastogenesis, the function of Nfat in cells of the osteoblastic lineage is controversial. Constitutive activation of Nfatc1 and c2 in osteoblasts suppresses cell function, although study of Nfat proteins *in vivo* yielded conflicting results. To establish the consequences of Nfatc2 activation in osteoblasts, we generated FVB transgenic mice, where a 3.6 kilobase fragment of the collagen type I α1 promoter directs Nfatc2 expression (*Col3.6-Nfatc2*). The *Nfatc2* transgene harbors serine to alanine substitutions that render Nfatc2 constitutively active. The skeletal phenotype of *Col3.6-Nfatc2* mice of both sexes and of sex-matched littermate controls was studied by microcomputed tomography and histomorphometry. *Col3.6-Nfatc2* mice had no obvious phenotype, and bone extracts from transgenics exhibited *Nfatc2* mRNA levels 5 to 11 fold higher than controls. Femurs were slightly shorter in *Col3.6-Nfatc2* mice but the effect was transient and observed only at 1 month of age. One month old *Col3.6-Nfatc2* male and female mice exhibited pronounced osteopenia. Femoral cancellous bone volume was reduced by 40 to 50% and trabeculae were reduced in number and were more rod-like in relationship to control mice. In addition, *Col3.6-Nfatc2* female mice exhibited a thin and porous cortical bone. The mechanisms underlying the osteopenia differed between sexes. *Col3.6-Nfatc2* female mice had a 30% reduction in bone formation. In contrast, male transgenics had an increase in osteoblast number. This finding suggests incomplete osteoblast maturation, since bone formation was not enhanced, and is consistent with previously established effects of Nfatc2 on osteoblastogenesis mediated by interactions with osterix. Osteoclast number and bone resorption were not affected in either sex. To explore the cellular mechanisms responsible for the osteopenia, bone marrow stromal cells from *Col3.6-Nfatc2* and control mice were cultured. In agreement with the *in vivo* observations, Nfatc2 inhibited alkaline phosphatase activity and mineralized nodule formation. In conclusion, *in vivo* Nfatc2 activation in osteoblasts causes cancellous and cortical bone osteopenia and inhibits bone formation. This confirms previous work *in vitro* and establishes Nfatc2 as an inhibitor and not a stimulator of osteoblast function and bone formation.

Cannabinoid CB1 Receptor in Sympathetic Nerves Regulates Bone Mass. Saif Deis*[1], Natalya Kogan[1], Lital Goldfine[1], Raj Kamal Srivastava[2], Saja Baraghithy[1], Esther Shohami[1], Beat Lutz[2], Itai Bab[3]. [1]Hebrew University of Jerusalem, Israel, [2]Johannes Gutenberg University, Germany, [3]The Hebrew University, Israel

It is now established that the endocannabinoid (EC) system, including the cannabinoid receptors and EC metabolizing enzymes, have an important role in bone health. Retrograde cannabinoid CB1 receptor (CB1) signaling regulates synapse activity throughout the brain. In addition, CB1 expression has been demonstrated in sympathetic terminals in peripheral organs, including the skeleton, where it transmits retrograde signals that restrain norepinephrin (NE) release thus transiently stimulating bone formation following an acute challenge. In agreement with these findings we show here in MC3T3 E1 and newborn calvarial osteoblasts that isoproterenol, a β-adrenergic receptor agonist having NE-like activity, stimulates production of the major EC, 2-arachidonoylglycerol (2AG) by increasing the expression of its biosynthetic enzyme diacylglycerol lipase α. These findings are consistent with a 2AG-NE negative feedback circuit that regulates the synaptic-like activity between sympathetic terminals and osteoblasts. To assess the occurrence of this circuit *in vivo* we characterized the skeletal phenotype of mice with conditional deletion of CB1 in sympathetic nerves (*DBH-Cre/CB1$^{f/f}$* mice). These mice have increased NE levels in the circulation and peripheral tissues. The CB1 deletion does not affect bone mass accrual determined by quantitative microcomputed tomography in the distal femoral metaphysis and vertebral bodies of young, 12-week old mice. By contrast, 35-week old *DBH-Cre/CB1$^{f/f}$* mice have a marked high bone mass phenotype, representing a paradox based on previous reports that adrenergic signaling decreases bone formation and bone mass. Quantitative mRNA analysis in the same mice shows increased expression of β2 adrenergic receptor (β2AR) and monoacylglycerol lipase, the 2AG rate limiting enzyme. These findings suggest that chronic inactivation of sympathetic CB1 leads to disruption of the 2-AG-NE circuit with possible desensitization of osteoblastic β2AR and decreased 2AG levels with the consequent increase in bone mass. Thus, the emerging peripheralized CB1 antagonists may be useful for combating osteoporosis.

Cyclooxygenase 2 deficiency impaired the bone regeneration capacity of muscle derived stem cells via cell autonomous and non-autonomous mechanisms. Xueqin Gao*[1], Arvydas Usas[1], Aiping Lu[1], Ying Tang[1], Minakashi Poddar[1], Adam Kozemchak[1], James Cummins[1], Johnny Huard[2]. [1]University of Pittsburgh, USA, [2]Orthopaedic Surgery, USA

Cycloxygenase-2 (COX-2) deficient mice have delayed and reduced bone fracture healing and we have observed that COX2 is expressed dynamically during muscle derived stem cell (MDSC) mediated bone healing. This study investigated the role that both donor and host COX-2 played in MDSC-mediated bone repair in a critical size calvarial defect model.

Experimental design: (1) Determine the role of host COX-2 in MDSC mediated bone healing. 5×10^5 BMP4/GFP transduced MDSCs were implanted into 5 mm critical size calvarial defects in COX-2KO and WT mice using fibrin sealant as a scaffold. Bone formation was monitored by μCT40 biweekly for 8 wks. (2) Determine the role of donor COX-2 in MDSC mediated bone healing. We isolated 3 populations of MDSCs from both WT and COX-2KO mice via the preplate technique. Cells were transduced with retro BMP4/GFP, implanted into skull defects created in CD-1 nude mice and bone formation was evaluated by μCT40 (biweekly), and Herovici's and GFP staining. (3) Determine the effect that donor cells have on host cells. 36 CD-1 nude mice were divided into WT MDSC/BMP4GFP and COX-2KOMDSC/BMP4/GFP groups. After implantation, mice were sacrificed at days 3, 7, and 14, and the skulls were harvested. Immunofluorescent staining for CD68, Gr-1, CD31, Ki67 was performed. Von Kossa staining was also performed at day 14. (4) In vitro pellet culture was used to determine the cells' osteogenic and chondrogenic capacities. (5) In vitro cells' oxidative stress resistance was determined using 250 and 400uM H2O2.

Results: (1) BMP4/GFP transduced MDSCs formed significantly less bone in COX-2KO mice than in WT mice. (2) COX2KO MDSCs/BMP4/GFP formed less bone in the CD-1 nude mice than WTMDSCs/BMP4/GFP. Histology showed less collagen type 1 and fewer GFP positive osteoblasts and osteocytes in the mice injected with COX2KO MDSC/BMP4GFP cells. (3) Fewer macrophages were recruited to the defect area by d3 and the resolution of inflammation was delayed in COX2KO MDSCs group; no effect was observed with Gr-1$^+$ neutrophil infiltration or with CD31$^+$ cell recruitment by d3 or d7. Fewer GFP$^+$Ki67$^+$ cells were found in the COX-2KO MDSC group than the WT MDSC group. Von Kossa staining indicated less mineralized tissue formation in the COX-2KO MDSC group than the WT group. (4) COX2KO MDSCs formed smaller mineralized pellets as determined by μCT, Von Kossa and osteocalcin staining. COX-2KO MDSCs did not efficiently differentiate into chondrocytes compared to the WT MDSCs. (5) COX-2KO MDSCs showed decreased cell survival at both H2O2 concentrations compared to the WT MDSCs.

Conclusion: Our results indicate that both donor and host COX2 play important roles in MDSC mediated bone regeneration. The impaired bone regeneration capacity of COX2KO MDSCs was mediated, at least in part, to a poor cell proliferation and survival, reduction in osteogenic differentiation and the deleterious paracrine effect they had on host cells.

Deletion of Rorβ, a Novel Regulator of Osteoblast Function, Slows Trabecular Bone Loss During Aging in Mice. Qian Xing[1], Kristy Nicks[1], Joshua Farr[1], Daniel Fraser[1], Sundeep Khosla[2], David Monroe*[3]. [1]Mayo Clinic, USA, [2]Mayo Clinic College of Medicine, USA, [3]Mayo Foundation, USA

The regulation of osteoblast differentiation requires the coordinate activities of numerous transcription factors. While factors such as Runx2 and osterix are essential, others act to fine-tune in response to external cues. One such factor is retinoic acid receptor-related orphan receptor beta (Rorβ). We have previously shown that Rorβ is as a negative regulator of osteoblast differentiation [*JBMR* 27(4):891-901, 2012] whose expression decreases throughout normal osteoblast differentiation. Sustained Rorβ expression inhibits mineralization and Rorβ also represses Runx2 transcriptional activity. Interestingly, Rorβ expression is highly elevated in bone marrow-derived osteoprogenitor cells during normal aging in mice and humans, suggesting that Rorβ may play a role during aging in bone. Collectively, these data suggest a model whereby Rorβ inhibits osteoblast differentiation through suppression of Runx2 activity in osteoprogenitors and that increased Rorβ expression has a negative impact on bone maintenance during aging. In order to test this hypothesis, we aged global Rorβ knockout (Rorβ$^{-/-}$) and wild-type littermate control mice and characterized both cortical and trabecular skeletal phenotypes at 6, 9 and 12 months using pQCT at the tibia. Trabecular vBMD at the tibial metaphysis was higher in Rorβ$^{-/-}$ mice at 6 months (10.8%; p=0.042), 9 months (13.0%; p=0.044) and 12 months (15.8%; p=0.040). No change was observed in any cortical parameter. We also assessed bone microarchitecture following sacrifice (12 months) using μCt. As shown in the Figure, increased trabecular bone at the femoral metaphysis is evident in the Rorβ$^{-/-}$ mice. A significant increase in BV/TV (20-fold; p=0.029) and trabecular number (44%; p=0.032), and a decrease in trabecular separation (-34%; p=0.0048) in the Rorβ$^{-/-}$ mice was observed. Calculation of the structure model index (SMI), which estimates the plate-rod characteristics of the trabecular structure, demonstrated significantly more plate-like structures in the Rorβ$^{-/-}$ mice (p=0.012). In summary, our data demonstrate the genetic loss of Rorβ in mice results in slowed trabecular bone loss during aging as compared to the bone loss in wild-type controls, in support of our hypothesis. These

data suggest that suppression of Rorβ activity during aging may represent a novel treatment for age-related bone loss.

miR-874-3p expressed during weaning phase positively regulates skeletal mass and plays an important role in primary osteoporosis. Priyanka Kushwaha*[1], Vikram Khedgikar[2], Jyoti Gautam[2], Anirudha Karvande[2], Nasser Ahmed[2], Deepika Mishra[3], Prabodh Kumar Trivedi[3], Ritu Trivedi[2]. [1]Central Drug Research -CSIR, India, [2]CSIR-CDRI, India, [3]CSIR-NBRI, India

Emerging evidences indicates that microRNAs (miRNAs) have important role in regulation of osteoblast differentiation and bone formation. Thus far, no study has established the relationship between post-weaning phase of maternal skeletal metabolism with bone formation. Microarray profiling of bone marrow cells during lactation and post-weaning phase revealed that 8 microRNAs were hugelyand differentially regulated, out of which 5 miRNAs were up-regulated and 3 were down-regulated. These miRNAs were validated into primary osteoblast cells. Out of these the most promising miR-874-3p, is a well characterized tumor suppressive miRNA, whose expression was up-regulated during post-weaning and osteoblast mineralization stages. Identified miR-874-3p promoted osteoblast differentiation and mineralization by repressing histone deacetylase-1 (HADC1) at post transcriptional level. Overexpression of miR-874-3p enhanced osteoblastogenesis whereas inhibition of miR-874-3p expression attenuated it. HADC1, an enhancer of Runt related transcription factor-2 (Runx2) degradation was confirmed by target validation. *In vivo* silencing of miR-874-3p led to decrease bone formation and reduced trabecular microarchitecture in sham and ovariectomized (OVx) mice. Our finding suggests that miR-874-3p is a potential miR and pharmacological inhibition of miR-874-3p reduced osteoblast mineralization, bone formation, trabecular bone and plays an important role in primary osteoporosis. miR-874-3p may provide potential therapeutic opportunity for treatment of primary osteoporosis.

***In Vivo* Maintenance of Cortical Bone Mass is Dependent on Estrogen Receptor Alpha Binding to Estrogen Response Elements in Mouse Osteoblasts.** Kristy Nicks*[1], Daniel Fraser[2], Sundeep Khosla[3], David Monroe[4]. [1]Mayo Clinic, USA, [2]Mayo Clinic, USA, [3]Mayo Clinic College of Medicine, USA, [4]Mayo Foundation, USA

Estrogen (E) is a key regulator of bone metabolism whose effects are primarily mediated by estrogen receptors (ER)-α and ERβ. ERs modulate transcription via either the ''classical'' pathway, which involves direct DNA binding to estrogen response elements (EREs) or the ''non-classical'' pathway, which is ERE-independent and acts through protein-protein interactions with other transcription factors. Our previous work demonstrated that mice expressing only an ERα that cannot bind EREs [non-classical ER knock-in (NERKI)] are osteopenic and have impaired bone formation associated with decreased osteoblast (OB) number. However, the interpretation of this data is potentially confounded by systemic hormonal changes (increased E and decreased IGF-1 levels) observed in the NERKI model that may have indirect effects on bone. To circumvent this issue, we selectively deleted ERα in OBs ($ER\alpha^{AOB}$) by crossing the osteocalcin (Oc)-Cre driver mouse with an ERα conditional allele ($ER\alpha^{flox/flox}$). Throughout this study we used the Oc-Cre littermates as our normal control (denoted WT). In 3-month old $ER\alpha^{AOB}$ female mice, we observed a 9% decrease in total tibial bone mineral density (BMD) as measured by pQCT when compared to WT mice ($P = 0.0001$). To establish if ERE binding was necessary for recovery of this bone deficit, we determined whether transgenic re-expression of either WT ERα or NERKI in $ER\alpha^{AOB}$ mice improved BMD measurements. The deficit was not only prevented in ERα-replaced mice but was increased by 16% ($P < 0.0001$), whereas the NERKI-replaced mice remained osteopenic (6% decrease), and had BMD measurements similar to $ER\alpha^{AOB}$ mice. These differences were associated with changes in cortical bone as there was a significant decrease in tibial cortical BMD in $ER\alpha^{AOB}$ mice compared to WT ($P = 0.0015$) that was prevented in ERα-replaced mice but not in NERKI-replaced mice. To ensure comparable transgenic ERα or NERKI expression, we isolated RNA from the femur diaphysis of all study mice and performed QPCR analyses using primers specific for the ERα or NERKI transgenes. No significant differences in expression levels of the transgenes were observed in either the ERα- or NERKI-replaced mice, demonstrating comparable ER replacement (WT or NERKI) in both groups. In summary, our data demonstrate that in osteoblasts, classical estrogen signaling is necessary for normal skeletal development in the cortical compartment.

HDAC4 integrates PTH and sympathetic signaling in osteoblasts to regulate *Rankl* expression and osteoclasts differentiation. Arnaud Obri*, Munevver Parla Makinistoglu, Gerard Karsenty. Columbia University, USA

Both the parathyroid hormone (PTH) and the sympathetic nervous system can enhance *Rankl* expression in osteoblasts and thereby osteoclast differentiation by increasing cAMP production in these cells. PTH does so through yet unknown transcriptional mechanisms whereas the sympathetic tone recruits for that purpose the osteoblast enriched transcription factor ATF4 that binds to and trans-activate the *Rankl* promoter. These observations raise the following question: how two extracellular cues that use the same second messenger can elicit, in the same cell type, transcriptional events of different nature? We addressed this question through molecular means and the analysis of several osteoblast-specific mutant mouse strains lacking various transcription factors or chromatin remodeling enzymes. Our study shows that PTH signaling in osteoblasts favors *Rankl* expression because it triggers the polyubiquitination of HDAC4, a class II histone deacetylase in these cells. To achieve this function, PTH enhances the expression in osteoblasts of an E3 ubiquitin ligase that binds to HDAC4 only in the presence of PTH. This PTH-induced degradation of HDAC4 releases MEF2c that is now able to trans-activate the *Rankl* promoter following its binding to a MEF2 consensus binding site that is conserved in all vertebrate species analyzed. Unlike PTH, the sympathetic nervous system favors the accumulation of HDAC4 and promotes its association with ATF4 in osteoblasts. As a result of this association with HDAC4, ATF4 transcriptional activity is increased. We further show that, in vivo, the sympathetic tone disrupts the association that can occur in vitro between HDAC4 and Runx2 thus explaining why HDAC4 does not regulate Runx2 functions in osteoblasts as it does in chondrocytes. This study demonstrates that HDAC4 allows the integration, through different mechanisms, of two distinct extracellular signals into the genome of the osteoblast; as a result it identifies *Hdac4* expression in osteoblasts as a major determinant of osteoclasts differentiation.

Knockout of Nuclear HMWFGF2 Isoforms in Mice Modulates Bone and Phosphate Homeostasis. Collin Homer-Bouthiette*[1], Marja Marie Hurley[2], Liping Xiao[1]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut Health Center School of Medicine, USA

Targeted overexpression of the Fibroblast Growth Factor 2 (FGF2) high molecular weight (HMW) isoforms in osteoblastic lineage cells in mice resulted in phenotypic changes, including dwarfism, rickets, osteomalacia, hypophosphatemia, increased serum PTH and increased levels of FGF23, in serum and bone. The current study examined the effects of genetically knocking out the HMWFGF2 isoforms (HMWKO) on bone and phosphate homeostasis in relation to wild type (WT) littermate mice as well as previously examined HMWTg mice versus Vector control. Two-month old male HMWKO mice were not dwarfed and had significantly increased bone mineral density (BMD) and bone mineral content (BMC) in femurs and lumbar vertebrae when compared to WT. Micro-CT and histomorphometry analysis of femurs revealed increased trabecular and cortical bone metrics consistent with improved bone mineralization. In vitro osteogenic bone marrow stromal cell cultures showed a significant increase in alkaline phosphatase positive colony number at 1 week and increased mineralization at week 3 in HMWKO. To assess the mechanism (s) for the observed bone phenotype in HMWKO, mRNA for genes important in osteoblast differentiation and matrix mineralization were determined in flushed tibiae of WT and HMWKO mice. In contrast to our published data in HMWTg in which type 1 collagen (Col1a1) was decreased, we observed increased Col1a1 in the HMWKO. In HMWKO, the mRNA for matrix-gla protein (Mgp) and matrix extracelluar phosphoglycoprotein (Mepe), negative regulators of matrix mineralization, were similar to WT in contrast to the profound increase observed in bones of HMWTg. Sclerostin (SOST), which regulates multiple downstream signaling pathways, was up regulated in bones of HMWTg, however, Sost mRNA was significantly decreased in the HMWKO. SOST can inhibit canonical Wnt signaling via binding of LRPs resulting in decreased osteoblast differentiation. SOST can also increase MEPE activity, which inhibits Phex activation of DMP1 thereby decreasing bone mineralization. Thus decreased Sost could contribute to the increased bone mass observed in HMWKO mice. We previously reported that increased FGF23 caused Pi

wasting via the bone/kidney axis in the HMWTg mice. In contrast, FGF23 mRNA was significantly decreased in HMWKO, which could contribute to normal serum Pi in HMWKO mice. This novel study demonstrates a significant negative impact of HMWFGF2 on biological functions in bone and phosphate homeostasis in mice.

Regulation of Bone Mass by Lrp4 and Secreted Wnt Antagonists. Youngwook Ahn*[1], Jesús Fuentes-Antrás[1], Mark Dallas[2], Mark Johnson[3], Robb Krumlauf[1]. [1]Stowers Institute for Medical Research, USA, [2]University of Missouri, Kansas City Dental School, USA, [3]University of Missouri, Kansas City Dental School, USA

The Wnt/β-catenin signaling pathway plays a key role in bone mass acquisition and maintenance. The Wnt antagonists, sclerostin and Dkk1, control postnatal bone formation and resorption via their inhibitory interaction with Wnt co-receptors, Lrp5 and Lrp6. Lrp4 is related to Lrp5/6 and has emerged as a potential regulator of bone mass based on mutations identified in mice and humans and recent genetic association studies in humans. It has been reported that Lrp4 interacts with the Wnt antagonists *in vitro* and modulates Wnt/β-catenin signaling during limb and skin appendage development. In our study, we investigated the role for Lrp4 in bone growth using loss- and gain-of-function mouse models to explore underlying mechanisms of Lrp4 function with respect to its interaction with the Wnt co-receptors and antagonists. We generated transgenic reporter lines using a BAC clone covering the *Lrp4* genomic region and observed reporter expression mainly in osteoblast lineages in postnatal bone. MicroCT analyses of adult bones revealed changes in microstructure and bone mass including increased cortical thickness and decreased trabecular BV/TV in *Lrp4* deficient mice. Conversely, over-expression of *Lrp4* in osteoblast lineages lead to bone defects including rib fracture. Genetic interaction analysis suggests that Lrp4 is required for sclerostin to exert its function, but not for Dkk1 during limb patterning and bone growth. This observation was validated by *in vitro* reporter assays which support a synergy between Lrp4 and sclerostin in inhibition of Wnt/β-catenin signaling. We propose that Lrp4 plays a critical role in regulation of bone growth and homeostasis in part by mediating Wnt inhibitory function of sclerostin. Given the emerging role of sclerostin antibodies as an anabolic therapy for treating osteoporosis and facilitating fracture healing, we suggest that Lrp4 is a similar target for future therapy development.

Unique Distal Enhancers Linked to the Mouse *Tnfsf11* Gene Direct Tissue-Specific Expression and Inflammation induced Regulation of RANKL Expression. Melda Onal*[1], Hillary St John[2], Allison Danielson[3], Charles O'Brien[4], J. Pike[2]. [1]university of wisconsin, USA, [2]University of Wisconsin-Madison, USA, [3]undergraduate student, USA, [4]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

RANKL is a multifunctional TNF-like cytokine with diverse roles in organ development, immune function, and skeletal remodeling. The expression of this factor from its *Tnfsf11* gene locus is cell-specific and regulated by an array of local and systemic factors. Earlier studies indicate that these features of RANKL expression are mediated by a complex series of enhancers located up to 155 kb upstream of the gene's transcriptional start site. Several of these enhancers favor RANKL expression in mesenchymal lineage cells; others direct expression in immune cells. The impact of one upstream enhancer, termed D5 (DCR), has been explored through genomic deletion in mice (D5KO), confirming its importance in RANKL expression and in skeletal remodeling. Interestingly; however, several *Tnfsf11* enhancers located further upstream display unique cell type-specific and regulatory properties *in vitro*. To explore these control regions further, we prepared several additional *in vivo* murine enhancer deletion models and examined the consequence of these deletions as well as that of D5 on RANKL expression, regulation, and skeletal phenotype. The D5KO mouse manifests reduced RANKL expression and regulation by $1,25(OH)_2D_3$, PTH and OSM in bone cells, and exhibits an age-exaggerated increase in BMD. In the D6KO mouse, however, basal RANKL expression was unaltered in bone cells and BMD levels were normal. Despite this, while RANKL induction by $1,25(OH)_2D_3$ was retained, both *in vivo* and *ex vivo* responses to OSM and inflammatory LPS were lost. These observations are consistent with D6-mediated RANKL stimulation by cytokines in bone cells *in vitro*. Finally, while the T1KO mouse also manifested normal basal RANKL expression at skeletal sites and unaltered BMD, basal RANKL expression was strikingly reduced by 80% in the spleen, thymus and lung of growing and adult mice. This decrease was also identified in isolated B and T cells suggesting that RANKL expression is dependent upon the T1 enhancer early in the hematopoietic lineage. *Ex vivo* studies confirmed that RANKL expression in response to T cell activation was also blunted. Interestingly, this depletion of RANKL in immune tissue was also observed modestly in the D5KO as well. These murine models demonstrate that individual *Tnfsf11* enhancers exhibit unique capabilities relative to cell type-specific RANKL expression and regulation, and will be valuable in assessing the contribution of unique cell types to inflammatory bone loss.

***Cbfβ promotes osteoblast lineage commitment and regulates the fate of mesenchymal stem cells by suppressing the expression of key adipocyte regulators and activating Wntlβ-catenin pathway* in vivo *and* in vitro.** Mengrui Wu*[1], Wei Chen[2], Yi-Ping Li[2]. [1]The University of Alabama at Birmingham, USA, [2]University of Alabama at Birmingham, USA

How osteoblast (OB) lineage commitment is achieved is a fundamental question in bone biology. Despite recent insights gained from the effects of targeted deletion of OB regulator genes, the mechanism of OB lineage commitment from mesenchymal stem cells (MSCs) remains unclear. Core-binding factor, beta (Cbfβ) plays an important role in skeletal development. However, the role of Cbfβ in MSC lineage determination has not been clarified yet. To determine its role, we generated *Cbfβ* conditional knockout mice using skeletal lineage-specific Cre-loxP systems. Oil red O staining showed that *Cbfβ$^{f/f}$Prx1-Cre*, *Cbfβ$^{f/f}$Col2α1-Cre*, and *Cbfβ$^{f/f}$Osx-Cre* mice, but not *Cbfβ$^{f/f}$Col1α1-Cre* mice, have dramatically decreased bone density and a pronounced accumulation of bone marrow adipocytes, which resembles osteoporosis in aging humans. Our findings indicate that the regulation of Cbfβ in OB lineage commitment is cell lineage-specific. Calvarial cells derived from *Cbfβ$^{f/f}$Osx-Cre* mice maintained strong adipogenic tendencies despite being cultured in osteogenic medium. qPCR and Western blot data demonstrated that compared to wild-type (WT) OBs, *Cbfβ$^{f/f}$Osx-Cre* and *Cbfβ$^{f/f}$Prx1-Cre* OBs highly expressed adipocyte regulator genes and marker genes (*e.g. Clebpα, PPARγ, FABP4*). Using chromosome immonoprecipitation (ChIP) analysis, we determined that Cbfβ binds to both *Clebpα* and *PPARγ* promoters at the Cbfβ/Runx binding sites near their transcription start sites. Promoter analysis data showed that Cbfβ and Runx2 co-transfection, but not Cbfβ alone, highly inhibited *Clebpα* promoter activity, indicating that inhibition functioned through the Cbfβ/Runx2 complex. We also wondered how Cbfβ promotes OB lineage commitment. Our data showed that although *β-catenin* mRNA expression was similar between WT and *Cbfβ$^{f/f}$Osx-Cre* cells, non-phosphorylated (active form) β-catenin protein was dramatically increased, and β-catenin cell nucleus translocation was also increased in *Cbfβ$^{f/f}$Osx-Cre* cells, indicating that Cbfβ may promote MSC lineage commitment through Wnt/β-catenin signaling. In summary, we demonstrated that Cbfβ regulates MSC differentiation toward osteoblastogenesis by inhibiting both *C/ebpα* and *PPARγ* expression at the transcriptional level and by activating Wnt/β-catenin signaling. Our study indicates that Cbfβ regulates MSC lineage determination and can be a new therapeutic target of aging-related bone diseases (*e.g.* human age-related osteoporosis).

FR0235

Bone lining cells are a major source of osteoblasts during bone remodeling. igor Matic*[1], Brya Matthews[2], Ivo Kalajzic[2]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut Health Center, USA

During development osteoblasts are derived from multipotent mesenchymal stem cells. Similarly, during bone remodeling mesenchymal progenitor cells from bone marrow are thought to provide a continuous supply of mature osteoblasts. Osteoblasts can undergo apoptosis, or differentiate into osteocytes or quiescent bone lining cells (BLC). Activation of BLCs has been recently identified as a source of osteoblasts following intermittent PTH administration. The aim of this study was to determine if BLCs serve as a source of active osteoblasts during bone remodeling.

To selectively identify BLCs we utilized a transgenic approach in which osteoblasts and a subset of osteocytes are labeled using 10kb-Dmp1-CreERt2/Ai9 (DMP-Ai9) mice following tamoxifen treatment (Cre directed Tomato expression). Cell fate was determined histologically at time points where osteoblasts would be expected to either undergo apoptosis or differentiation.

By 40 days after labeling, matrix producing osteoblasts were still labeled, suggesting continuous activation of BLCs and supporting the idea that they could be a source of mature osteoblasts. To eliminate the possibility that osteoblasts lifespan is much longer than expected we selectively eliminated osteoblasts using a Col2.3?TK suicide gene. We introduced the Col2.3ΔTK into DMP-Ai9 mice to ablate preosteoblasts/osteoblasts while retaining BLCs. Following ganciclovir treatment, cuboidal osteoblasts were absent, while flat BLCs were labeled. Following 21 days of recovery, new osteoblasts form, and new areas of active bone surface are covered by DMP-Ai9 expressing osteoblasts. EdU staining demonstrated DNA synthesis in some of these labeled cells, suggesting their ability to divide. Bone marrow derived stromal cells do not generate DMP-Ai9 labeled bone nodules confirming that DMP1 is not expressed in marrow progenitors. To evaluate the contribution of BLCs in fracture healing, we injected DMP-Ai9 mice with tamoxifen 40 days before fracture. 14 days post-fracture we did not observe contribution of labeled cells to the fracture callus.

Our results define the bone lining cells as a source of proliferating and mature osteoblasts during bone remodeling, but not during fracture healing.

Chondrocytes Are a Major Source of Osteoblasts in Endochondral Bones *in Vivo*. Xin Zhou*[1], Stephen Henry[2], Benoit de Crombrugghe[3], Klaus von der mark[4], Henry adams[5]. [1]MD Anderson Cancer Center, USA, [2]University of Texas MD Anderson, USA, [3]UT MD Andrson cancer center, USA, [4]University of Erlangen-Nuremberg, Germany, [5]UT MD Anderson, USA

One of the crucial steps in endochondral bone formation is the replacement of a cartilage matrix produced by chondrocytes with bone trabeculae made by osteoblasts. However, the precise sources of osteoblasts responsible for trabecular bone formation have not been fully defined. To investigate whether cells derived from hypertrophic chondrocytes contribute to the osteoblast pool in trabecular bones, we genetically labeled either hypertrophic chondrocytes by *Col10a1-Cre* or chondrocytes by tamoxifen-induced *Agc1-CreERT2* using either *EGFP*, or *LacZ or Tomato* expression. Both Cre drivers were specifically active in chondrocytic cells not in perichondrium, in periosteum and in any of the osteoblast lineage cells. These *in vivo* experiments allowed us to follow the fate of cells labeled in *Col10a1* or *Agc1*-expressing chondrocytes. After the labeling of chondrocytes, abundant non-chondrocytic labeled cells were present in the primary spongiosa from the onset of primary ossification to after birth. These cells were distributed throughout trabeculae surfaces and after birth were present in the endosteum, and embedded within the bone matrix. Co-expression studies using osteoblast markers indicated that a proportion of the non-chondrocytic cells derived from chondrocytes labeled by *Col10a1-Cre* or by *Agc1-CreERT2* were functional osteoblasts. Our results thus indicate that *Col10a1* or *Agc1*-expressing chondrocytes have the capacity to undergo transdifferentiation to become osteoblasts. The osteoblasts derived from *Col10a1*-expressing hypertrophic chondrocytes represent about sixty percent of all mature osteoblasts in endochondral bones of one month old mice. In addition to cells in the periosteum, *Col10a1* and *Agc1*-expressing chondrocytes represent another major source of osteoblasts contributing to endochondral bone formation *in vivo*.

EP1 Deletion Enhances Mitochondrial Activity in Mesenchymal Stem Cell and Promotes Osteogenicity. Marina Feigenson*[1], Jennifer Jonason[2], Alayna Loiselle[2], Roman Eliseev[2], Regis O'Keefe[2]. [1], USA, [2]UNIVERSITY OF ROCHESTER, USA

Prostaglandin E2 (PGE2) is an important regulator of bone metabolism and is essential for bone regeneration. The function of the PGE2 receptor, EP1, in bone, however, is not well understood. We have recently demonstrated that *EP1*$^{-/-}$ mice have enhanced fracture repair due to accelerated MSC osteoblastic differentiation, identifying EP1 as a negative regulator of bone formation. In the present study we sought to determine the cellular mechanisms through which loss of EP1 exerts a bone anabolic effect in mesenchymal stem cells (MSCs). Emerging evidence has identified mitochondrial function as a key factor in stem cell fate, while the loss of CD105 is associated with more committed stem cell populations. We tested the overall hypothesis that EP1 suppresses MSC osteoblastic differentiation and bone formation by inhibiting mitochondrial activity and increasing the population of CD105^{-} cells suggestive of more differentiated MSCs. Bone Marrow MSCs were isolated from wild type (WT) and *EP1*$^{-/-}$ mice; the progenitor cell populations were assessed by flow cytometry and colony forming unit (CFU) assays, while mitochondrial activity was measured using the XF24 analyzer, and mitochondrial numbers and structure determined by electron microscopy.

EP1$^{-/-}$ MSCs exhibited an increased CFU-F and CFU-O (8 and 10 times increase, respectively) and a 10 times increase in the CD45^{-}CD31^{-}Sca1^{+}CD105^{-} population relative to WT controls (Figure 1). Additionally, *EP1*$^{-/-}$ MSCs exhibited enhanced osteoblastic differentiation, supporting the concept of EP1 as negative regulator of bone formation. Also, we observed higher levels of mitochondrial activity as measured by levels of basal (6 times increase) and ATP-linked respiration (7 times increase) relative to WT controls (Figure 2). Electron microscopy showed *EP1*$^{-/-}$ MSCs have mitochondria with more developed cristae. Moreover, blocking the oxidative phosphorylation inhibited the enhanced osteoblastic differentiation of *EP1*$^{-/-}$ cells.

Taken together, these data identify PGE2/EP1 signaling as a negative regulator of bone formation, and suggest that EP1 maintains MSCs in an undifferentiated state by inhibiting the switch to oxidative phosphorylation. Conversely, loss of EP1 enhances mitochondrial activity, leading to more rapid osteoblastic differentiation and bone formation. These studies identify EP1 as a novel target to enhance bone regeneration, and suggest EP1 antagonism as a potential therapeutic mechanism.

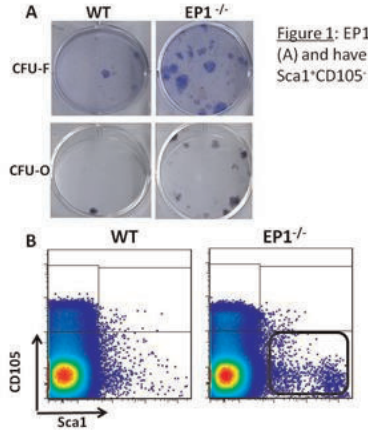

Figure 1: EP1$^{-/-}$ Bone marrow cells form more colonies (A) and have increased population of the C45^{-}CD31^{-} Sca1^{+}CD105^{-} cells (B).

ER Stress Signaling Molecule IRE1α Regulates Bone Develpment and Confers Genetic Risk for Human Osteoporosis. Shankar Revu*[1], Kai Liu[2], Fengming Wang[1], Konstantinos Verdelis[1], Mariana Bezamat[1], Alexandre Vieira[1], Hong-Jiao Ouyang[3]. [1]University of Pittsburgh, USA, [2], USA, [3]University of Pittsburgh, USA

The inositol-requiring enzyme 1α (IRE1α)/ X-box binding protein 1s (XBP1s) pathway is an evolutionarily conserved endoplasmic reticulum (ER) stress signaling and implicated in numerous physiological and pathological processes, such as the development of secretory organs and pathogenesis of inflammatory bowl disease, respectively. Upon ER stress, IRE1α acts through its endoribonuclease activity to generate spliced Xbp1 (Xbp1s) to maintain intracellular protein homeostasis. Osteoblasts are professional secretory cells. However, it remains essentially unknown whether IRE1α is required for bone development and homeostasis. To address this question, we performed a serial of functional and genetic studies as following. First, we, via immunohistochemical stains, observed that both IRE1α and XBP1 were highly expressed in osteoblastic cells of the developing bones. Further, it was observed that the endoribonuclease activity of IRE1α, as reflected by the ratio of Xbp1s vs. total Xbp1 (Xbp1t) mRNA, increased in bone tissues from post-natal day 14 to day 90. Moreover, ascorbic acid stimulated the gene expression of Sec61α, a XBP1s transcription target in osteoblastic MC3T3E1 cells. These results suggest that activation of IRE1α/XBP1s signaling is a physiological event intrinsic to osteoblast differentiation and bone development. Second, we generated mice lacking osteoblast-specific Ire1α (CKO) and their wild type littermates (WT) by breeding the Ire1αFlox/Flox mice with Osterix-Cre mice. It was observed that the Ire1α CKO mice exhibited reduced bone mass and increased marrow fat compared with the WT littermates, as shown by micro-qCT and histological analysis. Further, the CKO mice displayed reduced cell proliferation and dynamic bone formation of axial bones, as shown by calcein double labeling and BrdU immunostaining, respectively. These results demonstrate that the osteoblastic IRE1α is an important regulator for osteoblasto-genesis and bone marrow fat metabolism in vivo. Third, we performed association studies to detect over-representation of alleles in cases of human osteoporosis using common single nucleotide polymorphism (SNP) variants of IRE1α and XBP1s, and detected association between osteoporosis and IRE1 rs11655020 (p=5.0E-5) and XBP1 rs2097461 (p=0.004). Taken together, these findings, for the first time,

demonstrate that IRE1α is an essential regulator for bone development and a novel genetic risk factor for human osteoporosis.

Aging is a complex process that results in the decline of physiologic functions due to accumulation of damage in cells and tissues as well as in reduced repair capacities. The regenerative power of stem and progenitor cells has been found to decline with age and to be influenced by the systemic environment. In particular osteogenic differentiation capacity of mesenchymal stem cells (MSCs) has been shown to decrease with age thereby contributing to slowed down bone formation that might contribute to osteopenia or osteoporosis. Here, we set out to identify circulating factors of the aged systemic environment that influence the functionality of adult stem cells.

In order to identify such factors, serum of young versus elderly healthy individuals was tested for miRNAs and proteins. Indeed, we found miR-31 to be higher in elderly donors. As possible source we identified senescent endothelial cells that secrete miR-31 also in vitro, packaged into exosomes. Functionally characterizing miR-31 containing exosomes revealed that both, exosomes of senescent cells as well as exosomes of elderly donors, deliver miR-31 to mesenchymal stem cells and inhibit osteogenic differentiation. The effect of the vesicles can be rescued by antagonistic miR-31. One of the novel targets of miR-31 in this context is the Wnt ligand FZD3 whose knock-down leads to a similar inhibition of osteogenic differentiation as miR-31. In addition, we found that one microvesicular protein, Galectin 3 (Gal-3), that supports osteogenic differentiation is significantly decreased in the serum of elderly donors. Therefore, we postulate here that circulating microvesicles and their content might represent biomarkers and therapeutic targets whenever osteogenesis is a limiting factor, especially in age-related diseases like osteoporosis.

iPS cell derived Endothelial Cells in Fibrodysplasia Ossificans Progressiva. Emilie Barruet*[1], Wint Lwin[2], Marcela Morales[2], Ashley Urrutia[2], Hannah Kim[2], Christina Theodoris[3], Mark P. White[4], Deepak Srivastava[5], Edward Hsiao[1]. [1]University of California, San Francisco, USA, [2]University of California, San Francisco, USA, [3]Gladstone Institute of Cardiovascular Disease, USA, [4]Gladstone Institute of Cardiovascular Disease, San Francisco, CA, USA, [5]Gladstone Institutes, USA

Musculoskeletal disorders affecting the bones and joints are major health problems for children and adults. Unfortunately, treatments for skeletal diseases are still rudimentary. The recent advent of human induced pluripotent stem cells (hiPSCs) provides an unparalleled opportunity to create human-specific models of human skeletal diseases. Patients with mutations in the Activin A Type I receptor (ACVR1), a BMP (bone morphogenetic proteins) receptor, develop the debilitating disease fibrodysplasia ossificans progressiva (FOP) showing progressive ossification of muscle and tendon. The majority of ACVR1 mutations occur in a single amino acid (R206H) that may increase ACVR1 signaling activity. Recent data suggest that human endothelial cells (ECs) carrying the ACVR1 R206H mutation may contribute to the formation of FOP lesions. Our overall hypothesis is that activated BMP signaling caused by the ACVR1 R206H mutation in ECs increases heterotopic bone formation by increasing osteogenesis. In this study, we use a series of human iPSCs created from control and FOP donors to create iPS cell derived endothelial progenitor cells (iECs) as primary ECs cannot be isolated from FOP patients. $CD31^+/KDR^+$ iECs formed at equal yields of 25% from both control and FOP iPS lines. FACS analysis of these $CD31^+/KDR^+$ iECs showed that 95% of the cells expressed $CD31^+/CD144^+$, two markers found on mature ECs. We also found that FOP iPSCs could form iECs at lower BMP4 concentrations compared to control iPSCs, even in conditions lacking BMP4 (1% FOP vs 0.1% WT yield). Surprisingly, FOP endothelial cells showed little difference in mineralization using a 2D assay. However, a 3D protocol that recapitulates the endochondral bone formation through chondrogenic steps indicates that FOP iECs can form abundant chondrocytes by alcian blue staining. Here we show that FOP endothelial cells can have chondrogenic/osteogenic potential which may be critical for heterotopic ossification in FOP patients. These studies demonstrate the use of human iPSCs as a source for creating specific cell types to study their roles in human skeletal formation and diseases. The cellular mechanistic insights gained from these studies establish a foundation for understanding how endothelial cells contribute to heterotopic ossification and identifying new therapies not only for FOP but also other diseases of abnormal skeletal formation.

Neural Origin of Osteoblasts during Heterotopic Ossification. ZaWaunyka Lazard*[1], Elizabeth Salisbury[1], Eric Beal II[2], Elizabeth Olmsted-Davis[1], Alan Davis[1]. [1]Baylor College of Medicine, USA, [2]Baylor College of Medicine, USA

Heterotopic ossification (HO) is a disease in which *de novo* bone formation occurs in non-skeletal tissues. Although the clinical etiology of HO is unclear, it often follows traumatic injury to skeletal bone and/or soft tissues associated or the nervous system. Recently, our laboratory demonstrated immediate structural changes to the local peripheral nerves, as well as both sensory and sympathetic signaling, within 48 hours of inducing HO through localized delivery of BMP2. Here we identify and characterize a unique cell population within the endoneurial compartment of peripheral nerves that replicates, migrates and undergoes osteogenic differentiation in response to the BMP2. Immediately upon delivery of BMP2, cells within the endoneurium start to express osterix protein. By 48 hours after delivery these cells are now observed outside the nerve, co-expressing claudin 5, a tight junctional protein on endothelial cells shown to be involved in regulating the "blood nerve barrier". In the presence of BMP2, these cells start to express the replication marker ki-67. Quantification of the claudin 5^+ cells on day 0, 2, and 4, using fluorescence activated cell sorting (FACs) shows a significant increase in the number positive cells at 2 and 4 days after induction of HO. Isolation of these claudin 5 positive and negative populations confirmed expression of $osterix^+$ as well as $dlx5^+$ were found only in the positive population. Both markers are associated with osteogenesis in neural stem cell migration in the embryo. Interestingly, they also express the neural stem cell factor musashi, which is also associated with migrating neural crest stem cells. Immunohistochemical analysis of slides generated during each day of the HO process, suggests that these claudin 5^+ cells maybe extravasating out of the nerve, through newly formed vasculature, to be later deposited between the muscle fibers, where they eventually form osteoblasts associated with the new bone. These cells also co-express PDGFRα, a key regulatory factor associated with glial cells and previously reported to be on the osteogenic stem cell for HO. The data collectively suggests that endoneurial compartment of peripheral nerves may house a unique stem-progenitor, that can rapidly expand and undergo osteogenesis during heterotopic bone formation.

Choline Kinase Beta is an Important Regulator of Bone Homeostasis. Jennifer Tickner*[1], Jasreen Kular[2], Nathan Pavlos[3], Tamara Abel[4], BaySie Lim[5], Ming Hao Zheng[3], Jiake Xu[6]. [1]University of Western Australia, Australia, [2]University of Western Australia, Australia, [3]University of Western Australia, Australia, [4]Centre for Microscopy, Characterisation & Analysis, University of Western Australia, Australia, [5]University of Western Australia, Australia, [6]University of Western Australia, Australia

The maintenance of bone homeostasis requires tight coupling between the bone-forming osteoblasts and bone-resorbing osteoclasts. However, the precise molecular mechanism(s) underlying the activities of these specialized cells are still largely unknown. In search of novel molecules involved in bone homeostasis, we systematically screened a number of ENU-induced mutant mouse lines. Here we identify choline kinase beta (CHKB), a kinase involved in the biosynthesis of phosphatidylcholine, as a regulator of adult bone homeostasis. Choline kinase beta mutant mice (flp/flp) exhibit a systemic low bone mass phenotype comparable to osteoporosis. Consistently, osteoclast numbers and activity are elevated in flp/flp mice. Interestingly, although the area resorbed by flp/flp osteoclasts is not significantly different, pits are deeper, leading to increased CTX release in flp/flp cultures. Osteoclasts derived from flp/flp mice exhibit reduced sensitivity to excessive levels of extracellular calcium, a feature that allows them to persist at sites of bone resorption. We also demonstrated that, in addition to modulating osteoclast formation and function, a loss of CHKB also corresponds with a reduction in bone formation by

osteoblasts.1H-NMR spectroscopy revealed significant reductions in phosphocholine levels, the product of the choline kinase enzymatic reaction, in both osteoclasts and osteoblasts. Furthermore, levels of phosphatidylcholine, a major membrane phospholipid derived from phosphocholine were also reduced. Phosphocholine is an essential source of phosphate for biomineralisation by osteoblasts, we showed that osteoblasts from flp/flp mice had reduced phosphate release from matrix vesicles, consistent with their reduced phosphocholine levels. Supplementation of flp/flp mice with CDP-choline (Cytidine 5'-diphosphocholine) both *in vivo* and *in vitro*, a regimen which bypasses CHKB deficiency downstream of phosphocholine, restores osteoclast numbers to physiological levels, but does not restore osteoblast function. Taken together, these data posit CHKB as a new modulator of bone homeostasis through effects on both osteoclasts and osteoblasts.

Genetic Activation of *Nlrp3* Reveals NLRP3 Inflammasome Role in Osteoclast Activity. Chao Qu*[1], Samer Abu-Amer[2], Sheri Bonar[3], Jacqueline Kading[4], Yousef Abu-Amer[5], Roberto Civitelli[5], Gabriel Mbalaviele[5]. [1]Washington University in St Louis, USA, [2]Washington University in St. Louis, USA, [3]Washington University in St. Louis, USA, [4]Washington University in St Louis, USA, [5]Washington University in St. Louis School of Medicine, USA

Autosomal-activating mutations in *NLRP3* cause excessive maturation of IL-1β by the NLRP3 inflammasome, ultimately promoting systemic inflammation and bone resorption in humans. Yet, skeletal anomalies in these patients continue to worsen even under treatment with IL-1β inhibitors, while other symptoms related to systemic inflammation are resolved, suggesting alternative mechanisms of inflammasome actions in the skeleton. To gain insights into the skeletal complications caused by hyper-active NLRP3, we engineered a *floxed-Nlrp3* allele for conditional activation of the NLRP3 inflammasome. We find that myeloid activation of this inflammasome by *LysM-Cre* causes approximately 60% lower bone mass associated with severe inflammation. However, mice with osteoclast (OC)-restricted inflammasome activation by *CatK-Cre* (*CreK* mice) are osteopenic (approximately 50% reduction relative to control mice) in the absence of inflammation. Serum CTX-1 levels are higher in *CreK* mice relative to wild-type (WT) mice (72.77 ± 20.15 ng/ml vs. 42.93 ± 9.52 ng/ml), but there is no difference in OC number on bone surfaces between the two genotypes. These results suggest increased cell autonomous OC activity in mutant mice, and strengthen the emerging concept that the NLRP3 inflammasome has cytokine-autonomous functions. *In vitro,* the number of OC forming from *CreK* and WT bone marrow macrophages treated with RANKL and M-CSF is comparable between both genotypes, findings consistent with *in vivo* results. In contrast, *CreK* OC display larger F-actin rings, and form larger resorption lacunae than WT OC (5236 ± 502 μm^2 vs. 2623 ± 725 μm^2, $p<0.001$), despite comparable number on bone slices, results corroborated by higher release of CTX-1 by mutant cells relative to WT cells (16.55 ± 5.17 nM vs. 6.66 ± 7.28 nM, $p<0.05$). Immunofluorescence show a punctuate patterns of NLRP3 expression in WT and mutant cells, reminiscent of active inflammasome, and indicative of active NLRP3 inflammasome even in WT OC. Thus, we have uncovered a novel mechanism whereby the NLRP3 inflammasome regulates OC activity in a cell autonomous manner independently of the inflammatory process.

Osteoclast ruffled border formation and bone resorption require Plekhm1-regulated lysosomal secretion. Toshifumi Fujiwara*[1], Jian Zhou[2], Shiqiao Ye[1], Stavros Manolagas[1], Haibo Zhao[1]. [1]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [2]UAMS, USA

Osteoclasts (OCs) resorb the mineralized bone matrix by secreting protons and cathepsin K (CTSK) through the ruffled border (RB) which is circumscribed by the sealing zone (actin-ring). While the mechanisms of how RANKL and integrin signaling activate actin-ring formation through c-Src have been well defined, it is unknown whether and how RANKL and integrins promote the secretory function of OCs. Genetic studies in humans and rodents with osteopetrosis have uncovered a central role of lysosomal pathways in OC function. However, it has remained unclear whether RB formation requires de novo biogenesis of lysosomes and/or their secretion. Plekhm1 (PLK1) is a lysosome-associated protein the mutations of which lead to osteopetrosis in humans and rats. Because of earlier evidence that PLK1 is indispensable for CTSK secretion, we studied here the role of lysosome trafficking in RB formation by crossing PLK1-floxed mice with LysM-Cre mice, thus, deleting PLK1 in myeloid cells. OC differentiation, actin-ring formation, and microtubule organization remained normal in PLK1$^{-/-}$ cells. However, the resorptive capacity of PLK1$^{-/-}$ OCs was markedly reduced as compared to control cells (Con). Reconstitution of PLK1$^{-/-}$ OCs with wild type PLK1, but not PLK1 mutants of human and rat osteopetrosis , rescued CTSK secretion as well as RB formation and bone resorption. The morphology and function of the Golgi apparatus and endocytosis was unaffected by the loss of PLK1, as determined by immunofluorescent staining. Using an EGF receptor degradation assay - a classic readout of lysosome function- we determined that the degradation of this receptor was also unaffected; and so was autophagosome formation, as measured by LC3-II/I ratio and ATG5-ATG12 conjugation. However, while the level of Lamp2, a lysosomal membrane protein, was similar between Con and PLK1$^{-/-}$ OCs, loss of PLK1 caused an accumulation of enlarged lysosomes around the nuclei, as shown by live cell time-lapse imaging of actin-RFP and Lamp2-GFP expressing OCs. Furthermore, RB formation was completely absent in PLK1$^{-/-}$ OCs, as determined by electron microscopic examination. Finally, using mass spectrometry we found that the PLK1 protein was bound to Rab7 and several components of the RANKL and integrin signaling complexes as well as microtubule motors. Collectively, these results demonstrate that PLK1 functions as an indispensible adaptor protein that bridges the RANKL and integrin signalings to lysosomal secretion.

FR0254

Snx10-dependent osteoclastic activity and gastric acidification is required for bone and calcium homeostasis. Liang Ye*[1], Leslie Morse[2], Li Zhang[3], Hajime Sasaki[4], Jason Mills[5], Greg Sibbel[5], Ariane Zamarioli[6], Ricardo Battaglino[4]. [1]The Forsyth Institute & Harvard School of Dental Medicine, USA, [2]Harvard Medical School, USA, [3]The Forsyth Institute, USA, [4]The Forsyth Institute, USA, [5]Washington University School of Medicine, USA, [6]University of Sao Paulo, Brazil

Autosomal recessive osteopetrosis (ARO) is a heterogeneous genetic disease characterized by osteoclast failure and high childhood mortality. Approximately 25% of all human osteopetrosis cases are caused by mutations in unidentified genes. We previously identified Snx10 and demonstrated that this gene plays an essential role in osteoclast vesicle trafficking and bone resorption in vitro. Mutations in conserved residues in the human SNX10 were later described in patients with infantile osteopetrosis whose osteoclasts have altered endosomal pathways and reduced resorptive capacity. SNX10 is now known to account for ~4% of all cases of ARO. To study the role of Snx10 in bone homeostasis *in vivo*, we generated global and osteoclast-specific Snx10-deficient mouse strains. Global Snx10-deficient mice (Snx10 *ins/ins*) die prematurely at 3 weeks and exhibit a severe osteopetrosis with a superimposed mineralization defect. *Snx10 ins/ins* osteoclasts fail to endocytose dextran, form a ruffle border, or acidify the resorption lacuna. The mineralization defect, consistent with rickets, suggested that Snx10 is also required for calcium homeostasis. We found Snx10 to be also expressed in gastric zymogenic cells. Similar to osteoclasts, *Snx10 ins/ins* gut zymogenic cells exhibit a defect in secretory vesicle formation leading to hypochloridria and hypocalcemia. Osteoclast-specific Snx10 deficiency, on the other hand, has no effect on net calcium balance and consequently results in osteopetrosis with no rickets. *The global Snx10-deficient mice thus exhibit a complex phenotype that is a combination of osteopetrosis (due to impaired OC resorption) and rickets (impaired mineralization due to poor calcium absorption).* Finally, dietary supplementation with calcium gluconate rescues the rachitic phenotype and *dramatically extends life span* in Snx10-gobal deficient mice, suggesting that this may be a critical component of the clinical approach to Snx10-dependent human osteopetrosis that has previously gone unrecognized. We conclude that Snx10 is essential both for bone resorption and for gut acidification by regulating vesicular trafficking in both osteoclasts and gut zymogenic cells. Though the physiological links between the GI tract and bone have been known for decades, the current work is among the first to delineate the genetic mechanisms shared between these two tissues.

FR0255

Specific Ostm1 ablation in the hematopoietic mature osteoclast induce severe osteopetrosis. Jean Vacher*[1], Monica Pata[2]. [1]Institut De Recherches Cliniques De Montréal, Canada, [2]IRCM, Canada

The spontaneous recessive mouse mutant grey-lethal (gl/gl) in the Ostm1 gene causes severe osteopetrosis and neurodegeneration. Ostm1 gene has a wide expression pattern particularly in hematopoietic lineages in the myeloid osteoclast and lymphoid cells. Cellular characterization of gl/gl hematopoiesis showed that multipotent cells can differentiate into all lineages and that the osteoclast lineage, from early progenitors to mature cells, is markedly stimulated. The mature gl/gl osteoclasts are in contrast poorly functional and display cytoskeletal defects. Importantly, targeting Ostm1 expression to committed osteoclast progenitors by TRAP-Ostm1 transgenic mice was insufficient to rescue mature osteoclast defects. However, full rescue of the gl hematopoietic defects in myeloid and lymphoid lineages including osteoclast, B and T cells, was attained when Ostm1 was expressed from a PU.1-BAC transgene in gl/gl mice establishing a probable hematopoietic crosstalk. To specifically address the role of Ostm1 in mature osteoclasts, we generated a conditional Ostm1 allele and induced specific mature osteoclast ablation using the CathepsinK-Cre deleter mouse. Specific recombination was concomitant with osteoclast maturation and loss of Ostm1 reached ~100% efficiency in fully mature OCLs produced ex vivo. In vivo loss of Ostm1 in mature osteoclasts resulted in a severe osteopetrotic phenotype as determined by a massive increase of bone mass with inefficient bone resorption, a lack of tooth eruption and early death around three weeks of age. All these features closely recapitulate the skeletal phenotypes that we characterized in the spontaneous germline Ostm1-null gl/gl mouse mutant. Taken together our studies demonstrate that

loss of Ostm1 in mature osteoclasts is sufficient to induce severe osteopetrosis as well as highlight the intricate role of Ostm1 on the hematopoietic cellular interactions.

Targeting Cathepsin K to attenuate Toll-Like Receptor (TLR) signaling inhibits rheumatoid arthritis and periodontitis and reveals the critical function of Cathepsin K in osteoimmunology. Liang Hao*, Wei Chen, Yi-Ping Li. University of Alabama at Birmingham, USA

Despite many studies that have aimed to alleviate the effects of rheumatoid arthritis (RA) and periodontal disease, there is still an urgent need to improve the health of those suffering from these two inflammatory diseases. This study aims to discover new therapeutic targets and simultaneously reduce inflammation and bone resorption through a single target: Cathepsin K (Ctsk). The critical role of Ctsk in the immune response has not been established *in vivo* in RA and periodontitis. We hypothesized that RA and periodontitis may share the same immune response pathway. Thus, we explored the possible underlying mechanism using *Ctsk* knockout mice in the TNF-alpha overexpression-induced RA mouse model and the bacterial-induced periodontitis mouse model. Our data demonstrated that knockout of *Ctsk* can significantly reduce inflammation, meanwhile can inhibit cartilage destruction and bone resorption in both RA and periodontitis lesion areas. We also found that the number of macrophages, dendritic cells and T-cells were largely decreased in both lesion areas. Furthermore, knockout of *Ctsk* inhibited TLR4, 5 and 9 expressions in the gingival epithelial cell in periodontitis lesions and synovial fibroblast cells in RA lesions, indicating the innate immune response was also inhibited. Compared to wild-type (WT) dendritic cells (DCs) when stimulated by CpG DNA *in vitro*, the expression of inflammatory cytokines (*e.g.* TNFα, IL-1, and IL-6) in *Ctsk*$^{-/-}$ DCs was significantly impaired at both protein level and mRNA level. However, the expression of inflammatory c----ytokines in the *Ctsk*$^{-/-}$ DCs stimulated by Lipopolysaccharide (LPS) were not changed when compared to WT DCs. qRT-PCR analysis showed that the expression of *TLR4*, *5*, and *9* decreased in *Ctsk*$^{-/-}$ DCs when stimulated. However, knockout of *Ctsk* only affected TLR9 not TLR4 downstream signaling (*e.g. MyD88*, *TRAF6*, *IRAK1,* and *IRAK4*) when stimulated by CpG DNA and LPS. In summary, we demonstrated that Ctsk positively regulates immune responses in both RA and periodontitis disease models. Our data demonstrated that Ctsk promotes TLR4, 5 and 9 function and expression in immune cells both *in vivo* and *in vitro*. Inhibition of Ctsk can impair this immune response process, which may be a promising target to treat RA and periodontitis. Our study demonstrated the critical function of Ctsk in osteoimmunology and indicates that inhibition of Ctsk may have novel therapeutic functions in osteoclast and immune-related bone diseases.

TRAP-Positive Multinucleated Cell Independent Bone Resorption in a Mouse Model of Inflammatory Bone Disease. Mizuho Kittaka*[1], Tomoyuki Mukai[2], Teruhito Yoshitaka[3], Yasuyoshi Ueki[4]. [1]University of Missouri-Kansas City School of Dentistry, USA, [2]University of Missouri - Kansas City, USA, [3]University Missouri-Kansas CitySchool of Dentistry, USA, [4]University of Missouri-Kansas City, School of Dentistry, USA

Osteoclasts are regarded as the exclusive bone-resorbing cells in pathological inflammatory bone destruction. This is based on observations that bone destruction is absent in osteoclast-free animal models of inflammatory bone disease such as TNF-α transgenic mice deficient in c-fos. Therefore, we hypothesized that ablation of osteoclasts would rescue the inflammatory bone destruction in *Sh3bp2*$^{KI/KI}$ mice, a knock-in (KI) mouse model of cherubism (*Sh3bp2*$^{KI/KI}$). These mice exhibit TNF-α-dependent macrophage inflammation and increased RANKL-induced osteoclastogenesis resulting in inflammatory bone destruction. To test this hypothesis, we created *Sh3bp2*$^{KI/KI}$ mice on a c-fos-deficient background. Surprisingly, although the severity of bone erosion was less than on a *c-fos*$^{+/+}$ background, bone erosion was still present in *Sh3bp2*$^{KI/KI}$/*c-fos*$^{-/-}$ mice by microCT analysis. This bone erosion occurred even though no TRAP-positive (+) multinucleated cells were detected in *Sh3bp2*$^{KI/KI}$/*c-fos*$^{-/-}$ mice. H&E staining showed inflammatory infiltrates surrounding joints and on the surface of long bones in *Sh3bp2*$^{KI/KI}$/*c-fos*$^{-/-}$ mice, presumably responsible for the bone erosion. Inflammatory infiltrates were also observed in liver, stomach, and lymph nodes in addition to bone. Immunohistochemical staining with antibodies against F4/80 for macrophages and against matrix metalloproteinase (MMP)-9 showed that the cellular infiltrates at the eroded bone surfaces were positive for both. Real-time PCR analysis of spleen-derived M-CSF-dependent macrophages showed increased expression of MMP-9 (average 31-fold, n=2) and MMP-14 (average 46-fold, n=2) in *Sh3bp2*$^{KI/KI}$/*c-fos*$^{-/-}$ macrophages compared to *Sh3bp2*$^{+/+}$/*c-fos*$^{-/-}$ macrophages. Finally, *Sh3bp2*$^{KI/KI}$/*c-fos*$^{-/-}$ M-CSF-dependent macrophages derived from fetal liver cells formed resorption pits on dentin slices when cultured with TNF-α and RANKL. These results suggest that *Sh3bp2*$^{KI/KI}$/c-*fos*$^{-/-}$ mice develop TRAP+ multinucleated osteoclast-independent inflammatory bone resorption that is carried out by macrophages and that MMPs expressed in macrophages likely play a role in the bone resorption. In this model, macrophages gain functional competence to resorb bone via SH3BP2 gain of function. To our knowledge, the *Sh3bp2*$^{KI/KI}$/*c-fos*$^{-/-}$ mouse is the first *in vivo* model showing TRAP+ multinucleated osteoclast-independent inflammatory bone resorption.

Cytosolic Calcium Flickers Orchestrate Steering during Osteoclast Migration. Benjamin Wheal*[1], S. Jeffrey Dixon[2], Stephen M. Sims[3]. [1]The University of Western Ontario, Can, [2]The University of Western Ontario, Canada, [3]The University of Western Ontario, Canada

Osteoclasts are multinucleated cells responsible for the resorption of bone and other mineralized tissues during development, physiological remodeling and pathological bone loss. Lamellipods are dynamic membrane protrusions at the perimeter of the osteoclast that advance the cell front during migration and are responsible for steering during chemotaxis. The purpose of this study was to investigate the subcellular Ca^{2+} signaling events underlying lamellipod dynamics, and how this signaling orchestrates turning in response to a chemotactic stimulus. We used ratiometric live-cell imaging to map $[Ca^{2+}]_i$ in real time within isolated rat osteoclasts. Vigilant regional analysis of multiple areas of interest revealed subcellular changes in $[Ca^{2+}]_i$. Osteoclasts that were not translating were still motile, as exemplified by the continuous ebb and flow of the lamellipod due to localized retraction and outgrowth. Ca^{2+} flickers − microdomains of elevated $[Ca^{2+}]_i$ lasting 25.5 ± 1.7 seconds – were observed sporadically within lamellipods. In most cases, Ca^{2+} flickers were followed promptly by local retraction of the lamellipod (72%) as opposed to outgrowth (20%, 25 different regions from 10 cells, $p < 0.05$). In keeping with this observation, regions of lamellipods exhibiting outgrowth most often did NOT exhibit Ca^{2+} flicker activity (79%, 24 different regions from 9 cells, $p < 0.05$). Furthermore, many lamellipod regions showed outgrowth until a flicker promptly triggered localized retraction. Attenuation of flickers by the intracellular Ca^{2+} chelator BAPTA promoted unchecked lamellipod outgrowth accompanied by impaired lamellipod retraction, creating highly elongated osteoclasts with a dendritic appearance. The role of Ca^{2+} flickers in steering osteoclasts during chemotaxis was investigated by creating a localized gradient of M-CSF. Directed migration induced by M-CSF promoted asymmetric Ca^{2+} flicker activity in lamellipods across the cell. Flicker activity was predominantly on the side of the lamellipod distant from the source of M-CSF, causing regional retraction (pruning). Thus, lamellipod retraction at distant sites underlies turning of the osteoclast towards the M-CSF. Here we show, for the first time, a role for exquisite spatiotemporal regulation of subcellular Ca^{2+} in the steering of migrating osteoclasts. Ca^{2+} flickers orchestrate osteoclast steering through lamellipod pruning, thereby encoding directional preference in response to a chemical cue.

mTORC1 Activity in Osteoclasts is Regulated by Lysosomal pH. Luciene Carraro-Lacroix[1], Yingwei Hu[2], Celeste Owen[3], Irina Voronov*[4]. [1]Faculty of Dentistry, University of Toronto, Canada, [2]Institute of Dental Medicine, Qilu Hospital, Shandong University, China, [3]Centre for Modeling Human Disease, Samuel Lunenfeld Research Institute, Mt Sinai Hospital, Canada, [4]University of Toronto, Canada

During bone resorption, osteoclasts (OCs) utilize vacuolar H^+-ATPases (V-ATPases), multisubunit enzymes, to pump protons onto the surface that needs to be resorbed. We have a mouse model with a point mutation (R740S) in the V-ATPase *a*3 subunit. These mice have defective V-ATPase activity resulting in mild osteopetrosis in heterozygous (+/R740S) and severe osteopetrosis in homozygous animals. OCs with R740S mutation have increased lysosomal pH and decreased *in vitro* OC differentiation.

To explain a connection between impaired OC-genesis in +/R740S cells and high lysosomal pH, we looked at autophagy, a lysosomal protein degradation pathway. Autophagy is activated in response to starvation (amino acid deprivation); in the presence of amino acids and growth factors, autophagy activation is inhibited by a complex containing Ser/Thr protein kinase mammalian target of rapamycin (mTOR), called mTORC1.

To assess autophagic flux, bone marrow-derived OCs were incubated with HBSS (starvation) for up to 2 hrs. Protein expression of two key molecules, microtubule-associated protein light chain 3 (LC3) and sequestosome 1 (p62/SQSTM1), was increased in +/R740S compared to +/+ cells, consistent with blocked autophagy. Immunofluoresence confirmed higher LC3 expression in +/R740S OCs. To investigate activation of mTORC1, the cells were incubated with HBSS for 60 min and then in fully supplemented media (recovery) for 30 min. Unexpectedly, mTOR protein levels as well as mTORC1 activity, as measured by phosphorylation of its substrate p-4E-BP1, were increased in +/R740S cells compared to +/+. mTORC1 is reported to be located on the lysosome, suggesting a link between lysosomal function and mTORC1 activity. To elucidate the mechanism of increased mTOR activity in +/R740S OCs, we hypothesized that upon amino acid signaling mTORC1 complex undergoes lysosomal degradation *via* the autophagy pathway. To test this hypothesis we treated OCs with lysosomal inhibitor chloroquine, known to elevate lysosomal pH. As a positive control, the cells were treated with proteasomal inhibitor MG132. Results demonstrated that 2 hour treatment with chloroquine increased mTOR protein levels

in +/+ OCs, confirming our hypothesis. mTOR protein levels in +/R740S OCs were not significantly affected by chloroquine, suggesting that a certain pH threshold is necessary for lysosomal protein degradation. These results show a novel molecular mechanism regulating mTOR protein levels and activity in OCs.

CHMP5 Is a Novel Risk Factor of Paget's Disease of Bone Regulating the NF-kB Pathway in Osteoclasts. Jae Hyuck Shim*[1], Kwang Hwan Park[2], Matthew Greenblatt[3]. [1]Weill Cornell Medical College, USA, [2]Yonsei University College of Medicine, USA, [3]Weill Cornell Medical College/ Brigham & Women's Hospital, USA

Purpose of this study is to understand molecular mechanisms of a novel mouse model of Paget's Disease of Bone (PDB).

PDB is one of the most profound disorders of imbalanced bone homeostasis, characterized by a wave of increased lytic osteoclast activity followed by a wave of increased osteoblast activity, resulting ultimately in bone thickening, sclerosis and expansion. These increases in osteoblast function and bone formation are believed to be driven by altered osteoclast differentation. The classic secondary consequences of this process include local osteoarthritis and nerve entrapment, due to increased bone formation, as well as increased rates of osteosarcoma. While these clinical consequences make understanding mechanisms of PDB itself important, the dramatic increaes in osteoblast activity secondary to increased ostoclast activity seen in PDB must use molecular pathways of universal biological importance in regulating bone mass. Identification of these pathways of low bone mass such as osteoporosis and lytic bone tumors.

For decades attempts have been made to understand the pathogenesis of PDB. Recent advances include identification of genetic risk factors in the heritable form of PDB, including the autophagy/endocytosis-regulatory protein encoded by p62/ SQSTM1 gene, and genes for valosin-containing protein (VCP), and optineurin. However, the mechanistic contribution of these genetic risk factors to the development of PDB remains to be elucidated. Recently, we have identified Chromatic Modifying Profein 5 (CHMP5) as a key regulator of NF-kB pathway and deletion of this gene increases NF-kB activity in osteoclasts in response to Receptor activator of nuclear factor kB ligand (RANKL). Accordingly, CHMP5 deletion enhances RANKL-induced osteoclast differentiation and mice lacking CHMP5 in mature osteoclasts using Cathepsin K (CTK)-cre mice (Chmp5-CTK mice) develop a severe, spontaneous disorder with nearly all the classic features of PDB, including the progressive deposition of osteoclast-rich periosteal bone with a typical "Pagetoid" appearance, gradual expansion of bones in both the axial and appendicular skeleton, enlarged osteoclasts with nuclear inclusion body, and increases in serum and histomorphometirc measurements of bone turnover. Therefore, understanding molecular mechanisms in this mouse model of PDB will contribute to identify novel therapeutic targets for the treatment of diseases of disordered bone remodeling and bone loss.

***β-catenin* deletion in Ctsk-expressing cells decreases bone mass.** Paula Ruiz[1], Marta Martin-Millan[2], Shoshana Bartell[3], Maria Jose Almeida[3], Marian Ros[4], Jesús Gonzalez-Macias*[5]. [1]Fundación Instituto de Investigación Marqués de Valdecilla, Spain, [2]University of Cantabria, IDIVAL, HUMV, Spain, [3]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [4]Instituto de Biomedicina y Biotecnología de Cantabria, Spain, [5]University of Cantabria, HUMV, IDIVAL, RETICEF., Spain

It is well established that activation of Wnt/ß-catenin signaling in the osteoblast lineage leads to an increase in bone mass through a dual mechanism: increased osteoblastogenesis and decreased osteoclastogenesis. More recently, it has been shown that β-catenin in the osteoclast lineage decreases osteoclast formation. Specifically, removal of β-catenin from Lysozime-M expressing cells causes an increase in osteoclast numbers and decreases bone mass. We now examined if mature osteoclasts were the target of β-catenin by generating mice lacking β-catenin in Cathepsin-K;Cre expressing cells (here after ΔCatnb;CtsK). ΔCatnb;CtsK mice were born at the expected Mendelian ratio and had no significant changes in body weight than their littermate controls. Osteoclasts developed from non-adherent bone-marrow cells obtained from ΔCatnb;CtsK mice expressed significantly lower levels of β-catenin as determined by RT-PCR, while no differences were detected in macrophages. In line with our previous model, ΔCatnb;CtsK mice exhibited a significant decrease in bone mass. At 3 months of age, BMD was lower in vertebrae (female p=0.0007, male p=0.011) and femur (female p=0.007, male p=0.008) as determined by DEXA. Also, micro-CT showed a decreased BV/TV and a decreased trabecula number in vertebra and femur in both genders. However, in striking contrast to what was seen when β-catenin was deleted in osteoclast progenitors expressing Lysozime-M, ΔCatnb;CtsK animals exhibited a severe cortical bone phenotype in vertebrae, distal femur and proximal tibia, characterized by large holes which allowed the visualization of the bone marrow (Figure 1). These findings suggest that the absence of β-catenin in Ctsk-expressing cells interferes with the physiological modeling process. In the mechanistic interpretation of these findings it must be taken into account that Cathepsin-K is expressed in cells other than osteoclasts, such as the perichondrial groove of Ranvier, which is considered to contain chondroprogenitors responsible for circumferential cartilage growth.

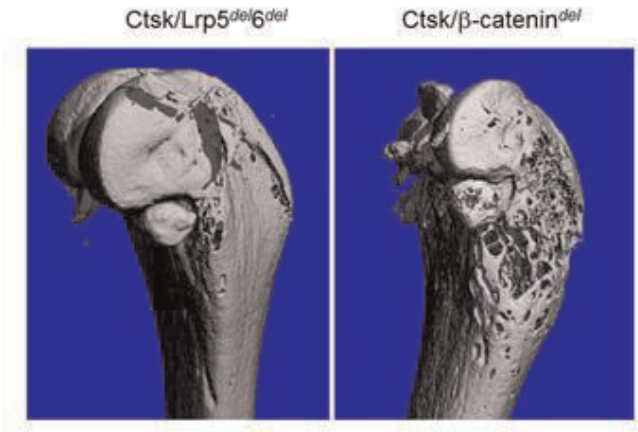
Deletion of Wnt Receptors Lrp5 and Lrp6 or ß-catenin in osteoclast precursors differentially affects skeletal development. Megan Weivoda*[1], Ming Ruan[2], Christine Hachfeld[2], Larry Pederson[2], Rachel Davey[3], Jeffrey Zajac[4], Yasuhiro Kobayashi[5], Bart Williams[6], Sundeep Khosla[7], Jennifer Westendorf[1], Merry Jo Oursler[1]. [1]Mayo Clinic, USA, [2]Mayo Clinic, USA, [3]University of Melbourne, Australia, [4]Austin Hospital, Australia, [5], Japan, [6]Van Andel Research Institute, USA, [7]Mayo Clinic College of Medicine, USA

Mutations to proteins in the Wnt signaling pathway result in human bone phenotypes. Many studies have examined the role of anabolic Wnt signaling in osteoblasts and osteocytes; however, few have investigated the role of Wnt signaling in the osteoclast lineage. We determined that the early but not late addition of Wnt3a to osteoclast precursors (pOCs) inhibits differentiation *in vitro*. Therefore, we tested the hypothesis that Wnt signaling in pOCs is an important contributor to skeletal development. Rank promoter Cre or cathepsin K (Ctsk)-Cre animals were crossed with Lrp5/Lrp6 flox mice to impair Wnt receptor signaling in early (Rank/Lrp$^{del/+}$) and late (Ctsk/Lrp^{del}) pOCs. In addition, Ctsk- Cre mice were crossed with ß-catenin (ßcat) flox mice to impair canonical Wnt signaling in late pOCs (Ctsk/ßcat^{del}). Rank-Cre double knockout of Lrp5/Lrp6 was not achieved; therefore, Rank/Lrp$^{del/+}$ mice were analyzed for bone phenotypes. Six week femurs were assessed by peripheral quantitative computed tomography (pQCT) and micro computed tomography (µCT). Ctsk/ßcat^{del} mice had significant decreases in cortical bone in the cancellous region (see figure). Trabecular number (TbN) was significantly decreased, while structure model index (SMI), trabecular thickness (TbTh), and trabecular spacing (TbSp) were significantly increased. In contrast, Ctsk/Lrp^{del} femurs did not differ from littermates. However, Rank/Lrp$^{del/+}$ mice exhibited a significant decrease in bone density by pQCT, and significant decreases in bone volume, TbN, and TbTh, and increased TbSp by µCT analysis. The observed phenotype in the Rank/Lrp$^{del/+}$ mice and no phenotype with later Lrp deletion (Ctsk/Lrp^{del}) are consistent with our *in vitro* data demonstrating that early, but not late addition of Wnt3a to pOCs cultures inhibits osteoclast formation. In contrast to the Ctsk/ßcat^{del} mice, Rank/Lrp$^{del/+}$mice did not have altered cortical bone. This indicates that ßcat may have effects independent of canonical Wnt signaling in pOCs. Alternatively, Ctsk/ßcat^{del} may lead to a cortical phenotype through off target expression of Cre within the Groove of Ranvier. Because of these potential caveats to the Ctsk/ßcat^{del} model, we believe that evaluation of Rank/Lrp$^{del/+}$ is a better approach for studying the effects of Wnt signaling in osteoclast differentiation. Importantly, these data demonstrate that canonical Wnt receptor signaling in pOCs is important to skeletal development.



MicroCT images exhibit differential cortical phenotypes

Inhibition of a cholesterol regulator, Srebp2, prevents bone loss induced by RANKL. Kazuki Inoue*[1], Yuuki Imai[2]. [1]Ehime University, Japan, [2]Ehime University, Japan

Clarification of the molecular mechanisms underlying osteoclastogenesis provides us new insights into both the physiology of bone metabolism and the pathophysiology of bone diseases. Recent studies revealed that osteoclastogenic transcription factors including *c-Fos,* and *Nfatc1*, sequentially and co-operatively facilitate the expression of osteoclast genes and determine osteoclast identity. However, there are still numerous other unidentified transcription factors involved in osteoclastogenesis.

To identify novel transcription factors in osteoclastogenesis, we performed a genome-wide analysis of open chromatin during RANKL-induced osteoclastogenesis using DNase-seq. As results from DNase-seq using RAW264 cells, we have successfully identified novel osteoclastogenic transcription factors including *Zscan10, Atf1, Nrf1,* and *Srebf2* (Inoue K and Imai Y. JBMR 2014 *in press*.). However, physiological and pathological functions of these transcription factors in bone metabolism remain unclear although osteoclastogenesis was impaired by knockdown of these factors. Among them, we focused on Srebp2 encoded by *Srebf2*, one of the master regulators of cholesterol regulation, because several studies reported a strong relationship between osteoclastogenesis and cholesterol homeostasis.

To investigate the *in vivo* functions of Srebp2, we treated RANKL-induced bone loss model mice with fatostatin, an inhibitor of Srebp2. Fatostatin was administered every day from 2 days before RANKL-injection. 48 hrs after RANKL-injection, the mice were sacrificed and the femora were harvested and analyzed by micro-computed tomography (μCT). As results of μCT analyses, fatostain treatment rescued the reduction of trabecular bone volume, bone mineral density, and trabecular number and the increase of trabecular separation in RANKL-treated mice. Moreover, fatostatin treatment suppressed osteoclast differentiation *in vitro*. These results suggested that fatostatin might affect osteoclast differentiation mediating through Srebp2 inhibition and inhibit RANKL-induced bone loss *in vivo*.

Taken together, our studies demonstrated that we succeed in identifying Srebp2 as a novel transcription factor regulating osteoclastogenesis by DNase-seq, and inhibition of Srebp2, such as fatostatin, might be a potential therapeutic strategy for osteoporosis. Further studies on Srebp2 functions will uncover more precise molecular mechanism underlying relationship between cholesterol homeostasis and bone metabolism.

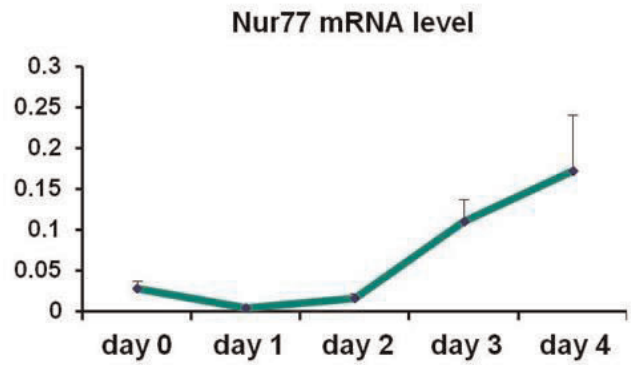
Orphan Nuclear Receptor Nur77 Decreases Osteoclast Differentiation by Promoting NFATc1 Degradation via Ubiquitin E3 Ligase Cbl-b. Xiaoxiao Li*[1], Wei Wei[2], HoangDinh Huynh[2], Yihong Wan[3]. [1], USA, [2]UT southwestern, USA, [3]University of Texas Southwestern Medical Center, USA

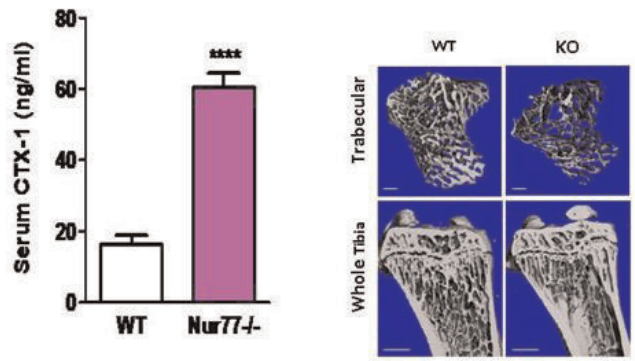
Osteoclasts are the only cells that can degrade bone, and their over-activity has been implicated in many skeletal diseases such as post-menopausal osteoporosis, rheumatoid arthritis and cancer metastasis to the bone. In our lab's attempt to screen for genes that regulate osteoclast activity, we observed that Nur77 mRNA level increases continuously during osteoclast differentiation. Nur77 is an orphan nuclear receptor that has been shown to regulate apoptosis, inflammation, and carcinogenesis. However, its role in osteoclast differentiation has been previously unknown. The goal of my research is to characterize Nur77's role in osteoclast differentiation and bone metabolism, and identify the mechanisms by which Nur77 regulate osteoclast activity.

To study Nur77's effect on osteoclast, we obtained Nur77 -/- mice and found that osteoclasts derived from Nur77 -/- mice exhibited accelerated differentiation compared with WT mice. Furthermore, Nur77 -/- mice developed severe osteopenia due to increased osteoclast activity and unchanged osteoblast activity. In elucidating the mechanism by which Nur77 regulates osteoclast differentiation, we found that Nur77 can significantly decrease the activity of NFATc1, the master regulatory transcription factor in osteoclastogenesis, by promoting its degradation. Over-expression of Nur77 decreases NFATc1 protein level without affecting its mRNA level; while Nur77 -/- osteoclasts fail to downregulate NFATc1 at late stage of osteoclast differentiation. Furthermore, we discovered that Nur77 can transcriptionally up-regulate Cbl-b, an E3 ligase that has been shown to mediate NFATc1 ubiquitination and degradation. Over-expression of Nur77 increases Cbl-b expression, and loss of Nur77 leads to decreased Cbl-b level. Finally, we found that Nur77 over-expression can significantly increase Cbl-b promoter activity, and that mutating either one of the two putative Nur77 Response Elements in the Cbl-b promoter decreased its activity.

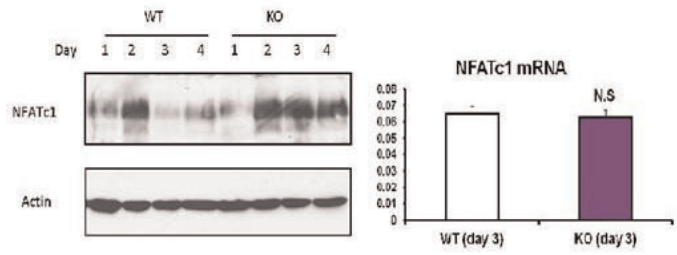
In summary, we've shown that Nur77 can decrease osteoclast differentiation by promoting NFATc1 degradation via upregulating Cbl-b. It is our hope that by understanding how Nur77 protects bone from excessive tissue loss, we can expand therapeutic options to treat osteoporosis, and other osteoclast related diseases.



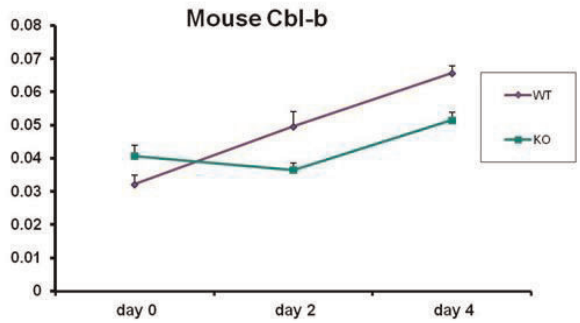
Nur77 mRNA increases during osteoclast differentiation



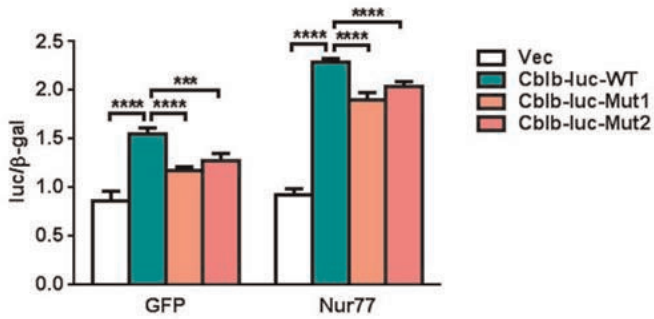
Loss of Nur77 increases osteoclast activity (CTX-1) and decreases bone density



Nur77 KO mice derived osteoclasts fail to down regulate NFATc1 protein level



Nur77 KO mice derived osteoclasts have lower level of Cbl-b than WT



Cblb-luc-WT = AAATATCAgaacatcTGAGATGA
Cblb-luc-Mut1 = AACCAGCAgaacatcTGAGATGA
Cblb-luc-Mut2 = AAATATCAgaacatcTGCGACGC

Nur77 increases WT Cbl-b promoter activity; Activity is Nur77 Response Element specific

Sirtuin 1 suppresses mitochondrial ATP and osteoclastogenesis via FoxO-mediated stimulation of Heme oxygenase 1. Ha-Neui Kim*[1], Shoshana Bartell[2], Li Han[2], Aaron Warren[3], Srividhya Iyer[2], Rafael de Cabo[4], Stavros Manolagas[2], Maria Jose Almeida[2]. [1]Univ. Arkansas for Medical Sciences, Central Arkansas VA Healthcare System, USA, [2]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [3]Center for Osteoporosis & Metabolic Bone Diseases, Univ. Arkansas for Medical Sciences, & Central Arkansas Veterans Healthcare System, USA, [4]Translational Gerontology Branch, National Institute on Aging, National Institutes of Health, USA

Mitochondria-derived H_2O_2 stimulates osteoclast progenitor proliferation and potentiates osteoclastogenesis and is critical for bone remodeling under physiological and pathological conditions. The FoxO family of transcription factors restrains osteoclastogenesis by attenuating H_2O_2 accumulation. Sirt1 – an NAD+ dependent deacetylase – regulates FoxO1 and FoxO3 transcriptional activity. Deletion of Sirt1 in osteoclast progenitors, like deletion of FoxO1, FoxO3 and FoxO4, increases osteoclast number and decreases bone mass. Conversely, systemic Sirt1 stimulation by synthetic activators attenuates the loss of bone mass induced by unloading or aging. Here we examined whether FoxOs mediate the actions of Sirt1 in osteoclasts. Sirt1 activation by two different synthetic activators (SRT2104 and SRT3025) as well as resveratrol dose-dependently inhibited RANKL-induced osteoclast differentiation of bone marrow-derived macrophages. This effect was associated with decreased mRNA expression of several genes, including NFATc1, a key transcription factor for osteoclast generation. The inhibitory effect of Sirt1 stimulators on osteoclastogenesis was abrogated in cells lacking FoxO1, FoxO3 and FoxO4. Consistent with this finding, resveratrol increased the expression of several FoxO target genes, including heme oxygenase (Hmox) 1. Hmox1 catabolises heme, an essential cofactor for the stability and function of proteins of complexes III and IV of the electron transport chain. In line with this, Sirt1 activation reduced ATP production and mitochondrial DNA. In contrast, Hmox1 mRNA levels were strongly reduced by RANKL or FoxO deletion in osteoclast progenitors; while FoxO3 overexpression increased Hmox1 mRNA. Furthermore, deletion of FoxOs in osteoclast progenitors increased ATP production and prevented the suppressive effects of Sirt1 stimulators on mitochondria function. Our findings suggest that by inhibiting mitochondria function via stimulation of Hmox1, FoxOs decreased ATP production and H_2O_2 accumulation and attenuate osteoclast progenitor proliferation. These effects of FoxO are stimulated by Sirt1. This mechanism of action might explain, at least in part, the positive effects of Sirt1 activators on bone mass.

Osteocyte Lacunar Density is Breed Related in Mice. Brett Rosauer[1], Mohammed Akhter*[2], Donald Kimmel[3], Joan Lappe[2], Robert Recker[4]. [1]Creighton University, USA, [2]Creighton University Osteoporosis Research Center, USA, [3]Kimmel Consulting Services, USA, [4]Creighton University, USA

Breed-related differences in skeletal macroarchitecture, microarchitecture, strength, and bone adaptation response to mechanical stimuli have been well documented in mice. The osteocyte lacunar-canalicular (Ot.La) network may play a role in the response to mechanical loading. Ot.La density and volume in mice has not been well-studied. The objective of this project is to determine the three dimensional (3D) volume and density of osteocyte lacunae in three mouse breeds (DBA/2J [D2], C57BL/6 [B6], and C3H/HeJ [C3]), using the MicroXCT-200 (Carl Zeiss [aka Xradia], Pleasanton, CA USA) 3D X-ray microscope. 200μm thick cross-sections of the ulnar mid-shaft (3/breed) from 14wk old mice were scanned at 0.6μm voxel resolution using the 40X objective with 10 sec exposure time (28kV/5W), obtaining 400 projections. Each scan lasted ~2hrs. Voids within mineralized bone in each ulna were segmented and analyzed for void volumes (volume [μm^3]) and number of voids within 100-200μm^3 and 200-300μm^3 ranges using AvizoFire^{TM} software. The segmented voids (i.e., lacunae) from these ranges are shown, with and without surrounding hard tissue, in the ulnar mid-shaft of a B6 mouse (Figure 1). B6 mice appear to have greater lacunar density in both volume ranges, than either C3 or D2 mice (Table). In addition, lacunar density appeared highest in the posteromedial quadrant (Figure 1). The lacunar count in the ranges of 100-200mm^3 and 200-300 mm^3 are shown in Figure 2. B6 mice are known to be more responsive to mechanical stimuli than C3 and D2 mice *(Akhter et al. 1998; Pedersen et al., 1999)*. Our data may suggest that the mechanotransduction response is positively related to the density of osteocytes in cortical bone tissue of the loaded bone. These are the first data to use 3D X-Ray microscopy to study the volume and density of osteocyte lacunae in relation to skeletal mechanosensitivity. Additional data will be presented and discussed.

Breed	D2	B6	C3
Average volume analyzed (mm^3)	0.0195	0.0135	0.0113
Lacunar density #/mm^3	2316	5704	3431

Table

Osteocytes Produce Interferon-β as a Negative Regulator of Osteoclastogenesis. Takuya Sato*[1], Chiyomi Hayashida[1], Junta Ito[2], Mai Nakayachi[2], Yoko Ohyama[2], Yoshiyuki Hakeda[3]. [1]Meikai University School of Dentistry, Japan, [2]Meikai University School of Dentistry, Japan, [3]Meikai University School of Dentistry, Japan

Osteoclastogenesis is controlled by osteocytes, however, osteocytic regulatory molecules for osteoclastogenesis are largely unknown. We searched for such factors using newly developed culture methods. Our culture system mimics the three-dimensional cellular structure of bone, consisting of collagen gel-embedded osteocytic MLO-Y4 cells, stromal ST2 cells on the gel as bone lining cells, and bone marrow (BM) cells. The gel-embedded MLO-Y4 cells inhibited the osteoclastogenesis induced by $1,25(OH)_2D_3$ without modulating receptor activator of NF-kB ligand (RANKL) and osteoprotegerin (OPG) production by the ST2 cells, despite the gel-embedded MLO-Y4 cells supported osteoclastogenesis in the absence of ST2 cell layer. We next examined how co-cultures of MLO-Y4 cells in culture inserts affect osteoclastic differentiation of BM cells supported by ST2 cells or MLO-Y4 cells in the presence of $1,25(OH)_2D_3$. The presence of MLO-Y4 cells in the culture inserts inhibited osteoclastogenesis supported by either ST2 cells or MLO-Y4 cells, suggesting that although MLO-Y4 cells are capable of supporting osteoclastogenesis through cell contact with BM cells, MLO-Y4 cells produce humoral inhibitory factor(s) of osteoclastogenesis. In the BM cell culture, the conditioned medium from MLO-Y4 cells (MLO-Y4-CM) decreased the capability of osteoclastic differentiation from the cells induced by macrophage colony-stimulating factor (M-CSF). This decreased capability was concomitant with an increase in *protein kinase R* mRNA expression and an inhibition of c-Fos translation. These changes were partially normalized by the simultaneous addition of an anti-interferon (IFN)-β neutralizing antibody (α-IFN-β-Ab) to MLO-Y4-CM. To study primary osteocytes, we prepared non-osteocytic cell-free osteocyte-enriched bone fragments (OEBFs). When osteoclast precursors were induced by M-CSF in the presence of OEBFs, the generated cells exhibited a diminished capacity for osteoclastogenesis. OEBFs prepared from *OPG*-knockout mice exhibited a similar effect, indicating OPG-independent inhibition. The addition of α-IFN-β-Ab during the co-culture with OEBFs partially recovered the osteoclastogenic potential of the generated cells. The MLO-Y4 cells and OEBFs expressed *IFN-β* mRNA. Although osteocytic RANKL is known to be important for osteoclastogenesis, our data suggest that osteocytes also produce IFN-β as an inhibitor of osteoclastogenesis.

Parathyroid Hormone (PTH) Downregulates Notch2 Signaling in Osteocytes. Stefano Zanotti*, Ernesto Canalis. University of Connecticut Health Center, USA

Osteocytes are terminally differentiated osteoblasts residing within the bone matrix and targeting of these cells by PTH and Notch plays a critical role in bone remodeling. However, the interactions of PTH and Notch signaling in osteocytes are not known. PTH induces the expression of the Notch ligand *Jag1* in cells of the endosteal lining and in osteoblasts, but the consequences of this effect are understood poorly. Cultures of isolated osteocytes do not preserve the three-dimensional cellular network required for the regulation of bone remodeling and osteocytic cell lines do not replicate the gene expression profile of osteocytes *in vivo*. Therefore, we developed cultures of femoral cortical bone as a new model to investigate the interactions of PTH and Notch in osteocytes. Cortical bones were obtained from femurs of 6 week old C57BL/6 mice following removal of epiphyses and bone marrow and enzymatic digestion of the endosteal and periosteal linings. Cortical bone cultures expressed high levels of the osteocyte gene markers *Sost* and *Dmp1* and responded to PTH with a suppression of *Sost* and an induction of *Rankl* expression. These findings recapitulate the effects of PTH in osteocytes *in vivo* and validate cultures of cortical bone as a model to study osteocyte function. Although PTH induced *Jag1* mRNA levels in osteocyte cultures, PTH suppressed the expression of the Notch target genes *Hey1*, *Hey2* and *HeyL*, indicating that the induction of *Jag1* by PTH in osteocytes does not translate into activation of Notch signaling. To verify the inhibition of Notch signaling by PTH, the effects of PTH were investigated in a model of Notch2 gain of function. To this end, cortical femoral cultures from mice harboring a *Notch2* point mutation that leads to the expression of a stable Notch2 protein and increased Notch signaling, and from littermate controls, were used. Mutant mice exhibit a phenotype that recapitulates the Hajdu-Cheney syndrome, an incurable disease of increased NOTCH2 activity. Notch2 activation induced *Hey1* and *Hey2* mRNA levels and PTH downregulated *Hey1* and *Hey2* transcripts in osteocyte cultures from control and Hajdu-Cheney mice, indicating that PTH acts downstream of Notch2 to suppress *Hey1* and *Hey2* expression. In conclusion, PTH suppresses Notch signaling in osteocytes. Since Notch inhibits osteoblastogenesis and bone formation, downregulation of Notch signaling may be required to achieve an anabolic response to PTH.

FR0281

Isolation of a hematopoietic cell-free preparation of highly purified DMP1-GFP+ osteocytes using fluorescence activated cell sorting (FACS). Ling Yeong Chia[1], Nicole Walsh[2], T. John Martin[3], Natalie Sims*[4]. [1]Department of Bone Cell Biology & Disease, Australia, [2]St Vincent's Institute of Medical Research, Australia, [3]St. Vincent's Institute of Medical Research, Australia, [4]St. Vincent's Institute of Medical Research, Australia

In order to identify specific genes expressed by osteocytes and thereby define their functions, osteocytes have commonly been isolated from bones of transgenic mice expressing GFP directed by the Dmp1 promoter (DMP1-GFP mice) using fluorescence activated cell sorting (FACS). However, while GFP-positive cells obtained in this manner express mRNA for known osteocyte genes, including *Sost*, *Dmp1* and *Mepe*, they have also been reported to express mRNA of genes associated with the osteoclast phenotype: *Dc-stamp*, *Oscar*, tartrate resistant acid phosphatase (*Acp5*) and calcitonin receptor (*Calcr*). This suggests either that osteoclasts and osteocytes share common genes and functions or that DMP1-GFP positive osteocyte populations contain osteoclasts.

To resolve this we isolated DMP1-GFP+ cells that were negative for hematopoietic and endothelial lineage markers by flow cytometry. This allowed us to isolate a population of DMP1-GFP expressing cells free of non-mesenchymal derived cell populations. Cells isolated by collagenase digestion from 7 day old DMP1-GFP calvariae were stained for hematopoietic lineage (Lin) surface markers (CD2, CD3e, CD4, CD45, CD5, CD8, CD11b, B220, Gr1, Ter119) and CD31 to identify myeloid, lymphoid and endothelial cells. Lin^-CD31^- and Lin^+CD31^+ cell populations were then analyzed for GFP expression, and the four distinct populations isolated and assessed by quantitative real-time PCR.

Lin-CD31-GFP+ cells expressed mRNAs for osteocytic genes *Sost, Dmp1*, and *Mepe*, but not *Dc-stamp* or *Oscar*, confirming their identity as osteocytes and exclusion of osteoclasts by this method. *Dc-stamp* and *Oscar* mRNAs were restricted to hematopoetic (Lin^+CD31^+) cells, while *Calcr* and *Acp5* were readily detected in the purified osteocytes.

We also assessed the capacity of the purified osteocytes to support osteoclastogenesis. The purified osteocyte population expressed lower levels of RANKL mRNA compared to the osteoblast-enriched population ($Lin^-CD31^-GFP^-$). Furthermore, when the highly purified osteocytes were cultured with C57BL/6 bone marrow macrophages and stimulated with 1,25-dihydroxyvitamin-D3 no TRAP+ cells with >2 nuclei were formed.

In conclusion, our data demonstrates the utility and importance of hematopoietic lineage depletion to generate a highly purified osteocyte population from DMP1-GFP mice. These purified osteocytes express *Acp5* and *Calcr* but do not express other osteoclast markers, and are unable to fully support osteoclast formation in vitro.

Osteocyte Microvesicles in Cell-Cell Communication in Bone. Kun Wang*[1], Andrew Keightley[2], Patricia Veno[1], Vladimir Dusevich[2], LeAnn Tiede-Lewis[1], Lynda Bonewald[1], Sarah Dallas[1]. [1]University of Missouri - Kansas City, USA, [2]University of Missouri - Kansas City, USA

Microvesicles (100-1000nm) and exosomes (50-100nm) are membrane-bound particles shed by cells that function in intercellular communication by delivering their cargo to target cells. This cargo includes proteins, mRNAs and miRNAs that regulate target cell function. Using transgenic mice expressing a membrane-bound GFP in osteocytes (Dmp1-mem-GFPmice), we have previously shown that osteocytes shed GFP+ve microvesicles, which are either deposited in bone matrix or can be released into the marrow and circulation. Microvesicles from osteocyte-enriched primary calvarial and IDG-SW3 cell cultures were shown to potently stimulate osteoblast-to-osteocyte differentiation and had a protein cargo that included microvesicle markers, early and late osteocyte markers and RANKL. To further understand the mechanisms of intercellular communication by osteocyte microvesicles and their potential relevance in aging, we have analyzed their composition by proteomics and qPCR analysis and have determined whether they are produced in adult (5Mo) and aged (22Mo) mouse bones.

qPCR analysis showed that these microvesicles contained mRNA for osteocyte marker genes, including E11/gp38, Dmp1, PHEX as well as mRNA for OPG, RANKL, HIF1α and β-actin. Proteomic analysis showed a microvesicle proteome rich in membrane and cytoplasmic proteins that included proteins associated with the cytoskeleton/cell motility, membrane fusion/exocytosis, G-protein signaling, intracellular membrane trafficking, neurite outgrowth/axonal guidance and cell polarity. The proteome also included osteocyte markers, PHEX and voltage dependent ion channels. Matrix proteins such as fibronectin and periostin were also identified as well as some osteoblast proteins including type I collagen and alkaline phosphatase. By confocal microscopy we have previously shown abundant GFP+ve microvesicles in the matrix around osteocytes in neonatal Dmp1-mem-GFP mice. Since Dmp1 expression is reduced in aged mice, confocal microscopy was performed using DiI staining for lipid. Abundant vesicle-like structures were seen in bone matrix of adult and aged mice, suggesting that microvesicles are continually produced with aging. Together, our data suggest that osteocytes shed microvesicles with a protein and mRNA cargo that can alter the function of target cells in the osteoblast/osteocyte local environment and may also have effects on distant tissues. These functions of microvesicles may be relevant in the young and aged skeleton.

Osteocytes directly communicate with sensory neuronal cells via cell-cell networks that are modulated under an acidic microenvironment. Masahiro Hiasa*[1], Yuki Nagata[2], Jesus Delgado-Calle[1], Yohance M Allette[2], Matthew S Ripsch[2], Teresita Bellido[1], G. David Roodman[3], Fletcher A White[2], Toshiyuki Yoneda[1]. [1]Indiana University School of Medicine, USA, [2]Indiana University, USA, [3]Indiana University, USA

Osteocytes form cell-cell networks by extending dendritic processes in mineralized cortical bone. During bone resorption, osteoclasts secrete protons to dissolve bone minerals via the a3 isoform vacuolar-H^+-ATPase in the ruffled borders, creating a localized acidic extracellular microenvironment. Thus, osteocytes are exposed to extracellular acidification at the proximal front end of osteoclastic bone resorption. We reasoned that the acidic microenvironment created by bone-resorbing osteoclasts affects osteocyte activity. Consistent with this hypothesis, Western analysis showed the expression of the acid sensing receptors, ASIC3, TRPV1 and TRPV4, on primary mouse calvarial osteocytes and the mouse osteocytic cell lines, MLO-A5 and MLO-Y4. Culture of primary osteocytes at pH 6.5 caused up-regulation of sclerostin expression and down-regulation of RANKL expression with activation of p65 NF-κB and IκB. These changes were inhibited by the specific ASIC3 antagonist, APETx2. These results suggest that osteocytes sense low pH via ASIC3 and consequently change their expression of genes associated with bone remodeling. Given that peripheral nerve fibers associated with cortical bone also sense acidic conditions via ASIC3 and are thought to control bone metabolism in which osteocytes play a central role, we next studied the functional communications between osteocytes and sensory neuronal cells in acidic conditions using the living dye transfer assay. We found that MLO-A5 osteocytic cells extended dendritic processes to contact the neurites of adjacent F11 sensory neuron-like cells and transferred the permeable living dye calcein to F11 cells. The gap junction inhibitors, 18α-glycyrrhetinic acid and GAP27, inhibited the calcein transfer, suggesting osteocytic cells and sensory neuronal cells develop direct cell-cell communications via gap junctions. Notably, extracellular acidification induced Ca^{2+} influx, an indicator for neuron cell excitation, in co-cultures of MLO-A5 cells and F11 cells. APETx2 inhibited this. In conclusion, our results demonstrate that osteocytes change their phenotype associated with bone remodeling in response to extracellular acidification, suggesting osteocytes are not only mechano-sensing but also acid-sensing cells. Our results also show that osteocytes communicate with and excite neighboring sensory neuron cells in acidic conditions, suggesting that osteocytes may relay acid-evoked pain signal to the sensory neurons innervating bone.

Are Biochemical Markers of Bone Turnover Representative of Bone Turnover Assessed with Histomorphometry? An Analysis in a Sample of 370 Postmenopausal Women with Osteoporosis. Pascale Chavassieux*[1], Nathalie Portero-Muzy[2], Jean-Paul Roux[3], Patrick Garnero[4], Roland Chapurlat[5]. [1]INSERM UMR1033, Université De Lyon, France, [2]INSERM UMR1033, Université de Lyon, France, [3]INSERM, UMR 1033, Université de Lyon, France, [4]INSERM Research Unit, France, [5]E. Herriot Hospital, France

The levels of bone formation and resorption can be assessed at the tissue level by bone histomorphometry. This invasive method allows assessing the bone turnover at the basic structural unit. Systemic biochemical markers of bone turnover reflect the overall bone formation and resorption at the level of the entire skeleton but cannot discriminate the bone turnover changes in the different skeletal compartments. Postmenopausal osteoporosis is characterized by an imbalance between resorption and formation. The purpose of the study was to investigate the correlations between the serum biochemical markers of formation (bone alkaline phosphatase, Bone ALP; collagen type 1 N-propeptide, P1NP) and resorption (C-terminal crosslinking telopeptide of collagen type 1, sCTX) and osteoprotegerin (OPG) with histomorphometric parameters in a large population of postmenopausal women. 370 untreated postmenopausal osteoporotic women aged 50 to 84 yrs were selected with a lumbar T-score≤-2.5 SD or ≤-1 SD with at least one fracture. Transiliac bone biopsies were obtained after a double tetracycline labeling. The static (Ob.S/BS, OS/BS, OV/BV) and dynamic (MS/BS, BFR/BS, Acf) parameters of formation, and the parameters of bone resorption (ES/BS, Oc.S/BS, EV/BV, E.De) were measured. The mean values of biochemical markers were: Bone ALP 15.0 ± 5.2 ng/ml; P1NP 56.2 ± 21.9 µg/ml; sCTX 0.58 ± 0.26 ng/ml; OPG 3.00 ± 1.45 pmol/ml. Bone ALP and P1NP were significantly correlated with both the static and dynamic parameters of formation ($0.13 \leq r \leq 0.34$, $0.015 \geqslant p \geqslant 0.0001$). sCTX was significantly correlated with all resorption parameters ($0.13 \leq r \leq 0.28$, $0.017 \geqslant p \geqslant 0.0001$). In contrast, no correlation was found between OPG and histomorphometric parameters or the other biochemical markers. Serum PTH was weakly correlated only with osteoid parameters ($r=0.15$, $p<0.005$).

In conclusion, bone turnover markers except OPG, were significantly but modestly associated with bone turnover parameters measured in iliac cancellous bone. The iliac crest bone may not represent perfectly the whole bone turnover.

Circulating Periostin: a Determinant of Cortical Bone Structure Heritability. Nicolas Bonnet*[1], Claire Durosier[2], Emmanuel Biver[2], Thierry Chevalley[3], Rene Rizzoli[4], Serge Ferrari[5]. [1]University Geneva Hospital (HUG), Switzerland, [2]Division of Bone Diseases, Geneva University Hospital & Faculty of Medicine, Switzerland, [3]University Hospitals of Geneva Division of Bone Diseases, Switzerland, [4]Geneva University Hospitals & Faculty of Medicine, Switzerland, [5]Geneva University Hospital & Faculty of Medicine, Switzerland

Periostin is a matricellular protein, which is mainly expressed by periosteal cells and osteocytes in cortical bone. Periostin down-regulates Sost gene expression and is necessary for the cortical bone response to loading and intermittent PTH. In mice receiving iPTH, circulating periostin (cPostn) levels increase and are correlated with cortical bone parameters. Recently, cPostn has been found to be a marker of fracture risk in postmenopausal women. We investigated the relationship between cPostn and bone microstructure in 65-yr old men and women and their offspring and calculated their heritability. We measured cPostn, sclerostin, bone turnover markers, areal bone mineral density (BMD) by DXA, bone trabecular (Tb) and cortical (Ct) parameters at the distal radius and tibia by HRpQCT (XtremeCT) in 84 parents aged 65.2 ± 1.5SD years and 92 of their descendants aged 38.5 ± 5.6SD. To test the association between cPostn and BMD, microstructure or turnover markers, we applied multiple regressions. Heritability (h2) by descent was estimated as twice the slope of the regression between parents and offspring. cPostn was higher in men compared to women. cPostn was negatively associated with age ($r2=0.64$, $p<0.0001$), Ct porosity (Ct.Po) and Ct pore diameter at distal radius ($r2=0.26$ & 0.15, $p<0.0001$) and tibia ($r2=0.34$ & 0.08, $p<0.0001$), but positively correlated with cortical area (Ct.area) and Ct thickness (Ct.Th) at distal radius ($r2=0.17$ & 0.15, $p<0.0001$) and tibia ($r2=0.24$ & 0.28, $p<0.0001$). These associations remained significant after adjustment for P1NP, CTX, and gender or age separately, but not after adjustment for both gender and age. In contrast, circulating sclerostin (cSost) was positively associated with BMD and BV/TV only but not with Ct.area or Ct.Po. H2 was 42-78% for BMD (depending of sites), 34-60% for Tb structure and 22-58% for Ct structure (depending of sites and parameters) (all $p<0.05$). For example, at the tibia, h2 was 58% for Ct.Perimeter and 26% for Ct.Po. H2 for cPostn and cSost was 50% and 40%, respectively ($p<0.05$). Radius Ct.Th in the offspring tended to be predicted by parents cPostn levels ($r2=0.08$, $p=0.0632$) after adjustment for P1PN, CTx and cSost. These results indicate that cPostn contributes to the age and gender-dependent alteration of the cortical bone compartment, independently of bone remodeling. Moreover, at least part of the heritability for cortical bone structure may be carried by additive genetic effects on cPostn.

Automatic QCT quantification of the proximal femur: vBMD, bone volume, cortical bone thickness and finite element modeling. Julio Carballido-Gamio*[1], Serena Bonaretti[1], Isra Saeed[2], Roy Harnish[2], Robert Recker[3], Andrew Burghardt[1], Joyce Keyak[4], Tamara Harris[5], Sundeep Khosla[6], Thomas Lang[1]. [1]University of California, San Francisco, USA, [2]University of California, San Francisco, USA, [3]Creighton University, USA, [4]Department of Radiological Sciences, University of California, Irvine, USA, [5]Intramural Research Program, National Institute on Aging, USA, [6]Mayo Clinic College of Medicine, USA

QCT imaging is the basis for multiple assessments of bone quality, including compartmental vBMD analysis, finite element modeling (FEM), and statistical parametric modeling of vBMD and morphometry distribution. We integrated these approaches into an automated comprehensive proximal femoral QCT analysis. Here, we present a fully automated technique to segment hip QCT scans, which is used as a basis to: 1) prescribe volumes of interest for vQCT analysis, 2) map 3D variations in cortical bone thickness, and 3) assess FEM bone strength. In this study, we measured the accuracy of the segmentation technique and the reproducibility of the derived measurements.

This study used 179 hip vQCT scans from 2 vendors and 3 sites. Using a minimum deformation template (MDT) of the proximal femur, we developed an atlas-based segmentation algorithm consisting of 3 main steps: 1) poly-affine registration of the MDT to individual scans; 2) model-guided nonlinear registration; and 3) region growing and patch-based cleaning of the segmented boundaries obtained after applying the inverse of the registrations. Of the 179 scans, 49 were used for training of the segmentation in step 2, yielding 130 automatically segmented scans. Of these, 78 scans with manual segmentations were used for segmentation accuracy assessment, and 44 (22 scan-rescan pairs) for reproducibility of vQCT, FEM and cortical thickness measures. Cortical bone thickness was measured with a variant of the minimum line integral thickness approach: non-local fuzzy c-means was used to estimate the endocortical boundary, and cortical thickness was measured with minimum Euclidean distances, fuzzy logic, vBMD, and numerical integration. We evaluated inter-scan reproducibility (Fig. 1A) of vBMD, bone volume, cortical thickness, and nonlinear FEM strength in stance and posterolateral fall loading [Keyak Bone 2013] using RMS pairwise precision errors.

Segmentation accuracy and precision of derived measures are shown in Table 1. Figs. 1B and 1C respectively show representative examples of an automatic segmentation and scan-rescan cortical bone thickness maps.

Our automated hip segmentations had high fidelity to gold-standard manual segmentations, and were used to derive highly reproducible vQCT, FEM strength and cortical bone thickness measures. Our subjects were elderly, with scans obtained across multiple clinical sites and vendors, documenting the value of this approach for clinical trials and other multi-site studies.

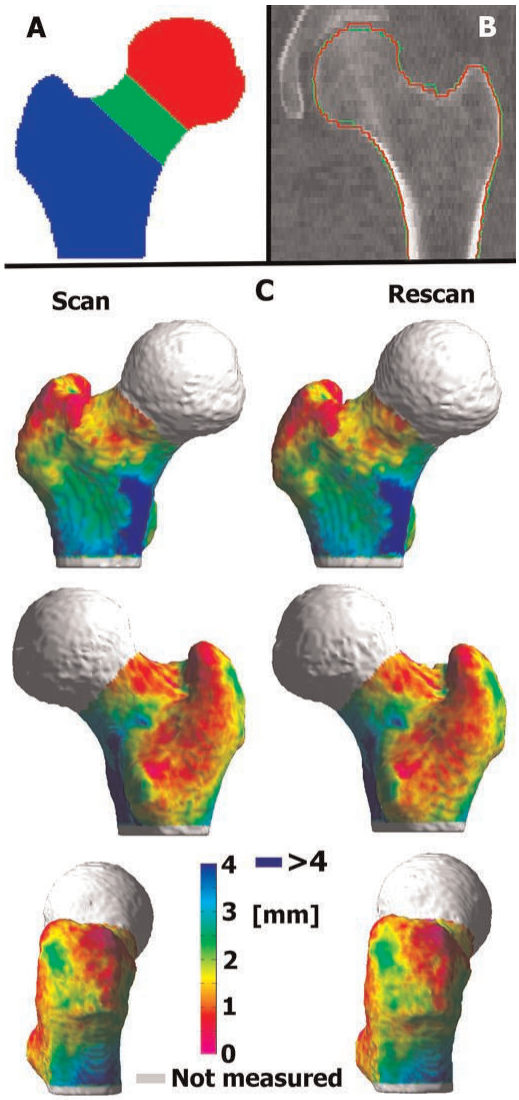

Fig. 1. A) Volumes of interest used in this study: head (red), neck (green), and trochanter (blue). B) Coronal cross-section of a representative automatic segmentation (red), also showing the manually derived contour (green). C) Anterior, posterior, and lateral views of a representative scan-rescan (left-right) 3D cortical bone thickness map.

Fig. 1

Table 1. Segmentation Accuracy and Reproducibility of Bone Measures

Accuracy (mean±SD) (n=78)		
DSC	FNR	SymDist [mm]
0.972±0.005	0.044±0.009	0.396±0.064

DSC = Dice similarity coefficient (a value of 0 indicates no overlap; a value of 1 indicates perfect agreement; higher numbers indicate that the results match the gold standard better)
FNR = False negative rate
SymDist = Average of minimum Euclidean distances between the automatically and the manually derived surface points
10 out of 130 scans failed locally: 8 in the head and 2 in the greater trochanter (7.7%). These scans were not part of the accuracy analysis

Reproducibility (RMS pairwise precision errors [%])						
vBMD (n=22)					Volume (n=22)	
T	I-Head	I-Neck	Tb-Neck	C-Neck	I-Troch	C-Troch
0.90	0.90	1.33	1.58	1.38	1.31	1.43

Cortical bone thickness (n=22)		
T	Neck	Troch
0.78	1.89	0.76

Finite element modeling strength (n=19)	
Nonlinear stance loading	Nonlinear FPL loading
3.21	3.40

T = Total; **I** = Integral; **Tb** = Trabecular bone; **C** = Cortical bone
Troch = Trochanter
FPL = Posterolateral fall

Cortical Bone Water in Renal Transplant Patients. Wenli Sun*[1], Mary Leonard[2], Hamidreza Saligheh Rad[3], Chamith Rajapakse[4], Felix Werner Wehrli[5]. [1]University of Pennsylvania, USA, [2]Stanford School of Medicine, USA, [3]Osteoporosis Research Center, Endocrinology & Metabolism Research Institute.Tehran University of Medical Sciences, Iran, [4]University of Pennsylvania School of Medicine, USA, [5]University of Pennsylvania Medical Center, USA

Renal Osteodystrophy (ROD) is a universal complication of end-stage renal disease. As renal disease progresses, excessive parathyroid hormone secretion results in abnormal trabecular bone connectivity, cortical bone thinning, and decreased cortical BMD. Noninvasive assessment of bone quality may evaluate fracture risk and guide therapy. In this study, we tested a new biomarker capable of evaluating cortical bone in ROD by measuring bone water concentration (BWC) using ultra-short echo time (UTE) MRI and compare the results with BMD measured by pQCT at the same anatomic site.

This prospective study involved 30 renal transplant recipients (16 males and 14 females; ages 25-60 years; BMI 16.2-38.0 kg/m^2) and 30 healthy controls matched one-to-one for race, sex, age (pair-wise mean difference $<$ 3 years), and BMI (pair-wise mean difference $<$ 4.8 kg/m^2). Micro-MR imaging was performed at 3T (Siemens Tim Trio, Erlangen, Germany) using an extremity quadrature bird-cage transmit/eight-channel receive (Invivo Corp., Orlando, FL). Transplant recipients were scanned within 2 weeks after renal transplantation (baseline) and 12 months later while the controls were examined at the baseline only. BWC was measured in the left tibial mid-shaft using a three-dimensional hybrid-radial UTE (3D HRUTE) sequence with slab-selective half-sinc pulse excitation.

Figure 1 shows BWC maps of a female transplant recipient and a matched control, superimposed on anatomic images. Transplant recipients had greater BWC than controls (25.2$\pm$3.6% versus 23.0$\pm$3.6%, +9.5%, $p<0.05$, paired t-test, Fig. 2) presumably secondary to greater porosity, which is a hallmark of renal disease. BMD measured by pQCT at the same site was only 1.8% lower in the patients compared to controls (1164.7$\pm$52.9 versus 1186.5$\pm$24.4 mg/cm^3, $p<0.05$). The greater BWC in patients is only partially explained by their lower BMD (Fig. 3). Data are suggestive of an increase in BWC 12 months post-transplantation (from 25.2$\pm$3.6% to 26.2$\pm$3.8%, +4.0%, p=0.2) as well as a slight increase in BMD (from 1162.3$\pm$52.9 to 1171.2$\pm$39.1 mg/cm^3, +0.8%, $p<0.05$). Data in larger cohorts will be needed as well as separation of

the BW measurements into collagen-bound and pore water, thereby eliminating the confounding effects of the two types of water that are known to change in opposite direction.

FR0289

Impact of lumbar syndesmophyte on bone heath as assessed by Bone density (BMD) and Bone Texture (TBS) in men with axial spondyloarthritis. Berengere Aubry-rozier*[1], Laura Wildberger[2], Vladimira Boiadjieva[3], Didier Hans[1], Nikolay Stoilov[3], Mariana Ivanova[3], Rumen Stoilov[3], Rasho Rashkov[3]. [1]Lausanne University Hospital, Switzerland, [2]Lausanne University Hospital, Switzerland, [3]Clinic of Rheumatology, University Hospital "St. Iv. Rilski", Bulgaria

Aim: Patients with spondyloarthritis (AS) have an elevated incidence of osteoporosis and are at increased risk of pathological vertebral fracture. Evaluation of bone by DXA has its limits in fracture prediction, already known in this population, probably because it only measures quantity, but not quality of bone. One hypothesis is that the presence of lumbar syndesmophyte could overestimate the spine BMD. Trabecular bone score (TBS) is a new texture measurement correlated with bone microarchitecture. Previous studies have shown that TBS is not impacted by osteoarthritis and thus could be a predictor of fracture better than spine BMD. We aimed to evaluate a male population of AS with BMD and TBS measurement and see the impact of lumbar syndesmophyte.

Method: Two cohorts of AS male patients (Lausanne, Sofia) with AS disease, clinical and bone parameters (femoral neck and total spine BMD + spine TBS) were merged. We compared BMD and TBS results regarding to the presence/absence of syndesmophyte and compared to young normative values (T-score for both BMD and TBS). T-tests were used to compare the two groups.

Results: Our study concerned 38 men (29 men with lumbar syndesmophytes (L1 to L4, $\geq$1), 9 without), all fulfilled the ASAS criteria, mean age 50 years old) and no difference in BMI (26.7 vs 25.3). Mean spine BMD T-score were 0.04+/-1.66 and -1.10+/-1.22 ($p<0.05$) respectively for AS men with and without syndesmophytes. Mean femoral neck BMD T-score was -1.32+/-1 and -0.96+/-0.78 ($p<0.05$) respectively for AS men with and without syndesmophytes. Mean TBS was 1.239+/-0.147 and 1.337+/-0.1($p<0.05$) respectively for AS men with and without syndesmophytes.

Conclusions: The two populations (Lausanne and Sofia) had comparable BMD and TBS results, after exclusion of degenerative vertebrae and adjustment for the two DXA machines. As expected, the only "normal" result was spine BMD in AS men with syndesmophytes. Others results were lower than in a normal population. Interestingly, even if men with syndesmophyte had normal spine BMD results, they had lower TBS results than men without syndesmophyte and lower femoral neck BMD. All results are statistically significant. These results have to be confirmed in term of disease activity and fracture risk. In conclusion, spine BMD is erroneously influenced by syndesmophyte unlike spine TBS and femoral BMD. We can recommend to evaluate bone health in AS male population with syndesmophyte by measurement of spine TBS and femoral BMD.

Microindentation in vivo captures elements of bone fragility independently of BMD. Natasha Appelman-dijkstra*[1], Frank Malgo[2], Socrates Papapoulos[3], Neveen Hamdy[3]. [1]LUMC Centre for Bone Quality Dept of Endocrinology, The Netherlands, [2]Leiden University Medical Center, Netherlands, [3]Leiden University Medical Center, The Netherlands

Introduction: The strength of bone is determined by its mass, structure and material composition. Age is associated with loss and structural decay of bone but there is no information about changes in material properties. Recently a new technique has been made available for in vivo quantification of the resistance of bone to microindentation "Bone Material Strength" (BMS). The objective of our study was twofold. First we wanted to assess the relation between age and BMS, secondly to assess the relation between BMS and the calculated 10 year fracture risk by FRAX.

Methods: Treatment-naive subjects $\geq$ 40 years with osteopenia or osteoporosis. Clinical risk factors for fractures were collected and the FRAX-score was calculated. Microindentation was performed on the midshaft of the tibia with the Osteoprobe® Reference Point Indenter (Active Life Scientific Inc.,Santa Barbara, CA. USA).

Results: 58 patients (26 men) were included. Mean age was 60.3 $\pm$ 9.6 years (range 40.9-85.5 years). Mean BMI 24.7 kg/m^2 $\pm$ 4.5 and 29(50%) had sustained a fracture. Eight patients had been or were currently treated with glucocorticosteroids, 11 used 3 or more units of alcohol a day and 11 patients were active smokers. 17 patients (29.3%) were diagnosed with osteoporosis. In fracture patients median FRAX-score was 7.0% (1.1-48.0) and 1.9 % (0.1-39.3) for major osteoporotic and hip fracture respectively. In non-fracture patients median FRAX-score was 3.6% (1.6-24.0) and 1% (0.2-8.6). Corrected for BMI and gender there was a significant correlation between Femoral Neck (FN) BMD and age. No relationship between FN-BMD and BMS was observed. There was a strong relationship between BMS and age (p=0.001) and furthermore, independently of BMD a significant correlation between BMS and the 10 year absolute fracture risk score by FRAX $p<0.001$.

Conclusion: Our findings demonstrate a significant relationship between Bone Material Strength and age as well as FRAX score. These data suggest that Bone Material Strength, as measured in vivo with microindentation, captures elements of bone fragility independently of BMD. Whether in clinical practice information about Bone Material Strength will improve the estimation of fracture risk warrants further investigation.

Cortical bone porosity significantly impacts skeletal integrity. Pathological porosity is associated with decreased bone strength and increased fracture incidence. Importantly, pathological porosity and resulting strength deficits are modifiable. Therefore cortical porosity is an important and viable target for bone fragility treatment.

To develop treatments that prevent or reverse pathological porosity and associated bone fragility, we must understand the mechanisms driving pathological porosity. We hypothesize that pore space *content* will reveal systems driving pathological porosity. In this study, we aim to develop a multi-modal in vivo technique to visualize pore content using high resolution peripheral quantitative computed tomography (HR-pQCT) and magnetic resonance imaging (MRI).

Distal tibiae of two volunteers were imaged using HR-pQCT (Scanco Medical AG) to identify cortical pore space and 3T MR (GE Healthcare) to identify marrow and vessels within pore space. A FIESTA-C sequence was used to identify marrow, followed by an axial T1-weighted 2D FSE sequence. Gadolinium-based contrast agent was then injected, and post-contrast FSE imaging was performed using a multi-phase perfusion protocol to identify vessels.

Our results confirm that in vivo imaging can discriminate marrow from vessels within detectable pores (Fig. 1). Fat-sensitive FIESTA-C scans positively identified fatty marrow-filled pores while contrast-enhanced FSE scans positively identified vessel-filled pores. Using these sequences we captured images in cortices displaying exclusively vessel-filled pores (Fig. 1A) and both marrow- and vessel-filled pores (Fig. 1B). Vessel identification was confirmed by quantifying signal enhancement over the multiphase acquisition. Vessels enhanced while marrow maintained a constant signal (Fig. 2).

This technique lays the groundwork for mechanistic and therapeutic studies of pathological porosity and associated bone fragility. Differences between marrow- and vessel-filled pores in their response to stimuli will be important indicators of pore formation mechanisms. Marrow within new pores may indicate endocortical 'trabecularization' (marrow cavity expansion into the cortical envelope), dictating an intervention to direct mesenchymal cell differentiation towards osteoblastogenesis or regulate adipokines. Vascular components within new pores may indicate vascular network expansion, dictating modulation of vasoregulators or anti-angiogenic therapy.

Clinical aspect of patients with and without vertebral fractures presenting at a fracture liaison service. Sandrine Bours*[1], Tineke Van Geel[2], Joop Van Den Bergh[3], Sabine Landewe[4], Debby Vosse[5], Piet Geusens[6]. [1]Maastricht University Medical Centre, The Netherlands, [2]Maastricht University, The Netherlands, [3]VieCuri MC Noord-Limburg & Maastricht UMC, The Netherlands, [4]Department of Internal Medicine, subdivision of Endocrinology, Maastricht University Medical Centre, Netherlands, [5]Department of Internal Medicine, subdivision of Rheumatology, Maastricht University Medical Centre, Netherlands, [6]University Hasselt, Belgium

Methods

Between May 2012 and October 2013, 1046 patients with a recent non-vertebral or clinical vertebral fracture (71.3% women and 28.6% men, mean age 65.8 ± 9.9 years) presented at the Fracture Liaison Service (FLS) of Maastricht University Medical Centre, the Netherlands. Of these patients, 89 (9.8%) presented with a clinical vertebral fracture. In all patients at the FLS, bone mineral density (BMD) measurement and laboratory tests (serum calcium, phosphate, 25(OH)D, protein electrophoresis, creatinine, PTH, TSH, and in men < 70 years with osteoporosis serum testosterone) were performed. Furthermore, assessment of prevalent vertebral fractures was performed, whether by Vertebral Fracture Assessment (VFA) or by conventional X-ray. A semi-quantitative scoring was performed according to Genant into grade 0 (<20%, no vertebral fracture), grade 1 (20-25%), grade 2 (25-40%) and grade 3 (>40%).

Results

In 997 (95.3%) of all patients assessment of prevalent vertebral fractures was performed. A prevalent vertebral fracture was found in 132 patients presenting with a non-vertebral fracture at baseline. Thus, a vertebral fracture (clinical and/or prevalent) was present in 221 (23.3%) patients presenting at the FLS with a recent fracture. The patients with a vertebral fracture (n=221) were compared to the patients without any vertebral fracture (n=726). Of the patients with a vertebral fracture, 94 (42.5%) had osteoporosis, 101 (45.7%) had osteopenia and 26 (11.8%) had a normal BMD, and in patients without a vertebral fracture these numbers were 205 (28.2%), 378 (53.1%) and 143 (29.7%), respectively ($p < 0.001$). Of the patients with a vertebral fracture, 61 (27.7%) had newly diagnosed contributors to secondary osteoporosis and bone loss (SECOB) compared to 162 (22.5%) of the patients without vertebral fracture (p=0.100). The prevalence of MGUS was not different in patients with and without vertebral fractures (9.6% vs. 9.4% respectively, p=0.879), and a multiple myeloma was diagnosed in 1 patient only.

Conclusion

At presentation at the FLS after a recent clinical fracture, nearly 25% of patients have a prevalent and/or clinical vertebral fracture. Patients with a vertebral fracture have a significantly lower BMD than patients without vertebral fractures. In patients with a vertebral fracture more frequently a newly diagnosed contributor to SECOB was found compared to patients without vertebral fracture, however this difference is not statistically significant.

FR0299

Clinical Performance of an Updated Version of Trabecular Bone Score in Men and Women: The Manitoba BMD Cohort. William Leslie*[1], Renaud Winzenrieth[2], Sumit Majumdar[3], Lisa Lix[4], Didier Hans[5]. [1]University of Manitoba, Canada, [2]Med-imaps, Hôpital X. Arnozan, PTIB, Pessac, France, France, [3]University of Alberta, Canada, [4]University of Manitoba, Canada, [5]Lausanne University Hospital, Switzerland

Lumbar spine TBS (Trabecular Bone Score) is a texture measurement from DXA that correlates with parameters of bone microarchitecture that can predict osteoporotic fractures independent of BMD. Limitations of the previous TBS algorithm (version 1.8), which was optimized for women of average body size, were identified when TBS was used in men or extremes of BMI due to prominent soft tissue effects. The current study evaluates an updated TBS algorithm (version 2.1) which was modified to address these technical issues.

Methods: From a clinical registry containing all DXA results for Manitoba, Canada, we identified women and men age >40 years with baseline spine DXA (GE Prodigy) from years 1999-2011. Spine TBS were measured using the previous (version 1.8) and updated TBS (version 2.1) algorithms by researchers at the University of Lausanne blinded to clinical outcomes. Incident major osteoporotic fractures (MOFs) and hip fractures (HFs) were obtained from population-based health services data. Descriptive statistics and correlations of both versions of TBS with age and BMI were determined. Fracture prediction was estimated from area under the ROC curve (AUROC). All analyses were sex-stratified.

Results (see tables): 47,736 women and 4348 men met the inclusion criteria. With the previous TBS algorithm, average TBS value for men appeared to be significantly lower than women. Under the updated algorithm, average values for men are slightly greater than for women. The updated algorithm is also minimally affected by BMI (Pearson r=0.01 in men, -0.01 in women). During mean follow up of 5 years in men there were 214 incident MOFs and 47 HFs; during 6 years in women there were 2895 incident MOFs and 694 HFs. Slight improvements in fracture prediction were seen with the updated TBS algorithm in both men (change in AUROC for MOFs +0.021, HFs +0.046) and women (change in AUROC for MOFs +0.012, HFs +0.020).

Summary: The updated TBS algorithm: (1) is less affected by soft tissue effects, (2) gives results for men that are consistent with their lower fracture risk, and (3) improves fracture prediction in both men and women compared with the previous algorithm.

Impaired trabecular bone microarchitecture improves after one year on gluten-free diet. A prospective HRp-QCT study in women with celiac disease. Maria Belen Zanchetta*[1], vanesa longobardi[2], Florencia Costa[2], julio cesar bai[2]. [1]Instituto de Investigaciones Metabolicas (IDIM), Argentina, [2]md, Argentina

Background: We have recently identified a significant deterioration of trabecular and cortical microarchitecture in peripheral bones of patients with recently diagnosed celiac disease (CD) by using high resolution-peripheral quantitative computed tomography (HR-pQCT). Such affectation was mainly produced in the trabecular bone and might be primarily responsible for bone fragility fractures. Up to now, the effect of the gluten-free diet (GFD) on microstructural parameters of peripheral bones has not been assessed.

Aim: to explore one-year changes in bone microstructure produced by the instauration of a GFD in a prospective cohort of premenopausal women with newly diagnosed CD.

Methods: We prospectively enrolled 31 consecutive females with newly diagnosed CD. Up to now, 24 patients have been reassessed one year after diagnosis. Clinical and biochemical status, CD specific serology, bone densitometry and microstructural determinations (HR-pQCT) were performed at both time points. HR-pQCT bone volumetric and structural measurements were determined at the distal non-dominant radius and tibia in all patients.

Results: The microstructure of the trabecular compartment in the distal radius was significantly improved (BV/TV, trabecular density and trabecular thickness: $p<0.0001$) at the one-year time point. At the level of tibia, treatment was associated with significant increase of the total volumetric density ($p<0.01$), cortical density ($p<0.002$), trabecular density ($p<0.0001$), BV7TV ($p<0.0001$) and trabecular thickness ($p<0.002$). In contrast, in radius cortical thickness decreased significantly ($p<0.001$). (Table)

Conclusions: This is the first study exploring the one-year effect of the GFD on microstructural parameters measured by HR-pQCT in patients with newly diagnosed CD. Our study shows that trabecular parameters impaired at the time of diagnosis improved significantly with treatment. In contrast, cortical bone parameters may need more time on GFD to evidence positive changes. We postulate that trabecular bone microarchitecture improvement might be the substrate associated with the decreased risk of fractures observed after GFD in former studies.

Endochrondral ossification, mesenchymal stem cell and Wnt pathway specific loci predict differential skeletal effects in High Bone Mass. Celia Gregson[1], John Kemp[2], Mhairi Marshall[3], Graeme Clarke[3], George Davey Smith[2], Matthew Brown[4], Emma Duncan[5], Jon Tobias*[6]. [1]University of Bristol, United Kingdom, [2]MRC Integrative Epidemiology Unit, University of Bristol, United Kingdom, [3]University of Queensland Diamantina Institute, Australia, [4]Diamantina Institute of Cancer, Immunology & Metabolic Medicine, Australia, [5]Royal Brisbane & Women's Hospital, Australia, [6]Musculoskeletal Research Unit, University of Bristol, United Kingdom

Introduction: Extreme high bone mass (HBM) may be monogenic (e.g. *LRP5* mutations) or polygenic, possibly from variants in the same genes that determine bone mineral density (BMD) in the general population where they explain 5.8% of variation in femoral neck (FN) BMD[1]. Having previously shown HBM cases carry excess variation in BMD-associated loci, we aimed to determine how variation in loci in different functional pathways, explains the phenotype of HBM.

Methods: 241 unexplained HBM cases (defined as lumbar spine (LS) L1 plus total hip Z-scores≥+4.4) were recruited from 15 UK centres, by screening 335,115 DXA scans. Established *LRP5* mutations were excluded by Sanger sequencing (n=6). Infinium OmniExpress-12v1.0 genotypes were imputed to UK10K; 57 autosomal SNPs had certainty>0.8. Using Estrada's FN or LS Betas[1], we calculated weighted genetic risk scores (GRS^{FN}/GRS^{LS}) for total (n=57), Wnt (n=12), OPG-RANK-RANKL (n=3), endochrondral ossification (n=6) and mesenchymal stem cell (MSC) differentiation (n=4) annotated loci. GRS^{FN} were compared with total hip BMD (TH-BMD) and total body BMD (TB-BMD), GRS^{LS} with LS-BMD.

Results: A one SD increase in total GRS^{FN} was associated with a 0.13 SD [-0.01, 0.27], p=0.06, increase in TH-BMD and 0.13 [0.01, 0.25], p=0.04, increase in TB-BMD, explaining 1.6% and 3.2% phenotypic variance respectively; however, GRS^{LS} was independent of LS-BMD (0.12 [-0.05, 0.29), p=0.17, r^2=0.8%).

Wnt GRS was associated with a 0.15 SD [0.01, 0.29], p=0.04, increase in TH-BMD (r^2=2%), but was independent of TB-BMD (0.03 [-0.08, 0.15], p=0.57, r^2=0.3%) and LS-BMD (-0.02 [-0.20, 0.15), p=0.79, r^2=0%). Conversely, the endochrondral ossification GRS were independent of TH-BMD (0.01 [-0.13, 0.15], p=0.85, r^2=0%) and LS-BMD (0.14 [-0.03, 0.31], p=0.11, r^2=1.2%), but explained 2.3% of variance in TB-BMD (0.11 [-0.01, 0.23], p=0.08). Whereas, the MSC GRS was associated with a 0.19 SD [0.02, 0.37], p=0.03, r^2=2.2%) increase in LS-BMD, but was independent of both TB-BMD and TH-BMD (p>0.8, r^2=0%). All BMD sites were independent of OPG-RANK-RANKL GRS.

Conclusion: BMD in HBM appears driven by osteoblast rather than osteoclast pathways. A greater proportion of phenotypic variance in (i) hip BMD is explained by wnt pathway loci, (ii) total body BMD by endochrondral ossification loci and (iii) lumbar spine BMD by mesenchymal stem cell differentiation loci, suggesting differential genetic regulation of individual skeletal sites.[1]Estrada Nat Gen 2012

FR0310

Changes in Bone Mineral Density and Trabecular Bone Score (TBS) as Indicators of On-Treatment Antifracture Effect: The Manitoba BMD Cohort. William Leslie*[1], Sumit Majumdar[2], Suzanne Morin[3], Lisa Lix[4], Didier Hans[5]. [1]University of Manitoba, Canada, [2]University of Alberta, Canada, [3]McGill University, Canada, [4]University of Manitoba, Canada, [5]Lausanne University Hospital, Switzerland

BMD and TBS (with clinical risk factors) help identify individuals at high fracture risk and guide initiation of osteoporosis treatment (OSRx). Whether changes in BMD or TBS are useful indicators of on-treatment antifracture effect is unclear.

Methods: From a clinical registry of all DXA results for Manitoba, Canada, we identified women age >40 years not receiving OSRx at baseline with two DXA examinations. Linkage to health service records provided covariates for calculating FRAX major osteoporotic fracture (MOF) probability with BMD, OSRx use between the scan dates (as medication possession ratio [MPR]), and incident MOF (to March 31st 2011). Cox proportional hazards models for first MOF were used to estimate the hazard ratio (HR) per SD change in BMD (L1-4, total hip, femoral neck) or SD change in TBS (L1-4), adjusted for FRAX probability. Analyses were stratified by OSRx and considered two index dates: the first and the second DXA.

Results: Our criteria identified 9044 women, baseline age 62±10y, baseline FRAX MOF probability 9.4%±6.1%. During mean 7.7y follow up, 770 women developed one or more incident MOF (448 before and 296 after the second DXA). Between the two DXA scans (average interval 4.1y), 5083 women initiated OSRx (MPR<0.5 in 2044, MPR 0.5-0.8 in 1155, MPR >0.8 in 1884; bisphoshonate use 89-91%) while 3961 women received no OSRx. Change in BMD and TBS differed according to OSRx with larger changes seen in those with greater MPR (ANOVA p<.001). With first DXA as the index date, change in BMD or TBS did not predict fractures in untreated women (Table). For women initiating OSRx, there was greater antifracture effect for each SD increase in total hip BMD (decrease 20%, 95%CI 13-26%, p<.001) and femoral neck BMD (decrease 19%, 95%CI 12-26%), while decreases in BMD (exceeding LSC) were associated with higher fracture risk (total hip HR 1.52, 95%CI 1.21-1.90, femoral neck HR 1.70, 95%CI 1.27-2.27). In contrast, change in L1-4 BMD showed only a borderline effect in all treated women combined (decrease 9%, 95%CI 0-17%, p=.049) while change in L1-4 TBS showed no significant antifracture effect. With second DXA as the index date, no BMD or TBS change measures showed a significant association with subsequent MOF.

Summary: Greater on-treatment increases in total hip and femoral neck BMD are associated with lower fracture risk while BMD decreases are associated with higher fracture risk. In contrast, change in spine BMD or TBS were not good indicators of antifracture effect.

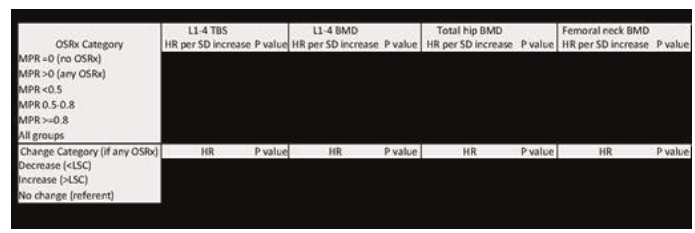

Table: HR (95%CI) for incident MOF according to change in BMD or TBS *.

Identification of Novel Serum Peptides and Proteins That Are Associated with Hip Bone Loss in Older Men. Jian Shen*[1], Jodi Lapidus[2], Aaron Baraff[2], Christine Lee[1], Arie Baratt[2], Shannon McWeeney[2], Vladislav Petyuk[3], Douglas Bauer[4], Nancy Lane[5], Eric Orwoll[1]. [1]Oregon Health & Science University, USA, [2]Oregon Health & Science University, USA, [3]Pacific Northwest National Laboratory, USA, [4]University of California, San Francisco, USA, [5]University of California, Davis Medical Center, USA

The mechanisms underlying bone loss remain incompletely understood, and there are few available biomarkers. We utilized a proteomics approach to identify serum peptides and proteins associated with bone loss in older men.

A subset of men (N=1875) were randomly chosen from the Osteoporotic Fracture in Men Study (age ⩾65 yrs), after excluding users of osteoporosis medications. Men had 2-3 measures of femoral neck DXA BMD over an average follow-up of 4.6 years. Change in BMD was estimated from mixed effects regression models and categorized into three groups: maintenance (no decline), expected loss (loss rate up to 1 SD below the mean change) or accelerated loss (loss rate >1 SD of the mean change). A high-throughput LC-IMS-MS proteomics platform was used to identify and quantify serum peptides. Linear regression models adjusted for age, site and BMI were used to compare peptide abundance in baseline serum across three groups, with specific comparisons made between maintenance and accelerated loss groups via tests of contrasts. P-value and fold change from peptides within the protein were meta-analyzed to generate a significance level and fold change for proteins. The samples were divided into discovery (N=960) and replication cohorts (N=915). To identify networks and important hubs in the networks, we repeated analyses from the whole cohort and used peptides with FDR< 5% to build protein networks using the MetaCore.

We analyzed 3100 peptides that mapped to 325 proteins. 11 peptides in the discovery cohort and 5 peptides in the replication cohort were more abundant in men with accelerated loss compared to the maintenance group (FDR<5%). Meta analyses of peptides suggested 6 proteins were more abundant in both cohorts (FDR <10%), including RNAS1, C163A, CD14, SHBG, ENPP2 and IBP6 (Table). Using combined data from the whole cohort, the network analysis of 48 candidate proteins indicated highly connected hubs, such as CD44, Cystatin C and IBP6. The identified networks were enriched for key biological processes, such as complement activation and regulation of immune response.

Using proteomic methods in a large population of older men, we identified multiple serum proteins and potential biological processes associated with bone loss, including several previously linked to bone metabolism and thus with biological plausibility. These methods and our results provide an opportunity to better understand pathophysiology, and to develop new biomarkers for bone loss.

Table . Proteins differentially abundant in men with accelerated bone loss compared to men with maintained BMD in both cohorts

		Discovery cohort (N=960)			Replication cohort (N=915)

Association of Incident Radiographic Vertebral Fracture with Back Pain Symptoms in Older Men: the Osteoporotic Fractures in Men (MrOS) Study. Howard Fink*[1], Lynn Marshall[2], Jian Shen[2], Steven Cummings[3], Peggy Cawthon[4], Kristine Ensrud[5], Rena Singleton[6], Jane Cauley[7], Elizabeth Barrett-Connor[8], Nancy Lane[9], Deborah Kado[8], John Schousboe[10]. [1]GRECC, Minneapolis VA Medical Center, USA, [2]Oregon Health & Science University, USA, [3]San Francisco Coordinating Center, USA, [4]California Pacific Medical Center Research Institute, USA, [5]University of Minnesota & Minneapolis VA Health Care System, USA, [6]University of Minnesota, USA, [7]University of Pittsburgh Graduate School of Public Health, USA, [8]University of California, San Diego, USA, [9]University of California, Davis Medical Center, USA, [10]Park Nicollet ClinicUniversity of Minnesota, USA

Incident radiographically-detected vertebral fractures (RVF) are associated with substantial back pain morbidity in older women. However, consequences of incident RVF on back pain symptoms in older men have not been examined prospectively.

To evaluate the association of incident RVF with subsequent back pain symptoms in older men, we used data from MrOS, a prospective cohort of community-dwelling men aged ⩾65 years. At baseline (V1) and visit 2 (V2), about 4.6 years later, lumbar and thoracic spine x-rays were obtained, and men self-reported back pain symptoms (any, severity, bother) and back pain-related daily activity limitation for the past 1 year. Prevalent (V1) and incident (V2) RVF were determined by Genant semi-quantitative grading criteria. V2 back pain severity, bother and activity limitation were the primary outcomes in 3 levels (Table). Frequencies and odds of these outcomes were compared between men with and without incident RVF using odd ratios (OR) and 95% confidence intervals (CI) from multinomial logistic regression. Analyses were adjusted for age, prevalent RVF, and V1 back pain (any, none).

Of 4383 men with complete V1 and V2 spine x-rays, 11% had a prevalent RVF at V1. During follow-up, 4.5% (196) of men had an incident RVF by V2. At V1, any back pain (61% vs. 67%, p=0.07) and bother most or all the time from back pain (p=0.04) were similarly or less common in men with versus those without a subsequent incident RVF. The two groups also had a similar V1 prevalence of moderate or severe back pain (p=0.22), and of activity limitation because of back pain (p=0.11). However, by V2, any back pain was reported significantly more often by men with incident RVF than by men without incident RVF (73% vs. 59%, p<0.0001). Further, for each back pain symptom, the percentage of men reporting the worst level was greater in men with incident RVF than in those without incident RVF (Table). Even after adjustment, ORs of all back pain symptom outcomes were significantly elevated.

In these older men, incident RVF were associated with large, statistically significant odds of severe, frequent, and activity limiting back pain at follow-up. However, residual confounding may affect these results. Further, because the exact dates of incident RVF are unknown, timing of changes in back pain symptoms relative to RVF occurrence cannot be determined. Incident RVF may be an important cause of new or worsened back pain symptoms in older men.

Back Pain Outcome	No new RVF	New RVF	OR (95% CI)*
Severity			
No back pain	40%	27%	1.0 (referent)
Mild	29%	30%	2.2 (1.5-3.3)
Moderate/Severe	31%	43%	3.0 (2.0-4.5)
Bother			
No back pain	40%	27%	1.0 (referent)

Atypical femoral fractures: Sensitivity and specificity of radiographic characteristics. Annette Adams*[1], Fei Xue[2], Jean Chantra[3], Richard Dell[4], Susan Ott[5], Stuart Silverman[6], Joseph Giaconi[7], Cathy Critchlow[8]. [1]Kaiser Permanente Southern California, USA, [2]Amgen, Inc., USA, [3]Kaiser Permanente Southern California, USA, [4]Kaiser, USA, [5]University of Washington Medical Center, USA, [6]Cedars-Sinai/UCLA, USA, [7]Cedars Sinai Medical Center, USA, [8]Amgen Inc., USA

Purpose: To understand the real-world application of the 2013 ASBMR atypical femoral fracture (AFF) case definition criteria by summarizing the sensitivity and specificity of radiographic features for distinguishing AFF from other subtrochanteric or diaphyseal fractures among women enrolled in a large integrated health care organization.

Methods: We identified 55 physician-validated AFFs from years 2010-2012 and a sample of 39 non-AFF (nAFF) subjects from years 2009-2012, all with available radiographs. One fracture image was selected per subject for review by each of 4 independent reviewers, osteoporosis experts representing 4 different medical specialties: internal medicine, rheumatology, orthopedics, and radiology. Using a standardized data collection tool based on the 2013 revised AFF case definition, reviewers indicated the presence or absence of the following characteristics viewable on radiograph: subtrochanteric or diaphyseal fracture location, fracture pattern, non-comminution, periosteal and/or endosteal thickening, and cortical thickening. Sensitivity and specificity for each characteristic was calculated for each reviewer, and summarized across reviewers with the mean and range.

Results: The most highly sensitive factors for distinguishing between AFF and nAFF were subtrochanteric/diaphyseal fracture location (mean 99.4%, range 97.7-100%), lateral cortex transverse fracture pattern (mean 95.3%, range 90.2-97.7%),

medial cortex transverse or oblique fracture pattern (mean 94.0%, range 83.3-100%), and minimal or non-comminution (mean 94.2%, range 88.6-97.7%). Of these factors, specificity was greatest for lateral cortex transverse fracture pattern (mean 72.8%, range 69.6-76.0%), while medial cortex transverse or oblique pattern was least specific (mean 11.2%, range 0-42.6%). Localized endosteal/periosteal reaction and generalized increase in cortical thickness were only moderately sensitive and specific.

Conclusion: Fracture location and transverse fracture pattern in the lateral cortex were the most sensitive characteristics and were most highly agreed upon across reviewers in clinical settings. Other characteristics were less readily agreed upon across reviewers. Measurement of discrete combinations of individual characteristics may enhance sensitivity and/or specificity.

Back Pain Is Associated with Increased Risk of Recurrent Falls Among Older US Women. Lynn Marshall*[1], Stephanie Harrison[2], Peggy Cawthon[3], Deborah Kado[4], Una Makris[5], Richard Deyo[6], Hans Carslon[6], Michael Nevitt[7]. [1]Oregon Health & Science University, USA, [2]San Francisco Coordinating Center, USA, [3]California Pacific Medical Center Research Institute, USA, [4]University of California, San Diego, USA, [5]University of Texas Southwestern Medical Center, USA, [6]Oregon Health & Science University, USA, [7]University of California San Francisco, USA

Falls among older adults are a major clinical and public health concern. Several fall risk factors, such as poor physical function, depression and prescription pain medication use, are more prevalent among older adults with back pain than in those without back pain. Whether back pain itself increases fall risk in elderly populations is unknown.

Our purpose was to determine the association of back pain to one-year risk of new falls among 6841 community dwelling U.S. women aged ⩾65 years enrolled in the Study of Osteoporotic Fractures. On questionnaires at the second study visit, women reported any back pain in the past year, back pain severity, frequency of being bothered by back pain, and limiting their usual activities because of back pain. Every four months for the next 1 year, women reported numbers of falls on mailed questionnaires or phone calls. The primary outcome was recurrent falls defined as ⩾2 falls. Risk of recurrent falls was compared between women with and without back pain symptoms using risk ratios (RR) and 95% confidence intervals (CI) from multivariable log-binomial regression. In the final model, RRs were adjusted for age, education, smoking history, fainting in the past year, hip pain, history of stroke, and Geriatric Depression Scale. During model building, factors assessed and found not to be potential confounders were prevalent radiographic vertebral fracture, difficulty with any instrumental activity of daily living, gait speed, grip strength, chair stand time, tandem stand time, and prescription medication use for pain, sleep problems or anxiety.

Most (61%) women reported any back pain in the past year. Of women with back pain, 58% reported moderate and 14% reported severe pain, 24% reported being bothered most or all of the time by back pain, and 22% reported limiting their usual activities because of back pain. During follow-up, 10% had recurrent falls. Any back pain was associated with a 50% increased risk of recurrent falls (adjusted RR=1.5, 95% CI: 1.3, 1.8). RRs for recurrent falls were of similar magnitude in all categories of back pain severity, frequency of bother, and for activities not limited by back pain (Table). The RR was highest for women who limited their activities because of back pain.Older community dwelling women with a recent history of back pain are at increased risk for recurrent falls. Whether back pain treatment reduces fall risk, or risk of injurious falls, in this population should be examined.

Table. Risk Ratios (RR) and 95% Confidence Intervals (CI) for Recurrent Falls in Relation to Back Pain Symptoms among Women Aged ≥65 Years

Back Pain Symptom	No.	Recurrent Falls, N (%)	Adjusted RR* (95% CI)
Severity			
No back pain	2,670	184 (7%)	1.0 (Referent)
Mild	1,174	121 (10%)	1.4 (1.1, 1.8)
Moderate	2,406	286 (12%)	1.6 (1.3, 1.9)
Severe	591	73 (12%)	1.5 (1.1, 1.9)
Frequency			
No back pain	2,670	184 (7%)	1.0 (Referent)
Rarely/Sometimes	3,160	347 (11%)	1.5 (1.2, 1.8)
Most/All of the time	1,011	133 (13%)	1.6 (1.3, 2.0)
Activities Limited by Back Pain			
No back pain	2,670	184 (7%)	1.0 (Referent)
No, activities not limited	3,240	339 (10%)	1.4 (1.2, 1.7)
Yes, activities limited	931	141 (15%)	1.8 (1.4, 2.3)

*Adjusted for age, education, smoking history, fainting in the past year, hip pain, history of stroke, and Geriatric Depression Scale.

Fractures Increasing in Oldest Age Groups Despite Decreasing Fracture Rates: A Population-based Study. Susan Jaglal*[1], Gillian Hawker[1], Cathy Cameron[2], Ruth Croxford[3]. [1]University of Toronto, Canada, [2]Women's College Research Institute, Canada, [3]Institute for Clinical Evaluative Sciences, Canada

Many studies in developed countries have found that while the older population has been increasing, hip fracture rates in particular have been decreasing thereby offsetting the expected increase due to the aging population. We examined numbers and rates of common osteoporotic fractures including the hip, wrist, pelvis, shoulder and spine in the province of Ontario, Canada by age and sex from fiscal year 2002/03 to 2012/13. For hip fractures, the age-standardized rates have decreased but the absolute numbers have increased. The largest growth in the number of fractures has been in the oldest age groups 80+ and 90+ years. In 2002/03 the number of hip fractures in the 90+ age group was 1558 compared to 2226 in 2012/13. There was a 39.4% increase in the number of hip fractures among men aged 90+ and 27.3% increase among women aged 90+. Overall larger percent increases in fractures from fiscal year 2002/03 to 2012/13 were seen among men. Among those age 80+ the increase was 25.5% for men and 12.3% for women. For the other fractures large percent increases were also seen in the 80+ age group for both men and women. For wrist fractures there was a 36.7% increase in men age 80+ and 23.5% increase in women age 80+; for pelvis 49.4% in men age 80+ and 38.4% in women age 80+; for shoulder age 33.5% in men age 80+ and 25.3% in women age 80+; for spine 52% in men age 80+ and 41% in women age 80+. Fractures of the pelvis and spine had the largest percent increase in those aged 80+ followed by wrist, shoulder and hip across the time period. The percent increases were greater among men than women across all of the fracture types. Also steady yearly increases across the time period were noted. Overall these large percent increases in fractures in the oldest old in the midst of declining fracture rates have major implications on the cost of fractures to the health care system and the targeting of screening and treatment efforts. Factors may include increased comorbidity and less than optimal fall and fracture prevention particularly among men. Future research needs to characterize these fracture patients compared to the general elderly population and examine the reasons for the increase in fractures particularly among the oldest old.

Incidence and Worsening of Vertebral Fracture, Disc Height Narrowing, and Facet Joint Osteoarthritis Evaluated by Computed Tomography: The Framingham Study. Mohamed Jarraya*[1], Yanhua Zhou[2], L Adrienne Cupples[2], Ali Guermazi[3], Ching-An Meng[4], Elana Borchin[5], Douglas Kiel[6], Mary Bouxsein[7], Elizabeth (Lisa) Samelson[8]. [1]Boston University School of Medicine, USA, [2]Boston University School of Public Health, USA, [3]Boston University School of Medicine, USA, [4]Hebrew SeniorLife, USA, [5]Hebrew SeniorLife, USA, [6]Hebrew SeniorLife, USA, [7]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [8]Hebrew SeniorLife, Harvard Medical School, USA

Prior studies have not described degenerative features across the whole spine assessed by CT in non-clinical populations. We conducted a longitudinal study of new or worsening vertebral fracture (VF), disc height narrowing (DHN), and facet joint osteoarthritis (FJOA) over 6 yr in a community-based sample of men and women, and characterized these changes by spinal level, age and sex.

Participants included 1,191 cohort members of the Framingham Study (538 men, 653 women; mean age 61 yr; range 40-85) who had CT scans 6 yr apart. A radiologist scored VF, DHN, and FJOA at each spinal level (T5-L4) as grade 0=normal, 1=mild, 2=moderate, or 3=severe. We used chi-square tests to compare prevalence of VF (grade⩾1), DHN (grade⩾2), and FJOA (grade⩾2) and frequency of new or worsening features (increase in ⩾1 grade) in women and men, and to test for trends with age.

Prevalence of VF, DHN, and FJOA was 31, 68, and 87%. Prevalence of all 3 features increased with age ($p<0.01$). Frequency of new or worsening VF was similar in women (15%) and men (16%) and increased with age in women ($p<0.01$) but not men (p=0.41). Worsening of DHN increased with age ($p<0.01$) in women and men. Frequency of worsening DHN was higher in women than men at each age group (<60, 60-69, ⩾70 yr; women 47, 64, 71%; men 38, 59, 60%), however, the difference between men and women was significant only for <60 yr (p=0.03). Worsening of FJOA did not increase with age in women (p=0.21) or men (p=0.15). However, women had greater frequency of FJOA worsening than men ($p<0.01$) in those <60 yr (54 vs 38%) and 60-69 yr (57 vs 39%), but not ⩾70 yr (44 vs 46%, p=0.77). Frequency of new or worsening VF showed a bimodal distribution with peaks at the midthoracic and thoracolumbar spine, whereas worsening of DHN was greatest at the lumbar (13-16%, L2-L4), and midthoracic (8%, T7-T8) regions (FIGURE). Frequency of worsening of FJOA decreased from the upper to lower thoracic spine (from 7% at T5 to 3% at T12), but increased from the upper to lower lumbar spine (from 8% at L1 to 24% at L4).

We found that over 6 yr, more than half of men and women in this population experienced new or worsening of DHN and FJOA, and 1/6 had new or worsening VF. The high frequency of progression and distribution of these radiographic changes along the spine suggest that pathology in bone, disc, and joint may occur interdependently. Further work is needed to determine the sequence and etiology of these changes and impact on clinical outcomes.

Serum Bioavailable Estradiol Adds Information Beyond FRAX® for Hip Fracture Reclassification in Elderly Swedish Men – MrOS Sweden. Liesbeth Vandenput[1], Maria Nilsson[2], Maria Nethander[3], Joel Eriksson[4], Osten Ljunggren[5], Andreas Kindmark[5], Mattias Lorentzon[6], Helena Johansson[7], Jodi Lapidus[8], Ying Wang[9], Eric Orwoll[9], Magnus Karlsson[10], Dan Mellstrom[11], Claes Ohlsson*[12]. [1]University of Gothenburg, Sweden, [2]Centre for Bone & Arthritis Research, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, Sweden, [3]Bioinformatics Core Facility, Sahlgrenska Academy, University of Gothenburg, Sweden, [4]Centre for Bone & Arthritis Research, Sweden, [5]Uppsala University Hospital, Sweden, [6]Geriatric Medicine, Center for Bone Research at the Sahlgrenska Academy, Sweden, [7]Centre for Metabolic Bone Diseases, University of Sheffield Medical School, Sweden, [8]Oregon Health & Science University, USA, [9]Oregon Health & Science University, USA, [10]Skåne University Hospital Malmö, Lund University, Sweden, [11]Sahlgrenska University Hospital, Sweden, [12]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden

Prospective cohort studies have reported that low serum estradiol (E2) and testosterone (T) and high sex hormone-binding globulin (SHBG) associate with increased fracture risk in men and that thresholds for these associations might exist. The aim of the present study was to determine the clinical utility of serum sex steroids for fracture risk prediction in men.

In the prospective population-based MrOS Sweden study, 2,542 men (69-80 years old) had baseline E2 and T analyzed by GC-MS and SHBG by RIA (exclusions; surgical or chemical castration, androgen treatment, anti-androgen treatment or not having all three serum parameters). Bioavailable (bio) E2 and bio T were calculated using law of mass equations. Incident X-ray verified hip (n=173, incidence 6.8%) and major osteoporotic (n=418, incidence 16.4%) fractures were evaluated (follow up @10 years). Discrimination was determined using C-statistics while net reclassification improvement (NRI) was used for reclassification analyses. The improvements of sex steroids as continuous parameters, as well as dichotomous parameters using predefined published thresholds (T < 300 ng/dl; bioT < 163.5 ng/dl; E2 < 16 pg/ml; bioE2 < 11.4 pg/ml; SHBG > 59.1 nM), were evaluated from base models of age (Model 1), age, BMI and BMD (Model 2), and FRAX®, including BMD (Model 3).

The improvements in fracture risk discrimination (AUC) from the different base models were minor for all sex steroids. However, when evaluated with the sensitive NRI, a significant improvement of all three base models was seen for low E2 (bio E2 < 11.4 pg/ml) both after 5 years (Model 1, 43%, $p = 9.3x10^{-4}$; Model 2, 42%, $p = 1.7x10^{-3}$; Model 3, 42%, $p = 1.7x10^{-3}$) and 10 years ($p \leq 1.1x10^{-3}$ for all three models) follow up for hip fractures. The increased NRI was mainly the result of a correct downward reclassification of those without a fracture. Similar significant improvements were observed for major osteoporotic fractures ($p < 1x10^{-4}$). Neither the different T nor SHBG parameters increased NRI significantly for hip fractures.

These findings demonstrate that low bio E2 (< 11.4 pg/ml) adds information beyond FRAX® for hip and major osteoporotic fracture reclassification in elderly Swedish men.

Associations of 25OHD and $1,25(OH)_2D$ with BMD, BMD Loss and Fracture. Christine Swanson*[1], Priya Srikanth[2], Christine Lee[1], Steven Cummings[3], Ivo Jans[4], Jane Cauley[5], Roger Bouillon[6], Dirk Vanderschueren[6], Eric Orwoll[1], Carrie Nielson[1]. [1]Oregon Health & Science University, USA, [2]Department of Public Health & Preventive Medicine, Oregon Health & Science University, USA, [3]San Francisco Coordinating Center, USA, [4]Laboratory of Diagnostic Medicine, KU Leuven, University of Leuven, Belgium, [5]University of Pittsburgh Graduate School of Public Health, USA, [6]Katholieke Universiteit Leuven, Belgium

Relationships between the biologically active vitamin D metabolite $1,25(OH)_2D$ and skeletal outcomes are uncertain. We examined the associations of $1,25(OH)_2D$ with BMD, BMD change, and incident fractures in a cohort of older men and compared them to those of 25OHD.

Using a case cohort design, we analyzed data from 1,000 men (age 74.6 ± 6.2 years) in the Osteoporotic Fractures in Men (MrOS) study, including 537 men that had DXA BMD obtained at baseline and at ~4.5 years of follow-up that were used for the longitudinal BMD change analyses. Incident non-spine fractures were ascertained. Cox proportional hazards models were used to test the association between vitamin D metabolite levels and non-vertebral and hip fractures. Linear regression models were used to estimate the association between vitamin D measures and baseline BMD and BMD change. Interactions between 25OHD and $1,25(OH)_2D$ were tested for each outcome.

There were 432 men with incident non-vertebral fractures and 81 with a hip fracture. As previously reported, higher 25OHD was associated with higher baseline BMD, slower BMD loss and lower hip fracture risk (Table). Conversely, men with

higher $1,25(OH)_2D$ had lower baseline BMD (Table). $1,25(OH)_2D$ associations with BMD loss and fracture were weaker than those for 25OHD and were usually not statistically significant (Table). However, the risk of hip fracture tended to be lower in men with higher $1,25(OH)_2D$ levels after adjustment for baseline hip BMD (HR 0.74, 95% CI 0.56-1.00), an effect that was similar in magnitude to that seen with higher 25OHD levels (Table). There were no interactions between 25OHD and $1,25(OH)_2D$ on any outcome (all $p \geqslant 0.60$). Adjustment of $1,25(OH)_2D$ data for 25OHD (and vice-versa) had little effect on the associations observed, however the protective effect of $1,25(OH)_2D$ on hip fracture seen after adjustment for baseline BMD was attenuated (Table).

In older men, higher $1,25(OH)_2D$ was associated with lower baseline BMD but was not related to the rate of bone loss or fracture risk. However, with BMD adjustment, a weakly protective association for hip fracture was seen with higher $1,25(OH)_2D$. The associations of 25OHD with skeletal outcomes were generally stronger and independent of $1,25(OH)_2D$.

Table. BMD and Fracture Associations with 25OHD and $1,25(OH)_2D$

	Base Model[a]	Base Model[a] + BMD[b]	Base model[a] + BMD[b], Adjusted for the other Vit D[g]

Visceral Adipose Tissue is Associated with Better Trabecular Density and Architecture but Increased Cortical Porosity: The Framingham Osteoporosis Study. Douglas Kiel*[1], Kerry Broe[2], Adrienne Cupples[3], Serkalem Demissie[3], Caroline Fox[4], Marian Hannan[5], Yi-Hsiang Hsu[6], David Karasik[7], Ching-Ti Liu[3], Robert McLean[8], Ching-An Meng[9], Elizabeth (Lisa) Samelson[10], Xiaochun Zhang[9], Mary Bouxsein[11]. [1]Hebrew SeniorLife, USA, [2]Institute for Aging ResearchHebrew SeniorLife, USA, [3]Boston University School of Public Health, USA, [4]National Institutes of Health, USA, [5]HSL Institute for Aging Research & Harvard Medical School, USA, [6]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, [7]Hebrew SeniorLife; Bar Ilan University, USA, [8]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, [9]Institute for Aging Research, Hebrew SeniorLife, USA, [10]Hebrew SeniorLife, Harvard Medical School, USA, [11]Beth Israel Deaconess Medical Center, Harvard Medical School, USA

Obesity has been considered to protect against osteoporosis and fx because of mechanical and hormonal factors. Recently, body fat has been shown to be associated with lower BMD and increased risk for some fractures. Few studies have examined associations between VAT, BMD and microarchitecture in cortical and trabecular compartments. Thus, we performed a cross-sectional study of VAT and BMD and bone microarchitecture in 381 participants (60% women), avg age 57.6 ± 7.4 yrs from the Framingham Offspring cohort to determine whether cortical and trabecular BMD and microarchitecture differ according to the amount of VAT. VAT was measured from multidetector CT abdominal imaging by manually tracing its position beneath the abdominal muscular wall. BMD and microarchitecture were measured at the tibia and radius using HR-pQCT (Scanco Medical AG), focusing on six bone parameters: cortical porosity (CtPo,%), cortical thickness (CtTh, mm), cortical bone area fraction CtA/TtA), trabecular BMD (TbBMD, mg/cm^3), trabecular number (TbN, 1mm), and total BMD (TtBMD, $mgcm^3$). To isolate the contribution of VAT to BMD and architecture, we calculated the ratio of VAT to body weight (WT) and used ANCOVA to assess the association between quartiles of VAT/WT and BMD or microarchitecture. Analyses were repeated using quartiles of VAT. Analyses adjusted for sex, age, ht (except for CtA/TtA), and in women, menopausal status. The average VAT was 1,977 ± 1013 cm^3. The average weight was 78 ± 16 kg. At the radius and tibia, CtTh and CtA/TtA increased across quartiles of VAT/WT (all p-trends <0.01). CtPo also increased by 8.2% at the radius (p-trend 0.06), but not the tibia (p-trend 0.43). TbBMD, TbN, and TtBMD increased with greater VAT/WT at the radius and tibia. When the analyses were repeated using quartiles of VAT, CtPo increased in the radius by 17% (p-trend 0.02) and in the tibia by 12% (p-trend 0.002) at the tibia. TbBMD and TbN generally increased while TtBMD did not. In conclusion, higher visceral adiposity is associated with greater total BMD, trabecular BMD and number, and greater cortical bone fraction, but also with greater cortical porosity. The finding that total density was positively associated with VAT/WT but not VAT may imply that weight increases total density while VAT affects cortical porosity. These complex effects on trabecular and cortical indices may partly explain why fractures occur at certain sites in obese persons such as the ankle and arm.

Association between visceral adipose tissue (VAT)/weight ratio and bone density and microarchitecture measures of the radius and tibia

How Long Does the Therapeutic Window of Opportunity Persist After a Fragility Fracture?. François Cabana[1], Marie-Claude Beaulieu[2], Nathalie Carrier[1], Sophie Roux[3], Gilles Boire*[4]. [1]Centre hospitalier universitaire de Sherbrooke, Canada, [2]Université de Sherbrooke, Canada, [3]University of Sherbrooke, Canada, [4]Centre Hospitalier Universitaire De Sherbrooke, Canada

Objective: To determine how long an incident fragility fracture (FF) remains a strong incentive to initiate osteoporosis (OP) treatment.

Methods: The OPTIMUS program was implemented in fracture clinics to educate women and men over age 50 on the link between incident FF and OP and to empower Family Physicians (FPs) to diagnose and treat OP. The 1409 (1022 untreated) patients were included after sustaining a FF, and were assigned to usual care (Control Group; CG), or Minimal or Intensive interventions. In both interventions, baseline individualized letters were sent to FPs explaining the rationale to treat OP after most FF. Intensive patients also received more frequent follow-up (FU) phone calls during the first year and results from baseline blood tests were sent to their FP. Over the first year, reminder letters were sent to FPs of intervention patients who remained untreated upon FU, again suggesting to treat. At one year, untreated patients in both the CG and Minimal groups were offered an Intensive intervention. Phone FU was completed up to 48 months.

Results: Within Minimal and Intensive intervention patients, OP treatment initiation had occurred by 6 months in 31.7% of those initially untreated, and by 12 months, in 25% of those still untreated at 6 months. By 24, 36 and 48 months, rates had decreased to 14.1%, 2.5% and 0.7% of patients still untreated at 12, 24 and 36 months, respectively. The corresponding rates in CG patients were 13.8%, 5.6%, 17.8%, 5.2% and 5.4% by 6, 12, 24, 36 and 48 months, respectively.

Of the 114 untreated CG patients offered Intensive intervention at 12 months, 37 (32.5%) accepted the intervention and 20 (17.5%) initiated treatment. Following 12 months of Minimal intervention, 33/150 (22%) untreated patients accepted Intensive intervention but only 6 (4%) got treated over the next 36 months.

Conclusion: Individualized interventions targeting FF patients and their FPs were most successful to initiate OP treatment during the first 6 to 12 months after the initial FF, and their impact rapidly decreased thereafter. Even when offered an effective Intensive intervention, patients still untreated after 12 months of Minimal Intervention were unlikely to get treated, and treatment initiation rates after 12 months were slightly higher but remained low in untreated usual care patients. These findings suggest that, although a FF represents an ideal opportunity to start OP treatment, the window has already closed by 1 year.

FR0343

Validation of ICD-9 Codes or Self-report for Osteoporotic Fractures in Women Aged 45-60. Susan Ott*[1], Rebecca Hubbard[2], Belinda Operskalski[2], Do Peterson[2], Kelly Hansen[2], Andrea Lacroix[3], Delia Scholes[4]. [1]University of Washington Medical Center, USA, [2]Group Health Research Institute, USA, [3]Fred Hutchinson Cancer Research Center, USA, [4]Group Health CooperativeGroup Health Research Institute, USA

Fractures (fx) are an important outcome for epidemiological studies. Reviewing individual medical records is a more expensive method of collecting data than using automated electronic medical records or self-reported fx from questionnaires. We studied the validity of ICD-9 codes to identify clinical fx from osteoporotic locations (including ankles) in women aged 45-60 from a US health care system compared to physician-adjudicated medical record review. We also examined the concordance between self-report and validated fx.

Methods: After excluding for estrogen use, hysterectomy, or no encounters, we searched computerized records of 56021 women for an outpatient or inpatient fx code between 1/1/08 and 3/30/13. We identified 3178 potential cases and reviewed their charts. A random sample of 4374 women without a code were age-matched to those with a fx. Those with a confirmed fx and the random sample were telephoned by trained interviewers who were unaware of the fx status. Surveys were completed by 1186 women with a validated fx and 2301 without. We asked whether they had experienced a fx and which bone, if any, was broken. We then reviewed charts from the 52 women without a code but who self-reported a fx. We assumed that women without a code who self-reported no fx had not had a clinical fx.

RESULTS-Codes: Of 2529 validated fx, most common locations were: forearm (28%), ankle (21.8%), ribs (10.4%). The positive predictive value was 78% (women with an ICD-9 code who had a current clinical osteoporotic fx). Fx occurred in 0.91% without a code. Sensitivity of ICD-9 codes was 83.7%, specificity was 98.7%. Nine percent of the ICD-9 codes were for non-specific locations, and only half of them were osteoporotic (the rest were in hands/feet or >1yr prior to the code). Specific codes for other skeletal sites correctly identified fx between 62 and 100% of the time (Fig1). In those who had a fx and a site-specific ICD-9 code, the skeletal site was accurate in 97%. Self-report: 88% of women who had a valid fx reported the fx and, if so, the location was correct in 99%. Vertebral fx were the most commonly unreported fx (Fig2).

Conclusion: Either ICD-9 codes or self-report can be used to identify osteoporotic fx in middle-aged women using large datasets. The sensitivity is good with 83.7% for ICD-9 codes and 88% for self-report, but there will be some errors when evaluating fx of the spine or ankle.

Where the ball was dropped. Why do patients fall off Secondary Fracture Prevention Programs?. Manju Chandran*, Xiao Feng Huang, Matthew Tan. Osteoporosis & Bone Metabolism Unit, Singapore General Hospital, Singapore

Introduction: OPTIMAL (Osteoporosis Patient Targeted and Integrated Management for Active Living) is a clinician champion driven, case manager run multi-component secondary fracture prevention program set up in the public hospitals and polyclinics of Singapore. At Singapore General Hospital (SGH), the largest public tertiary teaching hospital in Singapore, the program was set up as a collaborative effort between multiple departments and in the 6 years since inception has gained international recognition amongst the osteoporosis community for its work on recruiting patients with fragility fractures. We have previously reported on the set up of the program and the good medication compliance rates amongst patients who completed 2 year follow up in the program [1, 2]. The aim of this study is to enumerate the patients who discontinued the program during the course of follow up and to evaluate the reasons for such discontinuation.

Methods: Retrospective review of the Centralized Computerized Recorded Data (CCRD) base of patients recruited into the OPTIMAL program at SGH.

Results: 1214 patients with fragility fractures have been recruited into the program. 302 patients have completed 2 years of follow up. 156 patients have been ''right-sited'' (discharged to follow up care with General Practitioners) and 483 patients are in current active follow up at the hospital. 104 patients withdrew from the program citing various reasons and 129 just stopped showing up for follow up visits. 29 patients had other reasons for stopping the program including development of other medical conditions such as renal failure, following up with specialists outside the hospital and thus being lost to follow up etc. 11 patients died during the course of follow up. The reasons cited by patients for withdrawal are shown in Table 1.

Discussion: It is important whilst implementing and running a fracture liaison service to periodically look back and evaluate where all ''the ball was dropped''. Willingness by patients to participate and comply with antiosteoporosis strategies is important to ensure disruption of the otherwise inevitable fracture cascade. Though our ''drop out'' rate was low, it is still large enough to be concerning and ensure that we do not rest on our laurels and make continued efforts to make the services beneficial to patients. Educating individuals with fracture and their families on the consequences and treatment of osteoporosis may help to make them more accepting of secondary preventive measures. Knowledge of the challenges faced by patients may be of use to stakeholders interested in developing fracture liaison services.

FR0345

Individual Characteristics that Predict Higher Health Care Costs After Hip Fracture. John Schousboe*[1], Misti Paudel[2], Brent Taylor[3], Allyson Kats[4], Beth Virnig[5], Bryan Dowd[5], Kristine Ensrud[6]. [1]Park Nicollet ClinicUniversity of Minnesota, USA, [2]Division of Epidemiology University of Minnesota, USA, [3]University of Minnesota, USA, [4]Chronic Disease Research Group, USA, [5]Division of Health Policy & Management, University of Minnesota, USA, [6]University of Minnesota & Minneapolis VA Health Care System, USA

Purpose: Health care costs after hip fracture are highly variable. Our purpose was to estimate the association of pre-fracture individual patient characteristics with costs attributable to hip fracture by linking the Study of Osteoporotic Fractures (SOF) participants' data with their Medicare claims.

Methods: For women enrolled in the SOF as of 1/1/1991 with a confirmed match to their Medicare claims (n=9,228), incident hip fractures were identified in Medicare Analysis and Provider Review (MedPAR) files by a hospital discharge diagnosis code of 820.0x or 733.14. Inpatient and outpatient costs were estimated from MedPAR, Carrier, Outpatient, and Home Health Care files. The association of pre-fracture participant characteristics with log of total costs of care for the first year after hip fracture were estimated with random effects regression models, adjusted for total costs of care the year before hip fracture and comorbidity.

Results: 738 women had a hip fracture (at mean age 83.7 years) between 1/1/1992 and 12/31/2009 while enrolled in Medicare Fee for Service. Median total costs (2010 U.S. dollars) the years before and after hip fracture were $4,465 (IQR $0 to $14,066) and $35,556 (IQR $24,830 to $50,903), respectively. Pre-fracture predictors significantly associated with total costs of care after hip fracture were body mass index, walk speed and depressive symptoms (table).

Model predicted total costs after hip fracture for those with BMI ⩾ 30 kg/m2 compared to 20 to 24.9 kg/m2 were $43,383 vs. $33,916; for walk speed <1 m/sec vs. ⩾ 1.0 m/sec, $35,821 vs. 30,258; and for GDS score ⩾ 6 vs. < 3, $39,726 vs. $33,208.

Age, bone density, grip strength, chair stand speed, health status, cognition (modified Mini-mental state exam score) and functional status (ability to perform IADLs) were not associated with total costs of care after hip fracture.

Conclusions: Pre-fracture obesity, slow walk speed, and depression are associated with higher health care costs after hip fracture, adjusted for comorbidity and health care costs the year before hip fracture.

Predictor (number of women)	Coefficient* (95% C.I.)
Body Mass Index < 20 kg/m² (80)	0.01 (-0.22 to 0.24)
20-24.9 (339)	Reference
25-29.9 (241)	0.04 (-0.12 to 0.19)
≥ 30 (78)	*0.43 (0.20 to 0.66)*
Walk Speed < 1.0 m/sec (644)	*0.29 (0.08 to 0.50)*
≥ 1.0 (94)	Reference
Geriatric Depression Scale Score <3 (418)	Reference

A longitudinal analysis of the impact of very low energy diets on bone mineral density. Palak Choksi*[1], Amy Rothberg[2], Andrew Kraftson[2], Nicole Miller[2], Katherine Zurales[2], Charles Burant[2], Catherine Van Poznak[3], Mark Peterson[2]. [1]University of Michigan, USA, [2]University of Michigan, USA, [3]University of Michigan Comprehensive Cancer Center, USA

Background The rising prevalence of obesity and concerns associated with co-morbidities and healthcare expenditures have led to greater clinical emphases on weight reduction. Very low energy diets are increasingly popular mainly due to the rapid weight loss without adverse effects associated with gastric bypass procedures. Body mass is also known to be an important determinant of bone mineral density (BMD), and rapid weight reduction is associated with decreases in BMD and potentially increased fracture risk. However, the effect of long-term weight loss maintenance, achieved through intensive caloric restriction on bone, is not well known. The purpose of this study was to examine the effects of a 12 week very low energy diet (800 calories/day) to promote a 15% loss in weight on changes in body mass, fat-free mass (FFM), and BMD over a period of 2 years.

Methods: Participants were adult men and women (50.6 ± 7.2 years) with a BMI >35 kg/m2, or having a BMI >32 kg/m2 and a clinical diagnosis of Type 2 diabetes mellitus. Changes in body mass, total body BMD, and FFM were examined after 15% of weight reduction and at the end of 2 years. The influence of absolute and rate of weight reduction on BMD and FFM were assessed using general linear modeling, with baseline BMD (or FFM) as a covariate, and age, sex and change in body mass as model predictors.

Results Forty-nine subjects completed the 2-year study. The average weight loss was greater for men (23.51 ± 12.5 kg; 24.3%) than women (16.8 ± 19.2 kg; 19.2%) ($p<0.05$). At the end of 2 years, women lost greater FFM (8.2% vs. 5.0%; $p<0.05$), but not BMD (2.2% vs. 0.8%; p=0.13) than men. After adjusting for baseline BMD, age, and sex, there was a significant association between total weight loss and 2-year BMD (β = -0.001; p=0.01). Similarly, there was a significant independent association between total weight loss and 2-year FFM loss (β = -116.5; p=0.012). Age was an independent predictor of 2-year BMD (β = -0.002; $p<0.01$), but not FFM ($p>0.05$). Rapidity of weight reduction did not predict changes in BMD at 2 years; however it was independently associated with changes in FFM (β = -243.7; p=0.04).

Conclusions Diet-induced weight reduction may have deleterious effects on BMD and FFM. Although the clinical implications of these negative effects on bone and outcomes on fracture are unclear, these findings highlight the importance of focusing on bone health in individuals who are considering very low calorie diets.

FR0352

High Vitamin D is Associated with Low Fasting Insulin in Non-diabetic Men. Anna Nilsson*[1], Ewa Waern[2], Mattias Lorentzon[3], Magnus Karlsson[4], Claes Ohlsson[5], Dan Mellstrom[6]. [1]Sahlgrenska University Hospital, Sweden, [2]Sahlgrenska University Hospital, Sweden, [3]Geriatric Medicine, Center for Bone Research at the Sahlgrenska Academy, Sweden, [4]Skåne University Hospital Malmö, Lund University, Sweden, [5]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden, [6]Sahlgrenska University Hospital, Sweden

Vitamin D has been suggested as an important factor in glucose metabolism and vitamin D deficiency has been associated with insulin resistance. We have studied the covariation of vitamin D and fasting insulin levels in 1010 subjects participating in MrOS Gothenburg (a population-based study on randomly identified ambulant men aged 69 to 81 years). Fasting serum levels of 25-OH-vitamin D, adiponectin, leptin, insulin, parathyroid hormone, SHBG, and fasting plasma glucose were determined with commercially available kits. Season-adjusted z-scores of 25-OH-vitamin D levels were used for statistical calculations. All serum and plasma values except 25-OH-vitamin D and glucose were logarithmized after analysis of skewness. Patients with diabetes (n=148), defined as a previous diagnosis of diabetes mellitus or fasting plasma glucose levels above 7 mmol/L at the time of the blood sampling, were excluded prior to the statistical analysis leaving data from 822 non-diabetic men available for the statistical analysis. Mean age was 75.3 (SD: 3.2) years and mean BMI was 25.9 (SD: 3.3) kg/m2. A negative association was observed between 25-OH-vitamin D Z-scores and fasting insulin values ($r=-0.13$, $p<0.001$). Vitamin D levels were also negatively correlated to BMI ($r=-0.12$, $p<0.001$) and PTH ($r=-016$, $p<0.001$). Fasting insulin levels were negatively correlated to SHBG ($r=-0.18$, $p<0.001$) and adiponectin ($r=-0.39$, $p<0.001$) and positively correlated to BMI ($r=0.46$, $p<0.001$) and glucose ($r=0.33$, $p<0.001$). There was no association between fasting insulin and PTH levels (r=0.05). Adjustment for age did not change these linear correlations for insulin, nor did adjustment for age and BMI. Adjustment for age, BMI, and adiponectin eliminated any correlation between fasting insulin and SHBG (partial r=0.005) whereas vitamin D remained as a negative predictor of insulin (partial $r=-0.10$, $p<0.01$). Insulin levels were also positively correlated to leptin ($r=0.51$, $p<0.001$) and multiple regression showed that age, 25-OH-vitamin D, BMI, adiponectin, leptin and fasting plasma glucose explained 42 % of the variation of insulin levels ($p<0.001$). We conclude that there is a covariation in the concentrations of 25-OH-vitamin D and insulin in non-diabetic elderly men that is independent of age, PTH, SHBG, BMI, and adipocyte-derived hormones. The physiological explanation of this observation remains unclear, although previous studies suggest a possible insulin-sensitizing effect of vitamin D.

Sex-specific effects of PTH, total 25OHD, and free 25OHD on femoral neck BMD. Lisa Langsetmo*[1], Claudie Berger[2], Brent Richards[3], Christopher Kovacs[4], William Leslie[5], David Hanley[6], Jonathan Adachi[7], Jerilynn Prior[8], Suzanne Morin[3], K. Shawn Davison[9], Stephanie Kaiser[10], Robert Josse[11], David Goltzman[3]. [1]Canadian Multicenter Osteoporosis Study, Canada, [2]CaMos, McGill University, Canada, [3]McGill University, Canada, [4]Memorial University of Newfoundland, Canada, [5]University of Manitoba, Canada, [6]University of Calgary, Canada, [7]St. Joseph's Hospital, Canada, [8]University of British Columbia, Canada, [9]University of Victoria, Canada, [10]Dalhousie University, Canada, [11]St. Michael's Hospital, University of Toronto, Canada

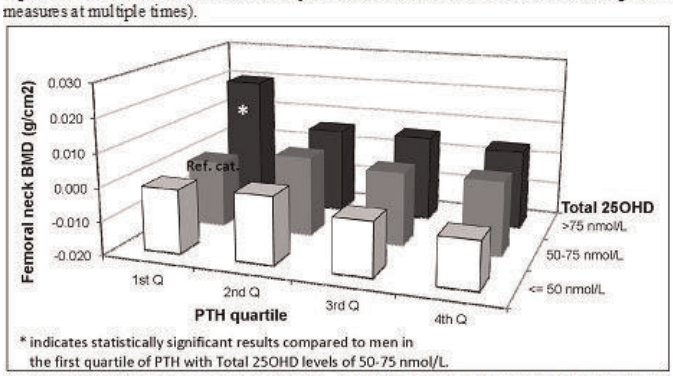
Serum 25-hydroxy vitamin D (25OHD) and parathyroid hormone (PTH) levels are inversely related and have been associated with changes in bone mineral density (BMD). Our objective was to examine relationships with femoral neck BMD of serum Total 25OHD (T-25OHD), Free 25OHD (F-25OHD), vitamin D binding protein (DBP) and PTH.

We measured levels in 3892 fasting serum samples taken during 1995-1997, 2000-02 and/or 2005-07 from 1902 women and 825 men (96% Caucasian) aged 25+ years in the longitudinal, population-based, Canadian Multicentre Osteoporosis Study. We used hierarchical models based on 10 years of longitudinal data to determine the associations between T-25OHD and PTH with femoral neck BMD. We considered pairwise interactions of T-25OHD, PTH, and antiresorptive use and adjusted for relevant covariates (see Figures). We also measured DBP concentrations and calculated F-25OHD levels in a subset of 1425 women and 605 men using only the most recent serum sample. We used linear regression models to determine the associations between F-25OHD, DBP and PTH with femoral neck BMD, considering similar interactions as above and adjusted for the same covariates.

Women with T-25OHD levels <50 nmol/L had lower femoral neck BMD values than those with T-25OHD between 50-75 nmol/L [0.008 g/cm^2 (95% C.I.: 0.002; 0.013) difference]. Higher PTH levels (> median) were also associated with lower femoral neck BMD [-0.010 g/cm^2 (-0.016; -0.003)] compared to women in the 1st quartile (Q) of PTH. Men with T-25OHD levels >75 nmol/L and with low PTH levels [1st Q] had femoral neck BMD higher by 0.020 g/cm^2 (0.006; 0.035) (Figure 1) than men in the 1st Q of PTH with T-25OHD of 50-75 nmol/L. When using the subset with measured DBP in women, femoral neck BMD was determined predominantly by quartiles of PTH, with a significant effect of F-25OHD only at the highest and lowest quartiles of PTH (Figure 2). Exclusion of DBP from the model did not modify PTH and F-25OHD estimates. F-25OHD and DBP were not associated with femoral neck BMD in men.

In summary, our results suggest a greater effect of PTH than 25OHD on femoral neck BMD with possible modification of effect by F-25OHD or T-25OHD level. DBP levels did not alter the relationship of PTH with BMD in either women or men.

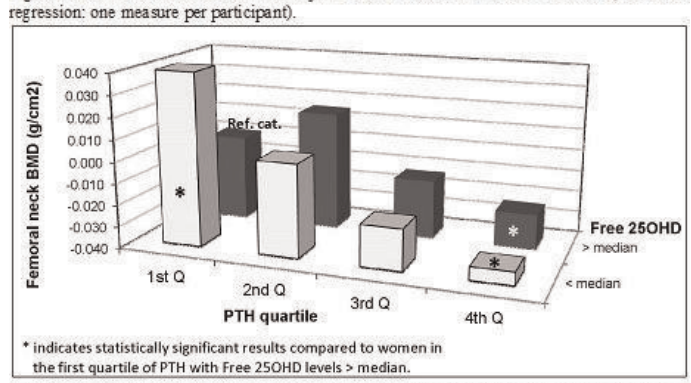
Figure 1: Femoral neck BMD estimates by PTH and Total 25OHD levels in men (using serum measures at multiple times).



Covariates included were age group, education, race, BMI, height, calcium intake, antiresorptive use, regular physical activity, regional centre.

Figure 1: Femoral neck BMD estimates by PTH and Total 25OHD levels in men

Figure 2: Femoral neck BMD estimates by PTH and Free 25OHD levels in women (from linea regression: one measure per participant).



Covariates included were age group, education, race, menopause, BMI, height, calcium intake antiresorptive and corticosteroid use, regular physical activity, regional centre.

Bone Anabolic Effect in Ovariectomized Mice by low-dose RANKL Mediated by FoxP3$^+$ CD8 T-Cells. Reggie Aurora*[1], Zachary Buchwald[2], Chang Yang[3], Suman Nellore[2], Elena Sashkova[2], Deborah Novack[4], Richard Di Paolo[2]. [1]Saint Louis University University, USA, [2]Saint Louis University School of Medicine, USA, [3]Washington University in St Louis School of Medicine, USA, [4]Washington University in St. Louis School of Medicine, USA

Estrogen loss at menopause increases effector T-cells that produce low-levels of proinflammatory cytokines in the bone marrow. These cytokines lead to a lower bone density and a higher risk of bone factures because they promote bone resorption, osteoclastogenesis and a deficit in new bone formation. Estrogen loss also increases levels of Receptor Activator of NF-κB ligand (RANKL), which promotes differentiation and bone resorption by osteoclasts. To treat osteoporosis, anti-RANKL therapy has been shown to be efficacious. Remarkably, we found while all doses of RANKL promote osteoclast activity in estrogen-replete mice, in ovariectomized (OVX) mice low-dose RANKL treatment ameliorated osteoporosis. Twelve week-old OVX mice were treated on two consecutive days, two weeks post-OVX, with 0.125 mg/kg RANKL. In addition to measuring bone resorption by serum CTX, mice were sacrificed and bones were harvested at ten days post-treatment for analysis by μCT, bone histomorphometry and FACS of bone marrow. We will present data that low-dose RANKL activates osteoclasts to induce FoxP3 expression in CD8 T-cells. FoxP3$^+$ T-cells suppress the aberrant activation of self-reactive T-cells and promote the resolution of inflammation. We refer to these FoxP3$^+$ CD8 T-cells as osteoclast-induced Tc$_{REG}$ (OC-iTc$_{REG}$). We have previously demonstrated that OC-iTc$_{REG}$ suppress osteoclast activity to form a novel feedback loop. We also have shown that OC-iTc$_{REG}$ are bifunctional, in addition to suppressing osteoclasts, they suppress the proliferation of CD4 and CD8 T-cells by dendritic cells. The effect of low-dose RANKL was superior to bisphosphonate treatment because it reduced levels of proinflammatory effector T-cells in the bone marrow allowing for new bone formation. We also demonstrate that proinflammatory cytokines (e.g. TNFα and IL-17) repress Tc$_{REG}$ induction, but a pulse of low-dose RANKL restores Tc$_{REG}$ induction by osteoclasts. Our studies therefore provide the mechanism by which low-dose RANKL leads to anabolic effect on the bone. Indeed, this anabolic effect of low-dose RANKL could not have been anticipated but can be explained by the negative feedback loop between osteoclasts and CD8 T-cells. These studies therefore extend the purview of Osteoimmunology by providing new insights into the effects of T-cells on osteoclasts and the effect of osteoclasts on regulating T-cells.

FR0358

Hyperlipidemia-induced Loss of Bone Mass is Caused by Decreased Bone Formation and is Associated with an Inflammatory Response in the Marrow: Evidence from the ApoE$^{-/-}$ Mouse Model of Atherosclerosis. Yu Liu*[1], Annick DeLoose[2], Kanan Vyas[2], Michela Palmieri[2], Amanda Hunt[2], Robert Weinstein[1], Charles O'Brien[1], Stavros Manolagas[1], Robert Jilka[1]. [1]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [2]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

Atherosclerosis and osteoporosis are epidemiologically linked. However, a common mechanism that may underlie these conditions has not been elucidated. In the ApoE$^{-/-}$ mouse model of atherosclerosis, high fat (HF) diet causes hyperlipidemia and subendothelial accumulation of low density lipoprotein (LDL), which is oxidized in macrophages by reactive oxygen species (ROS) and the lipoxygenase Alox15.

Oxidized LDL and ROS then initiate a pathogenetic inflammatory response, similar to the disease in humans. Because HF diet also causes loss of bone mass in this model, we investigated whether the loss of bone is associated with an inflammatory response. Four-month-old female ApoE-/- mice fed a HF diet (37.1% kcal from fat) exhibited progressive loss of DEXA BMD in both the spine and femur over a 12 week period, as compared to mice fed a control diet (17% kcal from fat). The loss of BMD was accompanied by a decrease in trabecular bone volume due to a reduction in trabecular thickness, as well as decreased cortical thickness and increased cortical porosity, as determined by microCT. In vertebral cancellous bone sections, both osteoblast and osteoclast number were reduced by 2-fold and bone formation rate was reduced by 7-fold. Indices of lipid oxidation and ROS levels measured in bone marrow supernatants and bone marrow cells, respectively, were also increased. The number of monocyte/macrophages in the marrow was 30-40% higher, as measured by flow cytometry of anti-CD11b stained cells, whereas T cell (CD3+) and B cell (CD19+) number was unaffected. Nonetheless, transcript levels of the inflammatory cytokines IL-1β, TNF, IL-6 and MCP-1 were increased by 2-10 fold in all three hematopoietic cell types, as determined by qPCR analysis of cells purified with magnetic beads. The pro-osteoclastogenic RANKL was increased by 2-fold in T cells and by 5 fold in B cells; but so was the anti-osteoclastogenic IFNγ in T cells (2-fold). Alox15 expression was detected only in monocytes/macrophages, but its level was unaffected by the HF diet. These results suggest that hyperlipidemia induces an inflammatory response in the bone marrow of $ApoE^{-/-}$ mice, caused by ROS- and Alox15-mediated lipid oxidation. Furthermore, our results reveal that the loss of bone mass caused by HF diet is the result of decreased bone formation, not increased bone resorption.

Eldecalcitol, a new-generation vitamin D_3 analog, increases trabecular bone via "minimodeling" in ovariectomized cynomolgus monkeys. Tomoka Hasegawa*[1], Saito Mitsuru[2], Doyle Nancy[3], Chouinard Luc[3], Smith Susan[3], Yamamoto Tomomaya[4], Oda Kimimitsu[5], Saito Hitoshi[6], Amizuka Norio[4]. [1]Hokkaido University, Japan, [2]Jikei University School of Medicine, Japan, [3]Charles River Laboratories, Canada, [4]Hokkaido University, Japan, [5]Niigata University, Japan, [6]Chugai Pharmaceutical Co., Ltd., Japan

Eldecalcitol, a new-generation vitamin D_3 analog, seems to be more bone anabolic compared with its predecessor alfacalcitol. Eldecalcitol inhibits osteoclast formation and bone resorption. It also promotes "minimodeling", a focal "budding" of new bone shown in the ovariectomized (OVX) rat model (Bone, 2011). Minimodeling is a type of bone formation independent of bone resorption: resting osteoblasts begin to deposit new bone onto existing bone surfaces without prior osteoclast-driven bone resorption. The objective of this study was to examine if eldecalcitol inhibits osteoclast formation and promotes minimodeling in a more complex animal model, the ovariectomized cynomolgus monkeys.

Twenty female cynomolgus monkeys of at least nine years of age were ovariectomized, and administered eldecalcitol (0.3μg/kg/day, ELD group) or vehicle (OVX group) for six months. All animals were injected with calcein prior to anesthesia. Femora and vertebrae were processed for histological examinations and collagen crosslinking evaluations. ELD bones showed increases in the number and thickness of femoral and vertebral trabeculae. OVX bones featured a relatively broader bone resorption area with several osteoclasts and rougher bone surfaces compared to those seen in ELD bones. Calcein labeling in ELD bones appeared as convex lines in the new bone buds deposited atop smooth arrest lines. Thus, eldecalcitol appears to induce minimodeling in cynomolgus monkeys. We also examined the occurrence of enzymatic cross-linking of collagen fibrils. Fractionated trabecular bone samples from both groups were separated in low-density (< 2.0 mg/mL) and high-density (≥ 2.0 mg/mL) fractions through stepwise centrifugation. In the OVX group, differences in the degree of enzymatic crosslinking between fractions was not evident, while in the ELD group higher enzymatic collagen crosslinking was verifiable in the high density fraction, suggesting the occurrence of bone formation despite inhibition of bone resorption. In summary, eldecalcitol appears to inhibit osteoclast formation and induce new bone formation by means of minimodeling in cynomolgus monkeys as well as rats.

Pregnancy and Lactation Bone Loss Cause Long-Lasting Structural Deterioration of the Maternal Skeleton that Accumulates over Multiple Reproductive Cycles. Chantal De Bakker*[1], Allison Altman[1], Connie Li[2], Wei-Ju Tseng[2], Xiaowei Liu[1]. [1]University of Pennsylvania, USA, [2]University of Pennsylvania, USA

Maternal bone undergoes dramatic changes during reproduction, as the mother's skeleton forms a source of calcium for the fetus and newborn. However, the extent of pregnancy bone loss and recovery post-weaning remain controversial, leading to important questions regarding the effect of multiple reproductive cycles and the precise roles of pregnancy, lactation, and weaning in maternal bone health. In this study we tracked changes in trabecular bone microarchitecture in the same rats (n=5) across 3 reproductive cycles (between ages 4-12 mo) using *in vivo* μCT (10.5 μm, Scanco vivaCT40). Each cycle consisted of a 3-wk pregnancy, 3-wk lactation, and 3-6 wk post-weaning recovery. 6 age-matched, virgin controls were used.

In the first reproductive cycle, trabecular structure declined rapidly during pregnancy and lactation (Fig 1A). At parturition, bone volume fraction (BV/TV) and trabecular number (Tb.N) were 46% and 24% lower than baseline, respectively, and after lactation, BV/TV, Tb.N, and Tb.Th were 82%, 56%, and 34% below baseline ($p<0.05$). After weaning, BV/TV recovered back to pre-lactation, but not to pre-pregnancy values, Tb.N did not recover, and Tb.Th recovered fully to baseline values. Serum TRACP 5b levels decreased 67% after weaning ($p<0.05$), but were not significantly different among control, lactation, and pregnancy rats. μCT-based *in vivo* bone dynamic histomorphometry indicates that bone resorption rate was highly elevated during pregnancy and lactation, and decreased 90% after weaning ($p<0.05$); bone formation rate increased 209% after weaning ($p<0.05$).

Subsequent reproductive cycles showed less total deterioration of BV/TV, Tb.N, and Tb.Th than the first cycle. Changes during pregnancy were less dramatic in later cycles but the effects of lactation and weaning remained pronounced (Fig 1C). For each cycle, recovery was incomplete, resulting in a net bone loss (Fig 1B). At the end of the study, trabecular structure of reproductive rats was substantially different from controls.

This study is the first longitudinal assessment of trabecular microstructure during multiple reproductive cycles. Each cycle induced a persistent, net bone loss, due to incomplete recovery after weaning. Comparison of the 3 cycles demonstrates decreased bone loss during later cycles, likely due to a reduction of bone lost during pregnancy. The first reproductive cycle causes significant pregnancy bone loss, which may have a long-lasting negative impact on bone quality.

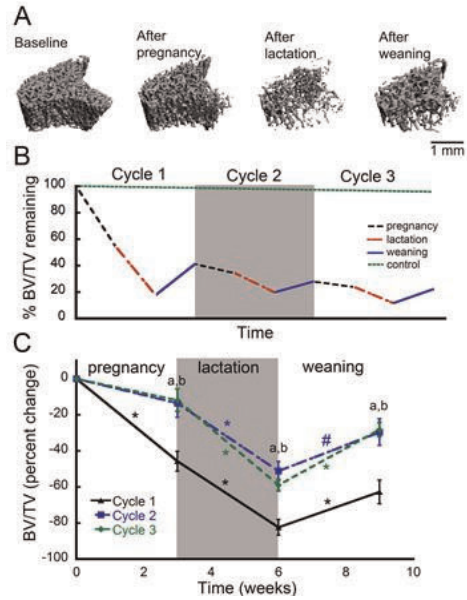

Fig 1. (A) Representative renderings of the trabecular compartment at baseline, after pregnancy, after lactation, and 6 weeks after weaning during the first reproductive cycle. The effect of multiple cycles is demonstrated by (B) a profile plot showing changes in the percentage of the baseline BV/TV that remains at each reproductive stage, and (C) percent change in BV/TV occurring during pregnancy, lactation, and weaning during each reproductive cycle. *: different from previous time point ($p<0.05$), #: trend towards difference from previous time point ($p<0.1$), [a]: Cycle1 ≠ Cycle2 ($p<0.05$), [b]: Cycle1 ≠ Cycle3 ($p<0.05$).

Chronic Stress Induces Bone Loss via Glucocorticoid Signaling in Osteoblasts. Holger Henneicke*[1], Jingbao Li[2], Sylvia Jane Gasparini[3], Markus Seibel[4], Hong Zhou[4]. [1]ANZAC Research Institute, The University of Sydney, Australia, [2]Key Laboratory for Space Bioscience & Biotechnology, Institute of Special Environmental Biophysics, Faculty of Life Sciences, Northwestern Polytechnical University, China, [3]Bone Biology Program, ANZAC Research Institute, The University of Sydney, Australia, [4]Bone Research Program, ANZAC Research Institute, University of Sydney, Australia

Chronic stress and depression are risk factors for low bone mineral density and increased fracture risk. However, the mechanisms underlying stress-induced bone loss are ill defined. We hypothesised that endogenous hypercortisolism and its effect on osteoblast function play a central role in stress-induced bone loss. The present study aimed to define the effects of chronic mild stress (CMS) on the skeletal phenotype of young adult mice.

Methods: We used a transgenic (tg) mouse model in which glucocorticoid signaling had been selectively disrupted in osteoblasts and osteocytes via targeted over-expression of the glucocorticoid-inactivating enzyme 11ß-hydroxysteroid dehydrogenase type 2. Eight-week old tg mice and their wild type (WT) littermates were exposed to CMS for the duration of 4 weeks. Stressors included restraint stress, exposure to hot and cold, tilted cages and overnight illuminations. At endpoint, corticosterone serum concentrations were determined by LCMS and both the L3-vertebra and tibia were analyzed by micro-CT and dynamic histomorphometry.

Results: Compared to non-stressed control mice, serum corticosterone levels increased ~3-fold in stressed WT and tg mice. Exposure to CMS resulted in loss of vertebral trabecular bone mass in WT but not tg mice when compared to their respective non-stressed controls (BV/TV WT: -16%; tg: +3%, $p<0.01$). This was mainly due to a decrease in trabecular number (WT: -14%; tg: +1%; $p<0.05$) and a corresponding increase in trabecular separation (WT: +12%; tg: +1%; $p<0.04$) in WT mice only. While trabecular bone in the tibia was unaffected in both WT and tg mice exposed to CMS, tibial cortical volume (WT: -9%; tg: +1%; $p<0.05$) as well as cortical thickness (WT: -6%; tg: +2%; $p<0.05$) were reduced in stress-exposed WT but not in stress-exposed tg mice. Dynamic histomorphometry of the tibia revealed reduced endocortical (WT: -14%; tg: +42%; $p=0.055$) and pericortical bone formation rates (WT: -86%; tg: -3%; $p=0.062$) in stressed WT mice only.

Conclusion: In mice, CMS induces loss of both trabecular (vertebra) and cortical bone (tibia) via increased glucocorticoid signaling in osteoblasts and osteocytes.

Deletion of TRAF3 Specifically in Mesenchymal Progenitor Cells Results in Age-related OsteoporosisThrough Effects on both Osteoblasts and Osteoclasts. Jinbo Li*[1], Zhenqiang Yao[2], Yan Xiu[3], Xiaoxiang Yin[4], Lianping Xing[2], Brendan Boyce[3]. [1], USA, [2]University of Rochester, USA, [3]University of Rochester Medical Center, USA, [4]University of Rochester Medical Center, USA

TNF receptor–associated factor 3 (TRAF3) negatively regulates non-canonical NF-κB signaling and thus limits RANKL- and TNF-induced osteoclast (OC) formation. However, it is not known if TRAF3 plays a role in osteoblast (OB) lineage cells. To study this question, we deleted TRAF3 specifically in mesenchymal precursor cells (MPCs) by crossing *Traf3$^{f/f}$* mice with *Prx-1^{cre}* mice to generate *Traf3$^{f/f}$;Prx-1^{cre}* conditional knockout (cKO) mice and examined tibiae from 3- and 9-m-old cKO and *Traf3$^{f/f}$* control (Ctl) mice by μCT and histiology. TV/BV and bone formation rates were normal in 3-m-old cKO mice, but these were significantly decreased in 9-m-old cKO mice (BV/TV: 3.6 ± 0.6 vs $15\pm3\%$ in Ctl; and BFR: 1.03 ± 0.05 vs 1.62 ± 0.16 $\mu m^3/\mu m^2/d$ in Ctl; $p<0.01$). Interestingly, cKO OC numbers in growth plate were increased at both ages (231 ± 26 vs 109 ± 16 and 270 ± 35 vs $143\pm17/mm^2$ tissue area in 3- and 9-m Ctl, respectively). MPCs from 3-m-old cKO mice had higher proliferation (% $BrdU^+$ cells in $CD45^-CD105^+Scal^+$ cells: 23% vs 8% in Ctl), but reduced OB differentiation (% ALP^+ cells in CFU-ALP^+ colonies: 43 ± 4 vs $79\pm6\%$ in Ctl). In contrast, MPCs from 9-m-old cKO mice had reduced proliferation (% $BrdU^+$ cells: 3% vs 8% in Ctl) and OB differentiation (% ALP^+ cells: 21 ± 3 vs $80\pm8\%$ in Ctl). Bone-derived MPCs from both 3- and 9-m-old cKO mice had more than 3-fold higher RANKL expression levels. Calvarial cells from neonatal cKO mice induced significantly more OCs from both cKO and Ctl spleen cells than cells from WT mice ($TRAP^+$ area: 2.7 ± 0.15 vs $1.3\pm0.4mm^2$ and 2.3 ± 0.4 vs $0.8\pm0.2mm^2$, respectively). To investigate if TRAF3 is involved in age-related bone loss, we examined TRAF3 protein levels in bone samples from 2- and 18–m-old WT mice and found that they were 80-90% lower than in young mice. In addition TGFb1 (which is released from bone resorption sites) induced TRAF3 ubiquitination and degradation. In summary, deletion of TRAF3 in MPCs results in osteoporosis as mice age due to increased RANKL-induced bone resorption and reduced OB formation and activity. We conclude that TRAF3 plays critical roles not only in OCs, but now also in MPCs to protect against age-related bone loss by limiting bone resorption and enhancing bone formation. Prevention of TRAF3 degradation in osteoblastic cells could be a new therapeutic approach for osteoporosis.

FR0363

Heterozygosity for *TGFβR3* Alters Osteoblast and Osteoclast Differentiation and Signaling, Increases Peak Bone Mass, and Sensitizes Mice to OVX-Induced Bone Loss. Nicole Fleming[1], Vanessa Bray[2], James Butler[3], Tristan Fowler[4], Joey Barnett[5], Dana Gaddy[6], Erick Fleming[1], Jeffry Nyman[7], Rashmi Pandey[3], Daniel Perrien*[7]. [1]VUIIS, Vanderbilt University, USA, [2]Dept of Orthopaedic Surgery & Rehabilitation, Vanderbilt University, USA, [3]Department of Orthopaedic Surgery & Rehabilitation, Vanderbilt University, USA, [4]Universität Wien, Aut, [5]Department of Pharmacology, Vanderbilt University, USA, [6]University of Arkansas for Medical Sciences, USA, [7]Vanderbilt University Medical Center, USA

TGFβ-superfamily ligands and their Type I and Type II receptors have established roles in bone. However, the role of the Type 3 TGFβ Receptor (TβR3/Betaglycan) in bone metabolism has not been reported. Deletion of *TβR3* in endothelial cells increases sensitivity to TGFβ and impairs sensitivity to BMP. Hence, we hypothesized that *TβR3*+/- bone cells would display altered sensitivity to these ligands. Bone marrow from TβR3+/- mice cultured in osteogenic media produced fewer alkaline phosphatase-positive (AP+) colonies and lower %AP+ colonies than wild-type (WT) marrow. Furthermore, TβR3+/- cells were >10-fold more sensitive to inhibition of differentiation by TGFβ1 and significantly less sensitive to enhancement by BMP2. However, TGFβ- or BMP2-induced phosphorylation of Smads, p38, or Erk1/2 was unaltered in TβR3+/- Ob. In contrast, bone marrow or splenocytes cultured with M-CSF and RANKL produced significantly more osteoclasts (OCL) and OCL differentiation was enhanced by TGFβ more in TβR3+/- than in WT. These data led us to examine the bone phenotype of TβR3+/- mice. MicroCT analysis of trabecular bone in the tibial metaphysis and L4 vertebra (VB) showed that 6-mo old male and female TβR3+/- mice (n=9-12/grp) had significantly greater bone volume fraction (BV/TV) and improved trabecular structure (Tb.N, Tb.Th, and Tb.Sp) compared to WT mice ($p<0.05$) in both genders. Because TGFβ-family ligands have been implicated in the development of osteoporosis, 4-mo old WT and TβR3+/- mice on a C57BL6 background underwent gonadectomy and were harvested 9 weeks later. Consistent with previous data, female WT C57BL6 mice were resistant to OVX-induced bone loss, as only Tb.Th was significantly lower than WT-Sham in either bone ($p<0.002$ for both). However, OVX caused significant trabecular bone loss in the tibia [BV/TV ($p<0.005$); Tb.N, Tb.Th, and Tb.Sp (all $p<0.05$)] and VB (BV/TV, Tb.Th; both $p<0.01$) of TβR3+/- OVX mice vs. TβR3-Sham. In contrast, ORX in male mice significantly decreased trabecular BV/TV and structural properties in both WT and TβR3+/- compared to male Sham mice of the same genotype ($p<0.05$ for all). These data demonstrate that haploinsufficiency of *TβR3* alters OB and OCL differentiation and sensitivity to TGFβ1 and BMP2 (possibly through a non-Smad mediated pathway), and confers a high bone volume phenotype in mice and sensitizes female mice to OVX-induced bone loss, establishing an important role for TβR3 in bone metabolism and the response to OVX.

High Cortico -Trabecular Junctional Zone Porosity and Reduced Trabecular Density in Persons with Stress Fractures. Afrodite Zendeli*[1], Christian Muschitz[2], Minh Bui[3], Lukas Fischer[4], Wolfgang Schima[5], Fritz Lomoschitz[6], Norbert Laimer[7], Ali Ghasem-Zadeh[8], Roger Zebaze[9], Ego Seeman[8]. [1]Endocrine Centre, Austin Health, University of Melbourne, Australia, Australia, [2]St. Vincent's Hospital, Austria, [3]Centre for Epidemiology & Biostatistics, Melbourne School of Population & Global Health, University of Melbourne, Australia, Australia, [4]Computational Imaging Research Lab, Department of Biomedical Imaging & Image-guided Therapy, Medical University of Vienna, Austria, Austria, [5]5 Department of Diagnostic & Interventional Radiology - St. Vincent Hospital Vienna, Austria, Austria, [6]Department of Diagnostic & Interventional Radiology - St. Vincent Hospital Vienna, Austria, Austria, [7]Medical Department II - St. Vincent Hospital Vienna - The VINFORCE Study Group, Austria, Austria, [8]Austin Health, University of Melbourne, Australia, [9]Austin Health, University of Melbourne, Australia

Introduction Stress fractures associated with repetitive loading are usually not accompanied by deficits in areal bone mineral density (aBMD). Metaphyseal cortical bone is formed by condensation or 'corticalization' of trabeculae as they arise from the periphery of the growth plate. Adjacent trabeculae coalesce by bone formation upon their surfaces while central trabeculae form trabecular bone.

Methods To determine whether bone fragility is due to abnormalities in bone microstructure high resolution peripheral quantitative computed tomography (HR-pQCT) images of the distal radius and distal unfractured tibia of 26 cases (11 females, 15 males; mean age 37.1 ± 3.1 years) with stress fractures in their lower limb were compared with measurements obtained in 62 age-matched healthy controls (38 females, 24 males; mean age 35.0 ± 1.6 years).

Results In men, relative to controls, at the radius, cases had 11.4% smaller cortical cross sectional area (CSA) ($p = 0.012$). Porosity was higher in the outer transitional zone (OTZ) (6.9%, $p = 0.006$), inner transitional zone (ITZ) (2.4% $p = 0.043$) and the compact-appearing cortex (CC) (13.4% $p = 0.023$). Trabecular vBMD was 22.0% lower ($p = 0.002$). Similarly, at the distal tibia, cases had a 9.7% smaller cortical CSA ($p = 0.008$). Cortical porosity was higher in the OTZ (3.4%, $p = 0.058$), ITZ (0.8%, NS), CC (7.4%, $p = 0.09$). Trabecular vBMD was 17.3% lower ($p = 0.001$). In women, relative to controls, at the distal radius, cases had higher porosity of the OTZ (5.3%, $p = 0.028$), ITZ (2.3%, $p = 0.030$) and CC (11.4%, $p = 0.054$). Trabecular vBMD was 27.4% lower ($p = 0.041$). At the distal tibia, porosity was higher in the OTZ (5.9%, $p = 0.035$), ITZ (3.3%, $p = 0.009$) and CC (12%, NS). For both sexes, the odds ratio (OR) of porosity in CC, OTZ and ITZ at distal radius and distal tibia ranged between 1.24 and 3.13. A higher trabecular vBMD was associated with a lower OR for fracture, ranged between 0.24 and 0.5.Conclusion We suggest that individuals sustaining stress fractures may have impairment of trabecular 'corticalization' during growth. Thinner and more widely spaced trabeculae emerging from the growth plate may fail to corticalize leaving transitional zone porosity and a lower trabecular density.

Pulsatile delivery of parathyroid hormone from an implantable device promotes bone regeneration in vivo. Ming Dang*[1], Amy Koh[2], Laurie McCauley[3], Peter Ma[4]. [1]Macromolecular Science & Engineering Center, University of Michigan, USA, [2]Department of Periodontics & Oral Medicine, University of Michigan, USA, [3]University of Michigan School of Dentistry, USA, [4]Department of Biologic & Materials Sciences, University of Michigan, USA

Objective: Pulsatile administration of parathyroid hormone (PTH) is known to improve bone architecture, bone mineral density and strength. PTH is currently the only anabolic agent clinically used in the US for the treatment of osteoporosis, but requires daily injection, making patient compliance inconvenient and an obstacle to effective treatment. In this study, an implantable multi-layer device loaded with PTH was developed and the anabolic actions of the PTH released from the device were evaluated in mice.

Methods: Biodegradable and biocompatible three-component polyanhydrides composed of sebacic acid, 1,3-bis(p-carboxyphenoxy)propane and poly(ethylene glycol) were synthesized and used as isolation layers. The device was fabricated by stacking the polyanhydrides isolation layers and PTH-loaded drug layers alternately, then sealing the frame of the device with PCL (polycaprolactone). Biologic activity of the released PTH was confirmed using a cell based cAMP binding assay. BSA (bovine serum albumin) loaded devices were prepared as the control group. The BSA protein release profile was measured using a MicroBCA protein assay in vitro. PTH and control devices were subcutaneously implanted in C57B6 mice (10d) for 3 weeks. The mice were then euthanized and vertebrae harvested for histological analyses.

Results: Polyanhydrides with various chemical composition exhibited typical surface erosion behavior and the erosion rate was controlled by the composition. Multi-pulse (more than 21) protein release was achieved using the multi-layer device and the interval time between two adjacent pulses was modulated by the thickness of the polyanhydride isolation layers. PTH release devices stimulated cAMP in human osteoblasts in a pulsatile fashion. Implantation devises delivering PTH increased vertebral bone area compared to control BSA devices measured by histomorphometric analyses. Histological staining of the capsule tissue surrounding the device showed an absence of significant invasion of inflammatory cells, suggesting low toxicity .

Conclusion: An implantable device capable of delivering PTH in a programmed pulsatile manner was developed. The PTH released from the device resulted in anabolic actions in vivo, thus promoting bone regeneration. The implantable device holds promise for treatment of conditions of bone loss without the burden of daily injection.

Site-specific Effects of Spaceflight on Cancellous Bone Architecture in Ovariectomized Rats with Established Osteopenia. Jessica Keune*, Dawn Olson, Urszula T. Iwaniec, Russell T. Turner. Oregon State University, USA

Site-specific reductions in bone mass are commonly observed in both male and female astronauts who are physically fit and have normal bone density. However, it is less clear whether spaceflight results in further bone loss in already osteopenic individuals. The goal of this study was to determine the effects of spaceflight on cancellous bone mass and microarchitecture in the ovariectomized (ovx) rat model with established osteopenia. Rats were ovx at 10 weeks of age, divided into two groups (ground control and flight, n = 12/group), and starting at 12 weeks of age flown aboard the Space Shuttle (STS-62) for 14 days. The rats were sacrificed on day of landing and cancellous bone mass and microarchitecture was evaluated in distal femur, distal humerus, and 2nd lumbar vertebral body using micro-computed tomography. Compared to ground controls, rats flown in space had lower cancellous bone volume fraction in distal femur metaphysis, distal femur epiphysis, and lumbar vertebra (Table). Significant differences in cancellous bone volume fraction were not detected in distal humerus. The lower cancellous bone volume fraction in the distal femur metaphysis in flight rats was associated with lower connectivity density and trabecular number and higher trabecular spacing; significant differences in trabecular thickness were not detected with treatment. In contrast, the lower cancellous bone volume fraction in the distal femur epiphysis was associated with lower connectivity density, trabecular number and trabecular thickness and higher trabecular spacing. The lower cancellous bone volume fraction in the vertebral body was associated with lower trabecular number and trabecular thickness and higher trabecular spacing; significant differences in connectivity density were not detected with treatment. In summary, the effects of spaceflight on bone microarchitecture in rats with low circulating estrogen levels differ with location, from no measured effect (e.g., distal humerus) to net loss of cancellous bone with variable effects on trabecular connectivity density and thickness (e.g., distal femur metaphysis and lumbar vertebra). These findings suggest that: 1) spaceflight aggravates bone loss associated with estrogen deficiency, and 2) interventions to prevent detrimental skeletal effects of spaceflight need to take into consideration that bone loss may be localized and site-specific.

Effects of spaceflight on cancellous bone volume fraction (bone volume/tissue volume, BV/TV) in distal femur, distal humerus, and lumbar vertebral body.

Anatomical Site	Ground Control (BV/TV, %)	Flight (BV/TV, %)	t-test p-value
Distal femur metaphysis	6.7 ± 0.3	4.9 ± 0.3	< 0.0007
Distal femur epiphysis	28.2 ± 0.2	24.1 ± 0.4	< 0.0001
Distal humerus	32.6 ± 0.5	32.6 ± 0.3	0.9135
2nd lumbar vertebra	20.9 ± 0.4	16.9 ± 0.8	< 0.0005

Data are mean ± SE

GILZ Protects TNF-alpha-induced Bone Loss in Mice. Nianlan Yang*[1], Babak Baban[1], William Hill[2], Mark Hamrick[3], Carlos Isales[1], Xing-Ming Shi[4]. [1]Georgia Regents University, USA, [2]Georgia Regents University & Charlie Norwood VAMC, USA, [3]Georgia Health Sciences University, USA

Background: Tumor necrosis factor-alpha (TNF-α) plays a key role in the pathogenesis of inflammatory diseases such as rheumatoid arthritis (RA). It is known that chronic inflammation causes bone loss. We showed previously that glucocorticoid (GC)-induced leucine zipper (GILZ), a GC anti-inflammatory effect mediator, can enhance osteogenic differentiation of bone marrow mesenchymal stem cells (MSCs), and antagonize the inhibitory effect of TNF-α on MSC differentiation. However, it is not known whether GILZ will have the same effects in vivo and thus serve as a potential new anti-arthritis drug candidate.

Methods: We created TNF-a:GILZ double transgenic mice by crossing a human TNF-a-expressing transgenic mouse with a GILZ transgenic mouse, in which the expression of GILZ is under the control of a 3.6kb type I collagen promoter fragment (Col3.6). The expression of TNF-α and GILZ in double transgenic mice was confirmed by RT-PCR, Western blot and ELISA, and the bone protective effects of GILZ were assessed with standard bone biology and histology techniques.

Results: Overexpression of GILZ blocked TNF-α-mediated bone loss in double transgenic mice as demonstrated by a significantly increased bone mineral density (BMD) in the femur (+13.5%, $p<0.01$), tibia (+12.9%, $p<0.05$) and vertebra (+14.5%, $p<0.05$) compared with that in the TNF-α transgenic mice. GILZ also reduced the expression levels of IL-6 mRNA and serum levels of RANKL, as well as the levels of overexpressed human TNF-α. Furthermore, GILZ antagonized the inhibitory effect of TNF-α on osteocalcin expression in GILZ-TNF-α double transgenic mice. As predicted, the TNF-α transgenic mice developed poly arthritic symptoms between week 8-9 along with significant body weight loss and bone loss. The double transgenic mice, somehow, showed little effect on inflammatory arthritic symptoms compared with the TNF-α transgenic mice. This could be due to the restricted GILZ transgene expression in osteoblastic lineage cells and ubiquitous and high level of TNF-α transgene expression in double transgenic mice because significant reductions of TNF-α was only observed in bone marrow mesenchymal lineage cells (-43.5%) but not in hematopoietic (or osteoclastic) lineage cells.Conclusion: Overexpression of GILZ in osteoprogenitor cells protects bone loss in mice with chronically elevated levels of proinflammatory cytokines such as TNF-α.

FR0368

Kinin receptor B1 and B2 knockout are resistant to the bone losing effects of glucocorticoid treatment. Charlles Castro[1], Marina Eloi*[2], Daniela Horvath[2], João Carlos Ortega[2], João Bosco Pesquero[2], Vera Szejnfeld[3]. [1]Universidade Federal de São Paulo, Brazil, [2]Universidade Federal de São Paulo, Brazil, [3]UNIFESP/EPM, Brazil

Glucocorticoid-induced osteoporosis (GIO), the most common form of secondary osteoporosis is frequently observed in patients with chronic inflammatory diseases. The role of kinins and their receptors B1 and B2 in acute and chronic inflammatory process is well established. On the other hand, the pro-inflammatory effect of kinins on bone remodeling has not been well studied. The present study was designed to investigate the effect of the deletion of the kinin receptors B1 and B2 genes in an animal model for GIO. C57BL/6 mice (both wild type, WT and kinin receptors B1 and B2 double-knockouts, B1B2KO mice) 16 weeks of age (10 animals per group) were treated for 5 weeks with prednisolone (5 mg/kg daily injections intraperitoneally) or saline. *In vivo* BMD measurements were performed at baseline, 2 and 5 weeks of treatment, while static and dynamic bone histomorphometry and serum bone markers were measured at the end of the protocol. As expected, densitometric data have shown that prednisolone treatment was associated with bone and lean mass loss and increased fat mass in WT mice ($p<0.01$). As described, B1B2KO mice had whole body BMD similar to WT controls at baseline and exhibited reduced fat mass from baseline to 5 weeks of the protocol when compared to their WT controls. Interestingly, B1B2KO mice did not lose bone with glucocorticoid treatment. B1B2KO mice had

preserved bone mass after 5 weeks of treatment with prednisolone (baseline BMD 0.0678 ± 0.0026 g/cm2, 5-week BMD 0.0673 ± 0.0021 g/cm2; p=0.536). Fat and lean mass during treatment with prednisolone did not differ from WT controls treated in the same manner. Hystomorphometric analyzes will evaluate whether the glucocorticoid effect on bone formation and resorption are modulated by the expression of B1 and B2 kinin receptors. Our data demonstrated that B1B2KO mice have normal bone mass with reduced adiposity. These mice present resistance to the adverse effect of glucocorticoid on bone homeostasis and that suggests that kinins may play a significant role in the setting of glucocorticoid-induced bone loss.

Vascular Defects Detected by Micro-MRI in the Femoral Head of Glucocorticoid Treated Mice: A Potential Early Diagnostic Predictor of Osteonecrosis. Robert Weinstein*[1], Erin A. Hogan[2], Marilina Piemontese[3], Jinhu Xiong[1], Charles A O'Brien[2], Stavros Manolagas[1]. [1]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [2]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [3]University of Arkansas for Medical Sciences, USA

Osteonecrosis of the hip develops in up to 40% of patients receiving long-term systemic therapy with glucocorticoids but the sequential pathological abnormalities that precede joint collapse remain obscure. Published evidence indicates that the primary adverse skeletal effects of glucocorticoid excess are directly on osteoclasts, osteoblasts, and osteocytes, prolonging the lifespan of the osteoclasts while decreasing the lifespan of osteoblasts and osteocytes. Furthermore, decrements in bone vascularity, blood flow, and water content contribute to the glucocorticoid-induced decrease in bone strength that occurs before and disproportionate to the decline in bone mass. The femoral head may be particularly susceptible to these effects because of the applied load and constrained blood supply. In support of this contention, in mice receiving placebo, the bone formation rate and expression of both the receptor activator of nuclear factor-κB ligand (RANKL) and vascular endothelial growth factor (VEGF) were higher in the cancellous bone of the femoral head than in the distal femur or lumbar vertebra. In C57BL/6 mice, 28 days after implantation of 2.1 mg/k·d slow-release prednisolone pellets, the cancellous bone volume, compression strength, and expression of osteocalcin, RANKL, and VEGF in the femoral head decreased but these changes did not occur in vertebral or distal femoral bone. In addition, the normal branching vascular tree of the femoral head was converted to dilated sinusoids as determined after infusion of lead chromate. Likewise, the trabecular canalicular circulation was diminished as revealed by injection of Procion red. To further investigate the role of changes in bone water in the pathogenesis of the loss of strength of the femoral head, a 7 Tesla Bruker magnetic resonance image scanner (MRI), custom-made surface coils, and 3D fast low angle short (FLASH) imaging were used to enhance T1 contrast of water protons in the murine femoral head, a site with only a 0.5 mm radius. The MRI results indicate that glucocorticoids cause a striking redistribution of marrow water and represent the first in vivo demonstration of glucocorticoid-induced damage to the femoral head. If translated to humans, application of MRI protocols designed to intensify T1 signaling could better identify patients at risk of osteonecrosis.

Estradiol: Endocrine or Autocrine Regulator of Bone? Insights from Mass Spectrometry in Male Mouse Models. Michaël Laurent*[1], Ivo Jans[2], Marco Blokland[3], Frederike van Tricht[3], Saskia Sterk[3], Leen Antonio[4], Brigitte Decallonne[4], Geert Carmeliet[1], Geoffrey Hammond[5], Frank Claessens[4], Dirk Vanderschueren[1]. [1]Katholieke Universiteit Leuven, Belgium, [2]University Hospitals Leuven, Belgium, [3]RIKILT, Wageningen UR, Netherlands, [4]Katholieke Universiteit Leuven, Belgium, [5]University of British Columbia, Canada

Estrogens regulate peak bone mass and age-related bone loss in men. Recent studies in humans have shown that immunoassays have insufficient specificity compared to mass spectrometry to measure low serum sex steroid concentrations, especially estradiol (E2). Despite their importance as a preclinical osteoporosis model, mice lack circulating sex hormone-binding globulin (SHBG), and their steroid metabolism may differ from humans.

We measured sex steroid concentrations in serum, urine and bone homogenate extracts from 2- or 6-month-old wildtype (WT) or transgenic mice overexpressing human SHBG using liquid chromatography tandem mass spectrometry. In a pilot study, SHBG or WT mice (n=5/group) were orchidectomized and given continuous release testosterone (T) or E2 for 4 weeks.

Male WT mice had undetectable circulating E2 (<LOQ i.e. 1.3 pg/ml). Male SHBG mice still only had E2 in the pg/ml range despite SHBG levels >100-fold than normal for human males, and >100-fold higher T and DHT than WT male mice. E2 was detectable in female mice or males given E2, and increased by SHBG. Continuous T did not increase E2 in SHBG or WT males. Steroid profiling revealed estradiol-3-sulphate and other catabolites in urine in equal amounts in WT and SHBG males. E2 was detected in appendicular bone of WT and SHBG male and female mice, even after bone marrow was flushed out. Weights of the androgen-sensitive seminal vesicles were lower and levator ani weights unaffected in SHBG males under both high T and basal conditions, and intraskeletal E2 was significantly decreased in T-treated SHBG mice.

We conclude that serum E2 is undetectable in male mice, in contrast to the vast majority of previous reports based on immunoassays. This absence can be explained by the known lack of aromatization in murine adipose tissue; lack of circulating SHBG and fluctuating T levels are not important explanations. SHBG raises total concentrations of active androgens and estrogens (when present) but restricts their bioavailability and activity in a tissue-specific manner. The presence of estrogen catabolites in urine even in WT males with undetectable serum E2 suggests that it acts as a local hormone (aromatization within tissues). This was confirmed by reliable intraskeletal E2 concentration, even in male WT mice with undetectable E2 in serum. Our results support the use of male mice as a model for estrogen regulation of male bone metabolism, albeit via mostly autocrine and not endocrine mechanisms.

FR0371

H_2O_2 generation in osteoclast mitochondria is indispensible for endocortical, but not cancellous, bone resorption in estrogen or androgen deficiency. Shoshana Bartell*[1], Li Han[1], Aaron Warren[2], Julie Crawford[2], Semahat Serra Ucer[3], Srividhya Iyer[1], Maria Jose Almeida[1], Stavros Manolagas[1]. [1]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [2]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [3]University of Arkansas for Medical Sciences, USA

Loss of bone mass following estrogen or androgen deficiency is caused by increased resorption of the cancellous compartment and of the endosteal surface of the cortex. Nonetheless, osteoclast (Oc) ERα mediates the protective effects of estrogens in the cancellous, but not the cortical, compartment. In contrast, the ERα of osteoblast (Ob) progenitors is required for normal periosteal bone accrual as well as the maintenance of cortical bone mass, but plays no role on cancellous bone. The Oc AR, on the other hand, has no effect on bone in males, whereas the Ob AR is required for the maintenance of cancellous bone. An increase in oxidative stress and phosphorylation of $p66^{Shc}$– an isoform of the growth factor adapter Shc that plays a critical role in mitochondrial metabolism, oxidative stress, and apoptosis – have been implicated in the increased bone resorption associated with estrogen or androgen deficiency. Here, we examined the role of $p66^{Shc}$ in ovariectomy (OVX)-induced bone loss using a mouse model of global deletion of $p66^{Shc}$. The loss of cortical and cancellous bone was similar in both the wild-type control and $p66^{Shc}$ KO mice, suggesting that $p66^{Shc}$ does not play a role in the anti-resorptive effects of estrogens. We next examined the role of mitochondria-derived H_2O_2 in cells of the Oc lineage by generating transgenic mice expressing human catalase targeted to the mitochondria, using the LysM-Cre strain. MitoCAT mice exhibited increased cortical and cancellous bone mass due to a decrease in Oc number. Six weeks following OVX of 12-week-old female mice, oxidative stress (including an increase in the phosphorylation of $p66^{Shc}$) and serum CTx were increased and DEXA BMD was decreased at the spine and femur in the LysM-Cre littermate controls. All of these changes were abrogated in the mitoCAT mice. Furthermore, the mitoCAT mice were protected against the OVX-induced cortical bone loss and increased porosity; but not the loss of cancellous bone, as determined by micro-CT. Similar to the females, orchidectomized (ORX) 18-week-old male mitoCAT mice were protected against cortical but not cancellous ORX-induced bone loss. These results indicate that both estrogens and androgens (or perhaps estrogens alone in both females and males) decrease bone resorption at the endocortical surface via an effect that is mediated by cells of the Ob lineage – perhaps suppression of an osteoclastogenic cytokine – and leads to reduced H_2O_2 generation in osteoclasts.

Bone Mineral Density Changes Among Women Initiating Proton Pump Inhibitors or H2 Receptor Antagonists: Results from the SWAN Bone Study. Daniel Solomon*[1], Susan Diem[2], Kristine Ruppert[3], YinJuan Lian[3], Chih-Chin Liu[4], Alyssa Wohlfarht[4], Gail Greendale[5], Joel Finkelstein[6]. [1]Harvard Medical School, USA, [2]University of Minnesota, USA, [3]University of Pittsburgh, USA, [4]Brigham & Women's Hospital, USA, [5]University of California, Los Angeles, USA, [6]Massachusetts General Hospital, USA

Background: Proton pump inhibitors (PPIs) have been associated with diminished bone mineral density (BMD) and an increased risk of fracture, however prior studies have not yielded consistent results and many have sub-optimal ascertainment of both PPI use and BMD.

Purpose: We used the Study of Women's Health Across the Nation (SWAN) longitudinal cohort to examine the association between annualized BMD changes and new use of PPIs compared with new use of Histamine 2 receptor antagonists (H2RAs) or neither.

Methods: We compared the longitudinal changes in BMD among new users of PPIs, H2RAs and non-users using regression analyses. Mixed linear regression models

included recognized risk factors for osteoporosis, including demographics, menopausal transition stage, BMI, lifestyle factors, as well as comorbidities and concomitant medications. To test these methods, we also examined the effects of hormone therapy (HT) on BMD as a "positive control".

Results: We identified 207 new users of PPIs, 185 new users of H2RAs and 1,676 non-users. Study subjects had a mean age of 50 years and were followed for a median of 9.9 years. Adjusted models found no difference in the annualized BMD change at the lumbar spine, femoral neck or total hip comparing PPI users to H2RA users or non-users (see Figure A). These results were robust to sensitivity analyses. As well, an analysis of HT found that new users of these drugs did gain BMD compared with non-users supporting the validity of our study design (see Figure B).

Conclusions: These longitudinal analyses, plus similar prior studies, argue against an association between PPI use and BMD loss.

Risedronate Prevents Anastrozole-Induced Bone Loss In The IBIS-II Prevention Trial. Ivana Sestak*[1], Shalini Singh[2], Jack Cuzick[3], Glen Blake[4], Rajesh Patel[5], Rob Coleman[6], Mitch Dowsett[7], John F. Forbes[8], Anthony Howell[9], Richard Eastell[10]. [1], United Kingdom, [2]Centre for Cancer Prevention, United Kingdom, [3]Centre for Cancer Prevention, Wolfson Institute of Preventive Medicine, Queen Mary University of London, United Kingdom, [4]King's College London, United Kingdom, [5]Imperial College London, United Kingdom, [6]Department of Oncology, Cancer Clinical Trials Centre, Academic Unit of Clinical Oncology, United Kingdom, [7]Royal Marsden Hospital, United Kingdom, [8]University of Newcastle, Calvary Mater Hospital, Australia, [9]Paterson Institute for Cancer Research, United Kingdom, [10]University of Sheffield, United Kingdom

Background: Aromatase inhibitors, such as anastrozole (A), have been shown to prevent breast cancer in postmenopausal women at high risk of the disease, but these drugs have been associated with accelerated bone loss. Here, we analyse the effect of risedronate (R) on bone mineral density (BMD) after 3 years of follow-up in the IBIS-II trial, which is a randomised, placebo-controlled trial of A in postmenopausal women at increased risk of breast cancer.

Methods: 1410 postmenopausal women were enrolled in the bone sub-study and stratified into three strata according to their baseline T-score at spine or femoral neck (stratum I (N=761): T-score>-1.0; stratum II (N=500): -1.0<T-score>-2.5; stratum III (N=149): -2.5<T-score>-4.0 or/and two fragility fractures). All women received regular monitoring by DXA scans. The primary objective of this analysis was to compare the effect of R versus placebo (P) in osteopenic women in stratum II who were randomised to A in the main study. Secondary objectives included investigating the effect of A on BMD in women not receiving R and furthermore in osteoporotic women all receiving R. All results are presented as mean % BMD changes (95% CI) between baseline and 3 years of follow-up.

Results: Baseline and 3-year BMD data was available for a total of 892 women (stratum I=493, stratum II=296, stratum III=103). 146 women in stratum II were randomised to A (A/R=74, A/P=72). 3-year mean % BMD change at the spine for women receiving A/R was 1.3 (95% CI 0.3 to 2.9) compared to -2.6 (95% CI -3.9 to -1.3) for those on A/P (P<0.0001, Figure). Similar results were seen for mean % BMD change at the total hip (Figure). Women in stratum I and/or II not receiving R had a significant BMD decrease at the spine and total hip when randomised to A compared to P after 3 years of follow-up (spine: -3.9% vs. -1.2%, P<0.0001, total hip: -3.9% vs. -1.8%, P<0.0001). Osteoporotic women all received R and a significant increase in BMD at the spine, but not total hip was seen for women randomised to P but also for those on A (spine: 3.9% vs. 1.3%, P=0.009; total hip: 1.6% vs. 0.3%, P=0.1).

Conclusions: Our results show that women with osteopenia on A and receiving R showed a highly significant increase in BMD at the spine and total hip compared to those not receiving R. Women with healthy bone or osteopenia receiving A showed a large BMD decrease when compared to P, but our results show that BMD loss due to A can be controlled with bisphosphonate treatment.

Figure: Mean % BMD changes at spine and total hip for women on anastrozole in stratum II according to risedronate randomisation.

FR0377

Acute Skeletal Effects of PTH in Combination with Denosumab or Alendronate. Joy Tsai*[1], Hang Lee[2], Yuli Zhu[3], Katelyn Foley[3], Sherri-Ann Burnett-Bowie[1], Robert Neer[1], Benjamin Leder[4]. [1]Massachusetts General Hospital, USA, [2]Massachusetts General Hospital, Biostatistics Center, USA, [3]Massachusetts General Hospital, Endocrine Unit, USA, [4]Massachusetts General Hospital Harvard Medical School, USA

Background: In contrast to the combination of bisphosphonates (BPs) and teriparatide (TPTD), the combination of TPTD and denosumab (DMAB) increases BMD at the spine and hip more than either drug alone. Furthermore, DMAB, unlike BPs, fully inhibits the stimulation of bone resorption induced by TPTD 20-mcg. We aimed to better define the resorptive properties of TPTD in the absence or presence of an antiresorptive drug, as well as the comparative capacity of DMAB and BP to inhibit TPTD-induced bone resorption even in the setting of high dose TPTD (40-mcg).

Methods: 18 postmenopausal osteoporotic women ages 52 to 81 who had not used oral BPs within 1-year were randomized to 2 treatment groups. At baseline, serum CTX, OC, and P1NP were measured both immediately prior to and 4-hours after a single 8 AM 40-mcg SC TPTD injection. When the 4-hour sampling was complete, subjects in group 1 received DMAB 60 mg SC and subjects in group 2 started oral weekly alendronate (ALN) 70 mg. 8-weeks later, CTX, P1NP, and OC were again measured in all subjects immediately before and 4-hours after a TPTD 40-mcg injection. Subjects were fasting at all visits. The within and between-group change in each marker at each visit was assessed by paired and unpaired t-test. The between-group difference between the TPTD-induced change at week 8 versus baseline was compared by ANCOVA.

Results (Fig): At baseline, TPTD induced a significant and similar increase in mean CTX in both treatment groups (ALN 47±13%, DMAB 49±17%). After 8

weeks of antiresorptive therapy, baseline CTX decreased by 63±18% in the ALN group and by 90±5% in the DMAB group (P=0.001 ALN versus DMAB). In the ALN group, TPTD maintained its ability to increase CTX (44±34%) but TPTD had no effect on CTX in the DMAB group (P=0.002 ALN vs DMAB). At baseline, TPTD had no effect on OC or P1NP in either group. At week 8 in the DMAB group, OC and P1NP decreased by 8.3±8.9% and 12.4±10.4%, respectively (P<0.04 for both).

Summary: In untreated women, a single 40-mcg SC injection of TPTD increases CTX within 4 hours. 8 weeks of DMAB, but not ALN, fully inhibits this high-dose TPTD–induced increase in CTX. The difference in the capacity of DMAB and ALN to inhibit the pro-resorptive effects of TPTD may, in part, explain the observed differences in TPTD combination therapies. These results suggest that combining DMAB with higher doses of TPTD may be an effective osteoporosis treatment strategy.

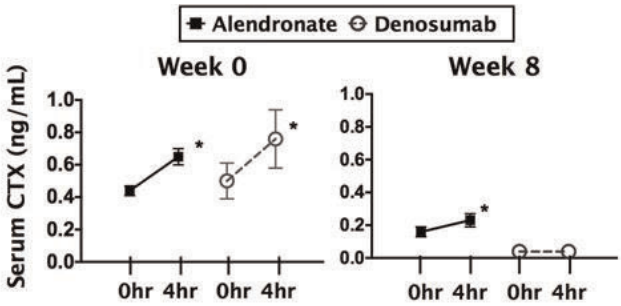

Figure. Serum CTX levels (mean ± SEM) before and 4 hours post-teriparatide injection in the alendronate-treated group and denosumab-treated group. *P<0.04 for the within-group increase.

Responder Analysis of the Effects of Abaloparatide and Teriparatide on Bone Mineral Density in Postmenopausal Women With Osteoporosis. Benjamin Leder*[1], Kathleen Banks[2], Louis O'Dea[2], C.R. Lyttle[2], John Yates[3], Gary Hattersley[4]. [1]Massachusetts General Hospital Harvard Medical School, USA, [2]Radius, USA, [3]Radius Health, USA, [4]Radius, USA

Introduction and Methods: The lack of early gains in hip BMD among patients treated with the anabolic agent teriparatide (TPTD) is of potential clinical concern, especially in patients at high risk of hip fracture.

In a 24-week phase 2 study of postmenopausal women aged 55-85 with a T-score <-2.5 at the spine or femoral neck or a T-score of ≤-2.0 with either a prior low-trauma fracture, age >65, or a maternal history of osteoporosis, the PTHrP analog, abaloparatide (ABL, 80-µg SC daily) increased lumbar spine (LS), total hip (TH), and femoral neck (FN) BMD more than TPTD 20-µg SC daily and PBO (all subjects were also treated with calcium and vitamin D supplementation per local practice). To determine if women treated with 24-weeks of ABL 80-µg (n=35) were more likely to experience BMD gains than those treated with either TPTD 20-µg (n=38) or PBO (n=41), we performed a responder analysis comparing the percentage of subjects experiencing BMD gains of >0% and >3% at the TH, FN, LS, or at all three anatomic sites. Between group differences were compared by 2-sided Chi-square test.

Results: Over 24-weeks, TH BMD increased in 80%, 53% and 63% of women in the ABL, TPTD and PBO groups, respectively (p=0.014 ABL vs. TPTD). Similarly, FN BMD increased in 86%, 58% and 54% of women in these three groups, respectively (ABL vs. TPTD p=0.009; ABL vs PBO p=0.003). Almost all women in the ABL (94%) and TPTD (93%) groups experienced BMD gains at the LS whereas 33% lost bone in the PBO group (PBO vs. both ABL and TPTD p<0.004). More patients experienced BMD gains at all three anatomic sites in the ABL group (66%) than in the TPTD (40%) and PBO (29%) groups (p<0.03 ABL vs. both TPTD and PBO). More ABL-treated women had a >3% TH BMD gain (37%) than those treated with TPTD (16%) or PBO (15%) (ABL p<0.04 vs. both TPTD and PBO). 43% of ABL-treated women had a >3% FN BMD gain compared to 29% in both the TPTD and PBO groups (p=NS). The percentage of subjects with a >3% BMD gain at the LS was higher in ABL (89%) than PBO (41%) (p<0.001) but not TPTD (73%) (p=0.073).

Summary: In postmenopausal women with osteoporosis, more subjects treated with ABL experienced BMD increases at the LS, FN, TH, or all 3 sites compared to those treated with TPTD or PBO. Additionally, more subjects treated with ABL experienced a >3% BMD increase at the TH compared to TPTD or PBO. The overall high responder rate of ABL, particularly at the TH and FN as compared to TPTD, provides a strong rationale for its clinical development as an anabolic treatment for postmenopausal osteoporosis.

Romosozumab Significantly Improves Vertebral Cortical Bone Mass and Structure Compared With Teriparatide: HR-QCT Analyses of Randomized Controlled Trial Results in Postmenopausal Women with Low BMD. T Damm*[1], C Libanati[2], J Peña[1], G Campbell[1], R Barkmann[1], Da Hanley[3], S Goemaere[4], Ma Bolognese[5], C Recknor[6], C Mautalen[7], YC Yang[2], CC Glüer[1]. [1]Christian-Albrechts-Universität zu Kiel, Germany, [2]Amgen Inc., USA, [3]University of Calgary, Canada, [4]Ghent University Hospital, Belgium, [5]Bethesda Health Research Center, USA, [6]United Osteoporosis Centers, USA, [7]Centro de Osteopatias Medicas, Argentina

Purpose: Understanding the effect of therapies in the vertebral compartments is relevant to bone biology and clinical practice. We developed an improved technique using cortical shell segmentation-based layering of high resolution quantitative computed tomography (HR-QCT) scans of T12 vertebral bodies to evaluate compartment-specific changes in bone mineral density (BMD) and microstructure.

Methods: In an international, randomized, phase 2 study (McClung et al., *N Engl J Med.* 2014), postmenopausal women with low BMD supplemented with calcium and vitamin D received romosozumab (210 mg SC QM), teriparatide (20 mcg SC QD), or placebo (PBO). A subset of these women received HR-QCT scans of T12 (N=11 romosozumab, 12 teriparatide, 8 PBO) at baseline and month 12. For cortical HR-QCT analysis (blinded to treatment assignment), adjacent 200 micron thin films of the cortical shell were evaluated to determine changes from the outer soft tissue bordering the vertebrae to the medullary spongiosa (Figure). In addition to the standard cancellous compartment variables previously described (Graeff et al., *JBMR.* 2007), this improved method allows accurate determination of cortical variables in the subregions, including apparent and corrected (deconvolved) cortical thickness, bone mineral content (BMC), and BMD. Changes in cortical thickness are modeled assuming an average 50% mineralization of newly added matrix.

Results: At baseline, mean (SD) apparent cortical thickness of 1.37 (0.13) mm was corrected to a cortical thickness of 0.29 (0.05) mm. At month 12, romosozumab significantly improved cortical BMC and BMD from baseline and in comparison to teriparatide or PBO (all $P \leq 0.0003$; Table). These gains were attained by both endosteal and periosteal bone matrix apposition. Improvements in cancellous BMD were similar between romosozumab and teriparatide.Conclusion: Using HR-QCT scans of the spine, it is possible to evaluate changes across the cortical shell of the vertebral bodies and determine alterations in the endosteal and periosteal regions. The anatomical location and magnitude of these changes could impact changes in bone strength and thus affect fracture risk. Romosozumab administration was associated with significant increases in cortical thickness and improvement in all measured cortical parameters at 12 months compared with teriparatide or PBO. The clinical effect of romosozumab to reduce fractures is being evaluated in an ongoing phase 3 clinical program.

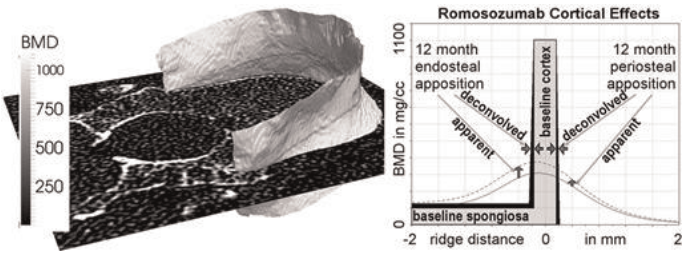

Figure. 3D Visualization of Vertebral Cortex (left) and Schematic Drawing of Bone Apposition (right)

Atypical subtrochanteric fracture is a rare phenomenon in osteoporotic patients treated with bisphosphonates. Christian Muschitz*[1], Hans Peter Dimai[2], Roland Kocijan[3], Heinrich Resch[4], Peter Pietschmann[5], Martina Kostic[6], Alexandra Kaider[7], Michael Szivak[8], Matthias Schilling[9], Heinrich W. Thaler[10]. [1]St. Vincent's Hospital, Austria, [2]Medical University of Graz – Department of Internal Medicine, Division of Endocrinology & Metabolism, Austria, [3]St. Vincent Hospital Vienna, Austria, [4]Medical University Vienna, Austria, [5]Department of Pathophysiology & Allergy Research, Medical University of Vienna, Austria, [6]St. Vincent Hospital – Medical Department II - Academic Teaching Hospital of Medical University of Vienna, Austria, [7]Center for Medical Statistics, Informatics & Intelligent Systems, Medical University of Vienna, Austria, [8]Austrian Trauma Insurance Agency (AUVA), Austria, [9]Institute for Medical Radiology, Diagnostics, Intervention; Clinical Center of Lower Austria, Austria, [10]Trauma Center Meidling, Austria

Purpose: Atypical femoral fractures (AFF) are fractures in the subtrochanteric region of the femur with characteristic appearance. Although an AFF is generally a rare event, several studies indicated a potential link between AFF and long-term bisphosphonate (BP) use. However, studies evaluating a possible interaction differed in study design and diagnostic criteria of AFF.

The aim was to investigate the incidence of AFF and a potential association of this fracture type with BP use and other medications over a period of 9 years (2002-2010).

Methods: We retrospectively analyzed the overall incidence of AFF and a potential association of this fracture type with BP use at one of the largest Austrian trauma hospitals with a catchment area of approximately 1.9 million people in the capital city Vienna. The incidence of hip fracture in this center was comparable to the incidence of hip fracture across Austria.

Results: A total of 5.322 patients who had sustained a de novo osteoporotic hip fracture were treated at this hospital. Subtrochanteric fractures were extracted from the database using ICD codes; every retrieved fracture case was radiographically analyzed by a blinded radiologist. 128 patients with a de novo low-traumatic subtrochanteric fracture were identified: 101 typical, 17 atypical and 10 borderline fractures. Median age of patients with typical femoral fractures and borderline fractures was 83.0 yrs. Patients with atypical fractures had a median age of 81.0 yrs. Female patients with a subtrochanteric femoral fracture were significantly older, with a median of 84.0 vs. 74.0 yrs ($p<0.0001$). Of the 6 patients with subtrochanteric fractures receiving bisphosphonates there was one female patient with an atypical fracture (oral bisphosphonate therapy for 29 months) and 5 patients had typical fractures and bisphosphonate therapy between 6 and 60 months. Comparison of the three fracture types showed no significant difference in medication use – neither with proton pump inhibitors nor tricyclic antidepressants or selective serotonine reuptake inhibitors - with the exception of phenprocoumon. This anticoagulant was used in 2%, 11.8% and 30% of patients with typical, atypical and borderline fractures, respectively ($p<0.002$).

Conclusions: Our data strongly indicate that cases of AFF are rare, even in patients with osteoporotic hip fractures. However, we did not detect an association of AFF and bisphosphonate use in this study group.

Evaluation of Invasive Oral Procedures and Events in Women With Postmenopausal Osteoporosis Treated With Denosumab: Results From the Pivotal Phase 3 Fracture Study Extension. Nelson B. Watts*[1], John T. Grbic[2], Michael McClung[3], Socrates Papapoulos[4], David Kendler[5], Christence S. Teglbjaerg[6], Lawrence O'Connor[7], Rachel B. Wagman[7], Eric Ng[7], Nadia S. Daizadeh[7], Pei-Ran Ho[7]. [1]Mercy Health, USA, [2]Columbia University, USA, [3]Oregon Osteoporosis Center, USA, [4]Leiden University Medical Center, Netherlands, [5]University of British Columbia, Canada, [6]CCBR, Denmark, [7]Amgen Inc., USA

Purpose: Osteonecrosis of the jaw (ONJ) is a rare but serious adverse event of some antiresorptive therapies, including denosumab (DMAb), and invasive oral procedures and events (OPEs) are suggested to be an important risk factor (Ruggiero, *J Oral Maxillofac Surg* 2009). The incidence of positively adjudicated ONJ in the DMAb bone loss clinical program is rare (between ⩾ 1 and < 10 per 10,000). In this study, we assessed the occurrence of invasive OPEs through Year 5 of the ongoing, 7-year FREEDOM Extension (EXT) trial.

Methods: In FREEDOM, women were randomized to receive DMAb 60 mg SC or placebo every 6 months for 3 years. Those who missed ≤ 1 dose of investigational product and completed the Year-3 visit were eligible for the open-label FREEDOM EXT; women in the EXT long-term group (N = 2343) received DMAb in FREEDOM and EXT, and women in the EXT cross-over group (N = 2207) received placebo in FREEDOM and DMAb in EXT. Women who reached the EXT Year-3 visit were asked to chronicle their history of invasive OPEs (eg, dental implants, tooth extraction, natural tooth loss, or scaling or root planing [extensive subgingival cleaning]) during the EXT. Every 6 months thereafter, women were asked to document their oral health history since the last visit. Jaw surgery information was collected starting from month 30 of the EXT.

Results: The majority of women (78%) participated in the survey. Over 5 years of the EXT, 42.4% of these women reported an invasive OPE; the incidence of the 5 individual OPEs reported were similar between groups (Table). ONJ incidence was 0.4% (7/1500 subjects) in women reporting invasive OPEs and 0.05% (1/2036 subjects) in women reporting no invasive OPEs. The actual number of invasive OPEs may be underestimated due to limited capture of OPEs in medical charts and due to recall bias by subjects of events that occurred in the first 3 years of the EXT. During the EXT (Years 1–5), the exposure-adjusted incidence of ONJ was 4.2 per 10,000 patient-years. Of the 8 ONJ cases, 6 have resolved, 1 is ongoing and continues to be followed, and the final outcome of 1 is unknown, as consent was withdrawn.

Conclusion: While invasive OPEs were common in this group of DMAb-treated women with postmenopausal osteoporosis, ONJ incidence was low. Invasive OPEs will continue to be queried prospectively in the EXT to characterize the long-term background rate.

Findings from Denosumab (Prolia®) Post-marketing Safety Surveillance for Atypical Femoral Fracture, Osteonecrosis of the Jaw, Severe Symptomatic Hypocalcemia, and Anaphylaxis. M Geller[1], RB Wagman*[1], PR Ho[1], S Siddhanti[1], C Stehman-Breen[1], NB Watts[2], S Papapoulos[3]. [1]Amgen Inc., USA, [2]Mercy Health Osteoporosis & Bone Health Services, USA, [3]Leiden University Medical Center, Netherlands

Purpose: We characterize the Prolia post-marketing experience for 4 adverse drug reactions (ADRs): atypical femoral fracture (AFF), osteonecrosis of the jaw (ONJ), severe symptomatic hypocalcemia (SSH), and anaphylaxis.

Methods: The Amgen post-marketing database undergoes continual assessment of adverse events reported by health care providers, patients, and other sources. AFF and ONJ cases were assessed and adjudicated by independent committees. SSH and anaphylaxis prompted further review by Amgen Global Safety because causality due to Prolia could not be excluded.

Results: As of September 2013, estimated Prolia exposure was 1,252,566 patient-years. Four post-marketing reports were adjudicated as consistent with the AFF ASBMR definition (Shane *JBMR* 2010). All patients had used bisphosphonate (BP); 2 subjects healed and 2 had no follow-up information. For ONJ, 32 post-marketing reports were adjudicated as consistent with the AAOMS definition (Position Paper *AAOMS* 2009). Risk factors included ⩾ 1: glucocorticoids, chemotherapy, prior BP use, older age, and invasive dental procedures. One-third of reports indicated resolution, 1/3 were ongoing, and the remainder were unknown. Routine pharmacovigilance in 2011 showed 8 reports of medically confirmed SSH that included symptoms of seizures and/or tetany; 7 of 8 patients had chronic kidney disease, a risk factor for hypocalcemia; most events occurred within 30 days of Prolia administration and responded to IV/PO calcium/vitamin D. Routine pharmacovigilance in 2012 showed 5 reports of medically confirmed anaphylaxis that included hypotension, dyspnea, throat tightness, facial and upper airway edema, pruritus, and/or urticaria. Most events occurred within 1 day of the first Prolia dose; emergency room treatments included antihistamines and IV/PO steroids with no fatal outcomes. Amgen assessment of SSH and anaphylaxis as possibly related to Prolia led to product labeling updates.

Conclusion: These Prolia post-marketing events have not shown any unexpected findings; the benefit/risk profile remains favorable. Ongoing safety surveillance continues through clinical studies and pharmacovigilance activities.

Percentage of Women Achieving Non-osteoporotic BMD T-scores at the Spine and Hip Over 8 Years of Denosumab Treatment. S Ferrari*[1], C Libanati[2], CJF Lin[2], S Adami[3], JP Brown[4], F Cosman[5], C Czerwiński[6], LH de Gregório[7], J Malouf[8], J-Y Reginster[9], NS Daizadeh[2], A Wang[10], RB Wagman[10], EM Lewiecki[11], S Cummings[12]. [1]Geneva University Hospital, Switzerland, [2]Amgen Inc., USA, [3]University of Verona, Italy, [4]Laval University & CHU de Québec Research Centre, Canada, [5]Helen Hayes Hospital, USA, [6]Krakow Medical Center, Poland, [7]CCBR, Brazil, [8]Universitat Autònoma de Barcelona, Spain, [9]University of Liège, Belgium, [10]Amgen Inc., USA, [11]New Mexico Clinical Research & Osteoporosis Center, USA, [12]San Francisco Coordinating Center, CPMC Research Institute, & UCSF, USA

Purpose: Guidelines for the treatment of chronic conditions such as hypertension and diabetes include specific biomarker targets. This differs from osteoporosis treatment guidelines, which currently do not define treatment targets or goals. In general, absence of BMD loss and fracture are considered treatment successes. This is far from ideal because success defined by the lack of a negative outcome does not set a real goal for therapy. Potential goals for osteoporosis treatment might include reaching a BMD T-score value somewhere above –2.5 that represents an acceptable level of fracture risk. To provide insight into T-score values achieved over time with denosumab (DMAb), we report on the percentage of women who achieved a range of possible target BMD T-scores at both the lumbar spine and total hip over 8 years of treatment.

Methods: For these analyses, women received 3 years of DMAb (60 mg SC Q6M) during FREEDOM and 5 years of DMAb during the Extension for a total of 8 years of continued treatment. The percentage of women with T-scores >−2.5, >−2.2, >−2.0, and >−1.8 at both the lumbar spine and total hip, and T-scores >−2.5 at either the lumbar spine or total hip at baseline and over 8 years of DMAb treatment were determined. The influence of baseline T-score on subsequent T-score improvement was also explored.

Results: At FREEDOM baseline, mean (SD) lumbar spine and total hip T-scores were −2.83 (0.67) and −1.85 (0.79), respectively, for the DMAb Extension participants (N=2343). The percentage of women with T-scores >−2.5, >−2.2, >−2.0, and >−1.8 at both the lumbar spine and total hip progressively increased from baseline over 8 years of DMAb treatment as follows: 11% to 82% (>−2.5), 4% to 65% (>−2.2), 2% to 53% (>−2.0), and 1% to 39% (>−1.8) (Fig. 1). At individual sites, the percentage of women with a T-score >–2.5 increased from baseline over 8 years of DMAb treatment from 19% to 86% (lumbar spine) and from 75% to 94% (total hip). Baseline T-scores by quartile remained largely consistent throughout the 8 years of DMAb treatment, which showed similar trajectory in BMD across subjects regardless of initial BMD (not shown).

Conclusion: DMAb enables a substantial proportion of women with osteoporosis to achieve non-osteoporotic T-scores. The data reported here contribute insightful information to discussions on the topic of treatment goals for osteoporosis.

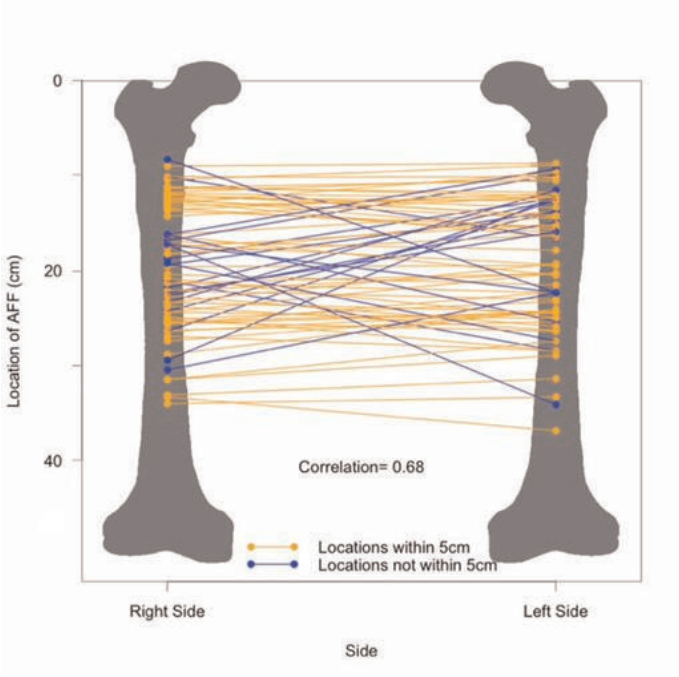
The Extent of Symmetry on Images of Bilateral Atypical Femoral Fractures. Linda Probyn*[1], Angela M. Cheung[2], Jonathan Adachi[3], Leon Lenchik[4], Aliya Khan[5], Earl Bogoch[6], Robert Josse[7], Catherine Lang[8], R Bleakney[9]. [1]University of Toronto, Sunnybrook Health SC, Dept. Medical Imaging, Canada, [2]University Health Network-University of Toronto, Canada, [3]St. Joseph's Hospital, Canada, [4]Wake Forest University, USA, [5]McMaster University, Canada, [6]St. Michael's Hospital, Canada, [7]St. Michael's Hospital, University of Toronto, Canada, [8]University of Toronto, Canada, [9]Mount Sinai Hospital, Canada

Purpose: Atypical Femoral Fractures (AFFs) are commonly bilateral. The purpose of this study is to evaluate bilateral AFFs and to determine if the imaging features of both fractures are similar.

Materials and Methods: Imaging studies of 76 patients with bilateral AFFs from the Ontario AFF cohort were retrospectively reviewed (3 men, 73 women, age range 31.1 to 91 years, mean age 67.3 years). The time interval between fracture diagnoses was determined. For each fracture, the following imaging features were evaluated: location of fracture, femoral angle, length of cortical thickening, comminution, medial spike (proximal or distal fragment) and fracture orientation (superior/inferior). Associations between imaging findings on pairs of bilateral fractures were assessed with Spearman's correlation (r_s) and the Kappa (κ) statistic.

Results: Bilateral fractures (62 incomplete and 14 complete) are diagnosed within 12 months of each other in 59/76 cases (77.6%). Average time between fracture diagnoses was 10.2 months. 90% of bilateral fractures was diagnosed within 2.9 years of each other (range 0 to 120 months). There was a strong correlation between fracture location (r_s =0.68) with 58/76 cases (76.3%) of bilateral fractures occurring within a distance of less than 5 cm. 41/76 cases (53.9%) had a distance of less than 2.5 cm between bilateral fractures. There was moderate correlation between femoral angles (r_s=0.4) and weak correlation between length of cortical thickening (r_s=0.28). There was substantial agreement for medial spike location (κ=0.67) and fracture orientation (κ=0.62) and moderate agreement for lack of comminution (κ=0.42). These findings were independent of time between fractures.

Conclusion: Patients with bilateral AFFs are likely to be diagnosed with the second one within the first year of presentation of the first one. Bilateral fractures are likely to have similar imaging findings and location along the femur, regardless of the time interval between fractures.



Bilateral Location image

Virtual Twin Estimates: Continued New Vertebral and Nonvertebral Anti-Fracture Efficacy Through 8 Years of Treatment With Denosumab. SR Cummings*[1], E Vittinghoff[2], NS Daizadeh[3], M Austin[3], A Wang[3], RB Wagman[3]. [1]San Francisco Coordinating Center, CPMC Research Institute, USA, [2]University of California San Francisco, USA, [3]Amgen Inc., USA

Purpose: Ethical concerns curtail duration of placebo (PBO) treatment in randomized clinical trials, which limits the ability to evaluate the efficacy of new therapies over the very long term. While open-label extensions with participants of the original trial permit long-term assessment, these subjects may be healthier and more persistent with treatment than those who dropped out of the original study or did not enroll in the extension. The virtual twin method addresses such limitations by simulating long-term PBO subjects (''virtual twins'') with identical characteristics to the subjects in the extension (Vittinghoff et al., *Stat Med*. 2010). The pivotal phase 3 fracture trial (FREEDOM) evaluated denosumab (DMAb) vs PBO for 3 years (Cummings et al., *N Engl J Med*. 2009) and has been extended with open-label DMAb for an additional 7 years for all subjects who missed no more than 1 dose of investigational product during the FREEDOM study, completed the 36-month visit, and agreed to enroll in the Extension. We used the virtual twin method to assess fracture risk reduction after 8 years of DMAb treatment (ie, 3 years in FREEDOM and 5 additional years in its Extension) relative to long-term virtual twin PBO.

Methods: Models were developed to simulate fracture outcome for a hypothetical long-term PBO-treated population (ie, virtual twin PBO group) with identical baseline characteristics predictive of fracture risk (ie, BMD, fracture history, BMI, and age) as long-term DMAb subjects, using FREEDOM data from subjects who received PBO in FREEDOM and enrolled in the Extension. Estimates of the relative risks (RRs) between the observed long-term DMAb and the virtual twin PBO groups with bootstrap 95% confidence intervals were calculated.

Results: After 5 years of the Extension, representing 8 years of continued treatment with DMAb, the observed new vertebral fracture incidence in the long-term DMAb-treated group (5.5%) was significantly lower than the estimated incidence in the virtual twin PBO group (9.2%; RR: 0.60; 95% CI: 0.44–0.81; Figure). The observed incidence of nonvertebral fracture in long-term DMAb-treated subjects also was significantly below the estimated incidence in the virtual twin PBO group (RR: 0.54; 95% CI: 0.42–0.70; Figure).

Conclusion: The virtual twin analysis suggests that 8 years of DMAb continued to significantly reduce the risk of new vertebral and nonvertebral fractures.

Zoledronic Acid in Frail Elders to Strengthen Bone: Three Year Results from ZEST Trial. Susan Greenspan*[1], Mary Anne Ferchak[1], Subashan Perera[2], Dave Nace[2], Neil Resnick[3]. [1]University of Pittsburgh, USA, [2]University of Pittsburgh, USA, [3]Univeristy of Pittsburgh, USA

Background: Although nearly 85% of frail seniors residing in long term care facilities have osteoporosis, the pivotal osteoporosis trials have systematically excluded fragile, functionally-impaired women. As a result, the vast majority are not treated even though they are at the greatest risk for fracture. The goal of the ZEST trial (Zoledronic acid in frail Elders to STrengthen bone) was to examine the safety and efficacy of a single dose of zoledronic acid over 2 years with a 1 year extension.

Methods: This double-blind, randomized controlled trial included women residents of a nursing home or assisted living facility, who were not on an antiresorptive agent despite having osteoporosis (BMD or fracture) and had a vitamin D level >20 ng/dL. We included residents with cognitive impairment, immobility, and multiple diseases and medications. All subjects (or their proxies) provided informed consent, and all received a single dose of zoledronic acid 5 mg or placebo IV, in addition to daily calcium (1200 mg) and vitamin D (800 IU). Participants were reconsented for the 1 year extension. The primary outcomes for the extension were the 36 month hip and spine BMD changes and safety. We measured BMD in a mobile unit and collected serious adverse events (AE) with an electronic surveillance system. We used linear mixed models for analyses.

Results: 181 women were randomized and 141 agreed to the one year extension. Mean age was 85.4 and there were no baseline differences between groups in age, BMI, calcium/vitamin D intake, BMD, activities of daily living, or cognitive or mental health status. The active treatment group included more women with diabetes, falls history, and slow gait speed. 92% of subjects completed 12 months; 67% completed 24 months and 49% completed 36 months. At 3 years, BMD percent changes at the total hip, femoral neck and spine were significantly greater in the active treatment group compared to placebo (all $p < 0.01$, table), with the adjusted differences of 5.4 percentage points at the total hip, 6.2 at the femoral neck and 4.5 at the spine. There were no significant differences in AEs during the third year.

Conclusions: This trial of single dose zoledronic acid for osteoporosis in cognitively impaired, frail osteoporotic women is the first to demonstrate that it is safe and effective in preserving/improving skeletal integrity over 3 years. Future studies are needed to determine if BMD improvement translates into fracture reduction.

Table: Percent change ± standard error in bone mineral density at the total hip, femoral neck and spine at 36 months

Skeletal site	Active (N=89)	Placebo (N=92)	P-value (between group difference)
Total hip	1.9±0.6**	-3.0±1.0**	p<0.0001
Femoral neck	1.7±1.3	-4.5±1.0**	p<0.0001
Spine	5.4±0.9**	0.7±0.8	p<0.0001

FR0405

Teriparatide Accelerates Healing of Bisphosphonate-Associated Atypical Femoral Fractures in Patients with Osteoporosis. Naohisa Miyakoshi*[1], Toshiaki Aizawa[2], Satoshi Sasaki[3], Shigeru Ando[4], Shigeto Maekawa[5], Hiroshi Aonuma[1], Hiroyuki Tsuchie[6], Hiroshi Sasaki[7], Yuji Kasukawa[1], Yoichi Shimada[8]. [1]Akita University Graduate School of Medicine, Japan, [2]Northern Akita Municipal Hospital, Japan, [3]Higashinaruse National Health Insurance Clinic, Japan, [4]Yamamoto-Kumiai General Hospital, Japan, [5]Ogachi Central Hospital, Japan, [6]Nakadori General Hospital, Japan, [7]Akita University School of Medicine, Japan, [8]Akita University Graduate School of Medicine, Japan

Introduction: Use of bisphosphonates, particularly long-term exposure, is associated with an increased risk of atypical femoral fracture (AFF). Teriparatide (TPTD) treatment may promote healing of AFFs, but few controlled studies have examined TPTD effects on healing of bisphosphonate-associated AFF. The aim of this study was therefore to compare fracture healing between patients with and without TPTD treatment after sustaining bisphosphonate-associated AFFs.

Methods: We retrospectively reviewed the medical records of 45 consecutive AFFs in 34 patients who had been prescribed oral bisphosphonates (alendronate or risedronate) for osteoporosis before AFF and with follow-up ⩾12 months (range, 12-90 months). Thirty-seven complete or incomplete AFFs (82%) were treated surgically and eight incomplete AFFs (18%) were treated conservatively. Bisphosphonates were stopped at diagnosis. Based on the non-use or use of TPTD after each fracture, AFFs were divided into a non-TPTD control group (n=24) and a TPTD group (n=21). Time to fracture healing and rate of delayed or non-union were compared between groups.

Results: Fracture type (complete or incomplete) and treatment (surgical or conservative) did not differ significantly between groups. The TPTD group showed significantly faster fracture healing (mean (±standard deviation), 5.9±3.1 months) than the non-TPTD group (8.8±4.8 months; P=0.025). Rate of delayed or non-union was significantly lower in the TPTD group than in the non-TPTD group (p=0.015); in the TPTD group, 19 AFFs (90.5%) achieved normal union and two (9.5%) showed delayed union; in the non-TPTD group, 14 (58.3%) achieved normal union, nine (37.5%) showed delayed union, and one (4.2%) showed non-union. Subanalyses for surgically treated AFFs yielded similar results.

Conclusions: These results suggest that TPTD treatment significantly shortens the time to fracture healing and reduces rates of delayed or non-union after bisphosphonate-associated AFF.TPTD appears useful for treating bisphosphonate-associated AFF.

FR0408

A novel approach to inhibit bone resorption: ectosite inhibitors against cathepsin K. Preety Panwar*[1], Kent Soe[2], Haoran Cui[3], Xin Du[4], Jean-Marie Delaisse[5], Dieter Bromme[6]. [1]University of British Columbia, Canada, [2]Vejle Hospital, University of Southern Denmark, Denmark, [3]Department of Oral Biological & Medical Sciences, University of British Columbia, Canada, [4]Department of Oral Biological & Medical Sciences, University of British Columbia, Canada, [5]Vejle Hospital, IRS, University of Southern Denmark, Denmark, [6]The University of British Columbia, Canada

Accelerated osteoclastic bone resorption plays an important role in the pathogenesis of osteoporosis. Cathepsin K (CatK) is the predominant collagenase in osteoclasts and thus an important target for the inhibition of bone resorption. Currently available active site inhibitors block the collagenase activity of CatK but also inhibit its other proteolytic activities. Various non-skeletal abnormalities observed in CatK knockout mice raise the concern of adverse effects, and therefore, it is important to find alternative approaches to inhibit bone resorption. Previous studies have postulated that the collagenase activity of CatK depends on the formation of protease oligomers in the presence of glycosaminoglycans. Therefore, we propose to use inhibitors of CatK complex formation, which specifically block the collagenase activity of CatK without interfering with its other functions. We call these inhibitors: ectosite inhibitors.

Ectosite inhibitors were screened from various drug and natural product libraries using florescence assays, and further selected based on their ability to inhibit collagen degradation. The best candidate was tested for its efficacy to inhibit bone resorption by human osteoclasts seeded on bone discs. The inhibition of bone resorption was evaluated based on resorption surface, number of resorption events, their depth, proportion of resorption pits and trenches, CTX release, and number of osteoclasts.

Dihydrotanshinone I (DHTI) was the most promising ectosite inhibitor of CatK with an IC_{50} ~10μM for collagen degradation. Docking experiments revealed the binding of DHTI in a protein-protein interface of CatK complexes. When DHTI was tested in bone resorption cultures in parallel to the active site inhibitor odanacatib, at optimum concentrations, DHTI was found to be a powerful inhibitor of resorption, comparable to odanacatib for all endpoints. The inhibitions induced by 10 μM DHTI and 50 nM odanacatib were respectively: 47 and 40 % for resorption surface, 43 and 50% for resorption depth, and 83 and 61% for CTX. Notably both inhibitors almost completely abolished resorption trenches (long excavations reflecting aggressive resorption). Metabolic activity and number of osteoclasts were unaffected.

Collectively, our observations show that an ectosite inhibitor of CatK can effectively inhibit bone resorption to a similar extent compared to odanacatib. Thus ectosite inhibitors appear to be an attractive approach for anti-resorptive therapy.

FR0410

Effects of Odanacatib on Bone Structure and Quality in Postmenopausal Women with Osteoporosis: Results from the Phase III Long-Term Odanacatib Fracture Trial (LOFT). Robert Recker*[1], David Dempster[2], Tobias de Villiers[3], Bente Langdahl[4], Paul Miller[5], Ivo Valter[6], Cristiano AF Zerbini[7], Dosinda Cohn[8], Steven Doleckyj[8], Le Duong[9], Boyd Scott[10], Nadia Verbruggen[11], Arthur Santora[12]. [1]Creighton University, USA, [2]Columbia University, USA, [3]Stellenbosch University, South Africa, [4]Aarhus University Hospital, Dnk, [5]Colorado Center for Bone Research, USA, [6]CCBR, Estonia, [7]Centro Paulista de Investigações Clínicas, Brazil, [8]Merck & Co., Inc., USA, [9]Merck Research Laboratories, USA, [10]Merck & Co., Inc., USA, [11]MSD Europe Inc., Belgium, [12]Merck & Co. Inc., USA

Odanacatib (ODN) is a selective oral inhibitor of cathepsin K in development for the treatment of osteoporosis. Unlike other osteoporosis treatments that reduce both bone resorption and formation, ODN reduces bone resorption with limited reduction of bone formation.[1] Bone histology in non-clinical and clinical studies indicates normal bone formation during ODN treatment. [2,3]

The skeletal benefits of once-weekly ODN were investigated in the event-driven, Phase III Long-Term ODN Fracture Trial (LOFT; NCT00529373). Postmenopausal women ⩾65 years of age with a BMD T-score of ≤-2.5 at the total hip (TH) or femoral neck (FN), or with prior vertebral fracture and T-score of ≤-1.5 at the TH or FN, were randomly assigned (1:1) to either 50 mg of ODN or placebo once-weekly. Participants also received weekly vitamin D_3 (5600 IU) and daily calcium supplements to ensure a total daily calcium intake of ~1200 mg. Primary efficacy outcomes were the effect of ODN on the risk of new morphometric vertebral, hip, and clinical non-vertebral fractures. Additional endpoints included the effects of ODN on bone histology and histomorphometry, and skeletal structure.

LOFT randomized 16,713 postmenopausal women (mean [SD] age 72.8 [5.3] years) at 387 centers in 40 countries, with 16,071 included in analyses. Mean baseline BMD T-scores were: lumbar spine -2.7, TH -2.4, and FN -2.7. Transilial bone biopsies were obtained from consenting patients at baseline, and at 12, 24 and 36 months, and assessed by qualitative histology, 2D histomorphometry and 3D micro-computed tomography. A total of 341 biopsy specimens were obtained from 272 participants. Forty biopsies were obtained at baseline and 301 at the following time points: 12 months (n=2), 24 months (n=219) or 36 months (n=80). Paired biopsies (baseline and follow-up) were obtained in 17 patients, and 52 patients had biopsies performed at both Months 24 and 36.

Analyses of these data will provide information on the effects of ODN on bone remodeling and the incidence of qualitative abnormalities of bone formed during treatment, further elucidating ODN's mechanism of action. At the time this abstract was written, final data analysis was not complete. The results will be available for presentation at the ASBMR meeting.

Inhibition NF-κB Signaling Pathway by Partial Ablation of the P65 Subunit Leads to Improved Bone Quality without Interfering with Bone Healing. Hongshuai Li*[1], Aiping Lu[2], Nicholas Oyster[2], Ying Tang[2], Bing Wang[2], Johnny Huard[3]. [1]University of Pittsburgh, USA, [2]University of Pittsburgh, USA, [3]Orthopaedic Surgery, USA

Background: Studies indicate that NF-κB antagonists hold great promise for the treatment of metabolic bone diseases such as osteoporosis; however, concerns about the inhibition of the NF-κB signaling pathway may also impair bone healing through the influence of inflammatory processes [1]. Therefore, exploring more specific targets in the NF-κB signaling pathway that could inhibit bone loss without affecting the bone healing process, remains important for developing novel and improved strategies for treating osteoporosis and inflammatory bone diseases. Materials: The mice lacking one allele of the NF-κB subunit p65 (p65+/–) and wild type (WT) mice at 1 year of age were used in this study. Results: Micro-CT revealed that p65+/– mice displayed more

dense bone tissues both in the lumber vertebra and the mid-shaft of their femurs compared to their WT littermates (Fig. 1 & Fig. 2). In vivo dynamic histomorphometric analysis revealed no significant differences in MAR (mineral apposition rate), MS (mineralizing surface), and BFR (bone formation rate) between the WT and p65+/– mice, both in their vertebra and skull (Fig. 3); however, p65+/– mice exhibited significantly decreased TRAP staining throughout their vertebra compared to WT mice (Fig. 4). A 1mm diameter unicortical bone defect was created on the medial side of the proximal tibia. The bone healing process was monitored with Micro-CT scanning and histology. At weeks 1 and 2 after surgery, X-ray radiographs and histology showed evidence of callus formation at the defect areas in both the p65+/– and WT mice. No significant differences were found in either of the groups regarding the volume of callus, BMD (Fig. 5), collagen deposition and calcification. Conclusion: Our results demonstrated that the specific inhibition of the NF-κB signaling pathway by partial ablation of the p65 subunit leads to improved bone quality without impairing bone healing. The improved bone quality is due, at least in part, to the reduction of osteoclastogenesis. These findings suggest that p65 subunit may represent an important therapeutic target for developing novel and improved strategies for treating osteoporosis and inflammatory bone diseases without interfering with the bone healing process.

FR0414

Bone Properties in Type 2 Diabetes are Associated with the Advanced Glycation Endproduct Pentosidine. Dorothy Fink*[1], Jessica Furst[2], Chiyuan Zhang[3], Laura Beth Anderson[3], Hongfeng Jiang[4], Serge Cremers[3], Kyle Nishiyama[3], Hua Zhou[5], David Dempster[6], Atharva Poundarik[7], Shonni Silverberg[3], Deepak Vashishth[8], Mishaela Rubin[3]. [1]NYP-Columbia, USA, [2]Columbia University College of Physicians & Surgeons, USA, [3]Columbia University, USA, [4]Columbia University College of Physician & Surgeons, USA, [5]Helen Hayes Hospital, USA, [6]Columbia University, USA, [7]Rensselaer Polytechnic University, USA, [8]Rensselaer Polytechnic Institute, USA

Fractures are a newly appreciated complication of type 2 diabetes (T2D) yet are not accounted for by bone mineral density (BMD). An explanation for this paradox may be accumulation of advanced glycation endproducts (AGEs) in bone matrix collagen and increased cortical porosity. Yet whether there is a relationship between AGEs and cortical porosity in T2D is unclear. We hypothesized that levels of the AGE pentosidine would be associated with cortical porosity and biomechanical indices in T2D.

We studied postmenopausal women with T2D (T2D; n=21) and postmenopausal healthy controls (C; n=28). There was no difference in age (T2D 59.4 ± 3 vs C 56.6 ± 0.9), or number of fractures (T2D: 4 vs C: 5) or BMD at the spine (T2D: 0.970 ± 0.07 vs C: 0.922 ± 0.02g/cm^2), or 1/3 radius (T2D: 0.674 ± 0.01 vs C: 0.655 ± 0.01g/cm^2), although femoral neck was greater in T2D (0.777 ± 0.06 vs 0.705 ± 0.02g/cm^2; p=0.03). HbA1c was higher in T2D (8.6 ± 0.9 vs 5.7 ± 0.07%; p<0.01) as was BMI (32 ± 3 vs 28 ± 1 kg/m^2; p=0.06). High resolution peripheral quantitative computed tomography (HRpQCT) was performed and pentosidine was measured in urine by UPLC/MS/MS. Tetracycline double-labeled iliac crest bone biopsies were performed in a random subset (6 T2D and 6 C). Bone strength was measured by reference point indentation as the total indentation distance (TID), or the distance that a test probe was able to be inserted into the bone biopsy sample.

Pentosidine levels did not differ between T2D and C (T2D: 90.8 ± 9 vs C: 84.2 ± 9 pmol/mg Cr, p=0.62). However, HRpQCT analysis revealed that pentosidine was associated with cortical porosity at the radius only in T2D (r=0.474, p=0.04). Histomorphometric analysis similarly revealed that pentosidine was associated with

the percent of cortical porosity area only in T2D (r=.896, p=0.04) and inversely associated with osteoid surface only in T2D (r= -0.97, p=0.006). Finally, microindentation showed that pentosidine was associated with greater TID (r=0.99, p=0.03) only in T2D.

These data provide proof of concept that pentosidine is related to cortical porosity in T2D. Accumulation of AGEs such as pentosidine in T2D may lead to impaired bone formation, as evidenced by low osteoid surface, and to the development of cortical porosity and compromised biomechanical indices. Further studies of skeletal organic matrix and bone microarchitecture properties are needed to shed light on the increased fracture risk associated with type 2 diabetes.

Effect of Teriparatide in Patients with Osteoporosis and Type 2 Diabetes Mellitus. Ann Schwartz*[1], John Krege[2], Jahangir Alam[3], Dara Schuster[3]. [1]University of California, San Francisco, USA, [2]Eli Lilly & Company, USA, [3]Eli Lilly & Company, USA

Purpose: To examine the effect of teriparatide (TPTD) on the incidence of nonvertebral (NONVERT) fragility fractures, bone density, and safety in the subgroup of patients with osteoporosis and Type 2 diabetes mellitus (T2D) enrolled in the DANCE study. Methods: This was a post hoc analysis of patients with vs. without T2D, excluding Type 1 diabetes, treated with TPTD 20 µg/day for ≤2 years enrolled in the DANCE open-label, prospective, observational study. Incident rates of new fragility NONVERT fracture (traumatic fractures excluded) after 6-24 months vs. 0-6 months of TPTD therapy within groups were compared using a Poisson regression model. Time to new NONVERT fracture was compared using Kaplan-Meier analysis. Mixed model repeated measures analysis was used to evaluate bone density changes. Results: Of 4044 patients who received ⩾1 dose of TPTD, 293 reported T2D. Patients with vs. without T2D at baseline had similar age (mean [SD] age, 69.2 [11.1] vs. 67.8 [11.9] years) and history of prior NONVERT fractures (59.0% vs. 55.8%), but higher L1-L4 T-scores (- 2.14 [1.45] vs. -2.51 [1.37], p<0.001) and more baseline clinical conditions (3.5 [1.6] vs. 1.7 [1.3], p<0.001). Mean TPTD exposure was similar (514.0 [290.1] vs. 544.4 [290.1] days). Over 18 months, bone density in the spine and total hip increased similarly in patients with vs. without T2D (both p-values>0.1); at the femoral neck, average increase was greater in T2D (p=0.01). There were 13 NONVERT fractures in the T2D group and 150 in the group without T2D. In the patients with T2D, the incidence of NONVERT fractures was 4.70 in the first 6 months vs. 2.11 per 100 patient years in months 6-24. In the patients without T2D, the incidence of NONVERT fracture was 3.54 in the first 6 months vs. 2.14 per 100 patient years during months 6-24. Fracture incidence declined 55% and 40% in those with and without T2D, respectively. The reduced incidence of NONVERT fracture over the 2 time periods was consistent (time by subgroup interaction p=0.56) in subjects with versus without T2D. There was no difference in the time to a new NONVERT fracture (p=0.94). Teriparatide was well tolerated and no new significant safety findings were observed. Conclusion: Patients with osteoporosis and diabetes receiving teriparatide showed similar increases in bone density at the spine and total hip and similar reductions over time in the incidence of nonvertebral fracture compared with osteoporosis patients without diabetes.

Predictors of mortality subsequent to a fracture in diabetes mellitus patients. Jakob Linde*[1], Søren Gregersen[2], Peter Vestergaard[3]. [1]Aarhus University Hospital, Denmark, [2]Aarhus University Hospital, Denmark, [3]Aalborg University Hospital, Denmark

Background: Diabetes Mellitus is associated with an increased fracture risk and perhaps an increased risk of mortality subsequent to a fracture.

Aim: To investigate the association between diabetes related drugs and mortality.Methods: A nested case-control study was conducted. Cases were patients with DM who subsequently to a fracture died; controls were surviving DM patients. Using the Danish National Hospital Discharge Register (1977-2011), we included DM patients with information on date of DM diagnosis, date of fracture and comorbidities, from the Danish Cause of Death Register the date of mortality was collected (2008-2011). From the Central Region of Jutland, Denmark, medication use was collected (2008-2011). Medication use was defined as having collected a prescription prior to fracture. Analysis was performed by unconditional logistic regression.

Results: 2,621 diabetes patients with a fracture subsequent to diabetes diagnosis and with information on medication use were included. Of these 229 died. In multivariate analysis statin use (odds ratio (OR)= 0.54, 95 % confidence interval (CI): 0.37-0.80) decreased the risk of dying subsequent to a fracture. 1,106 (42 %) received statin treatment. Male gender (OR=1.43, 95 % CI: 1.05-1.95), increasing age at diabetes diagnosis (OR=1.06, 95%CI 1.05-1.08), a diagnosis of retinopathy (OR=2.49, 95 % CI: 1.44-4.28), a diagnosis of peripheral artery disease (OR = 1.63, 95 % CI: 1.10-2.42), and use of glucocorticoids (OR=1.97, 95 % CI: 1.26-3.09) all increased the risk of death. None of the antidiabetics; biguanides, glucagon-like receptor agonists, β-cell stimulants, glitazones, and insulin were significantly associated with altered mortality.

Conclusion: Co-morbidity reflected by late onset complications, heart failure and glucocorticoid use were associated with an increased risk of mortality subsequent to a fracture. Statin use may reduce mortality subsequent to a fracture in diabetes patients, clinical trials should decide whether diabetes patients suffering from a fracture should start in statin treatment irrespective of current recomendations.

FR0417

The Risk of Hip Fracture Is Increased in Subjects with Late-Onset Autoimmune Diabetes (LADA): Results from the HUNT Study. Hanne Gulseth*[1], Lisa Forsen[2], Mari Hoff[3], Arnulf Langhammer[4], Siri Forsmo[5], Berit Schei[6], Kristian Midthjell[4], Haakon E. Meyer[7]. [1]Norwegian Institute of Public Health/ Oslo University Hospital, Norway, [2]Norwegian Institute of Public Health/University of Oslo, Norway, [3]Department of Public Health & General Practice, Faculty of Medicine, Norwegian University of Science & Technology, Norway, [4]HUNT Research Centre, Department of Public Health & General Practice, Faculty of Medicine, Norwegian University of Science & Technology, Norway, [5]Norwegian University of Science & Technology, Norway, [6]Women's Health, Department of Community Medicine, Norwegian University of Science & Technology/ Department of Obstetrics & Gynaecology St. Olavs Hospital Trondheim University Hospital, Norway, [7]Norwegian Institute of Public Health/ University of Oslo, Norway

Late-onset autoimmune diabetes in adults (LADA) is present in 5-10% of the diabetes population. LADA has an autoimmune nature, but shares the type 2 diabetes characteristic of insulin resistance. Our aim was to investigate, for the first time, whether hip and forearm fractures were increased in subjects with LADA compared to the general population.

We used data from the Norwegian population-based Nord-Trøndelag Health Study (HUNT2). Baseline assessments were done in 1995-1997 and fractures were retrieved from a registry covering all hip and forearm fractures in the county of Nord-Trøndelag from August 15th, 1995 to December 31th, 2012. All fractures were verified in medical records. The current analysis was restricted to participants ⩾ 40 years at screening (n= 43 004), and LADA were defined in 126 subjects (diabetes onset at age ⩾40 years; no insulin treatment during the first year after diagnosis). They were distinguished from type 2 diabetes by the presence of serum glutamic acid decarboxylase (GAD) autoantibodies. Hazard ratios adjusted for age, sex, and BMI were calculated with Cox regression.

During follow-up, 2271 persons sustained a hip fracture and 2806 persons sustained a forearm fracture. Participants with LADA had a doubled risk of hip fracture (HR = 2.2 (95% CI 1.4 – 3.4)) compared to those without diabetes. Additional adjustments for BMI did not change the results substantially. The hip fracture risk increased by disease duration, and those with duration ⩾10 years had a HR = 2.5 (95% CI 1.4 - 4.6) , whereas those with disease duration < 10 years had a HR = 1.9 (95% CI 0.98 – 3.6). The risk of forearm fracture was however not increased in those with LADA (HR = 0.41 (95% CI 0.13 – 1.26)). In conclusion, subjects with LADA had increased risk of hip, but not forearm, fractures.

Type 1 Diabetes Mellitus Effects on Bone: Results of Histomorphometric Analysis. Laura Armas*, Robert Recker. Creighton University, USA

Diabetes Mellitus has a detrimental effect on the body's microvascular system effecting the kidneys, eyes and nerves. The effect on bone is less well known. Patients with Type 1 diabetes have a higher fracture risk than the general population, but this is not thought to be exclusively a result of lower bone mass. The effect of diabetes on bone micro-architecture and turnover is not well elucidated. We report here results of 29 subjects (16 females, 13 males, age 19-50) with Type 1 diabetes (diagnosed~ 19 years before) and their age and sex matched controls. The subjects were otherwise healthy without diabetic complications and the females were premenopausal. Six diabetic subjects had experienced low trauma fractures. A transilial bone biopsy was obtained after tetracycline labeling. The biopsy specimens were fixed, embedded, sectioned, and evaluated as previously described by Baron et al. Two sections, >250 µm apart, were read from the central part of each biopsy. Wilcoxon signed ranks test was used to compare the results between pairs and Mann Whitney U test to compare between fracturing subjects and controls. Structural measures such as bone volume (BV/TV) and trabecular thickness (TbTh) were no different between the 29 diabetic subjects and their matched control. The dynamic data also showed no differences in mineralizing surface, mineral apposition rate, bone formation rate or activation frequency. The six subjects who had experienced low trauma fractures had slightly lower BV/TV and TbTh than healthy controls, but the only significant difference in measures of dynamic histomorphometry was a shorter mineralization lag time (Mlt) in the diabetics with fracture. Healthy diabetics without complications have no identifiable structural or dynamic differences on histomorphometric analysis compared to age and sex matched controls. However, diabetics who have sustained low trauma fractures have subtle differences in structure and mineralization than

either healthy controls or diabetics without fracture.

Variable	Diabetic w/ Fracture	Control	P value
Bone Volume (BV/TV %)	16.3(14.2-23.7)	21.9(17.6-25.5)	0.076
Trabecular Number (1 /mm)	1.5(1.2-2.0)	1.7(1.5-1.9)	0.480
Trabecular Thickness (mm)	107(101-133)	128(108-152)	0.093

Type 2 Diabetics with and without Fragility Fractures show characteristic Differences in their Serum MicroRNA Profiles that may be used for Fracture Risk Prediction. Ursula Heilmeier*[1], Matthias Hackl[2], Susanna Skalicky[3], Janina Patsch[4], Thomas Baum[5], Andrew Burghardt[6], Ann Schwartz[6], Johannes Grillari[7], Thomas Link[6]. [1]University of California San Francisco, USA, [2]TAmiRNA GmbH, Austria, [3]TAmiRNA GmbH, Austria, [4]Medical University of Vienna, Austria, [5]Klinikum rechts der Isar, TU Muenchen, Germany, [6]University of California, San Francisco, USA, [7]University of Natural Resources & Life Sciences Vienna, Austria

Type 2 diabetic (T2D) individuals are at increased risk for fragility fractures that is not fully captured by the current gold standard Dual X-ray absorptiometry. MicroRNAs (miRNAs) are small noncoding RNAs that master-regulate posttranscriptional gene expression and modulate various cell and disease processes, including the formation of extracellular matrix, oxidative stress, and angio- and osteogenesis. The purpose of this study was to determine and compare the serum miRNA expression levels in T2D women with history of fragility fractures (DMFx) and in fracture-free diabetics (DM) in order to identify miRNA candidates that could be used for fracture risk prediction in T2D. Serum from 38 postmenopausal T2D women (DM and DMFx, n=19 per group, similar eGFR) was used who were otherwise free of bone affecting diseases or medications. 375 circulating miRNAs were analyzed aside with standard quality controls by quantitative PCR using 384-well qPCR arrays. Ct values were corrected for background and technical variation and normalized. miRNAs with presence calls < 50% were excluded. Mann-Whitney-U testing identified 18 miRNAs with evidently small p-values (Table 1). Although these p-values did not survive Benjamini-Hochberg adjustments due to the small group sizes, the exploratory study design (false discovery rate of 0.2) revealed that 14 out of these 18 raw p-values can be regarded as significant and thus constitute potential novel markers to differentiate fracture status in T2D. Additional ROC analysis showed area under curve values (AUC) in the range of 0.76 to 0.85 for several miRNAs including the let-7 family, miR-148b-5b, miR-141-3p, miR-16-2-3p, and miR 340-3 (Fig.1). Interestingly, some of these miRNAs have previously been found to be upregulated during bone mineralization resulting in the repression of collagen expression (let-7 family), to regulate the activity of osteoclast inhibitors (miR-148), and to play a role in mesenchymal stem cell aging and oxidative stress response (miR-141-3p). We conclude, that T2D postmenopausal women with and without fragility fractures show characteristic differences in their serum miRNA profiles that may be used for fracture risk assessment in T2D. Differential miRNA profiling may also provide further insights in molecular mechanisms associated with diabetic bone disease. However, further validation studies are needed to replicate our findings and to establish definitive miRNA signatures for fracture risk assessment.

Table 1: List of 18 most promising miRNAs showing differential expresssion between T2D women with fractures (DMFx) and fracture-free T2D women (DM). Unadjusted p-values are provided in the left column, Benjamini-Hochberg-adjusted p-values at the right. With a False Discovery rate of 20 % only 3-4 of the listed miRNAs bear the risk of demonstrating a false positive raw p-value.

HR-pQCT Detects Abnormal Cortical and Trabecular Bone Density and Structure in Young Adults with Cystic Fibrosis. Kyle Nishiyama*[1], Anna Kepley[1], Fernando Rosete[2], Claire Keating[2], Emily DiMango[2], Elizabeth Shane[3]. [1]Columbia University, USA, [2]Columbia University, USA, [3]Columbia University College of Physicians & Surgeons, USA

The median life expectancy for patients with cystic fibrosis (CF) is now in the early forties. However, the incidence of premature osteoporosis in patients with CF is much higher than the general population and increases with advancing age. Many studies have shown that CF patients have lower bone mineral density (BMD) than healthy controls. However, most used DXA, a 2D measurement of areal BMD (aBMD) that is confounded by bone size. The true extent of the bone deficit is unclear as CF patients are generally smaller in stature, and in many studies, differences in aBMD do not persist after adjusting for their smaller bone size. We used high-resolution peripheral quantitative computed tomography (HR-pQCT) to measure true volumetric BMD (vBMD) and bone microarchitecture at the peripheral skeleton in 15 patients with CF (age 27±6yrs) and 15 age- and sex-matched controls (age 27±4yrs). We scanned participants both at the standard HR-pQCT measurement sites and at a subject-specific variable site based on 4% of the limb length to determine whether differences in bone size affected the outcome. CF patients did not differ significantly in height from controls but had lower BMI (-12%, p=0.03). CF patients had significantly ($p<0.05$) lower aBMD at the spine (-13%), total hip (-15%), femoral neck (-14%), and ultradistal radius (-17%). At the standard site (Table), total vBMD was lower in CF patients than controls at the radius (-22%) and tibia (-20%). In the trabecular compartment, trabecular vBMD was significantly lower at the tibia (-20%)

with a trend at the radius (-20%, p=0.07). There was evidence of trabecular structure deterioration in CF patients, although the differences were not significant. Within the cortical compartment, cortical area, thickness and vBMD were markedly lower in CF patients at both the radius and tibia. Using the 4% variable site, we found a similar pattern of differences to the standard site, but the differences were of greater magnitude, particularly in measurements of area and cortical thickness (Figure). To our knowledge, this is the first study to apply HR-pQCT to patients with CF. We conclude that there are significant deficits in bone structure and density in patients with CF that are independent of bone size. Both the cortical and trabecular regions of the peripheral skeleton are affected. Compared to the variable site, the standard HR-pQCT measurement site may not fully capture the deterioration in bone structure in patients with CF.

IGF Signaling in Periosteal Cells Plays a Crucial Role in Callus Formation and Bone Fracture Repair. Ping Ye*[1], Timothy Myers[2], Alessandra Esposito[3], Joseph Temple[3], Tieshi Li[1], Helen Willcockson[2], Billie Moats-Staats[4], Lara Longobardi[1], Anna Spagnoli[1]. [1]University of North Carolina at Chapel HIll, USA, [2]University of North Carolina, USA, [3]The University of North Carolina at Chapel Hill, USA, [4]University of North Carolina-Chapel Hill, USA

Bone fracture is one of most common injuries to skeletal tissue. Increasing experimental data, both in vivo and in vitro, has shown that periosteal cells play a critical role in fracture healing, at least in part, by contributing to the cellular callus formation. Previous studies also indicate that during development insulin-like growth factor (IGF) signaling is essential to the normal bone formation and growth by influencing cell proliferation, survival and calcification. We believe that IGF signaling in periosteal cells could play a key role in callus formation, thus, promoting bone fracture healing. To test our hypothesis, we, using the Cre-ER-LoxP strategy, generated and studied a new line of conditional mutant mice (igf1rPrx1KO mice), in which the expression of the type I IGF receptor (IGF1R) is specifically ablated in PRX1-positive periosteal cells in adult mice. At the age of 12-16 weeks, male mutant mice, as well as their male littermate controls, were given tamoxifen to induce IGF1R ablation, followed by tibia fracture. Following fracture, the number of Prx1-CreER transgene labeled cells gradually increased in the callus, positively correlating with the increased expression of callus Prx1 mRNA, suggesting that in the callus Prx1-positive cells are abundantly derived from the periosteum. Based on micro-CT analyses, the callus size was reduced in igf1rPrx1KO mice by 47% 10 days after fracture. With an increase in recovery time, the volume of callus was increased in both control mice and igf1rPrx1KO mice. However, the magnitude of the increase was much smaller in igf1rPrx1KO mice, leading to a further reduction (by 54%) in the callus volume at 14 days after fracture. Similar to its reduction in total callus volume, igf1rPrx1KO mice also exhibited a significant reduction in the volume of soft tissue and new bone in the callus. As compared to that in control mice, the volume of soft tissue and new bone in the callus of igf1rPrx1KO mice was reduced by 44% and by 56% at 10 and 14 days post fracture, respectively. Our data strongly indicate that IGF1R mediated signaling in Prx- positive periosteal cells is required for normal callus formation. Our study also provides important insight into the molecular mechanism of bone fracture recovery, which might help to develop a strategy to utilize IGF to treat bone fracture.

RANKL Inhibition in the Pathogenesis and Treatment of Fibrous Dysplasia. Andrea Burke*[1], Howard Wang[2], Jeffrey Tsai[3], Nisan Bhattacharyya[4], Alison Boyce[5], Rachel Gafni[1], Andrea Estrada[1], Alfredo Molinolo[4], Pamela Robey[6], Michael Collins[1]. [1]National Institutes of Health, USA, [2]University of Maryland, USA, [3]SUNY Buffalo, USA, [4]NIH, USA, [5]Children's National Medical Center, USA, [6]National Institute of Dental & Craniofacial Research, USA

Purpose: Fibrous dysplasia (FD) is a benign skeletal disease in which osteogenic precursors proliferate and replace normal bone with fibrous tissue. A somatic mutation in *GNAS* results in constitutive activation of Gs-alpha and elevated cAMP. Osteoclasts are prominent in FD, and receptor activator of nuclear factor kappa-B ligand (RANKL), a regulator of osteoclastogenesis, is overexpressed in an *in vitro* model of FD. RANKL expression is stimulated by cAMP, and its activity is inhibited by osteoprotegerin (OPG). Denosumab is a human monoclonal antibody to RANKL approved for treatment of osteoporosis and bone metastases. Limited experience in treating FD with Denosumab suggests its efficacy. We aim to investigate RANKL expression in FD and its inhibition with Denosumab.

Methods: Soluble RANKL and OPG were measured in serum of FD subjects and correlated with FD skeletal burden. FD tissue specimens were assessed for RANKL, RANK and Ki-67 by immunohistochemistry. RANKL expression was assessed in primary cultures of Vitamin D3/PGE2-stimulated control and patient-derived bone marrow stromal cells (BMSCs) by RT-PCR and ELISA. Control/FD BMSCs were co-cultured with M-CSF-stimulated human monocytes in the presence of Denosumab or isotype control IgG2 to study osteoclastogenesis. Effects on proliferation and cAMP levels were assessed.

Results: Patients had higher levels of circulating RANKL, lower OPG, and a higher RANKL/OPG ratio, which correlated with FD skeletal burden. FD tissue showed robust RANKL expression in highly proliferative, Ki-67 positive regions with RANK-positive giant cells. Primary cultures of FD BMSCs expressed more RANKL mRNA and protein in basal and stimulated state compared to controls. Stimulated FD BMSCs induced osteoclast differentiation in a co-culture system. Denosumab blocked osteoclastogenesis but had no effect on control/FD BMSC proliferation.

Conclusions: Increased levels of RANKL in FD specimens and *in vitro* systems supports the hypothesis that RANKL plays a role in FD pathogenesis, and that inhibition by Denosumab is a potential therapy. The effect of Denosumab on FD BMSC proliferation requires further study. Experiments are ongoing in a murine heterotopic ossicle model, which will provide a way to study molecular mechanisms of Denosumab in FD.

Adult Hypophosphatasia: Clinical Presentation and Diagnostic Findings. Lothar Seefried*[1], Franca Genest[2], Christine Hofmann[3], Sebastian v. d. Assen[2], Maximilian Rudert[2], Franz Jakob[2]. [1]Orthopedic Center for Musculoskeletal Research, Germany, [2]Orthopedic Center for Musculoskeletal Research, Germany, [3]University Childrens Hospital, Germany

Hypophosphatasia (HPP) is a rare, genetically determined metabolic disorder marked by deficient activity of Tissue-Nonspecific Alkaline Phosphatase (TNAP). The clinical spectrum of disease manifestations is very heterogenuous, especially in adults ranging from asymptomatic carriers to severely affected individuals with debilitating limitations and a high burden of disease.

To provide an overview of the frequency of distinctive disease symptoms, we extracted clinical, laboratory and genetic findings from the medical records of our cohort of affected adults. Analysis included patients with a documented mutation within the gene for ALPL and/or a coincidence of lowered ALP values combined with clinical symptoms of the disease.

In total 119 persons (77 females, 42 males) were identified meeting these criteria. Mean age of the individuals was 45.5 years (range 19-80y). In those persons where data could be obtained, antropometric data were (mean height/ BMI) 163.7 cm / 25.15 for women and 169.3 cm / 27.25 for men. The most frequent clinical symptom reported was musculoskeletal pain in 52 persons, followed by dental issues in 37 patients. Lab results showed Hypercalcaemia in 10 out of 70 persons, hyperpho-

sphatemia was present only in 6 out of 67. Serum-creatinine was elevated in 19 out of 68 patients. Vitamin D deficiency, defined als levels below 20ng/ml, was present in 35/60 patients. Renal issues were documented in nine of the patients. Results of genetic testing with documented ALPL-gene mutation was available for 75 of these patients with 54 of them having only one mutation thus being heterozygously affected and 21 harbouring at least two mutations. Distribution of the mutations over the 12 exons showed that Exon 6 was affect in 35 patients, while mutations in Exon 2 and 8 were only detected once, respectively.Due to the wide catchment area of included patients, together with their sometimes limited mobility, not all of the patients have been assessed personally. However, this analysis provides a preliminary insight in the frequency of widely accepted hallmarks of the disease, even in heterozygously affected patients which often prove to be not only asymptomatic carriers but rather experience reproducible symptoms and health limitations, especially in cases with dominant-negative mutations. Further evaluation of adult HPP patients is required to fully understand their burden of disease and develop respective therapeutic strategies, including non-medical, supportive measures as well as pharmacological interventions and adapted surgical procedures.

Enzyme-Replacement Therapy in Life-Threatening Hypophosphatasia: The 3-Year Experience with Asfotase Alfa. Michael Whyte*[1], Jill H. Simmons[2], Richard E. Lutz[3], Scott Moseley[4], Agustin Melian[5], Tatjana Odrljin[4], Nicholas Bishop[6]. [1]Shriners Hospital for Children-Saint Louis, USA, [2]Vanderbilt Children's Hospital, USA, [3]Nebraska Medical Center, USA, [4]Alexion Pharmaceuticals Inc, USA, [5]Alexion Pharmaceuticals Inc, USA, [6]University of Sheffield, Academic Unit of Child Health, United Kingdom

Hypophosphatasia (HPP) is the rare, life-threatening when severe, disorder caused by mutation(s) in the tissue-nonspecific alkaline phosphatase (TNSALP) gene. In 2012[1], we detailed significant improvement in skeletal mineralization and developmental milestones in patients (pts) with perinatal and infantile HPP treated for 48 wks with asfotase alfa, a bone-targeted recombinant human TNSALP. We now report the comprehensive experience of these pts following 3 yrs of treatment. This is a multicenter, phase 2, open-label trial of asfotase alfa (SC, 1-3mg/kg, 3x/wk). Skeletal disease was assessed by a Radiographic Global Impression of Change (RGI-C) scale[1] and a Rickets Severity Scale (RSS)[1,2]. We also evaluated survival, respiratory status, growth, gross motor function (Bayley Scales of Infant Development [BSID-III] subscale), adverse events (AEs) and anti-asfotase alfa antibodies. Data are reported as medians (min, max; n). Age at baseline (BL)[1] was 6.8 mos (2.9 wks, 3 yrs). 9/11 pts completed 3 yrs of treatment (1 pt died at 7.5 mo treatment [sepsis unrelated to asfotase alfa]; 1 pt withdrew after 1st dose)[1] At 3 yrs, pts showed sustained improvement in rickets (RGI-C +2.5 [+1.7, +3], $p = 0.008$; change in RSS -6.3 [-9.5, 0], p = 0.016; n=8, 1 pt missing data). Of the 3 pts who still required respiratory support at 1 yr of treatment (2: mechanical ventilation [MV]; 1: supplemental oxygen [O_2])[1], 2 were weaned from any support and 1 improved from MV to O_2 at last assessment (>3 yrs). Height/length Z-score,-3.7 (-9.2, -0.7; n=11) at BL, improved by a median change of +2.3 (-1.4, +4.1; n=8) at 3 yrs. BSID-III scaled score improved from 1 (1, 8; n=5) at BL/first assessment to 6 (2, 8; n=3) at 3yrs (mean for healthy peers=10). The most common AEs were mild/moderate injection-site reactions and upper respiratory infections (each in 6 pts). 3 serious AEs were considered possibly related to study drug (craniosynostosis, conductive deafness [same pt], and chronic hepatitis [1 pt]). Anti-asfotase alfa antibodies were detected in 6/10 pts; 4 pts tested positive for neutralizing antibodies without apparent effect on clinical efficacy. At 3 yrs, pts with perinatal and infantile HPP treated with asfotase alfa showed sustained improvement in bone mineralization, growth, motor function, and respiratory status. No definite drug-related serious AEs were reported. All 9 pts continue treatment.[1]Whyte *NEJM* (2012) 366:904-13 [2] Thacher *J Trop Pediatr (*2000) 46:132–9

Hypophosphatasia: Clinical Nosology In Childhood Validated From 25 Years Experience With 174 Pediatric Patients. Michael Whyte*[1], Fan Zhang[2], William McAlister[3], Deborah Wenkert[4], Karen Mack[5], Marci Benigno[2], Stephen P. Coburn[6], Susan Wagy[2], Donna M. Griffin[2], Karen Erickson[6], Steven Mumm[7]. [1]Shriners Hospital for Children-Saint Louis, USA, [2]Shriners Hospital for Children-Saint Louis, USA, [3]Department of Pediatric Radiology, Mallinckrodt Institute of Radiology at St. Louis Children's Hospital, Washington University School of Medicine, USA, [4]Amgen, Inc., USA, [5]Shriners Hospital for Children-Saint Louis, USA, [6]Department of Chemistry, Indiana University – Perdue University, USA, [7]Washington University School of Medicine, USA

Hypophosphatasia (HPP) is the inborn-error-of-metabolism caused by inactivating mutation(s) within the gene that encodes the "tissue-nonspecific" isoenzyme of alkaline phosphatase (TNSALP). Inorganic pyrophosphate, an inhibitor of mineralization and substrate for this cell-surface phosphohydrolase, accumulates extracellularly and can cause tooth loss, calcium crystal arthropathies, and rickets or osteomalacia. The remarkably broad expressivity of HPP, ranging from stillbirth due to profound skeletal hypomineralization to dental problems without bone disease in childhood or adult life, is largely explained by autosomal dominant versus recessive transmission of several hundred known *TNSALP* mutations. This expressivity has been codified primarily by patient age at presentation and diagnosis, but the extant classification scheme has not been validated.

To assess this nosology of HPP during childhood, we reviewed our 25 years of experience with 174 pediatric patients classified traditionally according to diminishing severity as perinatal, infantile, childhood, or odonto HPP, and with childhood HPP also designated severe or mild. Data came exclusively from inpatient investigations and focused on demographic, clinical, and DXA parameters as contrasted to healthy American children, and then compared among the patient groups.

The 174 patients comprised 13 survivors of infantile HPP, 96 with childhood HPP (58 severe, 38 mild), and 65 with odonto HPP. None was a survivor of perinatal HPP or an HPP "carrier". *TNSALP* mutation analysis has been positive in all but two of the 107 probands, with a gene dosage effect that reflected HPP severity. All assessed parameters (e.g., height, weight, number and age of premature tooth loss, grip strength, and spine and hip BMD) became more aberrant as the HPP severity classification increased, but with overlap between successive groups. For the 58 patients with severe childhood HPP, 42 were boys and 16 girls (p = 0.006), perhaps reflecting parental concern for reduced stature and strength in the boys versus girls.

Classification of pediatric HPP into infantile, severe and mild childhood, and odonto HPP organizes the disorder's remarkable expressivity, and will help to define its natural history and prognosis, and to evaluate emerging medical therapies.

Unrecognized Mild Hypophosphatasia in Adults. Leyre Riancho-Zarrabeitia[1], Mayte García-Unzueta[2], Juan Gomez-Gerique[2], Jose Riancho*[3]. [1]Hospital U.M.Valdecilla, Spain, [2]Hospital U.M. Valdecilla, Spain, [3]University of Cantabria, Spain

Severe forms of hypophosphatasia are usually diagnosed during infancy and childhood. Adult forms have less severe manifestations and may go unrecognized. In order to get a better knowledge of its clinical spectrum, we performed a computerized search of low total alkaline phosphatase. Bone alkaline phosphatase, serum pyridoxal phosphate (PLP) and urine phosphoetanolamine (PEA) were measured in selected individuals.

Results.- Among 12,103 determinations of total alkaline phosphatase in a 31 month period, we identified 130 individuals with at least one result below 26 u/l. After reviewing the clinical records, unexplained persistently low levels were found in 50 individuals. Forty two who could be localized and accepted to participate were included (10 men, 32 women). Age range was 20-77 yr (mean 51). Total alkaline phosphatase levels were positively correlated with bone alkaline phosphatase (r=0.52, p<0.001), and negatively with serum calcium (r=-0.38, p=0.012), PLP (r= -0.51, p=0.001) and urine PEA (r= -0.49, p=0.001). Serum PLP was positively correlated with serum phosphorus and urine PEA, and inversely with bone alkaline phosphatase. Ten individuals (24%) had PLP levels above the reference range of 175 nmol/l. In comparison with those with PP<175, they had lower levels of bone alkaline phosphatase (6.2 ± 1.6 vs 8.6 ± 2.1, p=0.003) and higher levels of serum phosphorus (4.3 ± 0.5 vs 3.4 ± 0.5, p<0.001) and urine PEA (41.3 ± 22.8 vs 14.9 ± 11.0, p<0.001). Likewise, these individuals had higher frequency of hypertension (50 vs 12%, p=0.02) and premature teeth loss (70 vs 19%, p=0.005).

Conclusion.- About one in four individuals with persistent low levels of total alkaline phosphatase had increased levels of PLP, consistent with hypophosphatasia. Most patients have mild disease. However, they may have an increased risk of hypertension and premature teeth loss.

Efficiency of whole exome sequencing for determining genetic origins of hypophosphatemic rickets patients without identified PHEX mutations. Catherine Brownstein*[1], Matthew Bainbridge[2], Meghan Towne[3], Nicholas Marinakis[3], Pankaj Agarwal[3], Alan Beggs[3], David Margulies[3], Gang-Qing Yao[4], Karl Insogna[4], Thomas Carpenter[4]. [1]Boston Children's Hospital & Harvard Medical School, USA, [2]Codified Genomics, USA, [3]Boston Children's Hospital, USA, [4]Yale University School of Medicine, USA

Introduction: Many genes are linked to phosphate homeostasis, and single gene sequencing is expensive (often over $400 per gene). Costs of whole exome sequencing (WES) has dropped exponentially, and annotation pipelines are increasingly accessible. We exome-sequenced 4 individuals who were diagnosed with hypopho-

sphatemic rickets on clinical grounds, however, sequencing of the coding regions of PHEX, DMP1, and FGF23 revealed no mutations.

Methods: Patients and family members were enrolled in The Manton Center for Orphan Disease Research. WES was performed at the Baylor School of Medicine Human Genome Sequencing Center, and sequences were run through pipelines at Claritas Genomics and at Codified Genomics.

Results: One *de novo* PHEX mutation missed during initial Sanger sequencing was identified (NM_000444:exon22:c.T2243G:p.L748R). Another patient and her affected son had heterozygous mutations in SLC9A3R1 (SLC9A3R1:NM_004252:exon2:c.G458A:p.R153Q), although neither patient exhibited the characteristic nephrolithiasis seen with that mutation.

Analysis of a fourth patient found two frameshifts in CYP27B1: (NM_000785:exon8:c.1326_1327insCCCACCC:p.P442fs and exon7:c.1160delA:p.N387fs). Interestingly, different pipelines had differing success rates in finding the CYP27B1 changes, and even Sanger confirmation results were not uniform for this sample .

Conclusion: PHEX is a large gene (215,558 bp), with 22 exons and multiple splice variants, and therefore mutations having escaped detection by pre-NGS methods is not surprising. However, NGS is not without issue- only 1 out of 2 pipelines identified both CYP27B1 frameshifts,

Our preliminary data suggests that WES is an efficient method to identify genetic basis of disease when a variety of candidate genes are possible causes of the condition. Multiple confirmatory pipelines may be necessary to achieve certainty in interpretation for difficult regions of the exome or genome. Investment in such approaches via WES for such unexplained cases may be important as more effective and appropriate therapies can be implemented .

The approach is likely to be a cost-effective method of determining genetic causes of newly diagnosed hypophosphatemia as well.

Loss of ERK1 and ERK2 in osteochondro progenitor cells causes metachondromatosis by enhancing chondrogenesis. Zhijun Chen*[1], Susan X. Yue[2], Guang Zhou[1], Edward Greenfield[1], Shunichi Murakami[1]. [1]Case Western Reserve University, USA, [2]Department of Orthopaedics, Case Western Reserve University, USA

Metachondromatosis, a human skeletal disorder caused by mutations in the *PTPN11* gene, is a rare hereditary disorder characterized by the formation of exostoses and enchondromas. Recently, conditional deletion of *Ptpn11* in skeletal cells has been shown to cause metachondromatosis-like phenotype in mice. However, the pathologic mechanisms whereby Ptpn11 deficiency leads to the development of metachondromatosis remain to be indentified. Ptpn11 encodes a tyrosine phosphatase Shp2 that plays an important role in ERK MAPK signaling. Our genetic study in mice has shown that ERK inactivation in the limb mesenchyme causes ectopic cartilage formation. In the present study, we therefore asked whether the inactivation of the ERK MAPK pathway in osteochondro progenitor cells can also lead to the metachondromatosis-like phenotype. We used *Prx1CreER-GFP* and *Osx-Cre* transgenes to inactivate *ERK2* in osteochondro progenitor cells of *ERK1*-null mice postnatally. Radiographic and histologic analyses indicated the formation of exostoses and enchondroma-like lesions in multiple bones, including the phalanges, metatarsals, and long bones in the limbs, in all of the 25 *Prx1CreER-GFP; ERK1*$^{-/-}$*; ERK2*$^{flox/flox}$ mice that were treated with tamoxifen. *Osx-Cre; ERK1*$^{-/-}$*; ERK2*$^{flox/flox}$ mice (3 out of 3) also showed multiple cartilaginous exostoses and enchondromas. Furthermore, *Prx1CreER-GFP; ERK1*$^{-/-}$*; ERK2*$^{flox/flox}$ mice showed ectopic cartilage formation in and around the muscles, tendons, knee menisci, and bony eminences, such as tibial, gluteal, and deltoid tuberosities. Lineage tracing experiment using the *ROSA26-LacZ* reporter revealed that the *Prx1CreER-GFP* transgene drives Cre-*loxP*-mediated recombination in multiple cell populations, including cells in the tendons, muscles, the perichondrial groove of Ranvier, and at the bone-ligament interface. Since those locations correspond to the ectopic cartilage formation, it is likely that ERK1/2 inactivation in these osteochondro progenitor cells induces chondrogenic differentiation leading to the development of exostoses. Immunostaining of ERK1/2 showed that the cartilaginous exostoses consisted of both ERK1/2-null and ERK1/2-positive chondrocytes, suggesting that ERK1/2-null cells signal to ERK1/2-positive cells and induce their chondrogenic differentiation. Collectively, our observations strongly suggest that ERK1/2 inactivation in osteochondro progenitor cells causes a metachondromatosis-like phenotype through enhancing chondrogenesis.

Increased peripheral vascular flow and aortic stiffness are associated with higher lean mass but lower muscle quality in middle-aged and older adults: the Framingham Heart Study. Shivani Sahni*[1], Na Wang[2], Alyssa Dufour[3], Douglas Kiel[3], Emelia Benjamin[4], Joanne Murabito[5], Joseph Vita[6], Marian Hannan[7], Paul Jacques[8], Robert McLean[9], Roger Fielding[10], Vasan Ramachandran[11], Gary Mitchell[12], Naomi Hamburg[6]. [1]Hebrew SeniorLife, Institute for Aging Research & Harvard Medical School, USA, [2]Boston University School of Public Health, USA, [3]Hebrew SeniorLife, USA, [4]Framingham Heart Study, Boston University School of Public Health, Boston University School of Medicine, USA, [5]Framingham Heart Study & Boston University School of Medicine, USA, [6]Boston University School of Medicine, USA, [7]HSL Institute for Aging Research & Harvard Medical School, USA, [8]Jean Mayer USDA HNRCA, Tufts University, USA, [9]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, [10]Jean Mayer USDA HNRCA At Tufts University, USA, [11]Framingham Heart Study, Boston University School of Medicine, USA, [12]Cardiovascular Engineering, Inc., USA

Impaired vascular function and increased aortic stiffness with aging is related to decreased physical function and performance of activities of daily living. Only one clinical study has reported the association of systemic vascular function with lower-limb muscular power in older adults with mobility limitations. We sought to evaluate whether alterations in peripheral blood flow and aortic stiffness may relate to muscle dysfunction in a large community-based cohort.

We examined the cross-sectional associations of peripheral vascular flow [resting flow velocity (RFV)] and aortic stiffness [carotid-femoral pulse wave velocity (CFPWV)] with arm lean mass, grip strength and arm muscle quality in 2,691 men and women from the Framingham Study Offspring Cohort (1998-2001). We further examined if RFV and CFPWV have interactive effects on muscle measures.

RFV was evaluated via high-resolution ultrasound and Doppler. CFPWV was evaluated using arterial tonometry and inverse transformed prior to analysis. Arm lean mass (both arms, kg) was measured using whole body DXA and grip strength (kg) was measured by isometric hand dynamometer (max. of 3 trials/hand). Arm muscle "quality" was calculated as the ratio of grip strength to arm lean mass. Multivariable linear regression was used to calculate the association of RFV and CFPWV with muscle measures, adjusting for sex, age; and height. Interaction between RFV and CFPWV was tested. If significant ($P<0.10$), adjusted least square means of muscle measures were calculated within sub-groups of RFV and CFPWV (dichotomized at median).

Mean age was 61 ± 10y (range 33-88). Mean arm lean mass, grip strength, arm muscle quality were: 5.0 ± 1.6 kg, 33 ± 12.9 kg, 6.31 ± 1.72, respectively. Higher RFV ($\beta \pm$SE: 0.124 ± 0.02, $P<0.0001$) and CFPWV ($\beta \pm$SE: 0.139 ± 0.03, $P<0.0001$) were associated with greater arm lean mass. The vascular measures were not significantly associated with grip strength (P range: 0.59-0.70). However, both higher RFV ($\beta \pm$SE: -0.178 ± 0.05, $P=0.0006$) and CFPWV ($\beta \pm$SE: -0.161 ± 0.07, $P=0.01$) were associated with lower arm muscle quality.

For muscle quality, a significant interaction was observed between RFV and CFPWV ($P=0.09$). Upon stratification, participants with lower RFV and lower CFPWV had higher muscle quality compared to those with either higher RFV ($P=0.03$) or higher CFPWV ($P=0.06$) or both ($P=0.09$, Figure).

These results suggest that high peripheral vascular flow, which may reflect aging-related metabolic disease, and high aortic stiffness are associated with greater muscle mass and with reduced muscle quality. Our findings are consistent with the possibility that altered vascular flow in conjunction with abnormal aortic stiffness induces microvascular damage in muscle tissue that adversely affects muscle function.

FR0449

Long-term bisphosphonate users have relatively lower skeletal muscle mass around the femur with increased serum pentosidine concentrations. Shigeharu Uchiyama*[1], Shota Ikegami[2], Keijiro Mukaiyama[2], Yukio Nakamura[3], Mikio Kamimura[4], Hiroyuki Kato[2]. [1]Shinshu University, School of Medicine, Japan, [2]Department of Orthopaedic Surgery, Shinshu University School of Medicine, Japan, [3]Dept of Orthopaedic Surgery Shinshu University School of Medicine, Japan, [4]Kamimura Clinic, Japan

One of the concerns regarding long-term use of bisphosphonate is the possible development of atypical femoral fractures(AFFs). AFFs show features consistent with stress or insufficiency fractures. We conducted a retrospective study to determine if the femurs of long-term bisphosphonate users could be exposed to excessive stress, which in turn could lead to AFFs. We recruited 31 female patients who had taken bisphosphonates for more than 3 years. Sixty-six female healthy volunteers matched with age, BMI, and DXA-derived BMD of the proximal femur, served as controls. We measured the skeletal muscle area around the proximal thigh and indices of the bone strength of the proximal femur with quantitative CT; we also measured several biochemical markers of bone metabolism. While no significant differences of the biomechanical indices of the proximal femur derived from qCT were detected, significant difference in the skeletal muscle area of the proximal thigh was observed between long-term bisphosphonate users and the controls (79 cm2 vs. 89 cm2, p = 0.0005). Furthermore, serum pentosidine levels were significantly greater in the bisphosphonate users than in the controls. The results suggest that long-term bisphosphonate users had a lower skeletal muscle mass around the femur, which had accumulated pentosidine. In such patients, repetitive load on the leg would not be well absorbed by the skeletal muscles. This would subject the brittle femur to excessive stress, leading to stress or insufficiency fractures.

Novel Mass Spectrometry Measurements of Circulating Myostatin Levels in Relation to Sarcopenia, Lean Mass and Bone Parameters in Women and Men. Joshua Farr*[1], Patrick Vanderboom[2], H. Robert Bergen[2], Sundeep Khosla[3], Nathan LeBrasseur[1]. [1]Mayo Clinic, USA, [2]Mayo Clinic, USA, [3]Mayo Clinic College of Medicine, USA

Over 50 yrs ago, circulating tissue-specific growth inhibitors were hypothesized to explain how tissue sizes are controlled. Since that seminal hypothesis, numerous such inhibitors have been discovered, including myostatin, a secreted protein that is derived from skeletal muscle and negatively regulates its mass. To date, however, conflicting data exist on how circulating myostatin levels change with aging and in patients with sarcopenia, possibly owing to poor assay validity.

Thus, we used high-performance liquid chromatography with tandem mass spectrometry to measure serum levels of myostatin as well as two of its key circulating inhibitors, follistatin-related gene protein (FLRG) and growth and serum protein-1 (GASP-1), in a population-based sample of 120 women and 120 men (within each sex: 40 younger subjects [mean age ± SD: 32.6 ± 4.7 yrs], 40 normal elderly subjects [age 75.4 ± 7.9 yrs] and 40 elderly subjects with sarcopenia [age 78.7 ± 7.5 yrs]). Myostatin levels were higher in men than women (8.6 ± 3.7 versus 6.7 ± 3.3 ng/mL, P<0.001) and were positively associated with total body lean mass (TBLM) in younger women and men (r = 0.34 and r = 0.36, respectively, P<0.05), but not in elderly subjects. Further, in patients with sarcopenia, the ratio of myostatin inhibitors (FLRG + GASP-1) to myostatin was significantly higher as compared to sex-matched normal elderly women (by 1.3-fold, P<0.01) and men (by 2.3-fold, P<0.01). Finally, after adjusting for age and sex in all subjects, serum myostatin levels relative to TBLM were negatively associated with hip and spine QCT-derived bone density (r = -0.16 and r = -0.15, respectively, P<0.05) and spine section modulus (r = -0.21; P=0.001).

Our data thus demonstrate that (1) circulating myostatin levels increase markedly with greater TBLM in younger adults, but not in the elderly population; (2) compared to healthy subjects of a similar age, patients with sarcopenia have higher levels of myostatin inhibitors for a given myostatin level; and (3) higher myostatin levels for a given amount of TBLM may have negative consequences for bone. These findings suggest that myostatin functions in a homeostatic regulatory mechanism to prevent excess skeletal muscle hypertrophy, and that in individuals with sarcopenia, natural inhibitors of myostatin are upregulated to limit further muscle wasting. Additional studies are needed to test this hypothesis as well as the potential role of myostatin in mediating bone loss.

Relationship of Muscle Function and Mass with the Health Assessment Questionnaire. Bjoern Buehring*[1], Sheeva Marvdashti[2], Christina C Lemon[2], Kaitlin R Chambers[2], Erin Johnson[2], Karen Hansen[3]. [1]University of Wisconsin, Madison, USA, [2]Department of Medicine, University of Wisconsin School of Medicine & Public Health, USA, [3]University of Wisconsin, USA

Introduction: The Health Assessment Questionnaire (HAQ) is a well validated, reliable and commonly used tool to assess physical function rheumatic diseases. It assesses 8 domains of function: Dressing / Grooming, Hygiene, Arising, Reach, Eating, Grip, Walking, and Common Daily Activities. Any of these activities requires not only good joint function but also different degrees of muscle strength and power. Sarcopenia, the age-related loss of muscle function and mass, is associated with a greater risk of falls, fractures and disability. This study aims to examine the relationship between muscle function/mass and HAQ scores obtained in a cohort of ambulatory, community-dwelling women. We hypothesized that muscle mass and function would correlate with HAQ scores, and that muscle function would more closely associate with HAQ scores than with muscle mass.

Methods: Subjects were 231 postmenopausal women (mean ± SD age 61 ± 6 years) participating in a double-blind, randomized, placebo controlled trial evaluating treatment of vitamin D insufficiency. Baseline data was used for the analysis. Participants underwent whole body DXA (GE Lunar) testing, completed a 4–day diet diary and underwent the Timed up and go test (TUG) and 5 sit to stand test (STS). They also had a blood draw to measure various parameters and filled out the Physical Activity of the Elderly (PASE) Questionnaire and HAQ. The HAQ has a score from 0-3 with 0 indicating no disability and 3 indicating severe disability. Descriptive analysis, correlations and regressions were performed using the HAQ as a continuous and a dichotomous measure (score 0 or >0).

Results: 26% of participants had a HAQ score >0. Those with elevated HAQ scores were older, had higher BMI and ALM/Ht^2 and lower TUG, STS, and PASE scores (Table). In a step-wise, multi-variate regression model using parameters significant in univariate analysis only STS, TUG, BMI and caffeine intake remained associated with HAQ (all p < 0.05). STS and TUG were also significant when using HAQ scores as a continuous variable.

Conclusion: In ambulatory postmenopausal women, decreased TUG and STS scores and higher BMI were associated with increased HAQ scores. Results underscore that decreased muscle function and obesity negatively affect physical function. Additionally, our results suggest that these factors might elevate HAQ scores, independent of rheumatologic disease. The relationship of caffeine intake and HAQ deserves further investigation.

Simple Functional Tests Predict Hip Fracture and Mortality in Postmenopausal Women; A 15 – Year Follow-Up. Toni Rikkonen*[1], Kenneth Poole[2], Joonas Sirola[3], Reijo Sund[4], Risto Honkanen[5], Heikki Kroger[6]. [1], Finland, [2]University of Cambridge, United Kingdom, [3]University of Eastern Finland / Kuopio, Finland, [4]University of Helsinki, Finland, [5]University of Eastern Finland, Finland, [6]Kuopio University Hospital, Finland

Aim

The earliest detectable sings of physical deterioration that predict hip fracture and mortality are not established. The aim of the study was to investigate the association of simple functional tests in relation to fracture risk and mortality in 15 year prospective follow-up.

Methods

Functional capacity and femoral neck bone mineral density (FN BMD) were measured in the population-based Osteoporosis Risk Factor and Prevention Study (OSTPRE) among 2791 women with a mean age of 59.1 years (range 53.2–65.6). Three physical tests were carried out and treated as dichotomous risk factors for functional decline; Ability to squat down (SQ) and touch the floor (y/n), ability to stand on one leg (SOL) for 10 seconds (y/n) and being ranked to the weakest grip strength (GS) quartile (y/n). FN BMD was measured with dual x-ray absorptiometry. Fractures and life style variables were recorded from self-reported questionnaires at baseline. Hip fractures (femoral neck, trochanteric and subtrochanteric) were verified from hospital discharge registry, deaths were recorded from national cause of death registry. Fracture risk and mortality were estimated by Cox proportional hazards model, with a mean follow-up time of 13.1 years and 13.8 years, respectively.

Results

A total of 578 fractures, including 35 hip fractures, were observed. Overall mortality during the follow-up was 9.2% (n=258). Altogether 56.9% (n=1587) of the women had none of the risk factors (SQ,SOL,WG) at baseline and were regarded as a reference group. Women with any of the risk factors acquired (n=1204) had higher risk for hip fracture, mortality and any fracture, with hazard ratios (HR) of 4.6 [95% confidence interval (CI) 2.1–10.1, $p<0.001$], 1.5(1.2-1.9, $p=0.001$), 1.5(1.2-1.7, $p<0.001$), respectively.

The strongest single determinant for hip fracture among tests was failed SOL, followed by failed SQ and weak GS, with their respective HR of 8.4(3.1-23.4, $p<0.001$), 5.2(2.3-11.8, $p<0.001$) and 4.3(1.8-10.3, $p=0.001$). Combinations of the risk factors only modestly increased the HR's. Adjusting fracture risks for FN BMD and age, or mortality for BMI and smoking did not alter the results.

Conclusion

Simple functional tests provide tools for risk assessment of the hip fracture, overall fractures and mortality. They also demonstrate the magnitude of frailty as an important predictor in hip fracture outcome.

FR0456

The effect of acute exercise on undercarboxylated osteocalcin and insulin sensitivity in obese men. Itamar Levinger*[1], George Jerums[2], Nigel Stepto[3], Lewan Parker[3], Fabio Serpiello[3], Glenn McConell[3], Mitchell Anderson[3], David Hare[2], Elizabeth Byrnes[4], Peter Ebeling[5], Ego Seeman[6]. [1]Institute of Sport, Exercise & Active Living (ISEAL), Victoria University, Australia, [2]Austin Health, Australia, [3]Institute of Sport, Exercise & Active Living (ISEAL), Victoria University, Australia, [4]PathWest QEII Medical Centre, Australia, [5]Department of Medicine, School of Clinical Sciences, Monash University, Australia, [6]Austin Health, University of Melbourne, Australia

Background: Acute exercise improves insulin sensitivity for hours after the exercise is ceased. The skeleton contributes to glucose metabolism and insulin sensitivity via osteocalcin (OC) in its undercarboxylated (ucOC) form in mice. We tested the hypothesis that improvement in insulin sensitivity following exercise is partly mediated via ucOC in human subjects.

Methods: Eleven middle-aged (58.1 ± 2.2year mean$\pm$SEM), obese (BMI=33.1 ± 1.4kgm-2) non-diabetic men completed a euglycaemic-hyperinsulinaemic clamp at rest (Rest-Control) and at 60 min post-exercise (44 min of cycling at 95% of HRpeak). Insulin sensitivity was determined by glucose infusion rate relative to body mass (GIR, $ml \cdot kg^{-1} \cdot min^{-1}$) as well as GIR per unit of insulin (M-value). Blood samples and 5 muscle biopsies were obtained; two at the Resting-control session, one before and one after clamping, and three in the Exercise session, at rest, 60min post-exercise and after the clamp.

Results: Exercise increased serum ucOC ($6.4 \pm 2.1\%$, $p= 0.013$) but not total OC ($p>0.05$). Blood glucose was ~6% lower and insulin sensitivity ~35% higher post-exercise compared with control (both $p<0.05$). P-AKT was higher after exercise and insulin compared to exercise alone (no insulin, ~2 fold, $p=0.006$,) and insulin alone (no exercise, ~1.8 fold, $p=0.029$). In a multiple-linear regression model that included BMI, age and aerobic fitness, ucOC was an independent predictor for whole body insulin sensitivity at rest and post-exercise ($b=0.59$, $p=0.023$ and $b= 0.66$, $p=0.005$, respectively) as was BMI.

Conclusions: Acute exercise partly mediates its beneficial effects on insulin sensitivity via ucOC in obese men. Whether ucOC has a direct effect on skeletal muscle insulin sensitivity after exercise is yet to be determined.

Hdac3 regulates osteoblastic glucocorticoid and lipid metabolism during aging. Meghan McGee-Lawrence*[1], Lomeli Carpio[1], Ryan Schulze[2], Mark McNiven[2], Sundeep Khosla[3], Merry Jo Oursler[1], Jennifer Westendorf[1]. [1]Mayo Clinic, USA, [2]Mayo Clinic, USA, [3]Mayo Clinic College of Medicine, USA

Histone deacetylase 3 (Hdac3) removes acetyl groups from lysine residues in histones and other proteins to epigenetically regulate gene expression. Hdac3 interacts with skeletal transcription factors and is essential for bone development and maintenance. We previously reported that conditional deletion of Hdac3 (Hdac3 CKO) in osteochondral progenitors, using Osx1-Cre, caused osteopenia and increased marrow adiposity, both hallmarks of an aging skeleton. Here we demonstrate that Hdac3 mRNA expression is reduced in bone cells from elderly women and primary bone marrow stromal cells (BMSC) and osteocytes from aged mice. More significantly, phosphorylation of S424-Hdac3, an event that stimulates deacetylase activity, is suppressed in osseous cells from old (22-26 months) mice as compared to young (1-2 months) animals. Lipid droplet formation was prevalent in the aged wildtype cultures as well as in osteogenic cultures of young Hdac3-depleted BMSCs. Gene expression analyses revealed insignificant changes in mRNA levels of Ppar gamma and fatty acid synthase, but Hdac3 CKO cultures demonstrated 10- to 20-fold increases in expression of genes related to lipid storage (Cidec, Perilipin1) and 2 to 3-fold changed in genes regulating glucocorticoid metabolism (11β-hydroxysteroid dehydrogenase type 1 (Hsd11b1)), suggesting that Hdac3 regulates local osteoblastic activation of glucocorticoids and lipid storage. In support of this hypothesis, lipid-containing cells in the Hdac3 CKO cultures expressed Runx2. In vitro lipid droplet formation was dependent on glucocorticoid signaling, as lipid storage and gene expression returned to near wildtype levels when dexamethosone (Dex) was excluded from the culture medium. Hdac3 attenuated Dex-induced activation of the glucocorticoid-responsive MMTV-luciferase reporter. Taken together, our data suggest that suppression of Hdac3 activity in bone cells contributes to reductions in bone density and increases in marrow adiposity that are associated with aging and long-term glucocorticoid treatment.

Loss of Progranulin Increases Bone Mass in Adult Mice in a Gender Dependent Manner. Liping Wang*[1], Theresa M. Roth[2], Thi A. Nguyen[3], Ping Zhou[3], Jiasheng Zhang[4], Mary Nakamura[5], Eric J. Huang[6], Robert V. Farese Jr.[7], Robert Nissenson[8]. [1]VA Medical Center, San Francisco, USA, [2]Endocrine Unit, VA Medical Center, USA, [3]Gladstone Institute of Cardiovascular Disease, USA, [4]Pathology, University of California, USA, [5]University of California, San Francisco/San Francisco VA Medical Center, USA, [6]Pathology, University of California / Pathology Service, VA Medical Center, USA, [7]Gladstone Institute of Cardiovascular Disease / Medicine & Biochemistry & Biophysics, University of California, USA, [8]VA Medical Center & University of California, San Francisco, USA

Progranulin (PGRN) is highly expressed in neurons and microglial cells. PGRN haploinsufficiency causes frontotemporal dementia and homozygous mutation causes neuronal ceroid lipofucinosis, a disease linked to defective lysosomal function, in humans. Recent studies have suggested that PGRN promotes heterotopic ossification and skeletal repair by serving as a downstream effector of BMP signaling. However, the role of PGRN in normal skeletal homeostasis has not been studied. We studied skeletal phenotypes of 6 month old PGRN null (KO) and wild type (WT) mice. μCT assessment revealed that female mice lacking PGRN maintained much greater fractional bone volume (BV/TV, %) (WT vs. KO, 6.89 ± 0.42 vs. 13.82 ± 1.79, $p<0.01$) at distal femur (DF) and increased cortical thickness (Ct.Th, mm) at the tibio-fibular junction (TFJ) (WT vs. KO, 0.218 ± 0.005 vs. 0.237 ± 0.004, $p<0.05$). In contrast, no statistically significant difference was seen in cancellous BV/TV or Ct.Th between male KO and WT mice (WT vs. KO, BV/TV: 18.48 ± 0.66 vs. 15.84 ± 1.34; Ct.Th: 0.234 ± 0.002 vs. 0.231 ± 0.009). To gain further insight into the role of PGRN in bone structure, histomorphometry was performed in the same bones. Compared to WT mice, there was a 45.6% increase in trabecular width ($p<0.05$), 59.3% increase in trabecular number ($p<0.01$), and a 41.5% decrease in trabecular separation ($p<0.001$) at DF in the female KO mice. R493X, the most common mutation worldwide in humans, causes loss of functional PGRN and therefore dementia in humans. We assessed the bone phenotype of the mice with R493x mutations (R493X) using μCT. Similarly to the findings with PGRN KO, mice bearing the R493X PGRN mutation displayed a striking increase in cancellous BV/TV (WT vs. R493X, 6.51 ± 0.85 vs. 12.17 ± 1.09, $p<0.01$) at DF and in Ct.Th at TFJ (WT vs. R493X, 0.228 ± 0.003 vs. 0.245 ± 0.003, $p<0.01$) in the 6-month-old female mice, while the age-matched male mice had no effect on cancellous BV/TV at DF (WT vs. R493X: 12.62 ± 0.91 vs. 13.45 ± 1.23), but increased Ct.Th (WT vs. R493X, 0.247 ± 0.007 vs. 0.266 ± 0.004, $p<0.05$) at TFJ. Bone marrow mononuclear cells from

PGRN null mice were found to be defective in osteoclastogenesis in vitro, producing fewer and smaller osteoclasts, suggesting that an osteoclast defect may contribute to the skeletal phenotype. In conclusion, PGRN is important in maintaining bone homeostasis in adult female mice and might serve as a useful therapeutic target for preventing age-related bone loss in humans.

Nox2-dependent ROS signaling protects against skeletal ageing. Jin-Ran Chen*[1], Oxana P. Lazarenko[2], Kelly Mercer[3], Michael L. Blackburn[3], Thomas M. Badger[3], Martin J. J. Ronis[4]. [1]University of Arkansas for Medical Science, Arkansas Children's Nutrition Center, USA, [2]Arkansas Children's Nutrition Center & The Department of Pediatrics, University of Arkansas for Medical Sciences, USA, [3]Arkansas Children's Nutrition Center, & The Department of Pediatrics, University of Arkansas for Medical Sciences, USA, [4]Arkansas Children's Nutrition Center, USA

Bone remodeling is age-dependently regulated and changes dramatically during the course of development. Progressive accumulation of reactive oxygen species (ROS), including superoxide, hydrogen peroxide, and hydroxyl radicals has been suspected to be the leading cause of many inflammatory and degenerative diseases and underlie the effects of ageing. In contrast, how reduced ROS signaling regulates inflammation and remodeling in bone remains unknown. Here, we utilized a p47phox knockout mouse model, in which an essential cytosolic co-activator of Nox2 is lost, to characterize bone metabolism at 6 weeks and 24 months of age. Using peripheral quantitative CT (pQCT), μCT and femur three point bending, and histomorphometric analyses, we show that bone mass and strength were all significantly higher in 6 weeks old $p47^{phox\ -/-}$ mice, but these were reversed in 24 month old $p47^{phox\ -/-}$ mice compared to their age-matched wild type controls. Increased bone formation with decreased bone resorption in 6 week old $p47^{phox\ -/-}$ mice, and decreased bone formation in 24 months old $p47^{phox\ -/-}$ mice reflected bone mass at these ages. Flow cytometric and Amplex Red hydrogen peroxide/peroxidase assays showed decreases in ROS generation in bone marrow cells and Nox2 signaling in osteoblastic cells from $p47^{phox\ -/-}$ mice compared to those from control wild type mice. Knocking down the Nox4 gene in neonatal osteoblastic cells from $p47^{phox\ -/-}$ mice in *ex vivo* blunted increased osteoblast differentiation. Expression of proinflammatory cytokines such as TNFα, IL6, RANKL and MMP9 in bone were all significantly increased in 24 month old $p47^{phox\ -/-}$ mice compared to their wild type controls, while we did not observe any differences in proinflammatory cytokine expression in 6-week-old $p47^{phox\ -/-}$ mice compared to wild type mice. These *in vivo* findings were mechanistically recapitulated in *ex vivo* cell culture of primary fetal calvarial cells, showed accelerated premature cell senescence accompanied by increased inflammation in cells from $p47^{phox\ -/-}$ mice. These data indicate that the observed age-related switch of bone mass in p47phox deficient mice occurs through an increased inflammatory milieu in bone and that Nox2-dependent physiological ROS signaling is redundant for osteoblast differentiation in early development, but it is required for suppression of inflammation in ageing bone. *Supported in part by ARS CRIS #6251-51000-005-03S (JRC) and R01 AA18282 (MJJR)*

Hip Fracture And Sarcopenia: A Model Of Osteoporosis-Related Muscle failure. Umberto Tarantino*[1], Jacopo Baldi[2], Eleonora Piccirilli[2], Maurizio Feola[2], Cecilia Rao[2], Elena Gasbarra[2]. [1]Università degli Studi di Roma Tor Vergata, Italy, [2]Università degli Studi di Roma "Tor Vergata", Italy

Introduction: The widespread increase in life expectancy is accompanied by an increased prevalence of physical diseases such as osteoporosis which is associated with loss of muscle bulk and power. Objectives: Aim of this study was to evaluate the degree of muscular atrophy in the vastus lateralis muscle of patients with osteoporosis and to determine the role of IGF-1/PI(3)/Akt signaling pathways in the genesis of a specific type II osteoporosis-related muscle atrophy. Moreover we investigate the microstructural features in muscles of osteoporotic by using diffusion tensor imaging (DTI). Methods: We performed vastus lateralis biopsy in 25 women with osteoporosis (OP) undergoing surgery for hip fracture and in 25 age matched women undergoing arthroplasty for hip osteoarthritis (OA). All patients gave informed consent. Muscle fibers were counted, measured and classified. A Magnetic Resonance (MR) operating at 9.4T equipped with a micro-imaging probe with a maximum gradient strength of 1200 mT/m was used to investigate muscle samples. We evaluated the Fractional Anisotrophy (FA), the mean Diffusivity (MD) and the three eigen values ($\lambda1>\lambda2>\lambda3$). All computation was made using an homemade script in MATLAB®. Mean values and standard deviation were obtained for each variable for OP and OA subjects, p values<.05 were considered statistically significant. Results: Our findings revealed a high percentage of atrophic type II fibers (37%) in OP, whereas in OA lower figures were observed (12%). Furthermore, we show that: 1) in OP, atrophic type-II fibers a) are 3-fold more frequent than atrophic type-I fibers ($p<.01$), b) significantly correlate with the degree of op ($p<0.05$); 2) in OA, type II fibers atrophy is 1.5-fold more frequent than type-I ($p<0.001$), correlates fiber atrophy, disease duration, pain and functional impairment hip joint. FA was higher compared to (p=-0.936) while MD, λ2 λ3 were compare (p=0.022), respectively. No significant difference λ1 found between linear correlation OP subjects only. Conclusions: This study shows in osteoporosis a preferential and diffuse type II fiber atrophy, that seems to be related to disease severity. FA is lower in OP when compared to OA. This outcome suggests that OP muscle has a more isotropic microstructure indicating that the micro-architetural alteration due to osteoporosis disease causes a higher radial diffusivity

***Asxl1* loss alters histone methylation status, leading to skeletal deficits.** Feng-Chun Yang*[1], Peng Zhang[2], Zhaomin Li[3], Yongzheng He[3], Lihn Nguyen[3], Jiapeng Wang[3], Khalid S. Mohammad[3], Theresa A. Guise[3], Mingjiang Xu[4]. [1]Indiana University, USA, [2]Indiana Univeristy, USA, [3]Indiana University, USA, [4]Indiana University School of Medicine, USA

Epigenetic mechanisms are critical in the tissue-specific regulation of gene expression. Histone methylation is one of the most important epigenetic modifications. However, whether histone methylation underlies the physiology and pathobiology of bone remodeling is not well established. *Additional sex combs* like 1 (*Asxl1*) has been shown to play an important role in both activation and silencing of *Hox* genes through interacting and regulating multiple histone modifying enzymes. Importantly, *ASXL1* is mutated in patients with Bohring-Opitz syndrome (BOS), characterized by severe bone deformities and other developmental deficits. Here, using an *Asxl1*-targeted mouse model, we challenged if *Asxl1* loss dysregulates critical genes controlling osteoblastogenesis and bone remodeling through altered histone modifications. Using *Asxl1:GFP* reporter knock-in strategy, we found that *Asxl1* loss lead to skeletal developmental defects in vivo, including dwarfism and hypoplastic supraorbital ridges. Dual energy X-ray absorptiometric analysis indicated a significantly lower bone mineral density in these mice. MicroCT confirmed decreased bone volume and reduced trabecular bone volume in these mice compared to WT controls. *Asxl1* loss resulted in markedly decreased frequency of bone marrow mesenchymal stem progenitor cells (MSPCs) with impaired osteoblast differentiation and much higher adipocyte differentiation compared to control MSPCs. The skewed MSPC differentiation was associated with the alteration of expression of multiple genes controlling osteoblastic and adipocytic differentiation, such as *Runx2, Bglap, Sp7, Alpl, Parg, Cebpa,* and *Lpl*. Furthermore, the loss of *Asxl1* dramatically altered the H3K4me3 levels in MSPCs. Importantly, re-expression of *Asxl1* restored both the cellular phenotypes and gene expression levels in *Asxl1* deleted cells. Collectively, these results indicate that *Asxl1* loss impaired skeletal development through dysregulation of histone methylation states, which in turn altered gene expression in MSPCs. This study demonstrated a pivotal role of histone modification in bone homeostasis.

FR0468

Dissociation of cortical and trabecular bone parameters in mice with conditional deletion of Solute carrier family 4 (anion exchanger), member 2 (SLC4A2) in mesenchymal cells. William O'Brien*[1], Julia Charles[2], Kelly Tsang[3], Kenichi Nagano[4], Gary Shull[5], Roland Baron[6], Antonios Aliprantis[1]. [1]Brigham & Women's Hospital, USA, [2]Brigham & Women's Hospital & Harvard School of Medicine, USA, [3]Brigham & Women's Hospital, USA, [4]Harvard School of Dental Medicine, USA, [5]University of Cincinnati College of Medicine, USA, [6]Harvard School of Medicine & of Dental Medicine, USA

Solute carrier family 4 (anion exchanger), member 2 (SLC4A2) regulates the intracellular pH of osteoclasts and is necessary for this cell to resorb bone. Osteoclast-specific deletion of *Slc4a2* however only partially recapitulates the severe osteopetrotic phenotype observed in germline $Slc4a2^{-/-}$ mice. Thus, we hypothesized that SLC4A2 also regulates bone mass through effects on mesenchymal lineage cells. To test this hypothesis, we used *Prx1-Cre* to delete a conditional allele of *Slc4a2* in the early limb bud mesenchyme ($Slc4a2^{Prx1Cre}$). Twelve-week-old male $Slc4a2^{Prx1Cre}$ mice were compared to sex-matched, littermate $Slc4a2^{fl/fl}$ $Prx1\text{-}Cre^{-}$ (WT) controls. By micro-CT, femurs of $Slc4a2^{Prx1Cre}$ mice displayed increased cortical bone (Cortical thickness 0.26 vs. 0.18mm, $p<0.05$) and decreased trabecular bone (BV/TV 4.2 vs. 14.7%, $p<0.05$). Histomorphometry confirmed both of these differences, and identified reduced osteoblast numbers and osteoid volume in the femoral trabecular compartment of the mutants. A trend towards decreased BFRs was also observed in $Slc4a2^{Prx1Cre}$ mice at this site. Furthermore, trabecular bone resorption activity (ES/BS 3.4 vs. 1.3%, $p<0.05$) and osteoclastogenesis (Oc.S/B.Pm 2.7 vs. 1.1%, N.Oc/B.Pm, 1.1 vs. 0.37/mm, $p<0.05$ for both) were increased in $Slc4a2^{Prx1Cre}$ mice. In cortical bone, histomorphometry identified increased periosteal bone formation parameters in the mutants (Ps.BFR/BS 225 vs. 102um^3/um^2/day, Ps.BFR/BV 554 vs. 198%/year, $p<0.05$ for both). To test for systemic effects of our deletion strategy, we analyzed vertebral trabecular bone by micro-CT and found $Slc4a2^{Prx1Cre}$ mice were indistinguishable from WT. This is consistent with the restricted expression of *Prx1* to limb bud mesenchyme. In summary, deletion of *Slc4a2* in limb bud mesenchyme increases cortical bone by elevating bone formation, and decreases trabecular bone mostly by promoting osteoclastic bone resorption. Thus, in addition to its previously appreciated function in osteoclasts, SLC4A2 also regulates bone remodeling through a direct function in mesenchyme-derived cells. The phenotype of $Slc4a2^{Prx1Cre}$ mice is a rare example of dissociation of cortical and trabecular bone

mass and may provide insight into how bone remodeling is differentially regulated at these sites.

***Dullard/Ctdnep1* regulates endochondral ossification via suppression of TGF-ß signaling.** Tadayoshi Hayata*[1], Yoichi Ezura[2], Makoto Asashima[3], Ryuichi Nishinakamura[4], Masaki Noda[5]. [1]Organization for Educational Initiatives, University of Tsukuba, Japan, [2]Tokyo Medical & Dental University, Medical Research Insititute, Japan, [3]Research Center of Stem Cell Engineering, National Institute of Advanced Industrial Science & Technology (AIST), Japan, [4]Department of Kidney Development, Institute of Molecular Embryology & Genetics, Kumamoto University, Japan, [5]Tokyo Medical & Dental University, Japan

Transforming growth factor (TGF)-ß signaling plays critical roles during skeletal development and its excessive signaling causes genetic diseases of connective tissues including Marfan syndrome and acromelic dysplasia. However, the mechanisms underlying prevention of excessive TGF-ß signaling in skeletogenesis remain unclear. We previously reported that *Dullard/Ctdnep1* encoding a small phosphatase is required for nephron maintenance after birth through suppression of bone morphogenetic protein (BMP) signaling. Unexpectedly, we found that *Dullard* is involved in suppression of TGF-ß signaling during endochondral ossification. Conditional *Dullard*-deficient mice in the limb and sternum mesenchyme by *Prx1-Cre* displayed impaired growth and ossification of skeletal elements leading to postnatal lethality. *Dullard* was expressed in early cartilage condensations and later in growth plate chondrocytes. Dullard deficiency enhanced the early cartilage condensation and differentiation, but impaired cartilage mineralization in micromass culture system, both of which was restored by treatment with TGF-ß type I receptor kinase blocker LY-364947. Protein levels of both phospho-Smad2/3 and total Smad2/3 were upregulated in Dullard-deficient micromass cultures, while Smad2/3 mRNA levels were not increased, suggesting that Dullard affects Samd2/3 protein stability. Response to TGF-ß signaling was also enhanced in Dullard-deficient primary chondrocyte cultures at late, but not early, time point. The phospho-Smad2/3 was upregulated in perichondrium and hypertrophic chondrocytes in *Dullard*-deficient embryos. Moreover, perinatal administration of LY-364947 ameliorated the skeletal deformity caused by Dullard deficiency in vivo. Thus, we identified Dullard as a new negative regulator of TGF-ß signaling in endochondral ossification.

Challenging the dogma of BMP canonical signaling in the absence of Smad4. Diana Rigueur*[1], Karen Lyons[2]. [1]Graduate Student, USA, [2]University of California, Los Angeles, USA

BMP signaling plays essential roles in the development and maintenance of bone and cartilage. However, the mechanisms by which BMP signaling regulates proliferation, differentiation, and apoptosis have yet to be completely elucidated. In the canonical BMP signaling pathway, the intracellular R-Smads 1, 5, and 8, transduce the signal by translocating to the nucleus with common Smad4 to activate BMP target genes. The majority of studies to date indicate that Smad4 is an essential component of canonical BMP signaling. However, there is some evidence in Drosophila that R-Smads transduce a limited amount of signaling in the absence of Smad4. To date, this has not been clearly demonstrated in vertebrates. Our recent findings provide evidence that Smad1/5/8-dependent, Smad4-independent BMP signaling does occur in vertebrates, and in the context of the cartilage growth plate, may be a major mode of BMP signaling. We find that cartilage specific loss of Smads1/5 in mice leads to a severe chondrodysplasia, yet cartilage-specific Smad4-knockout mice are viable and display a much milder cartilage phenotype. Through immunofluorescence, western blot analysis, and quantitative RT-PCR we show that transducers of the BMP pathway, both receptor activated Smads 1/5/8 and the non-canonical pathway, are ectopically elevated in the absence of Smad4. Moreover, a well-characterized BMP target gene, IHH, albeit reduced, responds to BMP stimulation in isolated Smad4 deficient primary chondrocytes. Through CHIP analysis, we show that Smads 1/5/8 are able to bind to the IHH promoter, although, at diminished levels in Smad4 deficient chondrocytes. Overall, these data exemplify that Smad4 may be required for canonical BMP transduction in many or most tissues; however, Smad4 may be dispensable for other systems, calling for a re-evaluation of the putative BMP canonical pathway and the extent of BMP signaling.

Contrasting Skeletal and Molecular Phenotypes in Mice Lacking Prolyl Hydroxylase Domain-containing Protein 2 (PHD2) Gene in Chondrocytes Versus Osteoblasts. Shaohong Cheng*[1], Weirong Xing[2], Sheila Pourteymoor[3], Subburaman Mohan[4], Jan Schulte[3], Bo Liu[3]. [1]VA Loma Linda Health Care Systems, USA, [2]Musculoskeletal Disease Center, Jerry L. Pettis Memorial Veteran's Admin., USA, [3]1Musculoskeletal Disease Center, Jerry L Pettis VA Medical Center, USA, [4]Jerry L. Pettis Memorial VA Medical Center, USA

Ascorbic acid (AA) is indispensable for osteoblast (OB) maturation as mutant mice lacking GULO, an enzyme required for AA biosynthesis, develop spontaneous fractures due to impaired bone formation (BF). In our studies on the mechanism for AA effects on OBs, we found that the AA effect on osterix (Osx) expression is dependent on PHD2. Accordingly, we recently reported that conditional knock out (cKO) of PHD2 in OBs results in decreased bone size, BMD and BF rate and premature death at 12-14 weeks of age. Since AA is also known to regulate chondrocyte (CC) functions, we evaluated the role of PHD2 in CCs in this study by crossing Phd2 floxed mice with transgenic Col2α1-Cre mice. In contrast to the osteopenia phenotype of OB-specific PHD2 cKO mice, PHD2 disruption in CCs increased areal BMD by >20% ($P<0.05$) in femur, tibia and vertebra of 4 week old mice. Micro-CT analysis revealed a 118% and 42% ($p<0.001$) increase in trabecular BV/TV of femur and vertebra. The femur cortical BV/TV was also increased by 10% ($p<0.001$) in the cKO mice. While the femur length and size were reduced by 20% and 7% respectively, the increased trabecular and cortical bone BMD were maintained at 12 weeks of age. Histomorphometric analyses revealed that while BFR was unaffected, the TRAP positive osteoclast surface to bone surface was reduced by 14% ($p<0.05$) in the trabecular bone of cKO mice. Quantitative RT-PCR revealed that PHD2 expression was reduced by >60% in growth plate CCs. Surprisingly, loss of PHD2 in growth plate CCs increased Osx expression which is in contrast to reduced Osx expression in bones of OB-specific cKO mice. Since PHD2 is a key regulator of HIF1α that is required for chondrocyte survival and differentiation, we examined the VEGF mRNA level, a marker for HIF1α signaling. Indeed we found a 80% increase of VEGF mRNA level in the growth plate CCs of the cKO mice, suggesting up-regulation of the HIF1α pathway in the CCs of PHD2 cKO growth plates. CCs-derived from PHD2 floxed mice were infected with adenoviral (Ad)-Cre to delete the PHD2 gene or Ad-GFP control. AA reduced Osx expression in Ad-GFP but not in Ad-Cre CCs. Based on these data and our published data that Osx is required for terminal differentiation of CCs, we conclude that PHD2 negatively regulates chondrocyte maturation and endochondral BF in part by inhibiting Osx and VEGF expression, which is in sharp contrast to its role as a positive regulator of differentiation and Osx expression in OBs.

RECQL4 regulates p53 function *in vivo* during skeletogenesis. Linchao Lu*[1], Karine Harutyunyan[2], Weidong Jin[3], Jianhong Wu[3], Tao Yang[4], Yuqing Chen[3], Kyu Sang Joeng[1], Yangjin Bae[1], Jianning Tao[1], Brian Dawson[3], Ming-Ming Jiang[3], Brendan Lee[1], Lisa Wang[1]. [1]Baylor College of Medicine, USA, [2]University of Texas M. D. Anderson Cancer Center, USA, [3]Baylor College of Medicine, USA, [4]Van Andel Research Institute, USA

RECQL4 is a DNA helicase and functions in DNA replication, homologous recombination and DNA damage repair. Mutations in *RECQL4* are associated with three human disorders: Rothmund-Thomson syndrome (RTS), RAPADILINO, and Baller-Gerold syndrome (BGS). All three syndromes have prominent skeletal abnormalities, including radial ray abnormalities, foreshortened limbs, and cranio-synostosis.

To study the function of *RECQL4* in skeletogenesis *in vivo*, we generated a mouse *Recql4* conditional allele (*Recql4$^{fl/fl}$*) by gene targeting. *Recql4$^{fl/fl}$* mice were crossed with *Prx1-Cre* transgenic mice to inactivate *Recql4* in mesenchymal progenitor cells. *Recql4$^{fl/fl}$;Prx1-Cre^{+}* mice had short, abnormally shaped limbs, missing digits, and cranial suture synostoses. H&E staining of E18.5 growth plates showed reduced chondrocyte density and increased cell size. Growth plates of 3 week old *Recql4$^{fl/fl}$;Prx1-Cre^{+}* mice displayed abnormal cell morphology and disorganized cells leading to reduced ossification. Furthermore, crossing *Recql4$^{fl/fl}$* mice with *Col2a1-Cre* transgenic mice resulted in offspring with small, abnormally shaped rib cages and perinatal lethality. Growth plates from these mice displayed similar chondrocyte defects as those in *Recql4$^{fl/fl}$;Prx1-Cre^{+}* mice. TUNEL and BrdU incorporation assays showed increased apoptosis and decreased cell proliferation in the growth plates from both mouse models. Real-time RT-PCR revealed that transcripts of p53 target genes, including *CDKN1A/p21* and *Bax,* were significantly up-regulated in tissues from both models. Immunoblot analysis demonstrated dramatically increased p53 serine15 phosphorylation and elevated p21 protein levels in forelimb tissues of E13.5 *Recql4$^{fl/fl}$;Prx1-Cre^{+}* embryos. Conditional deletion of both *Recql4* and *p53* partially rescued the skeletal defects observed in *Recql4* single mutants, indicating that *Recql4* genetically interacts with *p53 in vivo* during skeletal development.

The skeletal phenotypes in *Recql4$^{fl/fl}$;Prx1-Cre^{+}* and *Recql4$^{fl/fl}$;Col2a1-Cre^{+}* mice recapitulate the major skeletal findings in the *RECQL4* spectrum of disorders. Our *in vivo* findings suggest that: 1) deletion of *Recql4* causes p53 activation which leads to

increased apoptosis and reduced cell proliferation in skeletal progenitor cells; 2) *Recql4* is required for normal skeletogenesis by modulating p53 function during development; and 3) p53 response contributes to the pathogenesis of developmental bone anomalies in patients with *RECQL4* mutations.

The homeoboxgene *DLX4* promotes generation of human induced pluripotent stem cells. Naritaka Tamaoki*[1], Kazutoshi Takahashi[2], Hitomi Aoki[3], Kazuki Iida[1], Tomoko Kawaguchi[1], Daijirou Hatakeyama[1], Masatoshi Inden[4], Naoyuki Chosa[5], Akira Ishisaki[5], Takahiro Kunisada[3], Toshiyuki Shibata[1], Naoki Goshima[6], Shinya Yamanaka[2], Ken-Ichi Tezuka[7]. [1]Department of Oral & Maxillofacial Science, Gifu University Graduate School of Medicine, Japan, [2]Center for iPS Cell Research & Application, Japan, [3]Department of Tissue & Organ Development, Gifu University Graduate School of Medicine, Japan, [4]Laboratory of Medical Therapeutics & Molecular Therapeutics, Gifu Pharmaceutical Universit, Japan, [5]Division of Cellular Biosignal Sciences, Department of Biochemistry, Iwate Medical University, Japan, [6]Biomedicinal Information Research Center, National Institute of Advanced Industrial Science & Technology, Japan, [7]Gifu University Graduate School of Medicine, Japan

(Background) Potential tumorigenicity is a problem in the application of induced pluripotent stem cells (iPSCs) to regenerative medicine. Therefore, it is important to improve the efficiency of iPSC generation without using proto-oncogenes, such as c-MYC. In a previous study, we established more than 150 dental pulp cells (DPC) lines isolated from extracted wisdom teeth and evaluated the potential of DPCs for iPS cell banking. In this study, we hypothesized that the reprogramming efficiencies of DPCs are affected by the developmental stages of donor teeth. Next, we attempted to identify new reprogramming factors to promote human iPSCs generation without c-MYC by using gene expression profiling between DPCs isolated from immature and mature teeth. (Methods and Results) Firstly we evaluated the reprogramming efficiencies of 9 DPC lines isolated from various developmental stages of third molar teeth, and introduced *OCT3/4*, *SOX2*, *KLF4*, and *c-MYC* (OSKM) into them by retroviral gene delivery. We found that all immature teeth DPC lines showed significantly higher reprogramming efficiency than mature teeth DPC lines. Our result indicated that immature teeth DPCs were much more amenable to reprogramming than mature teeth DPCs, and prompted us to compare these two groups of DPCs for gene expression profiling to identify genes up-regulating the reprogramming efficiencies of DPCs. Among the 28 genes significantly up-regulated by more than five-fold in immature teeth DPCs, we focused a homeobox gene *DLX4*. Real-time PCR assay showed that the expression levels of *DLX4* in DPCs isolated from immature teeth were much higher than those of mature teeth DPCs. We next studied whether ectopic expression of *DLX4* could increase the reprogramming efficiency of DPCs. We observed a synergistic increase in the number of iPSC colonies when *DLX4* was co-introduced with *OCT3/4*, *SOX2*, and *KLF4* (OSKD), and the number of iPSC colonies obtained from both immature and mature teeth DPCs with OSKD was similar to the number obtained using OSKM. As observed in DPCs, the OSKD cocktail also increased the reprogramming efficiency in human dermal fibroblasts to the same level observed using OSKM. (Conclusion) Here we reported the screening of genes differentially expressed in immature and mature teeth DPCs, and found that DLX4 significantly enhanced human iPSC colony formation in combination with OSK. Our finding suggests that DLX4 may be used to replace c-MYC in the derivation of human iPSCs to generate safer iPSCs.

FR0478

Znf9 plays an indispensable role in skeletal development by upregulating the expression of Indian hedgehog (Ihh) and multiple limb development regulator genes. Yun Lu*[1], Guiqian Chen[2], Wei Chen[3], Guochun Zhu[4], Yi-Ping Li[3]. [1], USA, [2]University of Alabama at Birmingham, USA, [3]University of Alabama at Birmingham, USA, [4]The University of Alabama at Birmingham, USA

Znf9 is a cellular nucleic acid binding protein (CNBP) that is highly conserved among vertebrates and implicated in vertebrate craniofacial development. However, due to early embryonic lethality, the function of Znf9 in skeletal development and its molecular targets remain elusive. Hence, we generated $Znf9^{Loxp/Loxp}$ ($Znf9^{f/f}$) mice and then crossed $Znf9^{f/f}$ mice with the *Prx1*-Cre mice to generate mesenchymal stem cell-specific *Znf9*-deficient ($Znf9^{f/f}$*Prx1*-Cre) mice to study the role of Znf9 in limb, cartilage, and bone development. *Znf9* gene deletion was verified in the limb mesenchyme by qPCR and immunohistochemistry (IHC) in E14.5 $Znf9^{f/f}$*Prx1*-Cre embryos. Our data showed that at E17.5, depletion of Znf9 in the limb mesenchyme resulted in the extreme shortening of limbs. Histological analysis showed there is a significant decrease in chondrocyte proliferation. In addition, the transition from prehypertrophic to hypertrophic cells was severely impaired and the expression of osteopontin (*Opn*) and osterix (*Osx*) was largely decreased, indicating abnormal osteogenesis. The Heterozygous mice survived to adulthood, but exhibited very short limbs with malformations. However the Homozygous mice died at birth. 7-day-old $Znf9^{f/+}$*Prx1*-Cre mice, the resting zone was dramatically elongated, the proliferation zone and hypertrophic zone of the growth plates were drastically shortened and disorganized, and trabecular bone formation was reduced. Moreover, in one-month-old $Znf9^{f/+}$*Prx1*-Cre mice, the growth plates and long bone were severely deformed. In addition, *Znf9* deficiency impaired intramembranous bone formation. Interestingly, while the expression of indian hedgehog (*Ihh*) was largely reduced, the expression of parathyroid hormone-related protein (*PTHrP*) receptor (*PPR*) was dramatically increased in the $Znf9^{f/+}$*Prx1*-Cre mice growth plate, indicating that *Znf9* deficiency disrupted the Ihh-PTHrP negative regulatory loop. Furthermore, qRT-PCR revealed a significant reduction of limb development regulator genes (*e.g. Sox9, BMP2, Bmpr1b, Fgfr3, Runx2,* and *Shh*) in $Znf9^{f/+}$*Prx1*-Cre E17.5 mutant embryos when compared with WT embryos. Notably, Znf9 binding site analysis showed that there are Znf9 binding sites in the regulator gene promoter regions. Taken together, our study reveals that Znf9 is essential for limb development and that Znf9 regulates limb and growth plate development by upregulating the expression of multiple limb and growth plate development regulator genes.

SA0001

In Postmenopausal Women with Stage 3 CKD, Fractures are Associated with Abnormalities in Both Trabecular and Cortical Bone. Emily Stein*[1], Kyle Nishiyama[2], Thomas Nickolas[1], Stephanie Sutter[3], Donald McMahon[1], X Guo[2], Elizabeth Shane[1]. [1]Columbia University College of Physicians & Surgeons, USA, [2]Columbia University, USA, [3]Columbia University Medical Center, USA

Although evidence is accumulating that fracture risk is higher in postmenopausal (PM) women with mild stage 3 CKD than those with normal renal function, the pathogenesis has not been elucidated. Microarchitectural abnormalities have been reported in fracture patients with more severe CKD, but not in women with fractures and mild CKD. We hypothesized that among PM women with stage 3 CKD, those with fragility fractures would have higher PTH, worse cortical microarchitecture and lower stiffness. We enrolled 50 PM women with stage 3 CKD (age 72±8yrs, 72% Caucasian), 25 with a history of low trauma fracture after menopause (FX) and 25 non-fractured controls. All had areal BMD (aBMD) of lumbar spine (LS), total hip (TH), femoral neck (FN), and 1/3 (1/3R) radius by DXA. Trabecular (Tb) and cortical (Ct) volumetric BMD (vBMD) and Tb microarchitecture were measured by high resolution peripheral computed tomography (HRpQCT, voxel size ~82 μm) of the distal radius and tibia and whole bone stiffness was estimated by finite element analysis. Groups were similar with respect to age, race, BMI and years since menopause. Mean eGFR by MDRD (46 ml/min) and iPTH (60 pg/ml) did not differ. Forearm (40%), spine (28%) and ankle (16%) fractures were most common. Mean DXA T-scores, well above the osteoporotic threshold in both groups, were lower in FX subjects at LS, TH, FN (all $p<0.05$) but not 1/3R. There were substantial differences in vBMD and microarchitecture at both radius and tibia (Table). At both sites, bone size (cross-sectional area) was similar. At the radius, FX subjects had lower total vBMD, lower Ct area, thickness and density. They also had lower Tb vBMD and number, higher Tb separation and tended to have more heterogeneity. At the tibia, FX subjects had lower total vBMD, lower Ct area and thickness, lower Tb density and thickness and tended to have greater Tb separation. Whole bone stiffness was substantially lower in FX subjects at both sites. In summary, PM women with stage 3 CKD and fractures have both cortical and trabecular abnormalities and lower stiffness compared to those with no history of fracture. Contrary to our hypotheses, abnormalities in FX subjects were not confined to cortical bone, nor did PTH differ by fracture status. Our results suggest that both cortical and trabecular bone losses may be important mechanisms of fracture in the burgeoning population of PM women with mild CKD.

Assessment of C3-Epi-25-Hydroxyvitamin D concentration in adult serum: LC-MS/MS determination using [$^2H_3$] 3-epi-25OHD$_3$ internal standard and NIST traceable commercial 3-epi-25OHD calibrators. Jonathan Tang*[1], Christopher Washbourne[2], Isabelle Piec[3], William Fraser[2]. [1]University of East Anglia, Norwich, UK, United Kingdom, [2]University of East Anglia, United Kingdom, [3]BioAnalytical Facility, University of East Anglia, United Kingdom

Background: The C-3 Epimer of 25 Hydroxyvitamin D_3 (3-Epi-25OHD$_3$) is produced in the liver by the epimerisation pathway of 25-hydroxy vitamin D_3. It differs from 25OHD$_3$ in configuration of the hydroxyl group at the third carbon (C-3) position. Despite the fact that little is known regarding its clinical significance, concerns have been raised that isobaric interference may result in over-estimation of total 25OHD when measured by liquid chromatography tandem mass spectrometry (LC-MS/MS).

Objective: The aim of the study was to assess the occurrence of 3-Epi-25OHD$_3$ in adult serum samples. A LC-MS/MS technique was developed to resolve and quantify 3-Epi-25OHD$_3$ from 25OHD$_3$. The newly available NIST (SRM972a) traceable 3-Epi-25OHD commercial standards were used to ensure assay accuracy.

Method: Serum was precipitated with zinc sulphate and acetonitrile containing [$^2H_3$]-3-epi-25OHD$_3$ as internal standard. The extract was chromatographed using a 2.6μm 100 x 2.1mm I.D. solid core particle column. Mass detection and quantification were performed by positive electrospray ionization with MS/MS in multiple reaction monitoring mode.

Results: The method was able to fully resolved 3-Epi-25OHD$_3$ from 25OHD$_3$. The intraassay CVs for the epimer were 6.3% and 4.1% at 25.4 and 62.1 nmol/L respectively; and interassay CVs were 8.3% and 6.5% at 27.6 and 63.2 nmol/L, respectively. In our sample cohort with 25OHD$_3$ ranged between 3.4 – 165 nmol/L, 3-Epi-25OHD$_3$ was detected in 91.9% of samples (mean = 3.8 nmol/L). No detectable 3-Epi-25OHD$_2$ was found in our sample study. One patient sample had total 25OHD$_3$ of 187 nmol/L that was shown to contain 141 nmol/L of 25OHD$_3$ and 44 nmol/L of 3-Epi-25OHD$_3$. This patient was receiving a high dose of vitamin D supplementation.

Conclusion: Using [$^2H_3$]-3-epi-25OHD$_3$ as internal standard and NIST aligned calibrators enabled us to obtain an accurate assessment of 3-epi-25OHD concentration in adult serum. Although the concentration of serum 3-epi-25OHD$_3$ was found to be low the presence was observed in the majority of our samples. The findings in this study showed that 3-epi-25OHD$_3$ contributed to the overestimation of 25OHD$_3$ that could potentially resulted in misinterpretation of total vitamin D status.

SA0005

Vitamin D and Calcium Supplement Diminish Bone Pain and Improves Self-Rated Health in Pre-menopausal Vitamin D Deficient Patients. Darshana Durup*[1], Peter Schwarz[2], Lona Christrup[1], Bent Lind[3], Anne-Marie Heegaard[4]. [1]Department of Drug Design & Pharmacology, Faculty of Health & Medical Sciences, University of Copenhagen, Denmark, [2]Glostrup Hospital, Denmark, [3]The Elective Laboratory of the Capital Region, Denmark, [4]Faculty of Health & Medical Sciences, University of Copenhagen, Denmark

Purpose: The aim was to 1) quantify and 2) characterize bone pain in vitamin D deficient pre-menopausal women suffering from bone pain. Furthermore, to investigate the effect of vitamin D and calcium treatment on bone pain and self-evaluated health. Hopefully this will help with earlier diagnosing of vitamin D associated bone pain, which can be very disabling without proper treatment

Methods: Sternum and medial tibia was subjected to mechanical stimuli using computer connected pressure algometry with electronic VAS allowing continuous measurement. Pressure pain threshold was the first pressure pain endpoint. Moderate to severe pain (VAS 7) was the second endpoint. Two probe sizes were used; 1 cm2 (diameter: 10 mm), which is the most widely used in the literature and a smaller 0.03 cm2 (diameter: 2 mm) that has shown to have least influence from skin nociceptors. Characterization of the pain was estimated using pain and health questionnaires (McGill Pain Questionnaire, Brief Pain Inventory and SF-36). Patients were tested and filled out questionnaire at baseline and additional after 1, 3, 6 and 12 month on vitamin D (76 μg/day) and calcium (800 mg/day) treatment

Results: Pressure pain threshold was significantly lower in 22 vitamin D deficient patients, both with the bigger probe at medial tibia: 130 mN (SD 90) vs. 405 mN (SD 180) ($p < 0.0001$) and sternum: 77 mN (SD 47) vs. 146 (SD 73) ($p < 0.001$) and with the smaller probe at medial tibia: 75 mN (SD 37) vs. 101 mN (SD 41) ($p < 0.05$) and sternum 51 mN (SD 30) vs. 92 (SD 43) ($p < 0.001$). Moderate to severe pain was also experienced at lower pressure levels. Serum 25-hydroxyvitamin D and parathyroid hormone normalized after 1 month on vitamin D and calcium supplement and an increase in pressure pain threshold was observed but never raised to the same level as the control group. Self-rated health assessed by SF-36 was poorer in all dimensions ($p < 0.0001$). The most frequently chosen pain words were tingling, taut and tiring

Conclusions: Vitamin D deficient pre-menopausal patients suffering from bone pain had lower pressure threshold. The bone pain was characterized as tingling, taut and tiring and the patients had lower self-rated health. Vitamin D and calcium supplement normalized serum 25-hydroxyvitamin D and parathyroid hormone within

a month and bone pain was diminished and quality of life was improved. However still significantly lower compared to healthy controls even after 12 month of treatment

Is Strontium Ranelate a Therapeutic Option to Treat CRPS?. Manfred Herold*[1], Malgorzata Brunner-Palka[2]. [1]Innsbruck Medical University, Austria, [2]physician, Austria

CRPS (Complex regional pain syndrome) also referred to as reflex sympathetic dystrophy (RSD), Sudeck's atrophy or algodystrophy is a chronic painful condition with allodynia and hyperalgesia. An evidence based treatment is not known[1].

A 66-year old female was first time seen at the rheumatology unit in February 2013. She was unable to use the right hand in case of immobility in the metacarpo- and proximal interphalangeal joints and suffered from pain in the right hand. Sudeck's atrophy of the right hand was diagnosed 1995 after distal radius fracture. Several therapeutic interventions including physical therapy had been tried without success. Chronic pain remained and immobility was rapidly progressing.

Strontium ranelate 2 grams daily orally was started immediately. Fingertip hand distance, SF-SACRAH[2] and a visual analogue scale (VAS) of 100 mm (0=no pain) were used to document disease activity.

Already 6 weeks after first intake of strontium ranelate first improvements were reported. At the last visit in May 2014 the fingertip hand distance was 7 mm (70 mm at the beginning) and the right hand could again be used for easy working. According to the clinical improvement since February 2013 SF-SACRAH decreased from 6,2 to 2,0 and VAS from 80 to 22 mm.

CRPS is difficult to treat and usually results with major disability and pain. With strontium ranelate we observed an impressive improvement in hand motion, increase in functionality and decrease of pain. We suppose that the effect is based on strontium ranelate's dual mechanism of action with increasing bone formation and decreasing bone resorption.

Evaluation of Serum Sclerostin in Postmenopausal Women with Type 2 Diabetes Mellitus. Larissa Pimentel*[1], Francisco Bandeira[2], Sirley Vasconcelos[3], Luiz Griz[4], Vanessa Machado[5]. [1], Brazil, [2]University of Pernambuco, Brazil, [3]Hospital Agamenon Magalhães - Recife, Brazil, [4]Endocrinology & diabetes Uinit of Agamenon Magalhães Hospital, University of Pernambuco, Recife-PE-Brasil, Brazil, [5]Endocrinology & Diabetes Unit of Agamenon Magalhães, Brazil

Introduction: In type 2 diabetes mellitus (T2DM) there is an increased risk of fractures despite the elevated bone mineral density values. Several mechanisms have been proposed to explain the effect of glycemia control on bone. Few studies have evaluated serum sclerostin levels in patients with T2DM. The sclerostin is involved in the signaling pathway Wnt / β –catenin, which regulates the gene transcription essential for osteoblast cells. The study of this pathway led to the subsequent discovery of inhibitors of Wnt signaling secreted by osteocytes. These include sclerostin (SCL) and Dickkopf protein 1 (DKK1), which block the binding of the Wnt protein 5 to the related lipoprotein receptor (LDL -5) , thereby inhibiting osteoblastic stimulation.

Methods: This is a cross-sectional study comprising a population of 57 postmenopausal women with T2DM to evaluate serum sclerostin levels and correlate them to a control group of healthy young individuals. Serum sclerostin levels were assessed using a quantitative sandwich ELISA from Biomedica (Biomedica Gruppe, Vienna, Austria), with intra-assay and interassay value coefficients of 4 and 5.5%, respectively. This assay uses a polyclonal goat antihuman sclerostin antibody as a capture antibody and a biotin-labeled mouse monoclonal antisclerostin antibody for detection. Control and patient samples were run together.

Results: Mean age was 62,89 ± 8,9 years; duration of T2DM:12.99 9 ± 19 years; BMI: 30.16 ± 4.8 kg/m2; abdominal circumference: 103.11 ± 13.01cm; HDL-C : 51.19 ± 10.59mg/dL; LDL-C 118.63 ± 4.89; fasting plasma glucose 154.96 ± 74.17mg/dL; HBA1c:14.06 ± 2.94%; 25OHD 25.74 ± 11ng/dL. The mean age of the control group was 27.6 ± 3.6 years. Fifty percent of T2dm patient had SCL above the upper limit of normal. The mean serum sclerostin was 29.14± 12.29 pmol/L in the postmenopausal women with T2DM and 23.50± 6.62 pmol/L in the control group (p=0.031).

Conclusion: Our data demonstrated that T2DM patients have higher serum SCL concentrations and it may contribute to bone quality deterioration and an increased fracture risk.

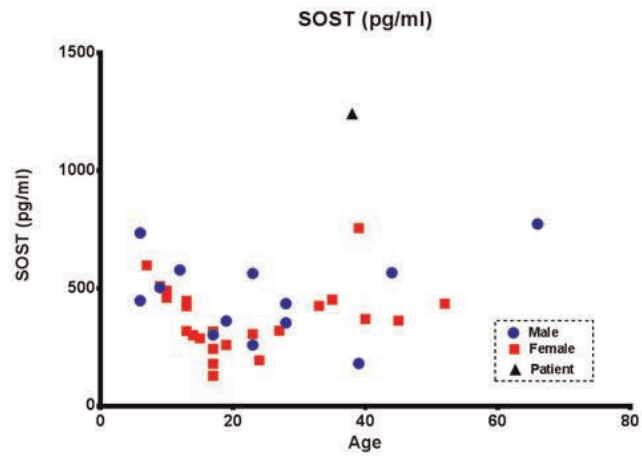
Progressive diffuse osteosclerosis in systemic lupus erythematosus. Nuria Guanabens*[1], Steven Mumm[2], Laia Gifre[3], Silvia Ruiz-Gaspà[4], Michael P. Whyte[5]. [1]Universitat De Barcelona, Spain, [2]Washington University School of Medicine, USA, [3]Hospital Clinic Barcelona, Spain, [4]CIBERehd. IDIBAPS, Spain, [5]Shriners Hospital for Children-Saint Louis, USA

Diffuse osteosclerosis is an unusual radiographic finding. We report a 38-year-old woman with idiopathic progressive diffuse osteosclerosis (PDO) of the central skeleton and focal sclerosis of proximal long bones. Systemic lupus erythematosus (SLE) was diagnosed in adolescence, and then well controlled. She had no history of intravenous drug abuse or hepatitis C, never fractured or taken antiresorptive therapy, and her family had low bone mass. Her first BMD measurement by dual photon absorptiometry was at age 17 years when she was receiving glucocorticoid treatment. Her lumbar BMD then was 79% of average age-matched normal values. Subsequent DXAs showed increasing lumbar BMD Z-scores (from +3.8 to +7.9), and increasing femoral neck BMD Z-scores from -1.1 to -0.7 from age 30 to 37 years. Serum calcium and phosphate levels were normal, with low urinary calcium excretion perhaps reflecting her positive bone balance. Serum 25OHD was <20 ng/mL and PTH slightly increased. eGFR was 41 – 48 mls/min. Serum multiplex biomarker profiling (SMBP) indicated normal bone remodeling (bone ALP, osteocalcin, sCTX, and TRAP5b were normal), without disturbances in levels of RANKL, OPG, FGF-23 or TGFb1. However, serum sclerostin was high (1241 pg/mL) (see Figure), as were matrix metalloproteinases MMP-3 (52 ng/mL) and MMP-7 (2126 pg/mL). Bone marrow biopsy revealed increased numbers of trabeculae and reticulum fibrosis in some areas, but no collagen fibrosis. Undecalcified transiliac bone showed increased numbers of thick trabeculae, few osteoclasts, absence of peritrabecular fibrosis, and scarce and irregular unmineralized osteoid with single diffuse fluorescent labels. Mutation analysis of LRP5 and SOST was negative. Our patient with SLE and PDO of unknown etiology showed increased circulating sclerostin in the absence of overt alterations in biochemical indices of bone remodeling, and no mutations in two candidate genes. Perhaps resistance to sclerostin accounts for her bone acquisition.



Serum sclerostin level in the patient and healthy controls

Gene-gene Interactions in Paget's Disease of Bone. Sabrina Guay-Bélanger*[1], David Simonyan[2], Edith Gagnon[2], Jean Morissette[3], Jacques P. Brown[4], Laetitia Michou[5]. [1]Centre de recherche du CHU de Québec-CHUL, Canada, [2]CHU de Québec Research Centre, Canada, [3]CHU de Québec Research Centre, Canada, [4]CHU de Québec Research Centre, Canada, [5]Université Laval, Canada

Purpose: Paget's disease of bone (PDB) is a uni or plurifocal metabolic bone disorder transmitted, in one third of cases, in an autosomal-dominant mode of inheritance with incomplete penetrance. To date, only the *SQSTM1* gene has been linked to the disease, with more than 20 mutations identified so far. Overall, these mutations are present in 40% of familial cases, and 10% of unrelated patients with PDB. Several other loci have been associated with the disease in patient non-carriers of a *SQSTM1* mutation, but these single nucleotide polymorphisms (SNPs) have a minor effect on PDB. The objective of this study was to investigate gene-gene interactions in PDB to determine whether these interactions could predict the PDB phenotype in patient non-carriers of a *SQSTM1* mutation.

Methods: We selected 31 SNPs previously reported in PDB, and located in 13 different loci. Every SNP was genotyped by Sequenom or Sanger sequencing in 244 PDB patients (French-Canadian and French populations) and 293 healthy individuals (French-Canadian population), all non-carriers of a *SQSTM1* mutation. We analyzed gene-gene interactions between all SNPs combined two by two. Statistical analyses included Fisher's exact tests or Chi-square tests, followed by a logistic regression analysis to search the interactions that were significantly associated with PDB. For all tests, a p value ≤ 0.05 was considered statistically significant.

Results: SNPs located in *EPS8L3*, *OPG*, *OPTN*, *DKK1* ($p<0.0001$) and *RANK* ($p=0.0005$) genes interacted together within the same gene, although they were not in linkage disequilibrium. There was also interactions between *KIAA1468*, *RPL17P14* and *PIGN* genes ($p<0.0001$), all located at the *18q21* locus. We also observed an interaction between *RANK* (*18q22*) and *RPL17P14* (*18q21*) genes ($p<0.0001$). Finally, the logistic regression analysis confirmed a statistically significant interaction between two SNPs in *OPG* ($p=0.0227$), and between *RANK* and *RPL17P14* ($p=0.0424$).

Conclusion: This preliminary study supports the existence of gene-gene interactions in PDB. The functional role of these interactions remains to be studied and may contribute to the PDB phenotype in absence of *SQSTM1* mutations.

Vitamin D Deficiency is Less Common in Mild Primary Hyperparathyroidism. Elaine Cong*[1], Marcella Walker[2], Anna Kepley[2], Chiyuan Zhang[2], Donald McMahon[3], Shonni Silverberg[2]. [1]Columbia Presbyterian Medical Center, USA, [2]Columbia University, USA, [3]Columbia University College of Physicians & Surgeons, USA

With the widespread use of vitamin D supplements in the general population, there are reports that the prevalence of vitamin D deficiency has declined. Whether this trend is also seen in patients with primary hyperparathyroidism (PHPT) is unclear. The prevalence of vitamin D deficiency (defined by 25-hydroxyvitamin D [25OHD] $\leq$20 ng/ml; profound deficiency $<$10) and insufficiency (25OHD$<$30) was assessed in 2 cohorts of PHPT patients recruited over twenty years apart at the same institution.

The two cohorts included 103 patients enrolled in a longitudinal natural history study of mild PHPT between 1984 and 1991 (79% female, 86% white, 16% Hispanic, age (mean$\pm$SD) 55$\pm$12 years, BMI 26$\pm$6 kg/m2), and a recently recruited cohort of 100 patients enrolled between 2010 and 2014 (78% female, 87% white, 17% Hispanic, age 62$\pm$12 years, BMI 28$\pm$6 kg/m2). The cohorts did not differ in gender, race, ethnicity or BMI, but the 1984-1991 cohort enrolled younger patients ($p<0.002$). Mean 25OHD levels were 26% higher in the recent cohort (29$\pm$10 vs. 23$\pm$10 ng/ml, $p<0.0001$). While 25OHD deficiency and insufficiency were very common in the older cohort (6% $<$ 10 ng/ml; 46%$\leq$20 ng/ml; 82%$<$30 ng/ml; see Table), the current cohort had a lower prevalence of vitamin D deficiency and insufficiency (4%$<$10 ng/ml; 20%$\leq$20 ng/ml; 54%$<$30ng/ml). Notably, none of the patients in the 1984-1991 cohort took vitamin D supplements, while 64% of the current cohort (and 80% of those with 25OHD$>$30 ng/ml) were taking vitamin D upon presentation (mean dose 1414$\pm$1489 IU/day [range 71-7143 IU]). The 1984-1991 cohort also had 35% higher PTH levels (127$\pm$69 vs. 83$\pm$41 pg/ml, $p<0.0001$), while serum calcium levels did not differ (10.6$\pm$0.6 vs. 10.7$\pm$0.6 mg/dl, p=0.13).

In summary, over the last two decades, the prevalence of vitamin D deficiency in patients with mild PHPT in the northeastern United States has declined by over 50%, while vitamin D insufficiency has decreased by over 30%. Today approximately half of our patients present with 25OHD levels $>$30 ng/ml. These changes are likely due to vitamin D supplementation. Vitamin D deficiency is thought to exacerbate PHPT. In our older cohort, the PTH elevations due to PHPT were most likely heightened by coexisting vitamin D deficiency. We conclude that differences in vitamin D status may underlie the observed 35% lower PTH concentration in the more recent, more vitamin D replete cohort of patients with mild PHPT.

Measurement (Mean±SD)	1984-1991 Cohort (N=103)	2010-2014 Cohort (N=100)	P-value
25OHD<10 (N/%)	10 (6%)	4 (4%)	0.55
25OHD (ng/ml)	7±2.5	8.3±1.5	0.28
PTH (pg/ml)	185±113	121±41	0.32
25OHD≤20 (N/%)	47 (46%)	20 (20%)	<0.0001
25OHD (ng/ml)	15±28	13.8±0.5	0.05
PTH (pg/ml)	148±76	111±36	0.05
25OHD<30 (N/%)	84 (82%)	54 (54%)	<0.0001
25OHD (ng/ml)	19±9	21±7	0.03
PTH (pg/ml)	132±74	92±44	0.0009

Prevalence of Vitamin D Deficiency and Insufficiency in Two PHPT Cohorts

A Novel Model to Predict Bone Mineral Density (BMD) in Cerebral Palsy (CP) Patients. Abdulhafez Selim*[1], Abeer Hegazy[2]. [1]Center for Chronic Disorders of Aging, PCOM, USA, [2]Agoza Rehabilitation Center, Egypt

Poor growth and nutrition in children with CP is a complex problem. Babies with CP may not gain weight at the same rate as other babies at their age. Multiple aspects of skeletal growth and development, including skeletal maturation, are frequently altered in children with moderate to severe CP. It is highly likely that certain growth pattern combinations are at high risk of developing severe osteoporosis. Clinicians need to able to predict those subgroups at high risk in order to prevent serious osteoporosis-related complications.

A cross-sectional study was conducted in order to study the correlation and interaction between various risk factors. The study included thirty patients with CP of both genders, between 5 and 8 years of age. Case record forms were used to capture full medical history. Full general medical and neurological examination was conducted for the selected group during the first visit. Evaluation of anthropometric measures including height weight and body mass index was also conducted. Patients were graded according to the Gross Motor Functional Classification (GMFC) for their level of affection. The current BMD scores were obtained using DXA scans. The collected data was organized, tabulated, and then analyzed.

A significant negative correlation was observed between the weight percentile rank and the BMD scores (0.8, P-value $<$0.001). On the other hand, a strong positive correlation was observed between quantitative values of calcium levels and the BMD Z scores (0.6, P-value = 0.001). Several other significant positive and negative correlations were also observed. Below normal BMI, height, severe spasticity, scoliosis, epilepsy, grade 4 GMFC, and anti-epileptic drugs had significant negative correlations with the BMD scores. Interaction analyses demonstrated that combination of more than two of these risk factors was associated with very low BMD ($<$ -3.0). Regression analysis yielded a novel model to predict the BMD score in those patients. The model is based on the serum calcium and weight ranking data. The model is demonstrating high accuracy with p-value of 0.001. This model may provide a good tool to predict the BMD scores in those patients. This model had several advantages: quick, cheap, and without risk of radiation exposure.

Accuracy of MRTA Measurements of Ulna Bending Stiffness and Strength in Cadaveric Human Arms. Lyn Bowman*, Emily R. Ellerbrock, Gabrielle C. Hausfeld, Margeaux J. Dennis, Timothy D. Law, Jr., John R. Cotton, Anne B. Loucks. Ohio University, USA

Osteoporosis is characterized by reduced bone strength, but no medical device measures bone strength directly *in vivo*. Bone strength and stiffness are strongly associated ($r \geq 0.95$), but no clinical method measures bone stiffness in vivo either. The reference method for directly measuring bone stiffness and strength is Quasistatic Mechanical Testing (QMT), but QMT cannot be employed *in vivo*.

Type 2 osteoporosis affects cortical bone, where 80% of fractures in men and women after age 60 occur. Cortical bone comprises 95% the shafts of long bones, the mechanics of which are well assessed by bending tests. Mechanical Response Tissue Analysis (MRTA) is a minimal-risk, non-invasive, radiation-free, vibration analysis technique for making immediate, direct, functional measurements of the bending stiffness of long bones in humans *in vivo*. MRTA systems have been used for research for more than 25 years, but are not commercially available and little has been published about their accuracy.

To compare bones of different length (L), bending stiffness (k_B) is converted to flexural rigidity ($EI = k_B \times L^3/48$). Recently, we reported that the relationship between our MRTA and QMT measurements of EI were indistinguishable from the identity line in artificial human ulnas (R^2=0.999) and in cadaveric human ulnas *in vitro* (R^2=0.99), and that our MRTA measurements of EI in cadaveric human ulnas *in vitro* accurately predicted QMT measurements of bending strength (Strength = 18.1 × EI_MRTA, R^2=0.99, SEE = 63 N). Here we report how our MRTA measurements of ulna EI in cadaveric human arms *in situ* are related to QMT measurements of ulna EI and bending strength.

20 cadaveric human arms from men and women age 48 to 96 yrs with BMI 14 to 40 kg/m^2 were obtained from a human tissue bank. Ulna EI was measured by MRTA *in situ*, and ulna EI and bending strength were measured by QMT *in vitro*. Ulnas were supported over the same span and centrally loaded in both tests.

The relationship between ulna EI_MRTA *in situ* and EI_QMT *in vitro* (Figure 1) was steeper than the identity line ($p = 10^{-4}$): EI_MRTA = 1.24 × EI_QMT (R^2=0.99), but EI_MRTA still predicted ulna bending strength (Figure 2): Strength = 14.8 × EI_MRTA, R^2=0.99, SEE = 71 N). We conclude that *in situ* the ulna is stiffened by other tissues, perhaps the radius bone via tension in the interosseous ligament. Nevertheless, MRTA measurements of ulna EI *in situ* accurately predict ulna bending strength measured by QMT.

Age-related changes in bone biomechanical parameters in African ancestry men. Pallavi Jonnalagadda*[1], Ryan Cvejkus[2], Joseph Zmuda[3], Clareann Bunker[2], Yahtyng Sheu[3], Alan Patrick[4], Christopher Gordon[5], Victor Wheeler[4]. [1]Pitt Public Health, University of Pittsburgh, USA, [2]University of Pittsburgh, USA, [3]University of Pittsburgh Graduate School of Public Health, USA, [4]Tobago Health Studies Office, Trinidad & tobago, [5]McMaster University, Canada

Very little is known about the patterns and correlates of skeletal changes with aging in men of African ancestry. The purpose of these analyses was to examine the annualized percentage changes in bone strength parameters in 1608 African ancestry men aged 40 years and over during an average follow-up period of 6.2 years. We measured changes in axial stress strain index (SSIx) and polar stress strain index (SSIp) using quantitative computed tomography at the 4% and 33% sites in the radius and tibia corresponding to trabecular and cortical bone respectively. There was a 0.31% (IQR: -0.9 to 0.19) and 0.08% (IQR: -0.53 to 0.34) decrease every year in SSIp at the 4% and 33% radial sites respectively ($p<0.0001$). The annual decrease in radial SSIx was 0.62 % (IQR: -1.37 to 0.12) and 0.1% (IQR: -0.68 to 0.49) at the 4% and 33% sites respectively ($p<0.001$). In the tibia, there was a 0.58% (IQR: -1.15 to -0.12) and 0.33% (IQR: -0.82 to 0.02) decrease every year in SSIp at the 4% and 33% sites respectively ($p<0.0001$). The annual decrease in SSIx in the tibia was 0.65% (IQR: -1.29 to -0.06) and 0.37% (IQR: -0.85 to 0.02) at the 4% and 33% sites respectively ($p<0.0001$). Age at baseline was negatively correlated with the rate of decline in all biomechanical parameters in both limbs at the trabecular sites. In contrast, age at baseline was not correlated with any biomechanical parameters at the cortical sites. We conclude that advancing age is associated with an accelerated rate of decline in trabecular but not cortical bone strength parameters in African ancestry men.

An Exploratory Study on Bone Densitometric and Micro-Architectural Changes During Distal Radius Fracture Healing: the Fractured vs. the Non-Fractured Region. Joost De Jong*[1], Paul Willems[2], Jacobus Arts[2], Sandrine Bours[3], Peter Brink[4], Piet Geusens[5], Bert van Rietbergen[6], Joop van den Bergh[7]. [1]Maastricht University Medical Center, The Netherlands, [2]Department of Orthopaedics & CAPRHI, Maastricht University Medical Center, Netherlands, [3]Department of Internal Medicine, Maastricht University Medical Center, Netherlands, [4]Department of Surgery, Maastricht University Medical Center, Netherlands, [5]Department of Internal Medicine & CAPHRI, Maastricht University Medical Center, Netherlands, [6]Faculty of Biomedical Engineering, Eindhoven University of Technology, Netherlands, [7]Department of Internal Medicine & NUTRIM, VieCuri Venlo & Maastricht University Medical Center, Netherlands

High resolution peripheral quantitative computed tomography (HR-pQCT) is a promising tool to assess in vivo metaphyseal fracture healing.[1,2] However, subtle changes in bone density and micro-architecture parameters in the fracture region might be averaged out if the whole distal radius is assessed.[1] A more localized approach in which the region of interest (ROI) only covers the fracture line is therefore desired. The purpose of this exploratory study is to test a novel algorithm that enables the automatic detection and separate analyses of the fractured and non-fractured region.

In 6 post-menopausal women with a stable distal radius fracture, treated by cast immobilization, HR-pQCT images of the fracture were obtained at 1-2 (baseline), 3-4, 6-8 and 12 weeks post-fracture. The fractured region was identified automatically as the region in which low mineralized bone was present in the HR-pQCT images at 6-8 week post-fracture (Fig. 1). The remaining region within the periosteal boundary was selected as non-fractured region. Both ROI's were transposed on the images at 1-2, 3-4 and 12 weeks post-fracture. Standard bone mineral density (BMD) and micro-architectural parameters were calculated for the total, fractured and non-fractured region at each visit. A linear mixed-effect model was used to test whether parameters significantly changed from baseline.

In the fractured region, the percent changes from baseline peaked at 6-8 weeks post-fracture: total BMD was increased by 29% ($p=0.02$); trabecular BMD, number and thickness were increased by 60%, 33% and 22%, respectively; and trabecular separation was decreased by 34% (all $p\leq0.01$). Cortical thickness did not change significantly. In the total region, percent changes from baseline did not reach significance at any time-point for all parameters, except total and trabecular BMD at 3-4 wks post-fracture with 8% and 6%, respectively. In the non-fractured region, only trabecular BMD was changed significantly at 3-4 wks post-fracture with 6%.

In addition to our previous studies[1,2] we now demonstrate that it is feasible to study the fractured and non-fractured region in distal radius fractures separately.

Changes in BMD and micro-architecture were significant and more pronounced in the fractured area compared to the total and non-fractured area. We thus expect that this approach can lead to a more accurate and sensitive evaluation of the bone healing process.

Atlas-based Correlation of Local Trabecular Directionality and Deformation with Serum Markers of Bone Turnover in Lung Transplant Recipients in a Longitudinal Setting. Lukas Fischer[1], Alexander Valentinitsch[2], Thomas Gross[3], Daniela Kienzl[1], Claudia Schueller-Weidekamm[1], Franz Kainberger[1], Janina Patsch[4], Georg Langs[1], Matthew DiFranco*[4]. [1]Medical University of Vienna, Austria, [2]Klinikum rechts der Isar, Technische Universität München, Germany, [3]Technical University of Vienna, Austria, [4]Medical University of Vienna, Austria

Non-invasive assessment of changes in bone microarchitecture over time can be performed by high-resolution peripheral quantitative computed tomography (HRpQCT). The aims of this pilot study were to develop a methodology for the quantification of trabecular reorganization beyond standard morphometry and to investigate the relation between trabecular reorganization, bone strength as captured by finite element analysis, and serum markers of bone turnover.

HRpQCT baseline and follow-up scans of the distal radius from lung transplant (LuTX) patients were obtained (n=33, 15±5 month mean interval). Serum markers (CTX, OCN) were captured at each time point. Finite element analysis (FEA) was employed to measure stiffness (k), failure force (F_{max}), bone strength (σ_{max}). Manufacturer-provided standard bone morphology parameters were also acquired.

Baseline and follow-up scans were rigidly registered and deformation maps were obtained for each case[1]. Three parameters related to local changes in trabecular orientation and the direction of deformation were obtained: entropy of directionality (ED), entropy of Jacobian (EJ), and symmetric Kullback-Leibler divergence (KLD). All derived parameters were then correlated to the serum, FEA and morphology values on 3D grid-based regions of an atlas generated from the entire study population.

Significant ($p<0.05$) localized negative correlations between EJ and changes in BMD, k, F_{max} and σ_{max} were seen. OCN at baseline showed significant localized correlations with ED (negative) and KLD (positive). CTX at baseline showed localized positive correlations (non-significant) with EJ.

The OCN to ED negative correlation suggest that within the LuTX cohort, region-specific dominant trabecular directionality is observed where OCN, a formation marker, is elevated. The positive OCN to KLD correlation suggests that trabecular thickening is occurring without a decrease in dominant orientation. A positive CTX to EJ correlation could indicate that direction-independent bone loss is observed in conjunction with elevated CTX, a resorption marker.

We have proposed a methodology for discovering localized correlations between image-derived measures of trabecular reorganization and various bone metabolism, biomechanical and morphology markers. Application of this method to a LuTX cohort reveals correlations between trabecular directionality and both local systematic bone turnover and bone strength.

Can bone quality markers predict nonunion?. Koji Nozaka*[1], Naohisa Miyakoshi[1], Michio Hongo[1], Yuji Kasukawa[1], Hiroshi Aonuma[1], Hiroyuki Tsuchie[2], Kentaro Ohuchi[1], Hayato Kinoshita[3], Chie Sato[4], Masashi Fujii[4], Yoichi Shimada[4]. [1]Akita University Graduate School of Medicine, Japan, [2]Nakadori General Hospital, Japan, [3]Akita University, Japan, [4]Dept.of Orthopedic Surgery, Akita University Graduate School of Medicine, Japan

Background: The ability to predict susceptibility to nonunion would enable measures to be taken at an earlier stage, such as performance of more rigid fixation before surgery. Although low-intensity pulsed ultrasound (LIPUS) has been used for nonunion, bone union is not always achieved even with this method. While blood homocysteine (Hcy) and urinary pentosidine (Pen) levels have been reported as useful predictive markers of fracture, relationships to nonunion have not been elucidated.

Objective: To retrospectively investigate bone quality markers, specifically uncarboxylated osteocalcin (ucOC) (reference value, <4.50 ng/ml), blood Hcy (reference range, 3.7-13.5 nmol/ml), and urinary Pen (reference range, 0.019-0.070 μg/mg?Cr) in patients with nonunion and to clarify relationships to nonunion.

Subjects: Subjects comprised 26 patients (18 men, 8 women; mean age, 55.7 years; range, 29-84 years) who underwent additional treatment due to lack of porosis with LIPUS alone among the 63 patients who provided consent for measurement of bone quality markers among the 278 patients who underwent LIPUS for nonunion after osteosynthesis (Exclusions: diabetes, renal failure, steroid use, warfarin use, infections, fracture gap distance ⩾9 mm).

Results: Elevated levels of bone quality markers were seen in all 26 patients, with elevated ucOC in 8 patients (mean, 6.91 ng/ml), Hcy in 10 (mean, 16.4 nmol/ml), and Pen in 18 (mean, 0.089 μg/mg?Cr)(including cases of overlap). Additional pharmacotherapy (e.g., PTH drug, vitamin K2, vitamin B12, etc.) was given to all 26 patients, and bone union tended to progress in many patients. In addition, further surgery was performed for 8 patients and combination with electric stimulation therapy was given for 2 patient.

Discussion: Management of nonunion involves many factors. However, causes of nonunion are often unclear. Bone quality markers may serve as predictors of nonunion. For further investigation, a comparison study with the group who had bone union with LIPUS alone is necessary.

SA0025

Characterization of Bone Quality in Rat Femur Performed Combination Therapy with $PTH_{1\text{-}34}$ and Vitamin K_2 Using FTIR Imaging. Teppei Ito*[1], Tomohiro Shimizu[2], Masahiro Todoh[3], Masahiko Takahata[4], Hiromi Kimura-Suda[1]. [1]Chitose Institute of Science & Technology, Japan, [2]Department of Orthopedic Surgery, School of Medicine, Hokkaido University, Japan, [3]Division of Human Mechanical Systems & Design, Faculty of Engineering, Hok kaido University, Japan, [4]Hokkaido University, School of Medicine, Japan

Teriparatide ($PTH_{1\text{-}34}$) has been shown to increase bone mass and promote skeletal repair, and vitamin K has been known to affect bone mineralization. We previously demonstrated that vitamin K influenced the efficacy of $PTH_{1\text{-}34}$ therapy for bone repair using a rat osteotomy model: The combination therapy with $PTH_{1\text{-}34}$ and vitamin K_2 improved mechanical properties and the bone mineral tissue density of fracture callus of the femur after the surgery. There are few reports written about the relationship between recovery of mechanical strength and bone quality in the skeletal site; however, the bone strength is determined by bone density and bone quality. In

this study, bone quality of the femur in the osteotomy model performed the combination therapy with PTH_{1-34} and Vitamin K_2 was characterized using FTIR imaging to investigate consequence for the bone strength. Twelve-week-old female Sprague-Dawley rats underwent a mid-shaft transverse femoral osteotomy were divided into four groups: Vehicle, PTH_{1-34} (daily 30 μg/kg/day subcutaneous injection) + solvent (p.o., three times a week), PTH_{1-34} + warfarin (0.4 mg/kg/day p.o., three times a week), and PTH_{1-34} + vitamin K_2 (menatetrenone, 30 mg/kg/day p.o., three times a week). The rats were subjected to the combination therapy for 8 weeks after the surgery, and then the femur was removed after euthanasia and was embedded in PMMA to prepare long-axial cross section for FTIR imaging. In three point bending test, the bone strength of the femur was determined in the following order: PTH_{1-34} + vitamin K_2 > PTH_{1-34} + solvent > PTH_{1-34} + warfarin > Vehicle. In FTIR images, the calcification of the femur underwent therapy with PTH_{1-34} + vitamin K_2 was higher than that of other groups, and the crystallinity of all PTH administrated groups slightly showed high level. The carbonate to phosphate ratio and the collagen cross-linking did not differ significantly between groups. The tendency of the bone strength was not coincident with that of the calcification, the crystallinity, the carbonate to phosphate ratio, and the collagen cross-linking. However, the collagen orientation was determined by FTIR imaging in the following order: PTH_{1-34} + vitamin K_2 > PTH_{1-34} + solvent > PTH_{1-34} + warfarin > Vehicle. We demonstrated that the collagen orientation significantly affected the bone strength in the rat osteotomy model.

Discriminants of Prevalent Fragility Fractures in Chronic Spinal Cord Injury. William Edwards*[1], Narina Simonian[2], Karen Troy[3], Thomas Schnitzer[4]. [1]University of Calgary, Canada, [2]Northwestern University, USA, [3]Worcester Polytechnic Institute, USA, [4]Northwestern University, USA

Spinal cord injury (SCI) is characterized by marked bone loss at regions below the neurological lesion. Within the first 2 to 3 years of SCI, some 50% of the bone mineral at the distal femur and proximal tibia is resorbed. The clinical consequence of this bone loss is a high incidence of low-energy fractures, most commonly observed at regions of the knee. Our purpose in this study was to identify and quantify clinical and bone-specific parameters that would discriminate prevalent fracture in chronic SCI.

Forty-two adults with SCI from 2.8 to 50.0 yrs of duration were recruited as part of a larger prospective intervention trial. Prior to treatment, computed tomography data were acquired for the proximal most 15cm of the non-dominant tibia. Bone mineral content (BMC) and volumetric bone mineral density (vBMD) were determined. Proximal tibia torsional strength (T_{ult}) was quantified using validated patient-specific finite element modeling procedures. The cause, location, and time of any lower-extremity fragility fractures that had occurred after SCI, and prior to treatment, were verified through medical records. The ability of SCI level and severity, BMC, vBMD, and T_{ult} to classify groups with and without fractures was determined using discriminant analyses.

Of the 42 participants, 14 had at least one prevalent fracture of the lower-extremity. The mean duration of SCI prior to first fracture was 15.8 yrs (range 3-38 yrs). SCI level and severity were not significant discriminants of individuals with and without prevalent fractures. The overall independent classification accuracy for T_{ult}, BMC, and vBMD were 71.4%, 69.0%, and 61.9%, respectively. On average, T_{ult} values were 33% lower for individuals with fractures compared to individuals without fractures (Figure 1). BMC and vBMD values were 25% and 17% lower for individuals with fractures compared to individuals without fractures.In summary, measures of bone mineral and strength, but not SCI level or severity, were significant discriminators of prevalent lower-extremity fragility fractures in individuals with chronic SCI. These preliminary findings suggest a critical need for the assessment of bone mineral and strength after SCI, which is currently not the standard of care for this population. Recruitment for our prospective intervention trial is still ongoing, and we anticipate that larger numbers of participants will allow us to more accurately predict individuals at high risk for fracture after SCI.

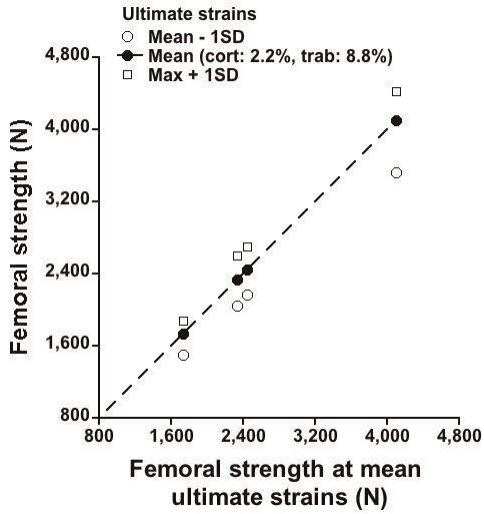
Effect of Variations in Tissue-Level Ductility on Femoral Strength. Shashank Nawathe*[1], Nasim Barzanian[2], Mary Bouxsein[3], Tony Keaveny[4]. [1]University Of California at Berkeley, USA, [2]University of California, Berkeley, USA, [3]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [4]University of California, Berkeley, USA

The ductility of bone tissue, which describes the ability of bone tissue to deform before it eventually breaks and fractures, is a unique element of bone quality and varies with age and across the population. However, little is known about how typical population-variations in tissue-level ductility influence femoral strength, and whether such variations in ductility are more influential for the cortical or trabecular bone — potentially important factors in the etiology of age-related hip fractures. To provide insight, we conducted a parameter study using micro-CT-based finite element analysis of four human proximal femurs (ages 66–68 years) subjected to a sideways fall loading, each model having a voxel-element size of 82 microns and containing up to 120 million elements. For each femur, we varied the assumed value of the tissue-level ultimate strain — the strain at which tissue-level cracking and fracture occurs — and all other tissue-level properties were kept constant, including the elastic modulus (E=7.3 GPa) and yield strains (0.81% in compression; 0.33% in tension). Nine combinations of tissue ultimate strains were simulated for each femur: the mean value and the mean ± 1SD value, separately for the cortical (2.2 ± 0.9%; McCalden, JBJS, 1993) and trabecular (8.8 ± 3.7%; Hernandez, Bone, 2005) bone. Using non-linear finite element analysis, the strength of each femur, for each of the nine cases of tissue-level ductility, was defined as the maximum force from the computed force-deformation curve. Across the four bones, there was only a 10–12% variation in the femoral strength when the cortical and trabecular bone tissue ultimate strains were simultaneously varied by ± 1 SD about their mean values (Figure). Altering only the cortical ultimate strain by ±1 SD about its mean varied the femoral strength by 4 ± 1%, whereas, a ±1 SD variation in only the trabecular tissue ultimate strain altered the femoral strength by 7 ± 1%. These results indicate that typical population variations in tissue-level ductility account for only 10–12% of femoral strength during a sideways fall, typical variations in trabecular ductility having a larger effect than typical variations in cortical ductility. Given that femoral strength can vary multiple-fold at any age across the population due to variations in bone geometry and mass, these effects are relatively modest. However, it remains to be seen if tissue-level ductility is particularly low in some individuals who fracture their hip.



Variation in the femoral strength with simultaneous ˜1 SD variation in cort & trab ultimate strains.

Glycation alters material properties of diabetic mice at multiple length scales. Atharva Poundarik*[1], Grazyna Sroga[2], Mishaela Rubin[3], Deepak Vashishth[2]. [1]Rensselaer Polytechnic University, USA, [2]Rensselaer Polytechnic Institute, USA, [3]Columbia University, USA

The ability of bone to resist fracture is determined not only by bone mineral density but also architecture and the quality of its organic extracellular matrix (ECM). Type-I collagen comprises over 90% of the organic matrix imparts bone, ductility and toughness [1]. Non-enzymatic glycation (NEG) of collagen, in the bones of aging or diabetic individuals, results in the formation of advanced glycation endproducts (AGEs). Studies have shown that non-enzymatic glycation and AGE accumulation not only deteriorates post-yield material properties but also increases stiffness and brittleness in bone. Furthermore, AGEs can increase up to five times with age, and have been strongly associated with an increased fracture risk [2].

Femora from the non-diabetic and diabetic mice (n=5-6 for each group) were harvested, notched in the anterior mid-diaphyseal region and stored in saline at -80°C prior to mechanical testing. Bending tests were done on a custom made fixture in the displacement feedback mode (Elf 3200, EnduraTEC), at cross-head rate of 0.001mm/s until fracture. The load-displacement curves were used to calculate the propagation toughness [3]. Subsequently, reference point indentation was performed on the anterior surface of the bones. This technique has recently been used to distinguish bone quality between fracture and non-fracture groups in humans [4]. Indentations were performed with a maximum applied load of 3 N for 10 cycles with a frequency of 2 Hz. Quantitative measures of indentation distance increase (IDI) were used in the analyses. Finally, a fluorescent AGE assay [2] was conducted to evaluate the presence of AGE in each the non-diabetic and diabetic group.

Fracture mechanics data showed that propagation toughness of the non-diabetic group (4.72 ± 0.79 MPa.m$^{0.5}$) was higher than the diabetic group (3.38 ± 0.58 MPa.m$^{0.5}$, p=0.012). Reference point indentation measurements revealed the indentation depth increase (IDI) in non-diabetic group (6.84 ± 1.07μm) was greater than in diabetic group (9.04 ± 1.89μm, p=0.033). AGE measurements showed a near significant difference between the non-diabetic and diabetic groups (p=0.072). Thus, diabetes induced post-translational modifications like AGEs, increase the propensity of fracture at multiple length scales.

MRI-derived porosity index provides quantitative insight into cortical pore architecture. Mahdieh Bashoor-Zadeh*[1], Chamith Rajapakse[2], Cheng Li[3], Wenli Sun[1], Mona Al Mukaddam[1], Alexander Wright[1], Felix Werner Wehrli[4]. [1]University of Pennsylvania, USA, [2]University of Pennsylvania School of Medicine, USA, [3]University of Pennsylvania Health System, USA, [4]University of Pennsylvania Medical Center, USA

Small changes in cortical bone (CB) pore network exert a more pronounced influence on bone mechanical properties than do similar changes in trabecular bone. Microstructure of CB pores cannot be resolved even with the state-of-the-art human bone imaging modalities *in vivo*. Ultra-short echo time (UTE) MRI allows the assessment of CB through the detection of proton signal arising from mobile water residing in pores (pore water) and water bound to collagen matrix (bound water). The aim of our study was to develop a clinically feasible method to assess CB pore network by measuring the signal decay at only two echo times (TE) as part of a single 3D UTE MRI scan, the idea being that the first echo contains essentially all water and the second predominantly pore water.

Whole-cross section bone covering 36mm axially, centered at the site of maximum CB thickness were harvested from the tibial diaphysis of 16 cadavers (ages 27-97 years). First, the CB specimens underwent 3D UTE MRI generating images at TE=50 and 2000μs and reconstructed to isotropic 0.5mm voxel size. A porosity index (PI), defined as the ratio between a long and short-TE image intensities, was computed pixel by pixel. A segmented μCT image (8.6μm) from center of each specimen was selected. Cross sectional area of pores was calculated and averaged for each specimen. Each pore was categorized into four groups (Fig.1a). The contribution of each group to the total pore space was calculated as the ratio of area occupied by each group over total pore space area (area fraction). MRI-derived PI was compared with area fraction and average pore area derived from μCT.

Increased CB pore size is visually apparent in the μCT images of the CB obtained from older donors compared to younger donors (Fig.1a). The contribution of normal pores in total pore area decreased with age, while that of giant pores increased (Fig.1b). Average pore area was found to increase with age (R^2=0.69, Fig.2a).PI correlated positively with area fraction occupied by giant pores (R^2=0.68), and negatively with area fraction occupied by normal pores (R^2=0.78, Fig.1c). Average pore area showed strong positive association with PI (R^2=0.81, Fig.2b). The data provides compelling evidence that the age-related increase in porosity is the result of expansion of existing pores rather than creation of new pores. Data suggest that the MRI PI provides a new biomarker that provides insight into pore size distribution of CB *in vivo*.

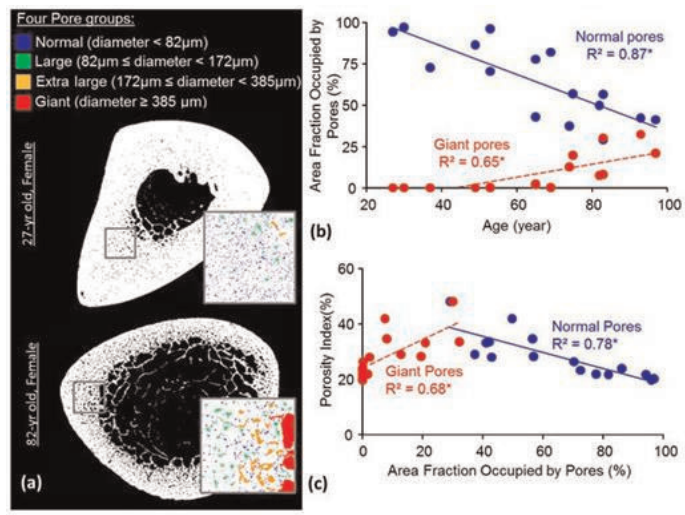

Figure1. a) μCT images obtained from cortical bone of two donors, with pore types color-coded (see magnification); b) association between age and area fraction occupied by normal and giant pores; c) correlation between porosity index and area fraction occupied by normal and giant pores (* indicates p<0.0005).

Nanomechanical Behavior of Extrafibrillar Matrix in Bone. Xiaodu Wang*[1], Liqiang Lin[2], Xiaowei Zeng[3], Haoran Xu[2], Anne Sheldrake[4], Jean Jiang[5]. [1]UTSA, USA, [2]Mechanical Engineering, UTSA, USA, [3]Mechanical Engineering, UTSA, USA, [4]Biomedical Engineering, UTSA, USA, [5]University of Texas Health Science Center at San Antonio, USA

In the hierarchy of bone, lamellae serve as the basic building unit for both human and animal bones. They are a sheet-like biocomposite of mineralized collagen fibrils embedded in an extrafibrillar matrix [1] and dictate, to large extent, the mechanical behavior of bone[2]. The structure and mechanical properties of mineralized collagen fibrils have been extensively studied, whereas only limited information is available regarding the role of the extrafibrillar matrix in bone mechanical behavior. In this study, a novel nanomechanical model of extrafibrillar matrix was proposed to assess its contribution to bone behavior from ultrastructural perspectives.

In this model, we assumed that the extrafibrillar matrix consists of hydroxyapatite (HA) polycrystals that are bounded through an organic interface of non-collagenous proteins (NCPs). This organic interface may facilitate relative sliding between individual mineral crystals, thereby imparting to bone more capability of dissipating energy during bone deformation and failure process. A novel cohesive finite element (FE) approach was used in this study to simulate the mechanical behavior of extrafibrillar matrix in both tension and compression modes. The polycrystals FE model was generated using Voronoi tessellation techniques with an average crystal size in the range of 22.5?0.87nm. The inter-crystal interface was simulated using a cohesive zone model with exponential traction-separation laws for defining both opening and sliding deformation/failure at the interface.

The simulation results indicated that this model was able to capture the following behaviors of bone as reported in experimental studies [3]: 1) the maximum strain of mineral phase in both tension and compression modes observed in synchrotron X-ray scattering studies; 2) the sudden drop of strain in the mineral phase at the bulk yielding of bone under both tension and compression; 3) the cross-hatch damage (shear band) formation in compression; 4) the upper bound of the in situ elastic modulus of bone; and more importantly, 5) the effect of the organic interface integrity on the mechanical behavior of extrafibrillar matrix in bone, which was verified by testing bone specimens with and without enzyme induced interruption of organic interface in nanoscratch experiments.

In summary, the proposed model has shown a great potential in assessing the ultrastructural contributions to bone fragility.

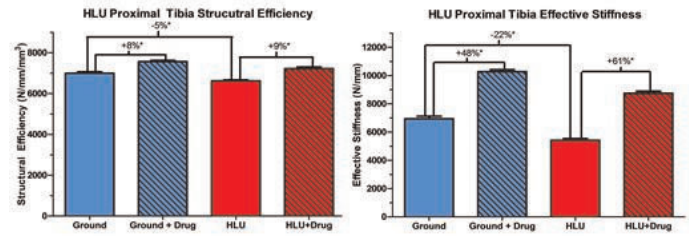
Comparing Proximal Tibia Bone Stiffness and Structural Efficiency in Spaceflight and Hind Limb Unloading with a Sclerostin Antibody Countermeasure. Taylor Comte*[1], Anthony Lau[2], Eric Livingston[3], Rachel Ellman[4], Jordan Spatz[5], Louis Stodieck[6], Mary Bouxsein[7], Virginia Ferguson[6], Ted Bateman[8]. [1]UNC Chapel Hill, USA, [2]University of North Carolina at Chapel Hill, USA, [3]Department of Biomedical Engineering, University of North Carolina, USA, [4]Beth Israel Deaconess Medical Center, USA, [5]Harvard-MIT Division of Health Sciences & Technology (HST), USA, [6]University of Colorado, USA, [7]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [8]Univesity of North Carolina, USA

Unloading during spaceflight alters the microstructure of bone resulting in a significant reduction in bone health. Hind Limb Unloading (HLU) in mice is used to mimic microgravity conditions by suspending the mouse by the tail. Bone stiffness and structural efficiency have not been investigated in the HLU model. Finite Element Analysis (FEA) of the proximal tibia was performed on a HLU study mimicking the profile of space shuttle mission STS-135 (13-days of spaceflight). This allowed a detailed comparison of structural bone health between HLU and spaceflight in terms of bone stiffness and structural efficiency as well as their response to Sclerostin antibody (Scl-Ab).

Meshes were made from microCT Scans of 1.0mm thick cross sections of proximal tibias just inferior to the growth plate. Bone was segmented out and imported into ABAQUS for FEA to determine the stiffness and structural efficiency of the bone. The stiffness was determined by a applying a 0.5% compressive displacement on the superior face of the bone while the inferior face was constrained. The stiffness was the measured resultant force from the applied displacement, and the structural efficiency was calculated as the stiffness per amount of bone present.

HLU resulted in a decrease in BV (-17%) and Stiffness (-22%) when compared to ground control as measured by FEA. The reduction in BV (-17%) from unloading was the same as that found from spaceflight. However, spaceflight caused a greater decrease in stiffness (-34%). Scl-Ab prevented this loss of BV (+48%) and stiffness (+61%) in the HLU mice when compared to vehicle groups. Structural efficiency in the HLU vehicle group decreased a small amount (-5%) when compared to ground control, whereas the spaceflight model showed a greater decrease in structural efficiency (-22%) between the flight vehicle and ground control groups. The difference in structural efficiency from unloading can be attributed to the incomplete unloading in HLU. Future studies should investigate the mechanisms resulting in the changes in structural efficiency to further characterize differences in the HLU model and microgravity in spaceflight.

In conclusion, HLU resulted in reductions in BV and stiffness that were similar to reductions seen in the spaceflight model. Scl-Ab caused BV and stiffness to increase similar to the spaceflight model. In addition, HLU resulted in a smaller reduction in structural efficiency compared to the spaceflight model.



Effective stiffness and structural efficiency of HLU proximal tibia determined by Finite Elements.

Differential Patterns of Bone Loss in the Femur and Vertebra of CD44$^{-/-}$ Mice during Hindlimb Unloading. Jeyantt Srinivas Sankaran*[1], Sherin Kuriakose[2], Weidong Zhang[3], Leah Rae Donahue[4], Stefan Judex[1]. [1]Stony Brook University, USA, [2]Stony Brook University, USA, [3]The Jackson Laboratory, USA, [4]Jackson Laboratory, USA

The extent of bone loss between astronauts varies greatly, highlighting the contribution of genetic make-up to musculoskeletal health during unloading in space as well as on Earth. In a recent mouse linkage study, we identified the specific locations of chromosomal regions (Quantitative Trait Loci or QTL) that modulate bone's response to the removal of weightbearing. A potential candidate gene within one of the QTL included CD44, a well-established marker of bone marrow mesenchymal stem cells. CD44 has been associated with cell-cell and cell-extracellular matrix interactions. It may also play a role in osteoclast fusion and formation of multinucleated cells. To test the skeletal functions of CD44 during unloading, 9wk old, female CD44 knockout (CD44$^{-/-}$, n=26) and wild type (WT, n=34) mice were assigned to baseline control, age matched control, or subjected to 2wk of hindlimb

unloading (HLU). At baseline and compared to WT B6 mice, CD44$^{-/-}$ mice had 40%, 17% and 14% (all P<0.005) lower trabecular bone volume fraction (BV/TV), trabecular number (Tb.N), and trabecular thickness (Tb.Th) in the femoral metaphysis. Cortical thickness, cortical area, periosteal and endosteal circumference were also different between CD44$^{-/-}$ mice and WT at baseline (P<0.05). In the fifth lumbar vertebral body, CD44$^{-/-}$ mice had 54% less BV, 26% less BV/TV, and 17% smaller Tb.Th (all P<0.05) while connectivity density and trabecular number were similar compared to WT mice. Upon unloading, changes in femoral trabecular indices were similar between CD44$^{-/-}$ and WT mice but vertebrae of CD44$^{-/-}$ mice when compared to their respective ambulatory controls were more sensitive to unloading than WT, with greater losses in Tb.N (14% in CD44$^{-/-}$ Vs. 2% in WT), connectivity density (21% decrease in CD44$^{-/-}$ Vs. 15% increase in WT) and an increase in trabecular separation (17% in CD44$^{-/-}$ Vs. 2% in WT) (Tb.Sp) (Gene*HLU, P<0.05). Cortical bone architecture of CD44$^{-/-}$ mice was also more sensitive to hindlimb unloading in the metaphysis, reflected by an increase in porosity (82% in CD44$^{-/-}$ Vs. 46% in WT) and pore size (72% in CD44$^{-/-}$ Vs. 37% in WT) and decrease in Ct.Th (11% in CD44$^{-/-}$ Vs. 7% in WT). These data indicate the importance of CD44 as a regulator of bone quantity and architecture both during habitual load bearing as well as during unloading.

Remodeling of Distribution of Elastic Modulus Gradients as Predictors of Early Stage Osteopenia. Kartikey Grover*[1], Minyi Hu[1], Liangjun Lin[2], Jesse Muir[3], Yi-Xian Qin[2]. [1]STONY BROOK UNIVERSITY, USA, [2]State University of New York at Stony Brook, USA, [3]STONY BROOK UNIVERSITY, USA

The objective of this study is to investigate remodeling in cortical bone due to functional disuse by measuring elastic modulus gradients in different regions by nano-indentation, and bone strain distribution.

Left tibial bone samples were obtained from 5-month old virgin female Sprague Dawley rats, including 1) baseline control (n=9), and 2) hind limb suspended (HLS) (4 weeks, n=9). 2mm segments were cut from the mid-shaft in the transverse plane, embedded in epoxy resin and elastic modulus measured by Nano indentation (Hysitron Triboindenter, Minneapolis). Three additional control rats were sacrificed and hind limbs axially loaded, from knee to the foot joint, (Bose Corporation, Minneapolis) using 6-10N at 1Hz. Strains at three rosette strain gauge sites around the mid-tibia (National Instruments Strain acquisition box) were measured for total of nine-channels. Bones were then scanned in micro-CT scanner (SCANCO Inc.) at 36μm resolution. Using linear beam theory MATLAB codes were built to find planar strain distribution.

Results: Elastic modulus gradient from periosteum to endosteum is much higher in the anterior and posterior regions (2.6GPa) than the medial regions (0.2GPa), in the control (Fig.1). In the same group, strain (peak to peak) distribution further showed similar higher strain gradient in the anterior-posterior directions(45με) but reduced to 5με in the lateral medial direction (Fig.2). Correlation between elastic modulus and strain gradient is significant (r^2>0.95, Fig.3). In the disuse group, however, the elastic modulus gradient in the anterior posterior regions reduced to 1.2GPa and increased in the medial, 2.7GPa (Fig.4).

The presence of elastic modulus gradient in the direction of strain gradient (r^2>0.95) in the control shows that material property of bone may be strongly influenced by overall strain magnitude. Under disuse condition, due to diminished mechanical loading, the nano-mechanical modulus gradient difference is decreased between different regions, implying progressive bone remodeling occurs during functional unloading. It is suggested that the variations in nano-mechanical gradients among different regions can serve as a predictor for early stage of osteopenia or bone weakening.

Bone quality after filling of the maxillary sinus with a bioactive glass. Brigitte Burt-Pichat*[1], Sebastien Rizzo[1], Julie Hemar[2], Laurent Venet[3], Thierry Sauvigne[3], Estelle Franca[4], Georges Boivin[5]. [1]INSERM UMR 1033, Université de Lyon, France, [2]Université de Lyon, France, [3]Centre Hospitalier Lyon Sud, France, [4]Noraker, France, [5]INSERM, UMR1033; Universite De Lyon, France

Our main purpose was to assess bone quality in patients having a filling of maxillar sinus with a bioactive glass 45S5 (GlassBONE®, Noraker, Villeurbanne, France). Nine patients (4 women and 5 men aged 57 ± 10 yrs) were included in the study for a total of 17 bone samples located at the posterior maxilla. Samples were taken 6 months after bone filling, during implantation. Undecalcified samples were embedded in methyl methacrylate. Bone quality was assessed by histomorphometry (measurement bone volume and bone remodeling) on 8 μm-thick sections stained with Goldner's

trichrome, by microindentation (1) on surfaced blocks to calculate the Vickers microhardness (Hv, kg/mm^2), and by quantitative microradiography (1) on 100±1 µm-thick sections to measure the degree of mineralization (DMB g/cm^3) and the heterogeneity index of mineralization (HI, g/cm^3). Histology showed bone structures composed of cortical and cancellous bone, a well vascularized marrow rich in bone cells. The residual bone was identified by its lamellar texture and the presence of bone marrow adipocytes. The newly-formed bone was characterized by a woven texture and the persistence in medullary cavity of biomaterial partially degraded. Bioactive glass 45S5, a bioceramic made of silicon, sodium, calcium, phosphorus, was well tolerated and caused no foreign-body reaction (inflammation, rejection). New bone volume varied between 4.4 and 54.4 % and the volume of residual bone was between 4.3 and 27.6 %. The bioactive glass increased bone formation stimulating osteoblast proliferation. Microhardness of new bone (38.96±4.47 kg/mm^2) was closed to that of residual bone (42.54±5.60 kg/mm^2). DMB were similar in newly-formed (1.02±0.13 g/cm^3) and residual bone (0.91±0.20 g/cm^3). HI was more heterogeneous in new bone (0.32±0.16 g/cm^3) than in residual bone (0.27±0.20 g/cm^3). The bioactive glass 45S5 was well osteointegrated and degraded with the formation of new bone. This biomaterial guided bone remodeling from the residual bone and promoted formation and mineralization of bone. Mineralization and microhardness of new bone were physiologically normal. Our data suggests the formation of bone tissue of good quality to secure the placement of the implant. Our results demonstrated the efficiency of bioactive glass 45S5 to fill maxillary sinus.[1]Boivin et al. 2008, Bone, 43:532-8.

Combinatorial cassettes, a high-throughout approach for the assessment of bone formation *in vivo*. Luis Fernandez De Castro*[1], Subdhadip Bodhak[2], Sergei Kuznetsov[3], Tina Kilts[3], Marian Young[4], Sheng Lin-Gibson[2], Carl Simon[2], Pamela Robey[5]. [1]NIDCR (NIH), Spain, [2]NIST, USA, [3]NIH, USA, [4]National Institutes of Health, USA, [5]National Institute of Dental & Craniofacial Research, USA

Models of subcutaneous transplantation in immunocompromised mice have been shown to be useful for a wide variety of purposes, including cancer research, cell therapy and biomaterial and drug screening. In bone regeneration, subcutaneous transplantation is the most reliable tool to assay the osteogenic potential of cells, molecules and biomaterials, because the existing in vitro models lack predictive value in assessing osteogenic differentiation *in vivo*. However, the subcutaneous transplantation assays also present some handicaps, such as their long duration, low yield of samples (up to 4 per mice), uncontrolled transplant shape and mouse to mouse variability in bone formation.

To address these issues, we designed two hexagonal Teflon combi-cassettes of 15x15x3 mm with different numbers and sizes of cylindrical slots for sample testing. One contained 7 slots of 44 mm^3 (3 mm height and 4.3 mm diameter) and the other contained 19 slots of 14 mm^3 (3 mm height and 2.4 mm diameter), and used them to test the osteogenic potential of normal human bone marrow stromal cells (hBMSCs) loaded on a hydroxyapatite/tricalcium phosphate (HA/TCP) scaffold in vivo. Cassettes were implanted subcutaneously at the lower back of the mice, centered over vertebrae L5-L6 to S2-S3 and a positive and a negative control were included, by making 'traditional' HA/TCP transplants with or without cells in subcutaneous pockets placed bilaterally at the upper back, over ribs T5 to T10. Also, as internal negative controls, some slots were filled with unloaded scaffold. Eight weeks after implantation, transplants were harvested, fixed and processed for histochemistry.

Transplants from the cassettes formed abundant bone with some areas of lamellar structure, high vascularization and host hematopoiesis when compared to 'traditional' transplants.

In this study, we have developed a cassette transplantation system that will allow for the assessment of bone formation of up to 19 samples, addressing some of the current weaknesses of subcutaneous bone transplantation models, as it increases in almost 5-fold the number of transplants produced per animal and standardizes the size and shape of the transplants. In future experiments, we plan to test other cell populations in this system, such as murine BMSCs loaded into a gelatin sponge scaffold and ectopic bone formation induced by BMP2.

Genetic regulation of skeletal robustness. Lauren Smith*[1], Erin M.R. Bigelow[2], Bonnie T. Nolan[2], Meghan Faillace[3], Joseph H. Nadeau[4], Karl Jepsen[5]. [1]Department of Orthopaedic Surgery, The University of Michigan, USA, [2]Department of Orthopaedic Surgery, The University of Michigan, USA, [3]GE Inspection Technologies, USA, [4]Pacific Northwest Research Institute, USA, [5]University of Michigan, USA

Skeletal robustness, a measure of how much a bone grows in width relative to length, is an important mechanical trait as variation in robustness accounts for 50-180% of the variation in bone strength among healthy adult men and women, depending on the bone site. This natural variation in strength is 5-10 times greater than the difference in bone strength reported between fracture and non-fracture groups, and may explain why individuals with slender bones show greater fracture incidence throughout life. Our goal is to better understand the genetic and environmental factors contributing to the variation in robustness.

An individual's skeletal robustness is established as early as 2 years in humans and 2 weeks in mice. Although we know this trait is genetically regulated, we know very little about the mechanisms by which this genetic variation arises. We previously reported an analysis of 16 week old male C57BL/6J – Chr$^{A/J}$/NaJ chromosome substitution strains (CSS), a panel of mice where individual B6 (robust bone) chromosomes are replaced by the corresponding A/J (slender bone) chromosome. Herein, we analyzed male B6, A/J and CSS at 4 weeks (n=9-40/strain; N_{ttl} = 250/age) to better understand how these genetic perturbations affect robustness during growth. Femora were imaged using nanoComputed Tomography (8 µm) to quantify cross-sectional morphology. CSS were compared to B6 using General Linear Model, adjusting for body size (body mass x femur length).

Fifteen CSS had similar robustness at both 4 and 16 weeks. Six strains (CSS-5, 8, 10, 12, 17, 18) were significantly more slender than B6 at both time points ($p<0.05$). However, five strains (CSS-1, 4, 11, 15, 19) showed different robustness phenotypes at 4 and 16 weeks. Of these, three were slender at 16 weeks but with normal robustness at 4 weeks (CSS-1, 15, 19); one was more robust at 16 weeks but had normal robustness at 4 weeks (CSS-4); and one had normal robustness at 16 weeks but was slender at 4 weeks (CSS-11).

The CSS showing similar alterations in robustness at both ages suggested that the genetic perturbation exerted its affect early during growth. In contrast, the CSS showing differences between 4 and 16 weeks indicate that the genetic perturbation exerted its effects much later during growth. This analysis showed that, robustness, a fairly simple trait, is under complex genetic regulation. Future work will examine how this variable genetic regulation of robustness affects mechanical function.

Kinetics of Maillard Reaction in Mineralized Human Bone. Grazyna Sroga*[1], Alankrita Siddula[2], Deepak Vashishth[1]. [1]Rensselaer Polytechnic Institute, USA, [2]Rensselaer Polytechnic Institute, USA

Advanced glycation end products (AGEs) accumulate with age due to non-enzymatic reaction between proteins and glucose or other reducing sugars. This post-translational modification process, termed glycation occurs under *in vivo* and *in vitro* conditions [1, 2]. To better understand glycation process of bone matrix proteins, we used *in vitro* glycation approach. The goal of the current work was to look for potential differences in the fluorescent AGEs formation in cortical and cancellous bones from human tibias glycated under glucose- or ribose-based conditions.

We determined that both sugars led to the formation of higher levels of AGEs and pentosidine (PEN) in cancellous than cortical bone originating from all tested donors (young, middle-age and elderly men and women). More efficient glycation of bone matrix proteins in cancellous bone most likely depended on a higher porosity of this tissue, which facilitated better accessibility of sugars to matrix proteins. Typically, the AGEs levels in glycated cortical bone from older donors were much higher than in young ones. Interestingly, the levels of PEN differed pronouncedly between glucose- vs. ribose-based glycation. Ribosylation generated primarily PEN (approx. 5- vs. 3-fold higher PEN level in the ribosylated than glucosylated bone samples).

Our studies on the kinetics of AGEs and PEN formation in human cortical and cancellous bone matrix revealed that after approx. one day of an induction period (a lag phase), the formation of fluorescent AGEs displayed steady increase in cortical as well as cancellous bone. Depending on the *in vitro* glycation conditions, the half-time of sugar conversion into AGEs varied from 6 to 7 days for ribose and 20 to 22 days for glucose. The corresponding half-time for PEN was approx. 5 to 6.5 days for ribose and approx. 15 to 17 days for glucose under the used *in vitro* glycation conditions.

In summary, our results show that *in vitro* glycation using glucose leads to the formation of lower levels of AGEs including PEN, whereas ribosylation appear to favor a pathway toward PEN formation. Our studies may help to understand differences in the progression of bone pathologies related to protein glycation by different sugars, for example, in osteoporosis, diabetes and aging.

Mandibular reconstructed bone quality after filling of defects with dental bone substitutes in beagles. Sebastien Rizzo*[1], Augusto André Baptista[2], Brigitte Burt-Pichat[1], Capucine Rondot[3], Antoine Alves[4], Catherine Wittmann[3], Christian Gagnieu[5], Patricia Forest[3], Georges Boivin[6], Jean-Pierre Bernard[7]. [1]INSERM UMR 1033, Université de Lyon, France, [2]Faculté d'Odontologie, Université de Lorraine, France, [3]Biom'up, France, [4]NAMSA, France, [5]MATEIS, INSA de Lyon, Université Claude Bernard Lyon1, France, [6]INSERM, UMR1033 ; Universite De Lyon, France, [7]Faculté de Médecine, Division de Stomatologie Chirurgie Orale et Radiologie Dentaire et Maxillofaciale, Université de Genève, Switzerland

In dental implantology, bone substitutes are increasingly used as an alternative to autogenous bone grafts, long considered as the gold standard material for bone augmentation. Three biomaterials BS1, BS2 and BS3 (MATRI^{TM}BONE MAX, Biom'Up, Saint-Priest, France) are evaluated in a canine model of mandibular defects in comparison to deproteinized bovine bone mineral (DBBM, Bio-Oss Collagen®, Geistlich, France), to particulated autogenous bone (positive control) or to coagulum (negative control). The purpose of this study was to evaluate the mechanical quality of reconstructed bony defects by measuring the microhardness of the newly formed bone. The healing time period was 12 weeks. A total of 36 mandibular bone samples were obtained from 6 beagles (6 different graft sites per dog). Undecalcified bone samples were fixed, dehydrated and then embedded in methyl methacrylate (Namsa, Chasse/Rhône, France). The blinded bone microhardness evaluation (kg/mm^2) was performed on blocks surfaced by microindentation (1). Vickers indenter was used at a load of 25 g for 10 s. Twenty indentations were performed in the newly formed bone, 5 in the native cancellous bone and 5 in the native cortical bone, to obtain a total of 30 measurements per bone sample. Under the experimental conditions, the microhardness of newly formed bone in groups BS1, BS2, BS3, DBBM, positive control and negative control were respectively 39.27 ± 2.28; 36.74 ± 3.48; 39.17 ± 2.73; 38.97 ± 3.78; 40.27 ± 3.16; 40.36 ± 3.55 kg/mm^2, without any significant difference between groups. Except for the negative control, in all groups, the microhardness of the newly formed bone was significantly lower than the one of native cancellous bone (41.00 to 46.05 kg/mm^2) and than the one of the native cortical bone (50.96 to 54.61 kg/mm^2). The microhardness is correlated to bone mineralization, itself influenced by the age of bone tissue (1). Differences of ageing between the newly formed bone tissue and the native one could explain differences in bone microhardness. After 12 weeks of implantation, the microhardness of newly formed bone in defects filled with MATRI^{TM}BONE MAX is similar to the one of defects filled with autogenous particulated bone.1 - Boivin et al. 2008, Bone 43:532-8

Tissue Mineral Density Dependent Mechanical Properties of Individual Trabecula Plates and Rods Do Not Differ in Anatomic Directions but Individual Trabecular Directions. Eric Yu*, Ji Wang, Bin Zhou, X Guo. Columbia University, USA

Trabecular bone, susceptible to osteoporosis, consists of individual trabecular plates and rods, which are distributed distinctly along the longitudinal, transverse, or oblique anatomic directions of the skeleton (Fig.1). In each anatomic direction, mechanical properties of bone tissue are also expected to differ in (axial) or against (lateral) the direction of individual trabeculae, *i.e.*, anisotropic mechanical properties. However, anisotropic mechanical properties of individual trabeculae along various anatomic directions are currently not available. Objectives of this study are: to measure anisotropic tissue modulus and TMD of individual trabeculae; to examine their dependence on trabecular types and anatomic directions; and to determine the relationship between anisotropic tissue modulus and TMD of individual trabeculae.

Twelve cylindrical human trabecular bone samples from proximal femurs were imaged with hydroxyapatite density calibration phantoms at 25 µm resolution by µCT. Individual trabecular types and their anatomic directions were determined using individual trabecula segmentation (ITS) technique. On the embedded samples, microindentation tests were performed under wet condition on both axial and lateral cross-sections (Fig 1.C) of selected plates and rods in longitudinal (L), transverse (T), and oblique (O) directions, respectively (Fig 1.D). The point-by-point registered grayscale values of the µCT image at the indentation sites were converted to TMD using calibration phantoms.

The tissue modulus and the co-localized TMD of trabecular plates were significantly higher than those of trabecular rods (Fig. 2A, B). The axial tissue modulus of individual trabeculae was significantly higher than the lateral tissue modulus (Fig. 2C). The tissue modulus correlated strongly with TMD. These correlations do not differ significantly between plates and rods or different anatomic directions. However, the axial modulus correlation was significantly different from the lateral modulus correlation (Fig. 2D).

We measured anisotropic elastic modulus of individual trabecular plates and rods of different anatomic directions. Surprisingly, the heterogeneous tissue modulus correlated with TMD similarly regardless of trabecular types and anatomic directions. The correlation only differs in the axial and lateral trabecular directions. It remains to be seen how this heterogeneous anisotropic tissue property plays a role in whole bone mechanical competence.

Using Atomic Force Microscopy and Nanoindentation to Characterize Matrix Integrity of Mineralized Bone from Perlecan/HSPG2 Hypomorphic Mice. Jerahme Martinez*[1], Ben Morgan[2], Lewis Francis[3], Mary Farach-Carson[1], Liyun Wang[4], Ashutosh Parajuli[5]. [1]Rice University, USA, [2]College of Medicine Swansea University, United Kingdom, [3]College of Medicine Swansea University, Uzbekistan, [4]University of Delaware, USA, [5]University of Delaware College of Engineering, USA

Schwartz-Jampel Syndrome (SJS) is a rare human skeletal disorder with pleiotropic abnormalities in bone formation and stability. Common symptoms include a shortened stature, joint contractures, osteoporosis and disruption of both endochondral and membranous bone. SJS results from mutations to the perlecan gene, *HSPG2*, on chromosome 1p36, that reduces the amount of normal full-length perlecan deposited in the extracellular matrix (ECM); SJS thus can be considered a hypomorphic syndrome. Perlecan, a large multi-domain heparan sulfate proteoglycan (HSPG), functions as a key structural component of musculoskeletal tissue.

Reduction of perlecan diminishes ECM function at tissue interfaces, such as the chondro-osseous junction (COJ) of developing bones, and disrupts the lacunar canalicular system (LCS) of mineralized bone where perlecan is part of the mechanosensing pericellular matrix (PCM) surrounding the osteocytic processes that preserve fluid flow throughout mineralized bone. Our work here focuses on perlecan's mechanical role within newly mineralized bone ECM, where we hypothesized that a reduction of perlecan creates the SJS bone phenotype at least in part due to a change in matrix stiffness and loss of bone quality. We chose to examine the mechanical properties of calvaria. Tissues were collected from a perlecan mouse hypomorph model mimicking the SJS phenotype. To evaluate tissue stiffness we performed nanoindentation by atomic force spectroscopy (AFM). Surface topography images along with force data sets were generated for each tissue sample, revealing a high resolution map of the calvarial surface. The Young's modulus, determined by the Hertz model, was used to evaluate differences in matrix properties in SJS and normal mice. Our initial findings suggest that a reduction of perlecan does not directly impact bone stiffness in newly formed bone, thus the functional changes observed in SJS bone in older mice are likely to be due to altered bone stability.

Insulinogenic sucrose+amino acids mixture ingestion immediately after resistance exercise has an anabolic effect on bone compared with non-insulinogenic fructose+amino acids mixture in growing rats. Takuya Notomi*[1], Ikuaki Karasaki[2], Yuichi Okazaki[3], Nobukazu Okimoto[4], Yushi Kato[2], Kiyoshi Ohura[5], Masaki Noda[6], Toshitaka Nakamura[7], Masashige Suzuki[2]. [1]Department of Pharmacology, Osaka Dental University, Japan, [2]University of Tsukuba, Japan, [3]University of Occupational & Environmental Health, Japan, [4]Okimoto Clinic, Japan, [5]Department of Pharmacology, Osaka Dental University, Japan, [6]Tokyo Medical & Dental University, Japan, [7]National Center for Global Health & Medicine, Japan

Maximizing peak bone mass is an important factor in osteoporosis prevention. Resistance exercise increases bone mass and strength, while nutritional supplements have beneficial effects on bone loss reduction. We have previously shown that the combined intake of sucrose and amino acids (AA), which is strongly insulinogenic, efficiently increased muscle protein synthesis in dogs. To investigate the effects of sugar and an AA solution immediately after resistance exercise, we compared insulinogenic sucrose and non-insulinogenic fructose combined with an AA solution with or without resistance exercise in growing rats.

Squat jumping is used as the resistance exercise model. The rats were divided into 4 groups (sucrose with/without sucrose, fructose with/without exercise). Sucrose intake immediately after resistance exercise increased the trabecular bone mass and compressive maximum load compared with fructose+AA intake after exercise. Additionally, combined sucrose+AA and exercise increased trabecular bone formation and decreased bone resorption more than combined fructose and exercise. Without exercise, no parameters differed between the fructose and sucrose with AA intake groups. Serum insulin levels were greatly increased by sucrose+AA intake with exercise. In culture experiments, neither sugar+AA affected osteoblast and osteoclast differentiation. In a gene expression study, sucrose+AA intake after resistance exercise was shown to upregulate the Runx2 expression level and decrease RANKL/OPG ratio.

These results suggest that the combined intake of sucrose and an AA solution immediately after resistance exercise exerts anabolic effects on bone by altering gene expression related to bone remodeling. Although translation of our bone remodeling findings from animal to human studies has been challenging, our findings suggest that exercise with sugar+AA intake may contribute to improved bone health.

Spaceflight Compromises the Bending Strength of Murine Spinal Segments. Britta Berg-Johansen*[1], Alan Hargens[2], Jeffrey Lotz[3]. [1]University of California, San Francisco, USA, [2]University of California, San Diego, USA, [3]University of California, San Francisco, USA

Background/Purpose: Microgravity adversely affects the human spine, increasing the risk for low back pain and injury. The risk of intervertebral disc herniation in astronauts is increased more than 4-fold following spaceflight [1]. Bending motions are significant contributors to disc herniation [2], yet the effects of microgravity on the bending properties of the spine are unknown. The purpose of this study was to determine the effects of microgravity on the bending properties of murine spinal segments, with the hypothesis that bending properties are reduced.

Methods: Murine tails were obtained through NASA's Biospecimen Sharing Program from mice that had returned from a 30-day Bion M1 mission (flight, n=6) and from vivarium controls (control, n=8). The C3-C4 caudal motion segment was isolated from each tail, radiographed to estimate disc height, and placed in a mechanical load frame (ElectroForce 3200). Motion segments were tested in four-point bending using a custom 3D-printed jig that applied bending in the ventral-dorsal plane (lower span = 7.5 mm; upper span = 2.5 mm). Loading consisted of 5 cycles of preconditioning (0-5 mm) at 0.05 mm/sec, followed by a ramp to failure at 0.006 mm/sec. Force-displacement data were analyzed for the following parameters: the toe region was defined as the displacement corresponding to an applied force of 1 N, the stiffness was defined as the slope of the linear region, and the strength was defined as the maximum force reached before failure.

Results: Microgravity reduced bending strength by 18% (6.17 $\pm$ 0.94 vs. 7.53 $\pm$ 1.13 N, $p < 0.05$) and reduced the toe region by 31% (0.53 $\pm$ 0.14 vs. 0.77 $\pm$ 0.21 mm, $p = 0.05$). Bending stiffness was not significantly different between groups ($p > 0.25$). Microgravity also tended to reduce disc height by 17% (0.24 $\pm$ 0.03 vs. 0.29 $\pm$ 0.04 mm, $p = 0.06$).

Conclusions: The adverse effect of microgravity on bending strength supports our hypothesis that reduced bending properties may be an important factor for explaining the increased herniation risk following spaceflight. Interestingly, microgravity also reduced the toe region. This is consistent with reports of decreased range of motion in astronauts, and together these findings motivate future work to investigate the underlying biochemical and structural mechanisms.

A study on the effect factors on BMD of affected femur neck in patients with hemiplegia. Yun Kyung Jeon*[1], Young Beom Shin[2], Myung Jun Shin[2], Chang Jae Hyeok[2]. [1]Pusan National University Hospital, South Korea, [2]Pusan National University Hospital, South Korea

The aim of this study was to investigate BMD of affected femur in patients with hemiplegic stroke. Medical records of 153 patients with stroke who admitted a rehabilitation clinic from January 2011 to March 2013 were retrospectively reviewed. We excluded the patients with non-hemiplegia, diseases which can affect the BMD such as diabetes mellitus, thyroid disease and anti-epileptic drugs. We also excluded

the patients who did not check both femur BMD. Total 68 subjects were finally enrolled in the study (38 males, 30 postmenopausal females). We measured BMD at affected and unaffected femur using dual energy X-ray absorptiometry, bone turnover markers and activity levels. The influences of factors on affected femur neck BMD were investigated by linear regression test. 31 subjects showed decreased BMD of affected femur neck (45%). In 16 males (61.9± 10.5 years), the mean duration after stroke was 51.3±31.5 days, body mass index (BMI) was 22.4±3.5 (kg/m2) and wheel chair ambulators were 12. The BMD ratio of affected and unaffected femur neck was 0.915±0.07. The 25-hydroxy vitamin D was 8.2±12.3 (ng/mL), serum osteocalcin was 5.25±6.67 (ng/mL) and serum CTX was 0.315±0.42 (ng/mL). In 15 postmenopausal females (68.3±10.4 years), the mean duration after stroke was 31.1±19.7 days, BMI was 22.6±3.0 and wheel chair ambulators were 8. The BMD ratio of affected and unaffected femur neck was 0.926±0.083. The 25-hydroxy vitamin D was 10.6±10.5, serum osteocalcin was 7.81±8.23 and serum CTX was 0.44±0.56. In linear regression test, ambulation classification was a only effect factor on the BMD ratio of affected and unaffected femur neck (ß=0.38, p=0.034). The femur neck BMD of hemiplegic side were not decreased in all stroke patients. This study showed BMD changes in affected femur neck were link to ambulation classification than bone turnover marker.

Bone mineral density in osteopenic men is increased afte resistance training or plyometric exercise. Pam Hinton*[1], John Thyfault[2], Peggy Nigh[2], Melissa Carter[2], Nantian Lin[2], Jun Jiang[2]. [1]University of Missouri, USA, [2]University of Missouri, USA

The purpose of this study was to test the efficacy of exercise-based interventions to increase bone mass in osteopenic men. This randomized clinical trial examined the effects of 12 months of resistance training (RT, 2x/wk, N= 19) or plyometric exercise (PLY, 3x/wk, N= 19) on bone mineral content (BMC) and density (BMD) in physically active (≥4hr/wk) men (mean age: 44 ± 2 y) with osteopenia of the hip or spine (i.e., -2.5<total hip or lumbar spine T-score£-1.0). Both the RT and PLY interventions were designed to load the hip and spine and to maximize the osteogenic response. All exercise training sessions were supervised by study personnel; and, participants rated pain and fatigue following each session on a scale of 0-100 with 100 being the highest fatigue or pain. Participants were provided daily supplemental calcium (1200 mg) and vitamin D (10 µg). Bone area, BMC, and BMD were measured at baseline and after 6 and 12 months of RT or PLY using dual-energy X-ray absorptiometry scans of the whole body (WB), hip and lumbar spine (LS). Serum 25(OH) vitamin D (25OHD) concentrations were measured at 0 and 12 months using ELISA. The effects of RT or PLY on changes in WB, hip, and LS BMC, BMD and 25OHD concentrations were evaluated using 2x2 repeated measures ANOVA (time, group). This study was conducted in accordance with the Declaration of Helsinki and was approved by the University of Missouri IRB. RT significantly increased muscular strength by 86, 118, 74, 45% for squat, lunge, deadlift, and military press, respectively; PLY significantly increased vertical jump by 8%. Thirty-six of 38 participants were vitamin D sufficient (25OHD>20 ng/ml) at baseline, and 25OHD did not differ between groups; 25OHD increased by 1.4 ± 1.2 ng/ml in RT and 4.4 ± 1.2 ng/ml in PLY at 12 months. WB and LS BMC and BMD significantly increased after 6 months of RT or PLY; hip BMC and BMD increased only in RT. Similar results were observed after 12 months of RT or PLY: WB and LS BMC and BMD increased after RT or PLY; hip BMD increased after RT only. The significant increases in BMC and BMD ranged from 0.8-1.6%. Pain ratings during the RT or PLY sessions were <10 at all timepoints, and fatigue ratings were <30 at all timepoints. In conclusion, resistance training or plyometric exercise, which appears safe and feasible, effectively increased bone mineral of the whole body and lumbar spine, while resistance training also increased BMD of the hip, in osteopenic men.

Fracture History in Oligo-amenorrheic Athletes, Eumenorrheic Athletes, and Non-athletes: Correlations with Bone Density and Microarchitecture. Kathryn Ackerman*[1], Natalia Cano Sokoloff[2], Giovana Maffazioli[3], Vibha Singhal[4], Meghan Slattery[5], Hannah Clarke[5], Nicholas Derrico[6], Madhusmita Misra[7]. [1]Division of Sports Medicine, Department of Orthopedics, Boston Children's Hospital & Harvard Medical School & Neuroendocrine Unit, Massachusetts General Hospital & Harvard Medical School, USA, [2]Neuroendocrine Unit, Massachusetts General Hospital & Harvard Medical School, USA, [3]Neuroendocrine Unit, Massachusetts General Hospital & Medical School, USA, [4]Neuroendocrine Unit, Massachusetts General Hospital & Harvard Medical School & Pediatric Endocrine Unit, Massachusetts General Hospital for Children & Harvard Medical School, USA, [5]Neuroendocrine Unit, Massachusetts General Hospital & Harvard Medical School, USA, [6]Endocrine Unit, Department of Medicine, Massachusetts General Hospital, USA, [7]Neuroendocrine Unit, Massachusetts General Hospital & Pediatric Endocrine Unit, Massachusetts General Hospital for Children, Harvard Medical School, USA

Purpose: To compare fracture prevalence in oligo-amenorrheic athletes (OA), eumenorrheic athletes (EA), and non-athlete controls (C) and determine if bone mineral density (BMD) and microarchitectural parameters predict fracture risk.

Methods: 164 females (101 OA, 34 EA, and 29 C) 14-25 yo were studied cross-sectionally. Lifetime fracture history was recorded by a physician during participant interviews. Areal BMD was assessed by DXA at the spine, hip and whole body. Bone structure was assessed by HRpQCT at the radius and tibia, and strength by finite element analysis.

Results: OA, EA, and C did not differ in age, sexual maturity, or height. OA had lower BMI, older menarcheal age, and longer duration since last menses than EA and C ($p \leq 0.001$ for all). Hours of exercise/week were similar in both athlete groups. Lifetime fracture risk was higher in OA than EA and C (47.5%, 23.5%, 17.2%, $p=0.002$). BMD Z-scores were lower in OA vs. EA at the total hip, femoral neck, spine, and whole body ($p \leq 0.005$). BMD Z-scores were lower in C vs. EA at the total hip, femoral neck, and whole body ($p \leq 0.004$). At the radius, OA had lower total volumetric BMD (vBMD), cortical (Ct) thickness and % Ct area, and greater Ct porosity and % trabecular (Tb) area than C ($p<0.05$). At the tibia, total and Tb area and Ct porosity were greater in both athlete groups vs. C ($p<0.05$). EA, but not OA, had greater Ct area than C ($p<0.05$). Stiffness and failure load were lower in OA than EA at both sites ($p \leq 0.05$). Within athletes, those with fracture had lower BMD Z (all sites) ($p \leq 0.02$), radial Tb vBMD and thickness ($p \leq 0.01$), and tibial Tb vBMD ($p=0.008$) than those without fracture. Within OA, those with fracture had lower whole body BMD Z ($p=0.02$) and radial Tb thickness ($p=0.03$) than those without fracture.Conclusion: While weight-bearing athletic activity increases BMD, it may increase fracture risk in those with menstrual dysfunction. With repetitive loading, BMD is enhanced, and the weight-bearing tibia develops greater moment of inertia (expansion of total area) to protect against loading forces. Athletes with menstrual dysfunction lack some bone building benefits of exercise. Within athletes, Tb vBMD and thickness differentiate those with and without a history of fracture. This is the first study to examine bone structure in relation to fractures in female athletes. Prospective studies are needed to better assess bone parameters as predictors of fracture prevalence in this population.

High Vitamin D and Physical Activity Status in Community-Dwelling Older Adults: Associations with Body Composition and Muscle Function Changes Over Five Years. David Scott[1], Peter Ebeling*[2], Kerrie Sanders[3], Dawn Aitken[4], Tania Winzenberg[5], Graeme Jones[6]. [1]The University of Melbourne, Australia, [2]Department of Medicine, School of Clinical Sciences, Monash University, Australia, [3]NorthWest Academic CentreThe University of MelbourneWestern Health, Australia, [4]Menzies Research Institute, University of Tasmania, Australia, [5]Menzies Research Institute Tasmania, Australia, [6]Menzies Research Institute, Australia

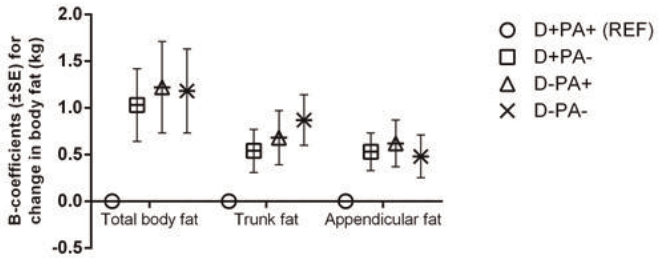
PURPOSE: Higher vitamin D and physical activity (PA) levels have been independently associated with improved body composition and muscle function. Greater fat oxidation and improvements in physical performance in response to exercise may also occur in older adults with higher serum 25-hydroxyvitamin D (25OHD) levels. We investigated the effects of combined high vitamin D and PA status on changes in body composition and muscle function in a prospective study of older adults over five years.

METHODS: 615 community-dwelling volunteers (61.3±6.9 [mean±SD] years; 52% female) were categorised according to baseline serum 25OHD (≥ or <50nmol/L) and PA (≥ or <10,000 pedometer-determined steps/day) levels into the following groups: high 25OHD and high PA (D+PA+; N=148), high 25OHD and low PA (D+PA-; N=225), low 25OHD and high PA (D-PA+; N=80), low 25OHD and low PA (D-PA-; N=162). Changes in DXA-assessed total body, trunk and appendicular

(AFM) fat mass, and appendicular lean mass, and changes in lower-limb strength (LLS; assessed by dynamometer) and muscle quality (LLS normalised to DXA-assessed lower-limb lean mass), were determined over 5.1 ± 0.5 years. Multivariable linear regression analyses adjusting for potential confounders including age, sex, comorbidities, and season of 25OHD/PA assessment compared the change in outcome variables between groups.

RESULTS: Compared with D+PA+, all other groups had significantly greater total body fat, trunk fat and AFM, and D-PA- had lower muscle quality, at baseline (all $P<0.05$). The other groups also had had significantly greater increases in total body fat, trunk fat and AFM over five years compared with D+PA+, as demonstrated in the Figure. Significant interactions were observed and revealed that baseline PA was negatively associated with the change in total body fat (β=-0.23; $P=0.001$) and AFM (β=-0.25; $P=0.001$) over five years for participants with high 25OHD, but not those with low 25OHD (β=-0.06 and β=-0.09; both $P>0.05$).

CONCLUSIONS: Older adults with both higher 25OHD and PA status had significantly smaller increases in body fat over five years, but no differences were observed for muscle mass or function. PA was negatively associated with age-related increases in body fat only in those with high baseline 25OHD status at baseline, suggesting correction of vitamin D deficiency may be important for older adults commencing exercise interventions in order to optimise fat loss.



Change in body fat over five years according to vitamin D and physical activity status at baseline.

***WNT16* genetic variation in fracture-prone children.** Minna Pekkinen*[1], Sara Mäkitie[2], Suvi Vallius[2], Mervi Mäyränpää[3], Outi Mäkitie[4]. [1]Folkhälsan Institute of Genetics, University of Helsinki, Finland, [2]Folkhälsan Research Center, Biomedicum Helsinki, Finland, [3]Children's Hospital, Helsinki University Central Hospital & University of Helsinki, Finland, [4]Folkhälsan Research Center, Biomedicum Helsinki, Department of Molecular Medicine & Surgery, Karolinska Institutet, Stockholm, Sweden, Department of Clinical Genetics, Karolinska University Hospital, Stockholm, Sweden, Finland

Introduction: *WNT16* has been shown to associate with bone mineral density (BMD), bone strength, and osteoporotic fractures in several genome-wide association studies. WNT signaling stimulates the differentiation of osteoblast precursors and plays a major role in skeletal development and homeostasis. WNT16, a ligand to the signaling pathway, has a crucial role in cortical bone homeostasis. The deletion of *Wnt16* specifically affects cortical bone in mice by increasing sclerostin and RANKL/OPG ratio and leading to increased cortical bone resorption and porosity, and to decreased thickness. Decreased cortical bone density is associated with non-vertebral osteoporotic fractures. We therefore wanted to explore the role of WNT16 genetic variation in fracture-prone children.

Subjects and methods: During a 12-month period we recorded fracture history for all children (n=1412) who were treated for an acute fracture at Helsinki University Hospital. All apparently healthy children over 4 years of age, who had sustained: (1) at least one vertebral fracture; (2) two long-bone fractures before age 10 years; or (3) three long-bone fractures before age 16 years, were recruited. A total of 72 (5.2%) children fulfilled these inclusion criteria. *WNT16* gene exons were Sanger sequenced in 62 of these fracture-prone children and in 95 healthy controls.

Results: In the fracture-prone children we found seven different *WNT16* polymorphisms: c.1-4insCCCA (rs72099717) and c.66C>G (rs35391640) in exon 1, c.214C>T, p.G72R (rs2908004) and c.270 C>A, p.T90T (rs17143291) in exon 3, c.600G>A, p.R200R (rs17143296), c.601A>C, p.Q201K (rs74389152) and c.758C>T, p.T253I (rs2707466) in exon 4. Genotypes among the fracture-prone subjects were for c.1-4ins -/- (63%), -/ins (34%) and ins/ins (3%); for c.66 C/C (86%) and C/G (15%); for c.214 C/C (32%), C/T (55%), and T/T (13%); for c.270 C/C (98%) and C/A (2%); for c.600 G/G (95%) and G/A (5%); for c.601 A/A (98%) and A/C (2%); and for c.758 C/C (35%), C/T (52%) and T/T (13%). However, all these polymorphisms were also found in healthy controls and genotype frequencies did not differ between the fracture-prone children and healthy controls.Conclusions: Despite recent observations demonstrating that *WNT16* genetic variation impacts cortical bone thickness, BMD, bone strength, and risk of fractures in mice and humans, our findings indicate that *WNT16* mutations or variations are not a common cause of increased fractures in children.

Effect of Long-Term Intravenous Bisphosphonate Treatment in Children with Osteogenesis Imperfecta. Telma Palomo De Oliveira*[1], Francis Glorieux[2], Frank Rauch[3]. [1]UNIFESP Sao PauloShriners Hospital for Children, McGill University, Canada, Brazil, [2]Shriners Hospital for Children & McGill University, Canada, [3]Shriners Hospital for Children, Montreal, Canada

Cyclical intravenous bisphosphonate therapy is widely used to treat children with osteogenesis imperfecta (OI), but little is known about long-term treatment outcomes. We therefore performed a retrospective chart review on 39 children (female: n=22 male:17) with OI who started intravenous bisphosphonate therapy before 5 years of age (median, 2.2 years; range, 5 weeks to 4.8 years),and who had a subsequent follow up period of at least 10 years (median,14.8 years; range 10.7 to 18.2 years) during which they had received intravenous bisphosphonate treatment (pamidronate or zoledronate) for at least 6 years. During follow-up, the lumbar spine areal bone mineral density z-score increased from -5.0 (SD:1.59) to -2.7(SD:1.25) and weight z-score increased from -3.2 (1.3) to -1.8 (1.8) ($p<0.001$ each). Height z-scores increased ($p=0.04$) from -5.2 (2.9) to -4.0 (2.0) in OI type IV (n=24), but did not change in OI-III (n=14). Patients had a median of 6 femur fractures (range, 0 to 18) and 4 tibia fractures (range, 0 to 17) during the follow-up period, and underwent a median of 9 (range, 0 to 24) intramedullary rodding procedures (upper and lower extremity segments combined). Spinal fusion surgery was performed in 17 patients. The median Cobb angle in the 22 patients who did not undergo spinal fusion was 21 degrees (range, 0 to 56). In conclusion,long-term intravenous bisphosphonate therapy was associated with higher z-scores forlumbar spineareal bone mineral density, weight and, in OI type IV, height, but the disease burden remains very high. More effective treatment approaches are required.

Letrozole and Ovariectomy Cause Bone Loss, Muscle Weakness and Increased Breast Cancer Bone Metastases in Mice. Laura Wright*[1], Ahmed Harhash[2], David Waning[3], Khalid Mohammad[1], Andrew Marks[4], Theresa Guise[1]. [1]Indiana University, USA, [2]Indiana University, USA, [3]Indiana University School of Medicine, USA, [4]Columbia University, USA

Adjuvant endocrine therapy using an aromatase inhibitor (AI) is a standard treatment for postmenopausal women with estrogen receptor (ER)-positive breast cancer. Unfortunately, 50% of women treated with an AI develop musculoskeletal complications. Previous studies in our laboratory have demonstrated bone loss and muscle weakness in ovariectomized (OVX) mice. We therefore hypothesized that complete estrogen deprivation using the AI letrozole would cause more profound muscle weakness and bone loss than OVX alone, and that this high bone turnover state could accelerate the progression of breast cancer bone metastases and negatively impact muscle function.

To test this, four-week female athymic nude mice underwent OVX or sham surgery and were treated daily with vehicle or AI (10μg/day; n=20/group). Two weeks after surgery and onset of treatment, bone mineral density was reduced in OVX-AI mice relative to vehicle-shams ($p<0.01$) as assessed by dual energy X-ray absorptiometry. Using bone micro-computed tomography (SCANCO viva40CT), trabecular bone volume fraction (BV/TV) of the proximal tibia was reduced by 53% is OVX-vehicle mice ($p<0.001$) and by 67% in OVX-AI mice ($p<0.001$) relative to vehicle-sham.

After confirming bone loss, the same animals were inoculated with ER-negative MDA-MB-231 human breast cancer cells into the left cardiac ventricle and were followed for osteolytic lesion formation (n=10-15/group). Since MDA-MB-231 is ER-negative, effects of complete estrogen deprivation should be indirect. Five weeks after inoculation, osteolytic lesion area was larger in OVX-AI mice relative to sham-vehicle ($p=0.0215$), while OVX or AI alone did not alter lytic lesion area. Skeletal muscle function was assessed by ex vivo measurement of maximal contractile specific-force of the extensor digitorum longus muscle. At 200Hz maximal contractile force in sham-letrozole and OVX-vehicle mice was reduced by 7% ($p<0.05$) and reduced by 12% in OVX-AI mice ($p<0.001$) relative to sham-vehicle.

Our murine studies confirm that AI treatment induces bone loss and skeletal muscle weakness, recapitulating effects in cancer patients. As hypothesized, the severe bone loss resulting from AI-induced estrogen depletion may prime the bone microenvironment for the development of breast cancer metastases to bone and potentiate muscle weakness. This model serves as an excellent tool to study the mechanisms of underlying musculoskeletal defects in cancer patients and assess potential therapeutics.

VEGF/HGF Inhibitor Cabozantinib Decreases RANKL Expression in Osteoblastic Cells and Inhibits Osteoclastogenesis and PTHrP-Stimulated Bone Resorption. Paula Stern*[1], Keith Alvares[2]. [1]Northwestern University Feinberg School of Medicine Department of Molecular Phar, USA, [2]Northwestern University, USA

Cabozantinib, a small molecule inhibitor of vascular endothelial growth factor (VEGF) and hepatocyte growth factor (HGF) signaling, has elicited impressive effects to decrease bone lesions in patients with prostate cancer metastases. To determine direct effects of the drug on bone, effects of the agents were examined on resorption in neonatal mouse bone organ cultures and on gene epxression, cell proliferation and phenotypic markers in osteoblast and osteoclast cell lines. Cabozantinib, 0.3 and 3 uM, prevented PTHrP-stimulated calcium release from neonatal mouse calvaria. The inhibitory effects were significant at 48 hr and sustained in longer cultures. 3 uM, but not 0.3 uM, inhibited calcium release from unstimulated bones. Since the effect on resorption culd reflect either effects on osteoblasts to prevent osteoclast activation, or direct inhibition of osteoclasts, responses in osteoblastic and osteoclast precursor cell lines were examined. 24 hr ptreatment of osteoblastic MC3T3-E1 cells with 3 uM cabozantinib results in decreased expression of receptor activator of NFkB ligand (RANKL) and alkaline phosphatase with no change in osteoprotegerin. 48 hr treatment of MC3T3-E1 cells with 3 uM cabozantinib resulted in inhibition of cell proliferation and decreased MTT activity. These effects of cabozantinib are consistent with earlier findings that VEGF promotes osteoblast survival and RANKL expression in MC3T3-E1 cells. Effects on alkaline phosphatase activity were biphasic, with small stimulatory effects from concentrations below 3 uM. When RAW 264.7 osteoclast precursor cells were differentiated with 20 ng/ml RANKL and c0-treated for 24 hr with 3 uM cabozantinib, there was no effect on the expression or RANK, TRAP, cathepsin K, alpha v or beta 3 integrin, or NFATc1. 5-day treatment of RANKL-treated RAW 264.7 cells with 3 uM cabozantinib decreased TRAP and MTT activity. These effects of cabozantinib are consistent with effects of VEGF to promote RANKL-stimulated osteoclast formation. The results suggest that the osteoblast could be the initial target for the effects of cabozantinib, with subsequent direct and indirect effects on osteoclastogenesis leading to decreased bone resorption. The multiple effects of cabozantinib on the bone microenvironment are consistent with the effectiveness of the drug in reducing the lesions resulting from prostate cancer metastases.

Estrogen-related receptor alpha confers Methotrexate resistance via attenuation of *reactive oxygen species* production and p53 apoptosis pathway in osteosarcoma U2OS cells. Peng Chen*[1], Haibin Wang[2], Zhijian Duan[3], June X Zou[3], Hongwu Chen[3], Wei He[2], Junjian Wang[3]. [1]First School of Clinical Medicine, Guangzhou University of Chinese Medicine/Cancer center, University of California at Davis, USA, [2]First Affiliated Hospital of Guangzhou University of Chinese Medicine, China, [3]Cancer center, University of California at Davis, USA

Osteosarcoma (OS) is a malignant tumor mainly occurring in children and adolescents. Methotrexate (MTX), chemotherapy agent, is widely used in treating OS. However, treatment failures are common due to acquired chemoresistance, for which the underlying molecular mechanisms are still unclear. In this study, we reported that overexpression of estrogen-related receptor alpha (ERRα), an orphan nuclear receptor, promoted cell survival and blocked MTX-induced cell death in U2OS cells. We showed that MTX induced ROS production in MTX-sensitive U2OS cells and that ERRα can effectively block the ROS production and ROS associated cell apoptosis. Our further studies demonstrated that ERRα suppressed ROS induction of tumor suppressor P53 and its target genes NOXA and XAF1, mediators of P53-dependent apoptosis. In conclusion, this study demonstrated that ERRα plays an important role in the development of MTX resistance through blocking MTX induced ROS production and attenuating the activation of p53 mediated apoptosis signaling pathway, and points to ERRα as a novel target for improving osteosarcoma therapy.

The purpose of this study is trying to elucidate the underlying molecular mechanisms of the development of MTX-resistance in osteosarcoma and improve the osteosarcoma therapy

Zinc Finger Protein 521 regulates retinoblastoma protein-dependent cell-cycle progression: Potential implications for osteosarcoma. Harikiran Nistala*[1], Coco Roening[2], Serhan Zenger[3], Ken-ichi Takeyama[3], Francesca Gori[4], Roland Baron[5]. [1]Harvard University, USA, [2]Massachusetts College of Pharmacy & Health Sciences, USA, [3]Harvard School of Dental Medicine, USA, [4]Harvard School of Dental MedicineMassachusetts General Hospital, USA, [5]Harvard School of Medicine & of Dental Medicine, USA

Zinc finger protein 521 (Zfp521) has been implicated in lineage determination of mouse ES cells and in the maintenance of precursor cells within the neuronal, mesenchymal and hematopoietic lineages. Zfp521 regulates chondrocyte and osteoblast maturation and represses adipocyte lineage determination. More recently, we demonstrated that Zfp521 interacts with the nucleosome remodeling deacetylase (NuRD) complex via retinoblastoma binding protein 4 (Rbbp4) in conjunction with nuclear transglutaminases (Tgm1 and Tgm3). Furthermore, we established that this effector complex regulates mesenchymal cell-fate determination and maintenance of pluripotency using the murine teratoma formation and somatic cell reprogramming assays respectively.

Instructive and permissive signals regulate mesenchymal stem cell fate between differentiation and self-renewal. It has become increasing clear that Zfp521 in association with lineage specific transcription factors mediates cell-fate determination. However, the role of Zfp521 in self-renewal and implicitly in the maintenance of pluripotency remains unknown.

In the present study, we demonstrate that Zfp521 interacts with the retinoblastoma protein (pRb/p110), thereby regulating G1/S transition within the cell cycle. In particular, in-silico bioinformatic analyses showed that Zfp521 shares a conserved LXCXQ motif (within zinc-finger 15) similar the LXCXE motif that several viral onco-proteins employ for high-affinity binding and inhibition of pRb. Site-specific mutagenesis resulting in the deletion of the zinc-finger domain spanning the LXCXQ motif or substitution of the Cys residue resulted in the loss of interaction between Zfp521 and pRb and a concomitant de-repression of E2F-dependent transcription in luciferase assays. Germline deletion of Zfp521 or knockdown of Zfp521 in various primary cell lines including human mesenchymal stem cells resulted in a significant reduction in BrdU incorporation despite unremarkable changes in PCNA labeling suggesting a block in G1/S transition. Taken together, these results suggest a possible oncogenic role of Zfp521 in retinoblastoma and osteosarcoma. Mouse models overexpressing Zfp521 should provide a valuable platform for investigating the molecular genetics of osteosarcoma and for developing novel therapeutic targets.

Natural Large-scale Regeneration of Rib Cartilage in a Mouse Model. Marissa Srour*[1], Kent Yamaguchi[1], Jennifer Fogel[1], Aaron Montgomery[1], Aaron Misakian[1], Stephanie Lam[1], Daniel Lakeland[1], Francesca Mariani[2]. [1]University of Southern California, USA, [2]University of Southern California, USA

The clinical need for methods to repair and regenerate large cartilage and bone lesions persists. One way to make new headway is to study skeletal regeneration when it occurs naturally. Cartilage repair is typically slow and incomplete. However, an exception to this observation can be found in costal cartilages where complete repair has been reported in humans but the cellular and molecular mechanisms have not been characterized. In this study, we establish a novel animal model for cartilage repair using the mouse rib costal cartilage. We further identify the perichondrium, the dense connective tissue that surrounds the cartilage, as a tissue essential for repair. Our results show that full replacement of the resected cartilage occurs quickly (within 1-2 months) and properly differentiates, but that repair occurs only in the presence of the perichondrium. During the healing period, the perichondrium changes its morphology, and when ectopically placed can support the formation of new cartilage. We hypothesize that the rib perichondrium contains a special niche that houses chondrogenic progenitors that possess qualities particularly suited for mediating repair. In support of this idea, label-retaining cells can be found within the perichondrium that appear to give rise to new chondrocytes. In conclusion, we have successfully established a model for hyaline cartilage repair in the mouse rib, which should be useful for a more detailed understanding of cartilage generation and ultimately for developing methods to improve cartilage and bone repair in other parts of the skeleton.

A Time Course of FoxO Transcription Factor Activation in a Binge Model of Alcohol-Induced Deficient Bone Fracture Repair. Philip Roper*[1], John Callaci[2]. [1]Loyola University Medical Center, USA, [2]Loyola University of Chicago, USA

Alcohol abuse has known deleterious effects on bone health. Binge drinking has become increasingly prevalent and the predominant alcohol abuse pattern associated

with traumatic orthopedic injury and fracture. Proper fracture healing relies on coordinated differentiation of mesenchymal stem cells (MSC) into osteoblasts and chondrocytes to form the callus. MSC differentiation is driven by the canonical Wnt signaling pathway, which activates the transcription factor β-catenin. β-catenin is also a necessary cofactor for the family of FoxO transcription factors, which are activated by oxidative stress. Oxidative stress is elevated by alcohol abuse, and contributes to much of the pathogenesis related to alcohol abuse. We hypothesize that the systemic administration of alcohol will inhibit fracture healing in mice by inducing systemic oxidative stress, activating FoxO-mediated oxidative stress signaling and concomitant antagonism of Wnt signaling.

7-8 week old male C57BL/6 mice received intraperitoneal injections of ethanol (2g/kg) or saline for three consecutive days per week for two weeks. One hour after the last injection, the left tibia was stabilized with an intramedullary pin and surgically fractured. Animals continued with daily ethanol injections until sacrifice. Fracture callus tissue was isolated for histology or homogenized for protein expression and activation assays.

At day 6 and 9 post fracture gross deficiencies in callus formation and fracture healing are seen in alcohol treated animals, with significant decreases in callus volume, chondrocyte maturation, and endochondral ossification ($p<0.05$). These time points are also marked by an increase in FoxO expression ($p<0.05$) and activation ($p<0.05$), with a parallel decrease in β-catenin activation ($p<0.05$).

These results support our hypothesis and begin to elucidate the mechanism of alcohol-induced deficient fracture repair. Alcohol administration increases FoxO signaling within the callus tissue while decreasing β-catenin activation. These changes coincide with drastic fracture callus malformations. Since Wnt signaling is required for MSC differentiation toward an osteo-chondro lineage, alcohol-related activation of FoxO signaling could antagonize necessary Wnt-mediated differentiation leading to this suppression of callus formation.

Histone Deacetylase 7 Suppresses Chondrocyte Proliferation and β-Catenin Activity during Endochondral Ossification. Elizabeth Bradley*[1], Lomeli Carpio[1], Eric Olson[2], Jennifer Westendorf[1]. [1]Mayo Clinic, USA, [2]University of Texas Southwestern Medical Center, USA

Histone deacetylases (Hdacs) are emerging as important regulators of endochondral ossification due to their ability to suppress gene transcription and modulate cellular responses to growth factors and cytokines. We previously showed that Hdac7 suppresses Runx2 activity and osteoblast differentiation. In this study, we examined the role of Hdac7 in chondrocyte differentiation. Hdac7 was highly expressed in proliferating chondrocytes within the growth plate. Pre-natal deletion of Hdac7 in type 2a1 collagen (Col2a1)-expressing chondrocytes produced few Hdac7-deficient animals, indicating partially penetrant embryonic lethality. To overcome this, we crossed $Hdac7^{fl/fl}$ mice with animals expressing a tamoxifen-inducible Col2a1-Cre transgene and administered tamoxifen at postnatal day 5. These Hdac7-deficient mice displayed low bone density but enhanced chondrocyte proliferation. Immunohistochemistry showed higher levels of active β-catenin within proliferative chondrocytes of the growth plates of Hdac7-deficient animals. Active β-catenin levels were also higher in ex vivo cultured Hdac7-depleted chondrocytes, whereas total levels of β-catenin remained constant. Transcripts of Lef1 and Axin2, downstream β-catenin target genes, were also elevated in Hdac7-deficient cells. Igf1 and insulin, two potent chondrogenic mitogens, induced proteasome-mediated degradation of Hdac7, increased active β-catenin levels and enhanced β-catenin transcriptional activity. These data demonstrate that Hdac7 suppresses chondrocyte proliferation rates and b-catenin stability during endochondral ossification.

SA0096

The Notch target genes, *Hes1* and *Hes5*, regulate chondrogenesis and chondrocyte maturation by modulating *Sox9* expression. Timothy Rutkowski*[1], Anat Kohn[2], Anthony Mirando[3], Deepika Sharma[2], Ryoichiro Kageyama[4], Michael Zuscik[5], Matthew Hilton[6]. [1]University of Rochester, USA, [2]Graduate Student, USA, [3]Lab Manager, USA, [4]Collaborator, Japan, [5]University of Rochester School of Medicine & Dentistry, USA, [6]Duke University Musculoskeletal Research Center, USA

We have demonstrated that RBPjk-dependent Notch signaling suppresses chondrogenesis and induces chondrocyte maturation potentially via the repression of *Sox9*, however the molecular mechanisms remain unclear. Many of the HES/HEY transcriptional repressors are RBPjk-dependent Notch target genes. We have identified *Hes1, Hes5, Hey1,* and *HeyL* as Notch-regulated genes in mesenchymal progenitor cells (MPCs) and chondrocytes during cartilage development. Analyses of MPCs with *Hey1* and *HeyL* knock-down or of $Hey1^{-/-}$;$HeyL^{-/-}$ mutant embryos demonstrated no significant change in chondrogenesis and chondrocyte maturation *in vitro* or *in vivo,* suggesting that HEY factors may not be important for cartilage development. Interestingly, knock-down and over-expression of *Hes1* and/or *Hes5 in vitro* altered chondrogenesis and chondrocyte maturation in a manner consistent with RBPjk-dependent Notch loss-of-function (LOF) and gain-of-function (GOF), respectively. To determine whether HES1 and HES5 are necessary for limb cartilage development *in vivo*, we analyzed HES1 and HES1/5 LOF ($Prx1Cre;Hes1^{f/f}$ and $Prx1Cre;Hes1^{f/f};Hes5^{-/-}$) mice at E11.5, E12.5, E13.5, E14.5, and E18.5. Histology, *in situ* hybridization, immunohistochemistry, and qPCR analyses of HES1/5 LOF limbs revealed accelerated chondrogenesis and delayed chondrocyte maturation with elevated and persistent SOX9 expression, a phenotype consistent with RBPjk-dependent Notch LOF models. Later stages of chondrocyte terminal maturation were only mildly delayed, suggesting that terminal chondrocyte hypertrophy and matrix turnover may be only partially HES-dependent. We also developed and analyzed HES1 GOF mice ($Prx1Cre;Rosa\text{-}Hes1^{f/f}$) using a similar approach. Interestingly, we observed delayed or reduced chondrogenesis without a significant decrease in early *Sox9* expression. Therefore, to determine whether HES5 is sufficient to suppress *Sox9*, we performed *in vitro* HES5 GOF studies that caused reduced chondrogenesis and reduced *Sox9* expression. Using a 1kb *Sox9* luciferase construct, we observed a significant decrease in *Sox9* luciferase activity when HES5 was over-expressed *in vitro*. Lastly, chromatin immunoprecipitation (ChIP) analyses showed HES5 binding to the *Sox9* promoter in MPCs. Collectively, these data demonstrate that the downstream RBPjk-dependent Notch targets, HES1 and HES5, are important regulators of chondrogenesis and chondrocyte maturation, and that HES5 is the likely direct Notch target suppressing *Sox9*.

Thrombospondin-2 contributes to whole bone mechanical properties through its effects on collagen fibrillogenesis, lysyl oxidase activity and mineralization. Eugene Manley, Jr.*[1], Joseph Perosky[1], Basma Khoury[2], Kenneth Kozloff[3], Andrea Alford[1]. [1]University of Michigan, USA, [2]University of Michigan, USA, [3]University of Michigan Department of Orthopaedic Surgery, USA

The matrix protein, thrombospondin-2 (TSP2) affects collagen fibrillogenesis in a variety of physiologic contexts. Given the importance of type I collagen for the biologic and mechanical integrity of the skeleton, our objectives were to determine the effects of TSP2-deficiency on structural and mechanical properties at the whole-bone

level and on markers of collagen matrix formation at the cellular level. Left femora of 6-week old male TSP2+/+ (n=3) and -/- (n=5) C57/B6 mice were imaged by microCT and subjected to 4-pt bending. Slivers of tibial diaphyseal cortical bone were viewed by transmission electron microscopy (TEM). Additional 6-week old male mice (n=6-8 per genotype) were used to establish primary marrow-derived MSC-osteoblast cultures. Data are mean ± SD. TSP2-/- femora demonstrated a brittle phenotype, reflected by reduced post-yield displacement (0.56 ± 0.18 vs. 0.73 ± 0.18 mm), with PYD assessed as the total displacement between yield load and when load decreased 25% after ultimate load. Despite a reduced bending moment of inertia in TSP2-/-, (0.079 ± 0.018 vs 0.094 ± 0.004 mm4), both genotypes displayed comparable stiffness (94.5 ±13.7 vs 97.8 ±3.7 N/mm). To identify possible tissue-level mechanisms by which TSP2-deficiency affects whole-bone mechanics, we examined mineralization by microCT and collagen fiber morphology by TEM. Tissue mineral density was higher in TSP2-/- bones (919.7 ± 13.09 vs 902.2 ± 15.0 mg/cc). TSP2 -/- collagen fibers captured in cross-section were large and had diffuse borders, and those captured longitudinally lacked the characteristic periodicity of collagen-rich tissues. To elucidate the mechanisms by which TSP2 might contribute to collagen fibrillogenesis and skeletal tissue function, we examined markers of collagen matrix formation in primary MSC-osteoblasts. On Western blot, relative levels of liberated lysyl oxidase (LOX) pro-peptide were significantly reduced in TSP2 -/- cultures at day 10 (402 ± 123 vs 1859 ± 296 pixels, $p<0.01$) and day 14 (402 ? 334 and 6080 ? 4785 pixels, $p<0.05$). Concurrently, LOX activity was reduced in TSP2 -/- cultures at day 14 (15.4 ± 8.5 vs 28.3 ± 13.3 nmoles/µl/min, $p<0.05$). LOX conducts the final step of collagen fibrillogenesis by catalyzing crosslinks between collagen fibrils and fibers. Together our data suggest that TSP2 contributes to normal bone tissue composition and function by facilitating LOX-mediated cross-linking and mineralization.

Lipoprotein lipase links systemic lipid transport to bone matrix and bone marrow fatty acid composition. Alexander Bartelt[1], Till Koehne[1], Till Koehne[2], Reimer Rudolph[3], Brigitte Mueller[2], Joerg Heeren[2], Ludger Scheja[4], Andreas Niemeier*[5]. [1]University Medical Center Hamburg-Eppendorf, Germany, [2]University Medical Center Hamburg-Eppendorf, Germany, [3]Heinrich Pette Institut Hamburg, Germany, [4]UKE Hamburg, Germany, [5]University Medical Center Hamburg-Eppendorf, Germany

Adipocytes are key regulators of energy homeostasis. Although the contribution of classical brown and white adipose tissue (BAT or WAT) to glucose and fatty acid metabolism are well characterized, the metabolic role of adipocytes in bone marrow remains elusive.

The purpose of this study was to characterize skeletal fatty acid metabolism and its contribution to systemic nutrient glucose and lipid handling in mice.

Whereas in parts of the skeleton the specific amount of fatty acids taken-up from the circulation was lower than in other metabolically active tissues such as BAT or liver, the overall contribution of the skeleton as a whole organ was quantitatively important, placing the skeleton among the top organs involved in systemic glucose as well as fatty acid clearance. We show that, especially in the bone marrow of the tibia, the fatty acid profile resembles classical BAT and WAT. Using a mouse model lacking a master regulator of plasma lipid turnover, lipoprotein lipase (LPL), specifically in adipocytes, we show that impaired fatty acid flux leads to reduced amounts of dietary essential fatty acids in both bone marrow and cortical bone while there was a profound increase in de novo produced fatty acids in both bone marrow and cortical bone.

In summary, we demonstrate that systemic fatty acid metabolism is intricately linked to local fatty acid metabolism in bone marrow and bone matrix.

Purpose: Interactions between bone tissue and energy metabolism have not been thoroughly investigated during early childhood. This study was designed to investigate undercarboxylated osteocalcin (ucOC) and carboxylated osteocalcin (cOC) and their association with metabolic parameters and anthropometric characteristics in normal and overweight children.

Methods: A subsample of the Swedish subjects (n=108) participating in the 2007-2008 baseline survey of the IDEFICS (Identification and prevention of Dietary- and lifestyle-induced health Effects In Children and infantS) Study was included. A total of 62 overweight children of whom 46 were matched with 46 normal weight children aged 2-9 years, with respect to age, gender and month in which blood samples were collected. Subjects were categorized into weight categories according to International Obesity Task Force, Cole, 2012. Serum OC was measured with an electrochemiluminescence immunoassay on a Cobas instrument (Roche). The carboxylated fraction of OC was also determined in serum and was separated from ucOC samples by adsorption on hydroxyapatite. Insulin, glucose, HbA1C levels were measured and HOMA index was calculated. Mann-Whitney test were used for group comparisons and Spearman test for correlations.

Results: For the normal weight and overweight group mean (SE), height was 124.5 cm (1.89); 125.9 cm (1.67) P=0.55, weight 24.7 kg (0.84); 31.3 kg (0.93) $P<0.0001$, Body Mass Index – Standard Deviation Score (BMI-SDS) 0.05 (0.09); 1.80 (0.07) $P<0.0001$, respectively. Normal weight children had significantly higher cOC levels, mean 75.6 µg/L compared with overweight children, mean 69.1 µg/L, $P<0.05$. Overweight children had mean ucOC levels of 7.9 µg/L and normal weight children had mean levels of 7.0 µg/L, P=0.067. No difference was found for total OC between the normal- and overweight group, mean 82.6 µg/L respectively 77.0 µg/L, P=0.11. Total OC and cOC correlated inversely with HbA1C (r= -0.28, P=0,03); (r=-0.3, P=0.02), respectively. Total OC, cOc and ucOC did not correlate with HOMA index, insulin, glucose levels or BMI-SDS score in the two subject groups.CONCLUSION: Carboxylated OC levels were lower in overweight young children. A tendency in increased uOC was found in overweight compared to normal weight children. Total OC and cOC was inversely correlated with HbA1C. Larger studies are warranted to explore the possible metabolic role of cOC in children.

Involvement of Sclerostin and FGF23 on Cardiovascular Disease in Men with or without type 2 Diabetes. Daniela Merlotti*[1], Luigi Gennari[1], Domenico Rendina[2], Konstantinos Stolakis[3], Claudio Corallo[3], Riccardo Muscariello[2], Stefano Rotatori[3], Maria Beatrice Franci[3], Barbara Lucani[3], Stefano Gonnelli[1], Nicola Giordano[3], Piero Tanganelli[4], Carlo Setacci[3], Pasquale Strazzullo[2], Ranuccio Nuti[1]. [1]University of Siena, Italy, [2]Department of Clinical & Experimental Medicine, Federico II University, Italy, [3]Department of Medicine, Surgery & Neurosciences, University of Siena, Italy, [4]Department of Medical biotechnologies, University of Siena, Italy

Sclerostin (SCL) and FGF23 are osteocyte-secreted factors which exert a major role in bone formation and mineral homeostasis. Recently, variations in their circulating levels were described in patients with diabetes (DM) and/or cardiovascular

disease (CVD). Moreover, both FGF23 and SCL are expressed in calcifying vascular smooth muscle cells in mice, suggesting an up-regulation of key osteocytic molecules during the vascular calcification process. In order to provide further insight on the relationship between these 2 osteocyte-derived factors and cardio-metabolic disorders we assessed their levels in a well characterized sample of 253 elderly DM and non-DM men from the Olivetti Heart Study cohort (an ongoing nationwide survey on the prevalence of cardiovascular risk factors) matched for age and BMI. Moreover, serum and tissue samples of 28 patients (11 DM and 17 non DM) who underwent carotid endarterectomy were collected and analyzed. Serum SCL levels significantly decreased with age in all subjects, and were inversely associated with renal function. The correlation was maintained when the 39 cases with renal impairment (GFR<60 mL/min) were excluded. Conversely, FGF23 levels were inversely associated with renal function only in patients with renal impairment. Both SCL and FGF23 levels were slightly but not significantly increased in DM vs non-DM patients, while a significant increase in SCL was observed in DM patients with CVD vs DM patients without CVD. On the opposite, FGF23 levels were increased in CVD patients irrespective of DM status. Importantly, SCL but not FGF23 levels were significantly affected by antidiabetic treatment, being reduced in metformin users and enhanced with insulin or sulphonylurea treatment. Finally, both SCL and FGF23 were significantly higher in patients with mild to severe abdominal aortic calcification (assessed by ultrasonography) than in subjects without calcifications. Consistent with the clinical data, a preliminary immunohistochemistry analysis of carotid plaques demonstrated SCL staining in most samples, particularly in calcifying smooth muscle cells and fibrotic tissue. Increased expression levels were observed in diabetic vs non-diabetic patients. Taken together these data indicate that both FGF23 and SCL play a role in the mechanisms of vascular calcification with a different impact in DM vs non-DM patients. Prospective studies are needed to evaluate the predictive power of these 2 osteocyte-derived markers on CVD.

Low Osteocalcin Levels are associated with Bone Marrow Transplant, more than Insulin Resistance, in Adult Survivors of Childhood Cancer. Christopher White*[1], Jan Walker[2], Richard Cohn[3], Kristen Neville[2]. [1]Prince of Wales Hospital, Australia, [2]Sydney Children's Hospital Randwick, Australia, [3]Sydney Chidlren's Hospital Randwick, Australia

Bone marrow fat may regulate bone mineral metabolism. Bone marrow transplant (BMT^+) demonstrates early adipogenic change[1]. Survivors of childhood cancer develop insulin resistance[2]. Osteocalcin (OC) has been shown to influence insulin insensitivity in mice. We explored the association between insulin resistance and bone mineral metabolism in a study of survivors of childhood cancer who underwent BMT^+.

Methods: OC and P1NP were measured in 99 adult survivors almost 20 years after the treatment of their primary cancer in childhood.Diagnoses included haematological malignancies, neuroblastoma, Wilms tumour, bone and soft tissue and brain tumours. Nineteen had BMT^+ and 12 received total body irradiation (TBI) for conditioning. Adults were overweight/obese if BMI was $\geq$25kg/m^2. Abdominal adiposity (AA^+) was defined as a waist:height ratio >0.5.Hyperinsulinemia (HI) was defined as a fasting insulin $\geq$20mU/L or peak insulin during OGTT $\geq$150mU/L and abnormal glucose tolerance (aGT) included those with either impaired glucose tolerance (IGT) or Diabetes Mellitus (DM) based on WHO criteria.

Results: BMT^+ is more insulin resistant than BMT^- despite lower BMI (Table 1). While BMT^+ is more likely to be male and slightly shorter these differences were not significant. In both groups AA^+ was associated with significantly lower OC but BMI and markers of insulin resistance (HI+aGT) had no significant effect. Following adjustment for age, gender and abdominal adiposity BMT^+ was associated with significantly lower levels of OC than BMT^- (Table 2) A similar but non-significant trend was seen for PINP.

Conclusions: Survivors of childhood cancer, particularly BMT^+, develop insulin resistance. OC, more so than the bone formation marker PINP, is reduced following BMT^+ and is associated with abdominal adiposity but not BMI nor a composite of HI, IGT or DM in adults surviving childhood cancer. These cross-sectional data suggest that the BMT^+ effect on OC is a consequence of engraftment; more so than from changes in insulin sensitivity though a contribution from AA^+ could exist. A longitudinal study of childhood cancer survivors will give greater insight into the factors that influence sequential changes in carbohydrate and bone mineral metabolism in this cohort.

Mechanisms of Mitochondrial Remodeling in Bone loss during Hyperhomocysteinemia: A therapeutic aspect of Hydrogen Sulfide. Anuradha Kalani*[1], Pradip K Kamat[2], Neetu Tyagi[3]. [1]PhD, USA, [2]Univeristy of Louisville, USA, [3], USA

Hyperhomocysteinemia (HHcy, elevated levels of homocysteine) is the risk factor for osteoporotic fracture. Additionally, bone quality and strength is compromised by HHcy due to negative impact on collagen maturation by homocysteine (Hcy) coupling, a process called homocysteinylation. Thiol (–SH) group of Hcy is readily oxidized and generated reactive oxygen species (ROS) that lead to mitochondrial (mito-) oxidative stress. Hydrogen sulfide (H2S), a gasotransmitter, is endogenously synthesized and exerts a regulatory impact on many physiological and pathophysiological processes. Hence, the objective of this study was to evaluate the effect of H2S on mitochondrial remodeling that mitigates bone pathology during HHcy. We hypothesize that Hcy induces mitochondrial dysfunction, in part by altering mitochondrial fission and fusion events while H2S mitigates altered mito-dynamic events and improve bone quality. To test this hypothesis we employed wild-type (WT) males ages 8-10 weeks, WT, WT+NaHS (precursor of hydrogen sulfide,15 μM/kg body weight, intraperitoneal route, 15 days) CBS+/-, CBS+/-+NaHS. The mice were tested for biomechanical, X-ray, bending, micro CT tests. The bones were isolated and proteins were extracted along with pure mitochondrial preparations. Mitochondria were subjected for determination of mitochondrial fission (DRP-1) and fusion (Mfn-2) markers using Western blot, quantitative PCR and immunohistochemical analysis. The extent of collagen cross-linking with Hcy was determined with immunoprecipitation. Alkaline phosphatase and tartrate-resistant acid phosphatase assays were performed to check osteoclast expression in the bone. Our results determined CBS+/- bone weak and less stiffed using bending and x-ray tests. Micro CT analysis confirmed increased bone loss in CBS+/- bone as compared to other groups. In context with micro CT, histomorphometry analysis determined anomaly of bone cells in CBS+/- mice as compared to WT and WT+NaHS groups. Further molecular and immunolocalization studies revealed increased DRP-1 and decreased Mfn2 expression in CBS+/- mitochondrial fractions as compared to WT and WT+NaHS. Interestingly, the treatment of NaHS in CBS+/- mice significantly alleviated the bone deformities and increased bone strength. In conclusion, these results suggest our understanding of the pathogenesis of bone disease that included mito-dynamic events. The study also paves the way for development of new treatment options in bone deformity during HHcy.

Phosphate and calcium phenotype of GLUT2-/- mice, an animal model for Fanconi-Bickel-Syndrome. Ruiye Bi*[1], Wenping Zhao[1], Hiroko Segawa[2], Bernard Thorens[3], Michael Mannstadt[4]. [1]Massachusetts General Hospital, USA, [2]University of Tokushima Graduate School, Japan, [3]University of Lausanne, Switzerland, [4]Massachusetts General Hospital Harvard Medical School, USA

Purpose: Fanconi-Bickel Syndrome (FBS), an autosomal-recessive disease caused by loss-of-function mutations in the glucose-transporter GLUT2, is characterized by renal tubulopathy and can be associated with severe hypophosphatemic rickets. To investigate the mechanisms leading to phosphaturia, we characterized a mouse model of FBS.

Methods: Mice homozygous for the deletion in GLUT2 (GLUT2-/-) were rescued from early lethality by allowing glucose-stimulated insulin secretion through the transgenic expression of the related GLUT1 in the pancreas (tgGLUT2-/-). We studied the phosphate and calcium phenotype of mice homozygous (tgGLUT2-/-) or wildtype (tgGLUT2+/+) for the Glut2 ablation.

Results: Similar to patients with FBS, and consistent with previous reports, tgGLUT2-/- mice show significant glycosuria and mild hypoglycemia. tgGLUT2-/- mice further exhibit a modest increase in urinary fractional excretion of phosphorus (1.25 ± 0.13 dl/mg) compared to tgGLUT2+/+ mice (0.75 ± 0.08) ($p<0.01$) but no difference in serum phosphate. Western blot analysis using kidney brush border membranes revealed a profound 60% reduction of Npt2c in tgGlut2-/- compared to tgGLUT2+/+ mice. Surprisingly, Npt2a was significantly increased by 45%, which we confirmed by immunohistochemical evaluation of kidney sections. This observation argues against a general transporter dysfunction in the proximal tubule. tgGlut2-/- mice, compared with tgGlut2+/+, displayed lower circulating PTH (41 ± 8 vs 168 ± 31 pg/ml, $p<0.01$), lower 1,25(OH)2D3 (22 ± 4 vs 60 ± 12 pmol/dl, $p<0.01$) levels, hypercalciuria, but indistinguishable blood ionized calcium levels. Increased bone resorption, as evidenced by higher serum CTX in tgGLUT2-/- mice compared to tgGLUT2+/+ mice (51 ± 2 vs 39 ± 3 ng/ml, $p<0.01$), is likely the cause for this finding and could explain the lower bone density (Piximus X-ray).

Conclusions: tgGLUT2-/- mice exhibit profound downregulation of Npt2c, increased urinary phosphate excretion, but normal serum phosphate levels, contrary to humans with GLUT2 mutations, who can develop severe hypophosphatemia. This might reflect the different roles of Npt2c in mice, where almost no phenotype is observed when deleted, compared to humans where Npt2c mutations lead to rickets (HHRH). The intriguing calcium phenotype (low PTH, low 1,25(OH)2D3, normal serum and high urinary calcium) is likely due to increased bone resorption. The reason for the increased bone resorption is to be determined.

Raman Micro-spectroscopic Analyses of Compositional Heterogeneity in Osteogenesis Imperfecta Mouse Bone. Xiaomei Yao*[1], Charlotte Phillips[2], Yong Wang[1]. [1]University of Missouri-Kansas City, USA, [2]University of Missouri-Columbia, USA

Osteogenesis imperfecta (OI) is characterized by bone fragility and skeletal deformities due to mutations in collagen resulting in abnormal collagen production or function. It remains unclear how collagen and mineral are altered at the molecular level or distributed at the tissue level. Raman micro-spectroscopy is a powerful non-invasive technique that allows *in vitro* studies on the organic and inorganic composition and distribution of mineralized tissues. Application of multivariate analysis can extract additional biochemical information from the high complexity of Raman spectra. Our goal was to investigate the molecular changes and distribution of the matrix and mineral in the *oim/oim* femoral cortical bone using Raman micro-spectroscopic analyses. The left femurs were dissected from 4-month-old male wild-type (*wt*) and homozygous (*oim/oim*) mice (n=3/group). Femurs were transversely sectioned using a diamond saw at the mid-shaft regions. Raman spectra were recorded with a JASCO NRS 2000 Raman spectrometer equipped with a 60X Olympus lens from medial region of the cross section. Over 300 spectra per group were collected and used for univariate spectral analysis and multivariate principle component analysis (PCA). PCA tests were performed in SPSS (v13.0). Raman spectra of *oim/oim* showed noticeable changes in the amide I and III spectral regions compared to *wt*. The collagen crosslinks (1660 cm^{-1}/ 1690 cm^{-1} peak heights) were 28% higher in *oim/oim* than *wt*, with a Standard Deviation (SD) that was 2500% greater in *oim/oim* than *wt*. The ratio of 1268 cm^{-1} / 1244 cm^{-1} of amide III peak increased 11% in *oim/oim* compared with *wt*, which suggests the lipid or α-helix content in the matrix is increased in *oim/oim,* and the *oim/oim* SD was 200% greater than *wt*. The phosphate-to-matrix ratios increased 20% in *oim/oim* compared to wt, with the *oim/oim* SD increased by 57% relative to *wt* SD. The mineral crystallinity increased 2% in *oim/oim* compared to *wt*, and its SD was 4% less in *oim/oim* than *wt*. PCA of Raman spectra clearly discriminates *oim/oim* and *wt* bones. Analysis of different principle components revealed which tissue component contributed to the spectral discrimination. *Oim/oim* femurs have increased bone collagen crosslinks and mineral-to-matrix ratios with greater heterogeneity in bone matrix content and structure than *wt* femurs. The univariate and multivariate methods are powerful tools for the analysis of Raman spectra of the mineralized tissue.

TRAPPC9 Regulates BMP2-mediated Osteoblast Differentiation through Down-Regulation of NF-kB Activation. Fayez Safadi[1], Thomas Mbimba*[2], Gregory Sondag[3], Fouad Moussa[3], Samir Abdelmagid[1]. [1]Northeast Ohio Medical University, USA, [2]Kent State University, USA, [3]Northeast Ohio Medical University, USA

Intellectual disability (ID) is a serious disorder of the central nervous system with a prevalence of 1-3% in the general population. Recent studies identified different nonsense mutations in the trafficking protein particle complex (TRAPPC9) gene in consanguineous and nonconsanguineous families. These patients exhibit severe bone phenotypes such as short stature, polydactily, craniofacial deformity and micro-cephaly. TRAPPC9 is known to bind NFkB inducing kinase (NIK) and IkB kinas-beta (IKKbeta) and enhances cytokine-induced NFkB activation by increasing the kinase activities of IKK2 (IKKbeta) and NIK. It thus plays a role in the canonical and non-canonical NFkB signaling. Recent studies have identified NF-kB as a major negative regulator of osteoblast proliferation and differentiation that binds and suppresses Runx2 activation. Bone morphogenetic proteins (BMPs) are a group of growth factors and cytokines capable of inducing bone and cartilage formation. Two biochemical pathways are known to be activated by BMPs, one mediates the intracellular signal transduction through type I receptor phosphorylation of Smad1, Smad5 and Smad8. The second mediates the p38/MAPK pathways downstream of TAK1 pathways. TAK1 regulation mediates NF-kB activation through phosphorylation of IKK kinases. We hypothesize that TRAPPC9 regulates BMP2-mediated activation of NF-kB through Samd/p38/MAPK activation. We first examined TRAPPC9 expression and localization in bone by qPCR, Western blot and immuneprecipitation, which confirmed its expression in both osteoclasts and osteoblasts. Co-immunoprecipitation studies confirmed TRAPPC9 binding to both NIK and IKK2 in osteoblasts. To examine TRAPPC9 role during osteoblast differentiation, we performed loss- and gain-of-function studies in both MC3T3 and Bone marrow-derived MSCs using shRNA viral system. TRAPPC9 down-regulation showed a marked increased in all osteogenic markers such Runx2, Osx, Ocn, ALP, ColA1A which were suppressed in cells overexpressing TRAPPC9. TRAPPC9 down-regulation increases matrix maturation and mineralization shown by an increase in ALP staining and activity, Von Kossa and Alizarin red staining. Next, we showed that TRAPPC9 down-regulation mediates an increase in Smad1,5,8 and p38 MAPK activation associated with NF-kB down-regulation. Taken together, these data suggest that TRAPPC9 enhances osteoblast differentiation through Smad1,5,8 and P38 activation by suppressing of NF-kB signaling.

Hyperactive *RAS* Mutations in the Bone have an Intrinsic Negative Effect on Mineralization in Cutaneous-Skeletal-Hypophosphatemia Syndrome. Diana Ovejero*[1], Nisan Bhattacharyya[2], Andrea Burke[1], Laura Tosi[3], Larry Fisher[4], Edward McCarthy[5], Young Lim[6], Keith Choate[7], Michael Collins[1]. [1]National Institutes of Health, USA, [2]National Institutes of Health, USA, [3]Children's National Medical Center, USA, [4]National Institute of Dental & Craniofacial Research, USA, [5]Johns Hopkins Medical Institutions, USA, [6]Yale University School of Medicine, USA, [7] Yale University School of Medicine, USA

Congenital mosaic cutaneous disorders, such as epidermal and large congenital melanocytic nevi, are associated rarely with fibroblast growth factor 23 (FGF23)-induced hypophosphatemic rickets. In such cases, concomitant segmental dysplastic skeletal lesions are consistently observed. We have designated this spectrum of systemic findings as cutaneous-skeletal hypophosphatemia syndrome (CSHS). Although FGF23 is physiologically generated in bone, the source of its excess in this disorder has not been identified to date. In a previous report we described five CSHS individuals. Sequencing of their nevi and their bone lesions identified somatic hyperactive *RAS* mutations, absent in healthy tissues. To increase our understanding of these mosaic disorders, an iliac crest biopsy was obtained from one of the subjects. The obtained specimen corresponded to an area that had a dysplastic appearance on x-ray imaging. Goldner trichrome staining of the biopsy revealed severe osteomalacia out of proportion to the relatively mild degree of hypophosphatemia. This prompted us to investigate the potential inhibitory role of hyperactive RAS in the mineralizing abilities of human bone marrow stromal cells (hBMSC) and its relationship with FGF23 production. Wild type (WT) and mutant colonies of *HRAS* G13R hBMSC colonies were isolated and cultured in osteogenic media for 21 days. Alizarin red staining revealed a significantly lower mineralizing capacity in cells that carried the mutation. FGF23 was not detectable in the media of either WT or mutant cells. To further investigate the role of hyperactive RAS in FGF23 production, WT hBMSCs were transduced with adenovirus carrying WT or mutant Q61R *NRAS*. FGF23 protein was not detectable in either media or cellular lysates by ELISA, nor was FGF23 mRNA detectable by qPCR. We speculate that, independent of the systemic effects of hypophosphatemia, hyperactive *RAS* mutations in dysplastic tissue have an intrinsic effect on mineralization in CSHS.

Identification of Gene Sets Dysregulated by Mutant ACVR1 Gene Causing A Rare Intractable Disease, Fibrodysplasia Ossificance Progressiva. Yoshihisa Matsumoto*[1], Makoto Ikeya[2], Takanobu Otsuka[3], Junya Toguchida[4]. [1]Kyoto University, Japan, [2]Kyoto University, Japan, [3]Nagoya city university, Japan, [4]Kyoto university, Japan

Fibrodysplasia Ossificans Progressiva (FOP) is a rare genetic disease characterized by progressive ectopic ossification. The responsible gene for FOP is the *ACVR1* gene, which is one of type I receptors for BMP. Mutant ACVR1 protein found in patients over-transduces the BMP signal upon ligand binding. This causes ectopic ossification in soft tissues after the initiation of BMP signal transduction triggered by unknown factors. Harvesting target tissues from patients is strictly prohibited because tissue damage accelerates the ectopic ossification. This issue now can be overcome by using iPSC derived from patients.

We have established iPSCs from patients with FOP and analyzed the difference between wild type iPSCs and FOP-iPSCs during osteogenesis and chondrogenesis. FOP-iPSCs show increased mineralization and chondrogenesis. We have, however, observed considerable clonal difference in terms of the differentiation property among clones in wild type and also in FOP-iPSCs. To overcome this problem, we have established rescued FOP iPSCs to replace mutant allele of ACVR1 gene in FOP iPSCs with wild type allele using homologous recombination technique. These rescued FOP iPSCs have identical genetic information except the mutation in ACVR1 and considered as an identical control iPSCs. We confirmed that rescued FOP-iPSCs showed reduced mineralization and chondrogenic properties compared with original FOP-iPSCs.In summary, FOP-iPSCs showed enhanced differentiation property in both osteogenic and chondrogenic lineages, and the results of rescued FOP-iPSCs indicated that these enhanced differentiation property was due to ACVR1 mutation.

Identification of the Third *LRP4* Mutation in a Patient Diagnosed with Sclerosteosis. Igor Fijalkowski*[1], Eveline Boudin[2], João Silva[3], Wim Van Hul[4]. [1]University of Antwerp, Belgium, [2]University of Antwerp, Belgium, [3]Instituto de Genética Médica, Portugal, [4]University of Antwerp, Belgium

Sclerosteosis is a rare, monogenic disorder characterized by a marked increase of bone mineral density, especially prominent at the skull and tubular bones. In addition, sclerosteosis patients present with tall stature, widened mandible and syndactyly. Typically, this autosomal recessive disorder is caused by mutations in the *SOST* gene encoding the sclerostin protein- a potent Wnt signaling inhibitor. However, we were able to show that this condition is genetically heterogeneous. Mutations in the gene encoding low density lipoprotein receptor-related protein 4 (LRP4) were found in two sclerosteosis patients. The protein has been shown to facilitate the inhibitory action of sclerostin. Identified mutations impaired the binding between LRP4 and sclerostin, thus mimicking the phenotype of *SOST* loss of function.

Here, we report the identification of a third *LRP4* mutation in a 48 year old Portuguese patient presented with hyperostosis and sclerosis of the calvarium and tubular bones, tall stature, bilateral syndactyly of 3rd and 4th finger and hearing loss. Genomic DNA of the patient was obtained from peripheral blood mononuclear cells and subjected to mutation screening with the use of sanger sequencing techniques. All coding exons and exon-intron boundaries of the *LRP4* gene were screened. The mutation found, c.G3509A affects the same amino acid (p.Arg1170) that was previously found to be mutated in another sclerosteosis patient. The biological relevance of the mutation (p.Arg1170Gln) was confirmed with the use of dual luciferase assay. Hek293T cells were transfected with either WT or mutant LRP4 construct together with luciferase reporter constructs. Previously described mutation (p.Arg1170Trp) was used as a control. This experiment revealed that both mutated constructs present an impaired response to sclerostin addition (at two different concentrations) as compared to the WT protein (Figure 1).

Based on the data presented we conclude that the novel *LRP4* mutation, p.Arg1170Gln, is causative for the patient phenotype.

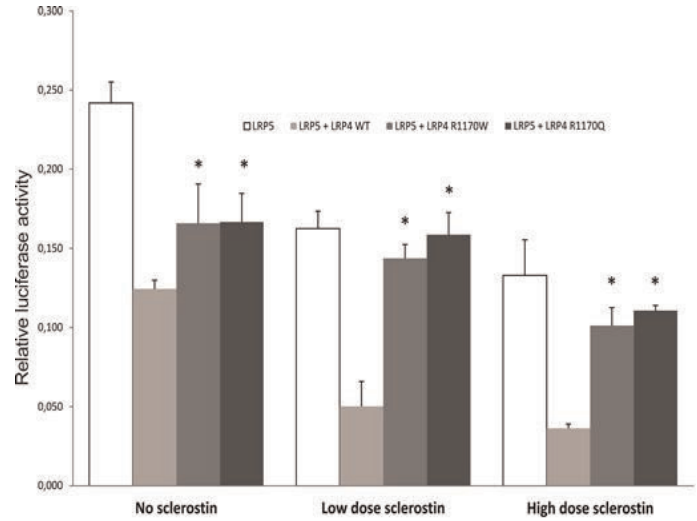

Figure 1: Sclerosteosis causing mutations in LRP4 result in a decreased inhibitory action of sclerostin on canonical Wnt signaling. In HEK293T cells Topflash, renilla and WT or mutant LRP4 constructs are transiently cotransfected with canonical Wnt signaling inducing plasmids (Wnt1 + LRP5) and different amounts of sclerostin. Novel Mutations in the Osteoprotegerin Gene *TNFRSF11B* in Two Patients with Juvenile Paget's Disease. Dorit Naot*[1], Ally Choi[2], David Musson[3], Pelin Özlem Simsek Kiper[4], Gulen Eda Utine[4], Koray Boduroglu[4], Munro Peacock[5], Linda Dimeglio[6], Tim Cundy[7]. [1]University of Auckland, New Zealand, [2]University of Auckland, New Zealand, [3]University of Auckland, New Zealand, New Zealand, [4]Hacettepe University, Turkey, [5]Indiana University Medical Center, USA, [6]Indiana University School of Medicine, USA, [7]Faculty of Medical & Health Sciences University of Auckland, New Zealand

Juvenile Paget's disease (JPD) is a rare genetic bone disorder characterized by progressive skeletal deformities, fractures and deafness. There is considerable variation in the phenotype of JPD patients, from presentation in infancy with severe progressive deformity through to presentation in late childhood with minimal deformity. JPD is caused by recessive inactivating mutations in *TNFRSF11B,* the gene encoding osteoprotegerin (OPG). When OPG activity is deficient, the regulation of RANK/RANKL interaction is impaired and osteoclastic bone resorption is pathologically high. So far, approximately 10 different OPG mutations have been described in JPD patients. The current study presents two novel OPG mutations that were identified in patients with JPD.

Case 1 was a 27 year old man with a history of numerous fractures, bone pain and hearing loss. Case 2, a 9 months old male infant, had bone deformity and very high levels of alkaline phosphatase (1692 U/L). In order to determine the genetic cause of

disease in these patients, DNA samples were amplified with primers for intronic regions flanking the five exons of *TNFRSF11B* and PCR products were sequenced. Patient 1 carried a homozygous missense mutation A>C in exon 2, producing a threonine to proline substitution at position 76 (T76P). In patient 2, only exon 1 of *TNFRSF11B* was present, and a large deletion spanning approximately 260Kbp was identified between intron 1 and a region downstream of the gene.

Taken in conjunction with previously published cases, these results are consistent with the hypothesis that a genotype-phenotype association exist in JPD. The most severe phenotypes are caused by major gene deletions and by mutations affecting cysteine residues in OPG ligand-binding domain. In our study, the patient with the large deletion was diagnosed at a very early age, whereas the patient with the missense mutation had a less severe phenotype. The two novel mutations provide further evidence for the causative role of OPG mutations in JPD and for an association between genotype-phenotype in this disease.

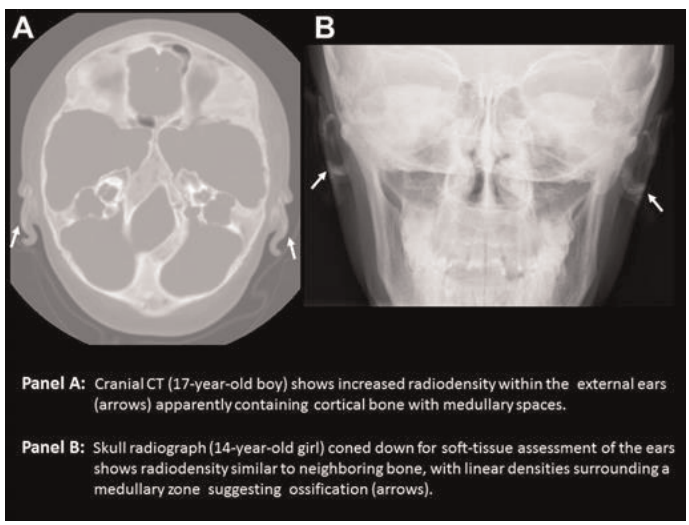
Ossified Auricles: A New Feature Of Osteoprotegerin Deficiency Juvenile Paget's Disease. Gary Gottesman*[1], Katherine Madson[1], William McAlister[2], Angela Nenninger[3], Steven Mumm[4], Michael Whyte[1]. [1]Shriners Hospital for Children-Saint Louis, USA, [2]Washington University School of Medicine, USA, [3]Shriners Hospital for Children-Saint Louis, USA, [4]Washington University School of Medicine, USA

We report two of three unrelated patients with osteoprotegerin (OPG) deficiency juvenile Paget's disease (JPD) (OMIM #239000) who have auricular ossification, establishing this finding as a new feature. The "ossified auricle" describes rigid pinnae (sparing the ear lobe) from ectopic calcification or ossification due to various etiologies. Trauma and frostbite are the most common causes of dystrophic calcification of the auricle, but it also occurs in metabolic disorders including alkaptonuria, acromegaly, Addison's disease, diabetes mellitus, hypopituitarism, and hypothyroidism. Metastatic calcification of the auricle can occur when hypercalcemia or hyperphosphatemia cause hydroxyapatite deposition in multiple soft tissues as in hyperparathyroidism, pseudohypoparathyroidism, tumoral calcinosis, sarcoidosis, milk-alkali syndrome, and vitamin D intoxication. JPD is a rare heritable disorder featuring markedly elevated serum alkaline phosphatase activity with bone pain and deformity from generalized rapid skeletal turnover. Loss-of-function mutations within *TNFRSF11B*, encoding OPG, are the most common cause of JPD. OPG deficiency also leads to generalized vascular microcalcification that can result in retinopathy with blindness, and perhaps cerebral aneurysms or coronary artery occlusion.

Our 2007 report of a 60-year-old man with JPD recorded bisphosphonate treatment since his 41st year. He described hardening of his external ears by his mid-40s (JBMR 22:938). Recently, during examination of our three patients with OPG deficiency JPD (each with distinct mutations in *TNFRSF11B*), we found the pinnae to be rigid in the 17-year-old boy and 14-year-old girl, yet pliable in the 10-year-old boy. The girl's sleep was disrupted by pain from her inflexible pinnae. The boys had been treated with pamidronate for several years, whereas the girl had been treated with alendronate. Cranial imaging and radiographs demonstrated ossification within the external ears of the teenagers, apparently containing cortical bone with medullary spaces (Figure). Auricular biopsies were not performed. Ossification of other sites of elastic cartilage (external auditory canal, Eustachian tube, epiglottis, arytenoid) was not apparent radiographically. Our findings indicate ossification of the auricular elastic cartilage is a new feature of OPG deficiency JPD and warrants evaluation and understanding in this disease.



OPG Ear

Rapid Turnover Skeletal Disease Caused By A Multiple-Exon Duplication of *TNFRSF11A* Encoding RANK. Steven Mumm*[1], Felicity Collins[2], Shenghui Duan[3], Margaret Huskey[3], William McAlister[3], David Sillence[4], Michael Whyte[5]. [1]Washington University School of Medicine, USA, [2]The Children's Hospital at Westmead & Sydney University Medical School, Australia, [3]Washington University School of Medicine, USA, [4]The Children's Hospital at Westmead & Sydney University Medical School, Australia, [5]Shriners Hospital for Children-Saint Louis, USA

Mendelian disorders of constitutive RANK activation are caused by in-frame 12, 15, 18, or 27-bp duplications in exon 1 of *TNFRSF11A* encoding the signal peptide of RANK. The similar rapid bone turnover disorder juvenile Paget's disease (JPD) is due to deactivating mutations in *TNFRSF11B* encoding OPG. We report a rapid turnover skeletal disease in a mother and fetus from a novel RANK defect.

The 38-year-old proposita is the child of nonconsanguineous parents. Family history was negative for fractures or deafness. She wore hearing aids for deafness at age 15 months. Brittle teeth were noted at age 3 years. Secondary tooth loss began at age 9 years. At age 10 years, she was non-dysmorphic and without bone pain or fractures. Bone scintigraphy showed increased uptake in the long bones, and CT revealed hypoplastic ossicles and semicircular canals and no cochleas. A skeletal survey revealed thickened cortices of tubular bones, but a normal skull. Biopsy of a tibia and ileum showed unremarkable lamellar bone, slightly increased vascularity, numerous osteoblasts, and normal marrow. Serum alkaline and acid phosphatase were elevated. An atypical form of JPD was diagnosed. At age 14 years, she had normal stature, slight knock-knee deformity, and fractured major limb bones. She received calcitonin and then a bisphosphonate. At age 16 years, biopsy of the maxilla and jaw showed areas resembling cementifying fibroma, irregular woven bone, and marked osteoblastic and osteoclastic activity in a highly cellular fibrovascular stroma resembling osteolytic Paget's disease. Teeth were eroded and replaced by osteocementum and fibrous tissue. She was edentulous by age 27 years. At age 30 years, she had a prominent forehead and nasal bridge, deep set eyes, and anterior tibial bowing. Then, ultrasound of her first pregnancy at 18 weeks showed abnormal fetal bones with angulated femurs.

Sequencing of coding exons and adjacent mRNA splice sites of the RANK and OPG genes of the mother and abortus was negative. However, in both, microarray-based copy number analysis showed amplification of exons 4-9 of the RANK gene. Confirmatory qPCR showed 3 copies of exons 4-9 in the mother, and >3 in the fetus. An in-frame tandem duplication of exons 4-9 creates a RANK fusion protein of one extracellular RANKL-binding domain combined with double intracellular activation domains. Thus, we have identified a new genetic basis within the family of disorders featuring constitutive RANK activation.

Genotype and Phenotype Analyses Suggest a Distinct Molecular Signature of Giant Cell Tumor Occurring in Paget's Disease of Bone. Luigi Gennari*[1], Domenico Rendina[2], Maria De Lucia[3], Laetitia Michou[4], Daniela Merlotti[1], Stuart Ralston[5], Giuseppina Divisato[3], Laura Pazzaglia[6], Maria Serena Benassi[6], Riccardo Muscariello[2], Gianpaolo De Filippo[2], Ranuccio Nuti[1], Pasquale Strazzullo[2], Teresa Esposito[3], Fernando Gianfrancesco[7]. [1]University of Siena, Italy, [2]Department of Clinical & Experimental Medicine, Federico II University, Italy, [3]Institute of Genetics & Biophysics, National Research Council of Italy, Italy, [4]Université Laval, Canada, [5]University of Edinburgh, United Kingdom, [6]Laboratory of Experimental Oncology, Rizzoli Orthopaedic Institute, Italy, [7]National Research Council of Italy, Italy

Giant cell tumor (GCT) is a rare but well-recognized neoplastic complication of Paget's disease of bone (PDB), accounting for a proportion of all neoplasms arising from pagetic tissue. In order to provide further insight on the phenotype of GCT in PDB we performed a systematic review of 117 GCT cases complicating PDB described to date. PDB patients who developed GCT were more likely to be polyostotic (93%), showed an higher male/female ratio (2.1), an increased prevalence of familial PDB (59%) and an earlier age at diagnosis of PDB (52 ± 12 yrs) compared with a reference cohort of 1483 pagetic patients without GCT. These GCT cases were also remarkably different from GCT described in non-pagetic patients. The latter mainly occurs in Asiatic subjects (while pagetic GCT affect white Caucasian patients in up to 83% of cases) is rarely multifocal (<1% vs 25% in pagetic GCT) and is more prevalent in females (male/female ratio 0.66) between the 2nd and 4rd decades of age. The skeletal localization of GCT was also different between pagetic and non pagetic patients, with involvement of the axial skeleton in 75% vs 15% of cases, respectively. Moreover, mortality rates were remarkably higher in PDB-GCT patients (with up to 50% mortality within 5 years from diagnosis of GCT) than those with GCT occurring in non-PDB patients or in PDB cases without GCT. Then we went on to investigate the molecular basis of pagetic and non-pagetic GCT. To this aim we collected the tumoral tissue samples from 8 and 44 pagetic and non-pagetic patients and peripheral blood samples for DNA analysis of a large PDB-GCT pedigree (with 14 affected relatives) and of 7 unrelated PDB-GCT cases. While 89% of non pagetic GCT tissues showed a recurrent somatic mutation of *H3F3A* gene (which is consistent with a previous report), we did not evidence any *H3F3A* variation in pagetic GCT tissue or in constitutive DNA from the unrelated GCT-PDB cases. A further genetic screening excluded the presence of somatic and germline mutations in *SQSTM1* or other genes known to be associated with PDB or PDB-related syndromes. Whole exome sequencing of the large PDB-GCT pedigree identified 3 variations in 2 candidate genes, in chromosome 1. Therefore, we conclude that the GCT associated with PDB recognizes a distinct molecular signature than GCT occurring in non-pagetic patients. Mutational analysis is being extended to the 7 unrelated PDB-GCT patients in order to identify the gene associated with GCT degeneration in PDB.

Induction of FGF23 expression in IDG-SW3 osteocytes by inflammatory stimuli. Nobuaki Ito[1], Asiri Wijenayaka[2], Matthew Prideaux[3], Masakazu Kogawa[4], Renee Ormsby[2], Lynda Bonewald[5], David Findlay[6], Gerald Atkins*[6]. [1]The university of Adelaide, Australia, [2]Centre for Orthopaedic & Trauma Research, University of Adelaide, Australia, [3]Centre for Orthopaedic & Trauma Research, University of Adelaide, Azerbaijan, [4]The University of Adelaide, Australia, [5]University of Missouri - Kansas City, USA, [6]University of Adelaide, Australia

Certain sepsis patients experience transient hypophosphatemia, of unknown origin but suggesting the involvement of pro-inflammatory cytokines. Osteocyte-derived fibroblast growth factor-23 (FGF23) has been recognised as the key physiological regulator of phosphate (Pi) homeostasis, although the regulatory mechanisms of FGF23 synthesis are not fully understood, in part due to the lack of suitable cell models. In the current study, we used the IDG-SW3 osteocyte-like cell line to investigate the effect of pro-inflammatory cytokines and lipopolysaccharide (LPS) on FGF23 production. In differentiated IDG-SW3 cultures, basal *Fgf23* mRNA was markedly up-regulated by tumour necrosis factor-α (TNF), interleukin-1β (IL-1β), TNF-related weak inducer of apoptosis (TWEAK) and LPS, in a dose-dependent manner. Similar effects were observed in human trabecular bone samples cultured *ex vivo*. TNF and IL-1β induced *Fgf23* expression was reversed by the NF-κB signalling inhibitor, BAY11-7082. Indicative of a coordinated response, mRNA encoding negative regulators of FGF23, phosphate regulating endopeptidase homolog, X-linked (*Phex*), dentin matrix protein 1 (*Dmp1*) and ectonucleotide pyrophosphatase/phosphodiesterase I (*Enpp1*), were suppressed by TNF, IL-1β, TWEAK and LPS, independent of NF-κβ signalling. Conversely, UDP-N-acetyl-alpha-D-galactosamine:polypeptide N-acetylgalactosaminyltransferase 3 (*Galnt3*), which protects intact FGF23 protein from cleavage by furin/furin-like proprotein convertases, slightly increased at certain time points and concentrations of these treatments. C-terminal FGF23 fragments in the media were robustly increased. However, there was no significant change in intact FGF23 protein levels except in the presence of Furin inhibitors. These observations confirm that cellular cleavage of intact FGF23 critically determines active FGF23 production. These results suggest that pro-inflammatory stimuli may contribute to hypophosphatemia during sepsis and likely other inflammatory conditions, by inducing the synthesis of FGF23 in osteocytes. IDG-SW3 is a suitable and unique cell line for the study of FGF23 regulation.

Identification and Functional Characterization of a Novel Activating Mutation in the Human Calcium-sensing Receptor Gene, Responsible for Autosomal Dominant Hypocalcemia. Anne Qvist Rasmussen*[1], Peter Schwarz[2], Niklas Jorgensen[3]. [1]Capital Region of Denmark, Denmark, [2]Glostrup Hospital, Denmark, [3]Copenhagen University Hospital Glostrup, Denmark

Introduction: The human calcium homeostasis is very exact responding to even small fluctuations in the extracellular calcium-ion concentration. One of the keys to the regulation of this homeostasis is the calcium-sensing receptor (CASR). Functionally important mutations in the gene of CASR have been shown to cause calcium metabolic disorders such as hypercalcemia when an inactivating CASR mutation or hypocalcemia when activating mutation as in patients with autosomal dominant hypocalcemia (ADH). It has been shown that activating CASR mutations can increase the receptor sensitivity, increase the maximal signal transduction and interfere with the gradient of the CASR protein expression at the cell surface.

Patients and methods: The proband, a 42 years old woman, and two of her three children were clinically diagnosed with ADH. The proband and two children were genotyped in order to determine if there is an association between genotype and phenotype in this family. Functional characterization of the specific mutant CASR gene was evaluated by extracellular Ca^{2+} stimulated phosphoinositide (PI) hydrolysis as well as intracellular Ca^{2+}-release in transient transfected HEK-293 cells. The expression level of the mutant receptor protein on the cell surface membrane was evaluated by immunoblot analysis.

Results: Genotyping showed a heterozygous missense mutation of the CASR gene revealing a higher basal response in PI hydrolysis and in intracellular calcium release compared to wild-type (WT) CASR gene, without a left-shifted calcium set-point. The maximal response was not significantly changed by increased Ca^{2+} stimulation corresponding to a decreased sensitivity of the mutant CASR. Additionally, the CASR expression at the cell surface was reduced related to the WT receptor corresponding to an abnormality in the maturating process of the receptor protein which still remains to be clarified.

Conclusion: In the present study we have identified a novelactivating mutation in the CASR gene. The novel identified D126V mutation is a rare constitutive activating mutation in a known hotspot in the CASR gene. The mutation in the CASR gene identified in these three related patients co-segregate with the phenotype of the ADH diagnosis.

PTHrP Stimulates Skeletal Growth And Osteoblastic Bone Formation in An Intracrine Manner By Inhibiting P16-Rb And P19-P53-P21 Signal Pathways Mediated By Bmi1. Yongli Han*[1], Ruilei Teng[1], Ying Zhang[1], Zhen Gu[1], Lin Chen[2], Baojie Li[3], David Goltzman[4], Andrew Karaplis[4], Dengshun Miao[5]. [1]Nanjing Medical University, China, [2]Daping Hospital, Peoples Republic of China, [3]Shanghai Jiao Tong University, Peoples Republic of China, [4]McGill University, Canada, [5]Nunjing Medical University, Peoples Republic of China

We previously demonstrated that mice with a deletion of the parathyroid hormone–related peptide (PTHrP) nuclear localization sequence (NLS) and C-terminal region (*Pthrp* KI) displayed skeletal growth retardation and defective osteoblastic bone formation with down-regulation of Bmi1 and up-regulation of p16 and p21; however, it is unclear whether PTHrP stimulates skeletal growth and osteoblastic bone formation in an intracrine manner by inhibiting the p16-Rb and p19-p53-p21 signal pathways mediated by Bmi1. To answer this question, we generated compound mutant mice that are homozygous for the *Pthrp* KI mutation and either *p16* or *p53* deletion (*Pthrp* KI $p16^{-/-}$ or *Pthrp* KI $p53^{-/-}$,respectively), and compared them with $p16^{-/-}$, $p53^{-/-}$, *Pthrp* KI, and WT littermates. Phenotypes were analyzed by histopathological, immunohistochemical, cellular and molecular approaches. Deletion of p16, but not p53 in *Pthrp* KI mice resulted in a longer lifespan. At 2 weeks of age, skeletal growth parameters, including length of long bones, size of epiphyses and PCNA positive chondrocytes, osteoblastic bone formation parameters, including BMD, trabecular bone volume, osteoblast numbers, and ALP, type I collagen and osteocalcin positive areas were increased in $p16^{-/-}$ and $p53^{-/-}$ mice, and reduced in *Pthrp* KI, *Pthrp* KI $p16^{-/-}$, and *Pthrp* KI $p53^{-/-}$ mice compared to WT mice; however these parameters were increased in *Pthrp* KI $p16^{-/-}$ and *Pthrp* KI $p53^{-/-}$mice compared to *Pthrp* KI mice. As well, the mRNA expression levels of Runx2, ALP, and type I collagen and the numbers of total CFU-f and ALP positive CFU-f generated from bone marrow cell cultures were increased significantly in $p16^{-/-}$ and $p53^{-/-}$ mice compared to WT mice and in *Pthrp* KI $p16^{-/-}$and *Pthrp* KI $p53^{-/-}$mice compared to *Pthrp* KI mice. Apoptotic osteoblasts and osteocytes were increased with the down-regulation of Bmi1 and Bcl-2 and the up-regulation of Caspase-3 at protein expression levels in *Pthrp* KI mice compared to WT mice and these alterations were rescued partially by deletion of either p16 or p53 in *Pthrp* KI mice. Our results demonstrate that deletion of either p16 or p53 in *Pthrp* KI mice can partially rescue defects in skeletal growth and osteoblastic bone formation by enhancing endochondral bone formation and osteogenesis. These studies therefore indicate that PTHrP can stimulate skeletal growth and osteoblastic bone formation in an intracrine manner through inhibiting p16-Rb and p19-p53-p21 signal pathways mediated by Bmi1.

Stapled Peptides as Long-Acting, Selective Parathyroid Hormone Antagonists. Manoj Samant*[1], Karen Olson[1], Aditi Mukherjee[1], Hubert Chen[2], Thomas Gardella[3], Allen Annis[4]. [1]Aileron Therapeutics, Inc., USA, [2], USA, [3]Massachusetts General Hospital, USA, [4]Aileron Therapeutics, Inc., USA

Stapled Peptides utilize an optimized hydrocarbon cross-linking chemistry that lock, or "staple", peptides into α-helices to mimic native protein structures and confer resistance to proteolysis. The resulting molecules exhibit extended plasma half-life after either intravenous or subcutaneous administration, while retaining molecular target specificity and potency of the underlying native protein structures. We have generated potent Stapled Peptide parathyroid hormone (PTH) antagonists as a novel and efficacious therapy for hyperparathyroidism. In SaOS-2 osteosarcoma cells (Figure 1), Stapled Peptide PTH antagonists (ATSP-10814 and ATSP-11302) inhibited PTH(1-34)-induced cAMP production at nanomolar and picomolar concentrations, up to 10,000-fold more potent than a PTH antagonist previously tested in the clinic (BIM-44002). Receptor binding assays using isolated PTHr1-containing membrane preparations correlated with cellular potency. Stapled Peptide PTH antagonists demonstrated equipotent activity against the native hormones PTH(1-34), full-length PTH(1-84), and PTH-related protein (PTHrP), and agonist activity was not measured at ≤10 μM in SaOS-2 cells. Stapled Peptide ATSP-10814 demonstrated a low plasma clearance of 231 mL/hr/kg, and a half-life of 1.6 hr following intravenous administration in Sprague-Dawley rats. Dose-dependent, statistically significant, and clinically relevant changes in serum calcium were detected in rats, with the maximal effect at 2 hr post-dose and lasting up to 7 hrs post-dose. To confirm the on-mechanism, calcium-lowering effects of Stapled Peptide PTH antagonists, we dosed thyroparathyroidectomized rats with vehicle or ATSP-10814, followed by PTH infusion at 1.25 μg/kg/h. ATSP-10814 markedly reduced PTH-induced increases in total and ionized serum calcium, whereas vehicle had no discernible effects. Collectively, these results demonstrate that Stapled Peptide PTH antagonists have enhanced pharmacokinetic and pharmacological properties relative to existing molecules, and the continued development of Stapled Peptides is warranted as a potential therapy for all major types of hyperparathyroidism.

TSH elevation as first laboratory evidence for pseudohypoparathyroidism type Ib (PHP-Ib). Harald Jueppner[1], Angelo Molinaro*[2], Dov Tiosano[3], William Russell[4], Dionisios Chrysis[5], Outi Makitie[6], Rieko Takatani[7], Massimo Tonacchera[8]. [1]Massachusetts General Hospital, USA, [2]Endocrine Unit, Massachusetts General Hospital, USA, [3]Division of Pediatric Endocrinology, Meyer Children's Hospital, Rambam Health Care Campus, Israel, [4]Division of Pediatric Endocrinology & Diabetes, Vanderbilt University School of Medicine, USA, [5]Division of Endocrinology, Department of Pediatrics, Medical School, University of Patras, Greece, [6]Children's Hospital, Helsinki University Central Hospital, Finland, [7]Massachusetts General Hospital & Harvard Medical School, USA, [8]Endocrinology Unit, Department of Internal Medicine, University of Pisa, Italy

Objective: Pseudohypoparathyroidism type Ib (PHP-Ib) is caused by *GNAS* methylation changes that occur either in association with maternally inherited deletions within *GNAS* or *STX16*, or as a sporadic disorder. PHP-Ib patients typically present with isolated resistance towards PTH in the proximal renal tubules, which leads hypocalcemia and hyperphosphatemia. However, some individuals affected by this disorder show also resistance towards other hormones, particularly TSH. We now wanted to determine whether TSH elevations can be the first evidence for PHP-Ib.

Patients: Four patients developed PTH-resistant hypocalcemia 3-20 years after establishing the diagnosis of idiopathic hypothyroidism (IH) during childhood and were found to show *GNAS* methylation changes, thus establishing the diagnosis of PHP-Ib. We also searched in adult IH patients without evidence for calcium and phosphate abnormalities for similar epigenetic changes.

Results: In genomic DNA from three pediatric patients, who developed hypothyroidism before the onset of PTH-resistance, we observed broad epigenetic *GNAS* abnormalities, including loss of methylation at the exons AS, XL and A/B, and gain of methylation at exon NESP55; these findings are consistent with sporadic PHP-Ib. In the fourth patient, an isolated loss of methylation at *GNAS* exon A/B led to the identification of the 3 kb deletion in *STX16* gene as the cause of PHP-Ib. DNA from the patient's healthy mother revealed the same deletion. No *GNAS* methylation changes were observed in IH patients.

Conclusions: PHP-Ib can present initially only with TSH elevation and the onset of PTH-resistance can be delayed by many years. No methylation *GNAS* change were observed in our adult patients with TSH elevation, indicating that adult-onset hypothyroidism is not or only rarely associated with epigenetic changes at the *GNAS* locus. Our findings indicate that silencing of Gs-alpha transcription from the paternal allele can be more pronounced in the thyroid than in the proximal renal tubules, and it will therefore be important to screen pediatric patients with hypothyroidism for extended periods of time for changes in calcium, phosphate, and PTH to prevent symptomatic hypocalcemia and associated complications.

SA0146

Co-expression Network Analysis Identifies Alpha-Synuclein (*Snca*) as a Mediator of Ovariectomy-induced Bone Loss. Gina Calabrese[1], Larry Mesner[2], Patricia Foley[3], Clifford Rosen[4], Charles Farber*[5]. [1], USA, [2]University of Virginia, USA, [3]University of Virginia, USA, [4]Maine Medical Center, USA, [5]University of Virginia, USA

Estrogen deficiency during the postmenopausal period leads to substantial bone loss. This loss is initiated, in part, by alterations in transcriptomic networks. Here, we utilized variation in global gene expression driven by natural genetic variation across inbred strains of mice to identify networks of co-expressed genes in bone that differ in response to OVX. Bilateral ovariectomy (OVX) or sham surgeries were performed in three inbred mouse strains (BALB/cJ, C3H/HeJ and C57BL/6J). MicroCT imaging of lumbar vertebrae and femora revealed significant effects of genotype on basal bone mass as well as the magnitude of bone loss after OVX. Global gene expression profiling of vertebrae and femora identified substantial transcriptomic differences due to genotype, with more subtle changes attributed to the effects of OVX. Across strains, surgical groups and skeletal sites, we identified 21 modules of co-expressed genes. The overall expression state of two of the 21 modules was significantly ($P<0.002$) different as a function of OVX. Intramodular connectivity, a measure of network connectedness, was highly correlated with the magnitude of differential gene expression due to OVX in one (L5-M13) of the two modules, suggesting that highly connected genes in this module play an important role in OVX-induced bone loss. The expression of all L5-M13 genes was decreased in OVX mice across all three strains and this module was enriched for genes involved in the response to oxidative stress. The most highly connected L5-M13 hub gene was alpha-synuclein (*Snca*). Mice deficient for *Snca* had less trabecular bone loss at the lumbar spine after OVX and this protection was associated with the specific disruption of the expression of L5-M13 genes and transcripts belonging to a separate module enriched for genes involved in neuronal function. These data, in general, highlight the power of co-expression network analysis for novel gene discovery and, specifically, identifies *Snca* as a key hub gene involved in coordinating transcriptomic networks in bone in response to estrogen deficiency.

A bone-testicular interaction for the maintenance of male steroidogenesis. Daniela Hofer[1], Julia Münzker[2], Matthias Ulbing[2], Philipp Stiegler[3], Karla Hutz[4], Richard Zigeuner[4], Thomas Pieber[2], Helmut Müller[3], Barbara Obermayer-Pietsch*[5]. [1]Division of Endocrinology & Metabolism, Medical University Graz, Austria, Austria, [2]Department of Internal Medicine, Division of Endocrinology & Metabolism, Medical University Graz, Austria, Austria, [3]Department of Surgery, Division of Transplantation Surgery, Medical University Graz, Austria, Austria, [4]Department of Urology, Medical University Graz, Austria, Austria, [5]Medical University Graz, Austria

Introduction: Significant interactions of androgens and bone metabolism have recently been proposed in rodents via the involvement of osteocalcin (OC).

In humans, we have shown a strong association of testosterone and vitamin D and their parallel seasonal variation in more than 2200 men. Our aim was to investigate the molecular mechanisms of vitamin D (1,25D) and osteocalcin in male androgen synthesis in a primary testicular cell culture model.

Methods: Human testicular cells were isolated from testes of braindead organ donors. After addition of different concentrations of either LH (luteinizing hormone), IGF-1 (insulin-like growth factor 1), 1,25D and OC alone or in combination, RNA was isolated and the expression of selected genes of the male androgen and steroid metabolism were studied by real time quantitative PCR at baseline compared to hormonal treatment. Testosterone and 5a-dihydrotestosterone (DHT) were measured by immunoassay in cell culture supernatants initially and after hormonal stimulation.

Results: In isolated human testicular primary cells, addition of physiological doses of LH, as well as the combination of LH with IGF-1, did not significantly change the gene expression pattern of the selected genes compared to baseline. Addition of 1,25D significantly raised testosterone delivery in human primary testicular cells, compared to baseline and treatment with LH. Treatment with osteocalcin increased testosterone as well as DHT levels in cell culture supernatants dose-dependently. A combined treatment of LH, IGF-1 together with 1,25D and OC resulted in a significant increase of mRNA levels of selected genes of androgen synthesis and metabolism pathways, namely cholesterol side-chain cleavage enzyme (CYP11A1), 3b-hydroxysteroid dehydrogenase (HSD3B2), aromatase (CYP19A1) and cytochrome P_{450} 3A4 (CYP3A4).

Conclusion: We have shown a reproducible and dose-dependent involvement of vitamin D and osteocalcin in human male steroid- and androgen-synthesis. Our results support the recent view of bone as an endocrine organ. Considering osteocalcin and vitamin D as important players in male steroidogenesis might open up new clinical approaches for hypogonadism and osteoporosis.

SA0149

Model-based Meta-analysis for Development of a Population-Pharmacokinetic (PPK) Model for Vitamin D3 and its 25OHD3 Metabolite. Alanna Ocampo*[1], Marc Gastonguay[2], Joseph Lorenzo[3], Matthew Riggs[4]. [1]University of Connecticut, USA, [2]Metrum Research Group LLC, USA, [3]University of Connecticut Health Center, USA, [4]Metrum Research Group LLC, USA

Purpose: Association of Vitamin D3 (D3) and its metabolite (25OHD3) levels with various diseases has become an active research focus in several areas, including bone health, diabetes, and cancer. Inherently, clinical studies investigating these relationships with D3 and 25OHD3 vary in dosing regimen, assays, demographics, and control of exogenous D3 production. This leads to uncertain and conflicting exposure-related associations with D3 and 25OHD3. To elucidate this parent-metabolite system, a PPK model was developed to predict D3 and 25OHD3 exposure from varied doses and administration routes to identify and understand sources of exposure variability within the complex network of D3-related physiology.

Methods: Specific search criteria were used in PUBMED to identify public source PK data pertaining to D3 and 25OHD3 in healthy or osteoporotic populations. Overall 77 studies with 12094 individuals were selected; this included 62 individual-level profiles as well as grouped data. Both IV, oral, single and multiple dose data were used, with D3 and 25OHD3 dosing (400-100000 IU/d and 15-1000 ug/d, respectively). A nonlinear mixed effects model was developed to simultaneously model the PK of D3 and 25OHD3 (NONMEM v7.2). Model development included consideration of 1- and 2-compartment (CMT) models with first-order absorption rate constant (ka) and linear or nonlinear clearance (CL). Random effects were weighted by arm sample size. Diagnostic plots and predictive checks assessed model adequacy.

Results: D3 and 25OHD3 dispositions were best described by 2-CMT models with nonlinear and linear clearances, respectively. D3 model estimates, relative to bioavailability (F) were: maximum rate of metabolism (Vmax, 1.15nmol/h), central volume of distribution (Vc, 11L/h), intercompartmental clearance (Q, 0.189L/h), peripheral volume of distribution (Vp, 1500L/h), and baseline concentration (Dbase, 5nmol/L). For 25OHD3: CL=0.0148 L/h, Vc=4.44 L, Vp=7.61 L, Q=0.0494 L/h, and Dbase=32.7nmol/L. Relative fraction of D3 conversion to 25OHD3 was described nonlinearly as 0.7*[D3/40]^0.169 (for D3 400-5600 IU/d). The same ka for D3 and 25OHD3 was assumed (0.323h-1).

Conclusions: The PK of D3 and 25OHD3, described by two CMT models with first order oral absorption, with nonlinear parent and linear metabolite CL, suggests that estimation of nonlinear CL may be important when considering comparisons of D3 and 25OHD3 exposures across studies and dosing regimens.

Renal CYP27B1 is essential to maintain circulating 1,25 dihydroxyvitamin D, and calcium and bone homeostasis. Yingben Xue*[1], Rene St-Arnaud[2], David Goltzman[3]. [1]Calcium Research Lab, McGill University, Canada, [2]Shriners Hospital for Children & McGill University, Canada, [3]McGill University, Canada

Although mainly expressed in kidney, CYP27B1, which converts 25 hydroxyvitamin D [25(OH)D] to 1,25 dihydroxyvitamin D [1,25$(OH)_2$D], is also expressed in other tissues, however, the physiological role of extrarenal CYP27B1 remains controversial. To study the impact of reducing renal CYP27B1 on circulating 1,25$(OH)_2$D, calcium and bone homeostatasis, we used a Tet-On system, in which rtTA is under the control of a Pax8 promoter, allowing inducible inactivation of a floxed CYP27B1 allele in renal tubules. We treated Pax8rtTA;tetOcre;$OH^{flox/flox}$ mice with dietary doxycycline (DOX) (870mg/kg) for 4 weeks after weaning to induce conditional CYP27B1 KO mice; DOX treated non-responsive mice (Pax8rtTA;$OH^{flox/flox}$, tetOcre;$OH^{flox/flox}$ and $OH^{flox/flox}$) were used as controls. We found that renal

CYP27B1 mRNA and protein were decreased by 65%, CYP24 mRNA was decreased by 62%, serum $1,25(OH)_2D$ was decreased by 49% and 25(OH)D was increased by 40% in KO mice. $1,25(OH)_2D$ biosynthesis was also decreased *in vitro* in cultured primary renal tubule cells of KO mice. KO mice showed normal serum calcium, secondary hyperparathyroidism and hypophosphatemia. Although CYP27B1 was expressed in intestine, intestinal CaBP9K and TRPV6 mRNA were decreased by 56% and 63%, respectively, suggesting that local CYP27B1 can not compensate for the deletion of renal CYP27B1 in regulating intestinal calcium transporter gene expression. We also confirmed expression of CYP27B1 in bone, however, in KO mice bone turnover was increased due to hyperparathyroidism, and bone mineral density (BMD) and bone mineral content (BMC) were decreased. To examine the response of KO mice to a low calcium (LCa) diet, mice were fed a DOX diet for 4wks after weaning followed by a LCa diet for 4 wks. In control mice, renal CYP27B1 mRNA levels were 2-fold higher after LCa diet stress; however, there was no change in KO mice. After LCa stress, CYP24 mRNA levels were decreased by 37% and 66% in control and KO mice, respectively. Serum $1,25(OH)_2D$ was increased from 71.6 pmol/L to 238.3 pmol/L in KO mice and from 140.4 pmol/L to 415.6 pmol/L in control mice. After LCa, bone turnover was significantly increased in control mice; BMD and BMC were decreased by 16% and 20%, respectively. In KO mice bone turnover did not change; BMD and BMC were decreased by only 6% and by 8%, respectively. We conclude that renal CYP27B1 is essential to maintain circulating $1,25(OH)_2D$ levels and normal calcium and bone homeostasis.

Vitamin D3 Regulates Frizzled 1 Expression in Osteoblasts. Shibing Yu[1], Yanxia Chu[2], Joseph Zmuda[3], Yingze Zhang*[4]. [1]University of Pittsburgh Medical Center, USA, [2]University of Pittsburgh Department of Medicine, USA, [3]University of Pittsburgh Graduate School of Public Health, USA, [4]University of Pittsburgh, USA

Frizzled 1 (FZD1) is a co-receptor for Wnt signaling and plays a role in osteoblast differentiation and mineralization. The expression of FZD1 is regulated by multiple transcription factors including Egr1 and E2F1. However, very little is known about the potential endocrinologic regulation of FZD1 expression. Vitamin D3 (1a,25-dihydroxy vitamin D3) plays an important role in bone mineralization and metabolism via direct actions on osteoblasts. It is well established that vitamin D3 and its receptor-VDR regulate gene expression in osteoblasts through interaction with a number of other genes, such as the Wnt co-receptor LRP5. To determine whether vitamin D regulates the expression and function of FZD1, we transfected FZD1 promoter constructs containing two promoter variants rs2232157 and rs2232158 in Saos2 cells for 12 hours and further treated the cells with control, 1nM, 5nM, 10nM and 100nM vitamin D3 for 24 hours. We demonstrated that vitamin D3 at the concentration of 100nM significantly suppressed FZD1 promoter activity independent of the polymorphisms. We further performed time course experiments for 2-, 6- and 24-hour treatment with 100nM vitamin D3 in Saos2 cells transfected with wild type FZD1 promoter. Interestingly, FZD1 promoter activity was significantly increased by 31% at 2 hours of vitamin D3 treatment, followed by a significant decrease by 27.5% at 24 hours after treatment. Quantitative PCR and Western blot confirmed altered expression levels of FZD1 mRNA and protein at 2- and 24-hour Vitamin D treatment. Taken together, our study demonstrates that vitamin D3 has a biphasic effect on FZD1 expression with an early increase and later decrease between 2 hour and 24 hour. Additional studies are needed to dissect the molecular mechanisms underlying this novel regulatory effect on FZD1.

Adenovirus 36, Adiposity and Inflammatory-Related Markers in Children. Paige Berger*[1], Emma Laing[1], Norman Pollock[2], Stuart Warden[3], Kathleen Hill Gallant[4], Dorothy Hausman[5], Ralph Tripp[5], Linda McCabe[6], George McCabe[6], Connie Weaver[4], Munro Peacock[7], Richard Lewis[1]. [1]The University of Georgia, USA, [2]Georgia Regents University, USA, [3]Indiana University School of Health & Rehabilitation Sciences, USA, [4]Purdue University, USA, [5]The University of Georgia, USA, [6]Purdue University, USA, [7]Indiana University Medical Center, USA

Purpose: Infection with a common respiratory virus, human adenovirus 36 (Ad36), may induce adipogenesis over osteogenesis, triggering obesity development at the expense of bone. Systemic inflammation may be partially responsible for this obesogenic effect. This study investigated the association of the serum human Ad36 antibody titer with markers of adiposity and inflammation in 291 children ages 9-13 years (50% female, 49% black, 21% obese). Methods: In this cross-sectional study, fasting blood samples were measured for Ad36-specific antibodies and inflammatory-related markers [tumor necrosis factor-alpha (TNF-α), interleukin-6 (IL-6), vascular endothelial growth factor (VEGF), and monocyte chemoattractant protein-1 (MCP-1)] using ELISA and multiplex assays, respectively. Obesity was defined as having a body mass index (BMI)-for-age ⩾95th percentile, and dual-energy X-ray absorptiometry was used to measure body fat percentage (BF%). Results: Of the 291 children, 42% were positive for Ad36-specific antibodies [Ad36(+)]. There were no significant differences between Ad36(+) versus Ad36(−) groups in BMI-for-age percentile (64.8 vs. 72.1, P=0.13) or BF% (30.2% vs. 31.4%, P=0.30) after adjusting for age, sex and race. Binary logistic regression, also adjusted for BF%, revealed that the odds for being Ad36(+) were greater for the following serum inflammatory-related markers: highest TNF-α tertile (⩾12.0 pg/mL) versus lowest (<8.2 pg/mL) (OR: 2.3; 95% CI: 1.2, 4.2), highest IL-6 tertile (⩾1.7 pg/mL) versus lowest (<1.0 pg/mL) (OR: 2.3; 95% CI: 1.4, 4.0) and highest VEGF tertile (⩾313 pg/mL) versus lowest (<136 pg/mL) (OR: 2.0; 95% CI: 1.1, 3.7). There was no relationship between Ad36(+) and MCP-1. Conclusions: Our data in children show that Ad36(+) is associated with several inflammatory-related markers, but not with greater adiposity.

Calcium-release activated calcium channel inhibitors suppress acute arthritis in vivo by blocking osteoclast development. Lisa Robinson[1], Jonathan Soboloff[2], Harry Blair*[1], John Barnett[3]. [1]University of Pittsburgh, USA, [2]Temple University, USA, [3]West Virginia University School of Medicine, USA

Our *in vitro* studies show that osteoclast maturation is suppressed when calcium-release activated calcium currents (CRAC) are blocked by siRNA or by a CRAC antagonist, 3,4-dichloropropionaniline (DCPA). This is consistent with work showing that Ca^{2+}-activated NFATc is required for transcription of osteoclastic proteins. Further, studies of mice deficient in the plasma membrane Ca^{2+} channel Orai1, a key component of CRAC, have reduced, but not absent, bone degradation. As such, we reasoned that responses to stimuli that cause pathological bone resorption might be suppressed by CRAC antagonists without severe side effects. Therefore, we did a trial of treating acute collagen-induced arthritis in mice using 10 μM DCPA. This *dramatically suppressed the development of arthritis* over five weeks. Findings included significant reduction in bone and cartilage damage in sections of feet of the animals, and reduction in overall swelling of joints. All of this analysis was done using blinded observers, with 10-12 replicates of CIA and treated CIA. This response did not affect anti-collagen titers. There were no adverse effects in the treated group on animal weight or activity, consistent with low toxicity, which also has been noted in humans exposed to DCPA. Inflammatory arthritis is a disabling condition that affects many thousands of people in the US each year; it occurs in adults and children, after trauma, and secondary to infections (e.g., *Borrelia*), but typically it is idiopathic. Millions of adults live with chronic rheumatoid arthritis, which has similar features. Inflammatory arthritis often requires treatments with dangerous side effects. This new approach, based on an inhibitor of osteoclast maturation, may thus be applicable to treating acute arthritis. While the crossover from inhibiting bone degradation to inhibiting acute arthritis was not initially expected, other agents show similar broad spectrum effects on bone turnover and arthritis, including TNFα antagonists. Specifically, targeting CRAC might be appropriate to manage acute arthritis with less risk than steroids, metabolic inhibitors, or TNFα antagonists.

Mouse Forearm Loading – Experimental Strain Quantification using a Digital Image Correlation Technique. Mark Begonia[1], Mark Dallas[1], Mark Johnson[2], Ganesh Thiagarajan*[3]. [1]University of Missouri Kansas City, USA, [2]University of Missouri, Kansas City Dental School, USA, [3]University of Missouri - Kansas City, USA

Gene expression in individual osteocytes in response to whole bone strain is heterogeneous. It has been hypothesized that gene expression is related to the actual strain on the individual osteocyte and its lacuna. In order to begin to correlate strain with biological response, we have performed a number of strain gage and Digital Image Correlation (DIC) studies to build finite element (FE) models approximating the strain fields experienced by osteocytes during loading. A 2D-DIC technique has been developed using two cameras to capture videos of both the medial and lateral

sides of the mouse forearm during compressive loading and a MATLAB based software employing a cross-correlation technique to quantify the displacement, strain histories, and strain contours in several distinct regions of the bone. Each ex vivo loading test was performed at multiple camera lens magnifications (2x, 3x and 4x). This methodology offers many advantages since; a) no additional stiffness is introduced by the adhesive between the strain gages and bones, b) the radius and ulna can be analyzed simultaneously using the same video, c) strain patterns can be studied in various regions of interest in either or both bones, and d) the medial and lateral strains in the forearm can be quantified simultaneously. At a magnification of 2x, the strain magnitudes were -3894 ± 1485 με in the medial ulna, 2642 ± 551 με in the lateral ulna,-2772 ± 507 με in the medial radius, and 1841 ± 191 με in the lateral radius. As the camera lens magnification increased to 3x and 4x, the strain magnitudes measured in the same region were higher in the lateral ulna (1.6x and 1.1x), lateral radius (1.7x and 1.8x), and medial radius (1.1x and 1.4x). Conversely, the medial ulna exhibited lower strain magnitudes (0.94x and 0.94x) with increasing magnification. This change is attributed to the increased sensitivity of the displacement magnitudes and consequently the strain magnitudes. This DIC method can be extended to in vivo testing to facilitate quantification of in situ strains and to avoid the calibrations required using existing ex vivo techniques. The eventual goal of this project is to use this data to build FE models to map macro strains on the bone surface and use them to build micro FE models that map actual locations of osteocytes to explain osteocyte activation in response to loading.

Endoplasmic Reticulum Calcium Handling in Osteocyte Mechanobiology. Genevieve Brown*[1], X. Edward Guo[2]. [1]Columbia University, USA, [2]Columbia University, USA

Osteocytes (OCY) exhibit spike-like oscillations in cytosolic calcium (Ca^{2+}) in response to mechanical stimuli both *in vitro* and *ex vivo*, whereas osteoblasts (OB) demonstrate fewer, weaker responses [Lu 2012; Jing 2014]. Previous work demonstrated the initial response of both cells relied on extracellular Ca^{2+}, while inhibitor studies implicated release of Ca^{2+} from endoplasmic reticulum (ER) stores as being critical to subsequent responses. Depletion of ER stores by thapsigargin or interruption of purinergic signaling all effectively abolished the multiple Ca^{2+} responses of OCY. Thus, it is possible the mechanisms of Ca^{2+} release and reuptake by the ER are important to OCY mechanobiology.

We sought to visualize the dynamics of Ca^{2+} signaling within bone cells under fluid flow by simultaneously monitoring Ca^{2+} separately in the cytosolic ($[Ca^{2+}]_{cyt}$) and endoplasmic ($[Ca^{2+}]_{ER}$) spaces using the cytosolic calcium indicator Fura Red and the ER-localized cameleon FRET biosensor D1ER, respectively [Palmer 2004]. In OCY, elevations of $[Ca^{2+}]_{cyt}$ coincided with depression of $[Ca^{2+}]_{ER}$, with subsequent peaks occurring after recovery of $[Ca^{2+}]_{ER}$ levels (Fig. 1A). In OB, only a single $[Ca^{2+}]_{cyt}$ response was observed, and while the ER contributed to this response, it did not refill in the time course of the experiment (Fig. 1B). Previous studies also implicated T-type voltage sensitive channels (VSCC) in regulating OCY Ca^{2+} oscillations. We explored the interaction between T-type VSCC and ER stores by treating OCY and OB with the inhibitor NNC 55-0396 prior to depleting the ER with thapsigargin (Fig. 2A). In OB, T-type inhibition had no effect on the depletion characteristics of the ER, consistent with its limited role in OB Ca^{2+} signaling. In OCY, treatment with the T-type inhibitor caused the ER to deplete faster than untreated controls, suggesting T-type channels are involved in ER Ca^{2+} release. Under flow, OCY pretreated with the inhibitor demonstrated fewer $[Ca^{2+}]_{cyt}$ spikes, corresponding to delayed recovery of $[Ca^{2+}]_{ER}$ (Fig. 2B).

These studies demonstrate the ER is more intimately involved in OCY calcium signaling than previously considered and support the hypothesis that OCY are capable of generating characteristic multiple responses by an ability to refill the ER stores. Future studies will further explore the role of VSCC and other channels on release and reuptake dynamics of ER Ca^{2+} trafficking in OCY, which may contribute to their mechanobiological function.

Polycystin-1 Mediates Mechanical Strain-Induced Osteoblastic Mechanoresponses via Potentiation of Intracellular Calcium and Akt/β-Catenin Pathway. Hua Wang*[1], Wen Sun[2], Junqing Ma[3], Yongchu Pan[3], Lin Wang[3], Wei-Bing Zhang[4]. [1]Institute of Stomatology, Nanjing Medical University, Peoples Republic of China, [2]Nanjing Medical UniversityThe Research Center for Bone & Stem Cells, Peoples Republic of China, [3]Institute of Stomatology, Nanjing Medical University, China, [4]School of Stomatology, Nanjing Medical University, Nanjing, China, USA

Mechanical regulation of bone formation involves a complex biophysical process, yet the underlying mechanisms remain poorly understood. Polycystin-1 (PC1) is postulated to function as a mechanosensory molecule mediating mechanical signal transduction in renal epithelial cells. To investigate the involvement of PC1 in mechanical strain-induced signaling cascades controlling osteogenesis, PKD1 gene was stably silenced in osteoblastic cell line MC3T3-E1 by using lentivirus-mediated shRNA technology. Here, our findings showed that mechanical tensile strain sufficiently enhanced osteogenic gene expressions and osteoblastic proliferation. However, PC1 deficiency resulted in the loss of the ability to sense external mechanical stimuli thereby promoting osteoblastic osteogenesis and proliferation. The signal pathways implicated in this process were intracellular calcium and Akt/β-catenin pathway. The basal levels of intracellular calcium, phospho-Akt, phospho-GSK-3β and nuclear accumulation of active β-catenin were significantly attenuated in PC1

deficient osteoblasts. In addition, PC1 deficiency impaired mechanical strain-induced potentiation of intracellular calcium, and activation of Akt-dependent and Wnt/β-catenin pathways, which was able to be partially reversed by calcium ionophore A23187 treatment. Furthermore, applications of LiCl or A23187 in PC1 deficient osteoblasts could promote osteoblastic differentiation and proliferation under mechanical strain conditions. Therefore, our results demonstrated that osteoblasts require mechanosensory molecule PC1 to adapt to external mechanical tensile strain thereby inducing osteoblastic mechanoresponse, partially through the potentiation of intracellular calcium and downstream Akt/β-catenin signaling pathway.

Examining the Effects of Migration on Bone Quantity and Microarchitecture in Migratory Landbirds. Maria Squire*[1], Robert Smith[2], Jennifer Owen[3]. [1]Department of Biology, The University of Scranton, USA, [2]The University of Scranton, USA, [3]Michigan State University, USA

Bone is a dynamic tissue and continuously remodels its structure in response to changes in mechanical loading. For example, it is well established that when chickens are exposed to increased mechanical loading, bone quantity increases significantly within a few weeks. What happens in the bones of migratory landbirds, who as part of the annual cycle increase mechanical loading on their wing bones as they fly thousands of miles during both spring and fall migration, is not well characterized. In the current study we examined how the events associated with migration may have affected the quantity and microarchitecture of bone in Veery (*Catharus fuscescens*) and Wood Thrush (*Hylocichla mustelina*). We used high-resolution (10 μm) micro-computed tomography scanning to examine trabecular bone in the proximal humeri. Specifically, birds from both species were collected during spring migration (in LA), on the breeding grounds (in PA), and during fall migration (in AL). The parameters measured included trabecular bone volume fraction (BV/TV), trabecular thickness (TbTh), and tissue mineral density (TMD). The results suggest a trend towards greater BV/TV in AL Veerys as compared to LA (+23%) and PA (+26%), though the differences were not statistically significant. AL Veerys had 17% and 20% greater TbTh ($p=0.05$ and $p<0.02$, respectively) but 17% and 21% less TMD ($p<0.01$ each) as compared to LA and PA, respectively. For Wood Thrush, again the results suggest a trend toward greater BV/TV in AL birds as compared to LA (+10%) and PA (+13%), though not statistically significant. Additionally, AL Wood Thrush had 26% greater TbTh but 9% less TMD as compared to the LA ($p<0.02$ and $p=0.05$, respectively), and 16% greater TbTh and 8% less TMD in comparison to the PA ($p=0.07$ and $p=0.09$, respectively). Analysis of the effects of migration on cortical bone in the mid-diaphysis of the humerus in these birds is on going. Importantly, the current data suggest that, despite no change or a potential increase in bone volume fraction, birds from both species have less mineralized bone during fall migration. Consequently, we hypothesize that the events associated with fall migration increase bone quantity but also have a detrimental effect on degree of mineralization. Additional work is needed to examine a larger sample size in order to gain further insight into the mechanisms influencing changes in bone quantity and microarchitecture associated with migratory events in these birds.

Mechanical Vibration Potentializes the Effect of Estrogen Hormone Replacement Therapy in Osteopenic Females Mice. Márcio Moura Moura*[1], Marise Lazaretti Castro[2], Helena Bonciani Nader[2], Ana Paula Mayumi Kawachi[2], Keico Okino Nonaka[3], Rejane Reginato[4]. [1]Luis Alves MouraAna lina de Almeida Moura, Brazil, [2]Federal University of São Paulo, Brazil, [3]Federal University of São Carlos, Brazil, [4]UNIFESP - Federal University of São Paulo, Brazil

Hormone replacement therapy is used to prevent bone loss during menopause. However, it is unknown whether this therapy can be enhanced when associated with mechanical vibration. The aim of this study was investigate the effects of estrogen hormone replacement therapy associated with low-intensity and high-frequency mechanical vibration on bone tissue of osteopenic female mice. Fifty, 3-month-old female Swiss mice were ovariectomized (OVX) or sham-operated (Sham). After 4 months, the animals were randomly separated into five groups (n=10): GI (Sham); GII (control) - OVX and treated only with vehicle solution (sunflower oil subcutaneously injected-7 days a week); GIII - OVX and submitted to mechanical vibration 60 Hz with acceleration of 0.6g for 60 days (30 min/day, 5 days/week) plus vehicle solution (7 days/week); GIV - OVX and treated with 10 μg/kg/day of 17β-estradiol subcutaneously injected (7 days/week); GV - OVX and submitted to mechanical vibration 60 Hz/0.6g for 60 days (30 min/day, 5 days/week) and treated with 10 μg/kg/day of 17β-estradiol subcutaneously injected (7 days/week). Bone mineral density (BMD) was performed before the ovariectomy, 120 days after OVX and at the end of the treatment. The animals were euthanized and femora were collected for the following analysis: histomorphometry, biochemistry, TRAP, Picro-Sirius red, immunohistochemical for caspase-3 and calcium quantification. The results showed that all groups increased BMD compared to GII. Trabecular bone area was increased in GIV and GV, but there was no difference in the cortical bone thickness. The highest concentration of hyaluronic acid and condroitin sulfate was observed in GV. Furthermore, GV exhibited the highest number of osteoclasts and intense greenish birefringence of collagen fibers on the cortical and cancellous bone. On the other hand, the number of osteocytes positive for caspase-3 decreased in GV, as revealed by immunohistochemistry. In addition, the group that received the combined therapy was the only one that showed calcium concentration similar to the sham group. Taken together, our results indicate that mechanical vibration potentiates the estrogen hormone replacement therapy by accelerate the bone remodeling process. The combined treatment demonstrated positive effect on bone tissue constituents, improving bone microarchitecture and bone mineral density, as well modifying the profile of glycosaminoglycans and collagen on bone tissue of osteopenic female mice.

Research of bone mass change by PTH administration to OPN-KO mice neurectomy. Takayuki Yamada*[1], Yoichi Ezura[2], Tadayoshi Hayata[3], Kiyoshi Harada[4], Masaki Noda[1]. [1]Tokyo Medical & Dental University, Japan, [2]Tokyo Medical & Dental University, Medical Research Insititute, Japan, [3]Organization for Educational Initiatives, University of Tsukuba, Japan, [4]Tokyo Medical & Dental University, Japan

Mechanical stimulations, the exercise or gravity from the earth, are known as a factors to maintain bone mass. In environments, such as bedridden state or flight to the space, bone mass decreases.

Osteopontin (OPN) is necessary for unloading induced enhancement of bone resorption and suppression of bone formation in vivo. OPN plays a key role in conveying the effect of mechanical stress to osteoclasts and osteoblasts.

In addition, it has been reported that the sympathetic nervous system is the dominant, bone loss is induced. However, molecular mechanisms of bone metabolic are not completely known.

Currently, about 13 million people are suffering from osteoporosis in Japan.

In the case of elderly people, especially woman, the risk of becoming bedridden due to lumbar fracture is high. Parathyroid hormone (PTH) is one of the bone anabolic drug.

Thus, we performed neurectomy to OPN-KO mice, and made an unloading condition. Then we researched bone mass and changes of bone metabolic markers by PTH administration.

We used Male wild-type and OPN-KO mice in a C57BL/6J background (17 week old). They were performed neurectomy to right legs and sham surgery to left legs for 4 weeks. During unloading condition, we administrated PTH (80 μg/kg) or Vehicle 5 times per week.

There was no change in body weight and tibiae length by Neurectomy, We found that neurectomy induced decreasing of bone mineral density (BMD) in wild type tibiae, but PTH administration suppressed it mildly. However, in the absence of OPN, changes in BMD due to PTH and neurectomy was not observed BV/TV changed in a similar manner with BMD.

In mineralized nodule formation, there was no difference by Neurectomy, but PTH promoted mineralization in wild type.

These data suggest that a apossible interaction between neurectomy, OPN and PTH regarding maintenance of bone mass.

Loss of N-cadherin in Osteoblasts Enhances the Osteo-Anabolic Effects of Lrp5/6 Signaling. Cynthia Brecks*[1], Valerie Salazar[2], Susan Grimston[3], Leila Revollo[4], Marcus Watkins[3], Gabriel Mbalaviele[3], Roberto Civitelli[3]. [1]Washington University In St Louis, USA, [2]Harvard School of Dental Medicine, USA, [3]Washington University in St. Louis School of Medicine, USA, [4]Washington UniversityDivision of Bone & Mineral Diseases, USA

It has been shown that N-cadherin negatively regulates canonical Wnt/β-catenin signaling in osteoblasts through physical interaction with low density lipoprotein receptor-related protein-5 or 6 (Lrp5/6) and Axin. To understand the biological significance of this function of N-cadherin, we tested in vivo whether loss of the

N-cadherin gene (*Cdh2*) alters the ability of osteogenic cells to build bone in response to Lrp5/6 signaling. First, we activated Lrp5/6 in vivo by systemic administration of a Dickkopf-1 (Dkk1) neutralizing antibody (αDkk1) to mice with osteoblast-specific *Cdh2* ablation driven by the 2.3 *Col1A1* promoter (*Col1-Cdh2* cKO). At the dose of 20 mg/kg i.p., 3 times/week for 4 weeks, αDkk1 increased trabecular bone volume/total volume (BV/TV; by μCT) in both wild type (WT) and *Col1-Cdh2* cKO mice (0.536 ± 0.130 vs. 0.475 ± 0.117% at study end; $p>0.10$). However, a 4-fold lower dose of the antibody (5 mg/kg) was ineffective in WT mice, but resulted in a 2-fold increase of BV/TV (0.496 ± 0.085% at study end; $p<0.01$ vs. baseline) in *Col-Cdh2* cKO mice. αDkk1 increased cortical thickness and dynamic indices of bone formation in both genotypes, without affecting bone resorption. In a second study, we induced high bone mass (HBM) by using *Osx1-Cre* to activate a Dkk1-resistant $Lrp5^{A214V}$ allele, and evaluated whether HBM was affected by compound conditional ablation of *Cdh2*. Consistent with increased anabolic response of *Col1-Cdh2* mice to αDkk1, BV/TV was higher in $Lrp5^{A214V}$;*Cdh2* double mutants relative to $Lrp5^{A214V}$ HBM mice. At the molecular level, bone marrow stromal cells (BMSCs) from *Col1-Cdh2* cKO mice expressed higher Lrp5, but not Lrp6 mRNA relative to WT BMSCs. Immunoblot analysis revealed Lrp5 and b-catenin proteins were more abundant in *Cdh2-cKO* versus WT BMSCs. And *Col1-Cdh2* cKO mice injected with a single dose of αDkk1 exhibited accelerated accumulation of β-catenin in bone relative to WT mice. In summary, our results demonstrate that mice lacking osteoblast *Cdh2* are hyper-responsive to bone anabolic effects of antibody-mediated Dkk1 inhibition or Lrp5 gain-of-function mutation, and suggest *Cdh2*-deficient osteoblasts are primed to respond to canonical Wnt signaling, most likely because of increased Lrp5 and b-catenin levels. These observations provide supporting evidence and assign biological significance with a skeletal outcome to a previously proposed model where N-cadherin negatively regulates Lrp5/6 signaling.

The bone anabolic potential of canonical WNT signaling requires epigenetic priming of endogenous BMP2 production: *in vitro, in vivo* and *in silico* studies. Young dan cho*[1], Kyung mi woo[2], Jeong hwa baek[2], Young Ku[3], van Wijnen Andre J.[4], Hyun mo ryoo[2]. [1]Seoul National University, South Korea, [2]Department of Molecular Genetics, School of Dentistry, Seoul National University, South Korea, [3]Department of Periodontology, School of Dentistry, Seoul National University, South Korea, [4]Departments of Orthopedic Surgery & Biochemistry & Molecular Biology, Mayo Clinic, USA

Bone loss is treated with anti-resorptive therapeutics (e.g., bisphosphonates) that inhibit bone-degrading osteoclasts or anabolic drugs that stimulate bone-depositing osteoblasts (e.g., BMP2, teriparatide and antibody inhibition of WNT antagonists). Activation of the WNT pathway can enhance BMP2 signaling, but only in cells primed to become osteoblasts. We solve this observation by showing that the osteogenic potential of BMP2 is epigenetically blocked by CpG methylation of the BMP2 gene promoter in non-osteogenic cells (e.g., adipocytes and fibroblasts). Data with methylation PCR, ChIP assay and in silico analysis by Next Generation Sequencing (NGS) showed that hypomethylation of this promoter by DNA methyltransferase (DNMT) inhibitor or histone deacetylase (HDAC) inhibitor enables WNT3A stimulation of autocrine BMP2 production in the non-osteogenic cells. In addition, direct injection to the bone marrow of DNMT inhibitor and WNT3A increased bone mass in the yellow marrow of 15 month old mouse.

Taken together, absence of epigenetic barrier allows WNT mediated induction of tandemly arranged autocrine loops that sustain endogenous BMP2 production. These findings clarify the potent bone anabolic activities of new antibody-based drugs that block the WNT inhibitor sclerostin. Furthermore, our data indicate that modulation of CpG methylation permits direct programming of non-osteogenic cells into osteoblasts for bone tissue-engineering applications.

The flavonoid fisetin promotes osteoblasts differentiation through Runx2 transcriptional activity. Cedric Darie*[1], Laurent Léotoing[2]. [1], France, [2], France

Scope: Flavonoids represent a group of polyphenolic compounds commonly found in daily nutrition with proven health benefits. Among this group, the flavonol fisetin has been previously shown to protect bone by repressing osteoclast differentiation. In the present study, we investigated the role of fisetin in regulating osteoblasts physiology.

Methods and results: In vivo mice treated with LPSs exhibited osteoporosis features associated with a dramatic repression of osteoblast marker expression. In this model, inhibition of osteocalcin and type I collagen alpha 1 transcription was partially countered by a daily consumption of fisetin. Interestingly, in vitro, fisetin promoted both osteoblast alkaline phosphatase activity and mineralization process. To decipher how fisetin may exert its positive effect on osteoblastogenesis, we analyzed its ability to control the runt-related transcription factor 2 (Runx2), a key organizer in developing and maturing osteoblasts. While fisetin did not impact Runx2 mRNA and protein levels, it upregulated its transcriptional activity. Actually, fisetin stimulated the luciferase activity of a reporter plasmid driven by the osteocalcin gene promoter that contains Runx2 binding sites and promoted the mRNA expression of osteocalcin and type I collagen alpha 1 targets.

Conclusion: Bone sparing properties of fisetin also rely on its positive influence on osteoblast differentiation and activity.

Carbon-containing Polyhedral Boron-cluster Carborane BA321 acts on bone tissues as selective androgen receptor modulator (SARM). Tsukasa Tominari[1], Chiho Matsumoto[2], Michiko Hirata[3], Masaki Inada[2], Chisato Miyaura*[2]. [1]Tokyo University of Agriculture & Technology, Japan, [2]Tokyo University of Agriculture & Technology, Japan, [3]Tokyo University of Agriculture & Technology, Japan

Carboranes are a class of carbon-containing polyhedral boron-cluster compounds having exceptional hydrophobicity, and their features allow a new medical application as a biologically active molecule that interacts with steroid hormone receptors. We have reported carborane BE360 having carborane structure with two phenols, binds to estrogen receptor and exhibits estrogenic action in bone but not in uterus as selective estrogen receptor modulator (SERM). We have challenged to design new carborane compounds having high affinity with androgen receptor (AR) and synthesized them to search effective compounds for osteoporosis in the male as selective androgen receptor modulator (SARM). Among several carborane compounds, we noticed carborane compound BA321 as a putative AR antagonist, in which a benzene ring with electron-withdrawing group ($-NO_2$) and a hydroxyl group are placed at the opposite vertices of the hydrophobic carborane cage. In this study, we report that the effects of BA321 on bone tissues in the presence or absence of endogenous androgen in male mice. To examine the effects of BA321 on bone tissues in the absence of androgen, male mice were orchidectomized (ORX) and some of mice were treated with BA321 (10, 30 μg/day/mouse) subcutaneously for 4 weeks. ORX mice showed severe bone loss due to androgen deficiency measured by femoral BMD and three dimensional micro-CT, and the bone loss was completely recovered by the treatment with BA321. The weight of seminal vesicle, male sex organ, was reduced in ORX mice, and not influenced by the treatment of BA321. Therefore, BA321 did not exhibit androgenic action in sex organ whereas BA321 increased bone mass in the male mice. We further examined the effects of BA321 in the normal mice, with having endogenous androgen. When normal male mice were treated with BA321 (10, 30 μg/day/mouse) subcutaneously, BA321 significantly increased femoral BMD, and the weight of seminal vesicle was significantly suppressed. Therefore, BA321 binds to AR and acts on bone tissues as androgen and on sex organs as anti-androgen. Carborane BA321 may utilize to the treatment for osteoporosis in men as a SARM.

Combination Therapy with Ibandronate and Eldecalcitol Enhances Bone Strength with upregulation of minimodeling in Aged Ovariectomized Rats. Sadaoki Sakai*[1], Satoshi Takeda[2], Masanori Sugimoto[3], Masaru Shimizu[4], Koichi Endo[4]. [1]Chugai Pharmaceutical Co., Ltd., Japan, [2]Chugai Pharmaceutical Co., Ltd., Japan, [3]Taisho Pharmaceutical Co., Ltd, Japan, [4]Chugai Pharmaceutical Co., Ltd., Japan

Ibandronate (IBN), a nitrogen-containing bisphosphonate, and eldecalcitol (ELD), an active vitamin D_3 derivative, are used for osteoporosis treatment. Active vitamin D_3 derivatives have been often used in combination therapy, however, there are no reports on the effects of combined IBN and ELD treatment.

Eight-month-old Wistar-Imamichi rats were ovariectomized and treated for 12 weeks with either vehicle, IBN (3 μg/kg/4week), ELD (15 ng/kg/day), or a combination of IBN and ELD.

Urinary DPD (deoxypyridinolin) was higher in vehicle control group than sham operated group and recovered in each monotherapy group. The combination treatment showed further suppression in DPD compared to each monotherapy group. Serum osteocalcin was higher in vehicle treated group and there were no differences between in all therapy groups versus in the sham group.

Lumbar BMD was higher in the monotherapy groups than in the vehicle control group, and was higher in the combination group than in both monotherapy groups. A mechanical strength of lumbar was improved in monotherapy groups and in the combination group. The maximum load was higher in the combination group than in the IBN monotherapy group.

In femurs, BMD was increased in both monotherapy groups, and was higher in the combination therapy group than in both monotherapy groups. The maximum load of femurs was higher in the combination group than in the vehicle control group.

Bone histomorphometry analysis revealed that combination therapy result in additive effects on reduction of ES/BS in cancellous and endosteal cortical bone in femurs, but bone formation parameters such as MS/BS or BFR/BS were not less than sham level. To elucidate this uncoupling of combination effect on bone formation and resorption, we focused on "minimodeling". The minimodeling in lumbar spine was significantly higher in ELD group than vehicle treated group. The combination treatment with IBN and ELD showed additional effect on elevation of minimodeling than ELD alone group.

This study suggests the additive effects of IBN and ELD combination therapy on the mechanical strengths of the lumbar vertebrae and femur. These effects may be induced by increased BMD via reduction of bone resorption without severe suppression of bone formation. The effect of combination treatment on minimodeling may play a part in maintaining bone formation at sham level with additive effect on reduction of bone resorption.

OPG-Fc but not Zoledronic Acid Discontinuation Reverses Radiographic and Histologic Indices of Osteonecrosis of the Jaws (ONJ) in a Mouse Model.
Rafael De Molon*[1], Hiroaki Shimamoto[2], Olga Bezouglaia[2], Flavia Pirih[1], Sara Dry[3], Paul Kostenuik[4], Denise Dwyer[5], Rogely Waite Boyce[6], Tara Aghaloo[7], Sotirios Tetradis[7]. [1]UCLA School of Dentistry, USA, [2]UCLA School of Dentistry, USA, [3]UCLA School of Medicine, USA, [4]Amgen Inc., USA, [5]Amgen Inc, USA, [6]Amgen Inc, USA, [7]University of California, Los Angeles, USA

Osteonecrosis of the jaws (ONJ) is a significant complication of antiresorptive medications such as bisphosphonates and denosumab. Local risk factors include oral surgical procedures, dental infection, and poor-fitting dentures. Discontinuation of antiresorptives prior to tooth extraction to reduce ONJ risk or after ONJ occurrence to promote healing has been proposed, but is largely controversial. Here, we investigated whether antiresorptive discontinuation alters radiographic and histologic features of established ONJ in a mouse model employing high doses zoledronic acid (ZA) or OPG-Fc and periapical disease. Mice were pre-treated with veh, ZA or OPG-Fc for 3 weeks (wk), right mandibular molars were drilled to induce periapical infection and treatment continued for 8 wk. Then, antiresorptives were discontinued for 6 or 10 wk. Both agents significantly decreased TRACP-5b levels by 11 wk. TRACP-5b rose above baseline by 4-6 wk post-OPG-Fc withdrawal and returned to baseline by 10 wk. TRACP-5b progressively returned to baseline by 10 wk post-ZA withdrawal. μCT showed periapical bone loss, widening of the periodontal ligament (PDL) space, loss of lamina dura and thinning of the lingual cortical plate in the diseased site of veh group. OPG-Fc and ZA prevented these changes. After OPG-Fc discontinuation all μCT measurements were similar to the veh group. In contrast, ZA discontinuation did not alter μCT findings. TRAP staining showed increased osteoclast numbers in the disease site of veh animals. No TRAP+ cells were seen in the OPG-Fc group, while TRAP+ cells detached from the bone with pyknotic nuclei were noted in the ZA group. After OPG-Fc withdrawal, TRAP+ cell numbers rose above baseline at 6 wk and returned to baseline by 10 wk. No significant change in TRAP+ cell number was seen after ZA withdrawal. Epithelial to alveolar crest distance increased in the diseased site of veh animals, denoting bone loss. This distance was preserved in OPG-Fc and ZA animals. Additionally, empty osteocytic lacunae and areas of osteonecrosis were present in the diseased site of OPG-Fc and ZA but not veh animals, consistent with ONJ. OPG-Fc, but not ZA, discontinuation increased the epithelial-alveolar crest distance at 6 and 10 wk and decreased the number of empty osteocytic lacunae and osteonecrotic area by 10 wk. These data collectively demonstrate that OPG-Fc but not ZA discontinuation reverses radiographic and histologic features of osteonecrosis in a mouse ONJ model.

The inhibitory effect of zoledronate on early-stage osteoinduction by recombinant human bone morphogenetic protein 2 in an osteoporosis model.
Jae Hyup Lee*[1], Kyung Mee Lee[2], Hae-Ri Baek[2], Hyun-Kyung Lee[2]. [1]Seoul National University, College of Medicine, South Korea, [2]Department of Orthopedic Surgery, College of Medicine, Seoul National University, South Korea

This study aims to understand the effect of the combined treatment of zoledronic acid(ZA) and rhBMP-2 on osteogenesis in an osteoporosis model. Bone marrow-derived stem cells of osteoporosis patients were cultured and divided into the following groups: Control, Induction, B50 (rhBMP-2 50 ng), B100 (rhBMP-2 100 ng), ZA (ZA 10-7 M), ZB50 (rhBMP-2 50 ng+ZA 10-7 M), and ZB100 (rhBMP-2 100 ng+ZA 10-7 M). The cells were subjected to alkaline phosphatase (ALP) staining assay, an ALP activity assay, an Alizarin red (AR)-S staining assay, and RT-PCR to test the expression levels of ALP, runx-2, osteopontin (OPN), bone sialoprotein (BSP), and collagen genes. Ovariectomy was performed on SD rats, and a calvarial defect model was generated. The groups treated with rhBMP-2 and/or ZA showed a higher ALT activity than the Induction group, with no statistical significance, and the level was similar between the rhBMP-2 groups and the ZA+rhBMP-2 groups. Compared to the Control group, the other groups showed stronger ALP staining and AR-S staining. Using an ovariectomized rat calvarial defect model, the experimental animals were intravenously injected with either saline or 0.08mg/kg of ZA. Each treatment group was further subdivided based on rhBMP-2 5 μg treatment status. New bone formation was then evaluated 4 or 8 weeks after the treatments using micro-CT. The rhBMP-2 group showed a significantly higher calvarial defect coverage ratio compared to the ZA+rhBMP-2 group at both 4 and 8 weeks after the treatment, and the calvarial defect coverage ratio was significantly higher in the ZA+rhBMP-2 group than in the ZA group at 8 weeks. In addition, the ZA treatment lowered bone formation indices, such as the percent bone volume and trabecular number, and the trabecular thickness induced by rhBMP-2 after 4 weeks of treatment. Eight weeks of ZA treatment also decreased the trabecular thickness induced by rhBMP-2. The ZA+rhBMP-2 group showed significantly higher bone formation and bone quality compared to the ZA group. However, the initial bone formation and bone quality of the ZA+rhBMP-2 group were significantly lower compared to those of the rhBMP-2 group, and the negative effect induced by ZA treatment was alleviated as time passed. Thus, the combined application of rhBMP-2 and ZA significantly increased bone formation, but the initial bone formation was lower compared to the treatment with rhBMP-2 only.

BMP2 and ibandronate combination therapy improves bone healing during non-weight bearing treatment of ischemic osteonecrosis of the femoral head.
Olumide Aruwajoye*[1], Justin Du[2], Nobuhiro Kamiya[3], Harry Kim[4]. [1]Texas Scottish Rite Hospital, USA, [2]Texas Scottish Rite Hospital, USA, [3]Texas Scottish Rite Hospital for Children, USA, [4]Scottish Rite Hospital for Children, USA

Ischemic osteonecrosis of the femoral head in children (Perthes disease) results in a flattening deformity of the femoral head due to excessive resorption of the necrotic bone without accompanying new bone formation. The main goal of treatment is to prevent deformity of the femoral head. Our previous studies using a piglet model of ischemic osteonecrosis showed that local non-weight bearing (NWB) treatment prevented the flattening deformity by mechanically unloading the joint but was ineffective in preventing excessive bone resorption or in promoting new bone formation. Since a balance of bone resorption and formation determines net bone loss, we studied the effect of treatment with BMP2 and bisphosphonate (ibandronate) that may increase bone formation and decrease bone resorption respectively, during NWB treatment in piglets. In this study, the right femoral head was surgically induced with ischemia and an above knee amputation of the right hindlimb was performed to prevent weight bearing. The piglets received either NWB alone or NWB along with a single intra-osseous infusion of BMP2 (BMP) or BMP2+ibandronate (BMP+IB) in the femoral head 1-2 weeks post-ischemia induction. The non-operated left hindlimb was used as the control (n=6 piglets/group). NWB minimized flattening deformity of the femoral head in all groups at 8 weeks post-ischemia induction as observed by radiographic analysis. Furthermore, evaluation of the bone volume by microCT analysis revealed significantly higher bone volume in the BMP+IB vs BMP ($p<0.03$) or BMP+IB vs NWB groups ($p<0.001$), (BV/TV%: Control 16.9 ± 1.9, NWB 3.3 ± 1.7, BMP 11.8 ± 3.7, BMP+IB 19.7 ± 6.5). The mean trabecular number was also significantly higher in the BMP+IB group vs BMP or NWB group ($p<0.01$) (Tb.N/mm: Control 2.1 ± 0.2, NWB 0.4 ± 0.2, BMP 1.1 ± 0.6, BMP+IB 2.3 ± 0.7). The increase in bone volume due to treatment with BMP+IB was confirmed by histomorphometry. In addition, the number of osteoclasts were significantly lower in the BMP+IB vs NWB group ($p<0.01$) (N.Oc/BS/mm: Control 2.0 ± 0.8, NWB 4.7 ± 3.0, BMP 2.0 ± 1.4, BMP+IB 0.9 ± 0.6) while the mineral apposition rate and the bone formation rate were significantly increased in the BMP and BMP+IB groups compared to NWB group ($p<0.01$). These results suggest that the local administration of BMP2 and ibandronate increases the bone volume by increasing bone formation

and decreasing bone resorption thereby enhancing bone healing during NWB treatment ischemic osteonecrosis of femoral head.

Brain-Specific PTEN Deletion Induces Abnormal Skeletal Activity in Mice. Marjorie Thompson*[1], Philippe Huber[2], Gregory Smith[3], Andrew Holley[3], Steven Bain[4], Edith Gardiner[4], Joaquin Lugo[3], Ronald Kwon[4]. [1], USA, [2]University of Washington, USA, [3]Baylor University, USA, [4]University of Washington, USA

The broad association of epilepsy, autism, and related neurological disorders with dysfunctional bone metabolism [1] suggests a potential neural link between the cerebral cortex and bone that may underlie these deficits. In NS-Pten mice (neuronal subset-specific; Gfap-Cre;Pten$^{loxp/loxp}$), PTEN deletion induces an overactive PI3K-Akt-mTOR pathway, resulting in macrocephaly, hypertrophic cortical neurons, and epileptiform activity with persistent seizures [2]. In this study, we present evidence that brain-specific knockout of the PTEN gene induces abnormal bone metabolism in growing mice. 6wk NS-Pten mice exhibited forelimb clonus, spontaneous seizures, and hyperactivity in open field testing ($p<0.001$), as observed in previous studies [2,3]. NS-Pten mice also exhibited impaired motor learning, as indicated by decreased rotarod test performance ($p<0.001$). MicroCT analysis in 8wk NS-Pten mice (Fig 1) revealed increased total volume in the proximal tibia ($p<0.001$) and mid-diaphysis ($p<0.001$), respectively, while TMD was lower in both locations ($p<0.001$). Effects of PTEN deletion were localized and compartment specific, as evidenced by the lower trabecular bone volume in the proximal tibia ($p<0.05$) but higher cortical area (but normal cortical thickness) in the mid-diaphysis ($p<0.05$). NS-Pten mice were recently shown to exhibit decreased hippocampal levels of the Kv4.2 potassium channel [3], which is associated with increased neuron excitability and seizure susceptibility [4]. MicroCT analysis of Kv4.2 knockout mice revealed no significant bone phenotype, suggesting that decreased Kv4.2 is not sufficient to alter skeletal activity. Collectively, these studies identify diverse morphological and densitometric bone alterations in mice with brain-specific PTEN deletion that is not attributable to decreased physical activity (an etiological factor broadly ascribed to account for low bone mass in epilepsy patients). Given the association of brain-specific PTEN deletion with aberrant cortical brain activity, as well as the known influence of autonomic and sensory nerves on bone cell function, these studies provide an essential first step toward understanding the role of the cerebral cortex in the central regulation of bone metabolism.

Effects of Circulating Osteocalcin on Bone Remodelling. Tara Brennan-Speranza*[1], Katharina Blankenstein[2], Hong Zhou[3], Markus Seibel[3]. [1]University of Sydney, Australia, [2]Bone Research Program, ANZAC Research Institute, University of Sydney, Australia, [3]Bone Research Program, ANZAC Research Institute, University of Sydney, Australia

Aim: Osteocalcin (OCN) is a protein synthesized solely by osteoblasts. While circulating OCN may play a role in regulating glucose metabolism, its functional role in bone is unclear. As osteocalcin knock-out mice display increased bone formation[1], we hypothesized that an increase in circulating OCN would lead to decreased bone formation.

Methods: Using in-vivo gene therapy [2], we transfected a wild-type osteocalcin (wtOCN) or a mutant osteocalcin construct (mOCN) which cannot be carboxylated into hepatocytes of 7-week-old mice. Empty vector (EV) was used as control. Tibiae were harvested at d21 post-transfection for mCT, histomorphometry and gene expression analysis.

Results: Compared to EV, total serum OCN levels were increased by 30% (wtOCN) and 40% (mOCN) on d21. BV/TV decreased from $17.9\pm1.8\%$ in EV to $11.5\pm1.2\%$ and $9.4\pm1.1\%$ in wtOCN and mOCN receiving mice, respectively ($p<0.01$). While trabecular spacing was increased, trabecular number and cortical thickness were significantly decreased by both OCN vectors. Trabecular thickness was unchanged. Histomorphometry revealed that compared to EV controls, both osteoblast and osteoclast surfaces were significantly increased in wtOCN and mOCN vector receiving mice. Furthermore, hepatic expression of the mOCN vector was associated with significant increases in Runx2 (1.5-fold), osterix (2-fold), BMP-4 (1.5-fold increase), BMP-7 (1.7-fold increase) and osteocalcin (1.5-fold) mRNA expression. . RANKL mRNA expression was significantly increased in both OCN vector-receiving mice. OPG remained unchanged.

Conclusion: Increasing circulating osteocalcin via gene therapy is associated with bone loss and accelerated bone turnover in mice.

Enhanced fracture healing following selective abrogation of Runx3 in the perisoteum. Do Yu Soung[1], Vanessa Piccullio[1], Archana Sanjay[2], Marc Hansen[3], Hicham Drissi*[3]. [1]University of Connecticut Health Center, USA, [2]UCHC, USA, [3]University of Connecticut Health Center, USA

Fracture healing of long bones occurs through both endochondral and intramembranous ossification. The absence of the periosteum was shown to impair fracture callus formation, rendering this source of progenitor cells necessary for the healing process. We previously demonstrated a role for the Runx family member of transcription factors, Runx1 in mediating chondrogenic differentiation during development and soft callus formation. Additionally, the Runx1 homologue, Runx3 was shown to mediate early and late stages of chondrocyte differentiation in vitro. However, the role of Runx3 during skeletal development is understudied and its function in bone repair remains unknown. We crossed Runx3 floxed mice (Runx3F/F) withPrx1-Cre transgenic mice to generate mice in which Runx3 was conditionally abrogated Runx3 expression in mesenchymal progenitors (Prx1-Cre;Runx3F/F). While Runx3 was not necessary for normal limb development, periosteal cultures from Prx1-Cre;Runx3F/F revealed decreased Runx3 expression, which was concomitant with decreased markers of

chondrogenic differentiation. However, bone mineral density of femurs harvested from these mice was enhanced as measured by DEXA scanning.

To examine if Runx3 plays a role during bone repair, we performed femoral fracture in Prx1-Cre;Runx3F/F mutants. Mice with 100% Runx3 activity (Runx3F/+) were used as controls. Radiographic analyses of the fractured bones showed smaller calluses during bone repair in the Prx1-Cre;Runx3F/F mutants. Histological and histomorphometric analyses revealed that Prx1-Cre; Runx3F/F calluses contained significantly reduced amounts of cartilaginous tissue at day 7 post-fracture compared to Runx3F/+. However, bone tissue content was also increased in Prx1-Cre; Runx3F/F at day 21 post-fracture. Gene expression of chondrogenic and osteogenic markers using RNA extracted from callus tissue harvested by laser capture microdissection confirmed these findings. Further examination of histological sections from fractured limbs showed that osteoblast surface over bone surface was enhanced at day 21 while the number of osteoclasts remained unchanged between both genotypes. Conditional deletion of both Runx1 and Runx3 revealed dose-dependent decrease of cartilage in early calluses of fractured bones. The data indicate that selective abrogation of Runx3 in periosteal progenitor cells results in accelerated fracture healing and suggest a redundant function between Runx1 and Runx3 in early fracture repair.

Lead Induced Differences in Bone Properties in Osteocalcin +/+ and -/- Female Mice. Terry Dowd*[1], Adele Boskey[2], Caren Gundberg[3], Marjolein Van Der Meulen[4], Olga Berezovska[5]. [1]Brooklyn College of the City University of New York, USA, [2]Hospital for Special Surgery, USA, [3]Yale University School of Medicine, USA, [4]Cornell University, USA, [5]Department of Chemsitry Brooklyn College, USA

Introduction: Lead (Pb) toxicity is a major health problem in children and older adults. Bone is the major reservoir for Pb and serves as an endogenous source of exposure. We have shown in mature female mouse femora that Pb has detrimental effects on bone mineral properties ((Bone 47:888 2010). Osteocalcin (OC) has been reported to inhibit bone formation (Nature 382:448, 1996) and to impair remodeling (Bone 23:187, 1998)) while Pb has been shown to increase bone turnover. Purpose: To determine whether OC plays a role in the detrimental effects of Pb on bone by comparing bones from Pb sufficient and Pb deficient OC +/+ and OC -/- mice. Methods: Two month old female OC +/+ and OC-/- mice, generously provided by G. Karsenty, were exposed to Pb in the drinking water (0 or 250 ppm, blood Pb of 20 μg/dl) for 4 months. Bone mineral properties from 6 mo old femora were assessed by Fourier Transform Infrared Imaging (FTIRI), Micro-computed tomography (uCT), bone biomechanical measurements and serum turnover markers (P1NP, CTX). Results: As in previous studies, the turnover markers in OC-/- mice showed a significantly higher bone formation rate and no change in bone resorption vs +/+ mice. Lead significantly enhanced formation in both -/- and +/+ mice and resorption in +/+ mice, with a trend toward an increase in -/- mice. A significantly lower mineral to matrix ratio was seen in the Pb-free -/- mice compared to +/+ mice, suggesting increased matrix retention in OC -/- bones. This was supported by a decrease in cortical bone stiffness in both Pb-free and Pb exposed -/- mice but not in +/+ mice . There was increased mineral to matrix ratio and crystal size in Pb treated -/- mice compared to untreated -/- mice, both of which are consistent with increased resorption. In contrast to +/+ mice, Pb increased cortical thickness, bone mineral density and decreased stiffness in cortical bones of -/- mice Conclusions: These results suggest that osteocalcin, through regulation of formation and resorption plays a role in the detrimental effects of Pb by increasing turnover, leading to decreased cortical thickness, BV/TV and increased marrow area/total area. This study sheds light on the molecular mechanism of Pb toxicity in bone and on the function of osteocalcin.

Muramyl dipeptide enhances Lipopolysaccharide-induced osteoclast formation and bone resorption by enhance of RANKL expression. Masahiko Ishida*[1], Hideki Kitaura[2], Keisuke Kimura[3], Jafari Saeed[4], Haruki Sugisawa[5], Haruhiko Takada[6], Teruko Takano-Yamamoto[7]. [1]Tohoku UniversityGraduate School of Dentistry, Japan, [2]Tohoku University, Japan, [3]Tohoku university, Japan, [4]Tohoku University Graduate School of Dentistry, Japan, [5] Tohoku University, Japan, [6]Tohoku University, Japan, [7]Tohoku University, Japan

Lipopolysaccharide (LPS) is a major component of cell wall of gram-negative bacteria that is able to induced osteoclast formation and pathological bone resorption. In addition, peptidoglycan is also a major component of cell membrane of gram-negative and gram-positive bacteria. Muramyl dipeptide (MDP) is the minimal essential structural unit responsible for the immunoadjuvant activity of peptidoglycans. It has also been reported that MDP synergistically enhanced LPS-induced proinflammatory cytokine production in human monocyte cells. In this study, we investigated that effect of MDP in LPS-induced osteoclast formation and bone-resorption. C57BL6/J mice were injected LPS, with or without MDP into supracalvariae. Animals were sacrificed, and fixation and demineralization were performed. Histological sections of calvaria were stained for tartrate-resistant acid phosphatase (TRAP), and osteoclast numbers were determined. The expression levels of mRNA for cathepsin K and TRAP in mice calvariae were quantified by real-time PCR. The number of osteoclasts and the level of mRNA for cathepsin K and TRAP in mice administrated both LPS and MDP were higher than that in mice administrated only LPS or MDP. The level of tartrate-resistant acid phosphatase form 5b (TRACP5b), as a marker of bone resorption, in mice administrated both LPS and MDP was also higher. Microfocal computed tomography was used to clarify the bone resorption pit in the calvariae. The ratio of the bone destraction area in the LPS and MDP administrated group was significantly higher than that in only LPS or MDP administrated group. Furthermore, LPS induced RANKL expression in the part of injection. MDP also enhanced LPS-induced RANKL expression in vivo and enhanced expression of RANKL in LPS activated stromal cell in vitro. Moreover, LPS induced TLR4, which is LPS receptor, expression and MDP enhanced LPS-induced TLR4 expression in vivo. Parathyroid hormone (PTH) was administrated with or without MDP. PTH induced osteoclast formation. However, MDP did not affect to PTH-induced osteoclast formation. These results suggested that MDP might enhance LPS-induced osteoclast formation through RANKL expression.

Scleraxis modulates fracture healing and callus formation. Megan L Killian*[1], Jennifer A McKenzie[2], Evan G Buettmann[2], Benjamin D Havelka[3], Matthew J Silva[2], Michael J Gardner[2]. [1], USA, [2]Washington University School of Medicine, USA, [3]Saint Louis University, USA

Scleraxis (Scx) is an important transcription factor for the development of tendons and has been identified as a modulator of bone morphogenetic protein-4 (BMP-4) during bone modeling (e.g., bone ridge formation) [1]. Periosteal colocalization of Scx- and Sox-9-positive progenitors, regulated by TGF-β, segregates tendon attachment units from bone during skeletogenesis [2]. While downstream factors of Scx, such as BMPs, are important for fracture healing, the role of Scx in fracture healing has not been explored. We hypothesized that Scx is upregulated during fracture healing, with its expression localized to the callus, and that loss of Scx in limbs would impair fracture healing.

Wildtype (C57BL6 WT with or without ScxGFP; N=8) and conditional knockouts (cKO: PRX1 Cre, Scx-floxed, N=10) were generated [3] and closed unilateral fractures were created and fixed in right femurs [4]. Five cKO mice had irreparable fractures and were immediately sacrificed. Left cKO femurs had greater mineral density (1136±56 mgHA/cm^3) than WT femurs (1046±38 mgHA/cm^3) but WT and cKO femurs were of comparable size. In WT mice, Scx was upregulated (p=0.04) and BMP-4 was downregulated (p=0.001) at 24hr post-fracture compared to contralateral limbs (2^-deltaCT, 18s ref; N=5, paired t-test). ScxGFP expression was localized to WT callus at 2wk post-fracture. While WT fracture healed well by 2wk (Fig1A-B'), cKO fracture healed non-uniformly (Fig1D-E'). Callus organization was impaired in cKO fracture (Fig1F) compared to WT fracture (Fig1C). cKO callus volume was smaller (11.0±4 mm^3) compared to WT mice (17.5±3 mm^3, p=0.07), and cKO mice had lower callus density (Fig 1E', 229±15 mg HA/cm^3) than WT mice (260±23 mg HA/cm^3, p=0.06).

This is the first study to demonstrate the role of Scx in fracture healing. Previously, others have identified contributions of Sox9+ periosteal cells in soft callus formation [5]. It is possible that Scx- and Sox9-expressing cells coordinate during the fracture healing process, as they do in development, and that both factors are required for robust callus formation. Future work is needed to identify 1) time course of fracture healing without Scx expression and 2) downstream and coordinated molecular cues, mediated by Scx, whose function(s) in callus formation and mineralization may be pharmacologically recovered.

Serotonin Reuptake Inhibitors Inhibit Osteoclast Differentiation And Function Through A Serotonin-Independent And Nfatc1-Dependent Mechanism. María José Ortuño*, Patricia Ducy. Columbia University, USA

Selective Serotonin Reuptake Inhibitors (SSRIs) are a class of drugs widely used for a variety of psychiatric conditions and in a broad spectrum of patients. It is now clear that a long-term treatment with SSRIs can have deleterious consequence on bone mass through yet poorly understood mechanisms. In an effort to determine whether SSRIs exert any function on bone cells we treated mouse primary osteoblasts and osteoclasts with fluoxetine, one of the most frequently prescribed SSRI. To our surprise fluoxetine did not have any overt effect on osteoblasts. In contrast, even a low dose of fluoxetine impaired the differentiation and function of osteoclasts as determined by quantification of TRAP activity, cell fusion and bone resorbing ability. This inhibitory effect was observed with all SSRIs tested. That the SSRIs inhibition of osteoclast differentiation and function occurred to the same extent in osteoclasts derived from wild-type, Tph1-deficient, Tph2-deficient and 5Htt-deficient mice indicated that it is independent of the known effect of this drug on serotonin reuptake. To elucidate how fluoxetine could affect so profoundly osteoclast biology we then surveyed the expression of a large number of transcription factors in osteoclasts and found that Nfatc1 expression was regulated by fluoxetine. Consequently, the expression of all NFATC1 target genes tested including Cathepsin K, DC-STAMP, Clcn7 and Tcirg1 was decreased thus explaining the multifaceted inhibitory effect of fluoxetine on osteoclast biology.

Next, we extended these studies in vivo by treating wild-type mice with fluoxetine for different lengths of time. While long-term regimens elicited a bone loss, a shorter treatment caused an increase in bone mass due to an isolated decrease in bone resorption, thus confirming the observations made in cell culture. A gene expression analysis performed in the bones of these mice identified the same regulatory bases for this effect than the ones we defined in vitro. These studies provide a molecular explanation for the decrease in resorption parameters associated with a short exposure to SSRIs in young depressed patients.

Strontium ranelate leads to bone matrix modifications and increases bone formation in ovariectomized and osteopenic rats. Jenifer Campos*[1], Mariana Freitas[2], Keico Okino Nonaka[3], Helena Nader[4], Eduardo Katchburian[4], Marise Lazaretti-Castro[2], Rejane Reginato[5]. [1]Universidade Federal de São Paulo, Brazil, [2]Federal University of São Paulo, Brazil, [3]Federal University of São Carlos, Brazil, [4]UNIFESP, Brazil, [5]UNIFESP - Federal University of São Paulo, Brazil

Strontium ranelate (SrR) has been used for the treatment of severe osteoporosis in some countries. However, the effects of this drug on bone tissue constituents are still not entirely elucidated. We investigated the effects of different doses of strontium ranelate on bone tissue of osteopenic female rats. Thirty 6-month-old female Wistar rats were ovariectomized and after 3 months were randomly divided into 3 groups (n=10): GI (control) - gavage with water, GII - gavage with 300 mg/kg/day of SrR and GIII - gavage with 625 mg/kg/day of SrR for 90 days. The animals were submitted to DEXA analysis before and after the treatment. Next, the distal femora were processed for histomorphometry, picrosirius red, TUNEL and TRAP method, physical properties, mechanical resistance and quantification of glycosaminoglycans and calcium/phosphorus. Independently of the dose, the SrR administration modified the profile of some bone matrix components and increased cortical thickness. Sulfate chondroitin and phosphorus concentration decreased in all SrR-treated groups. Calcium quantification is significantly increased in GIII. Moreover, hyaluronic acid is highly concentrated in distal femora of GII when compared with GIII as revealed by ELISA test. There was a predominance of reddish birefringence in cortical bone of GIII whereas greenish birefringence was increased in GII when compared to others groups as evidenced by picrosirius red, suggesting that SrR acts on collagen maturation, in a dependent-dose fashion. The highest BMD was observed in GIII as evaluated by DEXA. In addition, GIII exhibited also the highest mechanical strength and BV/TA higher than GI. The number of TUNEL-positive osteocytes decreased in all treated groups compared to control, while the group that received the lower dosage had the highest number of TRAP-positive cells. Taken together, our findings show that strontium ranelate in the highest dose improve bone microarchitecture, modifying the bone matrix constituints, leading to increase bone strength and have mainly anabolic effect in bone tissue of ovariectomized and osteopenic rats.

The whole-body analysis employing RANKL -/- and OPG -/- medaka fish reveals the in vivo bone resorption system. Masahiro Chatani*[1], Yoshiro Takano[2], Takeshi Todo[3], Akira Kudo[1]. [1]Tokyo Institute of Technology, Japan, [2]Tokyo Medical & Dental University, Japan, [3]Osaka University, Japan

Introduction: Bones have a variety of shapes in the body for supporting various organs, mainly nerves and blood vessels. The bone shapes are regulated by osteoclasts that are bone resorptive cells. Osteoclast precursors express RANK (Receptor Activator of Nuclear Factor Kappa-B) which binds to RANKL (RANK Ligand) to differentiate osteoclasts, while OPG (osteoprotegerin) binds to RANKL to inhibit osteoclast differentiation. However, it is unclear how RANKL and OPG cooperatively regulate bone resorption in a whole body in vivo. We previously established the live imaging system using medaka fish, which allowed observations of osteoclast behavior in a whole body (Chatani et al., 2011).

Aim: To clarify the mechanism how RANKL and OPG regulate bone resorption in a whole body during development using medaka as an experimental model.

Methods: RANKL-deficient (RANKL -/-) medaka and OPG-deficient (OPG -/-) medaka were established by using the Tilling (Targeting induced local lesions in genomes) and TALEN (*Transcription activator-like effector nucleases*) method, respectively. RANKL was specifically overexpressed in osteoblasts by using the osterix promoter-RANKL-2A-GFP vector. Osteoclasts were live-imaged by using the TRAP promoter-fluorescein protein transgenic line. Bone tissues were stained by Alizarin Red or ALC (alizarin complexone).

Results:RANKL -/- medaka survived to adulthood and generated offspring, and we found existence of a few osteoclasts in this fish. Due to a smaller number of osteoclasts in RANKL -/- medaka, the diameter of neural and hemal canals in the vertebral column became narrower as it grew, resulting in abnormal organogenesis in later development. Next, using the osterix promoter, TRAP-DsRed positive osteoclasts were induced around RANKL positive osteoblasts. Whereas no osteoclasts existed on the vertebral body under the normal condition, in OPG -/- medaka, numerous osteoclasts were induced around the vertebral column, including the vertebral body (Figure 1). OPG -/- medaka showed a short body (littermate +/?; 9.7 $\pm$ 0.46 mm, -/-; 4.6 $\pm$ 0.29 mm total length, $p<0.0001$, n=13, 22-29 days after hatch), due mostly to resorption of the vertebral column (Figure 2).

Conclusion: Bone resorption in RANKL-/- medaka was not properly regulated during development because of dysfunction of osteoclasts. Osteoclast precursors were forced to differentiate to osteoclasts with overexpressed RANKL from osterix positive osteoblasts. Loss of OPG induced numerous osteoclasts that destroyed the vertebral body, accompanied with a defect of body growth. These data suggest that the numerous osteoclast progenitors exist around the whole skeletal system and determine the appropriate level of total bone resorption under the regulation of RANKL and OPG.

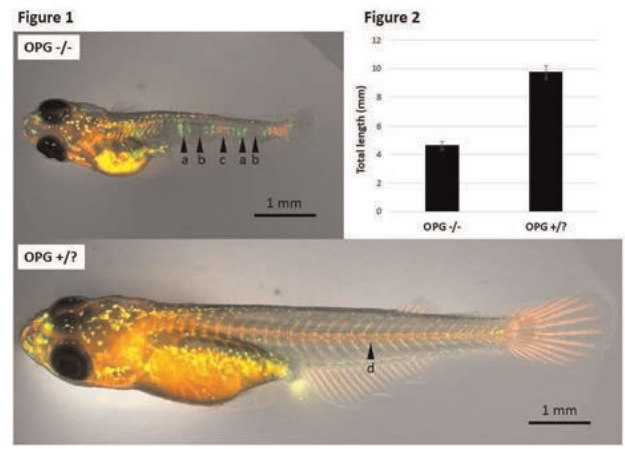

Figure 1. Whole images of OPG -/- and OPG +/? Medaka, crossed with TRAP-GFP transgenic line. Bone tissues were stained with ALC at days 23. Numerous osteoclasts (arrowhead a) completely resorbed the vertebral body in some areas, followed by the ALC negative regions (arrowhead b). There still remained some vertebral columns (arrowhead c). An arrowhead d shows the normal vertebral column.

Figure 2. Comparison of total body length between OPG -/- and OPG +/?. (littermate +/?; 9.7 ± 0.46 mm, -/-; 4.6 ± 0.29 mm, $p<0.0001$, n=13, 22-29 days after hatch)

A Longitudinal Study of Articular Cartilage and Subchondral Bone During Spontaneous Osteoarthritis in Dunkin-Hartley Guinea Pigs. Weiwei Zhao*[1], Ting Wang[2], Qiang Luo[3], Chunyi Wen[3], Haobo Pan[2], Songlin James Peng[4], KwongYuen Chiu[3], Xu Cao[5], William Lu[3]. [1]The University of Hong Kong, Hong Kong, [2]Centre for Human Tissues & Organs Degeneration, Shenzhen Institutes of Advanced Technology, Chinese Academy of Sciences, China, [3]Department of Orthopaedics & Traumatology, The University of Hong Kong, China, [4]Shenzhen People's Hospital, Jinan University School of Medicine, Peoples Republic of China, [5]Johns Hopkins University, USA

Osteoarthritis (OA) is a degenerative disease affected the whole joint. Current researches advocate the imbalance of adaptations between cartilage and subchondral bone contributes to the progression of osteoarthritis.The kinetics of the bone-cartilage unit during naturally-occurring OA in Dunkin-Hartley (DH) guinea pig has not been well characterized. The first aim of this study is to investigate the correlation between cartilage damage and sunbchondral bone alterations in DH guinea pigs. Besides, transforming growth factor-β (TGF-β) has been demonstrated as a potential treatment target for OA, however, the spatiotemporal alteration of TGF-β during spontaneous OA has not been studies. The second aim is to evaluate the role of TGF-β in subchondral bone of DH guinea pig.

Micro-CT and histological analysis were adopted to obtain the morphological parameters of subchondral bone and the grade of cartilage degeneration. Their correlation was analyzed by partial correlation test with age as controlling variance. The number of osteoprogenitors and the activity of TGF-β was measured through immunostaining of osterix and pSmad2/3.

There was a time lag between the increase of the bone mineral density and thickness of subchondral plate, whereas the bone volume fraction displayed an initial increase followed by a decline along with the elevation of the porosity. With age, the trabeculae increased in bone mineral density, volume fraction, thickness and became less connective and anisotropic. However, different alterative patterns of structure model index and trabecular pattern factor were found between the lateral and medial sides. The cartilage degeneration was purely correlated with the volume fraction (γ = 0.290, P = 0.021) and thickness (γ = 0.301, P = 0.017) of subchondral trabeculae. The number of osteoprogenitors was highest at 6 months and sharply decreased after then. Their distribution is heterogeneous, that the peripheric bone marrows own more while the central bone marrows own less. The spatiotemporal alteration of pSmad2/3+ cells follows the similar pattern.

This study indicated the abnormal micro-architecture changes of subchondral bone may influence its mechanical properties and the overlying cartilage. The similarity of the spatiotemporal alterations between osteoprogenitors and active TGF-β suggests TGF-β activity may affect the elevated bone formation during spontaneous OA in DH guinea pig.

Characterization of Skeletal Phenotype of Smurf2-Deficient Mice and the Potential Role of Smurf2-inhibition in Mitigating Osteoarthritis. Henry Huang*[1], Eric Veien[2], Hong Zhang[2], David Ayers[3], Jie Song[1]. [1]University of Massachusetts Medical School, USA, [2]University of Massachusetts Medical School, USA, [3]UMass Memorial Medical Center, USA

Background: Osteoarthritis (OA) is a degenerative joint disease leading to articular cartilage loss, osteophyte formation and subchondral bone thickening. OA is a leading cause of disability and is a significant socioeconomic burden. There is no effective disease modifying drugs for OA. Previously, it was shown that Smad ubiquitin regulatory factor (Smurf) 2 is expressed in human OA cartilage and that overexpression of Smurf2 in mouse chondrocytes leads to OA-like changes[1]. It is unclear whether Smurf2 is required for normal skeletal development or OA pathogenesis. Here we examined age-dependent skeletal phenotypes of Smurf2-deficient mice. We also compared changes in the joint of young, skeletally mature mice after surgical destabilization of the medial meniscus (DDM), an established model for OA[2].

Methods: A previously reported[3] C57BL/6 Smurf2-deficient MT and WT mice were used. Using microCT, we quantitatively compared femoral cortical bone and tibial subchondral bone of young (4 months) and old (18-22 months) male WT and MT mice (n=6). We also compared gender differences in the lumbar vertebrae between old mice (n=5). Using a semi-quantitative histology scoring system[4], Safranin O-stained femoral and tibial sections (⩾5) of each knee joint were blindly scored by 7 trained examiners. DMM surgery was carried out on 2-month old male WT and MT (n=13), and the cartilage and subchondral bone were examined 2 months post-op.

Results: No difference in cortical bone, trabecular bone or knee joint between WT and MT of a given age was detected. Age and gender-related changes such as trabecular bone loss and roughening of cartilage surface were comparable between genotypes. After DMM, 2/3 of WT developed moderate to severe OA (varying degrees of erosion from calcified cartilage down to subchondral bone), whereas majority of Smurf2 MT remained normal or developed mild OA (small superficial fibrillations with focal loss of proteoglycan staining), and only 1/3 exhibited moderate OA symptoms. Subchondral bone thickening after DMM was also detected, but no difference was detected between genotypes.

Conclusion: Smurf2 deficiency does not cause a detectable phenotypic change in skeletal tissues under normal development. However, under a pathological state such as DMM-induced OA, Smurf2 deficiency attenuated the severity of OA cartilage, suggesting a potential role of Smurf2 in modulating OA onset / progression or cartilage repair.

Hypoxia and vitamin D contribute to leptin and DKK2 production in human osteoarthritic subchondral bone osteoblasts. Béatrice Bouvard[1], Elie Abed*[2], Mélissa Yéléhé-Okouma[3], Arnaud Bianchi[4], Didier Mainard[5], Patrick Netter[5], Jean-Yves Jouzeau[5], Daniel Lajeunesse[6], Pascal Reboul[7]. [1]UMR 7365, CNRS-Université de Lorraine, IMoPA, France, France, [2]Crchum-hôpital Notre-dame, Canada, [3]UMR 7365, CNRS-Université de Lorraine, IMoPA, France, France, [4]UMR 7365, CNRS-Université de Lorraine, IMoPA, France, France, [5]Centre Hospitalier Universitaire, Nancy, France, France, [6]CRCHUM, Canada, [7]UHP Nancy 1 / CNRS UMR7561, France

Introduction: Bone remodelling and increased subchondral densification are important in Osteoarthritis (OA) pathology. Modifications of bone vascularisation parameters, which lead to ischemic episodes associated with hypoxic conditions, have been suspected to play a role in OA. Hypoxia drives several pathways in bone tissue such as growth and regeneration, and can lead to diseases. Among several factors potentially involved in OA pathogenesis, leptin and DKK2 are good candidates since they are produced by normal osteoblasts (Ob) and are up-regulated in OA Ob. The regulation of leptin expression by hypoxia seems to be cell specific- or cell environment- dependent in most tissues, whereas the regulation of DKK2 has not yet been described. Here, we investigated the hypothesis that hypoxia may be driving the expression of leptin and DKK2 in OA Ob. Methods: Human OA subchondral Ob from the sclerotic portion of the tibial plateaus was cultured either under 20% or 2% oxygen tension in the presence or not of VitD3. The expression of VEGF, Sirt1, TGF-β1, leptin, osteocalcin, DKK2, Hif-1α and -2 α was measured by qRT-PCR, and leptin production by ELISA. Gene expression was reduced using siRNA technique, and Hif-2α stabilization measured by WB. MAPK signaling was investigated using several inhibitors. Results: Hypoxia stimulated the expression of VEGF, Sirt1, TGF-β1, leptin and DKK2 expression in OA Ob. VitD3 stimulated leptin and DKK2 expression 2- and 4.2-fold under normoxia, and 28- and 6.2-fold under hypoxia. The hypoxia-induced leptin production was confirmed by ELISA, particularly in presence of VitD3. Silencing Hif-2α (siHif-2α),?inhibited VitD3-stimulated leptin mRNA and protein levels by 70% and 60% respectively, while it failed to significantly alter the expression of DKK2. SiHif-1α failed to alter the expression of either leptin or DKK2. Immunoblotting showed that VitD3 greatly stabilized Hif-2α at the protein level under hypoxic condition. The increase in leptin expression under hypoxia was also regulated, in addition to the role of Hif-2α, by p38 MAPK and PI-3 kinase. Finally, we evaluated if the expression of leptin and DKK2 were both related to each other under hypoxia. Silept under hypoxia had no effect on the expression of DKK2. Likewise, siDKK2 did not alter the expression of leptin. Conclusions: Hypoxic conditions trigger Ob to produce leptin particularly under VitD3 stimulation whereas DKK2 is mainly regulated by VitD3 rather than hypoxia

Inhibition of TGFb activity in Nucleus Pulposus Attenuate Disc Degeneration. Qin Bian*[1], Liwei Zheng[2], Xin Xu[2], Amit Jain[2], Khaled Kebaish[2], Gehua Zheng[2], Hui Xie[3], Janet Crane[4], Mei Wan[5], Paul Sponseller[2], zhengdong zhang[6], Edward Guo[6], Lee Riley[2], Yongjun Wang[7], Xu Cao[4]. [1], USA, [2]Johns Hopkins University, USA, [3]Johns Hopkins Medical Institution, USA, [4]Johns Hopkins University, USA, [5]Johns Hopkins University School of Medicine, USA, [6]Bone Bioengineering Laboratory, Columbia University, USA, [7]Othopedic Surgery, Peoples Republic of China

Degenerative disc disease (DDD) is a common cause of disability and functional limitation worldwide. Coordination of the activity of each component in the spine is essential in maintenance of disc homeostasis. However, little is known about how the notochordal cells maintain disc function and homeostasis in response to mechanical loading. We examined how altered mechanical loading in the spine leads to DDD using a spinal instability mouse model (SI) by resection of the L3-L5 spinous processes. Mid-sagittal images of ?CT scan revealed that the space between L4 and L5 vertebral bodies significantly narrowed in SI mice. 3D images of L4-5 endplates showed substantial decrease of disc space in SI. The spaces continued to decrease significantly from week 2 to 8 in SI mice. Both cranial and caudal endplates were significantly increased post-surgery with accelerated ossification of both cranial and caudal endplate. Endplates undergoes calcification and ossification in SI mice with significant increase of endplate score and Trap positive osteoclast numbers. Expansion and sclerosis of endplates in response to the alteration of mechanical loading decreased IVD space and may generate static compression force on disc contents. Temporal-spatial activation of latent TGFβ has been shown to maintain tissue homeostasis including bone and articular cartilage. We then examined the potential role of TGFβ in the notochordal cell morphologic changes and its potential contribution to disc degeneration with decreased IVD space. Phosphorylated Smad2/3 (pSmad2/3+) cells were significantly increased post-surgery and aggrecan expression was also increased. Furthermore, high protein levels of TGFβ1 were also observed in the discs from DDD patients. Importantly, neutralizing antibody against TGFβ was applied to an ex vivo IVD compression loading model. TGFβ?antibody inhibited loading-induced phosphorylation of Smad2/3 in notochordal cells and maintained their morphology relative to vehicle treatment. Finally, TGFβ type I receptor (TβRI) inhibitor (1 mg/kg) was systemically injected in the SI mice. As expected, pSmad2/3+ cells were reduced by TβRI inhibitor. Degeneration of IVD was prevented as assessed by IVD score and expression of aggrecan was maintained. Thus, narrowing of IVD space leads to aberrant activation of TGFβ and ultimately disc degeneration. Attenuation of activation of excess TGFβ may represent a therapeutic target for degenerative disc disease.

Intra-Articular Treatment with Recombinant Human Bone Morphogenetic Protein 7 (rhBMP-7) Attenuates the Development of Post-Traumatic Osteoarthritis in Rats. Jukka Morko*[1], Zhiqi Peng[1], Katja Fagerlund[1], Yvonne Konkol[2], Jukka Rissanen[1], Jenni Bernoulli[2], Jussi Halleen[3]. [1]Pharmatest Services Ltd, Finland, [2]Pharmatest Services Ltd, Finland, [3]Pharmatest Services Ltd, Fin

Recombinant human bone morphogenetic protein 7 (rhBMP-7) is a bone-inducing agent used in spinal fusions and during fracture repair in clinical practice. In knee joints, rhBMP-7 has been shown to attenuate the development of degenerative changes induced by anterior cruciate ligament transection in rabbits and by excessive running in rats and to repair cartilage damage in several species. In this study, we characterized the effects of intra-articular rhBMP-7 on the development of post-traumatic osteoarthritis (OA) in male Lewis rats. Unilateral OA was induced in rat knee joints by surgical medial meniscal tear (MMT) and medial collateral ligament transection (MCLT). Treatment was started one week after the operation and continued once a week for 5 weeks. Rats were treated intra-articularly with rhBMP-7 at 0.25 μg/wk or vehicle. Treatment effects on body weight, static weight bearing and static mechanical allodynia were followed during the study. After 6 post-surgery weeks, rats were terminated and treatment effects on knee joints were determined histologically following the recommendations of the OARSI histopathology initiative. Paw weight bearing and paw withdrawal threshold were decreased in operated hind limbs before the start of treatment indicating knee joint discomfort and pain. Intra-articular rhBMP-7 improved paw weight bearing and increased paw withdrawal threshold. Microscopic OA assessment demonstrated from mild to marked degenerative changes in the medial compartment of operated knee joints treated with vehicle. These changes included the loss of chondrocytes, proteoglycans and collagen matrix from superficial layer down to tidemark in medial tibial plateau and the presence of large osteophytes and moderate synovial inflammation. The loss of chondrocytes and collagen matrix was pronounced on the outer 1/3 of the plateau. Almost similar lesions were observed in the middle 1/3 and less severe lesions in the inner 1/3. From non-generation to marked degenerative changes were identified in the medial compartment of operated knee joints treated with rhBMP-7. The treatment attenuated the width of significant cartilage degeneration in medial tibial plateau and the severity of chondrocyte and collagen matrix lesions in the middle and inner 1/3 of the plateau. This study demonstrated a chondroprotective activity for intra-articular rhBMP-7 treatment in the rat MMT+MCLT model and supported the development of rhBMP-7 as a potent disease modifying OA drug.

The role of FoxA factors in the onset and development of Osteoarthritis. Andreia Ionescu*[1], Lin Xu[2], Elena Kozhemyakina[3], Klaus Kaestner[4], Yefu Li[2], Andrew Lassar[3]. [1]Harvard Medical School, USA, [2]HSDM, USA, [3]HMS, USA, [4]University of Pennsylvania, USA

We have recently identified FoxA transcription factors as key regulators of chondrocyte hypertrophy in the developing skeleton (Dev.Cell 22(5),2012).Therefore, we next asked whether the Fox A family is involved in the onset and development of osteoarthritis (OA) in the adult cartilage.To evaluate the expression of FoxA2 in postnatal articular cartilage, we employed a tamoxifen-inducible Cre driver knocked-into the 3' UTR of the FoxA2 gene. After crossing this mouse line into the ROSA26 reporter line, we observed that FoxA2 expression was highest in the knee and the femoral cap articular cartilage of one-month old animals, it precipitously declined at 3 months of age and remained at this low level through at least 1 year. To evaluate whether FoxA family members are necessary for cartilage degradation, we conditionally deleted FoxA2 in the articular cartilage of FoxA3 -/- mice, using a tamoxifen-inducible CRE recombinase driven by the Prg4 (Lubricin) regulatory sequences. Subsequently, we performed surgical destabilization of the medial meniscus on either the tamoxifen treated $Prg4^{CreERt2/+};FoxA2^{fl/fl};FoxA3^{-/-}$ mice or control *C57BL/6* animals. While the wild-type *C57BL/6* mice that have undergone surgery developed significant cartilage degradation (OARSI score 5.87 ± 0.12), the tamoxifen treated $Prg4^{CreERT2/+};FoxA2^{fl/fl};FoxA3^{-/-}$ mice showed very little sign of articular cartilage damage (OARSI score 1.45 ± 0.26). I next asked whether overexpression of FoxA2 in murine articular cartilage cells is sufficient to accelerate cartilage degradation. To drive exogenous FoxA2 expression in articular chondrocytes, I have generated mice containing the FoxA2 transgene driven by a reiterated reverse tetracycline transactivator (rtTA) response element (*TREtight-FoxA2*). This transgenic animal was in turn mated to a mouse containing rtTA knocked into the ROSA 26 locus downstream of a "floxed" STOP transcription cassette. Tissue specific expression of rtTA was achieved with the tamoxifen-inducible $Prg4^{CreERt2/+}$line. Control mice, lacking the FoxA2 transgene, that have undergone surgery developed mild symptoms of the disease (OARSI score 1.37 ± 0.33). In contrast, triple transgenic mice that have undergone surgery developed far more cartilage damage with more lesions on the articular cartilage (OARSI score 2.63 ± 0.43). These findings imply that the FoxA transcription factors are crucial regulators of osteoarthritis following surgically induced joint destabilization.

GPR40, a free fatty acid receptor, differentially impacts osteoblast behavior depending on differentiation stage and environment. Claire Philippe*. INRA, France

Scope: GPR40 is a free fatty acid receptor that has been recently shown to impact bone remodeling. This receptor protects skeleton by inhibiting bone resorbing osteoclast differentiation. Consistent with GPR40 expression on bone forming cells, we assumed that this receptor may also influence osteoblast activity.

Methods and results: To further investigate this hypothesis, biological effects of GW9508, a synthetic agonist for GPR40, was first tested on osteoblast differentiation

parameters. Assays were performed in two different cell models: the MC3T3-E1 osteoblastic cell line and primary bone marrow cultures extracted from *wild-type* and *GPR40 knock-out* mice. Both models showed a dual role of GPR40 on osteoblasts. Although receptor stimulation induced early stimulation of differentiation marker expression, it finally led to inhibition of mineralization process during late differentiation stages. To further elucidate this discrepancy, mice were ovariectomized to induce bone loss and received GPR40 agonist by gavage. Data revealed a weak influence of GPR40 agonist on osteoblast markers expression. Nevertheless, a significant increase in OPG expression was observed upon GW9508 treatment that contribute to explain the GPR40-related osteoporosis prevention.

Conclusion: To conclude, our results confirm the relevance of this new opportunity in the management of bone loss.

Possible role of RANKL-RANK signal in osteoblast differentiation. Midori Nakamura[1], Teruhito Yamashita[2], Yuko Nakamichi[1], Yuriko Furuya[3], Hisataka Yasuda[4], Nobuyuki Udagawa*[1]. [1]Matsumoto Dental University, Japan, [2]Matsumoto Dental University, Japan, [3]Oriental Yeast Co.,Ltd, Japan, [4]Oriental Yeast Company, Limited, Japan

A RANKL-binding peptide WP9QY (W9) is known to inhibit mouse osteoclastogenesis. In addition, W9 showed an anabolic effect on cortical bone in mice in vivo. W9 bound RANKL and differentiated osteoblasts with production of autocrine factors like BMP. In this experiment, effects of W9 on differentiation of osteoblasts and osteoclasts in mouse co-culture system of primary osteoblasts prepared from newborn mouse calvariae derived from RANKL-deficient or wild-type (WT) mice with WT-derived bone marrow mononuclear cells cultured in the presence of M-CSF for 24h. W9 strongly inhibited TRAP-positive multinucleated osteoclast formation as well as strikingly stimulated alkaline phosphatase (ALP)-positive osteoblast differentiation in the co-cultures of WT-derived osteoblasts and bone marrow cells in the presence of 1,25-dihydroxyvitamin D_3 or PTH. In contrast, RANKL-deficient osteoblasts had no osteoclastogenesis in co-cultures with bone marrow cells derived from WT mice in the presence of bone-resorbing factors. Importantly, W9 had weak activity of ALP-positive osteoblast differentiation in the co-cultures with RANKL-deficient osteoblasts even in the presence of W9, PTH or BMP-2. These experimental results indicate that W9 inhibited osteoclast formation via RANKL signaling in osteoblasts and directly stimulated osteoblast differentiation via RANKL signaling-mediated autocrine factors. Our findings suggest that the reverse signal from RANK on osteoclasts to RANKL on osteoblasts, and the forward signal from RANKL to RANK, could play an important role in the coupling between bone-formation and bone resorption.

The role of MACF1 in migration, proliferation and differentiation of preosteoblast and the screening of the natural antisense transcripts of MACF1. Airong Qian*[1], Lifang Hu[2], Yulong Sun[3], Dijie Li[2], Zhihao Chen[2], Peng Shang[4], Ge Zhang[5]. [1]Northwestern Polytechnical University, Peoples Republic of China, [2]Northwestern Polytechnical University, China, [3]Norhtwestern Polytechnical University, China, [4]Northwestern Polytechnical University, Peoples Republic of China, [5]Ge Zhang' S Lab, Hong Kong

Introduction: Microtubule-actin crosslinking factor 1 (MACF1), also referred to as actin cross-linking factor 7 (ACF7), is a member of plakin family. Based on previous studies, the role of MACF1 in osteoblast's function was investigated in this study. Moreover, the natural antisense transcripts (NATs) of MACF1 (MACF1-AS) were also screened.Materials and methods: MC3T3-E1 preosteoblasts were transfected with the recombinant lentivirus vector LV3-shRNA-MACF1 for knocking down MACF1 and cells transfected with the control recombinant lentivirus vector LV3-shRNA-NC was the negative control. After confirming the efficiency of LV3-shRNA-MACF1 and LV3-shRNA-NC by real time PCR and western blot. Real time PCR was used to detect the mRNA expression of osteogenic genes including runt-related transcription factor 2 (*Runx2*), type I collagen α1 (*Col Iα1*) and alkaline phosphatase (*ALP*). After induction of osteogenic differentiation for 17 d and 21 d, the mineralized nodules formation was detected by alizarin red s staining. The cell proliferation and migration were examined by cell counting with Vi-CELL cell viability analyzer and transwell assay, respectively. Moreover, with the aid of online NATs database, 6 MACF1-AS were obtained and the expression of MACF1 and MACF1-AS in primary pre-osteoblasts cultured under random position machine (RPM) was also evaluated by Real-time PCR.Results: After transfection with the recombinant lentivirus vector LV3-shRNA-MACF1, the expression of MACF1 in MC3T3-E1 was dramatically down-regulated . Real time PCR results showed that the mRNA expressions of *Runx2*, *Col Iα1* and *ALP* were all significantly down-regulated in LV3–shRNA-MACF1 transfected cells compared with the blank control cells. After 17 d and 21 d's osteogenic differentiation, the mineralized nodules formed in LV3-shRNA-MACF1 cells were significantly less than in LV3-shRNA-NC and blank cells. Besides, cell counting results showed that cell proliferation was significantly decreased in LV3–shRNA-MACF1 group. In addition, cell migration was also inhibited with low expression of MACF1 after 18 h transwell detection (Fig 1). Moreover, RPM exposure led to significantly down-regulation of MACF1 and MACF1-AS expression in primary pre-osteoblasts.

Conclusions: These findings show that MACF1 deficiency inhibits osteoblast migration, proliferation and differentiation, suggesting a key role of MACF1 in the osteoblast's function. Moreover, efficient MACF1-NATs were acquired.

SA0218

Administration of PTH and Tob deficiency in mice synergistically enhances the levels of both cancellous and cortical bone mass. Shuichi Moriya*[1], Tadayoshi Hayata[2], Toru Suzuki[3], Takayuki Yamada[4], Jumpei Shirakawa[5], Kazuo Kaneko[6], Tadashi Yamamoto[3], Yoichi Ezura[7], Masaki Noda[4]. [1]Department of Orthopaedics, Juntendo University School of Medicine, Japan, [2]Organization for Educational Initiatives, University of Tsukuba, Japan, [3]Okinawa Institute of Science & Technology Graduate University, Japan, [4]Tokyo Medical & Dental University, Japan, [5]Tokyo medical & dental university, Japan, [6]Department of Orthopedics, Juntendo University School of Medicine, Japan, Japan, [7]Tokyo Medical & Dental University, Medical Research Insititute, Japan

Administration of PTH enhances bone formation and increases bone mass. However, its mechanisms are not fully understood especially in the newborn animals where vigorous bone formation is taking place. Tob (Transducer of ErbB2) is an inhibitor of BMP-Smad signaling in osteoblasts while its role in the regulation of PTH actions in bone is not known. Here, we investigated the effects of intermittent PTH on newborn mice in the absence or the presence of Tob to examine the possible interaction. First, PTH(1-34) (human) enhanced the expression of Tob messenger RNA levels in MC3T3-E1 osteoblastic cells in a time and dose dependent manner. PTH enhanced Tob mRNA expression at least in part via transcriptional events without requirement for new protein synthesis, thus this effect is a direct one. PTH enhancement of Tob protein expression was confirmed based on western blot analysis. To examine such PTH effects are also seen *in vivo*, single injection into C57BL/6 male mice was conducted. This PTH treatment enhanced Tob mRNA in the long bones in a time and dose dependent manner. To further test the in vivo significance of Tob in PTH actions in osteoblasts, intermittent administration of PTH was conducted in newborn Tob KO and wild type mice for ten days. Intermittent PTH treatment (100 μg/kg) increased cancellous bone mass (BV/TV) about two fold (9% vs. 18%) in wild type newborn mice. Tob deficiency alone minimally affect bone mass compared to wild type (9% vs. 10%). In contrast to wild type, Tob deficiency enhanced PTH-induced increase in bone mass about three fold (10% vs. 27%). To analyze the molecular mechanism operating under the interaction between PTH and Tob deficiency, we examined the phosphorylation levels of a PTH-target transcription

factor CREB (cAMP Response Element Binding Protein) based on western blotting. In control, PTH enhanced pCREB protein levels as known before. In contrast, when endogenous Tob was knocked-down by using si-RNA, PTH-induced phosphorylation of CREB protein was further significantly increased. These observations indicate that Tob acts as a novel endogenous negative feedback regulator of PTH anabolic action and at least one of the regulatory points for the interaction between PTH and Tob deficiency would be at the levels of CREB regulation.

Expression of Glucose Transporters during Osteoblast Differentiation. Anna-Reeta Virta[1], Milja Arponen[1], Kaisa Ivaska*[2]. [1]University of Turku, Finland, [2]University of Turku, Finland

Cellular uptake of glucose is mediated by a family of facilitative glucose transporters (Glut), which carry sugar across plasma membrane into cells. Bone remodeling should require a large amount of energy and osteoblast-like cells have been shown to express some of the members of the glucose transporter family. Glucose sensing, uptake and utilization in primary osteoblasts are, however, still poorly understood. The purpose of this study was to evaluate the expression of glucose transporters during proliferation, differentiation and maturation of osteoblasts from their bone marrow progenitors, the mesenchymal stromal cells (MSCs).

Bone marrow cells were isolated from rat long bones and the plastic-adherent MSC population was differentiated to osteoblasts using culture medium supplemented with ascorbic acid and sodium beta-glycerophosphate. Osteoblast differentiation was verified by the expression of osteoblast marker genes (such as alkaline phosphatase and osteocalcin) by qPCR during differentiation. The expression of Glut1, -2, -3 and -4 were evaluated by qPCR in MSCs and at various time points during osteoblast differentiation. The expression of genes involved in glucose metabolism, such as insulin receptor, as well as glucose uptake were also evaluated. We also analyzed the effect of high glucose on the expression of glucose transporters.

Rat MSCs and osteoblasts expressed clearly detectable levels of Glut1, Glut3 and Glut4 whereas Glut2 was not detected. The expression of Glut1 was highest in MSCs and relatively constant during osteoblast differentiation. Glut3 and insulin receptor were also expressed at all time points analyzed. The expression of Glut4 increased during differentiation and appeared to be highest in the mature osteoblasts. Glucose uptake was also increased together with osteoblast maturation. Long-term exposure to high extracellular glucose levels appeared to suppress the expression of Gluts in osteoblasts.

In conclusion, primary rat osteoblasts express Glut1, Glut3 and Glut4 throughout osteoblast differentiation and the expression of Gluts is modulated by high glucose levels. Osteoblasts thus express mechanisms for glucose sensing and uptake, which may play a role in peripheral glucose disposal and in skeletal responses to hyperglycemia.

IGF-I Regulation of MicroRNA Expression in Osteoblasts. Chandrasekhar Kesavan*, Jon Wergedal, Subburaman Mohan. Jerry L. Pettis Memorial VA Medical Center, USA

The role of osteoblast produced IGF-I in regulating skeletal growth and mechanical strain effects on bone are well-established. However, little is known regarding the immediate downstream targets of IGF-I that mediate the IGF-I biological effects on bone cells. Because individual microRNA (miR)s can target multiple signaling pathways by influencing a number of mRNAs and because aberrant miR expression have been implicated in several disease states, we predicted miRs to be important mediators of IGF-I action in osteoblasts. To test this prediction, we first evaluated the expression levels of eight miRs that are known to be regulated and play important roles in regulating cellular processes in other tissues by real time RT-PCR using total RNA extracted from the bones of IGF-I conditional knockout (cKO) mice and corresponding wild type (WT) mice. We found that expression levels of miR92, miR20a, miR16, miR146a and miR222 were decreased by two to eight-fold ($P<0.05$) while the expression level of miR93 was increased by 70-fold in the bones of mice with a disruption of the IGF-I gene in type I collagen expressing osteoblasts compared to corresponding WT mice. To determine if IGF-I directly modulated the expression of these miRs, serum free cultures of MC3T3-E1 osteoblasts were treated with (100 ng/ml) or without IGF-I for 24 or 72 hours and expression levels were determined by real time RT-PCR. Expression levels of miR20a and miR146a were increased by 2- and 7-fold, respectively, at 24 hours while that of miR93 was decreased by 2-fold at 72 hours. By contrast miR93 expression was increased (1.5-fold, $P<0.05$) in response to IGF-I treatment in ATDC5 chondrocytes. Based on our data, we conclude that IGF-I both up regulates and down regulates miR expression levels in osteoblasts to mediate its biological effects.

PTH promotes the transcription of members of the LGR/Rspondin family in bone. Nicoletta Bivi*[1], Jonathan Lucchesi[2], Matthew Hamang[2], Qianqiang Zeng[2], Rick Cain[2], Mary Adrian[2], Masahiko Sato[3], Venkatesh Krishnan[4], Yanfei Ma[4]. [1]Eli Lilly & Co., USA, [2]Eli Lilly & Co., USA, [3]Indiana University School of Medicine, USA, [4]Eli Lilly & Company, USA

The LGR/Rspondin (RSPO) pathway is emerging as a novel modulator of Wnt signaling and recent data have suggested that members of the LGR/RSPO pathway may play a role in bone; however, little is known on the ability of the pathway to be regulated in osteoanabolic conditions. We sought to determine by qPCR whether an anabolic regimen of PTH(1-38) alters the levels of members of the LGR/RSPO pathway *in vivo* during fracture repair and in intact bone. Osteopenic rats (8 month old, 2 months post-ovaryectomy) were subjected to unilateral femoral osteotomy, in which a 1mm-gap was created and stabilized with external fixators. Rats were injected sc with 66 µg/kg hPTH(1-38) 3X/wk, starting from day 7 post-surgery, necropsied at 7, 14 or 21 days post-first dose. RNA was isolated from a portion of the femur encompassing the osteotomy site. At the fracture site, the most abundant transcripts were found to be LGR4 and RSPO1. Moreover, PTH(1-38) enhanced the levels of LGR6 6X at day 7 and 4X at day 14, while it diminished the levels of LGR4 at day 14. RSPO2 levels increased 3X at day 14 and day 21, while the levels of RSPO1 and RSPO3 were unchanged. Salmon calcitonin, injected at the concentration of 51 µg/kg 3X/wk, increased c-fos 2.4X at day 21, but did not affect members of the LGR/RSPO family, suggesting that a rise in cAMP is not sufficient to trigger the response, which requires activation of PTHR1. Of note, none of the members of the LGR/RSPO pathway was affected during the fracture repair process in vehicle-treated animals. Messenger RNA was also analyzed in the metaphysis of the distal femur of young, intact rats. Human PTH(1-38) at the dose of 70 µg/kg was injected sub-cutaneously and femur metaphysis were collected 3 h and 8 h after. Also in intact metaphysis, LGR6 was increased, while LGR4 was decreased and only RSPO3 was found to be decreased 8 h post-injection by PTH(1-38). In UMR 106 cells, 100 nM PTH(1-38) increased RSPO2 mRNA levels after 24h. Furthermore, 100 nM PTH(7-34) or PTH(1-84) had no effect and a 100-fold excess of PTH(3-34) blocked the increase in RSPO2, suggesting that PTH(1-38) modulates the LGR/RSPO pathway at least in part through cAMP/PKA. Moreover, lack of activation of RSPO2 by PTH(1-84) could explain its known reduced effect compared to PTH(1-38) *in vivo*. In summary, the LGR/RSPO signaling could in turn play a role in the bone anabolic effects of PTH through the modulation of Wnt signaling.

***Rest/Nrsf* Suppresses Osteoblast Differentiation by Down Regulating *Osterix* Expression.** Subburaman Mohan[1], Bo Liu*[2], Shaohong Cheng[3], Sheila Pouteymoor[2]. [1]Jerry L. Pettis Memorial VA Medical Center, USA, [2]VALLHCS, USA, [3]VA Loma Linda Health Care Systems, USA

Runx2 and Osterix (Osx) are two master transcription factors that control osteoblast differentiation and the bone formation process. Identifying molecules that regulate activities of these transcription factors could provide a means to regulate osteoblast function and, thereby, new bone formation. Here we report a novel negative regulator of osteoblast differentiation - Rest (RE1-silencing transcription factor), also known as the neuron restrictive silencing factor or Nrsf. Rest/Nrsf was initially identified as a master negative regulator of neuronal differentiation. We found that Rest/Nrsf is abundantly expressed in osteoblasts including MC3T3-E1 cells, bone marrow stromal (BMS) cells, and calvarial osteoblasts (COB). Treatment of MC3T3-E1 osteoblasts with differentiation media containing 50 µg/ml ascorbic acid (AA) and 10mM β-glycerophosphate for 24 hrs caused a 47% ($P<0.05$) reduction in Rest/Nrsf mRNA expression compared to cells treated with control media. By contrast, the Osx mRNA level was increased by 1.9 fold ($p<0.05$) in the AA treated cells. Down regulation of Rest/Nrsf expression induced by osteoblast differentiation media was also confirmed by western blot analysis. To further test the function of Rest/Nrsf in osteoblast differentiation, we knocked down Rest/Nrsf expression by 88% ($p<0.01$) in MC3T3-E1 cells using Rest/Nrsf specific lentiviral shRNA. The Rest/Nrsf knockdown cells showed a 1.5 fold increase ($p<0.05$) in Osx mRNA level compared to scramble shRNA control cells. ALP mRNA level was also increased by 2.4 fold ($p<0.05$) after Rest/Nrsf knockdown. Accordingly, ALP activity in cellular extracts of Rest/Nrsf knockdown MC3T3-E1 cells was increased by 1.4 fold ($p<0.05$) compared to scramble shRNA control cells. Based on these data, we conclude that Rest/Nrsf is a negative regulator of Osx expression and osteoblast differentiation.

Carbamazepine Inhibits Native Sodium Currents In Murine Osteoblasts. Sandra Petty*[1], Carol Milligan[2], Marian Todaro[3], Terence O'Brien[3], John Wark[4], Eleanor Mackie[5], Steven Petrou[2]. [1]The University of Melbourne, Australia, [2]The Florey Institute of Neuroscience & Mental Health, Australia, [3]The University of Melbourne, Australia, [4]University of Melbourne Department of Medicine, Australia, [5]University of Melbourne, Australia

PURPOSE: It is well-established that patients with epilepsy have an increase in fracture risk. However, the mechanism for this association is less well defined. We hypothesised that osteoblasts express ion currents, which could be inhibited by anti-epileptic medication. We aimed to investigate whether: (1) mouse primary calvarial osteoblasts expressed voltage-activated sodium current, and (2) the anti-epileptic medication carbamazepine (CBZ) inhibited this current.

Methods: Primary osteoblasts isolated from the calvariae of neonatal C57BL/6 mice were used to examine the impact of CBZ on whole-cell current recordings produced using Patchliner, an automated planar patch-clamp system (Nanion, Germany). Currents were elicited using a voltage protocol stepping from -100 mV to +60 mV in 10 mV increments, for 20 ms, from a holding potential of -80 mV or -60 mV. CBZ (50 μM) was applied to the cells in the continued presence of external Tetraethylammonium (10 mM) and internal Cs+. Following washout of CBZ, 10 μM tetrodotoxin (TTX) a known voltage-gated sodium channel blocker was applied.

Results: Robust voltage-activated inward currents were elicited and external application of CBZ (50 μM) resulted in a significant inhibition of current amplitude 31.6 ± 5.9 % (n = 7; $p<0.001$), which was partially reversed upon washout. Subsequent application of TTX (10 μM) produced almost complete inhibition of current amplitude 89.96 ± 2.14 % (n = 6; $p<0.0001$).

CONCLUSIONS: Here we demonstrate that mouse osteoblasts express native voltage-activated sodium channels, which are sensitive to CBZ. To our knowledge this is the first study to utilise a Patchliner to examine native primary osteoblast sodium currents, and to demonstrate an inhibitory effect of CBZ. Further study is required to determine whether the effects on ion channel activity observed here, translate to clinically-relevant changes in bone signaling and bone quality.

Cbfβ upregulates Atf4 promoter activity and plays an indispensable role in skeletal development and homeostasis. Guochun Zhu*[1], Wei Chen[2], Junqing Ma[3], Mengrui Wu[4], Matthew McConnell[3], Joel Jules[2], Christie Paulson[3], Yi-Ping Li[2]. [1]The University of Alabama at Birmingham, USA, [2]University of Alabama at Birmingham, USA, [3]University of Alabama at Birmingham, USA, [4]The University of Alabama at Birmingham, USA

Activating transcription factor 4 (Atf4) is a key factor which mediates osteoblast formation and function. However, how *Atf4* is regulated at the transcriptional level remains unclear. We hypothesized that the Core-binding factor, beta (Cbfβ)/Runt-related transcription factor 2 (Runx2) complex upregulates *Atf4* expression at the transcriptional level during osteoblast differentiation and that dysfunction of this regulation may result in skeletal disease, such as cleidocranial dysplasia (CCD). To test this hypothesis, we first performed GeneChip (microarray) analysis. The data showed that *Atf4* mRNA expression increased 15 folds during osteoblast differentiation. The increase in *Atf4* expression is similar to the gene expression of several osteoblast markers. The dramatic increase in *Atf4* mRNA expression was confirmed by quantitative RT-PCR analysis using total RNA from mouse calvarial osteoblast differentiation cell cultures. Notably, an increase in *Atf4* mRNA expression during osteoblast differentiation was not shown by qPCR analysis using total RNA from *Cbfβ$^{f/f}$ Osx-Cre* mouse calvarial cell cultures, indicating that Cbfβ may be the key regulator of *Atf4* expression. To address the question of whether Cbfβ directly regulates *Atf4* expression at the transcriptional level by regulating *Atf4* promoter activity, we analyzed the *Atf4* promoter region. We found several Cbfβ/Runx complex binding sites in the *Atf4* promoter region (-4000/+80) and designed primers accordingly for chromatin immunoprecipitation (ChIP) assays. DNA was pulled down using the anti-Cbfβ antibody and analyzed using ChIP. The resulting data showed that Cbfβ binds near the transcription start site in the *Atf4* promoter region, indicating that Cbfβ upregulates *Atf4* expression directly by associating with the *Atf4* promoter in *cis*. The promoter luciferase assay showed that luciferase activity driven by *Atf4* promoter segments is almost lost in *Cbfβ$^{f/f}$ Osx-Cre* mouse calvarial cells and that the binding site is critical to *Atf4* promoter activity. Importantly, our data showed that mice with *Cbfβ* ablation via *Osx*-Cre exhibit severe skeletal dysplasia with a phenotype recapitulating the clinical features of CCD and a dramatic reduction in *Atf4* expression both in mRNA and protein levels. Overall, our study demonstrates that Cbfβ upregulates *Atf4* promoter activity and revealed that Cbfβ plays an indispensable role in skeletal development and homeostasis by upregulating *Atf4* promoter activity in osteoblasts.

MEKK2 promotes osteoblast activity via phosphorylation and stabilization of β-catenin. Matthew Greenblatt*[1], Dong-Yeon Shin[2], Hwanhee Oh[3], Dou Liu[4], Bo Zhai[5], Sutada Lotinun[6], Roland Baron[7], Steven Gygi[8], Laurie Glimcher[2], Bing Su[9], Jae Hyuck Shim[10]. [1]Weill Cornell Medical College/ Brigham & Women's Hospital, USA, [2]Weill Cornell Medical College, USA, [3]Weill Medical College of Cornell University, USA, [4]Yale University, USA, [5]Harvard University, USA, [6]Chulalongkorn University, Thailand, [7]Harvard School of Medicine & of Dental Medicine, USA, [8]Harvard Medical School, USA, [9]Yale University, USA, [10]Weill Cornell Medical College, USA

Emerging evidence points to proper tuning of β-catenin activity in osteoblasts as a key determinant of both bone mass and hematopoietic niche functions. Here, we demonstrate that the mitogen-activated protein kinase kinase kinase (MAP3K) MEKK2 (MAP3K2) promotes osteoblast differentiation and bone formation both *in vitro* and *in vivo* via an unexpected activity to directly phosphorylate β-catenin at serine 675. This phosphorylation event stabilizes β-catenin by recruiting the deubiquinases OTUD4 and USP15, which prevents the basal turnover of β-catenin by inhibiting ubiquitin-dependent proteasomal degradation. A screen of several ligands acting on osteoblasts demonstrates that FGF2 activates MEKK2, and MEKK2 in turn mediates the ability of FGF2 to synergize with WNT stimulation to activate β-catenin and promote osteoblast differentiation. Lastly, genetic interaction studies between *Mekk2* and β-catenin (*Ctnnb1*) null alleles confirm that this pathway is an important physiologic regulator of bone mass *in vivo*. Thus, a FGF2/MEKK2 crosstalk pathway tunes β-catenin activity in osteoblasts, in turn tuning the rate of bone formation *in vivo*.

Pin1 promotes nuclear stay of β-catenin and controls Wnt3a-induced osteoblast differentiation. Hea-rim Shin*[1], Taegyung Lee[2], Han-sol Bae[1], Young-Dan Cho[3], Won-Joon Yoon[2], Hyun-Mo Ryoo[4]. [1]Seoul National University, South Korea, [2]School of Dentistry Seoul National University, Korea, democratic people's republic of, [3]Seoul National University, South Korea, [4]Seoul National University School of Dentistry, South Korea

Canonical Wnt signaling plays an important role in osteoblast differentiation, in which β-catenin is the key mediator. Pin1 (Peptidylprolyl cis/trans isomerase, NIMA-interacting 1) isomerizes only phophorylated Ser/The-Pro motif. It regulates the conformational change of β-catenin, which is known to be associated with increased cancer risk, because of increased β-catenin level in the nucleus. Canonical Wnt signaling is also very important in osteoblast differentiation, however, association of Pin1 in this signal transduction pathway is still unknown. The specific aim of this study was to investigate if Pin1 is involved in the Wnt-induced osteogenesis. We found that Pin1 KO mouse showed reduction of β-catenin levels in the proximal tibial osteoblasts. So, using TOP Flash in Pin1 WT/KO mouse embryonic fibroblast (MEF) cells, we identified that Pin1 can control Wnt-induced transactivation activity. Inhibition of Pin1 activity by Juglone treatment repressed Wnt3a-induced osteoblast differentiation and bone marker gene expression in C2C12 cells. In contrast, overexpression of Pin1 stimulated osteoblast differentiation by Wnt3a administration. The transcriptional synergy including TOP Flash and ALP promoter activity was observed with Pin1 and Wnt3a. We demonstrated that Pin1 binds to β-catenin in the nucleus and Pin1 activity increased nuclear stay of β-catenin, not stimulated translocation of β-catenin to nucleus. Because isomerized β-catenin couldn't bind to APC which is β-catenin export protein as tumor suppressor. Consequently, Pin1 increases retention of β-catenin in the nucleus, which may explain the increased reporter activity and protein levels in vivo. Taken together, our results reveal that Pin1 is a novel regulator that promotes osteoblast differentiation through structural modification and stabilization of β-catenin in the nucleus. These results provide us a great insight about the importance of Pin1 and isomerization of β-catenin by Pin1 in bone development.

Smad8 negatively regulats BMP signaling in a dominant negative fashion. Sho Tsukamoto*[1], Takato Mizuta[2], Mai Fujimoto[3], Satoshi Ohte[2], Kenji Osawa[2], Arei Miyamoto[4], Katsumi Yoneyama[2], Eiko Murata[5], Eijiro Jimi[6], Shoichiro Kokabu[7], Takenobu Katagiri[1]. [1]Saitama Medical University Research Center for Genomic Medicine, Japan, [2]Saitama Medical University Research Center for Genomic Medicine, Japan, [3]Saitama Medical University Research Center for Genomic Medicine, Jpn, [4]Saitama Medical University,Research Center for Genomic Medicine, Japan, [5]Faculty of Health & Medical Care, Saitama Medical University, Japan, [6]Kyushu Dental College, Japan, [7]Kyushu Dental College, Japan

The intracellular signaling of bone morphogenetic proteins (BMPs) is regulated by receptor-regulated Smads (R-Smads), Co-Smads and inhibitory Smads (I-Smads). BMP-regulated R-Smads, namely Smad1, Smad5 and Smad8, are activated by phosphorylation by ligand-bound type I receptor kinases. We examined the specific role of each R-Smad in BMP activity by establishing constitutively active Smad1, Smad5 and Smad8 by substituting the C-terminal phosphorylation sites. Overexpression of Smad8 showed less BMP activity than Smad1 and Smad5, even though it associated with Smad4 and bound to the target DNA. The linker region of Smad8 suppressed the transcriptional activity in the chimeric Smads constructed among Smad1, Smad5 and Smad8. The mRNA expression levels of Smad8 were upregulated by BMP signaling, similar to the I-Smads, Smad6 and Smad7. Moreover, overexpression of Smad8 suppressed BMP activity in vitro. In contrast to the I-Smads, however, Smad8 did not inhibit the phosphorylation of Smad1 by type I receptors and suppressed the constitutively active Smad1. Smad8 formed complexes with Smad1 and bound to the DNA but suppressed the transcription of the target gene in a dominant negative fashion. Taken together, our findings suggest that Smad8 negatively regulates BMP signaling in a dominant negative fashion. Thus, it was also suggested that Smad8 is a novel type of transcriptional regulator in BMP signaling.

The cooperation of CREB and NFAT is required for PTHrP-induced RANKL expression in mouse osteoblastic cells. Jeong-Hwa Baek*[1], Hyun-Jung Park[2], Kyunghwa Baek[3], Hyung-Ryong Kim[4]. [1]Seoul National University, School of Dentistry, South Korea, [2]Department of Molecular Genetics, Seoul National University School of Dentistry, South Korea, [3]Gangneung-Wonju national university, School of dentistry, South Korea, [4]Department of Dental Pharmacology, School of Dentistry, Wonkwang University, South Korea

Parathyroid hormone-related protein (PTHrP) is known to induce the expression of receptor activator of NF-κB ligand (RANKL) in stromal cells/osteoblasts. However, the signaling pathways involved remain controversial. In the present study, we investigated the role of cAMP/protein kinase A (PKA) and calcineurin/NFAT pathways in PTHrP-induced RANKL expression in C2C12 and primary cultured mouse calvarial cells. PTHrP-mediated induction of RANKL expression was significantly inhibited by H89 and FK506, an inhibitor of PKA and calcineurin, respectively. PTHrP upregulated CREB phosphorylation and the transcriptional activity of NFAT. Knockdown of CREB or NFATc1 blocked PTHrP-induced RANKL expression. PTHrP increased the activity of the RANKL promoter reporter that contains approximately 2 kb mouse RANKL promoter DNA sequences. Insertions of mutations in CRE-like element or in NFAT-binding element abrogated PTHrP-induced RANKL promoter activity. Chromatin immunoprecipitation assays showed that PTHrP increased the binding of CREB and NFATc1/NFATc3 to their cognate binding elements in the RANKL promoter. Inhibition of cAMP/PKA and its downstream ERK activity suppressed PTHrP-induced expression and transcriptional activity of NFATc1. CREB knockdown prevented PTHrP induction of NFATc1 expression. Furthermore, NFATc1 and CREB were co-immunoprecipitated. Mutations in CRE-like element completely blocked NFATc1-induced transactivation of the RANKL promoter reporter; however, mutations in NFAT-binding element partially suppressed CREB-induced RANKL promoter activity. Overexpression of CREB increased NFATc1 binding to the RANKL promoter and vice versa. These results suggest that PTHrP-induced RANKL expression depends on the activation of both cAMP/PKA and calcineurin/NFAT pathways, and subsequently, CREB and NFAT cooperate to transactivate the mouse RANKL gene.

Ucma, a downstream target gene regulated by both Runx2 and Osterix, promotes osteoblast differentiation. Yeon Ju Lee[1], So-Jeong Lee*[1], Eun-Hye Lee[1], Yeo Hyang Kim[2], Je-Yong Choi[3], Jung-Eun Kim[4]. [1]Kyungpook National University School of Medicine, South Korea, [2]Kyungpook National University Hospital, South Korea, [3]Kyungpook National University, School of Medicine, South Korea, [4]Kyungpook National University School of Medicine, South Korea

Runx2 and Osterix (Osx) are known as master transcription factors for bone formation. However, genes acting downstream of both Runx2 and Osx have yet to be fully characterized. To investigate Runx2 and Osx downstream target genes, DNA microarray analysis was conducted on calvaria of wild-type, Runx2 heterozygous, Osx heterozygous, and Runx2/Osx double heterozygous mice. During osteogenesis, many genes were regulated by both Runx2 and Osx. The expression of unique cartilage matrix-associated protein (Ucma) was decreased in Runx2 heterozygous and Osx heterozygous mice and was further decreased in double heterozygous mice. In contrast, Ucma expression was increased in osteoblasts overexpressing either Runx2 or Osx and was further increased upon overexpression of both Runx2 and Osx. To examine Ucma expression during osteoblast differentiation, MC3T3-E1 osteoblastic cells were cultured for 30 days in a medium supplemented with ascorbic acid and β-glycerophosphate. Ucma expression initiated mid-way through osteoblast differentiation and continued throughout the differentiation process. To investigate whether Runx2 and Osx modulate the transcriptional activity of Ucma, an Ucma reporter construct was co-transfected with Runx2 and/or Osx expression plasmids into MC3T3-E1. The transcriptional activity of the Ucma promoter was increased upon transfection of both Runx2 and Osx expression vectors. Within the Ucma promoter, two Sp1-binding sites and three Runx-binding sites were identified. Runx2- and Osx-mediated activation of the mouse Ucma promoter was directly regulated by Runx2- and/or Sp1-binding sites. During osteoblast differentiation, the formation of mineralized nodules in an Ucma-overexpressing stable clone was earlier and more increased than that of the mock-transfected control. Mineralized nodule formation was highly augmented in MC3T3-E1 cultured in a medium containing Ucma proteins secreted from Ucma-overexpressing cells. Collectively, the results of this study suggest that Ucma is a novel downstream target gene regulated by both Runx2 and Osx and has a positive effect on osteoblast differentiation and nodule formation.

Sensory Neuron Differentiation Enhances Osteoblast Differentiation Through Soluble Factors. Leah Worton*[1], Brandon Park[2], Anthony Redidoro[2], Edith Gardiner[1], Ronald Kwon[1]. [1]University of Washington, USA, [2]University of Washington, USA

Sensory nerves are known to regulate osteogenesis in conditions of bone formation such as fracture repair, heterotopic ossification and growth. Though significant innervation accompanies these processes understanding the osteo-anabolic potential of sensory nerves and their ability to directly guide osteoblast differentiation in these

physiologies is challenging. In this study we developed a novel *in vitro* model of sensory nerve-bone cell interaction using F11 sensory neuron-like and MC3T3 osteoblastic cells to examine the potential for sensory neuron differentiation to drive osteoblast differentiation through soluble factors. F11 cells differentiated with dibutyryl cAMP for 24h exhibited elongated morphology and neurite formation, compared to the rounded cell morphology of undifferentiated controls (Fig 1). Conditioned media (CM) from these F11 cells was then used to treat differentiating MC3T3 cells, and expression analysis performed. These cells had increased mRNA levels of signaling molecules, transcription factors and osteoblast differentiation markers which appeared to be expressed in a temporally relevant manner. Firstly, there were increased levels of AP-1 component genes including c-Fos (Fig 2A) in cells treated with CM from differentiated F11 cells for 24 and 48 h, compared to cells treated with media or with CM from undifferentiated F11 cells. Further evidence of altered signaling was seen with increased expression of VEGF (Fig 2B) and Cox2 after treatment with differentiated F11 CM at 48h. Regulation of osteoblast transcription factors Runx2 (Fig 2C), Dlx5 and Osx was also observed, though Runx2 expression did not differ between time-points and was similar with both types of F11 CM. Finally, for osteoblast differentiation markers, there was elevated OPN in MC3T3 cells after treatment with CM from both undifferentiated and differentiated F11 cells at 24h, though this up-regulation was not observed at 48h with undifferentiated F11 CM (Fig 2D). ALP mRNA was not detected after 24h of treatment, but was elevated at 48h in cells treated with CM from differentiated F11 cells (Fig 2E).These results demonstrate the potential for CM from F11 sensory neuron-like cells to directly enhance osteogenic gene expression in MC3T3 cells in the absence of cellular intermediaries or nerve-bone synaptic transmission. Thus, these studies provide a foundation for elucidating neural factors mediating crosstalk between sensory neurons and bone cells during osteogenesis.

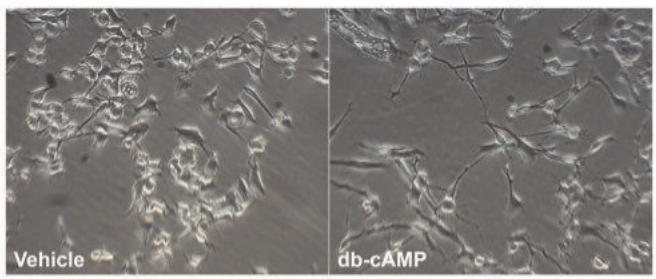

Figure 1. db-cAMP stimulates neuronal differentiation in F11 cells. Phase contrast images of F11 cells treated with vehicle (left) and db-cAMP (right) reveal enhanced neurite formation and more elongated morphology in db-cAMP-treated cells.

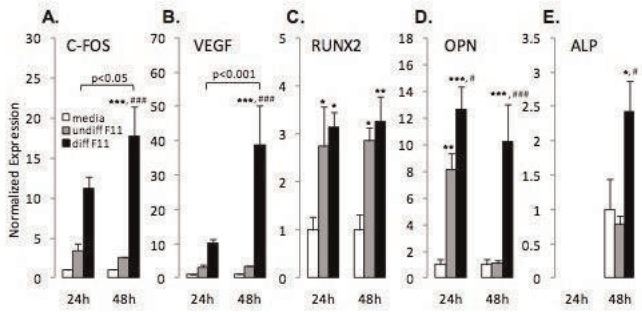

Figure 2. Conditioned media from F11 cells enhances MC3T3 gene expression in regard to signaling pathway components, osteoblastic transcription factors, and markers of osteoblastic differentiation. Shown are results for (A) c-Fos, (B) VEGF, (C) Runx2, (D) OPN, (E) ALP mRNA following treatment with F11 CM. *: p<0.05, **: p<0.01, ***: p<0.001 vs. media; #:p<0.05, ##:p<0.01, ###:p<0.001 vs. undifferentiated F11 CM.

Signaling by matrix-bound VEGF controls the lineage commitment of multipotent mesenchymal progenitors. Fiona Louis*[1], Sylvie Peyroche[2], Marie-Thérèse Linossier[2], Laurence Vico[3], Alain Guignandon[2]. [1]Unit of Integrative Biology of Bone Tissue, INSERM U1059, France, [2]Unit of Integrative Biology of Bone Tissue, INSERM U1059, France, [3]University of St-Etienne, France

Cell lineage commitment of multipotent progenitors is determined by their mechanical properties. Cellular tension is mainly controlled by Rho family GTPases (RhoA & Rac1). Elevated RhoA (=high cell tension) is often associated with osteogenesis (OS) while low RhoA causes commitment towards adipogenesis (AD). Among several signaling pathways controlling RhoA and Rac1 activities, VEGF signaling appears of first importance since Liu *et al.* (JCI, 2012) suggested that VEGF/KDR translocation in stem cell nuclei (intracriny) activates Runx2 (OS) and inhibits PPARG2 (AD) transcription. In this context, we studied the evolution of RhoA/Rac1 activity, the expression of VEGF-A variants and receptors during AD and OS in a 3D culture of murine multipotent C3H10T1/2 cells (MMC).

OS was induced by growing MMC in 5 mM strontium on apatite and collagen coated microbeads. AD was induced by 1µM rosiglitazone. We observed that AD was characterized by a significant reduction in RhoA and Rac1 activities (-25% and -70% respectively) while both were stimulated during OS (+100% and +30% respectively). These unexpected results suggest that conventional Rac1/AD and RhoA/OS associations need to be revisited. Interestingly, the dual stimulation of RhoA & Rac1 in OS fits nicely with the requirement of active fibrillogenesis (RhoA dependent) and β-catenin translocation (Rac1 dependent) during this process.

High soluble VEGF secretion was observed during AD, while OS is associated with increased expression of the matrix-bound VEGF188 isoform (VEGFm). Both Flt1 and KDR expressions decreased dramatically with AD (-75% and -50% respectively) and increased in OS (+50% and +40% respectively), suggesting a specific VEGFm role in osteoblast differentiation. To assess the importance of this signaling, we immobilized VEGF165 on microbeads and showed its ability to stimulate RhoA and Rac1 in MMC. In contrast VEGF165 in a soluble form did not display this ability when incubated with MMC cultivated on microbeads.

Interestingly, the ability of mechanical stresses to direct stem cells commitment might be explained by their known stimulatory effect on VEGFm production.

We proposed that production and immobilization of VEGFm in skeletal stem cells niches trigger RhoA and Rac1 activations leading to their commitment toward osteoblastogenesis.

Early Embryonic Stem Cell Markers are Commonly Induced in Both Fracture and in Ectopically Induced Bone Formation. Beth Bragdon*[1], Kyle Lybrand[2], Louis Gerstenfeld[3]. [1]Boston University School of Medicine Department of Orthopaedics, USA, [2]Boston University Dept of Orthopaedic Surgery, USA, [3]Boston University School of Medicine, USA

Introduction: Bone formation can be induced ectopically in muscle by Demineralized Bone Matrix (DBM) or BMPs suggesting that osteochondral progenitors may be found in non-skeletal tissues. A number of studies also show that osteochondral progenitor cells located in both the periosteum and surrounding skeletal muscles around a fracture site can contribute to the developing fracture callus. However, little is known regarding the earliest transcriptional regulators within the progenitor cell populations within these separate tissues that give rise to cells that contribute to early fracture healing or ectopic bone formation.

Methods: Human DBM was obtained from Medtronics Inc with an MTA. To generate ectopic bone formation, DBM (50mg) was implanted on the periosteum of the femur in male B6,129S7-Rag1tm1Mom/J mice. Implants were harvested at 2, 4, and 8 days post-operatively. Closed stabilized transverse fractures were generated in the right femora of male C57BL/6J mice. The callus was harvested at 1, 2, 3, and 5 days post-fracture. Total RNA was isolated and mRNA expression for embryonic stem cells (Sox2, Nanog, Oct4), muscle satellite cells (Pax7), and periosteal osteochondral progenitor cells (Prx1) were evaluated with real time qPCR.

Results: The embryonic stem cell markers showed increased expression in both the DBM-induced ectopic bone formation and fracture callus compared to the non-operative femurs. Sox2 and Nanog showed the most robust induction with over 100 fold increase expression in the ectopic bone while fracture repair was able to induce these genes over a 10 fold increase. Expression of these genes peaked in the DBM-induced ectopic bone formation at post-operative day 2 and subsequently decreased to base line levels by 5 days post fracture. Interestingly Prx1 and Pax7 were co induced with Nanog and Sox2 but showed more prolonged expression through day 5 and day 8 respectively in fracture callus and ectopic bone.

Conclusions: The robust induced expression of early embryonic stem cell markers during both ectopic bone formation and fracture repair is suggestive that these transcriptional regulators may be functional in postnatal skeletal stem cells. The expression of transcriptional regulators that have been separately associated with

periosteum and muscle suggests that these factors are not exclusively restricted to these tissues but may also be more generally functional in axial skeletal stem cell that contribute to bone repair.

Genome-wide Global Chromatin Landscape during Bone Differentiation from Normal and Osteogenesis Imperfecta iPS Cells. Lyuba Varticovski[1], Bethtrice Thompson*[2], Songjoon Baek[3], Jay Shapiro[4], Gordon Hager[3]. [1]NCI, National Institutes of Health, USA, [2]Howard U, USA, [3]LRBGE, NCI, NIH, USA, [4]Kennedy Krieger Institute, Johns Hopkins, USA

BACKGROUND: Although bone undergoes life-long remodeling, there is a substantial lack of information on the molecular basis of Mesenchymal Stem Cells (MSC) differentiation into osteoblast and key regulators of this process. We investigated genome-wide changes in chromatin landscape changes in iPS cells during MSC and osteoblast (OB) lineage differentiation, and how these changes affect gene expression. We compared these changes with OB differentiation of cells from a patient with Type III Osteogenesis Imperfecta (OI) who has a mutation in COL1A1. METHODS: Both iPS cell types were generated by retroviral transduction with 4 stem cell transcription factors: SOX2, OCT4, KLF4 and MYC. To investigate changes in chromatin landscape, we used DNase I or Benzonase, an alternative DNA cutting enzyme, combined with deep sequencing to detect DNA hypersensitivitie sites (DHS) which, by definition, are not protected by histones and thus are accessible to transcription factors (TF) binding. RESULTS: Normal and OI-derived iPS cells readily differentiated into MSC, and osteoblast or adipose lineages as detected by alizarin red and oil red staining, disappearance of stem cell markers by flow cytometry, and gene expression. Analysis of sites hypersensitive to DNA cutting enzymes exposed key regulatory elements, including sites in promoters of known OB genes, such as COL1A1, RUNX2, as well as changes in sites not previously known to be associated with bone formation. Comparison between normal and OI-derived iPS cells confirmed significant differences between 76,223 DHS in normal and 40,932 in OI iPS with only 25,310 overlapping sites. These data underscore significant genome-wide chromatin landscape differences between normal and OI iPS cells, and indicate constrained chromatin landscape in OI derived iPS cells. Analysis of TF motifs most frequently modified during differentiation showed disappearance of motifs associated with TFs initially used to derive iPS cells: SOX2, OCT4 and KLF4, and appearance of new TF motifs for AP-1 and TEAD during final OB differentiation. CONCLUSIONS Analysis of genome-wide chromatin landscape reveals chromatin changes in known osteogenesis-related genes as well as significant modifications in promoters and enhancers of genes that have not been previously associated with OB differentiation. This analysis offers an unprecedented view of chromatin modifications during OB differentiation and genes involved in this process..

Identifying Markers in Pre-Implantation hES and iPS-Derived Progenitor Cells for In Vivo Skeletal Tissue Formation. Xiaonan Xin*[1], Kyle Shin[2], Xi Jiang[3], Liping Wang[1], Nathaniel Dyment[2], Mark Kronenberg[1], Jianping Huang[2], David Rowe[1], Alexander Lichtler[1]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut Health Center, USA, [3]University of Connecticut Health Center, USA

Many studies that demonstrate in vitro MSC like differentiation from hES or iPS cells based on a CD profile lack evidence that these markers are predictive of in vivo bone or cartilage differentiation. We have reported a novel protocol, EB-EGM, for differentiation of hESC or iPSC into MSC-like cells, which form human cartilage and bone in a murine in vivo calvarial defect model. Histological analysis suggested that the implanted cells undergo endochondral-like bone formation. Flow cytometry analysis of the pre-implantation cells demonstrated that more then 95% of the cells at passage 3 expressed MSC surface marker proteins, CD44, CD73, CD90 and CD166, while only 1 or 2 % cells are positive for the endothelial marker CD31 or the hematopoietic markers CD34 and 45. However, in our hands, this panel of markers is not predictive of in vivo differentiation. To further characterize our EB-EGMprotocol, we extracted RNA at different differentiation stages. We demonstrated that the cells undergo an epithelial/mesenchymal transition (EMT) by RT-PCR for E-cadherin and vimentin mRNA expression. We also wished to identify a gene expression signature that can distinguish hES and iPS-derived MSC-like cells that have the potential to form skeletal tissues in our in vivo model from similar MSC-like cells, also derived from hES or iPS cells but using different protocols, that do not form bone in our model. Initially, we used an osteogenesis low density array plate to compare hESC-derived EB-EGM-MSC with non-differentiated hESC, hESC-derived MSC produced using an EB-based protocol in non-EGM medium, which has shown no cartilage or bone formation in our in vivo mouse model, and adult bone marrow MSC. We saw differential expression of several genes, including Msx2. Currently, these RNA samples are undergo deep sequencing, which will allow an in depth study of the genes that may be potentially related to skeletal tissue formation. We have also applied this protocol to control human iPS cells derived from both fibroblasts and blood cells and shown robust cartilage and bone formation, with histological evidence for endochondral-like bone formation. We are working to develop more specific evidence for this using antibody staining and molecular markers. Our studies further support the utility of our protocol or analyzing the pathophysiology of genetic skeletal diseases, and provide the basis for refining protocols from differentiating iPS cells for therapy of skeletal diseases.

Osteogenic commitment of mesenchymal stem cells is driven by epigenetic mechanisms characterized by dynamic changes in histone modifications. Hai Wu*[1], Jonathan Gordon[1], Troy Whitfield[2], Phillip Tai[3], Andre Van Wijnen[4], Gary Stein[5], Janet Stein[6], Jane Lian[7]. [1]University of Vermont, USA, [2]3Department of Cell & Developmental Biology, University of Massachusetts Medical School, USA, [3]University of VermontCollege of MedicineDepartment of Biochemistry, USA, [4]Mayo Clinic, USA, [5]University of VermontCollege of Medicine, USA, [6]Department of Biochemistry, University of Vermont College of Medicine, USA, [7]University of Vermont College of Medicine, USA

Changes in histone post-translational modifications are fundamental events for chromatin remodeling and gene expression, leading to cell lineage commitment from pluripotent stem cells. Multipotent bone marrow stromal cells (BMSCs) are crucial for supporting bone tissue homeostasis. To address the underlying epigenetic mechanisms for osteogenesis, we profiled gene expression and histone modifications by RNA-Seq and ChIP-Seq respectively in the primary BMSCs committing to the osteoblast lineage at four stages: proliferation, early commitment/preosteoblasts, matrix deposition and maturation, and mineralization. From our profiling data, we selected 6 distinct patterns associated with osteoblast differentiation that had most biological relevance (for example, genes continuously upregulated, downregulated, and peaked at commitment). These gene sets were then correlated with 7 histone modifications to define signatures of histone modifications for developmentally expressed osteoblast-related genes. Seventy-five highly upregulated genes peaking at mineralization (eg.,Ocn, Bsp, Sost, Dkk1, Mepe, Enpp6, Bmp2) continuously acquired marks H3K9ac and H3K27ac, both reflecting transcriptional activation at promoters. At the same time, this gene set lost two repressive marks of transcription (H3K27me3 and H3K9me3). One gene set characterized by peak expression at commitment followed by a substantial decrease in expression is comprised of 291 genes, including many growth factors, transmembrane proteins and signaling mediators. This gene group exhibited an initial increase of H3K36me3 (transcription elongation mark) followed by a rapid decrease of this mark, closely correlating with the gene expression pattern. This observation suggests that gaining H3K36me3 is a prime indicator of transient gene upregulation. In conclusion, our data identifies distinct histone codes for different gene expression categories that are important drivers to establish osteoblast lineage.

Paracrine effects of hematopoietic cells on human mesenchymal stem cells. Shuanhu Zhou*. Brigham & Women's Hospital, USA

A progressive decline in the ability of stem cells to maintain normal adult tissues or to repair injured tissues contributes aging. We and others uncovered that there are age-related intrinsic changes in human mesenchymal stem cells (hMSCs). Several lines of evidence indicate that the decline in stem cell function during aging can involve both cell intrinsic and extrinsic mechanisms. The bone and blood formation are intertwined in bone marrow, therefore hematopoietic cells and bone cells could be extrinsic factors for each other in bone marrow environment. In this study, by using an *in vitro* transwell co-culture platform, we assessed the paracrine effects of hematopoietic cells on hMSCs. Our data showed that hematopoietic cells stimulate proliferation and osteoblast differentiation and inhibit senescence in hMSCs. To determine the paracrine factors that are responsible for the effects of hematopoietic cells on hMSCs, gene profiles of growth factors, Wnts and cytokines were assessed in both hematopoietic cells and hMSCs. Results showed that TNF-α, PDGF-β and Wnt-related factors, *e.g.* Wnt1, 4, 6, 7a, and 10a, sFRP-3 and sFRP-5, are dominantly expressed in hematopoietic cells. We next determined the role of TNF-α and Wnt signaling pathways in the paracrine interactions during aging. There was an age-related increase in gene expression of TNF-α in hematopoietic cells and decrease in gene expression of TNF receptor 2 in hMSCs; TNF-α treatment induced cell death and senescence, reduced proliferation and osteoblast differentiation and stimulated NF-κB signaling in hMSCs. There was an age-related increase of β-catenin protein levels and TNF-α stimulated β-catenin signaling in hMSCs. Kockdown β-catenin by siRNA reduced SA-β-Gal$^+$ cells in hMSCs, implying that TNF-α *via* NF-κB as well as Wnt/β-catenin signaling performed as negative factors in paracrine actions of hematopoietic cells on hMSCs. In conclusion, our data demonstrate that there are paracrine actions of hematopoietic cells, *via* soluble factors, such as TNF-α, PDGF-β or Wnts etc., on hMSCs; the age-related increase of TNF-α in hematopoietic cells suggests that immunosenescence, *via* the actions of hematopoietic cells on mesenchymal stem cells, may be one of the extrinsic mechanisms of skeletal stem cell function decline during human skeletal aging.

Regulation of skeletal stem cell multipotency by MT1-MMP. Jason Horton*[1], Heba Degheidy[2], Steven Bauer[2], Pamela Robey[3], Kenn Holmbeck[4]. [1]National Institutes of HealthNational Cancer Institute, USA, [2]Laboratory of Stem Cell Biology, Division of Cell & Gene Therapies, Center for Biologics Evaluation & Research, Food & Drug Administration, USA, [3]National Institute of Dental & Craniofacial Research, USA, [4]National Institute of Dental & Craniofacial Research, USA

Plasticity of the skeletal stem/progenitor cell lineage is an essential homeostatic mechanism initiated by skeletal injury or insult. Under normal circumstances, these primitive cells re-establish a bone/marrow organ with the proper balance of osteoprogenitors, hematopoietic-supportive stromal cells and marrow adipocytes, but in some cases the balance of these elements is disrupted. The mechanisms that govern skeletal stem cell activation and plasticity have yet to be defined in great detail, but are likely to involve both autocrine and paracrine cell-signaling, as well as interactions with extracellular matrix molecules. MT1-MMP has been identified as an indispensable modulator of mesodermal cell behavior and differentiation, and global deletion results in a severe skeletal phenotype. Conditional deletion of *Mt1-Mmp* from mature osteoblastic cells expressing osteocalcin ($Ocn^{Cre;}$ $Mt1^{f/f}$) results in osteopenia, spontaneous fracture, and a dramatic conversion of red marrow to yellow marrow. This adipogenic shift is thought to arise from a failure to block the differentiation of skeletal stem/progenitor cells in the stromal-vascular compartment into adipocytes. Consistent with this notion, $Ocn^{Cre;}$ $Mt1^{f/f}$ mice display abnormalities of fracture repair, characterized by generation of a thin mineralized cortex, failure to locally reconstitute hematopoietic marrow and expansion of yellow marrow throughout the fracture site. These results demonstrate that Mt1-MMP is a critical factor expressed by mature osteoblastic cells that governs marrow adiposity, and suggests interaction with a protease-dependent regulatory ligand that opposes adipose differentiation of the skeletal stem/progenitor cells.

Understanding the periosteal response to mechanical load and injury. Candice GT Tahimic*[1], Tao Wang[2], Alicia T. Menendez[2], Chak Fong[2], Yongmei Wang[2], Shunichi Murakami[3], Daniel Bikle[1]. [1]Endocrine Research Unit, Division of Endocrinology UCSF & VAMC, USA, [2]Endocrine Research Unit, Division of Endocrinology UCSF & VAMC, USA, [3]Case Western Reserve University, USA

The periosteum is a multilayer structure that serves as a niche for stem and osteochondroprogenitor cell populations and a repository for molecules that contribute to bone formation. The long-term goal of our study is to understand the key cell populations and the molecular mechanisms by which a healthy periosteum is able to respond with robust bone formation during mechanical loading or injury. Towards this goal, we performed gene expression analysis of primary periosteal cell cultures from normal three month old ambulatory animals as they underwent directed differentiation into the osteogenic lineage. Differentiating periosteal-derived cells, like bone marrow stromal cells, display a similar trend in the progression of osteogenic markers such as alkaline phosphatase and osteocalcin. Periostin, a molecule that is commonly associated with periosteal cells was found to be upregulated in the later stages of periosteal differentiation consequent with downregulation of Prx-1 expression. By day 21, these periosteal cells display modest Alizarin red staining with significant mineralization occurring at day 28. We are currently examining the effect of mechanical loading on this differentiation process. To further understand the role of subsets of cell populations in the periosteum during the response to loading state or injury, we developed a double transgenic animal carrying a Rosa tdtomato reporter and a tamoxifen-inducible Cre-Prx1 transgene. This model allows cell fate tracing studies on the subset of Prx-1 expressing periosteal osteochondroprogenitors. Tamoxifen-treated three month-old animals exhibited increased tomato red labeling in the periosteum during the reloading phase after a period of skeletal unloading. In a fracture model, robust labeling was observed in early stage of callus formation. Moreover, derivatives of Prx1 osteochondroprogenitors persist in vivo as shown by the incorporation of the label into cortical bone. This finding is consistent with our in vitro studies wherein cultures of periosteal tissue from these transgenic animals show tomato red labeling from the early to late stages of osteogenic induction. In conclusion, major similarities exist between the differentiation program of BMSCs and periosteal-derived cells, although the timing of periostin expression distinguishes the periosteal cultures. In the adult, progeny of Prx1-expressing osteochondroprogenitors comprise a persistent subset of periosteal cells that are capable of responding to mechanical stimuli and fracture injury.

Arctigenin Inhibits Osteoclastogenesis by Suppressing Both Calcineurin-Dependent and Osteoblastic Cell-Dependent NFATc1 Pathways. Teruhito Yamashita*[1], Shunsuke Uehara[2], Nobuyuki Udagawa[3], Feng Li[4], Shigetoshi Kadota[4], Hiroyasu Esumi[5], Yasuhiro Kobayashi[2], Naoyuki Takahashi[1]. [1]Matsumoto Dental University, Japan, [2]Matsumoto Dental University, Japan, [3]Matsumoto Dental University, Japan, [4]University of Toyama, Japan, [5]Tokyo University of Science, Japan

Arctigenin, a lignan-derived compound, is known as an anti-inflammatory and anti-tumor reagent. Arctigenin was previously shown to inhibit osteoclastogenesis; however, this inhibitory mechanism has yet to be elucidated. Here, we showed that arctigenin inhibited the activity of nuclear factor of activated T-cells, cytoplasmic 1 (NFATc1), a key transcription factor for osteoclastogenesis. NFATc1 in osteoclast precursors was activated through two distinct pathways: the calcineurin-dependent and osteoblastic cell-dependent pathways. Arctigenin strongly inhibited receptor activator of nuclear factor κB ligand (RANKL)-induced osteoclast formation in mouse bone marrow macrophage (BMM) cultures, in which the calcineurin-dependent NFATc1 pathway was activated. Arctigenin suppressed neither the activation of NF-κB and MAP kinases nor the up-regulation of c-Fos expression in BMMs treated with RANKL. However, arctigenin suppressed RANKL-induced NFATc1 expression and its target genes. Interestingly, the treatment of osteoclasts with arctigenin converted NFATc1 into a lower molecular weight species, which was translocated into the nucleus even in the absence of RANKL. Nevertheless, arctigenin as well as cyclosporin A (CsA), a calcineurin inhibitor, suppressed the NFAT-luciferase reporter activity induced by ionomycin and PMA in BMMs. Chromatin immunoprecipitation analysis confirmed that arctigenin inhibited the recruitment of NFATc1 to the promoter region of the NFATc1 target gene. Arctigenin, but not CsA suppressed osteoclast formation in co-cultures of osteoblastic cells and bone marrow cells, in which the osteoblastic cell-dependent NFATc1 pathway was activated. The forced expression of constitutively active NFATc1 rescued osteoclastogenesis in BMM cultures treated with CsA, but not that treated with arctigenin. Arctigenin also suppressed the pit-forming activity of osteoclasts cultured on dentin slices. These results suggest that arctigenin induces a dominant negative species of NFATc1, which inhibits osteoclast differentiation and function by suppressing both calcineurin-dependent and osteoblastic cell-dependent NFATc1 pathways.

Caspase-2 Plays a Role in Osteoclastogenesis by Regulating Reactive Oxygen Species. Danielle Callaway*[1], Manuel Riquelme[2], Jean Jiang[1]. [1]University of Texas Health Science Center at San Antonio, USA, [2]University of Texas Science Center, San Antonio, USA

Loss of caspase-2 in mice results in an osteopenic phenotype characterized by increased numbers of osteoclasts in vivo. However, the role of caspase-2 within the osteoclast as well as how loss of caspase-2 may contribute to increased osteoclast numbers has not yet been established. In this study, we showed that caspase-2 is present throughout the differentiation process, but caspase-2 protein levels become significantly reduced. Next, we sought to identify whether loss of caspase-2 led to an increase in osteoclast numbers in vitro due to enhanced osteoclast differentiation from macrophage precursors. RAW 264.7 cells were treated with siRNA against caspase-2, which led to an increase in osteoclast numbers as well as TRAP activity when siRNA was added at the beginning of the experiment or at day 2 of differentiation. Cells from *Casp2*$^{-/-}$ animals treated with RANKL similarly induced increased osteoclast numbers as well as TRAP activity compared to wild-type (WT) controls. In addition, *Casp2*$^{-/-}$ osteoclasts exhibited increased fusion, were larger than the control, and had increased protein levels of NFATc1. In order to evaluate whether caspase-2 loss had an effect on early differentiation, bone marrow macrophages (BMMs) from WT and *Casp2*$^{-/-}$ animals were assessed for the activation of downstream signaling pathway following RANKL addition, but no significant differences were found. Combined, the data from *Casp2* knockdown as well as from primary cells suggests that loss of caspase-2 did not appear to be involved in regulating the earlier stages of differentiation, but had a greater consequence on later stages involving preosteoclast fusion. In order to assess the mechanism behind the effects of caspase-2 loss on differentiation, the total and mitochondrial levels of reactive oxygen species (ROS) were evaluated since ROS has been characterized as a crucial component of osteoclastogenesis and that loss of caspase-2 is associated with increased ROS levels. During osteoclastogenesis, both total and mitochondrial ROS were increased in cells lacking caspase-2 but only after RANKL administration with a concomitant reduction in FoxO3a-regulated enzymes catalase and SOD2. Because mitochondrial ROS has been identified to be a possible regulator of the later stages of differentiation, the heightened levels in *Casp2*$^{-/-}$ cells could be the predominant mechanism that results in increased precursor fusion and osteoclast numbers.

Pathway analysis of microRNA profile during early, mid and late osteoclastogenesis. Neha Dole*[1], Tiziana Franceschetti[1], Catherine Kessler[2], Sun-Kyeong Lee[1], Anne Delany[1]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut Health Center, USA

An understanding of the molecular mechanisms regulating the complex process of osteoclastogenesis is critical for the design of novel therapeutics for bone loss. Osteoclast formation and function are tightly regulated by transcriptional, post-transcriptional and post-translational mechanisms. Bone homeostasis requires such stringent regulation, to prevent excessive or insufficient bone resorption. microRNAs (miRNAs) are key post-transcriptional regulators of osteoclastogenesis. They bind to their target mRNAs to repress expression; controlling proliferation, differentiation, and apoptosis. Disruption of miRNA-mediated regulation alters osteoclast formation and bone resorption. Previous studies profiled miRNA expression in mouse osteoclast precursors treated with RANKL for 24 hours. However, a more complete miRNA signature, encompassing early, mid and late stages of osteoclastogenesis, is wanting.

Here, we analyzed miRNA expression in an enriched population of murine bone marrow osteoclast precursors (depleted of B220+ and CD3+ cells) undergoing 1, 3, or 5 days of RANKL-driven differentiation. The Agilent microarray platform was used to analyze expression of mature miRNAs. 93 miRNAs showed >2 fold-change during these early, mid, and late stages. Remarkably, many of these miRNAs were detected for the first time in osteoclasts. We identified 7 clusters of differentially expressed miRNAs, and validated the expression of selected miRNAs by qRT-PCR. Computational analyses predicted several recurring pathways that could be targeted by the miRNA clusters. These include mTOR, PI3 kinase/AKT, cell-matrix interactions, actin cytoskeleton organization, focal adhesion and axon guidance. This suggests that many miRNA clusters differentially expressed during osteoclastogenesis converge on the regulation of some key functional pathways. For example, cytoskeletal remodeling is crucial for osteoclast precursor migration, maturation, and bone resorption. Genes important for cytoskeletal remodeling are potential targets for abundantly expressed miRNAs such as miR-27b, miR-29 and let7 family members.

Overall, our study is unique in that we identified miRNAs differentially expressed during early, mid, and late osteoclastogenesis in a population of primary mouse bone marrow cells enriched for osteoclast progenitors. This novel data set contributes to our understanding of the molecular mechanisms regulating the complex process of osteoclast differentiation.

Rhinacanthin C Inhibits RANKL-induced Osteoclast Differentiation by Suppressing MAPKs/NF-κB/NFATc1 Pathways through Preventing TRAF6-TAK1 Formation. Mineko Tomomura*[1], Ryuichiro Suzuki[2], Yoshiaki Shirataki[2], Hiroshi Sakagami[3], Akito Tomomura[4]. [1]Meikai University School of Dentistry, Japan, [2]Faculty of Pharmaceutical Sciences, Josai University, Japan, [3]Divisions of Pharmacology, Meikai University School of Dentistry, Japan, [4]Meikai University, School of Dentistry, Japan

The shrub *Rhinacanthus nasutus* (L.) Kurz (Acanthaceae) is widely distributed in Southeast Asian countries and used for the treatment of pneumonia, diabetes, hypertension and skin diseases. In search of anti-osteoclastogenic activity from plants, we found the ethyl acetate (EtOAc) extracts of root of *Rhinacanthus nasutus* inhibited the osteoclastogenesis stimulated by receptor activator of nuclear factor-κB ligand (RANKL) in RAW 264.7 cells. To investigate further the anti-osteoclastogenic constituents of *Rhinacanthus nasutus*, we isolated five components (rhinacanthin C, G, N and Q, and rhinacanthone) from the EtOAc-soluble fraction of this plant. Among

them, rhinacanthin C most potently inhibited the RANKL-stimulated osteoclastogenesis from the mouse bone marrow macrophage (BMM) cultures. Rhinacanthin C dose-dependently inhibited tartrate-resistant acid phosphatase-positive multinuclear cell formation and pit formation without cell toxicity. Rhinacanthin C suppressed RANKL-stimulated c-Fos and NFATc1 expression, a master transcription factor for osteoclastogenesis. RANKL-induced phosphorylation of ERK, JNK and NF-κB were significantly inhibited by rhinacanthin C. Furthermore, rhinacanthin C inhibited RANKL-induced TRAF6-TAK1 complex formation, an upstream signaling event that is important for activation of MAPKs and NF-κB. This study suggests that rhinacanthin C may be the natural compound responsible for anti-osteoclastgenic activity of *Rhinacanthus nasutus* and it might be an alternative medicine for the prevention of osteoporosis.

Soluble silica: an osteoclast-macrophage linage regulator in early RAW264.7 osteoclastogenesis. Pamela Uribe-Trespalacios*[1], Zivko Mladenovic[2], Kaveh Shahabi[3], Anders Johnasson[3], Maria Ransjo[4]. [1]University of Gothenburg, Sweden, [2]Gothenburg University, Sweden, [3]Umeå University, Sweden, [4]University of GothenburgSahlgrenska academy, Sweden

Diet and dietary supplements play an important part in osteoporosis treatment and prevention. Beyond calcium and vitamin D, an emanating number of studies have in recent years suggested that dietary silicon/soluble silica (Si) plays an important part of normal development of the skeleton and connective tissue. From in vitro cell culture studies on osteoblasts it has been reported that Si stimulates proliferation and acts on collagen synthesis/stabilization. It has also been demonstrated that Si inhibits osteoclast formation and bone resorption. The molecular mechanisms of Si on bone cells are however still unclear. The purpose of the present study was to further investigate the role of Si in osteoclastogenesis. Using neutral red uptake assay it could be established that Si concentrations ranging from 0-125µg/ml did not have any adverse effects on RAW264.7 cells. Next we used flow cytometry to analyze if Si would promote the RAW264.7 cells towards the macrophage or the osteoclastic lineage. We also studied how Si would alter gene expressions associated with osteoclastogenesis using quantitative real-time PCR. Our results suggest that Si dose dependently alters the expression of F4/80 and RANK as well as gene expressions associated with osteoclast fusion making Si a potentially important regulator in osteoclastogenesis.

A possible role of DMP1 as a negative regulator of FGF23 production in functional heterogeneity osteocytes: Three-dimensional morphological approaches. Ji-Won Lee*[1], Akira Yamaguchi[2], Tadahiro Iimura[3]. [1]Ehime University, Proteo-Science Center (PROS), Japan, [2]Tokyo Medical & Dental University, Japan, [3]Ehime University, Proteo-Science Center (PROS), Japan

FGF23 and dentin matrix protein (DMP1) are predominantly expressed in osteocytes in bone, regulating bone mineralization and phosphate metabolism, respectively. However, the mechanisms underlying the actions of DMP1 as a local factor regulating FGF23 and bone mineralization are not well understood. We first observed spatially distinct distributions of FGF23-and DMP1-positive osteocytic lacunae in rat femurs using immunohistochemistry. Three-dimensional immunofluorescence morphometry further demonstrated that the distribution and relative expression levels of these two proteins exhibited reciprocally reversed patterns especially in midshaft cortical bone. These *in vivo* findings suggest a direct role of DMP1 in the regulation of FGF23 expression in osteocytes. We next observed that the exogeneous treatment of recombinant DMP1 in UMR-106 osteoblast/osteocyte-like cells and long-cultured MC3T3-E1 osteoblastic cells showed significant down-regulation of the FGF23 production. Moreover, exogenous DMP1 affect cellular morphological changes by increasing the number of focal adhesion points in both cells measured by 3D-reconstructed images. Consistently, the levels of phosphorylated FAK, ERK and p38 were significantly elevated, indicating that exogenous DMP1 is capable of activating FAK-mediated MAPK signaling. Our findings suggest that DMP1 is a local, direct and negative regulator of FGF23 production in osteocytes through in the FAK-mediated MAPK pathway, thus proposing a relevant pathway that coordinates the extracellular environment of osteocytic lacunae and phosphate metabolism.

Compartment-, Age-, and Disease-Specific Variability in the Architecture of Osteocyte Lacunar-Canalicular System. Xiaohan Lai*[1], Shannon Modla[2], Catherine B. Safran[3], Christopher Price[1], Liyun Wang[1]. [1]University of Delaware, USA, [2]DBI Bioimaging Center, University of Delaware, USA, [3]Department of Biological Sciences, University of Delaware, USA

Introduction: Osteocytes form an interconnected network through the lacunar-canalicular system (LCS). The LCS structure affects not only how osteocytes perceive external mechanical stimulation via fluid flow (outside-in signaling) but also how signaling molecules move from cell to cell (inside-out signaling). The LCS architecture is recently shown to correlate with tissue mineralization. Due to the large length scales spanning the LCS from the entire bone (~mm) to the canalicular annulus (~100nm), quantifying the LCS structure is challenging and data are lacking. The objective of this study was to quantify the compartment, age, and disease specific LCS variations in wildtype and two disease models (perlecan deficient Schwartz-Jampel Syndrome and Akita type I diabetes), which showed attenuated bone response to *in-vivo* loading and potential alterations in the osteocyte functions.

Methods: Right tibiae from male mice (Table 1) of either C57BL/6J (WT), perlecan deficiency (C1532Yneo), or Akita background with age of 15-32 weeks (N=3 mice/group) were stained in basic fuchsin, and embedded in plastic for confocal examination. Sagittal sections (50 mm thick) of both diaphyseal cortical bone and metaphyseal trabecular bone were imaged using a confocal. Osteocyte LCS architecture of individual lacunae and associated canaliculi was measured from the z-stack images using VOLOCITY and AMIRA software (Fig. 1). Low magnitude (10X) images were used to derive lacuna density. Diaphyseal and metaphyseal segments (~1mm) from the left tibiae were prepared for TEM microscopy. Ultrathin sections (~100nm thick) were post-stained and imaged at 6,300X magnification. LCS ultrastructure was quantified by tracing osteocyte lacunae, cell bodies, canaliculi, and cell processes in Adobe Photoshop (Figs. 2&3) and measured using BoneJ plugin in Image J. Student t-tests were performed for various comparisons with significance set at $p<0.05$. Results: Compartment and age did not affect the LCS structures significantly in the confocal-based measurements (lacunar size and canalicular/lacunar number density, Table 1) but altered the pericellular gaps between cell body to lacunar and canalicular walls under the TEM (Table 2). Perlecan deficiency and diabetes altered both the confocal and TEM measures of the LCS compared with WT (Tables 1, 2). These LCS anatomical alterations could partially account for the attenuated bone responses to mechanical forces observed in vivo.

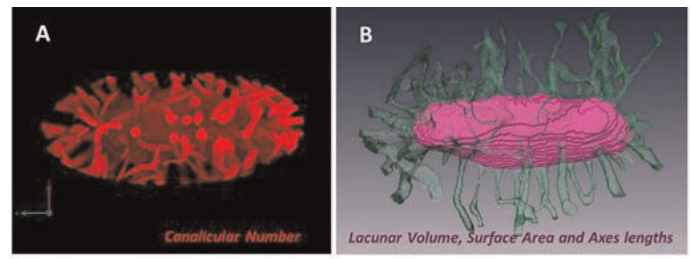

Fig. 1. Representative 3D renderings built from z-stack confocal images of lacunae and associated canaliculi were used to quantify (A) canalicular number in VOLOCITY ®and (B) lacunar volume, surface area and major and minor radii in AMIRA®.

Mechanical Loading and High Glucose Modify the Chemokine Secretion Profile of Osteocytes Affecting Osteoclast Differentiation and Activity. Arancha Gortazar*[1], Maria Teresa Portoles[2], Maria Concepcion Matesanz[2], Javier Linares[2], Maria Jose Feito[2], Daniel Arcos[3], Maria Vallet[4], Lilian Plotkin[5], Pedro Esbrit[6]. [1]Universidad San Pablo-CEU School of Medicine Madrid Spain, Spain, [2]Department of Biochemistry & Molecular Biology I, Faculty of Chemistry, UCM, Spain, [3]Department of Inorganic & Bioinorganic Chemistry, Faculty of Pharmacy, UCM, Instituto de Investigación Sanitaria Hospital 12 de Octubre i+12, Spain, [4]Department of Inorganic & Bioinorganic Chemistry, Faculty of Pharmacy, UCM, Instituto de Investigación Sanitaria Hospital 12 de Octubre i+12, Spain, [5]Indiana University School of Medicine, USA, [6]Instituto de Investigación Sanitaria (IIS)-Fundación Jiménez Díaz, Spain

Osteocytes, the most abundant cell type in bone, are buried in the mineralized bone matrix but regulate bone remodeling by altering osteoblast and osteoclast function. Osteocytes undergo apoptosis and recruit osteoclasts under conditions such as mechanical unloading, fatigue loading, and ovariectomy. Diabetes mellitus induces deleterious effects in bone, although the underlying mechanisms are not completely understood. Here, we aimed to evaluate the influence of high glucose (HG) exposure on the capacity of mechanical stimulation to affect osteoclast migration, differentiation and activity. To this end, MLO-Y4 cells were subjected or not (static control) to mechanical stimulation by fluid flow (FF, 10 dyn/cm^2, 15 min) following pre-treatment with HG or normal glucose for 48 h. Cell medium was changed, cells were cultured for additional 18 h and cell-conditioned medium (CM) was then collected. We first analyzed the secretion of various known chemokines: GM-CSF, IL-6, MCP-1, MIF-1a, MIF-1b, RANTES and VEGF in the CM, by Luminex multiplex assays. Both FF and HG, significantly inhibited chemokine secretion, compared to non-stimulated/static control osteocytes. We next exposed pre-osteoclastic RAW 264.7 cells to osteocyte CM for 14 d (renewing this medium every three days). Cell morphology, proliferation, reactive oxygen species (ROS) content and resorptive activity on hydroxyapatite disks in the presence of RANKL (40 ng/ml) and M-CSF (25 ng/ml) were determined. We found that the CM of static control osteocytes inhibited cell proliferation and ROS production in RAW 264.7 cells, but increased osteoclast differentiation and resorptive activity. Exactly opposite results were obtained when CM of FF stimulated osteocytes was added to RAW 264.7 cells. Interestingly, CM of osteocytes treated with HG, did not affect proliferation and ROS content, although induced the formation of multinucleated but inactive osteoclasts, in both FF and static control conditions. In conclusion, our in vitro findings demonstrate that osteocytes can change their chemokines secretion profile in response to mechanical stimulation and HG to control osteoclast differentiation and activity.

Microdamage and Mechanical Loading Have an Interactive Effect on Remodeling Signals Produced by Osteocyte. Chao Liu*[1], Xiaoqing Zhang[2], Michael Wu[2], Lidan You[3]. [1]University of Toronto, Canada, [2]University of Toronto, Canada, [3]Mechanical & Industrial Engineering, University of Toronto, Canada

Introduction: Microdamage in bone triggers remodeling with resorption and bone formation along the damage site [1]. Osteocytes are cells distributed throughout the bone. They have been observed to be physically damaged by microdamage [2]. Interestingly, microdamage-induced remodeling requires mechanical loading in vivo [3]. Since osteocytes are the mechanosensors of bone [4], they could react to mechanical loading at the same time to microdamage. We hypothesize that osteocyte damaged by physical trauma similar to microdamage would produce increased levels of remodeling-related molecules; and this response is mechanically regulated.

Methods: Osteocyte Microdamage model: MLO-Y4 cells on glass slides were damaged by tungsten needles (1 μm tip) mounted on a frame with horizontally travel, and adjustment of vertical position (Fig 1). The cell culture was damage to have ~15% dead cells. Cell damage was assessed with Trypan Blue and Live/Dead assay. Fluid shear stress treatment: parallel flow chambers were used to apply fluid shear stress. The flow was oscillatory with sinusoidal profile at frequency of 1 Hz, with peak shear stress of 2 Pa for 1 hr. Gene quantification: Reverse transcription real-time PCR was used to measure IL-6, TNFα, COX-2, RANKL, and OPG mRNA levels, normalized to 18s. Soluble signals: PGE_2 and VEGF concentration were measured using EIA and ELISA.

Results: Significant number of dead cells was observed near the damage sites, ranges from 1-10 μm (Fig 2). COX-2 and VEGF mRNA levels increased 24 hrs after cell damage (Fig 3). Other measured mRNA levels was not changed. Concurrent fluid shear stress and physical damage induced higher COX-2 and VEGF mRNA (Fig. 4) and released molecule level (Fig. 5) than the effect from each individual stimulus.

Conclusions: The cell damage system produced osteocytes resembling those exposed to fatigue loading in vivo [5]. Mechanical loading likely supported the targeted bone remodeling to microdamage by enhancing inflammatory and angiogenic gene and protein expression levels in osteocytes. But osteocytes are not responsible for the changes in RANKL, OPG, IL-6, TNF-α that were observed in fatigue damaged bone in vivo [1].

The Importance of Activated Vitamin D for the Mineralization by the Osteocyte in Patients with Renal Hyperparathyroidism. Aiji Yajima*[1], Ken Tsuchiya[2], Kosaku Nitta[2], Masaaki Inaba[3], Yoshihiro Tominaga[4], Norio Amizuka[5], Akemi Ito[6], Hironari Shindo[7]. [1]Otsuki Municipal Central Hospital, Japan, [2]Tokyo Women's Medical University, Japan, [3]Osaka City University, Japan, [4]Nagoya Second Red Cross Hospital, Japan, [5]Hokkaido University School of Dentistry, Japan, [6]Ito Bone Histomorphometry Institute, Japan, [7]Otsuki Municipal Central Hospital, Japan

Introduction;

Whether vitamin D is important for the mineralization by the osteocyte or not is controversial. High dose of activated Vitamin D_3 (VD_3) suppresses the mineralization by the osteocyte in the mouse (Lieben L, et al. J Clin Invest 2012). However, activated VD_3 is administered to the patients after parathyroidectomy for renal hyperparathyroidism (PTX) to avoid tetany, leading to an increase of bone mineral density. Low mineralized bone area was evaluated in patients with or without VD_3 after the neck surgery to investigate the importance of VD_3.

Methods;

Fifteen patients (Group I; Age; 56.1±9.3, Duration of Hemodialysis (HD); 13.8±7.3 years) received high doses of 1α-hydroxyvitamin D_3; alfacalcidol (2.0-3.0 μg/day) after PTX and four patients (Group II; Age 56, 63, 67 and 67, Duration of HD, 19, 15, 25 and 15 years, respectively) did not receive VD_3 at all. Iliac bone biopsies were performed before and at 2-4 weeks after PTX in Group I and before and 4 weeks in Group II. Histomorphometric parameters were as follows; osteoclast surface (Oc.S/BS;%), Osteoblast surface (Ob.S/BS;%), osteoid volume (OV/BV;%), fibrous volume (Fb.V/TV;%) bone formation rate (BFR/BS; mm^2/mm^3/years) and low mineralized bone volume (LMV/BV;%). BFR/BS was measured only after PTX.

Results;

Group I; Oc.S/BS decreased from 4.9±3.8 to 0.1±0.6 ($P<0.001$), OV/BV increased from 10.8±7.9 to 19.9±8.8 ($P=0.002$), Fb.V/TV decreased from 6.1±4.8 to 0.4±1.4 ($P<0.001$) and LMV decreased from 10.3±6.4 to 2.5±1.8,but Ob.S/BS didn't change. BFR/BS (0.011±0.009) was lower as compared with the normal value after PTX, meaning the development of low turnover osteomalacia.

Group II; Oc.S/BS and Fb.V/TV decreased and OV/BV increased in all patients, and Ob.S/BS didn't. In addition, BFR/BS was also lower in all patients in Group II. However, LMV/BV increased from 10.4 to 16.0 in Patient 1, 4.4 to 16.4 in Patient 2, 7.7 to 9.1 in Patient 3 and 1.4 to 15.9 in Patient 4 in this Group.

Conclusion; Bone formation rate was lower, meaning that mineralization by osteoblast decreased after PTX in both Groups although VD_3 was administered. By the way, the ability of mineralization by the osteocyte was surprisingly activated in patients receiving VD_3 because mineralization deficiency by the osteocyte leads to increased low mineralized bone volume. Therefore, VD_3 should be very important for the mineralization by the osteocyte, but not osteoblast in human being with renal insufficiency.

Identification of miRNAs Involved in the Differentiation Process from Osteoblasts to Osteocytes. Laura De Ugarte Corbalán*[1], Nicholas H. Farina[2], Matt Prideaux[3], Gary Stein[4], Jane Lian[5], Lynda Bonewald[6]. [1]University of Missouri, Kansas City, USA, [2]University of Vermont College of Medicine, USA, [3]University of Adelaide, Australia, [4]University of VermontCollege of Medicine, USA, [5]University of Vermont College of Medicine, USA, [6]University of Missouri - Kansas City, USA

Bone formation and osteoblast differentiation are now appreciated to be regulated by miRNAs which support the coordination of many key signaling pathways essential for the onset of osteogenesis and for maintaining bone mass. However little is known about the molecular regulation of osteoblast to osteocyte differentiation. To begin to understand the role of miRNAs in this process, we performed miRNA array analyses of the different stages of IDG-SW3 cells from late osteoblast to early osteocyte to mature osteocyte. Total RNA was extracted at 0, 3, 7, 14, 21 and 28 days of culture to perform miRNA qPCR based global expression profiling arrays (Fluidigim). QC, PCA and hierarchical clustering were performed to verify biological replicates and a threshold was set at ⩾2 fold change for comparison of expression levels. From 133 detected miRNA, 39 were significant to $p<0.05$, while 17 miRNAs were highly significant ($p < 0.01$). Included in 10 upregulated miRNAs ($p<0.01$), was miR-146b-5p, known to be elevated during osteogenic differentiation of muscle derived progenitor cells (Oishi et al, PLOS, 2014). Among the 7 downregulated miRNAs ($p<0.01$), miR-351-5p was identified, known to promote myogenesis (Chen et al, Physiol Gen, 2012). Multiple miRNAs were validated by the SYBR Green qPCR approach using primary osteoblasts and osteocytes isolated from 2 mo old murine long bones which replicated the results observed with the osteoblastic stage of IDG-SW3 cells (days 3-7) and late osteocyte stage IDG-SW3 cells (days 21-28). The DAVID v6.7 database was used to identify enriched KEGG pathways involved with

the genes predicted to be targeted by the 17 (significantly up or down regulated miRNAs) between day 0 and day 28. Pathways with established functions in osteoblast to osteocyte differentiation, such as Wnt signaling, were predicted targets of these miRNAs. In addition, several previously uncharacterized biological pathways potentially relevant to osteocyte cell structure, such axon guidance, were revealed. We propose that osteocytes have a unique subset of miRNAs consistent with their known properties, as well as revealing potentially novel activities.

Morphological analysis of Dentin Matrix Protein 1 (DMP1) phosphorylation by Fam20C in the bone. Kaori Oya*[1], Sunao Sato[2], Satoru Toyosawa[3]. [1]Osaka University Dental Hospital, Japan, [2]Osaka University Graduate School of Dentistry, Japan, [3]Osaka University, Japan

[Background]: DMP1 is one of the acidic phosphoproteins that are specifically expressed in osteocytes. DMP1 has abundant acidic domains, which are negatively charged at physiological pH. It also contains a large number of phosphorylation sites, and these regions become another highly negative-charged domain after phosphorylation. The highly phosphorylated, negative-charged DMP1 may play an important role in the bone mineralization by recruiting calcium ion and subsequent mineral deposition. Most recently, it has been reported that Fam20C was expressed in the bone tissue and phosphorylated DMP1 in vitro. In this study, to clarify in situ phosphorylation event of DMP1 by Fam20C in the bone, we verified the localization of phosphorylated DMP1 and Fam20C in the rat bone by immunohistochemical methods.[Materials and methods]: Wistar rats (days 28 of postnatal life) were used in this study. Tibiae were fixed with 4% paraformaldehyde in PBS and then demineralized in buffered 10% EDTA and embedded in paraffin. Serial sections of 4-μm thickness were cut and they were used for immunostaining or double immunofluorescence staining. Phosphorylated DMP1 was estimated by overlapping immunostainings of DMP1 and phosphoserine.

[Results and Discussion]: We described the localization of each protein according to osteocyte classification (osteoblastic-, osteoid-, young-, old-OCs) as previously reported. Double immunofluorescence staining with DMP1 and phosphoserine showed that osteoblastic- and osteoid-OCs had an accumulation of DMP1 without phosphorylation in the Golgi area. On the other hand, young-OCs had phosphorylated DMP1 in intracytoplasmic Golgi area and perilacunar and pericanalicular mineralized bone matrix. Further, old-OCs had phosphorylated DMP1 in perilacunar and pericanalicular mineralized bone matrix, but had no immunoreaction of DMP1 and phosphoserine in intracytoplasmic area. Fam20C (Golgi kinase) was highly expressed in osteoid- and young-OCs and it was colocalized with DMP1 in their Golgi apparatus. These findings suggest that DMP1 begins to be phosphorylated in the Golgi apparatus of osteoid-OCs and phosphorylated DMP1 is secreted into extracellular matrix by young-OCs.

Bone Microstructure Analysis in Men by HR-pQCT: Associations with Age, Body Mass Index, and Androgens. Narihiro Okazaki*[1], Andrew Burghardt[1], Ko Chiba[2], Makoto Osaki[3], Sharmila Majumdar[1]. [1]University of California, San Francisco, USA, [2]Nagasaki University School of Medicine, Japan, [3]Nagasaki University, Japan

Objective: Male osteoporosis has been recognized as a major clinical problem because the number of men with osteoporosis is increasing as the elderly population increases. In addition, men with hip fractures have significantly higher morbidity and mortality rates compared to women. High-resolution peripheral quantitative computed tomography (HR-pQCT) allows high-resolution bone microstructure analysis in vivo for peripheral skeletal sites. The aim of this study was to investigate the relationship between bone microstructure measured by HR-pQCT and age, body mass index (BMI), and serum androgen levels which are considered as primary risk factors of male osteoporosis.

Methods: Subjects included 49 healthy males (mean age 60.1 $\pm$ 7.1, range 50-78 years). The distal radius and distal tibia were scanned using HR-pQCT with an isotropic voxel size of 82μm. The following bone microstructure parameters were measured: bone volume fraction (BV/TV), trabecular thickness (Tb.Th), trabecular number (Tb.N), trabecular separation (Tb.Sp), trabecular bone mineral density (Tb.BMD), cortical thickness (Ct.Th), cortical porosity (Ct.Po), cortical pore diameter (Po.Dm), and cortical bone mineral density (Ct.BMD). The relationships between the bone microstructure parameters and age, BMI, serum calcium, vitamin D, and testosterone were analyzed.

Results: In distal tibia, age had significant positive correlations with Ct.Po, Po.Dm, and had a significant negative correlation with Ct.BMD. In distal radius, age had a significant positive correlation with Ct.Po. However, age did not have a relationship with trabecular bone parameters. In addition, BMI, serum calcium, vitamin D, and testosterone were not correlated with either trabecular or cortical bone parameters.

Conclusion: Cortical bone microstructure, but not trabecular bone, changed significantly with aging, especially at the tibia - a weight bearing site. However, no relationship between BMI or testosterone and bone microstructure was observed.

Osteoporotic women with clinical vertebral fractures have lower trabecular bone scores than controls matched by lumbar spine T-scores and age. Albrecht Popp*[1], Nadshathra Varathan[2], Helene Buffat[3], Christoph Röder[4], Didier Hans[5], Kurt Lippuner[1]. [1]Department of Osteoporosis, University Hospital & University of Berne, Switzerland, [2]Department of Osteoporosis, University Hospital & University of Berne, Switzerland, [3]Department of Osteoporosis, University Hospital & University of Berne, Switzerland, [4]Institute for Evaluative Research in Orthopaedic Surgery, University of Berne, Switzerland, [5]Lausanne University Hospital, Switzerland

Introduction:

The Trabecular Bone Score (TBS) is a grey-level texture measurement reflecting bone micro-architecture (MA) based on the quantification of the variogram from a given lumbar spine scan by dual energy X-ray absorptiometry (DXA). TBS has proven predictive value on fracture risk, partially independent of clinical risk factors and bone mineral density (BMD). The aim of this study is to evaluate its impact on clinical vertebral fracture risk in women with osteoporosis.

Methods:

Consecutive women who underwent vertebroplasty after clinical vertebral fracture(s) (cases) at the University Hospital of Berne, Switzerland, were compared with lumbar spine T-score and age matched, osteoporotic women without prevalent

clinical vertebral fracture (controls). Exclusion criteria were BMI <15 or >35 kg/m^2 for all women, any non-osteoporotic metabolic bone disease, traumatic or malignant origin of the vertebral fracture for the cases and prevalent morphometric severe vertebral fractures in the control group. Lumbar spine (with at least two assessable vertebrae) and hip BMD were assessed by DXA (Hologic^{TM}, USA) and remained blinded for MA evaluation by TBS (Medimaps^{TM}, France). From initially 281 cases and 720 controls, 136 women of each group remained after matching for lumbar spine T-scores and age. Finally, seventeen women were pairwise excluded due to missing data. Mann-Whitney U-test was applied to compare differences between the groups (SPSS^{TM}).

Results:

The characteristics of the patients are given below:

Conclusion:

In this nested case-control study, osteoporotic women with clinical vertebral fractures had lower trabecular bone scores than controls matched by lumbar spine T-scores and age.

	Cases n=119	Controls n=119	p
Age (years)	70.9±8.5	70.1±7.9	0.363
BMI (kg/m2)	24.7±3.7	22.8±3.7	<0.001
LS T-score (SD)	-2.96±0.7	-2.97±0.7	0.969
Neck T-score (SD)	-2.28±0.8	-2.17±0.8	0.315
TBS	1.156±0.100	1.201±0.107	0.001

Age-Related Changes in Lumbar Spine Trabecular Bone Score in Chinese-American Men. Barbara Silva*[1], Rajeev Babbar[2], George Liu[2], Chiyuan Zhang[3], Donald McMahon[4], Wen-Wei Fan[5], Didier Hans[6], John Bilezikian[4], Marcella Walker[3]. [1]Federal University of Minas Gerais, Brazil, Brazil, [2]Weill Cornell Medical college, NYP Lower Manhattan Hospital, USA, [3]Columbia University, USA, [4]Columbia University College of Physicians & Surgeons, USA, [5]Columbia University Medical Center, USA, [6]Lausanne University Hospital, Switzerland

Trabecular bone score (TBS) is an indirect index of trabecular microarchitecture that can be derived from the lumbar spine (LS) DXA image. LS TBS is associated with vertebral and non-vertebral fractures in postmenopausal women and men. While TBS is readily available from LS DXA images through the application of specific software, normal TBS values across age, gender and race remain to be defined. It has been shown that Chinese-Americans (CH) women and men have lower areal bone mineral density (aBMD) but similar or lower fracture rates than their Caucasian counterparts. More favorable bone microarchitecture has been observed in CH, which helps to explain their lower risk of fracture. TBS could be a useful adjunct to aBMD as determined by DXA for assessing fracture risk in this population. To this end, we investigated age- related changes in LS TBS and relationships between testosterone and TBS in a cohort of CH men.

We enrolled CH men of full Chinese descent, aged 20 to 90 years, with current residence in the US. Subjects who had sustained a hip fracture or those with conditions or medications known to affect bone metabolism were excluded. Additionally, we excluded individuals with BMI < 15 or > 35 kg/m^2. DXA of LS and hip sites (Hologic) as well as demographic, medical, and familial data were obtained. Serum total testosterone and 25OHD levels were measured. Site-matched LS TBS was extracted from the DXA image using TBS iNsight software (version 1.8).

We studied 341 CH men, mean age 56.1 $\pm$ 16.2 years, and mean BMI 24.3 $\pm$ 3.0 kg/m^2 (range 16.9- 34.7 kg/m^2). Mean duration of residence in the US was 18.1 $\pm$ 12.0 years. Serum testosterone levels were normal (466 $\pm$ 176 ng/dL); mean 25OHD serum concentration was 26.5 $\pm$ 8.6 ng/mL. The mean LS TBS in the entire population was 1.387 $\pm$ 0.084, and ranged from 1.073 to 1.586. TBS was weakly associated with testosterone levels (r= 0.140; p=0.01). As expected, there was a negative correlation between TBS and age (r= -0.344; p<0.0001). Figure 1 shows mean BMD and LS TBS values for each 10-year age group.

LS TBS, which reflects bone microarchitectural texture, decreases with advancing age and testosterone levels in CH men. The changes observed in TBS are similar to age-related changes in BMD at the hip, but not the LS. While further research is needed to establish the association between TBS and fracture risk in CH men, TBS may aid in the clinical evaluation of bone microarchitectural deterioration in CH men.

Figure 1: Mean (±SD) lumbar spine trabecular bone score (LS TBS) and BMD at the LS, total hip (TH) and femoral neck (FN) for each 10-year age group:

Unusual Cause of Increased Lumbar Bone Mineral Density - Case Report. Miro Cokolic*[1], Matej Rakusa[2]. [1]medical doctor, Slovenia, [2], Slovenia

A 78 - year old female with known osteoporosis was reassessed for bone mineral density (BMD) measurement in december 2013. She was treated with calcium supplements, cholecalciferol 7000 IE per week and bisphosphonate. Her baseline BMD and T-score of lumbar spine (L1-L4), measured 9 years before were 0.699 g/cm2, -3.5 SD and Echinococcal cyst wasn't seen. The treatment was successful and the BMD was stable. On last control dual x-ray absorptiometry scan (DXA) of lumbar spine and hip, BMD of total lumbar spine was 0.910 g/cm2, T-score was -1.2 SD. BMD and T-scores for each lumbar vertebrae were: L1 1.384 g/cm2, +4.2 SD; L2 0.667 g/cm2, -3.3 SD; L3 0.654 g/cm2, -3.9 SD; L4 0.785 g/cm2, -3.0 SD. The BMD and T-score of the neck were 0.463 g/cm2, -3.5 SD and of the total hip were 0.590 g/cm2, -2.9 SD. On examining of the picture, we identified a calcified mass in the projection of L1 vertebra. We repeated the analysis of DXA scan and excluded the calcified formation and L1 vertebra. BMD of analyzed lumbar spine (L2-L4) was 0.701 g/cm2, T-score was -3.4 SD. BMD and T-scores were: L2 0.614 g/cm2, -3.8 SD; L3 0.642 g/cm2, -4.0 SD; L4 0.785 g/cm2, -3.0 SD.

We checked her previous examinations. Eleven months before she had CT of abdomen because of suspected gastric carcinoma. Three centimeters large calcified Echinococcal cyst was found, which was previously unnoticed. On the last DXA scan echinococcal cyst was probably projected to the L1 vertebra because of developement of kyphosis and consequently reduction of height.

Discussion

Artifacts can interfere with BMD measurements. The study showed that bra wires and calcium carbonate pills positioned lateral to the spine can change BMD. Several medical conditions, such as osteophyte formation, osteoarthritis, ankylosing spondylitis, vertebral fractions, aortic calcifications, can also increase BMD. However after examining the literature on Pubmed, to our knowledge there was no cases of falsely increased BMD of lumbar spine because of calcified Echinococcal cyst.

Volumetric Bone Mineral Content changes assessed by 3D-DXA after two years of Alendronate Treatment. Luis Del Rio*[1], Silvana Di Gregorio[2], Ludovic Humbert[3], Yves Martelli[4]. [1]Cetir Centre Medical, Spain, [2]MD, Spain, [3]PhD, Spain, [4]Eng, Spain

3D-DXA is a new application that provides a 3D reconstruction of the proximal femur from a 2D DXA standard acquisition of the hip. This reconstruction method is based on a statistical model incorporating both the femoral shape and the 3D BMD distribution. A 3D personalized model is acquired by registering the statistical model onto the 2D DXA image of the patient so that the projection of the model matches the DXA image.

Objective: Measuring the bone mineral content changes in trabecular and cortical regions in patients after a 24-months treatment with alendronate.

Method: A group of 27 women with osteoporosis were included in this study. All the patients had alendronate treatment during two years. None of the patients had calcium or Vit D supplementation.

3D-DXA reconstruction was performed from images taken at baseline and 24-month follow-up visit. Bone changes were measured at the proximal femur region (excluding the femoral head). Bone mineral content (BMC) was measured in the cortical and trabecular bone in each 3D-DXA volumetric reconstruction. T-test was used to assess the differences between analyses at baseline and follow-up scans.

Results: We measured a 4.60% increase of proximal femur BMC (trabecular + cortical) (p=00001). The most significant change was observed in the trabecular region (increase of 5.53%, p=0.001). An increase of 2.9% was measured at the cortical bone (p=0.052).Conclusion: This method presents a high potential for clinical routine use, by providing 3D patient-specific reconstructions from a standard DXA acquisition and allowing for the assessment of the individual response to antifracture therapy.

Assessing Age, Sex, and Racial Differences in Cortical Porosity Requires Adjustment for Site-Specific Variation in the Selected Region of Interest. Ali Ghasem-Zadeh*[1], Andrew Burghardt[2], Afrodite Zendeli[3], Serena Bonaretti[2], Ashild Bjornerem[4], Xiao-Fang Wang[5], Yohann Bala[6], Galateia Kazakia[2], Roger Zebaze[7], Ego Seeman[1]. [1]Austin Health, University of Melbourne, Australia, [2]University of California, San Francisco, USA, [3]Endocrine Centre, Austin Health, University of Melbourne, Australia, Australia, [4]UiT The Arctic University of Norway, Norway, [5]University of Melbourne, Austin Health, Australia, [6]University of Melbourne, Dept. of Medicine, Australia, [7]Austin Health, University of Melbourne, Australia

High-resolution peripheral quantitative computed tomography (HR-pQCT) measures micro-architecture in a region of interest (ROI) at the distal radius and tibia. Bone width and micro-architecture vary slice by slice along the length of a bone so differences in micro-architecture by age, pubertal stage, sex and racial group may be the result of differences in the placement of the ROI rather than the characteristics of the subjects.

To assess the slice-by-slice variation in cortical porosity of radius, 18 radii scanned as standard ROI and extended to 9.02 mm distally and 18.04 mm proximally(440 slices).We used Strax 1.0 software to assess slice by slice of total cortex, compact cortex, and transitional zone porosity for whole 440 slices.

We found 1 mm replacing ROI distally, in comparison with standard ROI, produce 2.02, 3.49, and 0.61% increment on the measured porosity of total cortex, compact cortex and transitional zone, respectively, however replacing 1 mm proximally produce 2.8, 4.8, and 0.50% reduction.

We infer that a more distal ROI has a significant effect on cortical porosity measurement particularly compact cortex porosity which may result in erroneous age, sex and racial differences being reported. This variation needs to be considered when interpreting data in persons who differ in bone length.

Key words cortical porosity, bone structural variability, micro-architecture

	2mm Distally (Mean ±SD)	1mm distally (Mean ±SD)	Default (9.02mm from endplate) (Mean ±SD)	1mm proximally (Mean ±SD)	2mm proximally (Mean ±SD)
Porosity of total cortex(%)	46.5±5.0	44.6±5.1	43.2±5.2	41.9±5.3	40.5±5.4
Porosity of compact cortex(%)	40.0±4.9	38.3±5.1	36.3±5.2	34.7±5.3	32.9±5.4
Porosity of transitional zone(%)	62.2±3.5	61.8±3.6	61.4±3.7	61.1±3.8	60.7±3.9

Arnozan, PTIB, Pessac, France, France, [5]Centre D'Evaluation, Des Maladies Osseuses, France, [6]Med-Imaps, Plateforme Technologique d'Innovation Biomédicale (PTIB), France, [7]EOS imaging, R&D, Paris, France, France, [8]Université Paris Descartes,. Service de Radiologie, Hôpital Cochin. INSERM U 1153, France, [9]Hospital Cochin, France

Introduction

The EOS™ X-ray imaging system allows full body frontal and lateral scans to be acquired simultaneously in the upright position, at low dose (~125 µSv). The trabecular bone score (TBS) was shown to relate to the bone architecture and fracture risk, using DXA imaging. A new prototype version of TBS has been developed for the EOS™ system. The aim of this study was to assess the discriminative value of the TBS measured on EOS™ images (TBS_{EOS}) for osteoporotic fractures.

Methods

We conducted a case-control study to assess the diagnostic value of TBS_{EOS} on a sample of patients aged ⩾ 50 years, receiving no antiosteoporotic treatment. The sample consisted of 26 patients with severe osteoporotic fractures (11 vertebrae, 10 humeri, 2 hip and 3 proximal tibia fractures) and 51 patients without fracture. The TBS was computed on full-body EOS™ images, focusing on the lumbar spine region, blinded from clinical parameters. The patients were also scanned with a DXA bone densitometer (Hologic) and the Spine, Total hip and Femoral neck areal BMD (aBMD) were computed. Association of the TBS_{EOS} and aBMD (in $g.cm^{-2}$) with the fractures was assessed using ROC curves analysis (AUCs).

Results

Patients with fractures were significantly older than patients without fractures (mean age 68.5 vs 64.4 years, p=0.04) and had similar mean BMI (23.6 vs 22.6 kg/m^2, p=0.19). Prevalence of osteoporosis was similar in fracture and non-fracture groups (68 % vs 78.4%, p=0.97). aBMD measurements were also similar at lumbar spine (0.78 vs 0.79, p=0.92), total femur (0.73 vs 0.71, p=0.26) and femoral neck (0.60 vs 0.61, p=0.75). TBS_{EOS} values were significantly lower in fractured patients compared to non-fractured patients (0.646 vs 0.734, p=0.03). TBS_{EOS} was associated with the presence of fractures as reported by a significant AUC of 0.665.

Conclusion

This case-control study, based on a prototype version of the TBS_{EOS}, demonstrated the feasibility of TBS on low-dose EOS™ imaging devices. Results show that the TBS_{EOS} was successful in discriminating patients with osteoporotic fractures from controls independently of aBMD.

Concordance in Paired QCT and DXA at the Lumbar Spine. Gabriel Bodeen[1], Alan Brett*[2], Perry Pickhardt[3]. [1]Mindways Software, USA, [2]Mindways Software, Inc., USA, [3]University of Wisconsin, USA

Purpose: Quantitative CT (QCT) of the lumbar spine is used for diagnosis of osteoporosis and osteopoenia. The upper thresholds for these classifications are bone mineral densities (BMD) of 80 and 120 mg/cc, respectively, according to guidelines of the American College of Radiology (ACR). World Health Organization (WHO) standards for interpretation of DXA use T-Scores of -2.5 and -1 as thresholds for the same classifications. A study by Cann indicated that these QCT thresholds lead to the same rates of osteoporosis and osteopoenia in the population as the WHO thresholds. We investigated whether paired DXA and QCT measurements have similar thresholds as rate-based studies.

Methods: DXA and CT imaging of 58 subjects was completed at vertebrae L1 and L2, for 116 total vertebrae. Subject ages ranged from 49 to 86 years (mean 59 ± 8.7 SD). In each case, the time between DXA and CT imaging was less than 10 months (mean 72 days ± 57 SD). DXA imaging and analysis was done on a Lunar Prodigy (GE, Madison, WI). CT was collected on a LightSpeed Ultra and LightSpeed 16 (GE) and analyzed using asynchronous calibration data with QCT Pro (Mindways Software, Austin, TX). QCT T-Scores were calculated by linearly transforming the BMD thresholds to match the WHO thresholds.

Results: Equal rates for QCT and DXA occur in this cohort below BMD thresholds of 90 mg/cc for osteoporosis and 125 mg/cc for osteopoenia. (BMD estimates have been rounded to the nearest 5 mg/cc.) Concordance of classification at these thresholds by weighted Cohen's κ is κ=0.54. Maximum concordance is κ=0.58 and occurs nearest 75 – 130 mg/cc; the figure shows this as a scatterplot of QCT versus DXA T-Scores. Green curves at left and bottom show the projected distribution envelopes of the QCT and DXA, respectively. Horizontal and vertical red lines at -2.5

(solid) and -1 T-Scores (dashed) show regions with matched or unmatched classification. The cyan line is the line of best fit by Deming regression, which is equivalent to thresholds 75 – 120 mg/cc; a dotted black line is shown at unity for comparison.

Conclusions: For this cohort, concordance-based thresholds differ markedly from rate-based thresholds at the osteoporosis threshold, but they overlap at the osteopoenia threshold. The one-sided difference is explained by the variances around the best-fit line and the higher skewness of the DXA in this cohort (0.45 versus 0.13 for QCT). Concordance-based thresholds in this paired study support the ACR guidelines.

Osteoporosis treatment decision based on combining Bindex® and FRAX®. Janne Karjalainen*[1], Ossi Riekkinen[2], Juha Töyräs[3], Jukka Jurvelin[3], Heikki Kroger[4]. [1]Bone Index Finland Ltd., Finland, [2]Bone Index Finland, Ltd., Finland, [3]University of Eastern Finland, Finland, [4]Kuopio University Hospital, Finland

According to National Osteoporosis Foundation (NOF) guidelines[1], treatment is recommended for osteoporotic patients and patients with osteopenia and high fracture probability (FRAX® with BMD over 3% for hip and/or over 20% for other fractures). In this study, a pocket size pulse-echo (PE) ultrasound (US) device, Bindex® and FRAX® with BMI is used in treatment pathway analysis and compared to NOF guidelines.

Elderly Caucasian woman (n = 427, age = 69 $\pm$ 9 years) under osteoporosis suspicion were examined using Bindex® device. Bindex® reports a diagnostic parameter, Density index, DI[2]. Previously, the 90% sensitivity and specificity thresholds for DI were determined along ISCD and NOS guidelines[3,4] in diagnostics of osteoporosis (the triage approach). By using these thresholds, subjects were classified as healthy (green), osteoporotic (red) or in need of DXA examination to verify diagnosis (yellow). Further, bone mineral density of the femoral neck and total hip were determined with axial DXA. Osteoporosis was diagnosed in individuals with T-score lower than -2,5 at the total hip or femoral neck. In addition, FRAX® scores with BMD ($FRAX_{BMD}$) and with BMI ($FRAX_{BMI}$) were determined.

A total of 173 subjects (73 osteoporotic) were selected to be treated along NOF guidelines. $FRAX_{BMI}$ was analyzed for patients with DI value in yellow or green area. Subjects with red DI value and yellow DI value with $FRAX_{BMI}$ over 3%/20% were selected to be treated. The subjects with yellow or green DI value and FRAX under 3%/20% were considered healthy. Only the subjects with green DI value and $FRAX_{BMI}$ over 3%/20% were selected for additional DXA measurement. In the proposed diagnostic pathway, the sensitivity and specificity of treatment decisions compared to NOS guideline were 94% and 80%, respectively. Only 23% of the patients were found to require additional DXA measurement to verify the treatment decision. The present results demonstrate that the ultra-portable US instrument with $FRAX_{BMI}$ shows strong agreement (86%) with treatment decisions using NOF guidelines. In addition, by using the triage approach and the pocket size technology with no ionizing radiation the treatment of OP would significantly increase.

Performance Characteristics of Heel Quantitative Ultrasound (QUS) for the Assessment of Fracture Risk; an Individual-level Meta-analysis. Nicholas Harvey*[1], Helena Johansson[2], Anders Oden[3], Douglas Bauer[4], Claus-C Glueer[5], Didier Hans[6], Stephen Kaptoge[7], Marc-Antoine Krieg[8], Timothy Kwok[9], Fernando Marin[10], Alireza Moayyeri[11], Terry O'Neill[12], Eric Orwoll[13], John Kanis[14], Eugene McCloskey[15]. [1]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, [2]Centre for Metabolic Bone Diseases, University of Sheffield Medical School, Sweden, [3]Consulting Statistician, Sweden, [4]University of California, San Francisco, USA, [5]Christian Albrechts Universitaet zu Kiel, Germany, [6]Lausanne University Hospital, Switzerland, [7]University of Cambridge Bone Research Group, United Kingdom, [8]University Hospital, Switzerland, [9]The Chinese University of Hong Kong, Hong Kong, [10]Eli Lilly & Company, Spain, [11]King's College London, United Kingdom, [12]University of Manchester, United Kingdom, [13]Oregon Health & Science University, USA, [14]University of Sheffield, Belgium, [15]University of Sheffield, United Kingdom

Quantitative ultrasound (QUS) has an established role in screening for osteoporosis and/or assessing fracture risk. The aim of this meta-analysis was to undertake a more detailed examination of the relationships between QUS parameters and the risk of fracture using individual-level data.

In 9 prospective cohorts from Asia, Europe and North America, broadband ultrasonic attenuation (BUA dB/Mhz) and speed of sound (SOS m/sec) were measured at baseline in men and women subsequently followed for incident fractures. The latter were documented by self-report and in some cohorts confirmed by radiography. Measurements of femoral neck BMD were also available in a subset of individuals. Values of QUS and BMD were converted to z-scores within each cohort. An extension of Poisson regression was used to examine the relationship between fracture risk and BUA or SOS adjusted for age and time since baseline in each cohort. The results were merged and weighted according to the variance.

Baseline measurements of QUS were available in 46,124 men and women, mean age 70 years and 3018 osteoporotic fractures (including 787 hip fractures) occurred during a total follow up of 214,000 person-years. The summary gradient of risk (GR, hazard ratio per 1 SD) was 1.4 (95% CI: 1.4-1.5) for osteoporotic fracture for both BUA and SOS. For hip fracture the GR was 1.7 (95% CI: 1.6-1.8) for BUA and 1.6 (95% CI: 1.5-1.7) for SOS. The predictive value of QUS was the same for all ages ($p>0.20$) and across genders ($p\geq0.1$) and remained significant following adjustment for BMD. However the GR was significantly higher for both fracture outcomes the lower the baseline BUA and SOS ($p<0.001$); for example, when BUA was below a z-score of 0, the GR was 2.0 (95% CI 1.8, 2.3) but above 0 it was 1.2 (95% CI 1.0-1.4). For the outcome of osteoporotic fracture, but not hip fracture, the predictive value of QUS (both BUA and SOS) decreased with time since baseline ($p=0.018$ and $p=0.010$, respectively). Results were similar in the subset (n-19,473) with concurrent BMD measurements; the GR for BMD for osteoporotic and hip fractures remained stable with time since baseline.

Quantitative ultrasound is an independent predictor of fracture for men and women particularly at low QUS values, but the predictive value for osteoporotic fracture risk decreases with time from baseline. These observations should be taken into account if incorporating QUS into fracture risk algorithms.

Prediction of fracture risk by trabecular bone score (TBS). Tuan Nguyen*[1], Didier Hans[2], Jacqueline Center[1], John Eisman[1]. [1]Garvan Institute of Medical Research, Australia, [2]Lausanne University Hospital, Switzerland

TBS is bone texture index that reflects bone microarchitecture. The present study sought to determine the association between TBS and fracture, and to define its prognostic value in terms of fracture prediction in the elderly.

The study was designed as a population based prospective cohort of 1688 women aged 60 years and above. The women were recruited between 1989 and 1993. Baseline anthropometric and demographic characteristics were ascertained at baseline by a structured questionnaire. BMD at the femoral neck and lumbar spine was measured by DXA (GE-LUNAR Corp, Madison, WI). TBS was analyzed blindly from clinical outcome by TBS iNsight® software v1.9 (Medimaps SASU, Pessac, France). Low trauma and non-pathological fractures were ascertained from X-ray reports during the follow-up (from study entry till 31/12/2013).

During the follow-up period, 418 women had sustained a fragility fracture. Women with fracture were significantly older, had lower femoral BMD and lower TBS than those without a fracture. Each standard deviation lower TBS (0.12) was associated with a 67% increase in the odds of fracture (odds ratio [OR] 1.67; 95%CI 1.43-1.96). However, TBS was correlated with femoral neck BMD ($r = 0.38$, $P < 0.001$) and age ($r = -0.18$; $P < 0.001$). After adjusting for FNBMD and age, the association between TBS and fracture risk was weaker but remained statistically significant (OR 1.37 (95%CI 1.15-1.64). Further adjustment for covariates, which we have shown to predict fracture risk, i.e. fall, quadriceps strength and prior fracture) did not significantly alter the result. Among women without osteoporosis, i.e. no

BMD in the osteoporotic range, lower TBS was also significantly associated with increased risk of fracture (OR 1.72; 95%CI 1.43-2.17) independent of femoral neck BMD. The proportion of variance in fracture risk that could be attributed to variation in TBS was ~4%.

These results suggest that lower TBS is associated with an increase in fracture risk, and that TBS could improve the accuracy of fracture prediction over and above that of femoral neck BMD and other recognised risk factors.

Trabecular bone score improves prediction accuracy of FRAX® for major osteoporotic fractures in elderly Japanese men: The Fujiwara-kyo Osteoporosis Risk in Men (FORMEN) Cohort Study. Masayuki Iki*[1], Yuki Fujita[2], Junko Tamaki[3], Yuho Sato[4], Renaud Winzenrieth[5], Katsuyasu Kouda[6], Akiko Yura[6], Jong Seong Moon[7], Nozomi Okamoto[8], Norio Kurumatani[8]. [1]Kinki University Faculty of Medicine, Japan, [2]Kinki University Faculty of Medicine, Japan, [3]Department of Hygiene & Public Health, Osaka Medical College, Japan, [4]Jin-ai University, Japan, [5]Med-Imaps, France, [6]Department of Public Health, Kinki University Faculty of Medicine, Japan, [7]Kio University, Japan, [8]Department of Community Health & Epidemiology, Nara Medical University School of Medicine, Japan

Aims: To evaluate whether trabecular bone score (TBS) improves the prediction accuracy achieved by FRAX® for major osteoporotic fractures (MOFx) in elderly Japanese men.

Methods: 2012 community-dwelling men aged 65 years and older completed the baseline study of the Fujiwara-kyo Osteoporosis Risk in Men (FORMEN) Cohort Study comprising areal bone mineral density (aBMD) measurements at the spine and hip (QDR4500A, Hologic, USA), height and weight measurements, and interviews covering clinical risk factors required to estimate 10-year absolute risk of MOFx (hip, spine, distal forearm and proximal humerus) by the Japanese version of FRAX® (v.3.8). The risk from FRAX® was adjusted to each participant's duration of follow-up. TBS was calculated at baseline in the same vertebrae for aBMD using TBS iNsight software (Med-Imaps, France). Incident MOFx during the follow-up were identified by interviews or supplemental mail and telephone surveys. Prediction accuracy improvement of the logistic model incorporating TBS plus the fracture risk from FRAX® in comparison with FRAX® alone model was evaluated by integrated discrimination improvement (IDI) and net reclassification improvement (NRI) in addition to the area under receiver operating characteristic curve (AUC).

Results: We identified 20 incident MOFx (2.5/1000 person-years (PY)) during total follow-up of 7986 PY (median follow-up, 4.5 years) for 1868 men (mean age, 73.0±5.1 years at baseline). Participants with the MOFx had significantly lower femoral neck aBMD (0.681±0.124 vs 0.740±0.114, p=0.0182) and TBS (1.137±0.089 vs 1.193±0.083, p=0.0024) and higher risk of MOFx estimated by FRAX® (3.0×÷1.6% vs 2.4×÷1.7%), p=0.0407) than those without. Observed MOFx risk increased significantly with the increase in expected risk by FRAX® (p<0.0001). The numbers of observed MOFx in tertile groups of participants classified by the expected risk were smaller than the numbers of MOFx expected, but the difference was not significant (p=0.0918). AUC of FRAX® plus TBS model (0.699) for prediction of MOFx was not significantly different from AUC of FRAX® alone (0.671). However, NRI showed a significant increase in classification accuracy of FRAX® plus TBS model compared with FRAX® alone, (NRI: 47.4%, (95% confidence interval (CI): 4.2, 90.5)), and IDI showed a more modest but similar result (IDI: 0.003 (95% CI: 0.000, 0.012).

Conclusions: TBS improved prediction accuracy of FRAX® for MOFx in community-dwelling elderly Japanese men.

Trabecular bone score predicts fracture incidence in non-osteoporotic older Chinese men, independently of hip Bone Density. Timothy Kwok*. Hong Kong

Kwok T, Leung J, Aubry-Rozier A, Hans D

Department of Medicine & Therapeutics, the Chinese University of Hong Kong

Jockey Club Centre for osteoporosis care and control, the Chinese University of Hong Kong

Department of Bone and Joint, Center of Bone diseases, Lausanne University Hospital, Lausanne, Switzerland

Email: Berengere.Aubry@chuv.ch and didier.hans@ascendys.ch

Background

Trabecular bone score (TBS) based on secondary analysis of pixel gray-level variations in DXA images of the lumbar spine is an indirect novel surrogate marker of global bone microarchitecture. There are cross sectional and prospective data to suggest that TBS is independently associated with fracture. There is however a lack of prospective data to confirm its role in fracture prediction in Chinese population and whether such role remains in non-osteoporotic subjects.

Subject and method

2000 men and 2000 women aged 65 years or more were recruited in 2001-3 for predictors of osteoporotic fractures. At baseline, comprehensive health assessment was performed. Bone mineral density (BMD) of hip and spine was measured by Hologic dual energy X ray absorptiometry. All subjects were followed up for an average of ten years for incidence of fractures primarily by electronic medical record system of the public hospitals in Hong Kong. Cox regression was performed to examine the association between baseline TBS scores (as assessed by TBS iNsight, Medimaps SA) and the incidence of major osteoporotic fractures over ten years. Femoral neck BMD was used as covariate. The subjects with osteoporosis as defined by T-score ≤ -2.5 at either hip or spine were excluded from analysis.

Result

1665 men and 1071 women had BMD within the normal and osteopenia range at baseline. Out of these, 91 men and 91 women had major osteoporotic fractures over ten years. Out of these 41 men and 19 women had hip fractures. Cox regression after adjustment for hip BMD and age showed that TBS score was significantly associated with major osteoporotic fracture in older men, but not in women (p=0.025 and 0.112 in men and women respectively). In contrast, TBS predicted hip fracture in older women but not in older men (p=0.048 and 0.393 respectively). Similar results were obtained when FRAX score was used as covariate.

Conclusion

TBS of lumbar spine was predictive of major osteoporotic fracture in older Chinese men without osteoporosis independently of clinical risk factors and hip BMD. The role of TBS in predicting osteoporotic fractures in non-osteoporotic older women requires a larger study.

Unexpected Distinct Fall of Dental Alveolar Bone Density Measured by Computerized Microradiography (Bone Right) in Response to Teriparatide in Contrast to Its Bisphosphonate-Induced Rise. Yoshitomo Takaishi*[1], Takuo Fujita[2], Mutsumi Ohue[3], Tsuyoshi Jotoku[4], Yoshio Fujii[5], Akimitsu Miyauchi[6], Yasuyuki Takagi[7]. [1]Takaishi Dental Clinic, Japan, [2]Katsuragi Hospital, Japan, [3]Katsuragi Hospital, Japan, [4]Department of Orthopedic Surgery, Japan, [5]Calcium Research Institute Kobe Branch, Japan, [6]Miyauchi Medical Center, Japan, [7]National Hyogo Chuo Hospital, Japan

Background: Osteoporosis and periodontal disease, both quite prevalent in aging, appear to be closely related. Low values in computerized microdensitometry (Bone Right) was useful in predicting osteoporotic fracture (Takaishi et al., Adv Ther 2013), whereas very high values were pointed out around the lesions of osteonecrosis of the jaw (Takaishi et al 2010).

Methods: From among postmenopausal women attending Osteoporosis and Osteoarthritis Clinic of Katsuragi Hospital, 16 osteoporotic subjects consenting to participate the study were randomly divided into 2 groups, T and B. In Group T, 56? teriparatide (TP) was injected once a week and alendronate or minodronate (BP) was administered in Group B. Alverolar bone density (alBMD) was measured by computerized microdensitometry and lumbar bone mineral density (LBMD) and femoral neck bone mineral density (FNBMD) by DXA(Prodigy: GE Healthcare) before and after the treatment.

Results: In Group B, alBMD increased by 21.3±17.9% (Mean±SD). In group T, in contrast, it decreased by 18.9±20.9% with a highly significant difference between the 2 Groups (p=0.0011). LBMD(+2.6±4.9% and -0.4±6.3%, p=0.3018) and FNBMD(+4.4±5.5% and +4.1±5.3%, p=0.9087) failed to change significantly in response to BP and TP.

The Responses of alBMD to BP and TP were significantly different from those of LBMD and FNBMD in both B (p=0.0213 for LBMD and p=0.0331 for FNBMD) and T Groups (p=0.0428 and p=0.0170) indicating exaggerated responses of alBMD to therapeutic agents compared to those of LBMD and FNBMD.Conclusion: Bisphosphonate increases alBMD more effectively than LBMD and FNBMD. Teriparatide, on the contrary, distinctly decrease alBMD, but not LBMD and FNBMD. In view of the very high alBMD around the lesion of BRONJ, this may explain the therapeutic effect of teriparatide on osteonecrosis of the jaw.

Previous studies have identified common genetic variants associated with BMD; whether low-frequency (minor allele frequency [MAF] between 1-5%) or rare (MAF ≤1%) variants influence BMD in the general population has not been established. Here we aim to identify novel low-frequency and rare genetic variants influencing BMD variation in 13 population-based cohorts of European ancestry. Through a large-scale meta-analysis of these cohorts (Ntotal=31,508), using whole-genome sequencing data from the UK10K consortium (N=2,868), whole-exome sequencing (N=2,320) and deep imputation (N=26,320) of rare variants using a combined UK10K/1000Genomes reference panel from GEFOS consortium, we identified a novel low-frequency variant with large effect size near EN1, mapping to 2q14.2, (MAF=1.7%, effect size= +0.24 standard deviations [SD], P=4.1 x 10-9). Variants at this locus overlapped a DNase1 hypersensitivity site (DHS) in osteoblasts which resides in a topological domain that includes EN1. We detected En1 expression during osteoblastogenesis in developing and mature cultured murine calvarial osteoblasts, Next, we analysed the bones of En1lacZ/+ knock-in mice and detected En1 positive cells in adult vertebrae and long bones which co-localized with alkaline phosphatase activity, confirming expression of this gene in situ. We generated conditional En1Cre/flox mutants (n= 3) and demonstrated that mutants have higher trabecular number, higher tissue mineral density. We also identified a novel rare variant with large effect for forearm BMD mapping to 7q31.31 (MAF=0.9%, effect size= -0.47 SD, P=9.3 x 10-9) and demonstrated that this variant overlaps a DHS that appears to mark an enhancer of WNT16. We tested these newly identified variants for their effect on any type of fracture risk in a large dataset (Ncases=10,459, Ncontrols=27,581, 76.2% of these samples overlap the BMD samples). Finally, In addition to rare and low-frequency described above, we also identified common variants but across known BMD loci, including 3 genome-wide significant loci for forearm BMD, 14 for lumbar spine, 17 for femoral neck. These findings provide an example for gene-discovery through a sequencing-based approach with subsequent imputation to identify low-frequency and rare variants scrutinized for the first time for association with BMD in a large–scale setting.

Correlates of Heel Bone Mass in Young Adults: The Role of Cholesterol Over 20 Years from Childhood to Early Adulthood. Benny Samuel Eathakkattu Antony*[1], Changhai Ding[2], Alison Venn[2], Terence Dwyer[3], Graeme Jones[4]. [1]Menzies Research Institute Tasmania, University of Tasmania, Australia, Australia, [2]Menzies Research Institute Tasmania, University of Tasmania, Australia, Australia, [3]Murdoch Childrens Research Institute, Australia, [4]Menzies Research Institute, Australia

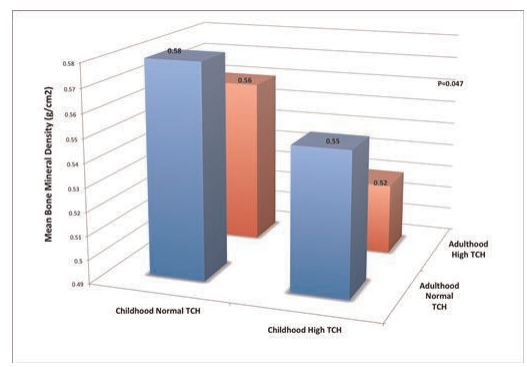
Purpose: The association between lipids and bone mass in adult life is controversial and there is limited evidence in childhood. The aim of this study was to describe the association between lipids measured in childhood and young adult life and bone mineral density (BMD) in younger adults.

Methods: Subjects broadly representative of the Australian population (n=1431, female=52%, age=26-36) were selected from the Australian Schools Health and Fitness Survey of 1985. They underwent various measurements including leg strength, standing long jump, and physical work capacity (PWC_{170}). Physical activity, smoking and alcohol history were recorded using questionnaires. Fasting lipid profiles were assessed in childhood and 20 years later in adulthood. A single Sahara bone ultrasound densitometer was used to determine heel bone mass in adulthood.

Results: In multivariable analysis, childhood High Density Lipoprotein (HDL) was positively (β: 0.056 g/cm^2, 95% CI: 0.005, 0.108) and total cholesterol (TCH, β: -0.042 g/cm^2, 95% CI: -0.081, -0.003) and Low Density Lipoprotein (LDL, β: -0.019 g/cm^2, 95% CI: -0.039, 0.000) were negatively associated with BMD in adulthood. Similarly, adulthood TCH (β: -0.007 g/cm^2, 95% CI: -0.015, -0.001) and LDL (β: -0.011 g/cm^2, 95% CI: -0.019, -0.003) were negatively associated with adult life BMD. Subjects who remained in the abnormal category of TCH from childhood to adulthood had the least bone mass compared to other category changes.

These results were independent of gender, alcohol consumption and duration of follow-up from childhood to adulthood. The other potential confounders included in this analysis were age (negatively associated with BMD, β: -3.58 mg/cm^2 per year, 95% CI: -6.14, -1.01), smoking (β: -18.34 mg/cm^2, 95% CI: -27.35, -9.34), physical activity (vigorous activity, β: 0.04 mg/cm^2 per min/week, 95% CI: 0.01, 0.08) and BMI in childhood and adulthood (both positively associated with BMD). BMD were positively associated with PWC_{170}, leg muscle strength and long jump.

Conclusions: HDL in childhood was beneficially and high TCH was detrimentally associated with adulthood BMD. LDL and TCH in adulthood were detrimentally associated with BMD. These associations were independent of the potential confounders including physical activity. The effect of childhood HDL was independent of the adulthood HDL levels. These results indicate that cholesterol may have long-term effects on bone mass from childhood to adulthood.



Mean BMD of subjects classified by their change in TCH levels from childhood to adulthood

No Association Between BMD and Telomere Length in Healthy Women aged 25-93 Years. Barbara Rubek Nielsen*[1], Peter Schwarz[2], Allan Linneberg[3], Kaare Christensen[4]. [1]Research Centre of Ageing & Osteoporosis, Department of Medicine, Copenhagen University Hospital, Glostrup, Denmark, Denmark, [2]Research Centre of Ageing & Osteoporosis, Department of Medicine, Faculty of Health Sciences, University of Copenhagen, Copenhagen, Denmark, Denmark, [3]Research Centre for Prevention & Health, Capital Region of Denmark, Glostrup, Denmark, Denmark, [4]Danish Aging Research Center, University of Southern Denmark, Denmark

Introduction: Telomere length and bone mineral density (BMD) are considered phenotypes of ageing since both declines with age. Further, both are affected by inflammatory processes.

The aim of our study, of 460 healthy randomly selected women, was to assess the association between BMD and telomere length.

Method: BMD was evaluated by DXA at the lumbar spine and both hips. Telomere length was analyzed by qPCR, which is a quantitative measurement, where relative average telomere length is proportional to a T/S-ratio. We analysed DNA samples on two separate days (duplicates) and samples were run in triplicates.

Results: We found the association between telomere length and chronological age highly significant estimated by linear regression and correlation ($P< 0.0001$). For the regression analysis the covariates hormone therapy, menopause, physical activity during leisure time, smoking and alcohol habits and $HbgA_1C$ were evaluated and showed no influence. R^2 of the linear model was 0.050, and the regression coefficient back transformed estimated that T/S were shortened 0.45% for every year in the range of 0.27%-0.64%.

By multiple regression analysis, the association between BMD and chronological age was estimated at the femoral neck, total hip and at the lumbar spine. For hip measurements, age was highly associated to BMD ($P< 0.0001$) whereas we found no association at lumbar spine. All analyzes were adjusted for BMI, menopause, physical activity as well as alcohol and smoking habits.

The association between BMD and telomere length was estimated by linear regression and showed only significance at left femoral neck. The association was further explored in a series of regression models successively adjusted for age, BMI, menopause, leisure time physical activity level and smoking and alcohol habits.

At all hip sites age and BMI were highly significant covariates, but at lumbar spine only BMI was highly significant ($P<0.0001$). Further, physical activity and menopause were at most sites significant covariates.

Conclusion: The prerequisites – that age is associated with telomere length and BMD – were met (except at the lumbar spine). We found no significant association between BMD and telomere length, but regression coefficients for all hip sites showed a positive trend.

Determinants of bone outcomes in obese and normal-weight young adults. Heli Viljakainen*[1], Helena Valta[2], Marita Lipsanen-Nyman[3], Tero Saukkonen[4], Eero Kajantie[5], Sture Andersson[3], Outi Makitie[6]. [1]University of Helsinki, Finland, [2]Hospital for Children & Adolescents, University of Helsinki, Helsinki Finland, Finland, [3]Children's Hospital, Helsinki University Central Hospital, University of Helsinki, Finland, [4]Novo Nordisk Pharma Oy, Finland, [5]National Institute for Health & Welfare, Diabetes Prevention Unit, Finland, [6]Children's Hospital, Helsinki University Central Hospital, Finland

Background: In children obesity associates with higher areal BMD yet leads to increased risk for peripheral fractures. We aimed to determine the contribution of lifestyle factors for bone outcomes in obese young adults and in normal-weight matched controls.

Methods: The study included 68 obese subjects with early-onset severe obesity and 73 normal-weight controls. History on physical activity (PA), data on dietary pattern, smoking and alcohol consumption were collected with a questionnaire. A food-based healthy eating index (HEI) was constituted based on nutrition recommendations. Bone characteristics were measured with DXA from central and with pQCT from peripheral sites; body composition was analyzed by DXA.

Results: The obese and control subjects were similar in age (mean 19.6 $\pm$2.6 yrs) and height but BMIs differed (39.7 and 22.6 kg/m^2). Obese subjects reported a shorter time (median 31-70% shorter) of total and supervised PA during primary and secondary school and currently than controls ($p<0.01$). Obese subjects were more likely to smoke (34% vs 14%), had lower HEI (27 and 31 of the maximum value 50; $p=0.007$) but similar alcohol consumption. All crude bone outcomes were higher in obese subjects. Body composition differed between groups ($p<0.001$). Lean mass (LM) and trunk fat mass (FM) were independent determinants for bone outcomes. Interestingly, together with sex and height, these explained a smaller part of the variation in bone outcomes in obese subjects than in controls: adjusted r^2 were on 0.6 times smaller. Relative to LM bone outcomes were similar between the groups, while relative to LM + trunk FM all bone outcomes were 30% lower in the obese. In linear regression, lifestyle factors associated more likely with bone outcomes in the controls than in the obese subjects. In the obese, only the amount of supervised PA (ln transformed) during secondary school associated with cortical thickness in tibia and hip BMD: 0.299 (95% CI: 0.103;0.495) and 0.145 (-0.043;0.33). In the controls, total PA during secondary school and currently, HEI and alcohol consumption contributed to the bone outcomes.

Conclusions: Early-onset obesity is accompanied by unhealthy lifestyles. Supervised PA during secondary school associated with bone outcomes in obese subjects, while in controls determinants included also current PA, HEI and alcohol consumption. As lifestyle explains a smaller part of the variation of bone outcomes in obese subjects than in controls, the role of endocrine factors for bone health in obesity remains to be investigated.

Vitamin D status in Young Adults is associated with gender, educational level and living. Rune Tønnesen*. Center of ageing & osteoporosis, Denmark

Background & Purpose: Vitamin D status might influence the risk of osteoporosis later in life. The level of circulating vitamin D was tested in healthy young adults.Characterize 25-hydroxyvitamin D [vitamin D] status in young adults (18-25 y/o) and examine if it's associated with gender, education and living.

Material & Methods: We present data from a cross sectional study from winter period (from 15th October to 15th April) examining vitamin D, education (the education the participant studies), gender, living among 18 to 25 years old students attending their educational institutions in the Copenhagen area. Education was grouped in four categories according to type of education and length of education after primary school; Vocational and trade school 2-3 years [VTS], Gymnasium 3 years [G], College level 4-6 years [CoL], College or University 7-9 years [CoU].

Results: 536 students participated; 261 females and 277 males. Female students had a 20.4%higher vitamin D status (p=0.0001), 95% CI[9.6%, 32.1%] than male students. Students living at their own had a 15.9% higher vitamin D (p=0.0073), 95% CI[4.1%, 29.1%] compared to students living at their parents home. Students studying at CoL had a Vitamin D status that was 32.2% (p=0.0014) 95% CI [11.4%, 56.8%] higher than students studying at VTS. Students studying at CoU had a Vitamin D status that was 23.9% (p=0.0021) 95% CI [8.1%, 41.9%] higher than students studying at VTS.

Conclusion: The Vitamin D level in young adults is associated with educational level, gender and living. In order to focus campaigns for increasing the vitamin D level in the population, strategies ought toconsider the differencesof the recipients, most of all gender, living situation and educational level.

Dose Trabecular Bone Score (TBS) Improve the Predictive Ability of FRAX® ? : The Japanese Population-based Osteoporosis (JPOS) Cohort Study. Junko Tamaki*[1], Masayuki Iki[2], Yuho Sato[3], Renaud Winzenrieth[4], Etsuko Kajita[5], Sadanobu Kagamimori Kagamimori[6], Yoshiko Kagawa[7], Hideo Yoneshima[8]. [1]Department of Hygiene & Public Health, Osaka Medical College, Japan, [2]Kinki University Faculty of Medicine, Japan, [3]Department of Domestic Sciences, Jin-ai University, Japan, [4]Center of Bone diseases, Lausanne University Hospital, Lausanne, Switzerland, France, [5]Department of Public Health & Home Nursing, Nagoya University School of Health Sciences, Japan, [6]University of Toyama, Japan, [7]Kagawa Nutrition University, Japan, [8]Shuuwa General Hospital, Japan

Objectives: The aim was to investigate whether or not trabecular bone score (TBS) improves the predictive ability of FRAX® for osteoporotic fractures in Japanese women.

Methods: Participants were 1541 women aged 40 years or older without medications for osteoporosis at the baseline survey in 1996. A major osteoporotic fracture defined as a clinical fracture of the hip, vertebra, distal forearm, or proximal humerus that occurred without strong external force during the 10-year follow-up period were ascertained in the follow-up surveys or mail questionnaires in the JPOS Cohort Study. TBS at the baseline survey was calculated at the first to fourth vertebrae. The goodness-of-fit of models to data was compared between logistic models incorporating absolute fracture risk from FRAX® alone and the fracture risk from FRAX® and TBS by using integrated discrimination improvement (IDI) and net reclassification improvement (NRI) in addition to area under receiver operating characteristic curve (AUC) and Akaike's information criterion (AIC).

Results: The major osteoporotic fracture events (N=67) were ascertained during the median follow-up time of 10.0 years (total person-years, 15306 PY). The incidence rates of the major osteoporotic and hip fracture events were 4.38 women/1000PY and 0.72 women /1000PY, respectively. The women with major osteoporotic fractures had significantly lower TBS than those with no fractures (1.122 $\pm$ 0.098 vs. 1.187 $\pm$ 0.117, $p<0.001$). The AUC of a model incorporating fracture risk from FRAX® and TBS combined for major osteoporotic fractures prediction was not significantly greater than the AUC of FRAX® alone. According to AIC, a model incorporating fracture risk from FRAX® using femoral neck (FN) BMD and TBS [adjusted odds ratio; FRAX®, 1.35 (95%CI, 1.09-1.67); TBS, 1.46 (95%CI, 1.08-1.98)] afforded significantly better fit to the data than did a model obtained FRAX® using FN BMD alone. The NRI values showed a significant increase of about 30% in prediction accuracy for major osteoporotic fractures achieved by the FRAX® and TBS model compared with FRAX® alone, although the IDI showed no significant increase. Neither IDI nor NRI showed significant increase in prediction accuracy for hip fracture achieved by the FRAX® and TBS model compared with FRAX®.

Conclusions:TBS might improve risk classification for major osteoporotic fractures using FRAX® among Japanese women.

FRAX (Aus) as a predictor of falls risk in men. Kara Holloway*[1], Mark Kotowicz[2], Stephen Lane[3], Sharon Brennan[4], Julie Pasco[4]. [1]Barwon Health, Australia, [2]Deakin University School of Medicine, Australia, [3]Barwon Health Biostatistics Unit, Australia, [4]Deakin University, Australia

Purpose: The FRAX score utilises clinical risk factors to estimate the probability of sustaining a fracture over a 10-year period. Although falls increase the risk for fracture they are not incorporated into the FRAX. The aim of our study was to investigate if the 10-year probability of fracture determined by use of the Australian-specific FRAX is associated with falls risk in a cohort study of Australian men.

Methods: Clinical risk factors were documented for 469 men (age 40-90 years) assessed at the 5-year follow-up (2006-2010) of the Geelong Osteoporosis Study (GOS). The probability of osteoporotic fracture was calculated using the FRAX (Aus) tool that included femoral neck BMD. Self-reported incident falls were documented from questionnaires returned approximately one year later (median time of follow-up 13 months, IQR 12-14). Two multivariable analyses were performed: (i) the cross-sectional association between the FRAX scores and a falls risk score (Elderly Falls Screening Test, EFST[1]) using a linear regression model and (ii) the prospective relationship between the FRAX score and the time to a fall, using a Cox proportional hazards model.

Results: EFST scores were correlated with FRAX scores (= 0.03, $p<0.003$); however, after adjusting the EFST scores for age, the relationship was not significant (= 0.00, $p=0.77$). Among 469 men, 82 (17%) had fallen during the previous 12 months and 78 (17%) reported at least one incident fall during follow-up. The risk of incident falls increased with increasing FRAX score (HR for one percentage point increase in FRAX = 1.06, 95% CI 1.02, 1.09). However, after adjusting for age, the relationship between FRAX score and incident falls risk was not significant (HR = 1.02, 95% CI 0.97, 1.07).

Conclusion: The positive association between the FRAX scores and falls found in both the cross-sectional analysis with EFST and the time-to-event hazard function of incident falls was explained by increasing age. These data provide insufficient evidence for excluding falls from fracture risk assessment.

Glucocorticoid Exposure and Fracture Risk in a Large Cohort of Commercially-Insured Rheumatoid Arthritis Patients Under Age 65. Akhila Balasubramanian*[1], Sally Wade[2], Robert Adler[3], Celia Lin[4], Michael Maricic[5], Cynthia O'Malley[6], Kenneth Saag[7], Jeffrey Curtis[7]. [1]Amgen Inc., USA, [2]Wade Outcomes Research & Consulting, USA, [3]McGuire VA Medical Center, USA, [4]Amgen, USA, [5]Catalina Pointe Rheumatology, USA, [6]Amgen, Inc, USA, [7]University of Alabama at Birmingham, USA

Systemic glucocorticoids (GCs) use can increase fracture risk, although dose-specific effects are incompletely understood, especially in younger adults. Underlying diseases (e.g., rheumatoid arthritis [RA]) can confound these associations. This study evaluated the impact of GC exposure on risk of fragility fracture (FF) in RA patients.

The 42,034 study patients identified in the MarketScan® claims database were newly treated for RA (index date) between 1/1/2005 and 12/31/2011, age 18-64 years at index, had benefits coverage for ⩾12 months pre-index and no pre-index cancer. Patients with pre-index GC use were GC-free for ⩾ 12 months prior to their first GC pharmacy claim, and had continuous benefits coverage from first GC claim to index date. GC use (any, cumulative dose [CD], peak dose, average daily dose [DD], cumulative days exposed, percent days exposed, days of continuous exposure, days since most recent use) was assessed for each patient-day and censored at the earliest of post-index FF, cancer diagnosis, or end of follow-up. Exposures were converted to prednisone equivalents and cumulative measures included pre-index use. Patient demographics at index and pre-index clinical characteristics were assessed. Incidence rates (IR) per 1,000 person-years for post-index FF were stratified by GC exposure. Cox's proportional hazards models estimated age- and sex-adjusted fracture risk by exposure level.

Patients averaged 738 (standard deviation [sd] 615) post-index follow-up days. Most patients (82%) had GC exposure during the study (43% with CD < 675 mgs; 73% had peak dose ⩾ 15 mg/day). Exposed and unexposed patients were demographically similar (74% female; mean age 49.4 [10.7] and 49.8 [10.2] years); 1% had pre-index fracture. IRs (95% confidence intervals) for FF were 5.1 (4.6, 5.6) at 0 mg/day DD, 16.8 (11.4, 24.0) at DD ⩾ 15 mgs/day, 4.8 (3.8, 6.0) at 0 mg CD, and 13.7 (10.6, 17.4) at CD ⩾ 5400 mgs. Among patients ever-exposed to GCs, fracture risk was significantly elevated at CD > 2700 mg and DD ⩾ 15 mg/day (Table). Following GC discontinuation, fracture risk (adjusted for age, sex, and CD) was 32% lower at 60-181 days since last exposure versus current exposure. Analyses restricted to patients younger than 50 years showed similar results.

In this large, relatively young cohort of RA patients, fracture risk increased by 2- to 3-fold at high levels of daily and cumulative GC dose, and began to decline within months of GC discontinuation.

Table: Risk of Post-Index Fragility Fracture among Rheumatoid Arthritis Patients Ever-Exposed to Systemic Glucocorticosteroids

		Hazard Ratio	95% C.I.	P-Value
Sex	Male (n=31,104)	ref		
	Female (n=10,930)	1.71	(1.33, 2.20)	<.0001
Age (years)	18 to 39 (n=7,230)	ref		
	40 to 44 (n=4,360)	1.81	(0.99, 3.31)	0.0524
	45 to 49 (n=6,168)	2.45	(1.44, 4.17)	0.0009
	50 to 54 (n=7,995)	2.94	(1.78, 4.86)	<.0001
	55 to 59 (n=8,736)	3.86	(2.37, 6.29)	<.0001
	60 to 64 (n=7,545)	5.57	(3.43, 9.04)	<.0001
Cumulative dose (mg)*†	> 0 to < 675	ref		
	675 to < 1350	1.07	(0.80, 1.44)	0.6504
	1350 to < 2700	1.00	(0.74, 1.36)	0.9854
	2700 to < 5400	1.41	(1.03, 1.93)	0.0317
	>= 5400	2.34	(1.68, 3.26)	<.0001
Average daily dose (mg/day)*†	0	ref		
	> 0 to < 5	1.43	(0.92, 2.23)	0.1091
	5 to < 7.5	1.00	(0.64, 1.55)	0.9891
	7.5 to < 15	1.21	(0.82, 1.80)	0.3439
	>= 15	2.67	(1.78, 3.99)	<.0001

*Exposure metrics were quantified on a person-time basis so patient numbers are not available.
†As the analysis represented in this table was restricted to patients ever-exposed to systemic glucocorticosteroids, all cumulative dose values are greater than zero. Average daily dose could have a value of zero during unexposed periods for this ever-exposed population.

Risk of post-index fracture among RA patients ever-exposed to systemic glucocorticosteroids

Low Risk for Hip Fracture Ten Years Before and After Total Hip Replacement Surgery in the Entire Swedish Population. Cecilie Vala*[1], Johan Kärrholm[2], Sabine Sten[3], Magnus Karlsson[4], Maria Vretemark[5], Valter Sundh[1], Mattias Lorentzon[6], Dan Mellstrom[7]. [1]Department of Geriatrics, Sweden, [2]department of orthopedic surgery, Sweden, [3]Department of Archaeology & Ancient History, Sweden, [4]Skåne University Hospital Malmö, Lund University, Sweden, [5]Västergötland Museum, Sweden, [6]Geriatric Medicine, Center for Bone Research at the Sahlgrenska Academy, Sweden, [7]Sahlgrenska University Hospital, Sweden

Background: Studies have shown that hip osteoarthritis (OA) is associated with high bone mass and that hip OA is uncommon in patients with hip fracture. We therefore studied the risk for having a hip fracture during the ten years before and after total hip replacement and investigated the mortality rates after these outcomes.

Method: We followed the total Swedish population born 1902-1952 (n=4 546 820) during the period 1987-2002. We identified from the patient register coordinated by the Swedish National Board of Health patients with diagnosis and surgical code for total hip replacement due to primary osteoarthritis (n=78 573), hip fracture (n=200 522), and both total hip replacement and hip fracture (n=2886). These data was linked with information from national census registers (Statistics Sweden) on mortality, marital status, migration, living place, professional occupation, income and education level. The risk time analyses are based on a Poisson regression model. Data is reported as mean with 95% confidence interval within brackets.

Results:The relative risk (RR) for patients with hip OA to have sustained a hip fracture during the ten years preceding the total hip replacement was 0.43 (0.40-0.46) and during the ten year after the surgery 0.42 (0.40-0.44). The lower risk of hip fracture before and after total hip replacement remains after adjustment for income, education, occupation and latitude. The RR for mortality the first year after a total hip replacement was 0.59 (0.56-0.62) and the first 10 years 0.71 (70-0.73) while the RR for mortality after a hip fracture during the first year was 4.00 (3.95-4.05) and during the first 10 years 2.05 (2.04-2.06).

Conclusion: Individuals with a total hip replacement due to primary OA had a low risk for hip fracture both the decade before and after surgery. This is probably explained by the association between primary hip OA and high bone mass. While the mortality rate the decade after a hip fracture is high, it is low after total hip replacement surgery. This could partly be explained by selection bias in that hip fracture is associated with morbidity and that patients with hip OA and serious morbidity is not referred to surgery.

Secular Decline In Fracture Incidence Is Not Associated With Better Post-fracture Outcomes. Dana Bliuc*[1], Mei Chan[2], Tuan Nguyen[1], John Eisman[1], Jacqueline Center[1]. [1]Garvan Institute of Medical Research, Australia, [2]Osteoporosis & Bone Biology, Australia

The last decade has been characterised by an improvement in the health of the elderly population. Hip fracture incidence has declined and life expectancy has improved. However, it is unclear whether the outcomes following osteoporotic fracture have changed accordingly. The aim of this study was to compare re-fracture risk and excess mortality following osteoporotic fracture between two cohorts with similar ages but separated in time.

Study participants comprised women and men 60+ participating into DOES1 (recruited from 1989 and born prior to 1930) and DOES2 (recruited from 2000 and born between 1930 and 1945). Femoral neck BMD was measured at baseline. All fractures excluding head fingers and toes were recorded. Mortality data was obtained from funeral directors and local Dubbo media records. Age-standardized fracture incidence and mortality rates were calculated. The difference in excess mortality between the 2 cohorts was assessed using standardized mortality ratios calculated for each study cohort using time-specific population mortality rates.

The prevalence of osteoporosis declined between the 2 cohorts in both women (24% in DOES1 and 10% in DOES2) and men (12% in DOES1 and 6% in DOES2). Correspondingly, the standardized fracture incidence also declined by approximately a third in both women and men. Although absolute re-fracture rates also declined in DOES2 compared to DOES1, after accounting for the reduction in initial fracture rates the relative risk of re-fracture was similar for the 2 cohorts [women age-adjusted RR 2.0 (95% CI, 1.6-2.5) in DOES1 and 1.9 (95% CI, 1.7- 2.3) in DOES2 and men, 3.5 (95% CI, 2.7-4.8) in DOES1 and 3.4 (95% CI, 2.7- 4.5) in DOES2]. Similarly, crude mortality rates decreased during study follow-up. However, after taking into account the difference in general population life expectancy during the study periods (a decline in mortality rates of 1.3%/yr), the excess mortality post-fracture was similar for the 2 cohorts [women, age-adjusted SMR 2.2 (95% CI, 1.9- 2.7) in DOES1 and 2.0 (95% CI, 1.5- 2.7) in DOES2, and men, 2.2 (95% CI, 1.7- 2.8) in DOES1 and 2.4 (95% CI, 1.8-3.3) in DOES2].

This study has demonstrated that despite a reduction in the prevalence of osteoporosis and fracture incidence during the last 2 decades, re-fracture risk as well as the fracture-associated excess mortality was similar. Whether this is due to differences between the fracture populations remains to be explored.

Temporal Trends in high- and low-trauma Hip, Femur and Pelvic Fracture Rates and Selected Quality of Care Indicators in Québec, Canada. Suzanne Morin*[1], Edward Harvey[2], Etienne Belzile[3], Jacques P. Brown[4], Sonia Jean[5]. [1]McGill University, Canada, [2]McGill University, Canada, [3]Université Laval, Canada, [4]CHU de Québec Research Centre, Canada, [5]Institut National De Santé Publique Du Québec, Canada

Purpose: Incidence rates of low-trauma (LT) fractures, particularly of the hip, have been noted to be decreasing. However, data on temporal trends in high-trauma (HT) fractures of the hip, femur and pelvis are lacking.

Methods: Using the hospital discharge database of the province of Québec, Canada, we performed a retrospective cohort study of men and women aged 50 years and older who sustained an incident hip, femur or pelvic fracture between1991-2010. Fractures and trauma intensity were identified using ICD-9-CM or ICD-10-CM diagnosis codes in medical records. We calculated age-standardized LT and HT fracture rates at each site and estimated time trends for fracture rates and selected quality of care indicators.

Results: Over 20 years, we identified 103 313 hip, 14 281 pelvic and 7 421 femur fractures of which 10%, 27% and 26% were HT fractures, respectively. Patients who sustained HT fractures were younger, were more frequently of male sex, and of worse social deprivation strata ($p<0.001$). (Table 1) Those with a HT pelvic or femur fractures were more likely to undergo surgical repair compared with LT fractures at similar sites ($p<0.05$ and <0.001, respectively). Mean surgical delay was similar in patients with LT and HT pelvic and hip fractures, but significantly shorter in patients with HT compared to LT femur fractures ($p<0.001$). Mean length of stay (LOS) was significantly shorter and mortality rates lower in patients with HT compared to LT fractures at any site ($p<0.001$). Overtime, the number of HT and LT fractures increased at all sites in the population. Age-standardized incidence rates of HT and LT fractures of the pelvis and femur increased significantly while LT fractures of the hip decreased and HT hip fractures remained stable. (Figure 1) Average age at the time of any LT fracture increased ($p<0.01$) and so did the proportions of patients with dementia and multiple comorbidities. Mean LOS decreased significantly following all fractures ($p<0.0001$) and in-hospitality death remained stable following any pelvic fractures but decreased over time following LT femur fractures ($p<0.05$) and any hip fractures ($p <0.001$). The proportion of patients discharged to LTC following LT pelvic and hip fractures increased but not after HT fractures.

Conclusion: HT and LT fractures are associated with different patient characteristics, interventions and clinical outcomes; healthcare policies should address these distinctions to develop targeted care paths.

Temporal Trends in Pelvic Fracture Rates and Selected Quality of Care Indicators in Québec, Canada. Sonia Jean*[1], Edward Harvey[2], Etienne Belzile[3], Jacques P. Brown[4], Suzanne Morin[5]. [1]Institut National De Santé Publique Du Québec, Canada, [2]McGill University, Canada, [3]Université Laval, Canada, [4]CHU de Québec Research Centre, Canada, [5]McGill University, Canada

Purpose: Like other major osteoporotic fractures, pelvic fractures are associated with recurrent fractures, reduced autonomy and excess mortality. Data depicting temporal trends and health outcomes associated with these fractures remain scarce.

Methods: Using the hospital discharge database of the province of Québec, Canada, we performed a retrospective cohort study of men and women aged 50 years and older who sustained an incident pelvis fracture between April 1, 1991, and March 31, 2010.

Fractures were identified using ICD-9-CM or ICD-10-CM diagnosis codes in medical records. We calculated age- and sex-specific rates and estimated time trends for fracture rates and selected quality of care indicators.

Results: Over 20 years, we identified 15 088 pelvic fractures (mean age 80 (SD 10) years in women, 72 (SD12) years in men, 73% women), of which 69% were low-trauma fractures and 52% were treated in a trauma center. (Table 1) Few patients (5%) underwent surgery; however the mean surgical delay was ⩾ 2 days in 61% of those who required surgery. The average length of stay (LOS) in acute care was 22 (SD 25) days, and the in-hospital mortality was 4% in women and 6 % in men ($p < 0.001$). Discharge destination was home in 77%, long-term care (LTC) in 15% and rehabilitation in 8 %, and 70% returned to their initial residential setting following discharge. There were 133 (1%) readmissions to the hospital associated with a pelvic fracture diagnostic ICD code within 6 months following discharge. Overtime, the number of pelvic fractures increased in the population, but age-standardized incidence rates remained stable, except in men and women ⩾80 years where there was a linear average annual increase of 2.2% (95% CI: 1.6 -2.7). (Figure 1) Average age at the time of fracture increased ($p<0.0001$) and so did the proportions of patients with dementia and multiple comorbidities. Mean LOS decreased by 9 days ($p<0.0001$) and in-hospitality death and re-admissions remained stable. The proportion of patients discharged to their home decreased by 6% ($p<0.0001$) due to an increase in discharge destination to LTC and rehabilitation.

Conclusion: Pelvic fractures rates are increasing in the older and frail population, and are associated with negative clinical outcomes. Care models should be reviewed to ensure adequate resources are provided to healthcare providers to offset the expected increase in demand resulting from ongoing changes in patients' characteristics.

Table 1: Characteristics of patients and outcomes related to pelvic fractures

The Influence of Lean Mass and Fat Mass on Fracture Outcome in a Prospective Community-Dwelling Korean Cohort. Jung Hee Kim*[1], Hyung Jin Choi[2], Sang Wan Kim[3], Nam H. Cho[4], Chan Soo Shin[1]. [1]Seoul National University College of Medicine, South Korea, [2]Chungbuk National University Hospital, South Korea, [3]Seoul National University College of Medicine, Boramae Hospital, South Korea, [4]Ajou University School of Medicine, South Korea

Lean mass (LM) and fat mass (FM) is known to be associated with osteoporosis. However, there were few studies regarding body composition and fracture outcome. We aimed to elucidate the effect of LM and FM on incidence of fractures in a prospective community-based Korean cohort.

We included 2,186 men and 2,750 women in a prospective community-dwelling cohort. LM and FM were measured by the bioelectrical impedance analysis at baseline (2001-2002). Fracture events included self-reported clinical fractures and low-trauma fractures at the hip, vertebrae, proximal humerus and radius sites during the follow-up period (mean duration, 9.4 years).

Mean age was 55.5 $\pm$ 8.8 years. The incidence of fracture events was 3.5% (77/2,186) in men and 7.8% (215/2,750) in women. When we compared the highest tertile with the lowest tertile of LM in men and women, the adjusted hazard ratios (95% CIs) of fracture were 0.158 (0.068-0.369) and 0.790 (0.547-1.141), respectively. Men within the highest tertile of FM had a lower risk fracture than those within the lowest tertile (adjusted HR [95% CI], 0.400 [0.211-0.758]). However, in women, higher FM did not reduce the fracture risk significantly (adjusted HR [95% CI], 1.162 [0.824-1.637]). In the composite analyses using LM and FM simultaneously, men within the highest tertile of LM and the lowest tertile of FM reduced the fracture risk by 91% compared with the lowest tertile of LM and FM. In women, subjects within the lowest tertile of LM and the highest tertile of FM showed a two-time higher risk for fracture than the lowest tertile of LM and FM.

Fat mass after removing mechanical loading components may be associated with increased fracture risk. High lean mass and low fat mass may protect against fracture.

Sex hormones and radiographic vertebral fractures in older men. Peggy Cawthon*[1], John Schousboe[2], Kristine Ensrud[3], Dennis Black[4], Jane Cauley[5], Steven Cummings[6], Erin LeBlanc[7], Gail Laughlin[8], Carrie Nielson[9], Deborah Kado[10], Andrew Hoffman[11], Elizabeth Barrett-Connor[10], Eric Orwoll[9]. [1]California Pacific Medical Center Research Institute, USA, [2]Park Nicollet ClinicUniversity of Minnesota, USA, [3]University of Minnesota & Minneapolis VA Health Care System, USA, [4]University of California, San Francisco, USA, [5]University of Pittsburgh Graduate School of Public Health, USA, [6]San Francisco Coordinating Center, USA, [7]Kaiser, USA, [8]UCSD, USA, [9]Oregon Health & Science University, USA, [10]University of California, San Diego, USA, [11]Stanford, USA

Previous reports have shown that low bioavailable estradiol (bioE) and high sex hormone binding globin (SHBG) are associated with increased non-spine fracture risk in men. However, there are few reports of the association between sex hormones and vertebral fractures, particularly in men.

MrOS is a prospective cohort study of 5,994 ambulatory men aged ⩾65 yrs at baseline of whom 1608 were randomly selected for measure of sex hormones. Estradiol (E2) and testosterone (T) were analyzed by spectrometry/ chromatographic methods and SHBG by automated immunoassay. Bioavailable estradiol (bioE2) and testosterone (bioT) were calculated using mass action equations. At baseline and again 4.6 years later, lateral spine films were obtained and radiographic vertebral fractures were identified using semi-quantitative (SQ) grading. Likelihood of prevalent fracture (SQ⩾2) and likelihood of new or worsening fracture (change in SQ grade ⩾1) was estimated by logistic regression models adjusted for covariates (see Table footnote). Sex hormones and SHBG were analyzed as continuous variables with odds ratio expressed per 1 SD increase. Complete fracture, sex hormone and covariate data were available for cross sectional analyses for 1451 men (mean age: 72.8 years) at baseline of whom 137 (9.4%) had a prevalent vertebral fracture. Complete data for prospective analyses were available for 1049 men during 4.6 years of follow-up, of whom 55 (5.2%) had a new or worsening vertebral fracture.

In cross-sectional analyses, each SD increase in bioE2 was associated with an 18% decreased likelihood of prevalent vertebral fracture, while each SD increase in SHBG was associated with a 20% increased likelihood of prevalent fracture (Table). E2, bioT and T were not associated with prevalent fracture.

In prospective analyses, each SD increase in SHBG was associated with a 29% increased likelihood of incident vertebral fracture; however there were no significant associations for E2, bioE2, T or bioT

Similar results were seen when analyses were limited to new radiographic vertebral fractures only; when results were adjusted for total hip BMD rather than lumbar spine BMD; and when SHBG results were adjusted for E and T or for bioE and bioT.

In summary, higher SHBG was associated with increased likelihood of prevalent and incident radiographic vertebral fractures in older men. However, we did not observe strong associations between E2, T, bioE2 or bioT and radiographic fracture in men.

Table. Likelihood of radiographic vertebral fracture (Odds ratio, 95% CI) by SD increase of sex hormone

		Fracture	
	SD	Prevalent (SQ≥2)	Incident (change SQ≥1)
E2	7.9 pg/ml	0.86 (0.71, 1.04)	1.09 (0.85, 1.41)
T	161.3 ng/dl	0.95 (0.78, 1.15)	1.06 (0.80, 1.39)
BioE2	4.pg/ml	0.82 (0.67, 0.99)	1.15 (0.84, 1.58)
BioT	64.9 ng/dl	0.83 (0.68, 1.01)	0.88 (0.66, 1.17)
SHBG	19.8 nM	1.20 (1.01, 1.43)	1.29 (1.00, 1.67)

*adjusted for age, race, clinical center, smoking, height, weight, fall history, # prescription medications, inability to rise from chair, physical activity and lumbar spine BMD (by Hologic 4500 DXA)

A good self-estimated health lowers hip fracture risk independent of FRAX and BMD. Hans Lundin*[1], Maria Sääf[2], Lars-Erik Strender[3], Sven Nyrén[3], Helena Salminen[4]. [1]Karolinska Institutet, Sweden, Sweden, [2]Karolinska University Hospital Solna, Sweden, [3]Karolinska Institutet, Sweden, [4]Karolinska Institutet, Sweden

Bone mineral density (BMD) measured with DXA at the femoral neck is a well documented and very strong predictor of hip fracture risk. FRAX is the most used fracture prediction tool worldwide and includes BMD along with eleven other risk factors for hip fracture. The aims of this study was to see if self-estimated health measured with a visual analog scale (VAS) was associated with the risk of a hip fracture.This was a population-based prospective cohort study on 351 Swedish women aged 69-79 years at inclusion. These women self-estimaed their health and were assessed with FRAX including bone mineral density (BMD) at inclusion between 1999-2001. Global health was self-estimated with a visual analog scale (VAS) by writing an "x" on a 10 centimeter line drawn between "worst possible health" and "best possible health". The distance from "worst possible health" was measured in centimeters. Follow up was performed ten years later through Swedish medical records. The main outcome was a hip fracture. No participant was lost to follow up.The age adjusted ten-year hip fracture risk was decreased by 19% with every one cm better self-estimated health (Hazard ratio (HR) 0.81, 95% confidence interval (CI) 0.70-0.92). This relation was independent of BMD, FRAX-risk, previous fractures, parents low energy fractures, and the presence at baseline of ischaemic heart disease, diabetes mellitus, hypertension or any type of present or previous cancer.To have a self-estimated health below four centimeters compared to over four centimeters, resulted in a 2.3 times greater risk of a hip fracture after adjustment for femoral neck BMD (HR 2.3, 95% CI 1.1-4.8). This HR was not altered significantly after adjustment for any of the risk factors mentioned above. Self-estimated health thus seems to be able to identify high risk individuals not identified by any of the clinically most often considered risk factors. A low self-estmated health was not associated with the presence of any of several different common chronic diseases.

Cardiovascular risk factor analysis in patients with a recent fracture at the Fracture Liaison Service. Caroline Wyers*[1], Lisanne Vranken[2], Robert Van Der Velde[3], Heinrich Janzing[4], Wim Morrenhof[5], Piet Geusens[6], Joop Van Den Bergh[7]. [1]Maastricht University, The Netherlands, [2]VieCuri Medical Centre, The Netherlands, [3]VieCuri Medical Center Venlo, the Netherlands, The Netherlands, [4]VieCuri Medical Centre, Department of Surgery, Netherlands, [5]VieCuri Medical Centre, Department of Orthopedic Surgery, Netherlands, [6]University Hasselt, Belgium, [7]VieCuri MC Noord-Limburg & Maastricht UMC, The Netherlands

Purpose: Patients with osteoporosis have an increased risk of cardiovascular diseases (CVD) and venous tromboembolic events (VTE). Medications such as NSAID's, strontium ranelate and raloxifene have a contra-indication for prescription in patients with a history of CVD, VTE or hyptertension (HT). The aim of this study was to investigate the prevalence of CVD, VTE, HT and diabetes mellitus type (DM2) in medical history in patients with a recent clinical fracture visiting the Fracture Liaison Service (FLS).

Methods: Retrospective chart review of all consecutive patients aged ⩾ 50 years presenting with a recent clinical fracture, who visited the FLS for fracture risk assessment including evaluation of medical history. A contra-indication is defined as having CVD or VTE or HT in medical history. Data were analysed using Chi-square tests, Fisher's Exact Test and logistic regression analysis adjusting for age, sex, BMD (normal vs. osteopenia vs. osteoporosis) and fracture classification according to Center (finger & toe vs. minor vs. major vs. hip).

Results: 1359 patients with a recent clinical fracture were included (72% women; mean age 65 years). Osteoporosis was diagnosed in 30% of patients, osteopenia in 47% and normal BMD in 23%. Based on medical history, 30% of patients had a history of CVD (14%), VTE (2%), HT (15%) and DM2 (7%) or a combination. The presence of CVD, VTE, HT and DM2 increased with increasing age (21% in patients aged 50-59 years to 48% in patients aged >80 years; p=.000) and was higher in men (36% vs 27% women, respectively; p=.001), but independent of BMD and fracture type. In patients aged ⩾ 70 years, 35% had a contra-indication and it was higher in men (46% vs. 33% women p=.000), but independent of BMD and fracture type. After adjustments, only men contributed significantly for having a contra-indication in the total study population (p=.000). In patients aged ⩾ 70 years, men and hip fracture contributed significantly for having a contra-indication (p=.012, p=.044 respectively).

Conclusion: In patients presenting with a recent fracture, 30% have a history of either CVD, VTE, HT or DM2; and 29% in patients diagnosed with osteoporosis. A contra-indication was more frequently present in men. Although NSAIDS, strontium ranelate and ralofixene can be described safely in the majority of patients, careful evaluation of medical history with respect to CVD, VTE and HT should be performed before starting treatment with these medications.

Direct and Indirect Effects of Frailty on Fractures: Potential Roles of Muscle and Bone. Andy Kin On Wong*[1], Courtney Kennedy[2], George Ioannidis[3], Karen Beattie[2], Christopher Gordon[2], Laura Pickard[2], Alexandra Papaioannou[4], David Goltzman[5], Jerilynn Prior[6], Heather Macdonald[6], Maureen Ashe[6], Leigh Gabel[6], Danmei Liu[6], Saija Kontulainen[7], Andrew Frank[7], Wojciech Olszynski[8], K. Shawn Davison[9], Lora Giangregorio[10], Robert Josse[11], Eva Szabo[12], Marta Erlandson[7], Tassos Anastassiades[13], Norma MacIntyre[2], Angela M. Cheung[14], Jonathan Adachi[15]. [1]McMaster UniversityUniversity Health Network, Canada, [2]McMaster University, Canada, [3]McMaster University, Canada, [4]Hamilton Health Sciences, Canada, [5]McGill University, Canada, [6]University of British Columbia, Canada, [7]University of Saskatchewan, Canada, [8]University of Saskatchewan, Canada, [9]University of Victoria, Canada, [10]University of Waterloo, Canada, [11]St. Michael's Hospital, University of Toronto, Canada, [12]University Health Network, Canada, [13]Queen's University, Canada, [14]University Health Network-University of Toronto, Canada, [15]St. Joseph's Hospital, Canada

Objective: To explore the potential role of muscle and bone properties as independent and serial mediators in the causal pathway from frailty to fractures.

Methods: Women 60-85 years old within the Canadian Multicentre Osteoporosis Study (CaMOS) completed peripheral quantitative computed tomography (pQCT) (20 mm/s, 38 kVp) scans at 66% of the tibial length (at year 15). Muscle and cortical bone densities, mass, and area were derived. Comorbidities, cognition, energy, function and mobility questions obtained at baseline and year 10 were used to compute the CaMOS frailty index (CFI). Incident fractures were ascertained and categorized as fractures since baseline and fractures since year 10. A path analysis was performed with fractures regressed on frailty at baseline or at year 10, with each bone and muscle property as potential independent or serial mediators, adjusting for age, body mass index (BMI) and education. Direct, indirect and total effects were quantified using Hayes' mediation analysis models. All analyses were performed using PROCESS in SAS v9.3.

Results: Among 377 women (mean age: 65.6 ± 6.6 years; BMI: 26.84 ± 4.88 kg/m^2, 179(47.5%) with fractures since baseline, 48 (12.7%) with fractures since year 10), baseline and year 10 CFI significantly related to muscle but only marginally to bone properties (Table I). Baseline CFI was related to fractures (rate ratio: 2.78(95%CI: 0.06,5.50)) with direct effects significant only for the lower two tertiles of age and BMI. Significant indirect effects were mediated by muscle density but not by bone properties. Year 10 CFI was only associated with fractures as mediated by muscle mass. In the serial mediators' path analyses (Figure 1), the indirect effect of baseline CFI on fractures was significant only through muscle density without any serial contribution from bone. The direct effect of baseline CFI on fractures was larger than the total indirect effects through muscle or bone density. Year 10 CFI did not exhibit significant direct effects on fractures, but indirect effects through muscle mass or area on fractures was evident. The serial mediations of muscle and bone densities and areas on the year 10 CFI and fracture relation were significant.Conclusions: Frailty experienced earlier remains a lingering influence on incident fractures years later. Frailty experienced more recently may impact bone fragility through its more immediate association with muscle, and in part muscle's relation to bone.

Table I. Effects of baseline and year 10 CFI on muscle and bone properties. Models adjusted for age, BMI and education

Muscle	Mass (mg)	Density (mg/cm^3)	Area (mm^2)
Baseline	**-16.08 (-24.13,-8.03)**	-0.36 (-0.79,0.08)	**-191.9 (-303.1,-807.9)**
Year 10	**-16.13 (-23.98,-8.28)**	-0.19 (-0.61,0.24)	**-210.4 (-318.3,-102.4)**
Bone	**Mass (mg)**	**Density (mg/cm^3)**	**Area (mm^2)**
Baseline	-1.94 (-9.29,5.41)	0.01 (0.00,0.02)	**-12.8 (-25.1,-0.5)**
Year 10	-6.39 (-13.53,0.75)	0.00 (-0.01,0.01)	-9.5 (-21.6,2.5)

SA0335

Increased risk for hip fracture after bereavement. Dan Mellstrom*[1], Valter Sundh[2], Magnus Karlsson[3], Claes Ohlsson[4], Mattias Lorentzon[5], John Kanis[6], Boo Johansson[7], Anders Odén[8]. [1]Sahlgrenska University Hospital, Sweden, [2]Department of Geriatrics, Gothenburg University, Sweden, [3]Skåne University Hospital Malmö, Lund University, Sweden, [4]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden, [5]Geriatric Medicine, Center for Bone Research at the Sahlgrenska Academy, Sweden, [6]University of Sheffield, Belgium, [7]Department of Psychology, Gothenburg University, Sweden, [8]Department of biostatistics, Chalmers University, Sweden

Bereavement is associated with increased mortality and broken heart syndrome. The question arises whether bereavement also is related to broken hip.

We studied the Swedish population in 1986 with birth years 1902-1942, and followed 904,394 married couples from 1987 to 2002 in national research and census registers, coordinating information on mortality, hospital care, civil status, income, education and place of living. The relative risk of hip fracture incidence was estimated with Poisson risk time models, separately for each gender. Married individuals whose spouse did not die during the 16 year follow-up defined the reference group. Age during risk exposure was a covariate in all models.

The number of fractures 0-10 years after bereavement was 6,303 in men and 20,404 in women. The total years of risk in the bereaved group amounted to 601,787 in men and 1,679,773 in women. The sixteen-year morality was 24% in women and 41% in men. The excess risk (Hazard Ratio, HR) for hip fracture during the first 3 months after bereavement was 1.82 (CI = 1.62 – 2.05) for men and 1.54 (CI = 1.42 – 1.68) for women. The absolute risk decreased significantly over time during the first 3 years, but remained stable thereafter at a significantly elevated level compared to non-bereaved individuals for 10 years in both sexes (Table 1). There was also seen an increased risk during the years prior to death of spouse, which indicate a pre-mortality stress load on the partner.

Conclusion: We demonstrate a novel finding that bereavement is associated with an increased risk of hip fracture in both sexes, and that this is more marked in men than in women. The increased risk is most apparent during the first 3 months after bereavement, but even though there is a slow decrease during the next few years, an excess risk seems to remain at a significantly high level for several years thereafter.

Table 1. Increased risk for hip fracture after bereavement versus non-bereaved.

Time after bereavement	HR women	HR men
0 – 3 years	1.34 (1.30 – 1.38)	1.59 (1.53 – 1.66)
3 – 6 years	1.26 (1.22 – 1.30)	1.36 (1.30 – 1.43)
6 –10 years	1.25 (1.22 – 1.30)	1.38 (1.30 – 1.46)

SA0336

Persistent low grade inflammation is associated with bone loss in elderly women. Kristina Akesson[1], Sofia Berglundh*[2], Linnea Malmgren[3], Fiona McGuigan[4], Paul Gerdhem[5], Holger Luthman[6]. [1]Skåne University Hospital, Malmö, Sweden, [2]Skåne University Hospital, Malmö, Sweden, [3]Skane University Hospital, Sweden, [4]University of Lund, Malmö, Skane University Hospital, Malmö, Sweden, [5]Karolinska Institutet, Sweden, [6]Lund University, Sweden

Introduction: Evidence suggests inflammation may contribute to the pathophysiology behind impaired bone metabolism. Systemic inflammation negatively affects bone mass in rheumatoid arthritis patients but an inverse correlation between C-reactive protein (CRP), a marker of inflammation and bone mineral density (BMD) has also been observed. The aim of this study was to investigate the association between persistently elevated CRP levels and BMD, bone loss, fractures and mortality in 1044 women from the OPRA cohort of 75 year old Swedish women.

Method: CRP was measured at baseline, and at age 80 and differences in BMD and bone loss were compared. To capture the effect of inflammation over an extended period, we also classified women according to CRP levels at BOTH ages as follows: Group 1 CRP <3mg/L at 75y AND 80y; Group CRP 2 ⩾3mg/L at 75y OR 80y; Group 3 CRP ⩾3mg/L at 75y AND 80y.

Result: Women in the highest quartile of CRP (mean 5.74 mg/L) had significantly higher BMD at total hip (0.871 vs. 0.809 g/cm^2, p<0.001) and femoral neck (0.778 vs. 0.737 g/cm^2, p=0.007) compared to the lowest (mean 0.63 mg/L). CRP level at age 75 was not associated with BMD or bone loss. However, women with CRP ⩾3mg/L at BOTH BL and at the 5 yr follow-up had higher bone loss compared to women with CRP<3mg/L at total hip (-0.125 vs. -0.085 g/cm^2, p=0.018) and FN (-0.127 vs. -0.078 g/cm^2, p=0.005) during 10 yrs of follow-up. Women in the highest quartile of CRP had a lower risk of major osteoporotic fractures (HR 0.76 (95 % CI 0.52-0.98) compared to the lowest, even after adjusting for weight and BMD. CRP was not associated with hip fracture or mortality.Conclusion: This study suggests that CRP is not indicative of osteoporosis or fracture risk in elderly women, however, in women with persistently elevated CRP there seems to be an increased rate of bone loss.

SA0337

Sex-specific Associations Between Income and Incident Major Osteoporotic Fractures: A Population-based Analysis. Sharon Brennan*[1], Lin Yan[2], Lisa Lix[2], Suzanne Morin[3], Sumit Majumdar[4], William Leslie[5]. [1]Deakin University, Australia, [2]University of Manitoba, Canada, [3]McGill University, Canada, [4]University of Alberta, Canada, [5]University of Manitoba, Canada

Purpose: Lower income has been associated with increased fracture incidence at the hip. However, few studies have examined associations between income and fractures at other sites. We investigated sex-specific associations between income and incident fractures of the hip, wrist, humerus, and spine.

Methods: Incident fractures were identified from administrative health data for all residents (age 50+ yrs) of Manitoba, Canada, 2000-2007. Mean neighborhood (postal code area) annual household incomes were extracted from 2006 census files and categorized into quintiles. Age-adjusted and sex-stratified fracture incidences (per 100,000 person years) across income quintiles were calculated. We used a generalized linear model with a negative binomial distribution to estimate the relative risks (RR) of fracture for income quintile 1 (lowest income) vs. income quintile 5.

Results: A total of 15,094 incident fractures (4,736 hip; 3,012 humerus; 1,979 spine; and 5,367 wrist) were identified in 3,866 males and 11,228 females. For males, a negative linear association was observed between age-adjusted fracture incidence at major osteoporotic sites and income quintile; 646.6 vs. 397.3 for males in the lowest vs. highest income quintile, respectively (quintile 1 vs. quintile 5 RR 1.63, 95%CI 1.42-1.87) (Table). Similar negative linear associations were seen for males when stratified by skeletal site. Compared to the highest income quintile, men with the lowest income had a much greater age-adjusted RR of fracture at the hip (1.62, 95%CI 1.30-2.02), spine (1.65, 95%CI 1.28-2.13), humerus (1.97, 95%CI 1.59-2.43) and wrist (1.41, 95%CI 1.23-1.62). For females, we observed a weak negative linear association between overall fracture incidence and increasing income quintile (p-trend=0.029, lowest vs. highest income quintile RR 1.14, 95%CI 1.01-1.28). The only individual site to show a significant association with income was the wrist (p-trend=0.015, lowest vs. highest income quintile RR 1.09, 95%CI 1.01-1.28).

Conclusions: We report a consistent linear association between decreasing income quintile and higher fracture incidence in men, with a much smaller association in women. Men in the lowest income quintile had a 1.5-2 fold increased risk of fracture at the major osteoporotic sites compared to men in the highest income quintile. These data provide evidence that men with lower income may be an important target population for intervention to reduce the burden of fracture.

Table: Age-adjusted fracture incidence per 100,000 person years (SE) and RR (95% CI) according to income quintile.

	Quintile 1*	Quintile 2	Quintile 3	Quintile 4	Quintile 5	p-linear trend	RR Q1 vs. Q5

Implementation of FLS in the Province of Quebec (Canada): perseverance and creativity. Marie-Claude Beaulieu*[1], Hélène Corriveau[2], Isabelle Gaboury[2], François Cabana[3], Gilles Boire[4]. [1]Université de Sherbrooke, Canada, [2]Université de Sherbrooke, Canada, [3]CHUS, Canada, [4]Centre Hospitalier Universitaire De Sherbrooke, Canada

In the early 2000's, despite existing guidelines and recommendations, gaps in care after a fragility fracture (FF) persisted. To address these gaps, the OPTIMUS program was implemented in the Estrie area of the Province of Quebec, to foster inter-professional collaboration and to facilitate the involvement of Family physicians in the care of FF patients. The results in over 1400 consecutive patients were strongly positive, with treatment after a FF increasing from less than 20% to more than 50%. Family physicians, as well as family medicine and orthopedic residents, have been

trained to respond to a FF and now actively collaborate to their patients' treatment. A provincial interdisciplinary group called FOCUS (Fractures = Osteoporosis Care for US) has been working since 2011 to improve FF care and to implement Fracture Liaison Services (FLS) across the Province, in various centers including urban and rural regions. FOCUS includes physician champions in various disciplines (family medicine, internal medicine, rheumatology and orthopedics) as well as nurses. Meetings and exchanges have been made with regional health agencies and the Ministry of Health. A FLS system is now in place for post-hip FF care in Sherbrooke as well as in 3 hospitals in Montréal. OPTI-FRAC, a CIHR-supported research program, integrates locally adapted FLS systems with fall prevention in 5 areas of the Province. Members of the group share their algorithms of treatment, tools and other materials including a website. One team member was involved in the Canadian group on FLS implementation by Osteoporosis Canada and in the French translation of the pamphlet 'Make the first break the last with FLS.' This is now being circulated among clinicians, knowledge users and bureaucrats. Multiple local and regional initiatives are under way, following the FLS 2i and 3i models. Collective orders for nurses, personnel training, webinar for family physicians, pharmacists, nurses, physical therapists and a workshop for family medicine residents are concrete results of the group's work. We now work on the implementation of FLS across the province (according to local needs and resources), and on the integration of inpatients with FF of the proximal humerus, pelvis, wrist and vertebra into the FLS currently in place. By remaining creative and perseverant, with collaboration and adaptation to local realities, we develop efficient but low cost programs.

Osteoporosis in Female Type 1 Diabetic Patient at the Veterans Affairs Medical Center. Foiqa Chaudhry*[1], Kwame Ntim[2]. [1]University of Florida, USA, [2]University of Florida, USA

Objective: To highlight the importance of thorough secondary workup of osteoporosis in a young Type 1 diabetic female presenting after fracture.

Case: This patient is a twenty nine year old female who presented to the endocrinology department at the VA Hospital for initial consultation regarding management of her uncontrolled Type 1 diabetes mellitus. She had been diagnosed at age 18 and had since developed retinopathy, gastroparesis and neuropathy. Her most recent A1c was 11.1%. In obtaining her complete history, it was stated that she suffered a fall from sitting height and sustained a rib fracture a few months prior. This was followed up with a DXA scan which revealed a spine L1-L4 T score -2.0, Z score -2.0, BMD 0.83 grams per centimeter squared and left femoral neck T score -2.6, Z score -2.6, and BMD 0.56 grams per centimeter squared. She was told the osteoporosis was due to her poor diabetes control and plans were to start her on oral bisphosphonate therapy. On further questioning, patient revealed that she had not had a menstrual cycle in over 3 years. Laboratory data also showed 25-OH vitamin d level of 18.57 ng/mL nearly two years ago with no current supplementation. Though diabetes is a risk factor for osteoporosis, a lengthy discussion was undertaken to discuss possible secondary causes of her condition including primary ovarian failure and celiac disease. FSH and LH were ordered and patient referred to GI for bowel biopsy.

Discussion: Secondary causes are commonly considered when osteoporosis is found in a young patient. When receiving care in a VA setting however, causes such as premature menopause may be overlooked given the skewed population demographics, i.e. mostly male patients. Also, associated autoimmune conditions such as Celiac disease and primary ovarian failure should always be considered when managing a patient with Type 1 diabetes mellitus. These conditions may be the underlying cause of osteoporosis and should be addressed before considering bisphosphonate therapy.

Physicians' Attitudes to Contemporary Issues on Osteoporosis Management in Korea. Young-Kyun Lee*[1], Yong-Ki Min[2], Hyoung-Moo Park[3], Deog-Yoon Kim[4], Ho-Yeon Chung[5], Yong-Chan Ha[6]. [1]Seoul National University Bundang Hospital, South Korea, [2]Samsung Medical Center, South Korea, [3]Chung-Ang University College of Medicine, South Korea, [4]Kyung Hee University Hospital, South Korea, [5]Kyung Hee University, South Korea, [6]Chung-Ang University Hospital, South Korea

Background: Recently, several concerns here have been raised in management of osteoporosis. The current issue included the utilization of DXA and FRAX, screening of vitamin D deficiency and secondary osteoporosis, and long-term use of bisphosphonate and calcium supplements. There was no study on physicians' attitude on these current issues in Korea. Therefore, we investigated the physicians' attitude on these issues by survey.

Methods: We administered a 30-item questionnaire to all members of Korean Society for Bone and Mineral Research by email survey form. One hundred participants answered the questionnaire. The questionnaire included the questions about the physicians' attitude to current issues and the barriers to osteoporosis treatment in Korea.

Results : Most physicians use bone densitometry devices (99 %) and, central DXA was the most accessible device (95 %). Eighty-eight percent were aware of FRAX®, but among them, only 19.3 % used it. The main reason for not using FRAX® was the lack of time in their proactive (76%) (Figure 1). Screening for vitamin D status and secondary osteoporosis was performed by 59% and 52 % of the respondents, respectively. The lack of awareness among patients and high costs of medication were perceived as the most important barriers to osteoporosis management in Korea (Figure 2).

Conclusion : This study provides physicians' perspective to the current issue for diagnostic and treatment of osteoporosis in Korea. To further improve osteoporosis management, educational programs for patients and doctor, and the improvement of reimbursement system should be considered in Korea.

Factors Associated With Early Functional Outcome After Hip Fracture Surgery. Matthew Cohn*[1], Ting Cong[2], Benedict Nwachukwu[3], Minda Patt[4], Pingal Desai[5], Kara Gasiorowski[4], Jin Chen[3], Jonathan Jo[6], Joseph Lane[5]. [1]Weill Medical College of Cornell University, USA, [2]Weill Cornell Medical College, USA, [3]Hospital for Special Surgery, USA, [4]NewYork Presbyterian-Weill Cornell Medical Center, USA, [5]Hospital for special surgery, USA, [6]Weill Cornell Medical College, Hospital for Special Surgery, USA

Background: Hip fractures are common among patients with osteoporosis and as the U.S. population ages they are likely to be more prevalent. Early functional status is an indicator of longer-term outcome, predictors of functional recovery after hip fracture surgery have not been well studied. The purpose of this study was to determine the impact of surgical delay beyond 48 hours, after-hours surgery and ancillary support staff on early functional outcome after hip fracture surgery.

Methods: Ninety-nine consecutive patients underwent hip fracture surgery by a single surgeon between 2009 and 2013. Surgery after 48 hours was deemed as surgical delay and surgery after 5pm was deemed as after-hours. Ancillary staff experience was determined by experts from our institution as well as documented level of training. Functional status was determined by independent ambulation on post-operative day 3.

Results: Our study consisted of 99 patients (62 females). The mean age of our population was 79 ($\pm$12.6) years with a mean American Society of Anesthesiologists (ASA) classification of 2.8 ($\pm$0.59). Sixty-two patients experienced no delay and 72 patients received surgery during daytime hours. On post-operative day three, 49 of 63 patients (78%) with no delay were ambulating whereas only 14 of 36 patients (39%) with delayed surgery were able to ambulate ($p < 0.001$). This relationship persisted

when adjusted for ASA classification. No delay in patients over 80 (OR, 6.91 95% CI 2.16, 22.10) and females (OR, 7.05 95% CI 2.34, 21.20) was associated in greater chance of early ambulation. After-hours surgery was not associated with ambulation (p=0.35). Anesthesiologist and circulating nurse experience had no impact on patient's ambulatory status however non-orthopaedic scrub technicians were associated with worse functional status (OR 7.50, 95% CI, 1.46, 38.44, p = 0.01).

Conclusions: Surgical delay and non-orthopaedic scrub technicians are associated with worse early functional outcome after hip fracture surgery. Surgical delay should be avoided in older patients and women. More work should be done to understand the impact of surgical team composition on outcome.

[1]Bone Metabolic Unit (RETICEF), Endocrinology Division, Hospital Universitario San Cecilio, Instituto de Investigación de Granada. Endocrinology Unit. Hospital General Universitario Rafael Mendez, Lorca, Murcia., Spain, [2]Bone Metabolic Unit (RETICEF), Endocrinology Division, Hospital Universitario San Cecilio, Instituto de Investigación de Granada., Spain, [3]Bone Metabolic Unit (RETICEF), Endocrinology Division, Hospital Universitario San Cecilio, Instituto de Investigación de Granada. Endocrinology. Hospital Comarcal del Noroeste, Caravaca de la Cruz, Murcia., Spain, [4]Palacios Institute of Women's Health, Spain, [5]Department of Obstetrics & Gynecology, University of Granada, Spain, [6]Endocrinology Division, Hospital Universitario San Cecilio, Spain, [7]Departamento de Investigación y Desarrollo. Lactalis Puleva, Spain, [8]Nutrition Department, Biosearch S.A, Spain

Background: Vitamin D deficiency is highly prevalent and can be associated with adverse health outcomes. Few studies have evaluated the effects of daily consumption of milk fortified with a high dose of vitamin D in a large cohort of healthy postmenopausal women.

Aims: To determine the effect of daily intake of milk enriched with vitamin D [with or without fructooligosaccharides (FOS)] on vitamin D status, bone mass and cardiovascular risk factors.

Patients and methods: This was a 2-year randomized controlled study in which five hundred healthy postmenopausal women (mean age 58.1 ± 4.8 years) were assigned to receive 500 ml/day of a dairy product to one of three groups: Control group (C) with skimmed milk (120 mg/100 ml calcium and vitamin D 0.75 ug/100 mL), group A with skimmed milk enriched with calcium and vitamin D (180 mg/100 mL and 3 ug/100 mL) and group B with skimmed milk enriched with calcium and vitamin D (180 mg/100 mL and 3 ug/100 mL) and FOS (5 g/L). We evaluated serum levels of 25-OH-vitamin D. We also measure anthropometric parameters, biochemical data of glucose metabolism and lipid prolife, body composition by electrical impedance and bone mineral density by DXA.

Results: After 24 months, changes in vitamin D in the control group (n=150) were non-significant (22.0 ± 7.3 vs 22.6 ± 7.3 ng/ml, p= 0.1). In group A (n=152) and group B (n=150) we observed a significant increase in vitamin D (Group A 21.3 ± 6.8 vs 26.6 ± 6.4 ng/ml; Group B 21.9 ± 9.5 ng/ml vs 25.2 ± 6.2 ng/ml, $p<0.001$ for both). The increase in vitamin D concentrations showed no differences according to the group of treatment (A or B). However, the changes observed in both groups of treatment were significantly higher compared to control group. In groups A (85.2%) and B (81.7%) a high percentage of women reached vitamin D levels>20 ng/ml, compared with the control group (53.9%), $p < 0.01$ for the comparison with control group.

Conclusions: Our data data confirms that daily intake of milk highly enriched with vitamin D, with or without FOS, in postmenopausal healthy women induces a significant improvement in vitamin D status.

SA0349

Eldecalcitol, a second generation active vitamin D analog, increases lumbar spine BMD in osteoporotic patients treated with alendronate regardless of their pretreatment levels of bone turnover. Akinori Sakai*[1], Masako Ito[2], Tatsushi Tomomitsu[3], Hiroshi Tsurukami[4], Satoshi Ikeda[5], Fumio Fukuda[6], Hideki Mizunuma[7], Tomoyuki Inoue[8], Hitoshi Saito[9], Toshitaka Nakamura[10]. [1]University of Occupational & Environmental Health, Japan, [2]Nagasaki University Hospital, Japan, [3]Department of Radiological Technology, Kawasaki College of Allied Health Professions, Japan, [4]Tsurukami Clinic of Orthopedics & Rheumatology, Japan, [5]Ken-Ai Memorial Hospital, Japan, [6]Kitakyushu General Hospital, Japan, [7]Department of Obstetrics & Gynecology, Hirosaki University School of Medicine, Japan, [8]Taisho Pharmaceutical Co., Ltd., Japan, [9]Chugai Pharmaceutical Company, Limited, Japan, [10]National Center for Global Health & Medicine, Japan

Purpose: In order to maximize the efficacy of bisphosphonate (BP), and to prevent negative calcium balance, osteoporotic patients on the BP therapy are generally recommended to take native vitamin D plus calcium concomitantly. In Japan, active vitamin D analog is often prescribed with BP for the same purpose. In this study, we compared the clinical efficacy and safety of concomitant use of a newly developed active vitamin D analog, eldecalcitol (ELD), with those of native vitamin D plus calcium supplementation, in patients with primary osteoporosis treated with alendronate (ALN).

Methods: A total of 219 patients were randomly assigned 1:1 to receive daily oral 0.75mg ELD plus weekly oral 35mg ALN, the licensed dose in Japan (ELD+ALN group; n=110), or daily oral vitamin D 400IU + calcium 610mg plus ALN (VitD/Ca+ALN group; n=109) for 48 weeks. The primary endpoint was percent change in lumbar spine BMD at the patient's last visit. Bone turnover markers and others were also evaluated.

Results: Compared with baseline, lumbar spine BMD increased 7.3% in the ELD+ALN group, 6.5% in VitD/Ca+ALN group in 48 weeks. There was no statistically significant difference between the two groups. All the bone turnover markers (serum BAP, P1NP, TRACP-5b, CTX and urinary NTX) measured were significantly reduced from the baseline in both groups. Reduction of the bone turnover markers was significantly greater in the ELD+ALN group than in the VitD/Ca+ALN group. Patients were then stratified by the pretreatment levels of each bone turnover marker. In patients with high pretreatment level of bone turnover markers (higher than upper normal limit), lumbar spine BMD significantly and equally increased from the baseline in both ELD+ALN and VitD/Ca+ALN groups. However, in patients with low or normal pretreatment level of bone turnover markers, the increases in lumbar spine BMD were blunted in the VitD/Ca+ALN group, on the other hand, treatment with ELD+ALN increased lumbar spine BMD comparable to those in patients with high pretreatment level of bone turnovers. No new safety concerns as well as no serum and urinary calcium abnormality were observed in both groups.Discussions: ELD increases lumbar spine BMD regardless of pretreatment levels of bone turnover markers in osteoporotic patients treated with ALN. Combination of ALN and ELD may be most beneficial in patients with low or normal baseline bone turnover.

Evaluating the Effects of High-Dose Supplemental Vitamin D on Bone Density and Structure: Design of the VITamin D and OmegA-3 TriaL (VITAL). Amy Yue*[1], JoAnn Manson[2], Julie Buring[2], Nancy Cook[2], Patricia Copeland[1], Meryl Leboff[3]. [1]Brigham & Women's Hospital, USA, [2]Brigham & Women's Hospital Professor of Medicine, Harvard Medical School, USA, [3]Brigham & Women's HospitalProfessor of Medicine, Harvard Medical School, USA

Despite enthusiasm for the use of vitamin D supplements for bone health, it is uncertain whether supplemental vitamin D *alone* or in high doses has beneficial effects on bone health measures. Previous clinical trials have been limited by the inability to separate the effects of supplemental calcium from vitamin D, small sample size, and lack of measured 25-hydroxyvitamin D [25(OH)D] levels. To test whether high-dose supplemental vitamin D vs. placebo prevents bone loss, and improves bone structure and the balance of bone remodeling, we are conducting an ancillary study to the *VIT*amin D and Omeg*A*-3 Tria*L* (VITAL). VITAL is a 2x2 factorial, double-blind, placebo-controlled trial testing the benefits and risks of daily supplemental vitamin D_3 (cholecalciferol; 2000 IU/d) and/or omega-3 fatty acids (EPA+DHA; 1 g/d) in the primary prevention of cancer and cardiovascular disease among ~26,000 men aged ⩾50 and women aged ⩾55 years in the U.S. A sub-cohort of >1000 VITAL participants in the New England region were enrolled for detailed, in-person assessments at baseline and year 2 post-randomization at Harvard Catalyst, the NIH-sponsored Clinical and Translational Science Center (CTSC). Among CTSC participants not using bone active medications at baseline, we measured bone mineral density (spine, hip, and total body) and body composition (total and regional fat and

lean tissue) by dual X-ray absorptiometry (DXA), bone turnover biomarkers (serum procollagen type I N-terminal propeptide, osteocalcin, C-terminal telopeptide levels) and bone structure at the distal radius and tibia by peripheral quantitative computed tomography (pQCT). DXA and pQCT assessments were completed in 778 (exceeding target of 600) and 684 participants, respectively. Baseline levels of 25(OH)D, calcium, and PTH were collected in VITAL. All CTSC-based measures will be repeated 2 yrs post-randomization. We will also obtain bone architecture measures by high-resolution pQCT at year 2 post-randomization. This ancillary bone study will determine whether high-dose, supplemental vitamin D confers protective effects on bone density, structure and turnover, has effects on body composition, and whether achieved 25(OH)D levels affect these outcomes and vary according to body mass index and body composition. Results from this study will fill gaps in knowledge and elucidate the mechanisms through which high-dose vitamin D alone may prevent age-related fractures and have beneficial effects on bone health.

Exposure to direct sunlight biodegrades vitamin D in milk. R. C. Hamdy, R. Mohseni, C. Magallanes, B. Som, T. Piggee. East Tennessee State University, Johnson City, TN 37614. Ronald Hamdy*. East Tennessee State University, USA

Vitamin D is essential for all phases of bone health. Its deficiency is very prevalent and one of the major causes of osteoporosis which affects about half the Caucasian female population over the age of 50 years. The mortality and morbidity associated with osteoporosis have profound psycho-socio-economic implications. Given that milk is fortified with vitamin D (cholecalciferol) and is considered a major source of this vitamin, we were concerned that direct exposure to sunlight would enhance its biodegradation and therefore lull consumers into a false sense of security regarding their dietary vitamin D intake.

The purpose of this study was to assess the effect of direct sunlight exposure on milk vitamin D content. The study was conducted on October 9, 2013 on a sunny day in North East Tennessee, average temperature 15°C/59°F. Commercially available skim milk (Kroger brand) within the recommended period of its 'Best used by date' was utilized. Two subsamples of milk were transferred to clear glass containers. One was placed under direct sunlight and the other in an adjacent shaded area. The tops were placed on the containers to avoid particulate matters getting in the containers. At 0, 15, 60, 120, and 180 minutes samples were taken from each container and transferred to clear glass vials. The modified AOAC Official Method 992.26 was utilized to extract vitamin D_3 (cholecalciferol). To validate the method, calibration curves were examined every time prior to analyzing the extracts. A sample of milk was also spiked with vitamin D_3 standard to validate the extraction procedure. The linear correlation between cholecalciferol concentration (range of 0.025-0.40 ppm) and peak area (R^2= 0.9986) confirms the validity of our methodology.

Our data show that about 65% of cholecalciferol in milk biodegrades within 15 minutes of exposure to direct sunlight. By 60 minutes only 17% of the original cholecalciferol remains in milk exposed to direct sunlight whereas 97% is still available in the sample kept in shade. These results have significant implications. Glass containers do not protect against cholecalciferol biodegradation.

SA0353

Rising Trend in Vitamin D Status in Ireland from 1993 to 2013: Concerns for the Future. Malachi McKenna*[1], Barbara Murray[2], Myra O'Keane[3], Mark Kilbane[3]. [1]St. Michael's Hospital, Ireland, [2]St. Michael's Hospital, Ireland, [3]St. Vincent's University Hospital, Ireland

Background. Concern has been expressed regarding the prevalence of vitamin D deficiency but also regarding unsubstantiated claims regarding benefit of high oral intakes. The Institute of Medicine (IOM) 2011 Report revised upwards dietary reference vitamin D intakes but cautioned against exceeding recommended intakes. They also specified corresponding 25-hydroxyvitamin D (25OHD) levels of 40 nmol/L (16 ng/mL) as the estimated average requirement (EAR) and 50 nmol/L (20 ng/mL) as the recommended daily allowance (RDA).

Objectives. We sought (1) to examine change in 25OHD over the last 20 years, (2) to create a model for trends in 25OHD from the dataset, and (3) to forecast levels of 25OHD based on the current trend.

Methods. We collated all 25OHD results from May 1993 until December 2013. The total number of results extracted was 69,012. After trimming the database to one sample per person, the total number was 43,997. We conducted a time series analysis that was analysed using a 4253H smoother, which is a running median smoothing function. We used the auto-regressive integrated moving average (ARIMA) model to examine trend, seasonality and cycles. The model was rebuilt excluding the final 3 years followed by comparison of the forecasted values with the actual values. Using the ARIMA model, forecasting 25OHD levels was extended to 2016. A single linear regression model was fitted to the last 6 years of the data in order to represent the moving average over time.

Results. The yearly average 25OHD increased from 30.6 nmol/L in 1993 to 50.8 nmol/L in 2013. The time series analysis using the 4253H smoother demonstrated seasonality of the data, as expected, and an upward trend without any cycles. The ARIMA model showed a close fit between the model and the data; the mean value of the errors was close to zero; the variance was least in the last 5 years; the error terms were normally distributed; and the rebuilt model performed well in predicting the values through 2011 to 2013. The forecast model up to 2016 showed an upward trend and seasonality. The regression equation was: 25OHD in nmol/L=month*0.057+43, indicating a yearly increase in average 25OHD of 0.68 nmol/L.

Conclusions. We noted a steady and consistent improvement in vitamin D status over the past 20 years such that the yearly average in 2013 at 50 nmol/L exceeded the IOM EAR of 40 nmol/L. This trend shows no sign of abating. There is now a dual concern about vitamin D depletion and overreplacement.

SA0355

The Impact of 25(OH) Vitamin D Reference Method Procedure (RMP) Alignment on Measurements Obtained with the IDS Chemiluminescent-based Automated Analyzer Assay. Christine Simpson*[1], Anna Maria Cusano[2], Karl Insogna[1]. [1]Yale University School of Medicine, USA, [2]Yale University School of Medicine, USA

To address uncertainty in measuring 25(OH) vitamin D, the Vitamin D Standardization Program (VDSP) was established by the NIH, NIST, the CDC, and Ghent University. This program identified ID-LC-MS/MS as the 25(OH) vitamin D Reference Measurement Procedure (RMP). This ID-LC/MS/MS method is traceable to NIST Standard SRM2972. As manufacturers align their product to the RMP, the concern is that results obtained in aligned assays will be divergent from those obtained with pre-alignment assays. This may result in confusion among clinicians and consumers. IDS offers a chemiluminescent assay for 25(OH) vitamin D on its iSYS platform which has recently been harmonized to the RMP. Using single donor human serum samples with RMP target values, supplied by the VDSP, IDS calibrated their master human serum samples library. This library was used to value-assign the internal calibrators to define the assay's master curve and kit lot-specific calibrators. The predefined master curve is adapted to the analyzer using kit lot-relevant calibrators. To determine the impact of standardization on results obtained with iSYS reagents, 120 single donor serum samples were analyzed in two non-standardized and one standardized iSYS assay. As summarized in the graph, regardless of disease category or metabolite concentration, there was excellent agreement in results obtained in all three assays. For all 120 samples the M $\pm$ SD for the two non-standardized assays were 43.8 $\pm$ 22 and 44.3 $\pm$ 22 as compared to a mean value of 45.8 $\pm$ 23 ng/mL in the standardized assay. These initial data provide confidence that the move to NIST standardized assay will have little impact on results obtained with the iSYS platform.

Vitamin D Levels in Young Women with Anorexia Nervosa during Nutritional Rehabilitation and Relationship with Bone Mass. Anna Svedlund*[1], Bojan Tubic[2], Cecilia Pettersson[2], Per Magnusson[3], Björn Wettergren[4], Diana Swolin-Eide[5]. [1], Sweden, [2]Queen Silvia Children's Hospital, Sweden, [3]Linkoping University,Sweden, Sweden, [4]Paediatric Primary Care, Sweden, [5]Queen Silvia Children's Hospital, Sweden

Purpose: Anorexia nervosa (AN) may result in permanent low bone mass. The aim of this study was to investigate relationship with vitamin D and bone mineral density (BMD), bone mineral content (BMC) and body mass index (BMI) in young women hospitalized for severe anorexia nervosa.

Methods: Seventeen female patients with AN admitted to a specialised eating disorder inpatient unit (20.0 $\pm$ 2.5 years, BMI 15.5 $\pm$ 0.8 kg/m^2) were included. Six patients had vitamin D supplements daily before study entry. Patients underwent nutritional rehabilitation for 12 weeks with an extra high energy diet, starting at median 75 kcal/kg/day and gradually declining to 48 kcal/kg/day during the study. The mean intake of vitamin D and calcium was 26 µg resp. 2700 mg daily at start. Serum 25-hydoxyvitamin D (25(OH)D) was assessed by an electrochemiluminescence assay (Roche Diagnostics). BMD, BMC and body composition were measured by dual-energy X-ray absorptiometry (DXA) (Lunar Prodigy). Tibia volumetric BMD and muscle area were measured by peripheral quantitative computed tomography (pQCT) (Stratec).

Results: The mean weight gain was 9.2 kg and mean BMI 18.8 $\pm$ 1.0 kg/m^2 after 12 weeks, $p<0.0001$. No patient was vitamin D deficient (<25 nmol/l) and 24 % of the patients had vitamin D levels <75 nmol/l at start. The median serum 25(OH)D was 84 nmol/l at baseline and 75 nmol/l after 12 weeks (no significant change). At baseline the total body BMD (TBBMD) Z-score was above -1 in 13 patients, and 2 patients had Z-scores less than -2. There was no significant difference in TBBMD. TBBMD Z-score was significantly lower after 12 weeks, $p<0.01$. No difference in lean mass was observed. The adipose tissue increased from 12.2 $\pm$ 5.1% to 26.3 $\pm$ 5.0%, $p<0.0001$. Total BMC was significantly higher after 12 weeks, $p<0.001$. Trabecular and cortical bone mass, assessed by pQCT, were significantly lower after 12 weeks. We found no significant associations between serum 25(OH)D and BMD, BMC or BMI.*Conclusion:* On a positive note, none of the patients were vitamin D deficient at the start of this study. 25(OH)D levels did not decrease during the study although very little exposure to sunlight. We suggest that the adequate vitamin D status could be explained by sufficient vitamin D levels prior to study start and the high content of vitamin D in the diet. The increased BMC values suggest a positive effect on bone mass but further longitudinal studies are required to determine the long-term effect on BMD.

A double-blind, randomized, Phase III, multicenter study in 300 pediatric subjects receiving isotretinoin therapy therapy demonstrate no effect on pediatric bone mineral densityPurpose:. Kevin Hoover*[1], Colin Miller[2], Craig Langman[3], Rick Gilbert[4], Jason Gross[5]. [1]Virginia Commonwealth University, USA, [2]BioClinica, Inc., USA, [3]Ann & Robert H Lurie Childrens Hospital of Chicago, USA, [4]TKL Research, USA, [5]Cipher Pharmaceuticals, Canada

Abstract

Purpose: Isotretinoin (13-cis-retinoic acid) is a treatment for recalcitrant nodular acne with a purported effect on bone mineral density (BMD) in the spine and proximal femur. The side effects of isotretinoin were evaluated in a recent study to assess the safety of a new FDA-approved isotretinoin formulation: Lidose-isotretinoin (CIP-Iso).

Methods: This double-blind, randomized, Phase III, active control, parallel-group, multicenter study evaluated the safety and efficacy of CIP-Iso compared to a marketed isotretinoin in patients with severe recalcitrant nodular acne. To ensure optimum DXA assessments the following were excluded at screening: those with metal prosthetics in the spine, hip, or femur; fewer than 3 evaluable lumbar vertebrae between L1 and L4; or BMD Z-score < -2.0. 300 pediatric male and female patients aged between 12 and 17 years with documented Tanner stages were enrolled. Female patients were carefully screened and monitored to avoid pregnancy. Patients underwent 20 weeks of treatment with doses of 0.5-1.0 mg/kg/d and baseline and post-treatment DXA measurements of the spine were obtained utilizing either Hologic or GE (Lunar) scanners. 127 of the 300 subjects had heights documented and height adjusted Z-scores (HAZ) calculated.

Results: Z-Scores on the 300 subjects at baseline and post-treatment were not different in the treatment groups. The mean overall Z-score at baseline was 0.39 (1.09) and post-treatment of 0.34 (1.08) (Figure 1) (p=.25). The change in Z-score after treatment showed a dependence on Tanner Stage ($p < 0.05$). In the subset of patients in whom HAZ could be calculated, there was no dependence on Tanner stage. A statistically insignificant mean rise in HAZ was identified after treatment.

Conclusion: Two formulations of isotretinoin do not demonstrate a statistically significant effect on BMD or difference from one another. Trial patients demonstrated mean positive baseline Z-scores at study entry, likely due of the excluding patients with Z-scores of < 2.0. Z-scores demonstrated a statistically insignificant decline in bone mineral density that disappeared in those patient scores adjusted for height. The data from this clinical trial suggests that there is not a clinically meaningful effect on BMD on pediatric subjects taking isotretinoins for up to 6 months to treat recalcitrant nodular acne.

Effects of long-term thyrotropin-suppressive therapy on bone mineral density and fracture prevalence in elderly women with differentiated thyroid carcinoma. Sabine Weidner[1], Albrecht Popp*[2], Sandra Grifone[3], Helene Buffat[3], Christian Boy[1], Thomas Krause[1], Kurt Lippuner[2]. [1]Department of Nuclear Medicine, Inselspital, University Hospital Berne, Switzerland, [2]Department of Osteoporosis, University Hospital & University of Berne, Switzerland, [3]Department of Osteoporosis, University Hospital & University of Berne, Switzerland

Introduction:

Patients with differentiated thyroid carcinoma (DTC) are commonly treated with thyroxine-based long-term thyrotropin (TSH)-suppressive therapy resulting in a state of chronic subclinical hyperthyroidism. Reported effects of TSH-suppressive therapy on bone are inconsistent. The aim of the present study was to determine the effects of TSH-suppression on areal bone mineral density (BMD) and fracture status in a homogeneous group of elderly women with DTC.

Methods:

Case-control study with consecutive women (>65 years) with DTC under current long-term TSH-suppressive therapy (>3 years) followed at the University Hospital of Berne, Switzerland, (cases) and age-matched healthy women from a representative age-matched population sample (controls). BMD was measured at lumbar spine (LS), hip (FN/TH), radius (rad 1/3), tibial diaphysis (T-DIA), and tibial epiphysis (T-EPI) by Dual Energy X-ray Absorptiometry (Hologic Discovery C^{TM}; Hologic, Bedford, MA, USA). Vertebral fracture assessment (VFA) was performed and the individual history of previous clinical fragility fractures collected. Fractures were categorized into major osteoporotic fractures (MOF at the hip, spine, distal radius, and proximal humerus) and non-MOF. Significances were assessed by Mann-Whitney U-test.

Results:

Of 61 cases, 40 could be matched with controls. Mean ($\pm$ SD) age was 75.7 ± 3.9 vs. 75.3 ± 3.8 years, respectively. Mean duration of TSH-suppression was 10.9 ± 5.7 years. Mean BMD T-scores by DXA were not significantly different between cases and controls: LS -0.7/-1.0; FN -1.3/-1.1; TH -0.9/-0.6; rad 1/3 -1.6/-1.4; T-DIA -0.6/-0.5; and T-EPI -1.2/-1.4. Similarly, the prevalence of morphometric vertebral fractures assessed by VFA, MOF, and non-MOF were not significantly different between groups.

Conclusion:

In elderly women with DTC under long-term thyrotropin-suppressive therapy, BMD T-scores at major skeletal sites and fragility fracture prevalence were not significantly different from those in age-matched healthy controls.

A risk factor for fracture in patients with rheumatoid arthritis is not the disease itself but the use of glucocorticoid–the third year results of the TOMORROW study-. Tatsuya Koike*[1], Yuko Sugioka[2], Kenji Mamoto[3], Tadashi Okano[3], Masahiro Tada[3], Kentaro Inui[4]. [1]Search Institute for Bone & Arthritis Disease (SINBAD), Japan, [2]Center for Senile Degenerative Disorder, Osaka City University Medical School, Japan, [3]Orthopaedic Surgery, Osaka City University Medical School, Japan, [4]Osaka City University Medical School, Japan

Background: Patients with rheumatoid arthritis (RA) who have muscle weakness and stiff or painful joints might be at increased risk of falling and fracture. The present study prospectively determines the incidence of falls, fractures, and their risk factors in patients with RA who participated in the TOMORROW study that began in 2010.

Methods: We evaluated anthropometric parameters, bone mineral density, disease activity and the occurrence of falls and fractures for a period of three years in 202 patients with RA (58 years) and 202 age- and gender-matched healthy volunteers (controls, 57 years).

Results: There is no difference in incidence of falls/fractures between RA patients (37%/9.4%) and controls (30%/7.4%) during three years. The patients with RA fell significantly more frequently than controls (2.76 vs. 1.91 falls/three years; p = 0.03). After adjusting for risk factors for falls and fractures, including age, sex, smoking and body mass index, multiple regression analysis revealed that a history of falls was the most significant parameter associated with the incidence of falls (odds ratio [OR], 3.59; 95% confidence interval [CI], 1.61–8.00; p = 0.002) in controls. However, a history of falls was not significantly associated in patients with RA (OR, 1.93; 95% CI, 0.99–3.77; p = 0.005). The total amount of glucocorticoid (GC), the average erythrocyte sedimentation rate (ESR) during the three years and anti- cyclic citrullinated peptide antibody (CCP) levels at entry were apparently related to the number of falls after adjusting for fall risk factors among the patients (GC, $\beta = 0.158$; $p = 0.028$; ESR, $\beta = -0.211$, $p = 0.005$; CCP, $\beta = 0.295$, $p < 0.001$). After adjusting for the same risk factors described above and RA, GC medication at entry (OR, 4.412, $p = 0.004$) and prevalence of vertebral fracture (OR, 3.14, p=0.005) were only associated with the incidence of fractures in whole population of this study.

Conclusions: The incidence of falls and fractures did not significantly differ between patients with RA and controls during a period of three years; however, more patients than controls fell repeatedly. Medicating RA with GC was apparently associated with the incidence of fractures and high doses of GC were associated with an increased frequently of falls among patients with RA.

Intermittent PTH (1-34) Administration Enhances Endothelium-Dependent Vasodilation of the Femoral Principal Nutrient Artery in Aged Rats and Alters the Marrow Microenvironment such that Vasodilation is Improved in its Presence. Seungyong Lee*[1], Ashley Bice[2], Brianna Hood[2], Rhonda Prisby[1]. [1]University of Delaware, USA, [2]University of Delaware, USA

BACKGROUND: Age-related declines in bone mass coincide with vascular dysfunction as evidenced by reduced vasodilation of the femoral principal nutrient artery (PNA), the primary conduit for blood flow to long bones (Prisby et al., 2007, Dominguez et al., 2010). In the presence of marrow, vasodilation of the PNA was impaired in young ($p<0.05$) and old (p=0.07) rats (Prisby et al., 2013a), suggesting a detrimental influence of marrow on bone vascular function. Young rats had augmented bone volume and vasodilation of the PNA following 15 days of intermittent parathyroid hormone (PTH) 1-84 administration (Prisby et al., 2013b). Accordingly, we sought to determine the influence of PTH 1-34 on 1) bone volume, 2) vasodilation of the PNA and 3) the marrow microenvironment as a function of age. *METHODS:* Young (4-6 mon) and old (22-24 mon) male Fisher-344 rats were grouped accordingly: 1) young control (CON; n=10), 2) young PTH (n=9), old CON (n=9) and old PTH (n=8). Rats received 43 µg/kg/day of PTH 1-34 or 100 µl/day of PBS for 15 days. Right femoral PNAs were isolated, cannulated and given cumulative doses of acetylcholine (ACh; 10^{-9} – 10^{-4} M) and DEA NONOate (DEA; 10^{-10}-10^{-4} M) in the absence and presence of marrow. Right distal femora (n=4/group) were scanned by µCT to obtain BV/TV (%), Tb.Th (µm), Tb.N (/mm^2) and Tb.Sp (µm). *RESULTS:* Body mass was higher ($p<0.05$) in old vs. young rats and marrow mass was similar among groups (range: 51-73 mg). BV/TV was higher (p=0.053) in young CON ($37\pm2\%$) vs. old CON ($28\pm1\%$), whereby Tb.N was augmented and Tb.Sp reduced. BV/TV was not enhanced with PTH treatment (young PTH; $38\pm2\%$ and old PTH; $29\pm3\%$). Vasodilation of the PNA to ACh was diminished ($p<0.05$) 38% in old rats and, in the presence of marrow, vasodilation was reduced ($p<0.05$) by 44% in young rats. Interestingly, PTH augmented endothelium-dependent vasodilation of the PNA in old rats in the absence (11%; p=0.07) and presence (15%; $p<0.05$) of marrow. In contrast, PTH had no influence on vasodilation or the marrow microenvironment in young rats. Vasodilation to the endothelium-independent factor DEA did not change with age, PTH or marrow exposure. *CONCLUSION:* Age-related declines in endothelium-dependent vasodilation with advanced age may be partially restored with intermittent PTH administration. In addition, intermittent PTH administration alters the marrow microenvironment in aged rats such that vasodilation in its presence is enhanced following treatment.

Teriparatide Treatment for Sacral Insufficiency Fractures. Yuji Kasukawa*[1], Naohisa Miyakoshi[1], Toshihito Ebina[2], Michio Hongo[1], Koji Nozaka[1], Yoshinori Ishikawa[3], Daisuke Kudo[3], Hayato Kinoshita[4], Kentaro Ohuchi[1], Masashi Fujii[3], Chie Sato[3], Yoichi Shimada[3]. [1]Akita University Graduate School of Medicine, Japan, [2]Dept. of Orthopedic Surgery, Kakunodate General Hospital, Japan, [3]Akita University Graduate School of Medicine, Japan, [4]Akita University, Japan

Purpose: Until now, we have treated sacral insufficiency fractures with vitamin D or vitamin K in combination with low-intensity pulsed ultrasound at our institution. However, the clinical outcomes did not translate into sufficient improvement of activities of daily living (ADL). Teriparatide is expected to stimulate bone repair in cases of insufficiency sacral fractures owing to its effect on bone formation. The purpose of this study was to evaluate the effects of teriparatide on clinical outcomes and radiological findings of sacral insufficiency fractures.

Methods: We enrolled seven women (average age: 76 years) with sacral insufficiency fractures who received teriparatide treatment (subcutaneous daily injection in five patients and weekly in two patients) during 3 months or more. We evaluated comorbidities, time elapsed from pain onset to diagnosis, ADL, radiological findings, and visual analog scale (VAS) both pre- and post-treatment.

Results: Six patients had comorbidities, including hypertension, rheumatoid arthritis, liver cirrhosis, diabetes mellitus, muscle dystrophy, and acoustic nerve tumor. Average time elapsed from onset of pain to diagnosis of sacral insufficiency fracture was 17 days (3 to 20 days). Six out of seven patients (86%) could not walk or sit because of severe pain at their first visit to our hospital. Computed tomography (CT) images revealed a fracture on the sacral wing in six patients, and a bone scintigram showed a bilateral H-shaped uptake over the sacral wings in one patient. All patients underwent teriparatide treatment after the diagnosis of sacral insufficiency fractures. Average VAS before treatment (87 mm, 69–100 mm) was significantly reduced after the 3-month teriparatide treatment (19 mm, 0–37 mm) (p=0.007). Five patients could walk after the 3-month treatment, and two patients were able to mobilize by themselves using a wheel chair. Six patients lived in their own homes, and one patient lived in an elderly care home. After the 3-month treatment, three patients presented bone union and four patients presented sclerotic changes (evidenced by CT images) at the fracture site.

Conclusion: We administered teriparatide treatment to seven elderly women with sacral insufficiency fractures within 30 days after the onset of pain. The pain was significantly improved and six patients showed bone union or sclerotic changes at the fracture site by 3 months of teriparatide treatment.

Antiresorptive Therapy – Yes, It is Sometimes 'Too Late'. Roger Zebaze[1], Cherie Chiang[2], Sandra Iuliano-Burns[3], Yohann Bala[4], Afrodite Zendeli[5], Negar Shahmoradi[6], Yu Peng[7], Ali Ghasem-Zadeh[3], Ego Seeman*[3]. [1]Austin Health, University of Melbourne, Australia, [2]Austin Health, Australia, [3]Austin Health, University of Melbourne, Australia, [4]University of Melbourne, Dept. of Medicine, Australia, [5]Endocrine Centre, Austin Health, University of Melbourne, Australia, Australia, [6]Department of Endocrinology, Austin Health, Australia, [7]Straxcorp Pty Ltd, Australia

The aim of treatment of bone fragility is to prevent fractures. However, current antiresorptive therapies reduce non-vertebral fracture (NVF) risk by only 20%. Even in the settings of randomized trials ~ 80% of treated patients sustain NVF despite compliance with therapy. The reason for treatment failure is not fully understood.

Antiresorptive do not restore bone structure, they reduce the size of the reversible remodeling transient. We propose that if structural decay is too advanced (i.e., severe porosity), fragility will remain at its precarious level despite compliance with therapy. Thus, there is porosity value indicative of a structural deterioration so severe that treatment does not reduce fracture risk in people with such deterioration.

To test this hypothesis, we studied 69 postmenopausal women of whom 37 sustained a NVF despite being compliant with therapy; and 32 who remain fracture free with therapy. Patients with fracture, and fracture-free ones were matched by age ((71.2 ± 1.2 vs. 73.6 ±1.64 years; NS) type, and duration of therapy (5.3 ±0.56 vs. 4.7 ± 0.8; NS). Images were collected at the distal radius using HRpQCT and microstructure was quantified using StrAx1.0. The sample was stratified into groups based on the percent porosity of the compact-appearing cortex (CC): Porosity >25% (entire population); >30%; >35%; >40%; 45%; >50%; >55%, and >60%

In groups with porosity below 45%, fracture rate was unchanged and independent of porosity (Fig, right panel). In groups with porosity >45%, fracture rate increased exponentially with increasing porosity (R^2=0.97; $p<0.0001$) and was 1.6 fold higher than that observed in those with porosity <45% (66.7 vs 41.6%; p=0.05). The OR for fracture according to groups followed the pattern, increasingly exponentially to reach 2.8 in patients with porosity>45% (fig Left panel) (OR similar to that observed in a similar population of untreated women[1]). About half (47.2%) of women treated with antiresorptives had a porosity >45%.

We infer that there is a level of structural deterioration (porosity >45%) above which antiresorptive therapy is ineffective. Whether or not anabolic therapy would be efficacious in such circumstances is unclear. Nevertheless, this calls into question the use of antiresorptives as first line therapy in all patients.

SA0385

Brand-Name vs. Generic Oral Bisphosphonate Medications: Prescribing Patterns and Variations over Eleven Years. Lisa-Ann Fraser*[1], Jordan Albaum[2], Mina Tadrous[3], Andrea Burden[3], Salimah Shariff[4], Suzanne Cadarette[3]. [1]Western University, Canada, [2]University of Toronto, Canada, [3]University of Toronto, Canada, [4]University of Western University, Canada

Purpose: Alendronate and risedronate have proven fracture reduction efficacy and are considered first-line osteoporosis therapies. In Ontario Canada these medications are covered for those aged 65 and older by the Ontario Drug Benefit (ODB) plan. ODB has a generic substitution policy resulting in dispensing of generic versions of drugs when available. However, there is controversy as to the efficacy and safety of generic bisphosphonates. We studied oral bisphosphonates dispensed province-wide by ODB over 11 years with the aim of describing prescribing patterns in relation to brand-name vs. generic medications.

Methods: We identified all prescriptions for alendronate and risedronate dispensed through ODB from April 2001 to December 2012. Individuals who used these medications prior to 2001 were excluded, as were bisphosphonate doses used to treat conditions other than osteoporosis. Patients who reside in long-term care (LTC) are clearly identified in ODB, and therefore we divided our sample into community-dwelling vs. LTC users. The number of prescriptions dispensed per month were plotted, separately for community and LTC patients, in order to identify trends over time.

Results: We found a rapid switch from brand-name to generic bisphosphonate equivalents immediately after the generic was available, with >88% of drug dispensed being the generic version by 2 months after the release of the generic in all cases. Despite the generic substitution policy of ODB, a small population of patients remained on brand-name drug over time. There was a reduction in the number of generic drugs dispensed when new brand-name alternatives were introduced: there was a decrease in generic alendronate when Fosavance (alendronate plus vitamin D3) became available. Similarly, there was a decrease in generic weekly risedronate when monthly Actonel became available, and again when Actonel DR came out. The dispensing trends were similar in the community and in LTC.

Conclusions: The ODB generic substitution policy has resulted in rapid up-take of generic oral bisphosphonates in seniors in Ontario. However, there seems to be a preference for name-brand bisphosphonates as evidence by a drop in generics dispensed each time a new proprietary drug becomes available. Similarly, there is a small population of patients who remain on a name-brand bisphosphonate over time despite the availability of a generic equivalent.

Dynamic analysis of short-term effects of bisphosphonates by using intravital two-photon microscopy. Junichi Kikuta*[1], Mai Shirazaki[2], Masaru Ishii[3]. [1]Graduate School of Medicine, Osaka University, Japan, [2]Graduate School of Medicine, Osaka University, Japan, [3]Graduate School of Medicine & Frontier Biosciences, Osaka University, Japan

Background/Purpose: Bisphosphonates have been clinically used for treatment of bone disorders such as osteoporosis. There have been many studies about the pharmacological properties of bisphosphonates, but most of them were analyzed by conventional methods such as micro-CT and histological analysis. These methods do not enable us to observe living mature osteoclasts. Thus, how bisphosphonates affect osteoclast dynamics *in vivo* remains elusive. This study aimed to investigate the short-term effects of bisphosphonates on the function of mature osteoclasts in living bone tissues by using intravital two-photon microscopy.

Methods: For visualizing mature osteoclasts, we utilized the mice expressing GFP under the promoter of a vacuolar type H^+-ATPase a3 subunit that were abundantly expressed in differentiated osteoclasts (a3-GFP mice). We observed calvaria bone tissues of a3-GFP mice by using an advanced imaging system for visualizing living bone tissues with intravital two-photon microscopy that we have originally established. For examining the short-term effects of bisphosphonates, risedronate (10 μg/kg), alendronate (20 μg/kg), or minodronate (4 μg/kg), was administered intravenously during imaging, and images were acquired consecutively.

Results: In control condition, we identified different populations of living mature osteoclasts in terms of their motility and function, i.e., 'static – bone resorptive (R)' and 'moving – non resorptive (N)'. Less than 1 hour after intravenous injection of risedronate, we found that many static osteoclasts changed their shapes and became moving cells, suggesting R to N functional switching without any change in the total number of mature osteoclasts. We also found that some osteoclasts had morphological signs suggestive of osteoclast apoptosis within several hours after risedronate administration. Furthermore, we could demonstrate that treatment of alendronate or minodronate also induced R to N conversion of mature osteoclasts on the bone surface.

Conclusion: By visualizing *in vivo* behaviors of mature osteoclasts, we found that bisphosphonates could change osteoclast morphology and inhibit bone resorption in living bone tissues within a short period.

Lack of Clinically Important Gender Differences in the Pharmacokinetics and Exposure-Response Relationship of Odanacatib. Julie Stone*[1], David Jaworowicz[2], Stefan Zajic[1], Rebecca Humphrey[3], Arthur Santora[4], Aubrey Stoch[5]. [1]Merck Research Laboratories, USA, [2]Cognigen Corporation, USA, [3]Cognigen Corporation, USA, [4]Merck & Co. Inc., USA, [5]Merck & Co., Inc., USA

Odanacatib is a selective cathepsin K inhibitor in development for the treatment of osteoporosis. A model-based analysis of pooled data from Phase 1, 2, and 3 clinical studies was undertaken to characterize the influence of gender on odanacatib exposures and the exposure-response relationship for the resorption biomarker uNTx/Cr, and for effects on lumbar spine bone mineral density (lsBMD).

A male population pharmacokinetic (PK) model was developed from pooled data from two Phase 1 studies, one Phase 2b study, and one Phase 3 study (918 plasma odanacatib concentrations from 180 men) and compared to a historical female PK model (Ref 1). The PK/PD dataset consisted of 1508 u-NTx/Cr values and 1269 lsBMD values from 283 men (n=126 receiving placebo) and 4999 u-NTx/Cr values and 4744 lsBMD values from 657 postmenopausal women from two Phase 2 studies. A semi-mechanistic PK/PD bone turnover model previously developed based on data from postmenopausal women was applied to the pooled male/female dataset (Ref 1). This model related odanacatib exposures to drug effects on resorption and osteoclast pharmacology to describe both uNTx/Cr and BMD longitudinal response data as a function of underlying formation and resorption rates and drug effects. The potential for gender differences in model parameters was tested using alpha 0.001 to account for the multiple evaluations applied.

The PK of odanacatib in men can be described by a one compartment model with first order absorption, dose dependent bioavailability, and linear elimination (apparent clearance of 0.976 L/hr, volume 116 L). The PK model parameter estimates in men were similar to those previously obtained in postmenopausal women with osteoporosis. Clearance in men with low testosterone levels (<250 ng/dL, n=8) was decreased 47% (95% CI 36-58%) relative to that in men with normal levels.

There were no statistically significant differences in the PK/PD relationship for anti-resorptive effects and effects on osteoclast pharmacology between men and women. Gender effects were identified on the bone formation rate component which is applied to both active and placebo subjects to reflect transient response to calcium and Vitamin D supplementation. This finding may reflect differences in diet or supplement usage by gender prior to study entry. No gender differences in endogenous bone resorption and formation rates were identified in the model suggesting that the underlying biology of turnover was not meaningfully different between male and female patients with similar disease severity.

In these analyses, no clinically important gender differences in the pharmacokinetics or exposure-response relationship of odanacatib were identified. These results support the evaluation of the same 50 mg odanacatib once-weekly dosing regimen in men and women for treatment of osteoporosis.Ref 1: Zajic et al. Mechanically improved femoral bone strength by risedronate in postmenopausal women with breast cancer taking aromatase inhibitors : 2-year-longitudinal data. Su Jin Lee*[1], JO EUN Kim[2], Sung-Kil Lim[2], Yumie Rhee[3]. [1]Yonsei University Health System, South Korea, [2]Yonsei University College of Medicine, South Korea, [3]Department of Internal Medicine, College of Medicine, Yonsei University, South Korea

Objective: Risedronate has been proven to prevent aromatase inhibitor-induced bone loss (AIBL) assessed by 2D dual X-ray absorptiometry. We hypothesized that bisphosphonate treatment would also have benefit in the longitudinal changes in volumetric bone mineral density (vBMD) and geometric parameters in postmenopausal women with breast cancer taking aromatase inhibitors. We used quantitative computed tomography (QCT).

Methods: We retrospectively analyzed endocrine-responsive breast cancer patients who had undergone QCT measurement twice over 2 years and used propensity score analysis for matching age between two groups. All patients had been taking AIs and calcium carbonate 1250 mg plus 1000 IU as cholecalciferol. Among these patients, we classified them into two groups according to risedronate administration; calcium and vitamin D only administered group as the control (n=24), and risedronate-treated group as the RIS (n=26). The bone mineral density and cortical geometry parameters of neck, trochanter, intertrochanter, and total hip of the proximal femur were analyzed.

Results: Average age of all patients was 58.1 ± 4.7 years. Average of duration of risedronate was 633 days. CT data were obtained at baseline and follow-up scans were performed at almost 2 years. Risedronate blunted the decrease in vBMD and buckling ratio. Mean 2-year percent change from baseline in total vBMD was -0.98% (vs. -5.9% in control, p=0.022), +1.47% (vs. -2.3% in control, p=0.015), +0.1% (vs. -1.9% in control, p=0.202) and +0.77% (vs. -2.8% in control, p=0.016) in RIS group at the femoral neck, trochanter, intertrochanter, and total hip, respectively. We also found that risedronate treatment to breast cancer patients taking AIs significantly increased cortical thickness of total hip +0.3% (vs. –8.1% in control group, p=0.007) and decreased cortical buckling ratio compared to the patients taking AI only without risedronate at neck, trochanter and total hip. (Figure 1.)

Conclusion: This study shows preventive effects of oral risedronate on bone geometry as well as volumetric bone mineral density at the proximal femur by using QCT in postmenopausal women with endocrine responsive breast cancer taking AIs which can deteriorate the bone quality.

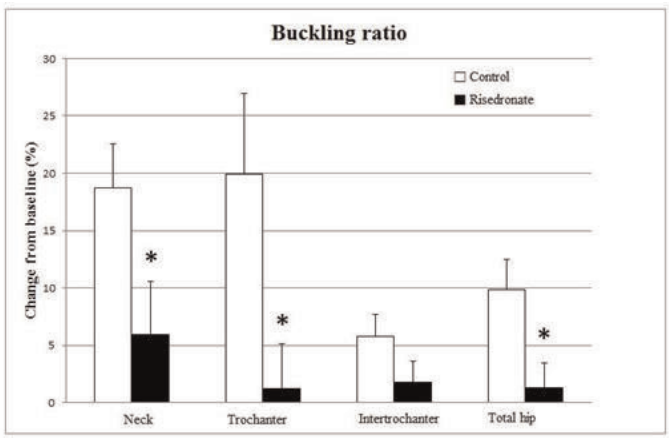

Figure 1. Percenta change from baseline of buckling ratio

Response in Subgroups based on Baseline 25-Hydroxyvitamin D and Bone Turnover Markers: Alendronate Sodium/Vitamin D_3 versus Calcitriol for Treatment of Osteoporosis in Chinese Women. Zhen Lin Zhang*[1], Er Yuan Liao[2], Weibo Xia[3], Hua Lin[4], Qun Cheng[5], Li Wang[6], Yong Qiang Hao[7], De Cai Chen[8], Hai Tang[9], Yong De Peng[10], Li You[10], Liang He[11], Zhao Heng Hu[12], Chun Li Song[13], Fang Wei[14], Jue Wang[14], Lei Zhang[14], Arthur Santora[15]. [1]Shanghai Sixth People's Hospital, Shanghai Jiaotong University School of Medicine, China, [2]The Second Xiangya Hospital, Central South University, China, [3]Peking Union Medical College HospitalDepartment of Endocrinology, Chn, [4]Peking Union Medical College Hospital, China, [5]Huadong Hospital Affiliated to Fudan University, China, [6]TianJin Hospital, China, [7]Shanghai Ninth People's Hospital, China, [8]West China Hospital, West China School of Medicine, Sichuan University, China, [9]Beijing Friendship Hospital, Capital Medical University, China, [10]Shanghai First People's Hospital, China, [11]Beijing Jishuitan Hospital, China, [12]Peking University People's Hospital, China, [13]Peking University Third Hospital, China, [14]MSD China, China, [15]Merck & Co. Inc., USA

Purpose: Postmenopausal osteoporosis co-morbid with vitamin D insufficiency is a health concern in China. A previous 6-month, randomized, open-label study (plus 6-month extension) demonstrated superior efficacy of alendronate 70mg/vitamin D_3 5600 IU weekly (ALN/D5600) vs calcitriol 0.25μg daily on BMD and 25-hydroxyvitamin D [25(OH)D] increases and bone turnover marker (BTM) decreases in Chinese osteoporotic women. Our aim was to further investigate the relationship between BMD increases and baseline 25(OH)D and BTM and thus identify subgroup(s) with greater BMD increases during ALN/D5600 treatment.

Methods: In the original study, 219 women were randomized to ALN/D5600 weekly (n=111) or calcitriol 0.25μg daily (n=108) for 12 months. BMD, BTM (s-CTX/P1NP) and 25(OH)D were measured at baseline, Month 6 and 12. A post-hoc analysis was performed to assess BMD percent changes at month 12 in the ALN/D5600 group based on baseline 25(OH)D (tertiles) and BTM (median). Longitudinal data analysis was applied to model the correlation among repeated measurements. Analyses were based on the FAS with no missing data imputation. In addition, the relationship between baseline and Month 12 25(OH)D was further explored.

Results: In the ALN/D5600 group, baseline 25(OH)D tertile cut-offs were 16ng/mL and 23ng/mL. At month 12, the lumbar spine (LS) BMD percent changes were 5.34±0.69% in the 1st tertile, (n=29), 5.00±0.62% in the 2nd tertile (n=36), and 4.49±0.65% in 3rd tertile (n=32). Baseline median P1NP and s-CTx were 47.1μg/L and 533ng/L. The LS BMD changes were 5.79±0.52% above P1NP median (n=48) and 4.09±0.51% below median (n=49); and 5.18±0.54% above s-CTx median (n=47) and 4.70±0.52% below median (n=50). Post-hoc repeated measures in BMD percent changes suggested a statistical non-significance for all comparisons ($p>0.05$) between baseline 25(OH)D tertiles by ALN/D5600 treatment at the LS, femoral neck and total hip. However, significant differences in BMD percent change in subgroups between P1NP above and below median were seen at the LS (1.70±0.7%, 95%CI: 0.26, 3.15, p=0.02) and total hip (2.69±0.68%, 95%CI: 1.35, 4.03, p=0.0001). At Month 12, women in 2nd and 3rd baseline 25(OH)D tertiles had significantly higher 25(OH)D levels (mean>30ng/mL, $p<0.05$) vs. 1st tertile.

Conclusions: A 12-month ALN/D5600 treatment, increased BMD more in osteoporotic women with higher baseline BTMs and increased 25(OH)D more in women with vitamin D insufficiency at baseline.

SA0393

Risk factor for the Non-Responder of Bisphosphonates and Active Vitamin D Analog for the Treatment of Osteoporosis. Mayuko Kinoshita*[1], Muneaki Ishijima[2], Yuko Sakamoto[3], Hidetoshi Nojiri[4], Liu Liz[5], Haruka Kaneko[6], Ryo Sadatsuki[1], Shinnosuke Hada[1], Kazuo Kaneko[1]. [1]Department of Orthopaedics & Motor Organ, Juntendo University Graduate School of Medicine, Tokyo, JAPAN, Japan, [2]Juntendo University Graduate School of Medicine, Japan, [3]Department of Orthopaedics, Juntendo Nerima Hospital, Tokyo, JAPAN, Japan, [4]Juntendo University, School of Medicine, Japan, [5]University Graduate School of Medicine, Tokyo, JAPAN, Japan, [6]Department of Orthopaedics & Motor Organ, Juntendo University Graduate School of Medicine, Tokyo, JAPA, Japan

It has been revealed that vitamin D insufficiency is common in the community, especially for patients with osteoporosis. We have revealed that vitamin D insufficiency impaired the increase in lumber spine bone mineral density (LS-BMD) by bisphosphonates (BPs) without active vitamin D analogs for the patients with osteoporosis (CTI 2009). Combination with BPs and active vitamin D analog for osteoporosis treatment haa become widespread in Japan. We speculated that a ''non-responder'' for this combination therapy may exist in patients with osteoporosis. The aim of this retrospective study was to find out the factors related to the ''non-responder'' in this combination therapy. This study was approved by the institutional ethical review committee. During 2002 to 2012, 261 patients with osteoporosis were started to use BPs. As the 168 were excluded, the remaining 93 female patients were included in the study. BPs used in the study were alendronate, risedronate or minodronate. Active vitamin D analogs used were alfacalcidol and eldecalcidol. Multiple regression analysis was used to find the risk factors at first visit those affect %LS-BMD. A p value < 0.05 was considered to be statistically significant. LS-BMD of the patients was significantly increased by the combination therapy ($p<0.001$, 5.4% in average). Serum levels of iPTH were significantly decreased by the treatment ($p<0.002$), while serum levels of calcium were significantly increased by the treatment ($p<0.001$). When the patients were divided into four groups in terms of the %LS-BMD (Q1; -1.74%, Q2; 1.64%, Q3; 3.28%, Q4; 10.86%), no significant differences of the baseline characteristics of the patients were observed [e.g.; age, BMI, LS-BMD, sCa (adjusted), sPi, s25(OH)D, iPTH]. Multiple regression analysis revealed that the factor that affects the %LS-BMD was serum levels of calcium (sCa) at first visit ($r^2=0.234$, $p=0.003$). When sCa (reference range; 8.8 to 10.5 mg/ml) were 8.8-9.0 mg/ml, odds ratio for the decrease in %LS-BMD by the combination therapy for two years was 4.0 (95%CI: 1.41 to 11.38). In conclusion, when the osteoporotic patients were treated by the combination therapy for two years, the lower quarter of the patients with osteoporosis could be a ''non-responder'' (%LS-BMD; -1.74%). Lower serum levels of calcium at baseline, even in the reference range, is a risk factor for the ''non-responder'' for the treatment by the combination with BPs and active vitamin D analog.

Sustained P1NP suppression with monthtly 150 mg risedronate treatment of postmenopausal women with low bone mass during 1 year treatment. Gregorio Riera-Espinoza*[1], Yamila Cordero[2], Sandra Mendoza[3], Yuneci Gonzalez[3], Jeny Ramos[3]. [1]Unidad Metabolica. CEAM, Venezuela, [2]Unidad Metabolica., Venezuela, [3]Unidad Metabolica, Venezuela

Objective. It is to evaluate response of risedronate 150 mg once-a-month on P1NP, a highly specific marker of bone formation and its correlation with another high specific marker of bone resorption, C telopeptide after 1 year treatment in women with low bone mass. This two measurements has been suggested by IOF and IFCC as a reliable, specific and reproductible bone markers

Material and Methods. N-terminal propeptide of procollagen type I (P1NP) and serum Beta-CrossLaps (CTx) were evaluated in 80 postmenopausic Venezuelan women with low bone mass (T-score below -1.5) either at lumbar spine(LS) or femoral neck(FN) (Lunar Prodigy Advance, CV 1.5%). P1NP and CTx were measured on fully automated Cobas e411 (Electro-chemiluminescent immunoassay analyzer).

Results. Age was 59.8 ± 8.3, age of menopause 46.8 ± 6.3, 26% had received HRT for a mean of 2.99 years. BMD increased at lumbar spine 3.58% and 3.45% at femoral neck . P1NP reduction was: 46.3% and 54.3% at 3 and 12 months. Serum P1NP decreased more than 10% in 94.7% and 95.8% of patients at 3 and 12 months respectively

Conclusion. Risedronate 150 mg once-a-month suppressed bone remodeling into normal premenopausal reference range measured by 46.3% reduction on P1NP at 3 months and 54.3% at 12 months. CTx decreased 48% and 42% at 3 and 12 months respectively. Serum P1NP decreased more than 10% in 94.7% and 95.8% of patients at 3 and 12 months respectively . BMD increases 3.58% at lumbar spine and 3.45% at femoral neck. Our data support the use of changes in P1NP as a good indicator of effectiveness during, early 3 months or sustained 12 months, treatment of postmenopausal women with low bone mass with risedronate 150mg once-a-month

The Effect of Monthly i.v. Ibandronate Injections on Japanese Patients with High-Risk Primary Osteoporosis: Subgroup Analysis of the Phase III MOVER Study. Hiroshi Hagino*[1], Toshitaka Nakamura[2], Masako Ito[3], Tetsuo Nakano[4], Junko Hashimoto[5], Masato Tobinai[6], Hideki Mizunuma[7]. [1]Tottori University, Japan, [2]National Center for Global Health & Medicine, Japan, [3]Nagasaki University Hospital, Japan, [4]Tamana Central Hospital, Japan, [5]Chugai Pharmaceutical Corporation Limited, Japan, [6]Chugai Pharmaceutical Co. Ltd., Japan, [7]Hirosaki University, Japan

Purpose: The MOVER study compared the efficacy and safety of monthly i.v. ibandronate (IBN) with oral risedronate (RIS) in patients (pts) with primary osteoporosis. The aim was to show non-inferiority of IBN vs RIS in the incidence of non-traumatic vertebral fractures over 3 yrs. We present 3-yr subgroup data on the incidence of new/worsening vertebral fractures in pts with prevalent vertebral fractures (1 or >1, and ⩾3) and femoral neck (FN) bone mineral density (BMD) T-scores ⩾–2.5 or <–2.5, and <–3.0 at baseline.

Methods: MOVER was a randomized, double-blind study in ambulatory pts aged ⩾60 yrs with fragile bone fracture, BMD of the lumbar spine L2–L4 or proximal femur (hip and FN) <80% of the young adult mean (T-score: –1.7, –1.6, and –1.4), and 1–5 vertebral fractures in the thoracic and lumbar spine. 1265 pts were randomized to receive i.v. IBN 0.5 or 1mg/month + oral daily placebo, or oral RIS 2.5mg/day (licensed Japanese dose) + monthly i.v. placebo.

Results: The per-protocol set comprised 1134 pts (IBN 0.5mg n=376; IBN 1mg n=382; RIS n=376). Baseline characteristics were balanced. Over 3 yrs, cumulative incidences of new/worsening vertebral fractures were 19.9% (95% CI 15.6–24.1) for IBN 0.5mg, 16.1% (95% CI 12.2–19.9) for IBN 1mg, and 17.6% (95% CI 13.6–21.6) for RIS. Both IBN doses were non-inferior to RIS (non-inferiority limit 1.55): 0.5mg, hazard ratio (HR) 1.09 (95% CI 0.77–1.54); 1mg, HR 0.88 (95% CI 0.61–1.27). The incidence of new/worsening vertebral fractures in any subgroup was lower with IBN 1mg than with RIS over 3 yrs. The fracture incidence in pts with 1 or >1 prevalent vertebral fractures was 11.2% and 20.4%, respectively, in the IBN 1mg group and 12.6% and 22.1%, respectively, in the RIS group. The fracture incidence in pts with FN BMD T-score ⩾–2.5 or <–2.5 was 13.7% and 16.4% in the IBN 1mg group, and 15.0% and 19.1% in the RIS group. The fracture incidence in pts with ⩾3 prevalent vertebral fractures or FN BMD T-score <–3.0 at baseline was 25.2% and 21.4% with IBN 1mg, and 31.3% and 22.2% with RIS. The fracture incidence in high risk pts was consistently lower with IBN 1mg than with RIS.Conclusions: Monthly i.v. IBN is non-inferior to oral RIS in reducing the incidence of vertebral fractures in Japanese pts with osteoporosis. IBN 1mg showed a lower numerical incidence of fractures than RIS; subgroup analyses were consistent with these findings. Monthly i.v. IBN appears to be most beneficial in pts with high fracture risk.

Effective secondary fracture prevention: a global quality exercise. Muhammad Javaid*[1], Carey Kyer[2], Charlotte Moss[3], Paul Mitchell[4], Dominique Pierroz[5], Judy Stenmark[2], Kristina Akesson[6], Cyrus Cooper[7], and the IOF Fracture Working Group[8]. [1]University of Oxford, United Kingdom, [2]IOF, Switzerland, [3]MRC Lifecourse Epidemiology Unit, United Kingdom, [4]Synthesis Medical, New Zealand, [5]International Osteoporosis Foundation, Switzerland, [6]Skåne University Hospital, Malmö, Sweden, [7]University of Southampton, United Kingdom, [8]International Osteoporosis Foundation, Switzerland

Despite robust evidence for the effectiveness of secondary fracture prevention using a range of pharmaceutical agents, translation in the real world setting remains disappointing. One key aspect is whether the adopted the service delivery model will deliver effective case finding, assessment, treatment initiation and adherence at the population level. To support local initiatives across the globe, the International Osteoporosis Foundation developed Best Practice Framework standards providing a quality benchmark. We now report findings after the first 12 months of implementation.

30 hospitals across 5 continents submitted their questionnaires. The hospitals served populations from 100,000 to 1.3 million and were a mix of private and publicly funded. Fourteen services were led by orthopedics/ trauma, 8 by rheumatology, 4 by endocrinology and one by each of gynecology, geriatrics, radiology and rehabilitation. Each hospital managed 181 to 2530 fragility fracture patients per year with a total of 26,214 patients across all sites. Overall, 16 hospitals scored gold, 8 silver and 4 bronze. The pathway for the hip fracture patients had the highest proportion of gold grading, with vertebral fracture the lowest (figure).

In the first 12 months, we have successfully tested the implementation of the tool in a range of health settings across the globe. Initial findings confirm a significant heterogeneity in service provision and highlight the importance of a global approach to ensure high quality secondary fracture prevention services.

Factors Associated with Sub-optimal Adherence to Bisphosphonate Therapy among Patients with Postmenopausal Osteoporosis. Maral DerSarkissian[1], Cynthia O'Malley*[2], Irene Ferreira[3], Stuart Silverman[4], Deborah Gold[5], Rachel Wagman[6], Andreas Grauer[7]. [1]Amgen Incorporated, USA, [2]Amgen, Inc, USA, [3]Amgen Limited, United Kingdom, [4]Cedars-Sinai/UCLA, USA, [5]Duke University Medical Center, USA, [6]Amgen, Incorporated, USA, [7]Amgen Inc., USA

Introduction: Patients are often sub-optimally adherent with bisphosphonates (BPs), which may result in diminished treatment effectiveness and increased risk of fracture. To explore why patients fail to adhere to prescribed therapies, we used patient-reported data to assess patient characteristics and beliefs associated with sub-optimal adherence to BP therapy.

Methods: We used a convenience sample of women aged ⩾ 55 with postmenopausal osteoporosis screened for 2 clinical trials in Europe, Australia, and North America from 2009-2010 who were still on daily or weekly oral BPs at the time of screening. Patients were classified as adherent if they scored 6 or greater on the Osteoporosis Specific-Morisky Medication Adherence Scale (OS-MMAS) or sub-optimally adherent if they scored less than 6. Self-reported baseline demographics, medical history, clinical characteristics, health behaviors, and patient reported outcomes were evaluated as predictors of sub-optimal adherence. Multivariable logistic regression was used to derive odds ratios (OR) and 95% confidence intervals (CI) to assess the association of factors on sub-optimal adherence.

Results: Of the 377 women included in our analysis, 93 (24.7%) were classified as adherent and 284 (75.3%) were classified as sub-optimally adherent. North American women were 3 times more likely to be sub-optimally adherent compared to women from Europe and Australia (OR = 3.00, 95% CI: 1.43, 6.32). Compared with women aged ⩾ 75, women between the ages of 55-64 (OR=0.63 95% CI: 0.31-1.28) and 65-74 (OR=0.39 95% CI: 0.17-0.89) had lower odds of sub-optimal adherence. Beliefs about both the ability to take medication appropriately and the convenience of medication were also significantly associated with decreased odds of sub-optimal adherence. The odds of sub-optimal adherence increased with increasing number of reported comorbidities, but decreased with greater consumption of alcohol compared to no daily consumption of alcohol.

Conclusion: Our results suggest there are significant differences in self-reported adherence to oral BPs by geographic region. In addition, addressing women's beliefs about their ability to use medications appropriately and their perceived convenience of medication use may help improve adherence as these factors were significant predictors of adherence.

More Than 90% Two Year Adherence to 6-MonthlyDenosumab Injections in Patients with Different Forms of Osteoporosis. Johann Ringe*[1], Parvis Farahmand[2]. [1]Klinikum Leverkusen, University of Cologne, Germany, [2]West German Osteoporosis Center (WOC), Klinikum Leverkusen, University of Cologne, Germany

Introduction:

Bisphosphonate treatment in osteoporosis is discontinued in almost 50% of patients within the first year after starting application. Denosumab's longer dosing interval with its administration every 6 months as an s.c. injection might result in a better real life treatment adherence than weekly or monthly oral bisphosphonate treatment regimens.

Methods:

In an open investigator-initiated prospective observational study in routine clinical practice we investigated whether a careful medical explanation of treatment results every 6 months after the respective denosumab injections focussing on no or only mild and probably not drug related AE as well as on improvements of back pain and significant BMD increases have positive effects on patients' drug perception and its related future adherence to subsequent denosumab injections. We included 142 patients (69 with postmenopausal, 41 with male, and 32 with glucocorticoid-induced osteoporosis).

Results:

In the first year patients reported only 11 AEs (=7.6%) in the second year 9 AEs (=6.7%). All AEs were mild to moderate, disappeared without intervention and were obviously not drug related. Patients were very impressed by demonstrating them the original DXA-protocols every six months. After two years there were average increases of 9-11% at the lumbar spine and 5-6% at the total hip for the 3 groups. In parallel we found a significant decrease in back pain in the majority of patients and an average rate of new vertebral plus non-vert. fractures per patient year below 0.1. All together this resulted in a very low number of drop outs. At month 24 still 135 of the initially 142 patients accepted a fifth injection of denosumab, which is 95%.

Conclusion:

Results indicate that the reduced dosage frequency together with the rarity of adverse events as well as a consistency of rapid and highly significant increases in BMD during therapy used as a positive reinforcement during doctor-patient interactions had a significant, positive impact on osteoporotic patient's adherence to continue with the 6-monthly s.c. denosumab injections.Key words: osteoporosis, denosumab, treatment adherence, positive feedback

National Bone Health Alliance: A Multi-SectorPublic-Private Partnership Working Together to Improve America's Bone Health. Debbie Zeldow[1], David Lee*[2]. [1]National Bone Health Alliance, USA, [2]NBHA, USA

The National Bone Health Alliance (www.nbha.org) is a public-private partnership launched in late 2010 that brings together the expertise and resources of its members to collectively promote bone health and prevent disease; improve diagnosis and treatment of bone disease; and enhance bone research, surveillance and evaluation.

NBHA currently includes 56 participating organizations (35 non-profit member organizations, 17 member companies and liaisons representing CDC, FDA, NASA and NIH).

The concept for NBHA stems from the 2004 Bone Health and Osteoporosis: A Report of the Surgeon General and the June 2008 Summit for a National Action Plan for Bone Health.

NBHA's "20/20 vision" is to reduce the incidence of hip and other bone breaks 20% by the year 2020.

NBHA provides a platform for its collective voice to weigh in on subjects important to bone health, particularly vitamin D, calcium, bone mineral density reimbursement and utilization and the risks and benefits of the use of bone health therapies; communication among organizations interested in bone health; shared priorities to become reality through pooled funding; and working together towards the goals and recommendations of the National Action Plan.

Activities for 2014 include:

Fracture Prevention CENTRAL (www.FracturePreventionCENTRAL.org) provides tools to health professionals, health insurers, hospitals and other sites interested in implementing this model of care.

NBHA Clinical Diagnosis of Osteoporosis Working Group position paper recently published online by *Osteoporosis International*.

Bone Turnover Marker Standardization Project: NBHA is leading the effort to standardize U.S. bone marker sample collection procedures, establish a U.S. reference range for one bone formation and one bone resorption marker and standardize bone turnover marker assays.

FLS Demonstration Study: The Bone Health Collaborative has launched a cloud-based study that will provides study sites with the FLS model of care and a cloud-based platform, to assess adoption and implementation of a fracture liaison service.

2Million2Many Public and Health Professional Awareness Campaign is educates about the 2 million bone breaks in the U.S. each year that are not accidents but signs of osteoporosis.

Real-World Evidence on Treatment Initiation and Discontinuation in Canadian Osteoporotic Patients. Marie-Claude Meilleur*[1], Martin Cloutier[2], Jimmy Royer[3], Arun Krishna[4]. [1]Merck Canada Inc., Canada, [2]Analysis Group Inc., Canada, [3]Analysis Group Inc. & Université de Sherbrooke, Canada, [4]Merck, USA

OBJECTIVES: Patients with osteoporosis (OP) have several treatment options for the prevention of fragility fractures and treatment of OP. This study aims to assess rates of treatment initiation with antiresorptive agents (AAs) among Canadian patients with OP and a fragility fracture, and to assess discontinuation rates in patients treated with AAs.

METHODS: Patients ⩾50 years of age with an OP-related event, defined as either a diagnosis for OP, a diagnosis for a fragility fracture, or a prescription fill for an AA were identified in Quebec's healthcare database, Régie de l'assurance maladie du Québec (RAMQ) between 06/2005 and 06/2013. Patients with a diagnosis for Paget's disease or a neoplasm were excluded. The index date was defined as a patient's first OP-related event date for the treatment initiation analysis and as a patient's first prescription fill date for an AA for the treatment discontinuation analysis. Patients were observed from their index date until the end of their continuous RAMQ healthcare plan enrollment or end of data availability (observation period). A treatment discontinuation was defined as a gap of ⩾60 consecutive days between the last day of supply of the first AA initiated and the next prescription for this AA or the end of the observation period. Treatment initiation and discontinuation rates were measured using Kaplan Meier (KM) survival analyses. Patients were censored at the end of their observation period.

RESULTS: A total of 86,435 patients met the sample selection criteria. The sample was composed of 80.3% of females and 64.8% of patients ⩾ 65 years old. Patients were observed for a median period of 4.7 years following their first OP-related event. Over the observation period, 45.2% of the patients initiated an AA. Among the 23,260 patients with a fragility fracture as their first OP-related event, 23.6% initiated an AA over their observation period; treatment initiation rates were 7.9% at 3 months and 13.5% at 12 months. Among the 37,291 patients who initiated an AA, a majority of patients had a treatment discontinuation (60-month KM rate: 66.4%) over their observation period; 15.5% of patients discontinued their treatment during the first month and 39.8% during the first 12 months following a treatment initiation.

CONCLUSIONS: Following a fragility fracture, less than 1 in 4 patients initiated an AA and about 2 in 5 patients who initiated an AA discontinued treatment within the first 12 months.

Effects of combination therapy of zoledronic acid plus teriparatide [rhPTH(1–34)] for fracture healing in mice. Tsuyoshi Sugiura*[1], Masafumi Kashii[2], Kazuma Kitaguchi[3], Masayuki Furuya[4], Tokimitsu Morimoto[4], Yohei Matsuo[5], Takahiro Makino[4], Kousuke Ebina[3], Takashi Kaito[4], Motoki Iwasaki[4], Hideki Yoshikawa[6]. [1]Faculty of Medicine, Graduate School of Medicine, Osaka University, Japan, [2]Osaka University Graduate School of Medicine, Japan, [3] Faculty of Medicine, Graduate School of Medicine, Osaka University, Japan, [4]Faculty of Medicine, Graduate School of Medicine, Osaka University, Japan, [5], Japan, [6]Osaka University Graduate School of Medicine, Japan

Introduction: Intermittent administration of teriparatide (TPTD) has a potent stimulatory effect on bone remodeling, and stimulates fracture healing. Clinical data suggest combination therapy with bisphosphonates and TPTD blunt the anabolic effect of TPTD, but animal models suggest that infrequently administered bisphosphonates interact differently. Recent clinical study also reported that the combination therapy of TPTD and zoledronic acid (ZOL) provided an additive effect on BMD of either spine or hip compared with ZOL or TPTD monotherapy. However, the effect of this combination therapy on fracture healing is unknown. The purpose of this study is to elucidate the individual and combined effects of TPTD and ZOL on fracture healing in mice fracture model.

Materials and Methods: Left femur was fractured and stabilized using intramedullary nail in eight-weeks-old female C57BL/6N mice. They were assigned to 4 different groups to receive 0.9% saline (0.1ml, five times per week, subcutaneous injection, Control group: n=5), ZOL alone (50 μg/kg single subcutaneous injection just after fracture, ZOL group: n=5), TPTD alone (40 μg/kg/day, 5 times per week, subcutaneous injection for 4 weeks, TPTD group: n=5), or ZOL plus TPTD (ZOL+TPTD group: n=5). Time-course microstructural analysis of fractured femur was performed using in vivo micro-CT at 0, 2, 3 and 4 weeks after fracture. Mice were euthanized 4 weeks after fracture. Volumetric BMD (vBMD) measurement of lumber spine (L4) was performed using micro-CT, and histological examination of fractured femur and lumber spine and biochemical examination including bone turnover markers were performed.

Results: Callus volume increased and reached its peak at 2 weeks after fracture in TPTD group and at 3weeks in the other three groups. Compared with TPTD or ZOL group, BV/TV and TbTh tended to be greater and TbSp tended to be smaller in ZOL+TPTD group at 4 weeks after fracture, but there were no statistical significant differences. Bony union rate increased over time, and reached to 100% in Control and TPTD group and to 80% in ZOL and ZOL+TPTD group at 3weeks after fracture. L4 vBMD was significantly greater in ZOL+ TPTD group than in other three groups (+13.7% vs Control, +4.5% vs ZOL, +18.6% vs TPTD)

Conclusion: Combined treatment of TPTD and ZOL had additive effects on BMD of lumbar spine as previously reported, but there were not obvious effects in fracture healing of mice compared with individual treatment.

The effect of teriparatide against pain and vertebral collapse after fresh osteoporotic vertebral fracture. Hiroyuki Tsuchie*[1], Naohisa Miyakoshi[2], Yuji Kasukawa[2], Tomio Nishi[3], Hidekazu Abe[3], Toyohito Segawa[4], Yoichi Shimada[5]. [1]Nakadori General Hospital, Japan, [2]Akita University Graduate School of Medicine, Japan, [3]Ugo Municipal Hospital, Japan, [4]Akita University Graduate School of Medicine, Japan, [5]Akita University Graduate School of Medicine, Japan

Purpose: Vertebral fracture is often seen in aged osteoporotic patients, and it causes a decline in activities of daily living. Teriparatide is expected to promote bone union after fracture. Therefore, we evaluated the analgesic action of and vertebral collapse prevention by administering teriparatide to fresh vertebral fracture patients.

Methods: Thirty-three patients with fresh osteoporotic vertebral fracture (48 vertebrae) hospitalized for treatment (male/female: 4/29, mean age: 82 years) participated in the present study. They were administered either teriparatide (daily or weekly) or risedronate for osteoporosis treatment based on their choice, and 9 patients (19 vertebrae) were administered teriparatide daily (Daily group), 11 patients (15 vertebrae) were administered teriparatide weekly (Weekly group), and 13 patients (14 vertebrae) were administered risedronate (RIS group). We compared serum cross-linked N-telopeptide of type I collagen, bone-specific alkaline phosphatase, calcium, inorganic phosphorus, the visual analogue scale (VAS), hospitalization period, vertebral collapse rate and local kyphotic angle of fractured vertebrae compared to that at the initial visit, and the frequency of the cleft in the vertebrae. In addition, we evaluated 22 fresh osteoporotic vertebral fracture patients (25 vertebrae) who did not take any osteoporotic medicines before and after hospitalization (Control group, male/female: 4/18, mean age: 82 years).

Results: At the start of treatment, there was no significant difference in the age, laboratory examinations, bone mineral density, VAS, vertebral collapse rate, or local kyphotic angle between the 4 groups. At 8 and 12 weeks after the initial visit, VAS scores in the Daily and Weekly group were significantly lower than in the RIS group ($P<0.05$). At 8 and 12 weeks after the initial visit, the differences in the vertebral collapse rate and local kyphotic angle in the Daily group were significantly lower than in the RIS and control groups ($P<0.01$ and $P<0.05$, respectively), and those in the Weekly group were significantly lower than in the control groups ($P<0.05$). The frequency of the cleft in the fractured vertebrae in the Daily group was significantly lower than in the RIS group ($P<0.05$). There was no significant difference in the hospitalization period.

Conclusion: Teriparatide is promising for the prevention of vertebral collapse progression after fresh osteoporotic vertebral compression fracture.

A Multicenter, Randomized, Double-blind, and Placebo-controlled Study of Chinese Medicine Zuogui Pill and Yougui Pill for Improving Bone Mineral Density. Dezhi Tang*[1], Chenguang Li[2], Xuejun Cui[2], Dongfeng Zhao[2], Xiaofeng Li[2], Qin Bian[2], Bing Shu[2], Jing Wang[2], Weiwei Da[2], Wen Mo[2], Qi Shi[2], Yongjun Wang[3]. [1]Longhua Hospital, Shanghai University of Traditional Chinese Medicine, Peoples Republic of China, [2]Longhua Hospital, Shanghai University of Traditional Chinese Medicine, China, [3]Othopedic Surgery, Peoples Republic of China

Natural herbal therapy offers an attractive alternative for the treatment of osteoporosis. The objective of this study is to evaluate the efficacy and safety of Chinese herbs, Zuogui Pill (ZGP) and Yougui Pill (YGP), for use in patients to improve bone mineral density (BMD). In this study, 200 subjects were included double-blindly and randomly allocated into two groups, treatment and control. All subjects were diagnosed with low bone mineral density and kidney deficiency in Traditional Chinese Medicine (TCM). Subjects in treatment group were treated for 6 months with either ZGP or YGP based on clinical characters of TCM, while control group received placebo for the same period of time. Primary outcome was lumbar spine BMD as determined by using dual-energy X-ray absorptiometry. Secondary outcomes included visual analogue scale (VAS), quality of life (ECOS-16), and serum markers of bone metabolism. Adverse effects were documented for safety assessment. Follow-ups were performed at regular intervals during a one-year period. We found that, in ZGP group, lumbar spine BMD was increased by 4.1% immediately after the

treatment from the baseline (P=0.047) and by 4.7% from the baseline at the end of the additional 6-month follow-up (P=0.055). Bone anabolic marker was also significantly improved after treatment (P<0.05). In YGP group, the VAS and ECOS-16 scores were also significantly reduced after treatment (P<0.05). Furthermore, bone resorption marker was significantly suppressed after treatment in YGP group (P<0.05), and bone anabolic marker was significantly increased (P<0.05), respectively. No severe adverse effects were observed in either ZGP group or YGP group. Taken together, ZGP and YGP are effective and safe therapeutic drugs for osteoporosis, which improve lumbar spine BMD, reduce pain intensity, alleviate bone resorption, and stimulate bone formation. This study was supported by the National Basic Research Program of China (2010CB530400), the Development Program of Innovation Team of Ministry of Education (1RT1270), the Program of Natural Science Foundation of China (81102604), the Scientific Research Innovation Project of Shanghai Education Committee (14YZ051), and Outstanding Young Talent Training Plan of Shanghai Health System (XYQ2013085).

Animal Models of Osteoporosis Correlate with Clinical Bone Marker Data in Women Treated with Ospemifene. Ginger Constantine*[1], Shelli Graham[2]. [1]EndoRheum Consultants, USA, [2]Shionogi Inc, USA

SERMs have been shown to prevent osteoporosis and reduce fracture risk. Ospemifene 60 mg/day is a nonhormonal, oral, selective estrogen receptor modulator (SERM) approved for the treatment of moderate to severe dyspareunia in postmenopausal women with vulvovaginal atrophy (VVA). It has shown bone-preserving effects in rats, including inhibition of OVX-induced decreases in ash weight at the femoral and tibial epiphyses, increases in tibial stiffness, improvement in bone markers and BMD changes, similar to the effects of estrogen treatment. Ospemifene 1-10 mg/kg reduced bone markers indicative of collagen degradation in a dose-dependent manner. The S-ICTP was reduced by 67 -82% compared with OVX rats ($p < 0.05$), equivalent to the effects of raloxifene.

Two randomized phase II clinical trials of ospemifene on serum bone markers in postmenopausal women have been performed. Ospemifene 30, 60 and 90 mg/day was compared with raloxifene 60 mg/day (the approved dose for osteoporosis) over 12 weeks. Markers of bone resorption (urinary N- and serum C-terminal cross linking telopeptides of type I collagen (NTX and CTX), and markers of bone formation (serum osteocalcin, bone-specific alkaline phosphatase [bone ALP], and procollagen type 1 N and C peptides [P1NP and P1CP]) were measured in 118 postmenopausal women with a mean age of ~57 years. Changes in bone markers were comparable in the ospemifene 60 and 90 mg/day and raloxifene groups. A similarly designed second phase II randomized clinical trial evaluated ospemifene 30, 60, and 90 mg/day versus placebo on bone turnover markers. Ospemifene reduced bone markers in a dose-dependent manner in this study of 176 healthy post-menopausal women (mean age of ~57 years). NTX decreased in all dosage groups, whereas CTX decreased in the 90 mg/day group. Formation markers (P1NP, P1CP, and bone ALP) were significantly decreased in all treatment arms and P1NP and bone ALP statistically differed from placebo.

Correlating animal models with human disease is often unreliable. However, in this large pre-clinical and clinical program OVX-rats treated with ospemifene had similar reductions in markers of bone turnover as did post-menopausal women treated with ospemifene. Bone turnover markers have been shown to correlate with fracture outcomes, thus the totality of the animal and human data support further evaluation of ospemifene as a treatment option for women desiring treatment of VVA and osteoporosis prevention.

Melatonin improves bone mineral density (BMD) at the femoral neck in post-menopausal women with osteopenia: A randomized controlled trial. Anne-Kristine Amstrup*[1], Tanja Sikjaer[2], Leif Mosekilde[3], Lars Rejnmark[3]. [1]Aarhus University, Denmark, [2]Department of Medicine & Endocrinology, MEA Aarhus University Hospital, Denmark, [3]Aarhus University Hospital, Denmark

Background: Melatonin is known for its regulation of circadian rhythm, however over the recent years, in vivo and vitro studies with melatonin have shown that melatonin also may affect bone by increasing osteoblast differentiation and inhibiting osteoclast activity. Melatonin levels normally peaks around midnight, but the amplitude of the peak is attenuated with age. It is unknown whether decreased melatonin levels in the elderly may be associated with increased bone loss.

We aimed to investigate whether treatment with melatonin may improve BMD.

Method and design: In a double-blind placebo-controlled investigator initiated study, we randomized 81 healthy post-menopausal women with osteopenia to one-year of treatment with melatonin in a daily dose of 1 mg (N=20), or 3 mg (N=20), or similar placebo (N=41). Tablets were administrated at bedtime. All participants also received a daily supplement of 800 mg of calcium and 20 mg of vitamin D3. BMD was measured by DXA (Hologic Discovery scanner) at baseline and after 12 months of treatment

Results: Our studied women had a mean age of 63 years (range 56-73) years. Compared with placebo, BMD at the femoral neck increased by 1.4% in response to melatonin (p<0.05). A dose-response relationship was present (p<0.01) as femoral neck BMD decreased by 1.5% in the placebo group, by 1.0% in the 1 mg melatonin group, whereas BMD increased by 0.9% in the 3 mg melatonin group. At total hip, 3 mg melatonin increased BMD by 1.7% (p=0.01) compared to 1 mg melatonin. Treatment did not affect BMD significantly at the lumbar spine, or whole body. Melatonin did not change body weight, but did affect body composition. Compared with placebo, melatonin decreased fat mass by 6.9% (p<0.02), while lean body mass tended to increase by 2.4% (p=0.06). Treatment was well tolerated. Effects on biochemical bone markers are being analyzed and will presented at the meeting.

In conclusion: One year of treatment with melatonin improved BMD dose-dependently at femoral neck and showed beneficial effects on body composition in terms of a reduced fat mass. Large scaled studies are needed to further investigate whether melatonin may protect against fractures.

SA0413

Hepatitis C Co-infection is Associated With Lower Areal and Volumetric BMD and Abnormal Trabecular Microarchitecture in HIV-infected Post-menopausal Minority Women. Michael Yin*[1], Chiyuan Zhang[1], Susan Olender[2], David Ferris[3], Mariana Bucovsky[1], Ivelisse Colon[4], Nientara Anderson[3], Cosmina Zeana[5], Elizabeth Shane[6]. [1]Columbia University, USA, [2]Columbia University, USA, [3]Mt Sinai St Lukes & Mt Sinai Roosevelt, USA, [4]Columbia University Medical Center, USA, [5]Bronx Lebanon Hospital Center, USA, [6]Columbia University College of Physicians & Surgeons, USA

Introduction: Fracture incidence is higher in HIV-infected patients with HCV-co-infection (HIV+/HCV+) than those with HIV infection alone (HIV+). Therefore, we hypothesized that HIV+/HCV+ women would have lower bone mineral density (BMD) and worse microarchitecture than HIV+ women.

Methods: We measured areal BMD (aBMD) by DXA at the spine (LS), femoral neck (FN), total hip (TH), distal 1/3 radius (1/3R) and ultradistal radius (UDR) and volumetric BMD of the distal radius and tibia by high-resolution peripheral quantitative CT (HR-pQCT) in 171 African American or Hispanic postmenopausal women, 44 HIV+/HCV+ and 127 HIV+. Data are presented as Mean + SEM. GLM was used with group status as a fixed effect, and age, BMI, and race entered as covariates.

Results: HIV+/HCV+ women were similar to HIV+ women with regard to age (57 vs 57) and BMI (28 vs 30 kg/m2), both p>0.05. HIV+/HCV+ women were more likely to be African American than Hispanic (59% vs 43%), but the difference was not significant (p=0.06). HIV+/HCV+ women had lower aBMD T scores (ranging from 0.40 to 0.48 SD lower) at the LS, TH, UDR (p<0.05); differences remained significant at TH and UDR, but not at the LS (p=0.08) after adjustment for age, race/ethnicity and BMI. Prevalence of osteoporosis tended to be higher in HIV+/HCV+ than HIV+ women (67% vs 33%, p=0.19). There were no group differences in HR-pQCT measures at the radius. At the tibia, however, HIV+/HCV+ women had lower total vBMD (227 $\pm$ 8 vs 253 $\pm$ 5 mgHA/cm^3; p<0.05) than HIV+ women. Cortical vBMD and thickness were similar between groups, while trabecular vBMD (113 $\pm$ 5 vs 123 $\pm$ 4 mgHA/cm^3) and trabecular thickness (61 $\pm$ 2 vs 69 $\pm$ 1 mm) were significantly lower in HIV+/HCV+ than HIV+ women, before and after adjustment for group differences in age, race/ethnicity and BMI (p<0.05).

Conclusion: Areal BMD by DXA is significantly lower in HIV+/HCV+ than HIV+ postmenopausal minority women at the hip and radius. By HR-pQCT, BMD deficits were confined to the trabecular compartment and to the tibia, a weight-bearing site. These data suggest that the higher fracture rates observed in HIV+/HCV+ than HIV+ individuals are due in part to true deficits in areal and volumetric bone density, that are more severe in trabecular than cortical bone.

Network-based Proteomic Analysis for Postmenopausal Osteoporosis in Caucasian Females. Lan Zhang*, Yingchun Zhao, Hong-Wen Deng. Tulane University, USA

As one of the crucial physiological events in female's life, menopause occurs during women's late 40s or early 50s. Transition of menopause status is accompanied with fluctuations in hormone levels and increasing risk for numerous health problems like cardiovascular disease and osteoporosis. Peripheral blood monocytes (PBM), well known as the potential osteoclast precursors, can differentiate into various cell types closely related to immune response, and produce cytokines important for osteoclast activity. By using the quantitative proteomics methodology LC-nano-ESI-MS^E, we performed protein expression profiles of PBM in 42 postmenopausal females with discordant bone mineral density (BMD) level. Traditional comparative analysis showed proteins encoded by 4 genes (LOC654188, PPIA, TAGLN2, YWHAB) and 3 genes (LMNB1, ANXA2P2, ANXA2) were significantly down- and up regulated in extremely low BMD group, and these results were consistent with previous research evidence. To study network pattern of the detected proteins, we performed weighted gene co-expression network analysis (WGCNA) and gene set enrichment analysis (GSEA). WGCNA showed that the module including annexin gene family (ANXA1, ANXA2, ANXA5, and ANXA6) was most significantly correlated with low BMD group and enriched GO categories in this module shared similar molecular functions associated with proinflammatroy cytokines in postmenopausal osteoporosis. GSEA revealed some complementary evidence of probable gene set involved in the regulation of monocyte activities. In this study, we evaluate the application of network-based analysis to quantitative proteomic data and the findings promote our understanding of biological function of important gene and protein clusters in postmenopausal osteoporosis.

Keywords: Circulating monocyte, GSEA, Menopause, LC-MS, WGCNA

Osteoporosis Treatment and Chronic Kidney Disease as Measured by Creatinine Clearance and Estimated Glomerular Filtration Rate. Brian Decker*[1], Ziyue Liu[2], Allison Martin Nguyen[3], Marc Rosenman[1], Joel Martin[4], Katie Allen[5], Siu Lui Hui[6], Erik Imel[6]. [1]Indiana University School of Medicine, USA, [2]Department of Biostatistics, Indiana School of Medicine & Public Health, USA, [3]Merck & Co, USA, [4]Regenstrief Institute, USA, [5]Regenstrief Institute, USA, [6]Indiana University School of Medicine, USA

Chronic kidney disease (CKD) increases osteoporosis (OP) and fracture risks. Due to lack of data, bisphosphonates (BIS) are not recommended when creatinine clearance (CrCl) is <30 ml/min (risedronate, ibandronate) or <35ml/min (alendronate, zoledronate). Renal function assessment can differ between estimated CrCl or glomerular filtration rate (GFR), but clinical labs often report GFR. The objectives were to estimate the percent of OP treatment candidates with CKD, CKD rates using estimated CrCl vs. GFR, and frequency of BIS in these patients.

Candidates for OP treatment were identified from a multi-system health information network from 2000-2012. Patients were included if age 50+ and BMD via DXA or ICD9 code indicated OP; or osteopenia with fracture ICD9 codes; and had ⩾2 creatinine values ⩾90 days apart. GFR via the CKD-EPI and CrCl via the Cockcroft-Gault equations were estimated. ''Persistent low'' GFR or CrCl was defined as values <35 for ⩾90 days without resolving; ''transient low'' was defined as values <35 which resolved.

Of 71293 patients (85% female, 90% white, 9% black) identified as OP treatment candidates, 27% (n=19273) had transient GFR <35 and 4.6% (n=3280) had persistent GFR <35. In the subset with both GFR and CrCl (21.2%, n=15102), transient values <35 occurred in 40.7% (GFR) and 55.7% (CrCl); while persistent values <35 occurred in 7.5% (GFR) and 21% (CrCl). In the persistent low CrCl group, only 33.4% had GFR <35 at the start of CrCl <35. In contrast, of those with persistent low GFR, 96.4% had CrCl <35 at the start of GFR <35.

Of the total sample, 29.4% received any OP treatment and 27.2% BIS. The closest GFR before treatment was <35 in 709 patients (3.4%) initiating any OP treatment; and 508 patients initiating BIS (3.0%). Among those with persistent low GFR, 5.4% continued previous OP treatment and an additional 5.9% initiated OP treatment after reaching GFR<35 (collectively 11.4%). Most of these were BIS (4.8% continuing, 4.5% initiating). Among those with persistent low CrCl, 6.1% continued and 15.6% initiated OP treatments after CrCl<35. Most were BIS (5.4% continuing, 13.5% initiating).

Nearly 5% of OP treatment candidates had persistent GFR below BIS recommendations and 27% had transient GFR <35. Of note is that GFR underestimated the prevalence of CKD relative to the CrCl estimate. Low GFR/CrCl occurs frequently in OP patients; new OP treatments for CKD patients are needed.

SA0423

Risk and Prevalence of Vertebral Fractures among Breast Cancer Survivors in China. Evelyn Hsieh*[1], Qin Wang[2], Renzhi Zhang[2], Chun-Wu Zhou[2], Youlin Qiao[2], Liana Fraenkel[3], Weibo Xia[4], Karl Insogna[5], Jennifer Smith[6], Pin Zhang[2]. [1]Yale School of Medicine, Section of Rheumatology, USA, [2]Cancer Institute & Hospital, Chinese Academy of Medical Sciences, China, [3]Section of Rheumatology, Yale School of Medicine, USA, [4]Peking Union Medical College HospitalDepartment of Endocrinology, Chn, [5]Yale University School of Medicine, USA, [6]Gillings School of Public Health, University of North Carolina, USA

Background/Purpose: Osteoporotic fractures lead to significant morbidity and mortality worldwide. Women with breast cancer (BC) are at high risk for fracture due to the deleterious impact of BC therapies on bone density. In China, BC survival is improving as screening, diagnosis and treatment programs expand, however the long-term impact of BC therapy on fracture risk among Chinese women remains unknown and no guidelines exist to prevent BC treatment induced bone loss. We designed a pilot study to evaluate the scope of this problem among BC survivors at a large cancer referral hospital in Beijing.

Methodology: BC survivors receiving care at the Cancer Institute and Hospital of the Chinese Academy of Medical Sciences between April-December 2013 were invited to participate. Women were eligible if they were between the ages of 50-70 years of age, had initiated treatment for BC at least 5 years prior to enrollment, and had no evidence of metastatic bone disease. Study procedures included a self-administered questionnaire regarding risk factors for and personal history of fracture and a thoracolumbar x-ray to assess for presence of vertebral fractures.

Results: 100 women were enrolled with a mean age of 57 ± 5 years, and BMI of 26.6 ± 4.8 kg/m^2. Mean years since BC diagnosis was 6.0 ± 0.8. The majority of cases were stage I or II at diagnosis (79.2%) and estrogen and/or progesterone receptor positive (87%). In total, 12 vertebral fractures were identified via thoracolumbar x-ray. In terms of risk factors for fracture, average reported lifetime height loss was 1.7 ± 1.1 cm, 11% reported a parental history of fracture, 9% reported a personal history of fracture, and 22% of women reported falling within the past year. Forty-five percent of all participants reported taking calcium supplements, but only 4% reported taking vitamin D supplements. Only 25% of women reported having a bone density scan since being diagnosed with BC and 14.4% had been told by a provider they had low bone density or osteoporosis.

Conclusions: Prevalence of fracture among our cohort of Chinese BC survivors was 12%, much higher than recently reported rates among age-matched healthy Chinese women in Beijing of less than 5%. Chinese women undergoing BC therapy should be routinely evaluated for osteoporotic fracture risk. Larger studies are necessary to identify sub-groups at particularly high risk in order to inform screening and prevention guidelines.

SA0424

Teriparatide (PTH1-34) treatment effectively increases bone mineral density in patients with pregnancy and lactation associated osteoporosis. JO EUN Kim*[1], Su Jin Lee[2], Sung-Kil Lim[1], Yumie Rhee[3]. [1]Yonsei University College of Medicine, South Korea, [2]Yonsei University Health System, South Korea, [3]Department of Internal Medicine, College of Medicine, Yonsei University, South Korea

Pregnancy and lactation-associated osteoporosis (PLO) is a rare disease characterized by the occurrence of fragility fracture(s), most commonly vertebral, in late pregnancy or the early postpartum period. The etiology and treatment of PLO is not established yet. Although bone turnover rate is increased in PLO patients, long-term treatment of bisphosphonate could be often inappropriate. Because most of the patients are young women in their late twenty to early thirty, and primiparas, so they want subsequent pregnancies. Thus in this study, we report demographic data of 36 PLO patients and the effect of 12~16 months-teriparatide therapy in 15 patients. Mean age of 36 patients was 30.5 years and they all had low traumatic fracture during postpartum. Mean fracture number was 3.8, and most prevalent fracture site was thoracic and/or lumbar vertebrae (94.4%). Z-score of lumbar spine was -2.8±0.8 (mean±SD) and serum β-CTx was slightly increased as 0.618±0.359 ng/mL (premenopausal reference <0.573). After a 12~16 months of teriparatide treatment in 15 patients, their lumbar spine BMD (median, interquartile range) (g/m^2) increased from baseline of 0.725 (0.716 ~ 0.786) to 0.852 (0.772 ~ 0.897) (17.0 % increase, p=0.004) and Z-score was increased from -2.6 (-3.1 ~ -2.5) to -1.4 (-2.3 ~ -0.9) (p=0.002). Total hip BMD was increased from 0.678 (0.597 ~ 0.731) to 0.732 (0.653 ~ 0.778)(7.7% increase, p= 0.031) and Z-score increased from -1.7 to -1.1 (p=0.001). Serum β-CTx (ng/mL) was reduced from 0.683 (0.242 ~ 0.988) to 0.358 (0.271 ~ 0.484)(p=0.198) and osteocalcin (ng/mL) remained slightly elevated state from 24.71 (18.44 ~ 33.08) to 31.71(22.09 ~ 44.18)(p=0.109). Most patients experienced low back pain relief during one or two months of initial teriparatide treatment. In conclusion, teriparatide was effective to increase in lumbar spine and total hip BMD significantly, even though in PLO patients with high bone turnover. Teriparatide could be a good option as treatment for PLO patients with multiple vertebral fractures, alleviating long term accumulation of bisphosphonates, since most patients were primiparas.

Long-term Changes in Bone Mineral Density in Kidney Transplant Recipients. Kyla Naylor*[1], Amit Garg[2], Anthony Hodsman[1], David Rush[3], William Leslie[4]. [1]Western University, Canada, [2]Western University, Canada, [3]University of Manitoba, Canada, [4]University of Manitoba, Canada

Background: Alterations in bone mineral metabolism occur when kidney function declines and often continue post-transplant. We investigated long-term changes in bone mineral density (BMD) among kidney transplant recipients undergoing routine clinical BMD monitoring and management.

Methods: We identified all adults receiving a kidney transplant in Manitoba, Canada (1996-2011) who had ⩾2 post-transplant DXA examinations. BMD tests have been standard practice in the Manitoba renal transplant program since 1997. All BMD results are captured through the population-based Manitoba BMD program and were linked with health service records to identify medication use. BMD was expressed as sex- and age-matched Z-scores. Predictors of BMD change (g/cm^2/year) between successive scans were modeled using generalized estimating equations (GEE) stratified by prior osteoporosis treatment status (candidate predictors age, sex, baseline body mass index [BMI], change in BMI, osteoporosis treatment and glucocorticoid treatment).

Results: 326 kidney transplant recipients were included (mean age 45 years, 61% men). Recipients were followed for an average of 8.2 years (326 baseline and 766 follow-up DXA measurements). At baseline (first scan, median 0.5 years post-transplant) bone density was slightly below average for age and sex (mean Z-scores: lumbar spine -0.4±1.6; femoral neck -0.7±1.1; total hip - 0.7±1.1). At the second scan (mean 2.7 years after first scan) mean bone density Z-scores had increased (lumbar spine -0.2±1.6; femoral neck -0.6±1; total hip -0.6±1.1; matched P <0.01 at all sites). Even after restricting the analysis to recipients who had not received osteoporosis treatment, final mean bone density (mean 8.2 years after first scan) was average for age and sex (mean Z-scores: lumbar spine +0.7±1.6; femoral neck -0.1±1.1; total hip 0.0±1.1). Change in osteoporosis medication use in the year after a DXA scan occurred in 19% of recipients, with most of this (16%) representing initiation of osteoporosis treatment and only a small component (3%) stopping treatment. The only factor associated with significant BMD change at all sites from GEE was osteoporosis treatment (BMD increase). Greater glucocorticoids exposure was not associated with a significant change in BMD regardless of osteoporosis treatment status (P >0.05).

Conclusions: With routine BMD monitoring and management, post-transplant bone density typically remains stable or improves with mean values that are average for age and sex.

Monocyte Chemotactic Protein-1 (MCP-1) is a Key Regulator of Remodeling Activation. Mark Forwood*[1], Gemma Diessel[2], Andy Wu[3], Wendy Kelly[2], Nigel Morrison[4]. [1]Griffith University, Australia, [2]Griffith University, Australia, [3]Mater Medical Research Institute, Australia, [4]Griffith University, Gold Coast Campus, Australia

Monocyte chemotactic protein-1 (MCP-1) belongs to the CC chemokine superfamily (CCL2). It plays a critical role in recruitment and activation of leukocytes during acute inflammation, and has the highest level of gene induction in bone following anabolic PTH treatment[1]. We reported that MCP-1 is also specifically regulated during bone remodeling that is activated to repair stress fracture[2]. We hypothesized that MCP-1 is a necessary regulator of recruitment and activation of osteoclasts required for skeletal repair and remodeling. We used the ulnar stress fracture model, allowing scrutiny of focal remodeling with a known time course and precise anatomical location. Within 4 hours of stress fracture initiation, we observed significant increases in MCP-1 gene expression ($P < 0.01$), followed by increased serum levels within 24h ($P < 0.05$). To test our hypothesis, we used a plasmid DNA encoding a dominant negative mutant of MCP-1 (7ND) to specifically inhibit MCP-1 in vivo. Stress fracture was created in the right ulna of Wistar rats using cyclic end-loading. Unloaded animals were used as a control. 24 h prior to loading, 7ND plasmid vector, saline or empty vector control (pcDNA3.1), were injected in the thigh muscle to overexpress 7ND protein, effecting its secretion into systemic circulation. Rats were euthanized 4h (n=5/group) or 2 weeks (n=10/group) after loading for gene expression or histomorphometric analysis, respectively. Using qPCR analysis, there was 33-fold increase in MCP-1 expression 4h after loading ($P<0.001$), which was abolished by 7ND treatment. At 2 weeks, there was a profound suppression of osteoclast number (61%), resorption area (50%) and new bone formation (60%) in basic multicellular units that initiate remodelling of the stress fracture ($P < 0.05$). Conversely, 7ND treatment had no effect on formation of periosteal woven bone. MCP-1 is markedly upregulated by stress fracture, but also by intermittent PTH treatment[1]. We therefore conclude that MCP-1 is a critical regulator of chemotaxis and osteoclast differentiation during initiation events of bone remodeling.

sCSF-1 Maintains Cortical Bone Thickness During Aging. Ramaswamy Sharma*[1], Diane Horn[2], Kathleen Woodruff[2], Jean Jiang[3], Roberto Fajardo[4], Sherry Abboud Werner[3]. [1]University of Texas Health Sciences Center At San Antonio, USA, [2]University of Texas Health Science Center at San Antonio, USA, [3]University of Texas Health Science Center at San Antonio, USA, [4]UT Health Science Center, San Antonio, USA

CSF-1 is a key regulatory molecule for bone homeostasis. Osteoblasts express CSF-1 isoforms/CSF-1R and are essential for maintaining bone mass. Studies indicate that expression of the soluble form of CSF-1 (sCSF-1) in osteoblasts of transgenic mice increases cortical bone thickness. However, the effect of sCSF-1 on bone remodeling during aging has not been explored. We established transgenic mice expressing human sCSF-1 driven by the osteocalcin promoter (sCSF-1Tg) and examined the bone phenotype at 3.5 months and 1 year of age using μCT, histology and histomorphometry. At 3.5 months, sCSF-1Tg mice showed elevated human CSF-1 levels in serum and bone. Trabecular bone in sCSF-1Tg mice was similar to WT littermates, whereas the diaphysis, although normal in diameter, showed increased cortical thickness and BMD. Sections of the diaphysis showed increased intracortical remodeling due to increased osteoclast activity and osteoblastic bone formation, resulting in a slightly more porous cortex. Fluorochome labeling revealed enhanced BFR along the endocortical surface that contributed to increased cortical thickness. At one year, trabecular bone in sCSF-1Tg mice was preserved, with BV/TV and BFR similar to that in WT mice, whereas the diameter of the femur and tibia mid-diaphysis was increased. Total cross-sectional area was 28% higher and cortical thickness and cortical bone area were increased in sCSF-1Tg mice. The BFR along both the periosteal and endocortical surface was increased and new bone along the endocortical surface resulted in narrowing of the marrow cavity. Osteoclasts in CSF-1Tg mice were identified along the endosteum, with some tunneling into the subendocortical region. The diaphysis in sCSF-1Tg mice showed persistent intracortical remodeling with cavities covered with osteoid and lined by osteoblasts and osteoclasts. Results suggest that sCSF-1, released by osteoblasts, likely mediates its effect via an autocrine and/or paracrine manner. These findings are novel and indicate that sCSF-1 expression during aging preserves cancellous bone volume and stimulates bone formation and turnover within cortical bone. Although remodeling created a slightly more porous cortex, this was overridden by apposition of new periosteal and endocortical bone, which increased diaphyseal thickness. Importantly, strategies to sustain sCSF-1 expression in bone during aging may be useful for preventing bone loss and enhancing cortical bone integrity.

Stimulating the release of soluble Rankl by osteoblasts is a unique property of PTH. Timo Heckt*[1], Johannes Keller[2], Athena Chalaris[3], Stefan Rose-John[3], Michael Amling[4], Thorsten Schinke[5]. [1]University Medical Center Hamburg-Eppendorf, Germany, [2]Department of Osteology & Biomechanics, University Medical Center Hamburg-Eppendorf, Germany, [3]Biochemical Institute, University of Kiel, Germany, [4]University Medical Center Hamburg-Eppendorf, Germany, [5]Department of Osteology & BiomechanicsUniversity Medical Center Hamburg Eppe, Germany

Rankl, representing the major pro-osteoclastogenic cytokine, is synthesized as a transmembrane protein that can be cleaved by specific endopeptidases to release a soluble form into the circulation. We have previously reported that interleukin-33 (IL-33) induces expression of *Tnfsf11*, the Rankl-encoding gene, in primary osteoblasts, but we failed to detect Rankl in the medium of these cells following IL-33 administration. Based on this surprising observation we treated primary osteoblasts with various molecules (PTH, IL-33, 1,25-(OH)-Vitamin D3, TNFa, IL-11 and IL-17) for 6 hours, and found that all of them significantly induced *Tnfsf11* expression to a similar extent. Importantly however, only treatment with PTH, but not with any of the other cytokines, resulted in detectable Rankl concentrations in the medium, thereby uncovering a unique property of PTH, which does not only stimulate RANKL production, but also the release of its soluble form. To uncover the potential underlying mechanism we first monitored expression of *Adam10*, *Adam17* and *Mmp14*, encoding three putative Rankl-processing enzymes, but we failed to detect differential expression in response to PTH. We next applied genome-wide expression analysis to identify direct transcriptional targets of PTH in an unbiased approach. We thereby confirmed some of the transcriptional effects of PTH previously established in other systems, and we additionally identified few genes encoding putative endopeptidases that were significantly increased by PTH treatment of primary osteoblasts for 6 hours. A subsequent qRT-PCR expression analysis identified three genes of the Adam/Adamts family that were significantly induced by PTH, but not by IL-33. Taken together, our results demonstrate that transcriptional effects on *Tnfsf11* expression are not predicting an increased Rankl-release into the circulation and provide a basis to identify a Rankl-specific endopeptidase in a physiologically relevant setting.

PTH-Stimulated β-Catenin Signaling via PKA in Osteoblasts Is Blocked by a Factor Secreted by Osteoclasts. Thomas Estus*[1], Shilpa Choudhary[2], Carol Pilbeam[2]. [1]University of Connecticut, USA, [2]University of Connecticut Health Center, USA

Parathyroid hormone (PTH) is anabolic when given intermittently but catabolic when given continuously. Previous in vitro studies in our lab have shown that prostaglandins produced by cyclooxygenase-2 (Cox-2) can inhibit PTH-stimulated osteoblast differentiation. This inhibition was mediated by a factor secreted by bone marrow macrophages (BMMs) that had been treated with RANKL to commit them to the osteoclast lineage. We also found that continuous infusion of PTH was anabolic in Cox-2 knockout (KO) mice but not in wild type (WT) mice and increased expression of Wnt target genes, such as Wnt10b, Wisp1 and BMP-2, only in KO bone, not WT bone. The goal of this study was to test the hypothesis that the inhibitory factor secreted by BMMs blocks the osteogenic effects of PTH in vitro by inhibiting PTH-stimulated protein kinase A (PKA) signaling and, as a consequence, the phosphorylation of β-catenin at Ser552 and Ser675. Phosphorylation at these two sites has been shown to promote the transcriptional activity of β-catenin. Conditioned media (CM) was collected from WT and KO BMMs treated for 3 days with RANKL (30 ng/ml). Primary osteoblasts (POBs) were isolated from neonatal calvariae of Cox-2 KO mice and grown for 5 days before addition of WT or KO CM for 1.5 hours and treatment with PTH (10 nM) or vehicle for the last 20 minutes. PTH increased cAMP production in the presence of KO, but not WT, CM. PTH stimulated phosphorylation of β-catenin at both Ser552 and Ser675 sites in the presence of KO, but not WT, CM. Addition of H89, a PKA inhibitor, inhibited PTH-stimulated β-catenin phosphorylation. Similar results were obtained with forskolin, a direct activator of adenylyl cyclase. To rule out effects of protein kinase C (PKC), we treated with a specific PKC inhibitor, GF109203X, and found no effect on PTH-stimulated β-catenin phosphorylation. We conclude that the inhibitory factor made by RANKL-treated WT BMMs blocks PTH-stimulated β-catenin phosphorylation by inhibiting cAMP production and subsequent PKA activation. We speculate that some of the effects of this factor on PTH-stimulated osteoblast differentiation are due to inhibiting the Wnt signaling pathway.

Wnt Signaling Does Not Affect Inflammatory-driven Bone Resorption in Experimental Periodontal Disease. Sabrina Garcia Aquino[1], Morgana Rodrigues Guimaraes[1], Ligia Araujo Barbosa[2], Bruna C S Rodrigues[2], Debora Emy Miyazaki Lopes[2], Carlos Rossa*[3]. [1]School of Dentistry at Araraquara-Univ Estadual Paulista (UNESP), Brazil, [2]School of Dentistry at Araraquara - Univ Estadual Paulista (UNESP), Brazil, [3]School of Dentistry at Araraquara - Univ Estadual Paulista (UNESP), Brazil

The role of Wnt signaling on bone development is extensively studied; however its impact on bone turnover associated with inflammation is largely unknown. Periodontal disease is the most prevalent lytic disease of bone in humans and represents an interesting model to study bone resorption associated with inflammation. The hypothesis we test in this study is that modulation of Wnt signaling influence bone resorption in the LPS-induced experimental periodontal disease model by affecting the host response. We used Balb/c mice and induced periodontal disease by injections of 3 μL of a 10 mg/mL LPS suspension in the palatal mucosa adjacent to the first molars. These injections were performed 3 times/week for 4 weeks under inhalation anesthesia. Controls received injections of the same volume of PBS diluent. Injections of 2 μL of mouse recombinant proteins Wnt3a (40 μg/mL) or of its inhibitor DKK-1 (100 μg/mL) were performed 2x/week during the 4 weeks on the same anatomical sites in alternating days with the LPS/PBS injections. Negative controls received injections of the vehicle (0.1% BSA). All animals were euthanized 30 days after the start of the LPS or PBS injections. The maxillae were dissected, fixed in 10% buffered formalin for 24 h and transferred to 70% ethanol. Bone resorption was assessed by microcomputer tomography using 18 μm slices in a standardized region of interest (ROI) of 3,200 μm^3. Stereometric analysis assessed the inflammatory cell infiltrate in H/E stained semi-serial sections. We used ELISA to determine OPG and RANKL levels in the gingival tissues. LPS injections resulted in significant ($p<0.05$) bone loss, which was not affected by concomitant activation of Wnt signaling and only attenuated (not significantly) by inhibition of Wnt signaling with DKK-1. Interestingly, Wnt3a injection in animals without periodontal disease induction (PBS-injected) also resulted in significant bone resorption. Stereometric analysis of the gingival tissues indicated that injections of either Wnt3a or DKK-1 aggravated the inflammatory cell infiltrate. The decrease on OPG/RANKL ratios in the tissues injected with LPS was not affected by concomitant injections of Wnt3a or DKK-1. We conclude that Wnt signaling does not affect the inflammatory infiltrate and the inflammatory-driven bone resorption in the LPS-induced periodontal disease model. Activation of Wnt signaling increased ($p<0.005$) alveolar bone resorption in the absence of LPS-induced inflammation

Altered pyrophosphate homeostasis contributes to NF1 hyperosteoidosis and bone fragility. Jean De La Croix Ndong*[1], Alexander Makowski[2], Sasidhar Uppuganti[3], Guillaume Vignaux[3], Koichiro Ono[4], Daniel Perrien[5], Simon Joubert[6], Serena R. Baglio[7], donatella granch[7], david A. stevenson[8], Jonathan J. Rios[9], Jeffry Nyman[5], Florent Elefteriou[1]. Seay Center for Musculoskeletal Research, Texas Scottish Rite Hospital for Children, USA

Children with neurofibromatosis type I (NF1) can present with long bone and vertebral dysplasiae. The etiology of these skeletal complications is unclear, thus their clinical management remains difficult. Hypomineralization has been observed in bone biopsies from individuals with NF1 and from mouse models of NF1 skeletal dysplasia, but the contribution of this defect to the suboptimal bone mass, strength and poor healing associated with NF1 remains unclear. We show here that Nf1-deficient chondrocytes and osteoprogenitors are characterized by an ERK-dependent increase in Ank and PC1/Enpp1 expression, leading to accumulation of extracellular pyrophosphate and poor matrix mineralization. Nf1-deficient osteoprogenitors also exhibit impaired differentiation caused by an ERK-dependent blunted response to BMP2, hence reduced alkaline phosphatase (TNSALP) activity and low pyrophosphate catabolism. Consistent with these observations, bone mineralization and mechanical properties are reduced in mice lacking Nf1 in chondrocytes or osteoprogenitors. Importantly, a bone-targeted form of TNSAP (sALP-FcD10), which increases pyrophosphate catabolism, has significant beneficial effects on bone growth, mineralization, structure and mechanical properties in these mice. Bone mineralization and pyrophosphate homeostasis are thus dependent of proper control of the RAS-MAPK pathway by NF1, and sALP-FcD10 may represent a therapeutic avenue to prevent bone fracture in individuals with NF1.

Challenges in localizing the tumor in tumor-induced osteomalacia with whole body venous sampling. Su Jin Lee*[1], Sung-Kil Lim[2], Yumie Rhee[3]. [1]Yonsei University Health System, South Korea, [2]Yonsei University College of Medicine, South Korea, [3]Department of Internal Medicine, College of Medicine, Yonsei University, South Korea

Tumor-induced osteomalacia (TIO) is a rare disease characterized by hypophosphatemia with impaired renal tubular phosphate reabsorption generally via increased fibroblast growth factor-23 (FGF-23). Thus, complete resection of the tumor is utmost important. As systemic whole body venous sampling for FGF-23 has been reported as a helpful tool to confirm preoperative diagnosis of TIO, we performed 5 cases of systemic venous sampling in patients who had negative findings in whole body magnetic resonance imaging (MRI) and In111 Octreotide scan. Blood samples were collected from 18-19 sites per patient and were analyzed by using FGF-23 ELISA KIT (Kainos Laboratories, Inc., Tokyo, Japan). There were no complications caused by whole body venous sampling. We classified into 8 sections as head and neck, right arm, left arm, intra-abdomen, right lower leg, right upper leg, left lower leg and left upper leg. After whole body venous sampling, the section of the highest FGF-23 level were further evaluated by MRI of the regions of interest.

All 5 patients had single dominant vein which showed the highest FGF23 levels. However, only two cases were successful of localizing the tumor responsible for TIO. The location of tumor corresponded to the highest FGF23 levels of single dominant vein in two cases. FGF23 level in all patients ranged from 78.16 pg/mL up to 1435.56 pg/mL, however, the higher FGF23 level did not mean the higher chance of finding the origin of the tumor. We also compared the ratio of FGF23 level of the highest section to that of the lowest of all the sections. The ratio was 1.54 in the first case and 1.34 in the second case. The ratio of failed cases was 1.78, 1.60 and 1.32, respectively. The ratio was not that higher even in successful cases compared to the failed cases. Previous report by N. Ito *et. al.* had done total 10 cases of whole body sampling with a successful rate of localization, 80%. The average ratio of the highest level to the lowest level in these 8 successful cases was 1.83 $\pm$ 0.59 pg/mL (range 1.24 - 2.89 pg/mL).

To resect the tumor responsible for TIO properly, accurate localization is important. Systemic venous sampling based on a distinguished lesion with high level of FGF23 could give a clue for finding a tumor but not all tumors as our results, therefore, it has still limitation in identifying the tumor in TIO.

Clinical Characterization of a Cohort of Patients with Familial Tumoral Calcinosis. Mary Ramnitz*[1], Pravitt Gourh[2], Jaydira Del Rivero[2], Diana Ovejero[1], Nisan Bhattacharyya[2], Lori Guthrie[2], Raphaela Goldbach-Mansky[2], Felasfa Wodajo[3], Shoji Ichikawa[4], Erik Imel[4], Michael Econs[5], Kenneth White[4], Brian Kirmse[6], Adele Boskey[7], Alfredo Molinolo[2], Rachel Gafni[1], Michael Collins[2]. [1]National Institutes of Health, USA, [2]National Institutes of Health, USA, [3]Virginia Hospital Center, USA, [4]Indiana University School of Medicine, USA, [5]Indiana University, USA, [6]Children's National Medical Center, USA, [7]Hospital for Special Surgery, USA

Introduction: Familial tumoral calcinosis (FTC)/hyperostosis-hyperphosphatemia syndrome (HHS) is an autosomal recessive disorder caused by mutations in *FGF23*, *GALNT3*, or *KLOTHO*. The result is a deficiency in, or resistance to, intact FGF23 causing hyperphosphatemia, increased renal tubular reabsorption of phosphorus (TRP), and elevated or inappropriately normal 1,25-dihydroxyvitamin D_3 (1,25-D_3). Affected individuals may develop ectopic calcifications and/or diaphyseal hyperostosis. Methods: Seven patients with FTC/HHS were evaluated. Radiographic, biochemical, histologic, and genetic analyses were performed and therapeutic interventions were attempted. Results: Clinical manifestations ranged from asymptomatic to multiple, large disabling calcifications. All patients had hyperphosphatemia, increased TRP, and elevated or inappropriately normal 1,25-D_3. C-terminal FGF23 was elevated while intact FGF23 was low in all patients. Two patients had overwhelming systemic inflammation (C-reactive protein (CRP) $>$ 80 mg/L, nl $<$3.0). Radiographic findings ranged from diaphyseal thickening alone to massive calcification. All subjects tested to date had *GALNT3* mutations (2 siblings homozygous, 4 patients compound heterozygous). Sperm analyses were normal in one patient, but abnormal in his sibling. Histologic analyses of resected tissue showed chronic inflammation, and not only ectopic calcification, but also ossification. Fourier transform infrared spectroscopy revealed hydroxyapatite crystals of varying size and composition. Low phosphate diet and combinations of phosphate-lowering therapy were attempted with variable response. One patient experienced complete resolution of a calcific mass after 13 months of medical treatment. In patients with systemic inflammation, treatment with an IL-1 antagonist decreased CRP with a decrease in peri-lesional edema in one patient and improvement in both patients' well-being. Conclusion: This cohort expands the phenotypic and genotypic understanding of FTC/HHS and demonstrates the range of clinical manifestations despite similar biochemical profiles and genetic mutations and backgrounds. Two patients had overwhelming systemic inflammation which had not been described previously in FTC/HHS; their response to IL-1 antagonists suggests that anti-inflammatory treatment may be a useful adjuvant. Importantly, this is the first description of true ectopic ossification reported in FTC/HHS, possibly driven by the adjacent inflammation.

Measurement of autoantibodies against osteoprotegerin in adult human serum: Development of a novel ELISA assay. Isabelle Piec*[1], Jonathan Tang[2], Christopher Washbourne[3], Emily Fisher[4], Julie Greeves[5], Sarah Jackson[6], Stuart Ralston[7], Philip Riches[8], William Fraser[3]. [1]BioAnalytical Facility, University of East Anglia, United Kingdom, [2]University of East Anglia, Norwich, UK, United Kingdom, [3]University of East Anglia, United Kingdom, [4]University of East Anglia, United Kingdom, [5]HQ Army Recruiting & Training Division, United Kingdom, [6]MOD, United Kingdom, [7]University of Edinburgh, United Kingdom, [8]Rheumatoic Disease Unit, Institute of Genetics & Molecular Medecine, United Kingdom

Introduction: In 2009, neutralizing autoantibodies against OPG (α-OPGAb) blocking the inhibitory effect of OPG on RANK signaling pathway were identified in a man with celiac disease associated with severe osteoporosis. Although this finding was not reproduced in thirty patients presenting coeliac disease and low bone mineral

density, Hauser *et al* (2013) recently detected the presence of α-OPGAb in patients presenting Rheumatoid Arthritis, Systemic Lupus Erythematosus, Spondyloarthritis and Osteoporosis. There is a growing focus on OPG autoantibodies as primary cause of high bone turnover in disorders with unknown etiology.

Objective: To develop an enzyme linked immunosorbent assay (ELISA) for detection and quantification of α-OPGAb in patient serum samples.

Method: A full-length human recombinant OPG is immobilized on a plate to allow capture of the antibodies from the sera. In a two-step reaction, the αOPGAb is detected using a biotinylated antibody and a horseradish peroxidase-labelled streptavidin. Substrate is incubated in a timed reaction and color development measured in a spectrophotometric microtiter plate reader. The concentration of human α-OPGAb in the samples is determined directly from a 4PL-fit standard curve.

Results: Intra-assay imprecision was <5% at 274.4 ± 18.8 and 98.5 ± 2.9 ng/mL. Inter-assay imprecision was <20% at 324.2 ± 53.3 and 166.8 ± 30.6 ng/mL. Linear range was 0-500ng/mL. Lower and upper limit of quantification were 3.9 and 500 ng/mL. Cross reactivity was assessed against human sera containing raised thyroid antibody and RANKL to ensure assay specificity. Using the method presented, we established that the adult population would be considered positive with a titer above the cut-off limit (95%) of 68ng/mL. Our preliminary data suggested that 14% of our sample population (n=136) presented elevated α-OPGAb.

Conclusion: We presented a novel ELISA assay for the detection and measurement of anti-OPG autoantibodies in human serum. The validated method showed excellent assay characteristics and is suitable for use in research and clinical hospital laboratories. In patients with severe form of osteoporosis, measurement of OPG autoantibodies could help clinicians identify appropriate treatment options for this particular subgroup of patients.

Serum Levels of Amino-terminal Propeptide of C-type Natriuretic Peptide may Predict Growth Response to Growth Hormone Treatment in Patients with Achondroplasia/hypochondroplasia. Takuo Kubota*[1], Kohji Miura[2], Wei Wang[2], Keiko Yamamoto[3], Makoto Fujiwara[4], Yasuhisa Ohata[5], Makiko Tachibana[4], Taichi Kitaoka[6], Yoko Miyoshi[4], Noriyuki Namba[6], Keiichi Ozono[7]. [1]Osaka University Graduate School of Medicine & Dentistry, Japan, [2]Osaka University Graduate School of Medicine, Japan, [3]Osaka University Graduate School of Medicine, Japan, [4]Osaka University Graduate School of Medicine, Japan, [5]Osaka University Graduate School of Medicine, Japan, [6]Osaka University Graduate School of Medicine, Japan, [7]Osaka University Graduate School of Medicine, Japan

C-type natriuretic peptide (CNP) plays a vital role in endochondral growth and its derivative is on clinical trial to improve the growth of patients with achondroplasia. The amino-terminal propeptide of CNP (NT-proCNP) is an equimolar product of CNP biosynthesis and has a longer half-life in serum than CNP. NT-proCNP has been proposed as a biomarker of linear growth in healthy children and patients with growth hormone (GH) deficiency. However, the usefulness of serum NT-proCNP levels in patients with achondroplasia (ACH)/hypochondroplasia (HCH) remains to be elucidated. In this study, we studied serum NT-proCNP levels in untreated patients with ACH/HCH (n = 20: ACH 14; HCH 6), and compared with those in idiopathic short stature (ISS) (n = 24). All the patients with HCH have the N540K mutation in the fibroblast growth factor receptor 3 gene. The mean age and height SD score (SDS) are 3.1 years old and −4.5 in the patients with ACH/HCH, respectively, and 5.6 years old and −2.4 in the patients with ISS, respectively. Serum NT-proCNP levels inversely correlated with ages of patients with ISS in infancy and childhood. There were no obvious differences in NT-proCNP levels between patients with ACH/HCH and ISS at the age of 3 years despite a difference in height SDS. ACH/HCH patients with height SDS below −2.5 were treated with 0.35 mg/kg/week of GH. The mean height SDS significantly increased from −4.8 to −4.3 with one-year GH treatment. NT-proCNP levels in patients with ACH/HCH were increased 3 months following GH treatment. A similar response was observed in serum insulin-like growth factor I (IGF-I) SDS and alkaline phosphatase (AP) levels. When the patients with ACH/HCH were divided into halves regarding an increase in NT-proCNP levels: the upper half and the lower half, a gain of height SDS was significantly larger at the year after GH treatment in the upper half (+0.8 SDS) than in the lower half (+0.3 SDS). In contrast, an increase in IGF-I SDS and AP levels had no correlation with a gain of height SDS. These results indicate that GH increases height by stimulating the production of CNP and that unlike IGF-I SDS and AP levels, serum NT-proCNP levels may predict growth response to GH treatment in patients with ACH/HCH.

Assessment of physical performance in patients with a recent clinical fracture at the Fracture Liaison Service. Lisanne Vranken*[1], Caroline Wyers[2], Kenneth Meijer[3], Robert Van Der Velde[4], Heinrich Janzing[5], Wim Morrenhof[6], Piet Geusens[7], Joop Van Den Bergh[8]. [1]VieCuri Medical Centre, The Netherlands, [2]Maastricht University, The Netherlands, [3]Department of Human Movement Sciences, NUTRIM , Maastricht University, Netherlands, [4]VieCuri Medical Center Venlo, the Netherlands, The Netherlands, [5]VieCuri Medical Centre, Department of Surgery, Netherlands, [6]VieCuri Medical Centre, Department of Orthopedic Surgery, Netherlands, [7]University Hasselt, Belgium, [8]VieCuri MC Noord-Limburg & Maastricht UMC, The Netherlands

Purpose

To assess physical performance and muscle function in patients presenting with a recent fracture (fx) evaluated at the Fracture Liaison Service (FLS).

Methods

All consecutive patients presenting with a recent fx (including VF), who had fx risk assessment (DXA at lumbar spine, femoral neck and hip) were evaluated for physical performance (Chair Stand Test (CST), Timed Up & Go Test (TUG), 6 minutes walking test (WD) and handgrip strength (HGS) at the FLS. Data were analysed using linear regression, Spearman's correlation and multiple regression adjusting for age, sex, BMD (normal vs. osteopenia vs. osteoporosis) and fx classification (finger & toe vs. minor vs. major vs. hip).

Results

372 consecutive patients (⩾50 yrs) were evaluated (70% women; mean age 66 yrs), 61% with a minor, 22% major, 7% hip and 10% finger or toe fx. Osteoporosis was diagnosed in 28%, osteopenia in 51% and 20% had a normal BMD. At the CST women did 12 (2-26) rise and sit repetitions, men 13 (2-22) (p=.001). Lower CST performance was found with higher age (p=.000), lower BMD (p=.010) and severity of fx (p=.046). 38% had a CST below sex and age specific normative scores. TUG took 8s for women (4-33s), 8s for men (5-31s) (p=.018). Time to perform TUG increased with age (p=.000), lower BMD (p=.012) and severity of fx (p=.003). WD was lower in women (380m (60-673m) vs. 423m (134-674m) men p=.000), decreased with age (p=.000), with lower BMD (p=.000) and severity of fx (p=.000). HGS in women was 20kg (2-46kg), in men 38kg (18-60kg) (p=.000), decreased with age (p=.000), lower BMD (p=.004) and severity of fx (p=.024). 64% had HGS below sex and age specific normative values. After adjustments, age and hip fx were significant predictors for TUG and WD; age and sex for HGS and age for CST. In adjusted analyses for both sexes separately age was a significant predictor for all tests, hip fx in women for TUG and hip fx in men for TUG and WD. 94% performed all tests, 89% had a result below normative values for at least one test (51% 1, 35% 2, 3% 3 tests).

Conclusion

Assessment of physical performance in patients with a recent fx showed that 94% of patients were able to perform the tests. 89% of these patients had a score below normative values for at least one assessment. After adjustments, age, sex and hip fx were significant predictors for WD; age and sex for HGS; age and hip fx for TUG and only age for CST (with lower scores at older age, in women and after hip fx respectively).

Fall risk assessment using body composition, muscle strength and physical performance in hospitalized adults. Hideki Tsuboi*[1], Jun Hashimoto[2]. [1]Osaka Minami Medical Center, Japan, [2]National Hospital Organization, Osaka Minami Medical Center, Japan

Introduction; Falls in elderly are problems associated with increased morbidity and disability. Falls are also severe problem in hospitalized adults. In many hospitals, the fall risks are assessed by questionnaires provided by their medical safety committees. Therefore, the purpose of this study is to investigate the possibility to assess fall risks by body composition, muscle strength and physical performance.

Materials and Methods; 103 patients (69 male, 34 female) were enrolled in the study. The patients had a mean age of; male, 68.8 (43-87) years and female, 69.8 (39-88) years. All patients were classified in three groups at the time of admission using fall risk assessment questionnaire provided by medical safety committee in our hospital, A; high risk group, B; moderate risk group, C; low risk group. In addition, the body composition of the muscle mass in lower extremity was measured using by BIA (Bioelectrical Impedance Analysis; MC190,Tanita, Tokyo, Japan) method and muscle strength was assessed by hand grip strength. Moreover, physical performance assessment was evaluated measuring timed up and go test (TUG).

Results; 10 patients (4 male, 6 female) were assessed in Group A, 54 patients (38, 16) were assessed in Group B and 39 (27, 12) were group C. In Group A, muscle mass of lower extremities were 12.9±2.7 kg in male and 11.0±1.6 kg in female respectively. In Group B, 16.1±2.1 and 11.5±2.3 respectively, and in Group C, 16.5±2.3 and 11.4±1.5 respectively. Hand grip strength in Group A were 25.8±2.5 kg in male and 11.8±7.3 kg in female respectively, in Group B;25.9±8.5 and 15.5±4.9 respectively, and in Group C; 30.5±8.3 and 17.2±6.6 respectively. TUG in Group A were 9.3±2.0 sec. in male and 21.5±16.5 sec. in female respectively, in Group B; 9.5±4.6 and 10.8±3.4 respectively, and in Group C; 8.2±2.6 and 7.0±1.9 respectively.

Discussions; This study shows that results of muscle mass in lower extremities, hand grip strength and TUG were tend to decrease as the assessment for fall risks was worse. In male, muscle mass were reflected more clearly in fall risks, on the other hand, hand power strength and TUG were reflected more clearly in fall risks in female.

Conclusion; The examination of the combination among body composition, muscle strength and TUG may be useful as a screening test for assessment for fall risk in hospitalized adults.

Gender and Race Disparities in Body Composition: an Analysis of National Health and Nutrition Examination Survey (NHANES) Data. Didier Chalhoub*[1], Hussein Abu Daya[2], Robert Boudreau[3], Jane Cauley[4]. [1]University of Pittsburgh, USA, [2]University of Pittsburgh Medical Center (UPMC), USA, [3]University of Pittsburgh, USA, [4]University of Pittsburgh Graduate School of Public Health, USA

Body composition changes occur with age. However, gender and race differences in muscle and fat mass are not very well understood. We propose to study the patterns of muscle and fat distribution based on age, gender, and race.

The study population consisted of 15,356 white, black, and Hispanic individuals age ⩾20. Data was obtained from the National Health and Nutrition Examination Surveys (NHANES) from 1999-2006. Subjects were stratified by gender, race, and age group. Appendicular lean mass (ALM) and appendicular fat mass (AFM) were calculated based on whole body dual-energy X-ray absorptiometry (DXA) scans results. The mean and standard deviation of the ALM, AFM, trunk fat, and total body fat were calculated.

Men had a higher appendicular lean mass (kg) (mean=26.8±0.1) compared to women (mean=17.8±0.1). In both genders, blacks had the highest ALM (men=29.4±0.2, women=21.0±0.1) followed by whites (men=26.9±0.1, women=17.6±0.1) and Hispanics (men=24.6±0.1, women=16.7±0.1). The ALM was lower in older age groups (figure 1). The total body fat (kg) was higher in women (mean=31.0±0.2) compared to men (25.5±0.2). In men, whites had the highest total body fat and trunk fat, whereas in women, blacks had the highest levels. Total body fat and trunk fat had a similar pattern increasing across age groups until age 70. Those >age70 old had lower total body fat and trunk fat compared to younger age groups (figure 2). In women, AFM followed a similar pattern. Despite having the highest total and trunk fat, white men had similar AFM to black men (figure 3).

Gender and race differences exist in body composition. Such differences should be accounted for while assessing muscle and fat mass.

Figure 1. Race distribution of appendicular lean mass (ALM) in men and women across age groups

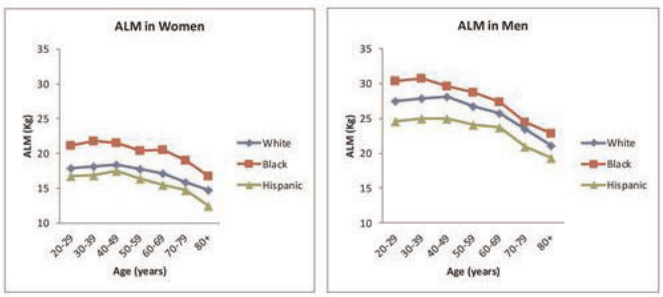

Figure 1. Appendicular lean mass

Figure 2. Race distribution of total body fat (TBF) in men and women across age groups

Muscle, Fat and Bone tissues in Patients with Hip Fracture. M José Montoya*[1], Mercè Giner[2], M Angeles Vázquez[3], Marta Rey[4], Aurora Gil-Bernal[3], David García-Romero[3], M Carmen Cañamero[5], Presentación Zambrano[5], Ramón Pérez-Cano[6]. [1]University of Seville, Spain, [2]Bone Metabolism Unit, Internal Medicine, ''Virgen Macarena'' University Hospital, Spain, [3]Medicine Department, University of Seville, Spain, [4]Viamed Sta. Angela de la Cruz Hospital, Spain, [5]Traumatology & Orthopaedic Unit, ''Virgen Macarena'' University Hospital, Spain, [6]Bone Metabolism Unit, Internal Medicine, ''Virgen Macarena'' University Hospital / Medicine Department, University of Seville, Spain

Sarcopenia-related falls and fractures are becoming an emerging problem as a result of rapid aging worldwide. We aimed to evaluate the prevalence of sarcopenia in patients with hip fracture, testing the muscle mass of the arms and legs and the relationship among sarcopenia, bone mass, fat tissue and risk of falls.

M&M This cross-sectional study examined 88 patients immediately after a hip fracture. We carried out whole-body dual energy X-ray absorptiometry to analyze skeletal muscle mass (MM), total fat (TF), skeletal muscle mass index (SMI), appendicular skeletal muscle mass index (appendicular SMI), bone mineral density, neck BMD and hip BMD. Also, we analyzed bone parameters (PTH, 25(OH)Vitamin D, β-Crosslaps and PINP).

Sarcopenia was defined according to the criteria reported by Baumgartner: appendicular SMI below 7.26 kg / m2 in men and below 5.45 kg/m2 in women.

Statistical analysis of the results was conducted using the T-student test and correlations between variables were assessed with the Pearson correlation coefficient (SPSS 21.0).

Results:

Age, TF, SMI, appendicular SMI and neck BMD were similar in both groups. Women showed higher BMI (body mass index),(28.5 ± 5.5 vs 25.6 ± 4.8 kg/m2), lower MM (37.3 ± 5.2 vs 44.1 ± 5.7 kg) and worst hip BMD value (0.73 ± 0.11 vs 0.80 ± 0.14 gHA/cm2) than men, in all cases $p < 0.05$.

The prevalence of sarcopenia in men was higher, 70.6 % (12/17), than in women 16.4% (11/67), OR = 4.3, (95% CI 2.31 to 8), p = 0.0001. Sarcopenia risk increased with age in men (62.5% in <80 years old and 77.8% in > 80 years old), while it decreased in women (21.7 % vs 13.6%).

92% of women and 61% of men had insufficient levels of 25(OH)vitD (below 20 ng/mL), and we observed correlation between 25(OH)vitD levels and hip BMD (r= 0.333; p= 0.018) and with vitD and PTH (r= - 0.446; p= 0.0001).

The frequency of falls was not related with SMI and appendicular SMI.

We observed correlation between hip BMD or neck BMD with MM (r = 0.42; p = 0.0001/ r = 0.291; p = 0.10)Conclusions: The prevalence of sarcopenia in hip fracture patients is higher in men than in women, mainly above 80 years old. Muscle tissue influences in bone mass values. The majority of patients with hip fracture has insufficient levels of 25(OH)vitD.

Precision and Monitoring Time Intervals for Muscle Area and Density in Older Adults: A Comparison of Stratec and BoneJ Analyses. Andrew Frank*[1], Wojciech Olszynski[2], Saija Kontulainen[1]. [1]University of Saskatchewan, Canada, [2]Saskatoon Osteoporosis & Arthritis Infusion Centre, Canada

Introduction: Peripheral quantitative computed tomography (pQCT) is commonly applied to measure muscle area and density (a surrogate of inter- and intramuscular adipose infiltration). Precision and follow-up data can be used to calculate the monitoring time interval (MTI); an estimate of the time required between measurements where 50% of population will demonstrate a significant age-related change. MTI's assist to inform and optimize pQCT-based study designs in aging populations. We previously reported muscle precision and MTI values for older adult images analyzed using the commonly reported manufacturer's pQCT analysis software. Our purpose was to determine and compare the precision error and MTIs for pQCT-derived muscle area and density analyzed using Stratec XCT 6.00 (manufacturer's software) and BoneJ (a freely available software plugin for ImageJ).

Methods: Women (N=115) age 60 to 90 (mean 73.9, SD 7.9y) were recruited from the Saskatoon Cohort of the Canadian Multicentre Osteoporosis Study. Repeat pQCT scans were acquired an average of 347 (SD 15) days apart at 65% of forearm and 66% of lower leg length. A randomly selected subsample (n=35, mean age 73.7, SD 7.7y) were randomly selected for the calculation of short-term precision error from duplicate scans measured 9.7 (SD 3.6) days apart. Precision error was calculated as a root mean square coefficient of variation (CV_{rms}%). Paired t-tests compared software precision on log-transformed absolute mean differences. MTIs were calculated as the least significant change (2.77*CV_{rms}%) divided by the median annual percent change.

Results: The precision error for forearm area 2.2% vs 2.4%, and density 1.4% vs 1.3%, did not differ between Stratec and BoneJ respectively. Precision error for lower leg area 3.6% vs 2.5%, and density 1.9% vs 0.7%, differed (P=0.047 and P=0.006) between Stratec and BoneJ. For the Stratec vs BoneJ analyses the resulting MTIs were both 3yrs for area and 18 vs 45yrs for density in the forearm, and 18 vs 4yrs for area and 7 vs 3yrs for density in the lower leg.

Conclusion: Precision errors for muscle properties were comparable in the forearm and smaller in the lower leg when assessed with BoneJ versus Stratec. Researchers can reasonably expect to detect changes in forearm muscle area, and lower leg muscle area and density within 3-4 years when utilizing BoneJ to analyze pQCT-derived muscle outcomes in older adults.

Serological peptide biomarkers derived from intramuscular connective tissue collagens are biomarkers of muscle mass. Anders Nedergaard*[1], Ulrik Dalgas[2], Hanne Primdahl[3], Jørgen Johansen[4], Jens Overgaard[5], Kristian Overgaard[2], Kim Henriksen[6], Simon Lønbro[2]. [1]Nordic Bioscience, Denmark, [2]Department of Public Health - Sport Science, Aarhus University, Denmark, [3]Department of Clinical Medicine - The Department of Oncology, Denmark, [4]Department of Oncology, Odense University Hospital, Denmark, [5]Dept. Experimental Clinicall Oncology, Aarhus University Hospital, Denmark, [6]Nordic Bioscience A/S, Denmark

Background

Cancer or iatrogenic cachexia are important clinical complications in clinical practice and improved biomarkers are needed to monitor and predict muscle loss. Our group has previously shown that the collagen fragment biomarkers ProC3 and IC6 are markers of muscle mass in young men and that the biomarker C6M is an indicator of anabolic response to reloading following unloading in the same group. Furthermore we found that the IC6/C6M ratio may also be related to muscle mass. In this study we set out to validate and expand our previous findings to recovering cancer patients and an age and gender matched control group.

Methods

Recovering head and neck cancer subjects from the DAHANCA25B cohort and age- and gender-matched controls were included in the study. Subjects in the DAHANCA cohort were randomized to resistance training either in the first or last 3 months (out of 6) after coming out of therapy and being habitually physically active in the remaining period. Subjects had blood drawn and muscle mass measured at baseline and the intervention subjects were also sampled at 3 and 6 months.

Results

We found that the biomarkers ProC3, IC6 and the IC6/C6M biomarker ratio all correlated significantly with muscle mass in the control group only. We also found that the C6M biomarker was not related to change in muscle mass in the intervention groups.

Conclusions

We have confirmed that the serological peptide biomarkers ProC3, IC6 and the IC6/C6M ratio are significantly correlated with muscle mass in healthy adults of both genders, but not in recovering head and neck cancer patients. Unfortunately, we were unable to extend our previous results where C6M was correlated to change in muscle mass to this cohort. The reason that these correlations are absent in the patient population is likely due to pathology-induced extra-muscular biomarker production.

Caloric Restriction and the Adipokine Leptin alter the SDF-1 signaling axis and autophagy in Bone and MSCs. Sudharsan Periyasamy-Thandavan*[1], Samuel Herberg[2], Phonepasong Arounleut[3], Sunil Upadhyay[4], Amy Dukes[5], Colleen Davis[4], Maribeth Johnson[5], Mark Hamrick[6], Carlos Isales[4], William Hill[7]. [1]Georgia Regents University & Charlie Norwood VAMC, USA, [2]Case Western Reserve University, USA, [3]Georgia Regents University (formally Georgia Health Sciences University), USA, [4]Georgia Regents University, USA, [5]Georgia Regents University, USA, [6]Georgia Health Sciences University, USA, [7]Georgia Regents University & Charlie Norwood VAMC, USA

Within the bone marrow (BM), both osteogenic and adipogenic lineage cells originate from multipotent mesenchymal stromal/stem cells (MSCs). MSCs are a major source of the secreted chemokine stromal cell-derived factor-1 (SDF-1), which is critical in MSC differentiation and BM residence, largely via its receptor CXCR4. A major factor in age-associated osteoporosis is the fate of MSCs. Growing evidence suggests that SDF-1 is critical in regulating MSC differentiation resulting in either a pro-osteogenic fate, or an adipogenic one that leads to reduced bone mass and mineral density, as well as increased BM adipocytes. Leptin, a cytokine-like hormone is secreted in large part by adipocytes, exhibits anti-osteogenic effects via hypothalamic receptors. However, peripheral administration of leptin can demonstrate bone protective effects. Previous studies in mice suggest that dietary restriction decreases circulating leptin while increasing serum SDF-1 levels similar to the effect of aging. In contrast, the opposite occurs with diet-induced obesity. This study investigates the effects of caloric restriction (CR) and leptin on the SDF-1/CXCR4 axis in bone and BM tissues. For *in vivo* studies, we collected bone, BM cells and BM interstitial fluid from 12 and 20 month-old C57Bl6 mice fed ad-libitum (AL), and 20 month-old mice on CR with, or without, leptin for 10 days (10mg/kg body weight). To mimic conditions of CR *in vitro,* murine BM derived MSCs were treated with 1) *control (Ctrl):* normal proliferation medium, 2) *CR:* low glucose, low serum medium, or 3) *CR+leptin:* low glucose, low serum medium + 100 ng/ml rmLeptin for 6-72 h. Both SDF-1 and CXCR4 protein and mRNA expression in MSCs were increased by CR and CR + leptin. In contrast, the alternate SDF-1 receptor CXCR7 was decreased, this supports a change in SDF-1 signaling due to a shift in receptor availability. Additionally, autophagic flux was increased with CR and attenuated with the addition of leptin. However, mRNA isolated from bone shows SDF-1 and CXCR4 & 7 increase with age and this is reversed with CR, but addition of leptin returns this to the "aged" level. This suggests that in bone CR and leptin alter the nutrient signaling pathways in different ways to affect autophagy and the osteogenic cytokine SDF-1's local action. Studies focusing on the molecular interaction between nutrient signaling and autophagy mediated by CR, leptin and SDF-1 axis may help to address age-related musculoskeletal changes

Aged-related Bone Loss (Osteopenia) in Old Male Mice Results From Diminished Activity and Availability of TGF-b and WNT Signaling. Shen-chin Hsu[1], I-HUI Shu[2], Shanshan shi*[3], Hsin-chu Ho[4], Tzong-Jen Sheu[5], Wei Hsu[6], J. Edward Puzas[7]. [1]Chung Shan Medical University Hospital Dept of Pharmacy, Taiwan, [2]Fanglio General Hospital, Taiwan, [3]University of Rochester, USA, [4]Wan-Chuan Clinics, Fangliao General Hospital, Taiwan, [5]University of Rochester, USA, [6]University of Rochester Medical Center, USA, [7]University of Rochester School of Medicine, USA

Both TGFb and WNT signaling are important for the development and maintenance of the skeletal system from embryogenesis till the whole life. TGFb can corss-talk and activate the WNT signaling with the establishment of extracellular

morphogens gradients, formation the smad/b-catenin-LEF protein complex in the nucleus. There are several groups who used different TGF-b and WNT-signaling pathway genetic modified mice to describe and demonstrate the importance of both signaling pathways in skeletal system. We used TGF-b reporter mice and in-vivo images these mice with luciferase substrate injection to understand which tissues had active TGF-b signal at varied postnatal stages. Most of the positive signals located in the calvaria and spine region especially in the tail area. In the twelve months old, the signals started to fade significantly if we kept the same sensitivity setting. This fade TGF-b signaling can be rescued with TGF-b ligand injection. We also used micro-ct to scan the bone density and ELISA to monitor the serum TGF-b amount at different time points (every two months till 14 months old). TGF-bRII is the only TGFb receptor that is capable of accepting all of three TGFb isoforms and eliciting functional signaling. Therefore, its ablation allows the study of Tgfb signaling while avoiding the functional redundancy of the ligands. Several other groups also reported different skeletal related tissues targeted TGFb-RII knockout mice. These TBRII knockout mice were either embryonic lethal or dead at birth and all showed skeletal malformation. Thus we decide to generate inducible-osteoblast-specific (Collagen-I-cre ERT2) TGF-bRII knockout mice and observe the bone loss phenotype of these mice. Both wild type (without Tamoxifen-TAM) and TGF-bRII (Het+TAM) did not have significant morphology changes under X-ray image and m-CT scan. The TGF-bRII (Homo+TAM) had significant bone loss. Other groups ever reported similar finding several years ago but just diminished activity and availability of TGF-b cannot explain the bone loss phenotype. WNT is the downstream signaling of TGF-b signaling pathway. There were several negative WNT regulators, ex FRZb, DKK, AXIN, SOST. We screened these four molecules and checked their expression level in wt(CRE), Col1-cre-ERT-TAM TBRII-het and homo mice. SOST had the highest expression level in TGF-bRII knockout mice and other three molecules did show significant change. We used SOST knockout mice to rescue this osteoblast-specific TGF-bRII caused bone loss and demonstrated the both TGF-b and WNT signalling were important to maintain the spine skeletal morphology integrity.

Aromatic Amino Acids Ameliorate Ovariectomy Induced Bone Loss. Kehong Ding*[1], Aleena Lakhanpal[2], Qing Zhong[1], Wendy Bollag[2], Jianrui Xu[2], William Hill[3], Xing-Ming Shi[1], Mona El Refaey[1], Monte Hunter[2], Mark Hamrick[4], Carlos Isales[1]. [1]Georgia Regents University, USA, [2]Georgia Regents University, USA, [3]Georgia Regents University & Charlie Norwood VAMC, USA, [4]Georgia Health Sciences University, USA

Postmenopausal bone loss is a major cause of osteoporosis in women. It has been proposed that estrogens may protect from bone loss in part by amelorating reactive oxygen species and oxidative stress induced damage to osteoblasts which occurs in postmenopausal states. Recently, our laboratory has shown that dietary aromatic amino acids have antioxidant properties, and when fed to aged C57Bl6 mices prevenst age-induced bone loss. However, the anabolic properties of aromatic amino acids on bone mass has not been investigated in low estrogen states. Based on these findings we hypothesized that endogenous antioxidants in the form of dietary supplements (aromatic amino acids) could prevent hypoestrogenic-induced bone loss. To address this question we placed three-month-old mice on a standard (18%) or low (8%) protein diet with/without aromatic amino acids supplements for four weeks after ovariectomy (OVX; n=10/group). Efffectiveness of the OVX was confirmed by uterine weight at the end of the experimental period. After four weeks the animals were sacrificed and analyzes included: bone densitometry (DXA), µCT, bone histomorphometry and serum markers of bone turnover. We found that OVX resulted in both trabecular and cortical bone loss (as measured by DXA and µ CT). Both cortical and trabecular bone loss was significantly ameliorated by the addition of aromatic amino acids ($p<0.03$; $p<0.05$ respectively). Further the OVX associated increase in PYD (a marker of bone breakdown) was inhibited by the aromatic amino acid supplement. Biomechanically, OVX was associated was associated with a decrease in ultimate force and stress at break and in Young's modulus, all significantly improved by the dietary aromatic amino acids. Taken together these data demonstrate that dietary aromatic amino acids significantly ameliorate OVX induced bone loss and that part of this protective effect may be through their antioxidant properties.

Effects of aging on bone turnover markers and bone density regulating hormones in cynomolgus monkeys. Rana Samadfam*, Susan Y. Smith. Charles River Laboratories, Canada

Values for bone turnover markers and hormones regulating bone density, including parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D3 (VD3) in monkeys, can vary significantly depending on diet, kit supplier, origin of animals, time of day for sample collection, age and/or gender. This study investigated the effect of aging on biochemical markers of bone turnover and hormones in male and female monkeys originating from Mauritius and China. The variability was minimized by using the same diet, the same time of day for sample collection and the same kit supplier. Serum samples were collected for measurement of bone formation markers: bone specific alkaline phosphatase (BAP), osteocalcin and P1NP, PTH and VD3 and bone resorption markers: C telopeptide (urinary and serum), urinary N-telopeptide and urinary Deoxypyridinoline (DPD). Urine markers were corrected for urinary creatinine. Serum and urine samples were collected in the morning from food deprived animals. Monkeys ranged in age from 12 months to over 15 years. Although the same suppliers were used for each kit, the lot number was different depending on the kit availability. The analyses for each parameter were carried out on separate occasions, months or years apart. Serum total calcium and phosphorus were also evaluated. All evaluated bone formation and bone resorption markers decreased with age. PTH levels did not decline with age however decreases were noted for VD3. Aging had no effect on serum total calcium levels although a trend for a decline was noted for serum phosphorous. No marked differences were noted between Mauritius and China origin animals or between males and females. The sharpest declines (2 to 6-fold) were noted between 6 to 9 years of age consistent with skeletal maturation (6 years). Values were the lowest and generally stable after the age of 9 years old (age of peak bone mass). In conclusion age-related decreases in serum and urinary bone turnover markers, serum phosphorous and VD3 were noted for cynomolgus monkeys.

Sirtuin1 increases ATP production, Wnt signaling, osteoblastogenesis, and bone mass in mice via a FoxO-mediated mechanism. Srividhya Iyer*[1], Li Han[1], Shoshana Bartell[1], Ha-Neui Kim[2], Aaron Warren[3], Julie Crawford[4], Igor Gubrij[5], Charles O'Brien[1], Stavros Manolagas[1], Maria Jose Almeida[1]. [1]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [2]Univ. Arkansas for Medical Sciences, Central Arkansas VA Healthcare System, USA, [3]University of Arkansas for Medical Sciences, & Central Arkansas Veterans Healthcare System, USA, [4]University of Arkansas for Medical Sciences, USA, [5]Central Arkansas Veterans Healthcare System, Division of Pulmonary & Critical Care, University of Arkansas for Medical Sciences, USA

FoxOs attenuate bone formation by binding to β-Catenin and preventing β-Catenin/TCF mediated transcription in osteoblast progenitors. The transcriptional activity of FoxOs is modulated by several post-translational modifications including deacetylation by Sirt1 – a NAD^+ dependent deacetylase. Based on this and evidence that Sirt1 activation by synthetic molecules attenuates the age-dependent loss of bone mass, we investigated whether the anabolic effects of Sirt1 on bone are mediated by FoxOs. To this end, we generated mice in which a Sirt1 floxed allele was deleted using an Osx1-Cre transgene ($Sirt1^{\Delta Osx1}$). $Sirt1^{\Delta Osx1}$ mice exhibited lower femoral and vertebral cortical bone mass as compared to Osx1-Cre littermate controls. In addition, bone marrow-derived osteoprogenitors from the $Sirt1^{\Delta Osx1}$ mice showed an increase in the association between FoxO3 and β-Catenin, as measured by co-immunoprecipitation assays. In line with this latter finding, the expression of the Wnt-target genes axin2 and cyclinD1 was decreased, as was the proliferation of osteoprogenitors as well as osteoblastogenesis, measured by Alizarin Red staining. In contrast, FoxO-mediated transcription (measured by the activity of a FoxO-luciferase reporter construct), as well as the mRNA levels of the FoxO-target genes Nocturnin, RhoE and hemeoxygenase (Hmox) 1, were increased. Hmox1 degrades heme – an essential cofactor for the stability and function of complexes III and IV of the electron transport chain – and thereby decreases ATP production. Consistent with evidence that ATP promotes cell growth and proliferation, osteoprogenitors from mice lacking FoxO1, 3 and 4 in Osx1-Cre expressing cells had lower Hmox1 expression, increased ATP production, and higher proliferation. Conversely, reconstitution of FoxO activity in an osteoprogenitor cell line (established from bone marrow of the mice lacking FoxO1, 3 and 4), increased Hmox1 mRNA, decreased ATP levels, and decreased proliferation. Taken together with evidence that NAD^+ and Sirt1 activity decline with age, our results suggest for the first time that the age-associated decline of bone formation is due, at least in part, to a FoxO-mediated increase in Hmox1 and the suppression of mitochondria ATP production. Stimulation of Sirt1 with synthetic activators antagonizes this effect and can explain the positive effects of these small molecules on bone formation.

Testosterone and its derivatives for the treatment of Sarcopenia in elderly males: A systematic review and Meta-analysis. Sara Mursleen*[1], Sultan Alamri[2], Alexandra Papaioannou[3]. [1]McMaster University, Canada, [2]King Abdulaziz University, Saudi Arabia, [3]Hamilton Health Sciences, Canada

Background: The incidence and burden of disease inflicting the elderly, such as Sarcopenia, is increasing with the aging demographic.The prevalence of Sarcopenia is 5-13% among individuals 60-70 years of age, and it increases to 11-50% among individuals 80 years and older. In 2010, the European Working group on Sarcopenia in older people reached a consensus on the definition of sarcopenia, which is a generalized loss of skeletal muscle mass and in addition a loss of either skeletal muscle strength or function.

Objective: To determine the impact of the administration of testosterone or testosterone-derivatives on muscle mass, strength, and function in elderly men.

Methods: A comprehensive and exhaustive search strategy was developed with a research librarian to identify randomized controlled trails which used testosterone/ derivatives as an intervention for men 50 years and older, with outcomes including muscle mass, strength, function, quality of life (assesed by using the Aging Male Symptoms Scale), and adverse events.

Results: 58 studies were identified for inclusion in the systematic review. A meta-analysis was completed on 8 studies up to date, with 50 studies pending. A statistically significant improvement in the intervention group was observed for muscle strength (SMD=0.37(95% CI 0.08,0.65) p=0.01). Muscle mass (SMD=0.38 (95% CI -0.19, 0.96), p=0.19), muscle function (SMD=0.04 (95% CI -0.14, 0.21), p=0.68),Somatic QoL (MD=-0.66 (95% CI -2.14, 0.83), p=0.39), Psychological QoL (MD=-0.71 (95% CI -1.47, 0.05), p=0.07), and Sexual QoL (MD=0.07 (95% CI -3.20, 3.34), p=0.97) did not yield statistically significant changes. There was no difference between groups in terms of major adverse events (OR=1.03 (0.72, 1.46), p=0.88).

Conclusion: Testosterone and its derivatives may be an important clinical intervention to increase muscle strength in sarcopenic individuals. Completion of meta-analysis of all 50 studies may provide greater insight into efficacy of remaining outcomes.

FGFR Inhibition Partially Corrects Size Abnormalities in $Nf1_{Col2}^{-/-}$ Mice. Matthew Karolak*, Xiangli Yang, Florent Elefteriou. Vanderbilt University, USA

Endochondral bone formation is a fascinating yet complex process by which long bones elongate during development and heal in adults. Genetic diseases and pathophysiological conditions can disrupt this process, causing various forms of dwarfism or fracture healing defects (non-union), for which therapeutic options are limited. Understanding how bones grow and mineralize with the proper speed and proportion during development should provide directions to design novel therapies promoting harmonious bone formation toward a functional skeleton and preventing cases of non-union. The chondrocyte is central to endochondral bone formation and repair, as the formation of a cartilage anlage/callus is a requisite first step in both processes and requires precise, spacio-temporal interactions. Patients with Neurofibromatosis Type 1 (NF1) can present with bowing of the tibia, fracture and impaired fracture healing, characterized by the presence of fibrotic, cartilaginous pseudoarthrosis (PA) tissue, suggesting that inactivating mutations in *NF1* negatively alters mesenchymal stem cells differentiation and chondrocyte differentiation/function during fracture healing. Our past work in mice lacking *Nf1* in *Col2a1*-positive cells ($Nf1_{Col2}^{-/-}$) showed that neurofibromin (the RAS/GTPase-activating protein encoded by *Nf1*) is required for normal growth plate formation and elongation. Mouse/human bone phenotypes associated by constitutive FGFR1 activation closely match with mouse models of *Nf1* loss-of-function in bone. Also, *Nf1* and *Fgfr1* expression overlaps in the growth plate. We thus hypothesized that neurofibromin is a negative regulator of FGFR1 signaling, and loss of FGFR1 in the growth plate would rescue the growth plate defects observed in $Nf1_{Col2}^{-/-}$ mice. We present here data indicating that genetic deletion of *Fgfr1* and *Nf1* together in *Col2a1*-positive cells does not rescue the defects observed in the $Nf1_{Col2}^{-/-}$ growth plates, including increased matrix catabolism at the osteochondral border and shortened hypertrophic zone length. These results suggest that pharmacological targeting of FGFR1 to treat NF1 PA may not be warranted. However, when $Nf1_{Col2}^{-/-}$ mice were treated with a pan-FGFR inhibitor (BGJ398), a partial correction of naso-anal length was observed after 18 days of treatment. Current studies are underway to determine the mechanism for this partial correction, including determining whether *Fgfr3* is ectopically expressed in the context of *Nf1* and/or *Fgfr1* deletion.

IGF-I Signaling in Osterix-expressing Cells Is Required for Secondary Ossification Center Formation during Postnatal Bone Development. Yongmei Wang*[1], Alicia Menendez[2], Chak Fong[3], Daniel Bikle[4]. [1]Endocrine Unit, University of California, San Francisco/VA Medical Center, USA, [2]Endocrine Unit, University of California, San Francisco/ Veterans Affairs Medical Center, USA, [3]Endocrine Unit, University of California San Francisco/Veterans Affairs Medical Center, USA, [4]Endocrine Research Unit, Division of Endocrinology UCSF & VAMC, USA

Secondary ossification center (SOC) formation is an important event during postnatal bone development, but its regulating mechanism is unclear. Our previous studies demonstrated that global insulin-like growth factor-I (IGF-I) knockout (KO) mice had delayed SOC formation. In the current study, we use bone and cartilage specific IGF-I receptor (IGF-IR) KO mice (^{OSX}IGF-IRKO) [floxed IGF-IR mice X GFP labelled osterix (OSX) promoter driven cre (^{OSX}GFP-cre)]. At Day 2 after birth (P2), ^{OSX}GFP-cre was highly expressed in the osteoblasts (OBs) in the bone surface of the metaphysis and in the prehypertrophic chondrocytes (PHCs) and inner layer of perichondral cells (IPCs). From P7, ^{OSX}GFP-cre was highly expressed in PHCs, IPCs, cartilage canals (CCs) and OBs in the epiphyseal SOC, but was only slightly expressed in the OBs in the metaphysis. H&E staining demonstrated that at P2, only cartilaginous tissue was found in the proximal epiphysis of the tibia in the ^{OSX}IGF-IRKO and their control littermates. In both mice, the perichondrium at the top of the epiphysis was getting thicker, but the small invaginations of the thickened perichondrium were observed only in the controls. At P7, in both mice, invaginations of the perichondrium invaded into the surrounding cartilage matrix and began to form the CCs, but the CCs formed in the ^{OSX}IGF-IRKOs were smaller and less in number. At P14, in both mice, canals excavated into the center of the cartilage generating the marrow space forming the SOC, but a smaller marrow space, less bone matrix, and more cartilage matrix were observed in the ^{OSX}IGF-IRKOs compared to the controls. Compared to the controls, the number of vessels and VEGF expression were less in the ^{OSX}IGF-IRKOs, as indicated by immunohistochemistry using antibodies against CD31 and VEGF, respectively. Ephrin B2, a regulator of VEGF production, was decreased in the ^{OSX}IGF-IRKOs compared with the controls. Quantitative real-time PCR revealed that the mRNA levels of the matrix degradation markers, MMP-9, 13 and 14 were decreased by 50%, 59% and 58%, respectively, in the ^{OSX}IGF-IRKOs compared to the controls. Our data indicate that during postnatal bone development, IGF-I signaling in OSX-expressing cells promotes cartilage matrix degradation and increases ephrin B2 production to stimulate VEGF expression and vascularization. These processes are required for normal CC formation in the establishment of the SOC.

Rotopol and MicroCT Imaging in the Regenerating Zebrafish Fin for BMD Therapeutic Discovery. Ronald Kwon*[1], Anthony Recidoro[2], Werner Kaminsky[2]. [1]University of Washington, USA, [2]University of Washington, USA

Osteoporosis is defined by low bone mineral density (BMD), an integrated measure of bone mass and mineralization that is associated with fracture risk. Though in vivo chemical and genetic screens hold unique potential to identify new therapeutic targets for enhancing BMD, they are challenged by the lack of models that are amenable to high-throughput approaches. Recently, we have initiated efforts to utilize the regenerating zebrafish tail fin, a model of rapid osteogenesis that recapitulates the major phases of human bone formation, for BMD therapeutic discovery. However, a major hurdle to such efforts is the lack of quantitative modalities for mineralization analysis in the zebrafish skeleton. Thus, our goals were to assess the correspondence between Rotopol microscopy (a quantitative form of birefringence imaging) and microCT in the regenerating fin, and to determine whether Botulinum toxin (BTx), a paralytic neurotoxin associated with mammalian osteogenic dysfunction, impairs bone mineralization in zebrafish. For Rotopol imaging, we implemented a custom polarized light microscope to synchronously acquire images under a stepwise rotating polarizer. By applying the appropriate relations [1], this enabled birefringence to be decoupled from transmittance and orientation, directly enabling quantitative analysis. Similar to our previous studies [2], BTx-injected fish exhibited reduced bone regrowth following tail fin amputation relative to saline-injected fish ($p<0.001$, d9). Rotopol and microCT imaging in regenerated bone rays revealed birefringence and TMD were highly correlated (R2=0.88, Fig 1AB), with correspondence occurring over the entire bone ray except near joints in non-regenerated tissue (due to birefringence from the fibrous inter-joint ligaments). In BTx-treated fish, Rotopol analysis revealed decreased birefringence ($p<0.05$ relative to saline controls) in the regenerated (but not non-regenerated) bone tissue (Fig 1C), suggesting that BTx impaired late-stage mineralization and/or secondary bone apposition but did not systemically induce demineralization in intact bone. Together, these studies establish sensitive and quantitative assays for bone mineralization analysis in the regenerating zebrafish fin, an essential first step toward integrating high-content microscopy with quantitative mineralization imaging for large-scale, systems-based screens of BMD accrual.

Use of Quantitative Micro-computed Tomography for Assessment of Skeletal Growth and Whole-body Composition in Mice. Kim Beaucage*[1], Steven I. Pollmann[2], Stephen M. Sims[2], S. Jeffrey Dixon[1], David Holdsworth[1]. [1]The University of Western Ontario, Canada, [2]The University of Western Ontario, Canada

Micro-computed tomography (micro-CT) is the gold standard technique for quantification of radio-opaque tissue mass in small animal models. Our goals were: i) to evaluate repeated *in vivo* micro-CT imaging as a means for monitoring whole-body composition in short and long-term studies of growth and development in mice; and ii) to establish reference values for normative comparisons. Male C57BL/6 mice from 2 to 52 weeks of age were anesthetized and imaged using an eXplore Locus Ultra and/or eXplore speCZT micro-CT scanner (GE Healthcare Biosciences). Micro-CT images were reconstructed into 3D volumes with nominal isotropic voxel spacing of 100, 150 or 154 μm. We assessed changes in whole-body composition (WBC) including adipose tissue (AT), lean tissue (LT) and skeletal tissue (ST) volumes, and bone mineral density (BMD) and content (BMC). Signal-intensity thresholds were used to classify each voxel as adipose, lean or skeletal tissue, and tissue masses were calculated from assumed densities of 0.95 (adipose), 1.05 (lean), and 1.92 (skeletal) g/cm^3. Images revealed changes in tissue distribution with aging, such as the mineralization of caudal vertebrae, loss of subcutaneous fat and increase in visceral adipose tissue. Quantification showed biphasic increases in total volumetric body mass, LT and ST masses and BMC, consisting of rapid increases between 2 and 8 weeks of age, followed by slow linear increases to 52 weeks. On the other hand, BMD rapidly increased to a stable plateau at ~14 weeks of age, doubling from 171 $\pm$ 7 at 2 weeks to 340 $\pm$ 6 mg HA/cm^3 at 52 weeks of age. In contrast, AT mass increased exponentially with age. A micro-CT-derived total mass was calculated for each mouse and compared with the gravimetrically measured mass, which differed on average by less than 3%. Body composition parameters were highly reproducible for mice of the same age, but variability increased slightly with age. There was also good agreement in parameters obtained from the same group of mice scanned on the eXplore Locus Ultra and eXplore speCZT systems. This study provides reference data for researchers using the C57BL/6 mouse model. As well, it demonstrates the ability of *in vivo* single-energy micro-CT scans to quantify whole body composition in high-throughput studies of development and aging in mice.

Bone Mineral Density Predicts Fractures in Predialysis Chronic Kidney Disease. Sarah West*[1], Charmaine E Lok[2], Roxana Bucur[3], Angela M. Cheung[4], Eva Szabo[2], Dawn Pearce[5], Sophie Jamal[6]. [1]University of Toronto, Canada, [2]University Health Network, Canada, [3], Canada, [4]University Health Network-University of Toronto, Canada, [5]St Michael's Hospital, Canada, [6]The University of Toronto, Canada

Fractures are common in chronic kidney disease (CKD). We utilized data from our cohort of 130 men and women with predialysis CKD to determine if low bone mineral density (BMD) by dual energy X-ray absorptiometry (DXA; at the lumbar spine, total hip, 1/3 and ultradistal radius), or high resolution peripheral quantitative computed tomography (HRpQCT; at the radius) at baseline would increase the risk of fractures over 2 years of follow-up.

Subjects were recruited from 3 predialysis clinics in the Greater Toronto Area. We included men and women aged 18 and older with stages 3 to 5 CKD estimated by the CKD-EPI formula. We excluded subjects taking bone active agents and those with prior renal transplants. We used T-tests to determine if BMD measures (by HRpQCT and DXA) and the annual percent loss of BMD differed by fracture status.

The mean age of the 130 subjects was 61.6 $\pm$ 2.4 years, mean weight was 73.9 $\pm$ 2.3 kg, most subjects were Caucasian (71%) and the number of subjects were equally divided into stages 3, 4 and 5 CKD. The most common cause of CKD was diabetes (56%) and the mean duration of CKD was 92 months. Over 2 years there were 101 fractures (61 morphometric vertebral) in 59 subjects. Compared to those without incident fractures, those with incident fractures were more likely to report falls at baseline (34% vs. 77%) and were more likely to have had a prevalent vertebral fracture (12% vs. 83%). BMD by DXA at baseline was significantly lower at the lumbar spine, total hip, 1/3 and ultradistal radius among those with incident fractures compared to those without. For example, the mean BMD at the total hip was 0.83 g/cm^2 (95% Confidence Interval (CI): 0.79 to 0.86) for the entire cohort, 0.86 g/cm^2 (95% CI: 0.82 to 0.91) in those without fractures and 0.79 g/cm^2 (95% CI: 0.75 to 0.84) in those with incident fractures. Similarly, all baseline HRpQCT measures were lower in those with incident fracture compared to those without. For example, volumetric BMD by HRpQCT at the radius was 273.07 mg HA/cm^3 (95% CI: 256.94 to 289.21) for the entire cohort, 304.45 mg HA/cm^3 (95%CI: 280.69 to 328.22) in those without fractures and 246.82 mg HA/cm^3 (95% CI: 227.06 to 266.58) in those with incident fractures. Bone loss, by DXA and HRpQCT occurred in all subjects over 2 years, but was statistically significantly greater among those with incident fractures.Our data suggest that low BMD by DXA and HRpQCT is a risk factor for fracture in predialysis CKD.

Effect of parathyroid function and bone turnover on bone structural and material properties in dialysis patients. Junichiro Kazama*[1], Ichiei Narita[2], Yoshiko Iwasaki[3], Masafumi Fukagawa[4]. [1]Niigata University Medical & Dental Hospital, Japan, [2]Niigata University, Japan, [3]Oita University of Nursing & Health Sciences, Japan, [4]Tokai University School of Medicine, Japan

[Background] A fracture risk in patients with chronic kidney disease (CKD) is remarkably high. Although abnormalities in parathyroid function and bone turnover are common found among CKD patients, their influence on bone microscopic structural properties and/or material properties remain obscure.

[Methods] Biopsied iliac bone samples obtained from 48 stable dialysis patients were subjected for the analyses. Quantitative histomorphometric studies were performed in the virtual 3-dimensional space generated from the serial micro-CT sections. Semi-quantitative analyses of bone material properties were performed with a Raman spectrometric method. The data were compared with the biochemical and tetracycline labeling–based 2-dimensional histomorphometric results.

[Results] Both the trabecular pattern factor and the structural model index showed significant inverse correlations with bone formation rate, whereas none of the marrow cavity star volume, the connection density, or the number of nodes showed significant correlation with it. Circulating intact PTH levels showed a significant inverse correlation with cortical bone thickness, whereas none of above 5 cancellous bone structural parameters showed correlation with parathyroid function. None of the pentosidine/collagen ratio, mineral /matrix ratio, maturity of physiological crosslinks, maturity of crystal showed significant association with bone turnover or parathyroid function. [Conclusions] In dialysis patients, cancellous bone structure becomes more like plate-shaped pattern with uneven surface, along with increased bone turnover. However, this morphological change did not directly link to altered cancellous bone connectivity. Although bone material changes are commonly found among dialysis patients, we could not detect any factors dependent on parathyroid function or bone turnover. Cortical bone thinning was the only likely findings related to parathyroid function, which would potentially increase fracture risk.

Inflammation and iron deficiency stimulate FGF23 production. Valentin David*[1], Aline Martin[2], Kimberly Zumbrennen-Bullough[3], Chia Chi Sun[3], Herbert Lin[3], Tamara Isakova[4], Jodie Babitt[3], Myles Wolf[5]. [1]University of Miami,Miller School of Medicine, USA, [2]University of Miami, USA, [3]Massachusetts General Hospital, USA, [4]Feinberg School of Medicine, Northwestern University, USA, [5]Feinberg School of Medicine, Northwestern University, USA

Iron deficiency and inflammation are common in CKD, and associated with elevated circulating levels of fibroblast growth factor-23 (FGF23). We tested the hypothesis that iron deficiency and inflammation regulate FGF23 production.

To investigate the effects of inflammation on FGF23 production, wild-type (WT) mice were injected with heat-killed Brucella abortus (BA), interleukin-1B (IL1B) or saline (control). To test the effects of iron deficiency, WT mice were fed low-iron or normal diets for 3 weeks.

Inflammation decreased serum iron levels 6 hours after injection of both BA and IL1B mice compared to control mice. In BA mice, inflammation was accompanied by increased FGF23 mRNA expression in bone and a 9-fold increase in serum C-terminal FGF23 levels (cFGF23, which detects both intact FGF23 and its inactive C-terminal cleavage fragments). IL1B-injected mice demonstrated a comparable 3.5-fold and 8-fold increase in cFGF23 at 3 and 6 hours post-injection, respectively. No acute changes in intact FGF23 (iFGF23) levels were observed during the early post-injection period in either model, suggesting that FGF23 production and cleavage initially increase in parallel in response to inflammation. By 4 days post-injection, serum iFGF23 levels increased by 1.4-fold in IL1B mice compared to controls. Consistent with increased bioactive FGF23, mRNA expression of renal Cyp24a1 increased 4–fold, Cyp27b1 decreased 3-fold, and Npt2a decreased 2-fold, resulting in increased urinary phosphate excretion. Sustained iron deficiency induced by a low iron diet mimicked the effects of inflammation and resulted in a 2.5-fold increase in cFGF23, a 3-fold increase in osseous FGF23 mRNA expression, and a 2-fold increase in iFGF23.

Inflammation and iron deficiency stimulate FGF23 production but secretion of the intact protein is overridden initially by a simultaneous increase in proteolytic cleavage of FGF23. Chronic inflammation and sustained iron deficiency, however, lead to increased intact FGF23. These data suggest that iron deficiency and inflammation may contribute to elevated FGF23 levels in CKD.

SU0004

Parathyroidectomy and serum leptin levels in stage 5 CKD patients. Ningning Wang*[1], Jingjing Zhang[2], Xiaoming Zha[2], Jianling Bai[3], Lina Zhang[2], Guang Yang[2], Changying Xing[2]. [1]Nanjing Medical University, Peoples Republic of China, [2]First Affiliated Hospital of Nanjing Medical University, China, [3]Nanjing Medical University, China

Background and objectives: Serum leptin is related to bone-mineral metabolism, nutrition and hematopoiesis in stage 5 chronic kidney disease (CKD) patients. Change of serum leptin level and its effects in CKD patients are controversial. This study aimed to evaluate the correlation between serum leptin with clinical and laboratory parameters and longitudinal changes of serum leptin after parathyroidectomy (PTX) in stage 5 CKD patients.

Methods: This cross-sectional study included 113 stage 5 CKD patients together with 76 controls, and a follow-up of two subgroups classified as successful (n=23) and unsuccessful (n=4) PTX from March of 2011 to October of 2013. Biochemical indices and serum leptin levels were measured.

Results: There was no difference between serum lnleptin (leptin values have been expressed as natural logarithms) levels in stage 5 CKD patients and healthy subjects(Table 1). Serum lnleptin in patients with stage 5 CKD was positive with BMI,serum triglyceride and albumin levels in males; BMI, hemoglobin, hematocrit and serum triglyceride level in females. However, serum lnleptin has a negative relationship with serum HDL (high density lipoprotein) and serum lniPTH (intact parathyroid hormone) in males, and serum HDL in females(Table 2). Compared with baseline, successful PTX subgroup had significant improvement in serum lnleptin level with a median follow-up of 5.70 months. Lnleptin change is positive related to weigt change, hemoglobin change and hematocrit change, while negative to lniPTH change. There was no significant change of serum lnleptin level in unsuccessful parathyroidectomy group with a median follow-up of 5.65 months(Table 3). From Table 4, serum lnleptin change correlated significantly with weight change(r=0.44, P=0.032), hemoglobin change(r=0.55, P=0.007), hematocrit change(r=0.51, P=0.013), and lniPTH change(r=0.44, P=0.034) in successful PTX group.

Conclusions: Serum lnleptin level has no difference between stage 5 CKD patients and healthy subjects. Serum lnleptin level is associated with bone-mineral metabolism, nutrition and hematopoiesis indexes in stage 5 CKD patients. Successful parathyroidectomy contributes to increased serum lnleptin level. Serum lnleptin change is positively related to weigt change, hemoglobin change and hematocrit change, while negatively to serum lniPTH change in successful PTX group.

Procollagen type-1 N-terminal propeptide (P1NP) levels by Elecsys assay correlate with bone formation rate in Chronic Kidney Disease. Serge Cremers*[1], David Dempster[2], Hua Zhou[3], Elzbieta Dworakowski[4], Mafo Kamanda-Kosseh[1], Thomas Nickolas[5]. [1]Columbia University, USA, [2]Columbia University, USA, [3]Helen Hayes Hospital, USA, [4]Columbia University Medical Center, USA, [5]Columbia University College of Physicians & Surgeons, USA

Renal osteodystrophy is characterized by a spectrum of bone turnover ranging from adynamic bone disease to osteitis fibrosa cystica. Bone turnover assessment is an absolute required for treatment and is currently determined by tetracycline double-labeled transiliac crest bone biopsy. Non-invasive turnover determination in CKD is controversial because most bone turnover markers (BTMs) are renally cleared. P1NP is a bone formation marker, circulating in a mono- and a trimeric form, which are cleared both renally and non-renally. Our group reported that higher total levels of P1NP predict bone loss in pre-dialysis and dialysis-dependent CKD patients. We

hypothesized that in CKD levels of total P1NP would correlate with bone formation rate (BFR) measured by biopsy.

In 22 patients (male=8; female=14; mean age ± SD 68 ± 11 years,) with CKD stages 2-5D, fasting morning blood was collected within 6-months of double tetracycline double-labeled transiliac bone biopsy. Total serum P1NP was measured by ECLIA (Elecsys 2010, Roche Diagnostics, Indianapolis, IN). Reference range was 20-100 ug/L. BFR (μm^3/ μm^2/day) was determined histomorphometrically in trabecular, endocortical and intra-cortical bone from biopsy using ASBMR criteria. Data is presented as mean ± SD. P1NP and BFR were log transformed prior to analysis and relationships were determined by Pearson correlations.

Results: Five patients were on hemodialysis (HD) and mean estimated GFR in pre-dialysis patients was 36 ± 17 mL/min. Mean BFR at trabecular, endocortical and intracortical regions were 0.018 ± 0.031, 0.019 ± 0.035 and 0.030 ± 0.038 respectively and there were no significant differences in BFR between pre-dialysis and HD patients. P1NP for the total, pre-dialysis and HD cohorts was 332 ± 585ug/L, 98 ± 51ug/L and 1125 ± 878ug/L respectively. P1NP levels were significantly greater in HD compared to pre-dialysis (p=0.004) and there were no significant relationships between P1NP and eGFR among pre-dialysis patients. There were significant, moderate and direct associations between P1NP and BFR in the three envelopes (R^2 0.41, 0.34 and 0.34, all $p<0.05$ for trabecular, endocortical and intracortical bone, respectively).

These data suggest that measurement of serum P1NP by the Elecsys assay correlates well with BFR in CKD. Larger studies are needed in CKD populations to validate this finding, and to determine whether P1NP predicts future fracture and can be used to guide treatment to protect against bone loss and fracture.

The increased expression of ASARM-MEPE by osteocytes is associated with bone mineralisation defect in hemodialysed patients. Martin Jannot*[1], Vasili Gnyubkin[1], Myriam Lessard[2], Norbert Laroche[1], Christophe Mariat[3], Luc Malaval[4], Laurence Vico[5], Marie-Helene Lafage-Proust[6]. [1]INSERM-U1059, France, [2]Hôpital du Sacré-Coeur , Service de Néphrologie, France, [3]Service de Néphrologie-CHU, France, [4]INSERM U1059-Université de Lyon-Université Jean Monnet, Saint-Etienne, France, [5]University of St-Etienne, France, [6]INSERM Unit 1059, France

Renal osteodystrophy (ROD) observed in chronic kidney disease (CKD) include 4 types of bone lesions according to the level of bone remodeling (high: osteitis fibrosa -OF- or low: adynamic bone disease -ABD) and mineralisation (osteomalacia -OM- and mixed uremic osteopathy). While high bone turnover is mostly linked to increased PTH serum levels, the pathophysiology of mineralisation defects and ABD remains obscure. DMP-1 and MEPE, two osteocyte matrix proteins of the SIBLINGs family are involved in bone mineralisation, indirectly (via DMP1-controlled FGF23 expression) and directly, their cleavage leading to the release of ASARM fragments which are both potent local inhibitors of mineralisation and phosphatonins. Furthermore, serum levels of sclerostin, another osteocyte protein which inhibits bone formation are highly increased in CKD. In this context, our working hypothesis was that osteocyte expression of these proteins might differ according to the ROD type.

Material and Methods: 26 iliac crest resin-embeded bone biopsies from hemodialysed patients (17 men, 10 women, mean age 59 ± 14 yrs) performed after double tetracycline labeling where selected and included: 5 ABD, 8 OF of various severity, and 13 patients with a mineralisation defect (OM or MUO). ROD type diagnosis was established according to bone histomorphometric criteria using Bone Formation Rate and mineralisation parameters (Osteoid volume and thickness and Mineralisation Lag Time). A control group consisting in bone biopsies from 10 non uremic osteoporotic patients or patients with normal bone histology was also analysed. We studied quantitatively, via semiautomatic image analysis, and qualitatively, the osteocyte expression of DMP1 , MEPE, ASARM-MEPE and sclerostin using indirect immunofluorescence after bone section decalcification and deplastification.

Results: MEPE was expressed in most of the osteocytes in both OF and OM lesions. In contrast, ASARM-MEPE was mainly observed in osteocytes of OM and MUO patients. (Fig-1:b: bone, m: marrow, arrow: immunolabelled osteocytes). While sclerostin was only present in osteocytes located at the center of trabeculae of OF and OM patients, a higher number of sclerostin-positive osteocytes were found in ABD. Finally, compared to non uremic bone, a dramatic increase in DMP-1 positive osteocytes was observed in all uremic patients.

Our results suggest that ASARM MEPE and Sclerostin may be involved in the pathophysiology of OM and ABD, respectively.

SU0007

Uremia exacerbates bone mechanical property in chronic kidney disease model rats with secondary hyperparathyroidism. Yoshiko Iwasaki[1], Junichiro Kazama[2], Masafumi Fukagawa*[3]. [1]Oita University of Nursing & Health Sciences, Japan, [2]Niigata University Medical & Dental Hospital, Japan, [3]Tokai University School of Medicine, Japan

Bone fragility has been demonstrated often in patients with chronic kidney disease (CKD) including dialysis patients. High turnover bone induced by elevated parathyroid hormone (PTH) could be a possible cause of reduced bone volume. However, relationship between bone fragility and PTH has not been clearly shown except for those with very high PTH level. In order to elucidate the mechanisms underlying bone fragility in CKD patients with secondary hyperparathyroidism, we analyzed property of bone from animal model. Rats underwent 5/6 partial nephrectomy (Nx) or sham operation (Sham). After 8 weeks, these Nx rats were divided into two groups. One group was treated with the oral adsorbent AST-120 (4g/kg body weight admixed in animal feed) (CKD Trt rats), which decreases the accumulation of uremic toxins in sera such as indoxyl sulfate, and the other group was treated with vehicle (CKD rats). All rats were sacrificed at 16weeks after Nx, then serum and femur were obtained. Value of femoral storage modulus in CKD rats assessed by dynamic mechanical analysis was lower than that of Sham rats. The degree of reduction reached to 60% of sham value. Bone chemical composition measured by raman spectroscopy, that mineral matrix ratio, the ratio of physical crosslinks, and apatite crystallinity was reduced whereas pentosidine to matrix ratio increased in CKD rats. In addition, cortical area and thickness decreased in CKD rats compared with that of sham rats. Administered oral adsorbent treatment suppressed the reduction of storage modulus. Chemical composition parameters in CKD Trt rat were similar to that of in sham rats. The levels of PTH concentration, the values of cortical area, and cortical thickness were not different in CKD rats either with or without adsorbent treatment. These results suggest that the accumulation of uremic toxins facilitate deteriorating mechanical properties through changes of material properties independent of bone micro structural changes in CKD with secondary hyperparathyroidism.

SU0008

What is the Threshold of Renal Function that Influences the Measurement of Biochemical Markers of Bone Turnover among Postmenopausal Women with Osteoporosis?. Pascale Chavassieux*[1], Jean-Paul Roux[2], Nathalie Portero-Muzy[3], Patrick Garnero[4], Roland Chapurlat[5]. [1]INSERM UMR1033, Université De Lyon, France, [2]INSERM, UMR 1033, Université de Lyon, France, [3]INSERM UMR 1033, Université de Lyon, France, [4]INSERM Research Unit, France, [5]E. Herriot Hospital, France

Some biochemical markers of bone turnover are excreted by the kidney. Consequently their serum concentration can be increased by renal failure, although the threshold of glomerular filtration rate (GFR) at which their concentration starts to rise is unknown. Abnormalities of bone remodeling are also observed when the renal function is declining (osteodystrophy), which also confounds the increase in

serum markers. The purpose of this study was to evaluate the relationship between the GFR and the bone remodeling assessed either by serum biochemical markers (bone alkaline phosphatase, Bone ALP; collagen type 1 N-propeptide, P1NP) and resorption (C-terminal crosslinking telopeptide of collagen type 1, sCTX) and osteoprotegerin (OPG) or the gold standard bone histomorphometry, in a large population of postmenopausal women with osteoporosis. 370 untreated postmenopausal osteoporotic women aged 50 to 84 yrs were selected. The creatinine clearance was estimated by the CKD-EPI equation. Transiliac bone biopsies were obtained after a double tetracycline labeling. The static (Ob.S/BS, OS/BS, OV/BV) and dynamic (MS/BS, BFR/BS, FP, Omt, Mlt, Acf) parameters of formation, and the parameters of bone resorption (ES/BS, Oc.S/BS, EV/BV, E.De) were measured.

In patients with CKD-EPI > 60 ml/min/1.73m2, the markers of formation (Bone ALP, P1NP) and of resorption (sCTX) were significantly correlated with the histomorphometric parameters of formation and resorption, respectively, but no significant correlation was observed between CKD-EPI and the biochemical markers or the histomorphometric parameters of bone turnover. In contrast, in patients with an altered renal function (CKD-EPI<60 ml/min/1.73m2), significant and negative correlations were observed between CKD-EPI and the histomorphometric parameters of formation (OS/BS, OV/BV, O.Th, FPa, Omt): -0.59<r<-0.43, 0.03>p>0.002, but no correlation was found between the biochemical markers and the histomorphometric parameters.

These results suggest that when the renal function is normal or moderately impaired (CKD-EPI>60 ml/min/1.73m2), serum levels of bone markers are not influenced and reflect the bone turnover. In contrast, when the renal function is impaired more importantly (CKD-EPI<60 ml/min/1.73m2) the serum biochemical bone markers reflect the renal function rather than the bone turnover itself.

No significant change in Bone mineral density after vitamin D supplementation in young and elderly women : Results from 2 randomized trials. SRI HARSHA Tella*[1], J. Christopher Gallagher[2], Lynette Smith[3]. [1]Creighton University School of Medicine, USA, [2]Creighton University Medical Center, USA, [3]University of Nebraska, USA

BACKGROUND: Vitamin D is often recommended for use with calcium supplements to increase bone mineral density (BMD) and prevent osteoporosis, however there are few systematic studies on effect of different doses of vitamin D supplementation on BMD.

METHODS:We conducted two randomized, placebo-controlled trials in women with vitamin D insufficiency (serum 25-hydroxyvitamin D ≤20 ng/dl/50 nmol/liter). Subjects in one trial were aged 25–45 years (198 Caucasian and African American) and in the other were aged 57-90 years (273 Caucasian and African American women). Older women were randomly assigned to placebo, vitamin D3 400, 800, 1600, 2400, 3200, 4000, or 4800 IU daily; calcium supplements were given to maintain total calcium intake of 1200-1400 mg/d. Younger women were randomized to placebo, 400, 800, 1600 and 2400IU/d and calcium intake was increased to 1000mg/d. Statistical difference between groups was tested by ANOVA.

RESULTS: In the older women the mean percent change in all subjects for BMD at 12 months was; total body, 0.62%(+2.72), there was no difference between Caucasian and African Americans (p=0.74). The percent change in femoral neck was 0.59% (+3.58) and there was no difference between races (p=0.64). The percent change in spine was 0.43% (+2.80) and there was no difference between the races. There was no significant difference in BMD at any site between various vitamin D doses and placebo.In the younger women the percent change in all subjects for BMD at 12 months was; total body 0.57% (+2.09),there was no difference between Caucasian and African Americans (p=0.70). The percent change in femoral neck was 0.79% (+3.02) ,there was no difference between races (p=0.62). the percent change in spine was 1.22% (+2.41) and no difference between races(p=0.60). There was no significant effect of vitamin D on BMD at any site between various doses of vitamin D and placebo.

CONCLUSION: The increase in total body, spine and hip BMD in young and elderly women given vitamin D doses between 400 and 4800 IU daily and calcium supplementation is small and is not different from placebo. It remains to be seen whether there is any effect on fractures in these populations.

Large genomic deletions inactivate the MEN1 gene in Multiple Endocrine Neoplasia (MEN1) families. Filomena Cetani*[1], Elena Pardi[2], Simona Borsari[2], Federica Saponaro[2], Chiara Banti[2], Edda Vignali[3], Antonella Picone[2], Antonella Meola[2], Claudio Marcocci[4]. [1]University Hospital of Pisa, Italy, [2]Department of Clinical & Experimental Medicine, University of Pisa, Italy, [3]University Hospital of Pisa, Italy, [4]University of Pisa, Italy

MEN1 is an autosomal dominant disorder characterized by tumours in multiple endocrine glands, most commonly parathyroid, enteropancreatic and anterior pituitary glands. To date, germline mutations in the MEN1 gene have been identified in about 70–80% and 30% in familial and sporadic MEN1 cases, respectively. The MEN1 gene exons spans 9 kb of the genome encoding the menin protein with tumor suppressor function. More of 2/3 of MEN1 mutations, spread across the coding region, lead to a truncated protein, confirming a loss-of-function mechanism. A lack of a genotype-phenotype correlation has been observed. Approximately 20–30% of MEN1 patients do not have MEN1 mutations detected with conventional mutation screening methods. Up to date 12 large germline MEN1 deletions have been reported in unrelated MEN1 probands, accounting for around 3% of MEN1 cases analyzed.

The aim of this work was to evaluate if the MEN1 mutation detection rate can be increased by the occurrence of large monoallelic MEN1 gene deletions. We used Multiplex Multiplex Ligation-dependent Probe Amplification (MLPA) assay to identify gene copy number variations in a group of 25 MEN1 index cases (7 familial and 18 sporadic) negative for MEN1 mutations on direct sequencing. These cases belong to a cohort of 54 MEN1 probands, 33 of whom with a family history of the disease. At MEN1 sequencing analysis we found 29 germline mutations (54%), 26 of whom occurring in familial cases (79%). 72% of all detected mutations were frameshift, nonsense or affecting splice site junctions. MLPA experiments were performed on DNA obtained by patients' blood samples, using the SALSA MLPA probemix kit P244-B1 (MRCHolland), according to the manufacturer's instructions.

We found four MEN1 large deletions; a deletion spanning the whole gene in 2 kindreds, one encompassing the 5'UTR region, exons 1 and 2 in one sporadic case, and a deletion of exons 9-10 in a familial case.

We established that in our study alteration of the MEN1 gene can explain around 90% of MEN1 familial cases of Italian origin, since MEN1 large deletions account for 10% of all germline MEN1 mutations in MEN1 kindreds. We didn't observe any association between the type of mutations and the clinical characteristics of the disease. We recommend to include MLPA assay in the routine analysis for MEN1 mutations, especially in families without detected germline mutations, as this type of large MEN1 deletions were detected in 40% of MEN1 mutation negative cases.

Urinary Calcium Excretion in Postmenopausal Women of African Ancestry. Mageda Mikhail*[1], shahidul islam[2], Albert Shieh[3], John Aloia[4]. [1]Winthrop University Hospital, USA, [2]winthrop university hospital, USA, [3]University of California, Los Angeles, USA, [4]Winthrop University Hospital, USA

PURPOSE: African Americans have lower urinary calcium excretion than white Americans. The primary purpose of this study was to develop a reference range for calcium excretion in postmenopausal black women and compare it to white women. A secondary objective was to evaluate the reliability of the fasting urinary calcium/creatinine ratio in predicting 24-hour urinary calcium excretion.

METHODS: Baseline data collected in 7 studies at one site for research purposes in 1,042 healthy black and white postmenopausal women were analyzed. In some studies, only fasting urinary calcium/creatinine ratio was available whereas in others, 24-hour urinary calcium excretion was measured as well. Reference ranges were calculated for 24-hour urinary calcium and fasting urinary calcium/creatinine ratio in each ethnic group. Correlations with demographics and selected laboratory values were calculated. Multiple linear regression model was developed to determine the predictors of the 24-hour urinary calcium excretion. Sensitivity-Specificity and agreement analyses were employed to determine the usefulness of fasting urinary calcium/creatinine ratio compared to 24-hour urinary calcium for detecting hypercalciuria and hypocalciuria.

RESULTS: Reference intervals for the 24-hour urinary calcium and for the fasting urinary calcium/creatinine ratio were 16 -180 mg /24 hours and 0.008 - 0.16 for African American women compared to 25 - 212 mg/24 hours and 0.026 - 0.23 in white women, respectively. Urinary creatinine excretion was higher in African Americans consistent with their higher muscle mass. Fasting urinary calcium/creatinine ratio was not a reliable predictor of 24-hour urinary calcium in either ethnic group.

CONCLUSION: Clinicians should be aware of the lower calcium excretion in African American women. In particular, the lower reference range should be considered when evaluation is made for hypocalciuria disease. The fasting urinary calcium/creatinine ratio should not be used as a substitute for 24-hour urinary calcium excretion.

A mutation in the TRAF6-binding domain of SQSTM1/p62 associated with Paget's disease of bone is associated with hyper-activation of signalling. Sarah Rea*[1], Melanie Sultana[2], John Walsh[2], Nathan Pavlos[3], Jiake Xu[4], Lynley Ward[2], Robert Layfield[5], Thomas Ratajczak[2]. [1]Sir Charles Gairdner Hospital, Australia, [2]Dept Endocrinology & Diabetes, Sir Charles Gairdner Hospital, Australia, [3]University of Western Australia, Australia, [4]University of Western Australia, Australia, [5]University of Nottingham, United Kingdom

Introduction: Paget's disease of bone (PDB) is characterised by focal areas of increased bone remodelling, thought to be initiated by increased bone resorption by hyperactive osteoclasts and exacerbated by abnormal bone formation. Mutations in the SQSTM1/p62 gene are a common genetic cause of PDB and commonly affect the ubiquitin associated (UBA) domain region of the protein.

Methods: We assessed mutational effects on NF-κB and activator protein 1 (AP-1) activity using the Dual Luciferase assay (Promega). To assess mutational effects on TRAF6 ubiquitination, we co-transfected cells with expression plasmids for Ubiquitin, TRAF6 and SQSTM1/p62. Cells were lysed with RIPA buffer, clarified and subjected to immunoprecipitation with FLAG antibody. Antibody and bound proteins were bead-captured and following extensive washes bound proteins were eluted with SDS sample buffer and separated by SDS-PAGE, followed by Western blot analysis.

Results and Discussion: We report a non-conservative change (K238E) that manifests within the TRAF6-binding domain of SQSTM1/p62 that co-segregates with PDB in a family that displays a severe disease phenotype. Over-expression of this mutant protein leads to increased basal activity of NF-κB and AP-1, important mediators of osteoclast formation. These transcription factors are induced by upstream activation of TRAF6 (via auto-ubiquitination).

SQSTM1/p62 is required for TRAF6 ubiquitination, yet also mediates negative regulation of NF-κB and osteoclastogenesis by linking the de-ubiquitinating enzyme CYLD with TRAF6 at the proteasome. We find that K238E expression leads to a marked increase in the amount of poly-ubiquitinated TRAF6 observed. This finding is consistent with the increased signalling we routinely observe with this and other SQSTM1/p62 mutant proteins, and is thought to contribute to increased osteoclasts and bone resorption in PDB lesions.

Conclusions: We find that mutant SQSTM1/p62 expression leads to increased activation of transcription factors important for osteoclast signaling. This is associated with increased levels of ubiquitinated TRAF6, which may partially explain the molecular mechanisms of increased osteoclast activity in SQSTM1/p62 associated PDB.

SU0014

A Prospective Study on Juvenile Primary Hyperparathyroidism Population. Federica Saponaro*[1], Federica Cacciatore[2], Elena Pardi[2], Simona Borsari[2], Claudio Marcocci[3], Filomena Cetani[4]. [1]M.D., Italy, [2]U.O. Endocrinology 2, Italy, [3]University of Pisa, Italy, [4]University Hospital of Pisa, Italy

Primary hyperparathyroidism (PHPT) is generally an adult disease and features of PHPT in juvenile population (J-PHPT) are still unclear.

The aim of the study was to evaluate the clinical, biochemical, densitometric and hystological characteristics in patients with J-PHPT, comparing sporadic (S) and familiar (F) J-PHPT.

We conducted a monocentric prospective study in 154 patients with ≤40 years and a median follow-up of 2 years (1-8). We compared the clinical presentation, the changes of biochemical, densitometric, histological parameters at diagnosis and at the last follow-up visit, between S and F-JPHPT.

One hundred-twelve patients had S-J-PHPT (neuroendocrine markers, calcitonin, pituitary hormones and serum calcium in relatives were in the normal range). Thirty-one patients had Multiple Endocrine Neoplasia type 1 (MEN1) syndrome and 11 Familiar Isolated Hyperparathyroidism (FIHP). Symptomatic nephrolitiasis was observed in 69.44% of S-J-PHPT and in 48.4% of F-J-PHPT.

Ninety S-J-PHPT and 27 F-J-PHPT underwent PTx. The histology showed in S-J-PHPT and F-J-PHPT respectively: a single adenoma in 85 and 7 patients, hyperplasia in 2 and 19 patients , carcinoma in 2 S - JPHPT and white cervicotomy was observed in one S-JPHPT and one F-JPHPT.

Ionized serum calcium and PTH significantly decreased after PTx in both S and F-JPHPT. Eleven (15%) patients with S-PHPT had persistence/recidive of PHPT and included one with white cervicotomy, one with hyperplasia and 9 with single adenoma. The persistence/recurrence rate was higher (n=10, 52.63%) in F-JPHPT compared with S-PHPT.

In both groups a more severe disease in term of serum Ca++ (S-PHPT p=0.039, F p=0.027), PTH (S p= 0.045, F p= 0.7) and radial Z score (S p= 0.001, F p=0.002) was observed in males compared with females.

Age was not significantly correlated with the severity of disease in term of Ca++, PTH and Z score in both groups; basaline serum Ca++ was significantly associated with PTH levels and severity of bone disease (Z score)

When the patients were stratified for age ≤25 and > 26 years, there was no statistical difference in the overall group or when comparing F-JPHPT and S-JPHPT.

In conclusion, J-PHPT seems to be a sintomatic disease confirming literature's data. J-PHPT is more severe in male than in females and has a higher rate of persistence/recurrent disease, even in S-J-PHPT patients. The severity of disease is independ from age and the clinical characteristic between S and F patients are similar.

SU0015

Beneficial Effects of PTH(1-84) in Hypoparathyroidism as Determined by Trabecular Bone Score (TBS). Cristiana Cipriani*[1], Barbara Silva[2], Natalie Cusano[3], Aline Costa[4], Dinaz Irani[5], Alice Abraham[4], Donald McMahon[3], Laura Beth Anderson[4], Elizabeth Levy[6], Mishaela Rubin[4], John Bilezikian[3]. [1]"Sapienza", University of Rome, Italy, [2]Federal University of Minas Gerais, Brazil, Brazil, [3]Columbia University College of Physicians & Surgeons, USA, [4]Columbia University, USA, [5]Columbia University Medical Center, USA, [6]Columbia University, USA

Trabecular bone score (TBS) is a texturral index reflecting trabecular micro-architecture, as seen more directly by μCT and HRpQCT measurements. We have shown previously that TBS is normal in hypoparathyroid (HypoPT) patients, that PTH(1-84) improves TBS in premenopausal (PreM) women, and that PTH(1-84) preserves it in postmenopausal (PostM) women and men over a 4-year treatment period. Yet, no data are available on the effects of PTH(1-84) using TBS in HypoPT over a longer period of time. In this report, we provide new data on the effects of PTH(1-84) on TBS in HypoPT patients over an average of 5.5 years.

We studied 29 HypoPT subjects [22 women (10 PreM and 12 PostM) and 7 men; mean age 48.2 ± 13.4 yrs] treated with PTH(1-84) for a mean follow-up time of 69 ± 16 months (range 48-102). Site-matched LS TBS data were extracted from the DXA image (Hologic) using TBS iNsight software. Linear mixed model for repeated measures was performed to assess the % change in TBS relative to baseline by evaluating sex-specific differences and all results are adjusted for weight.

PreM women were younger than postM (35.6 ± 8 and 56.4 ± 8.9;$p<0.0001$) and men (52.1 ± 13.5;$p<0.01$). Mean TBS value was normal (1.428 ± 0.138; normal ⩾1.35) but lower in PostM (1.358 ± 0.136) than in PreM women (1.491 ± 0.105;$p<0.05$) at baseline. In the entire cohort, PTH(1-84) improved TBS throughout the entire follow-up period ($p<0.0001$). In particular, there was a significant increase from 42 (+2.25 ± 0.94%;$p<0.02$) to 60 months (+2.85 ± 1.02%;$p<0.01$). The mean gain at 102 months was 1.73 ± 3.55%. TBS significantly increased in PreM women by 2.96 ± 1.25% ($p<0.02$) at 36 and up to 84 months (+5.38 ± 2.17%;$p<0.05$), and in PostM women at 42 (+3.66 ± 1.53%;$p<0.02$) and 48 months (+4.24 ± 1.5%; $p<0.01$), while no changes were observed in men. Percent TBS changes were different among the 3 groups at 72 months (male vs PreM and PostM:$p<0.05$; PreM vs PostM:$p<0.0001$). A positive correlation between the % changes in TBS and LS BMD was observed at 24, 36 ($r=0.4$;$p<0.05$), 48 ($r=0.4$;$p<0.01$), 60 and 66 months ($r=0.5$ and 0.6;$p<0.02$).

In this study, we have shown that PTH(1-84) improves TBS in hypoPT over a period of time that exceeds any previous experience with long term use of PTH(1-84). In PreM women, TBS continues to increase for up to 7 yrs, thus confirming that microstructural improvements due to PTH(1-84) are particularly evident in younger individuals. There were no safety issues associated with long-term administration of PTH(1-84).

Parathyroidectomy-Associated Thyrotoxicosis: A Prospective Cohort Study. Lisa-Ann Fraser*[1], Stan Van Uum[2], Terri Paul[3], John Yoo[2]. [1]Western University, Canada, [2]University of Western Ontario, Canada, [3]St. Joseph's Health Centre, Canada

Purpose: Reports exist describing transient thyroid hormone elevation occurring after parathyroidectomy. We aimed to describe, in detail, changes in thyroid function occurring around the time of parathyroidectomy.

Methods: Consecutive adult patients with hyperparathyroidism who underwent parathyroidectomy were studied. Pre-operative bloodwork measured TSH, free T4, free T3, 25-hydroxyvitamin D, parathyroid status, and thyroid auto-antibodies. The type of surgery performed, and extent of thyroid manipulation was documented. Patients had blood work repeated on post-operative days 1, 3, 7, and 14. Between post-operative day 7 and 14 an Endocrinologist administered a standardized questionnaire and physical assessment and continued follow up out to 2 months.

Results: Nine consecutive patients were reviewed, 6 females and 3 males, 4 (females) were excluded due to pre-existing hypothyroidism. Of the 5 patients followed, all underwent 4-gland exploration, and 4(80%) developed hyperthyroidism in the post-operative period as documented by elevated serum free T3 and/or free T4. Two patients (40%) experienced symptomatic thyrotoxicosis. Free T3 was the first hormone to move outside of the normal range; it was found to be elevated as early as the first post-operative day. Free T4 showed maximal elevation at post-operative day 3. By post-operative day 14 all levels had fully normalized and remained normal when checked 1 month, and 2 months post-surgery. Symptomatic patients reported that symptoms lasted for approximately 2 weeks after their operation and then resolved completely. There was no association between pre-operative calcium level severity and

the subsequent development of post-operative hyperthyroidism. Similarly, vitamin D insufficiency did not predict thyroid hormone changes. No patient tested positive for anti-thyroid antibodies either pre or post-operatively, and none had recent iodine exposure or family history of hyperthyroidism.

Conclusions: Hyperthyroidism, including symptomatic thyrotoxicosis, occurs commonly after parathyroidectomy for hyperparathyroidism. Thyroid hormone levels seem to peak early in the first week after the operation, but stay elevated for up to 14 days. It may be prudent for physicians to warn their patients about this potential complication of surgery, and possibly consider adding beta-blockers during the first two weeks post-op in patients who are at high risk of cardiac complications from thyrotoxicosis.

Protein Expression of Fibroblast Growth Factor Receptor/α-klotho, Vitamin D Receptor, CYP24A1 and CYP27B1 in Parathyroid Adenoma. A Ram Hong*[1], Jung Hee Kim[2], Chan Soo Shin[2], Seong Yeon Kim[1], Hye Sook Min[1], Sang Wan Kim[3]. [1]Seoul National University Hospital, South Korea, [2]Seoul National University College of Medicine, South Korea, [3]Seoul National University College of Medicine, Boramae Hospital, South Korea

Objective: Parathyroid hormone (PTH) secretion from parathyroid gland is regulated by circulating 1,25(OH)2D3, FGF23 and extracellular calcium. We aimed to investigate the role of FGFR, α-klotho, VDR, CYP24A1 and CYP27B1 in the pathogenesis of primary hyperparathyroidism (PHPT).

Methods: We included 66 patients who underwent parathyroidectomy for PHPT and 29 control patients with normal parathyroid in Seoul National University Hospital from January 2001 to December 2011. All patients diagnosed with PHPT had parathyroid adenomas. We evaluated the protein expression of FGFR, α-klotho, VDR, CYP24A1 and CYP27B1 in parathyroid gland using tissue microarray.

Results: FGFR, CYP24A1 and CYP27B1 were mainly expressed in cytoplasm, whereas α-klotho and VDR were expressed both in nucleus and cytoplasm. Nuclear and overall VDR expressions were significantly reduced in PHPT compared with the control group ($P<0.001$ and $P=0.012$, respectively). There were no significant differences in FGFR, α-Klotho, CYP24A1 and CYP27B expressions between the PHPT and the control. Nuclear VDR negatively correlated with serum levels of PTH ($R=-0.229$, $P=0.033$). There was negative correlation between α-klotho expression and serum levels of PTH ($R=-0.429$, $P<0.001$), whereas positive correlation was found between α-klotho expression and serum 25(OH) vitamin D3 levels ($R=0.452$, $P=0.015$).

Protein expression of α-Klotho, VDR, CYP24A1 and CYP27B1 were positively correlated in both PHPT and control group. Interestingly, FGFR expression was positively correlated with CYP24A1 expression only in PHPT group ($R=0.224$, $P=0.036$).

Conclusion: The protein expression of VDR was reduced in patients with parathyroid adenoma. Moreover, it was negatively correlated with serum PTH levels. This study showed low VDR and interaction among VDR, FGFR/α-klotho and enzymes involved in vitamin D metabolism may contribute to development of parathyroid adenoma.

SU0018

A Semi-Automated Method for Defining Cortical Bone Breaks in Cadaveric Finger Joints using High-Resolution peripheral QCT and MicroCT. Michiel Peters*[1], Andrea Scharmga[2], Astrid Van Tubergen[3], Joop Van Den Bergh[4], Chris Arts[3], Bert Rietbergen[5], Piet Geusens[6]. [1]Maastricht University, The Netherlands, [2]Maastricht University, Netherlands, [3]MUMC, Netherlands, [4]VieCuri MC Noord-Limburg & Maastricht UMC, The Netherlands, [5]Eindhoven University of Technology, The Netherlands, [6]University Hasselt, Belgium

Radiography is considered the gold standard for visualizing bone erosions in rheumatic diseases. Detection of these erosions at an early stage may be relevant for clinical practice. Cortical breaks, which may be the first signs of erosions, cannot be seen on radiographs but are visible on High-Resolution peripheral QCT (HR-pQCT) and microCT (μCT). Visual scoring for these scans is laborious and inaccurate though.

To develop a semi-automatic algorithm for detection of cortical breaks in interphalangeal joints based on HR-pQCT and μCT scans and compare the results with visual scoring.

Fifteen interphalangeal joints from 8 female cadaveric index fingers were scanned by HR-pQCT (82 μm) and μCT (18μm). A semi-automated algorithm was applied twice by 2 independent readers to the HR-pQCT and once to the μCT scans. First, the periosteal surface of the bone structure was contoured. Second, a constant thickness of 0.25mm was chosen to identify the cortical bone. Last, breaks <0.5mm were discarded from this cortical bone structure. Separately, cortical breaks were visually scored from μCT images by 2 independent readers. A cortical break was defined as an interruption of cortical bone seen on 8 consecutive slices in two orthogonal planes. Descriptives and intraclass correlation coefficients (ICC) were calculated.

When applying the algorithm for the HR-pQCT scans, 252 cortical breaks (mean ± SD; 16.8 ± 13.5 per joint) were found by reader 1 and 249 (16.6 ± 14.3 per joint) by reader 2, with an ICC of .962, $p<.001$. The total number of cortical breaks found on the μCT was 491 (32.7 ± 27.1 per joint) with the algorithm and 225 (15.0 ± 5.0 per joint) with visual scoring, with an ICC of .012, $p=.488$. The ICC for comparison of μCT with HR-pQCT when applying the algorithm was .728, $p=.001$. The ICC between reader 1 and 2 with visual scoring on μCT was .563, $p=.054$.

Although some user input is still needed, a high inter observer reliability with the algorithm was found for the HR-pQCT. A good correlation was found between the HR-pQCT and μCT with the algorithm, although the number of cortical breaks detected by μCT was about twice as high with respect to HR-pQCT. The correlation between visual scoring and the algorithm was poor. In conclusion, the use of a semi-automated algorithm is a promising tool in the early detection of cortical breaks. Further research is needed for clarification of the difference in visual scoring and the algorithm.

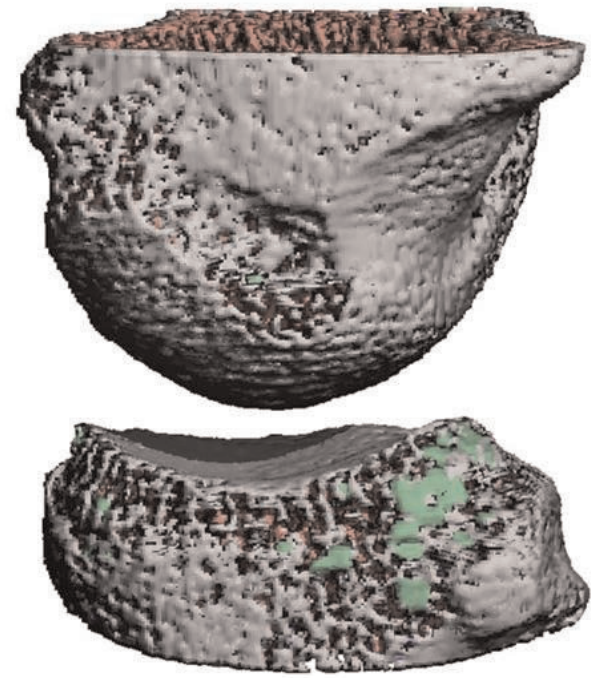

Figure 1. Shown is an example of a 3D reconstruction of a finger joint of a HR-pQCT scan. Shown in different colors are the different bone compartments as obtained by the algorithm. White: cortical bone structure. Red: trabecular bone structure. Green: cortical breaks >0.5mm

Age Related Changes in the Structure, Composition and Properties of Porcine Cortical Bone. Iwona Jasiuk*[1], Michael Chittenden[2]. [1]University of Illinois at Urbana-Champaign, USA, [2]University of Illinois, USA

Composition-structure-property relations of bone provide fundamental understanding of bone quality. In this paper we report on the age dependent changes in the composition, structure, and mechanical properties of porcine femoral cortical bone at the mid-diaphysis region from six age groups (1, 3.5, 6, 12, 30 and 48 months). This study was motivated by the fact that limited date is available in the literature on porcine cortical bone during development. Porcine bone was chosen because its biology is similar to human bone. Scanning electron microscopy was used to quantify changes in the ultrastructure of bone at different quadrant positions. High resolution microscopy was used to measure the porosity and visualize three dimensional void structures (canals, resorption cavities and lacunae). Ash and water content tests were performed to measure water and organic and mineral contents of bone as a function of age. The mineral content increased with age while the porosity decreased. Nanoindentation technique with Berkovich fluid tip was employed to measure the elastic modulus and hardness at the nanoscale. Individual lamellae were indented in the longitudinal direction of bone in differetn structural components (osteonal, interstitial and plexiform bone). We found that the elastic modulus and hardness increased with age but at different rates in each microstructural component. Finally, reference point indentation was used to measure the average stiffness (Avg US), indentation distance increase (IDI), total indentation distance (TID), average energy dissipated (Avg ED), and creep indentation distance (CID) as a function of anatomical position within the femoral cross-section and as a function of loading direction (transverse and longitudinal). The Avg US increased, while IDI, TID, Avg

ED, and CID decreased with age on both transverse and longitudinal surfaces. The transverse surface measurements generally exhibited higher Avg US and lower IDI and TID compared to those measured on the subperiosteal surface. This research provides new insights on the composition, structure and properties changes in cortical bone at early ages.

SU0020

Association Between Reference Point Indentation Measures and Cortical Bone Composition, Bending Properties, and Fracture Toughness. Lamya Karim*[1], Nathalie Portero-Muzy[2], Daniel Brooks[3], Evelyne Gineyts[2], Pascale Chavassieux[4], Roland Chapurlat[5], Mary Bouxsein[1]. [1]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [2]Universite de Lyon, France, [3]Beth Israel Deaconess Medical Center, USA, [4]INSERM UMR1033, Université De Lyon, France, [5]E. Herriot Hospital, France

Assessment of cortical bone tissue mechanical properties both *in vivo* and *in vitro* is now possible by reference point indentation (RPI, Active Life Scientific) [1,2]. Clinical studies show worse cortical bone properties in women with hip fracture and type II diabetes [3,4]. Yet, little is known regarding the factors that influence RPI measurements and whether RPI measurements are associated with bone mechanical properties assessed by standard testing protocols [5]. Thus, we aimed to determine factors that may influence RPI measurements and the ability of RPI to reflect traditional mechanical properties using cortical bone specimens from sheep.

Sixteen sheep (age 8.1 ± 0.4 years) were randomly assigned to receive a vehicle or zoledronic acid for 3 months [6]. Two cortical beam specimens (~3.4 x 2.8 x 36.1 mm) per sheep were excised from the femoral posterior-lateral and posterior-medial quadrants. Cortical tissue mineral density (TMD) and cortical porosity (Ct.Po) were assessed by microCT, and indentation properties by RPI (9 N, 2 Hz, 10 cycles). Then one beam per animal was tested to failure by 4-point bending and the other by fracture toughness testing. A portion of cortical bone was used to quantify pentosidine, an advanced glycation end-product (AGE), using HPLC.

There were no differences between ZOL and VEH-treated specimens, so they were pooled for all analyses. RPI variables worsened with increasing Ct.Po and decreasing TMD (Table 1). Indentation distances were greater with increasing pentosidine content (r=0.44-0.67). Bending work-to-failure correlated positively with RPI-assessed average energy dissipation, whereas fracture initiation and propagation toughness values correlated negatively with RPI-derived loading and unloading slopes. No other RPI variables were associated with bending or fracture toughness properties.

In summary, our results indicate that increased porosity, decreased mineralization, and increased AGE content are associated with worse cortical bone indentation properties. Moreover, stiffer bone, as assessed by RPI, has less resistance to crack initiation and propagation. These findings provide insight into the factors that influence RPI measurements, as well as the interpretation of RPI measurements with respect to standard bending and fracture toughness tests.

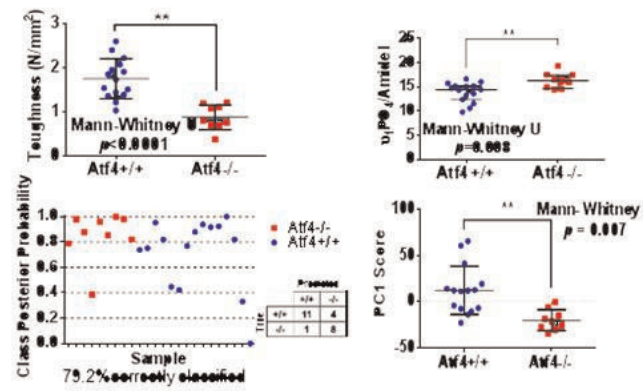
Brittle Bone Explained?: Multivariate Polarization Raman Spectroscopy for Assessing Bone Toughness. Alexander Makowski*[1], Sasidhar Uppuganti[2], Meredith Huszagh[2], Ahbid Zein-Sabbato[2], Anita Mahadevan-Jansen[2], Jeffry Nyman[3]. [1]Department of Veterans AffairsVanderbilt University, USA, [2]Vanderbilt University, USA, [3]Vanderbilt University Medical Center, USA

The age related decrease in human bone toughness is more severe than the age related loss of strength, yet current X-ray based diagnostics focus on the link between mineral and strength, ignoring collagen and subsequently toughness. Raman spectroscopy (RS) may complement existing tools, but RS for bone has been limited to peak ratios of composition. These represent only a fraction of the Raman spectra, ignoring subtle changes in shoulders or band widening, both seen in polarization changes that infer mineral and collagen organization. Here we present for the first time that full spectrum analysis including polarization information increases RS's ability to explain toughness differences in a mouse model of altered osteoblast differentiation.

Femurs were harvested from 20wk male mice (9 Atf4-/-, 15 Atf4+/+), and mid-shafts were μCT scanned at 12 μm voxels. RS was obtained using a confocal microscope (785nm diode; 50x NA=.75). Polarization RS parallel and orthogonal to the bone's long axis were acquired from the anterior midshaft for peak ratio intensity of mineral to collagen ratios (MCR). Full spectrum (300-1800cm^{-1}) principal components analysis (PCA) was used to find signatures that identify the Atf4-/- phenotype. Peak ratios and components significantly separating genotype (Mann Whitney; $p<0.05$) were classified by Sparse Multinomial Logistic Regression (SMLR).

Bones from Atf4-/- have 74% lower toughness than Atf4+/+ mice, but no TMD difference. Polarization sensitive MCR ν1 phosphate/AmideI significantly separates genotype but only explains 32% of variance and SMLR misclassifies all 9 Atf4-/- mice. Moreover, ν1/AmideI correlation v. toughness is only significant for longitudinal orientation (R^2=27.3%, $p<0.01$). Gradually adding more RS information improves classification accuracy: full spectrum PCA at either orientation accurately classifies at most 70.8%; the average of both orientations achieves 75%, while including both orientations separately classifies 79.2%.Performing PCA of full Raman spectra improves classification and also allows analysis of subtle spectral components weighted in the explanation of toughness. The primary direction of RS variance (26%, PC1) was the only PC to significantly separate genotype (p=0.001; figure) and explain toughness, heavily weighting polarization sensitive wavenumbers. PCA of spectra collected at orthogonal polarization angles adds organization sensitivity, possibly improving RS assessments of fracture resistance.



(A) Atf4-/- mice demonstrate significant toughness loss. (B) Polarization sensitive MCR separate tough from brittle bones.(C) SMLR correctly classified 79% of bones using PC1. (D) PC1 scores significantly separate brittle from tough bones

Classification of Brittle Bone

Clinical Applicability of Trabecular Microarchitecture Class (TMAC) Assessement using Multi-Detector Comptuted Tomography. Alexander Valentinitsch*[1], Lukas Fischer[2], Janina Patsch[3], Jan Bauer[4], Franz Kainberger[2], Georg Langs[5], Matthew DiFranco[3]. [1]Klinikum rechts der Isar, Technische Universität München, Germany, [2]Medical University of Vienna, Austria, [3]Medical University of Vienna, Austria, [4]Klinikum rechts der Isar, Technische Universität München, Germany, [5]Medical University of Vienna, Computational Imaging Research Lab, Austria

Computational trabecular microarchitecture assessment in high-resolution peripheral quantitative computed tomography (HR-pQCT) has recently proposed the clustering of voxels into one of three trabecular microarchitectural classes (TMACs) using pattern recognition methods applied to textural and orientation features.

Motivated by promising clinical applications of TMACs in osteoporotic women and lung transplant recipients, we extend the method to multi-detector CT (MDCT) images in order to validate their reproducibility at lower, anisotropic resolutions, which can be acquired during clinical routine.

Twelve right forearms were obtained from human cadavers of males (n=4) and females (n=8). Imaging was performed on these fresh frozen specimen using the standard in vivo protocol of the HR-pQCT scanner (isotropic resolution 82μm). MDCT images were acquired using a 64-slice scanner with two optimized protocols, differing only in tube current-time product (UH1: 150mAs; UH2: 300mAs; both with spatial resolution 130x130x500μm). TMACs were calculated and visualized via "bone quality maps" for each of the 12 cadaver specimens for both modalities. To assess variability between TMACs from different modalities and protocols, cluster volume fraction (CL.V/TV) was calculated and compared using a repeated measures ANOVA with subsequent Bonferroni correction. The overlap statistics of the TMACs were quantified with the Dice coefficient (DC).

Post hoc tests revealed that both MDCT scan protocols resulted in a reduction of CL.V/TV for TMAC1 as compared to HR-pQCT, but it was not statistically significant (UH2: −8.8%,p=0.175; UH1: −9.1%, p=0.166). No significant differences were found for TMAC2 (UH2: +2.2%, $p > 0.5$; UH1:−0.4%, $p > 0.5$). However, for TMAC3, a significant increase in CL.V/TV was seen for UH1 (+16.2%, p=0.005). When considering radiation dose, we noted that MDCT protocol UH2 outperformed UH1 in terms of overall Dice score by <2%, but effective dose (ED) was 81.8μSv for UH1 and 163.5μSv for UH2. This result also suggests that TMAC-based maps can be reliably generated at lower doses.

We demonstrated that TMAC mapping, initially validated for HR-pQCT, is applicable to MDCT. TMACs show good agreement despite MDCT having poorer spatial resolution, lower contrast and diminished sharpness. Future work should focus on in-vivo validation, possibly including central skeletal sites.

Differences in Assessment of Micro-Indentation Resistance between BioDent and OsteoProbe. Mathilde Granke*[1], Sasidhar Uppuganti[2], Mary Katherine Manhard[2], Mark Does[2], Donald Lee[2], Daniel Perrien[1], Jeffry Nyman[1]. As a potential tool to improve fracture risk assessment, reference point indentation (RPI) directly measures the resistance of a patient's bone to microindentation. There are two clinically viable RPI techniques (both from ActiveLife Scientific, Inc.) using 20 cycles of loading in force control at a peak 10 N (BioDent) or a one-time impact load at ~45 N (OsteoProbe). As the loading mechanisms and presumably depth of penetration differ between OsteoProbe (~200 μm) compared to BioDent (~70 μm), we hypothesized that indentation resistance by OsteoProbe is more sensitive to the underlying microstructure than the BioDent. To test the hypothesis, we indented the tibia midshaft, a clinically viable site, as well as the distal radius and proximal humerus, near typical fracture sites, from 10 cadavers (>70 yo; male and female). First, 8 indents were performed per bone using the OsteoProbe (Fig). The indent depth was normalized by mean depth into a PMMA standard to give so-called bone material strength (BMS). Next, 8 neighboring indents were performed with the BioDent. Outcomes included total indentation distance (TID), indentation distance increase (IDI), creep indentation distance (avgCID), and unloading slope (avgUS). UTE MRI provided bulk pore water (i.e., cortical porosity), and μCT (10 μm voxel) was used to determine local porosity in the region below indents (diaphysis). RPI properties from the BioDent did not vary among the neighboring 8 indent locations in all bones, but BMS was lower in the thinner metaphyseal than in the thicker diaphyseal cortex of the forearm bones (Fig). Mean BMS was lower for both forearm bones than for the tibia (Fig), whereas TID (Fig) and AvgCID were higher for just the humerus compared to the tibia. There were no anatomical differences in IDI or avgUS. The avgCID was the only BioDent property correlated with BMS in the tibia (r=0.75, p=0.017). The expected inverse correlation between TID and BMS existed for only the radius with nominal significance (r=-0.56, p=0.096). As an explanation of the anatomical differences in BMS, this property correlated with bulk pore water (r=-0.69, p<0.001) and local intracortical porosity (r=-0.69, p<0.001), although not for tibia alone (Fig). None of the BioDent properties correlated with pore water and porosity. The assessment of indentation resistance likely differs between BioDent and OsteoProbe in that the latter may be sensitive to the underlying microstructure in addition to tissue properties.
