
Refererence point indentation was performed at 8 locations using the hand-held OsteoProbe (top panel) and the bench-top BioDent (neighboring surface). Dividing each BMS value by the mean BMS among 8 locations per bone, relative BMS varied for the forearms bones (proximal humerus not shown) but did not for the tibia mid-shaft. Averaged among indentation locations on the diaphysis, BMS was less for the forearm bones than for the tibia, while TID (effectively the inverse of BMS) was greater for proximal humerus than for the tibia. Box and wiskers with mean at '+'; Difference between groups if letters are different.

Do Contralateral Femora Differ in Strength? A Multicentric Finite Element Study in Post-menopausal Women. Enrico Schileo*[1], Cristina Falcinelli[2], Luca Balistreri[3], Fabio Baruffaldi[3], Sigurdur Sigurdsson[4], Vilmundur Gudnason[5], Roswitha Dietzel[6], Gabriele Armbrecht[7], Stephanie Boutroy[8], Fulvia Taddei[3]. [1]Istituto Ortopedico Rizzoli, Bologna, Italy, Italy, [2]Istituto Ortopedico Rizzoli & University of Rome Tor Vergata, Italy, [3]Istituto Ortopedico Rizzoli, Italy, [4]Icelandic Heart Association, Iceland, [5]Icelandic Heart Association Research Institute, Iceland, [6]Charité, Germany, [7]Centre of Muscle & Bone Research, Charite-CBF, Germany, [8]INSERM U1033 & Université de Lyon, France

Introduction: the diagnosis of osteoporosis usually involves unilateral aBMD measurements. Conversely, small but significant asymmetries between contralateral proximal femora were reported for anatomy [1] and aBMD [2]. Finite Element (FE) models of bone strength, which combine anatomy and densitometry, recently improved aBMD classification of bone fracture risk [3], but so far neglected laterality.

Aim: to investigate the asymmetry in proximal femur strength as assessed by FE models from QCT data, in stance and sideways fall loading conditions, in a homogeneous cohort of post-menopausal women.

Methods: 198 QCT scans of intact proximal femora were obtained from three studies on osteoporotic fractures: AGES-Reykjavik (71 cases); Emilia-Romagna Regional Project on Osteoporosis (33); VPHOP European Project (94). A CT-based FE model of both proximal femora was generated [4]. Linear analyses were performed adopting a maximum principal strain criterion to define strength for each loading direction (validated with R^2=0.90 and RMSE 15%, against experimentally measured strength in 14 femora). The minimum strength among a range of loading directions mimicking the in-vivo variability of hip reactions (stance) and accidental conditions (fall) was determined for each femur. Femoral strength results in stance and fall were analysed separately.

Results: the average femoral strength was 5063 ± 1292N in stance and 2814 ± 626N in fall. Contralateral differences in stance and fall were comparable: only fall results are reported for brevity. Right femora were on average stronger (4.5%, p<0.005) but such difference might be close to model repeatability and is of little biomechanical relevance. The most relevant result was the large scatter observed, independently from the magnitude of strength, in Bland-Altman plots (95% CI: +37%, -28%). The mean absolute difference between contralateral bones was 14% (p<0.0001), close to the only similar existing study [5], performed in vitro on a smaller sample size. In summary the observed difference between contralateral femur strength is significant (exceeds 15% in 32% of subjects) and points to further studies to verify possible misclassification issues.

Evaluation of Bone Quality and Mechanics in a Mouse Model of Pseudoachondroplasia. Hao Ding*[1], Xiaohong Bi[2], Annie Abraham[1], Catherine Ambrose[3], Karen Posey[1], Jacqueline Hecht[1]. [1]University of Texas Health Science Center at Houston, USA, [2]University of Texas Health Science Center at Houst, USA, [3]University of Texas Health Science Center at Houston, USA

Mutations in the cartilage oligomeric matrix protein (COMP) gene cause pseudoachondroplasia (PSACH), a severe dwarfing condition associated with short limbs, pectus carinatum, joint laxity and an attractive face. Using an inducible system to express D469del-COMP in mice (MT-COMP), we have generated an *in vivo* model that replicates the critical cellular and clinical features of PSACH including intracellular retention of MT-COMP and reductions in long bone growth (12-18%). Although alterations in the growth plate and articular cartilage have been reported, there has been little research investigating the effects of MT-COMP on bone material properties and composition. Here, we report bone quality and mechanical properties from the femurs of the MT-COMP mouse.

Femurs from 4 week old male MT-COMP and wildtype (WT) mice were assessed by three-point bending mechanical tests. Both extrinisic and intrinsic mechanical properties of bones were then calculated using beam theory and geometric data from μCT analysis. Bone composition was determined by analyzing Raman spectra acquired from the broken femurs. Statistical analyses were performed to determine which parameters were significantly different between the two groups and to identify significant correlations between the mechanics and composition.

The MT-COMP bones were significantly less stiff, and withstood less loads before yield and failure. After accounting for the significantly smaller size of the bones, the intrinsic properties of MT-COMP bones were not significantly different from WT, indicating that anatomical geometry accounts for the variation in the mechanical function of mutant mice. The MT-COMP animals did not demonstrate any significant difference in terms of bone composition when compared to WT, which is in agreement with the outcome from mechanical testing. Correlation evaluation between bone composition and material properties revealed that collagen density correlated positively and significantly to bone elasticity (ie, pre-yield displacement, toughness and strain) while the mineral/matrix ratio correlated significantly to post-yield energy. In summary, the impaired bone mechanical function of MT-COMP mice arose from the smaller limb size but not the intrinsic material properties or bone composition. PSACH therapies that promote bone growth should improve the bone quality.

Finite Element Analysis Accurately Reflects the Improvements in Vertebral Strength with Denosumab in Ovariectomized Cynomolgus Monkeys. David Lee*[1], Paul Hoffmann[2], Aurore Varela[3], Paul Kostenuik[4], Michael Ominsky[4], Tony Keaveny[5]. [1]O.N. Diagnostics, USA, [2]O.N. Diagnostics, USA, [3]Charles River Laboratories, Canada, [4]Amgen Inc., USA, [5]University of California, Berkeley, USA

Finite element analysis of clinical-resolution computed tomography scans of the hip and spine provides non-invasive measures of bone strength that are now cleared by the FDA for clinical use in assessing fracture risk and monitoring treatment. However, the accuracy of such clinical-type strength estimates for predicting true hip or spine strength has not yet been established in bones after treatment with osteoporosis therapeutic agents. To determine whether such clinical-type finite element analysis can correctly quantify changes in bone strength after treatment with denosumab, vertebrae from ovariectomized cynomolgus monkeys (cynos) treated with denosumab (DMab) were subjected to mechanical testing and finite element analysis. After 16 once-monthly injections, T12 vertebral specimens were prepared from the cynos in three groups: Sham (n=17), OVX+vehicle (n=20), and OVX+DMab (50 mg/kg, n=17). These samples were micro-CT scanned (34 μm voxel size) and tested in compression to failure. To produce clinical-type finite element analyses, the images were coarsened to 300 μm resolution and converted into continuum models having about 30,000 elements, and were then analyzed in a blinded manner using the VirtuOst finite element software. After unblinding, both sets of strength data were then normalized to the mean of the Sham group, to estimate strength changes from baseline and to account for potential human-cynos differences in BMD-strength relationships. We found that denosumab significantly increased bone strength as determined by both mechanical testing (50±9%) and finite element analysis (46±9%) as compared to the Sham group, which in turn was not significantly different than the OVX group (Figure). Correlation analysis indicated excellent agreement in normalized strength as measured by mechanical testing and finite element analysis (R^2=0.97, $p<0.0001$, $Y=X$ type of agreement) with no significant differences between the two measurements for any group. These results validate this continuum type of finite element analysis for quantifying treatment effects of denosumab on vertebral strength in this monkey model of postmenopausal osteoporosis. Since this same continuum approach is used clinically, these results also support its use to estimate strength in patients treated with denosumab, while demonstrating that denosumab-induced improvements in bone strength are driven primarily by the features captured in these models, namely, bone mass and its distribution.

HR-pQCT based measurements of the distal tibial segment predict whole tibia stiffness. Bin Zhou*[1], Ji Wang[1], Eric Yu[1], Zhendong Zhang[2], Kyle Nishiyama[1], Elizabeth Shane[3], X Guo[1]. [1]Columbia University, USA, [2]Columbia University, USA, [3]Columbia University College of Physicians & Surgeons, USA

High-resolution peripheral quantitative computed tomography (HR-pQCT) is used to assess 3-dimensional microstructure *in vivo* of the distal tibia and radius. HR-pQCT of the distal tibia has shown thinner trabecular plates and lower cortical thickness in patients with fragility fractures and those with diseases like primary hyperparathyroidism. The standard HR-pQCT technique scans a 9.02-mm segment of the distal tibia. However, it remains to be determined whether the scanned segment is representative of bone quality of the entire tibia. In this study, we examined associations between mechanical and microstructural properties of tibia segment imaged by HR-pQCT and mechanical properties of the whole tibia.

Twenty-seven tibiae were collected from cadaver donors screened to exclude those with fracture or metabolic bone disease. The entire tibia was cleaned of soft tissue and embedded with PMMA at both ends. Non-destructive uniaxial mechanical testing with 5mm/min loading rate to 0.3% of the total length was performed after overnight curing. The standard HR-pQCT region was cut with a customized jig, immersed in saline to expel air bubbles and scanned by HR-pQCT. Volumetric BMD (vBMD), geometry and microstructure were measured by standard HR-pQCT procedures and trabecular plate/rod related microstructural parameters were evaluated by individual trabecula segmentation (ITS). Stiffness of the tibial segment was both measured by mechanical testing and predicted by finite element (FE) analysis; both correlated strongly with stiffness of whole tibia (R^2>0.9). Correlations between bone microstructure and whole tibia stiffness were also examined. The highest correlations with bone stiffness were found with total vBMD, trabecular number and cortical thickness (all R^2>0.5). Bone size, trabecular and cortical vBMD, and trabecular separation were moderately correlated with whole bone stiffness (R^2: 0.3-0.5). Several ITS measurements, including axial bone volume fraction, rod trabecular number, plate-rod, plate-plate and rod-rod junction densities, were significantly but modestly correlated with whole bone stiffness (R^2: 0.2-0.33). In summary, we detected highly significant associations between mechanical and microstructural properties of the tibial segment imaged by standard HR-pQCT scans and whole tibia bone stiffness. We conclude that the mechanical properties of the whole tibia are best approximated by estimated stiffness of the section of the tibia scanned by HR-pQCT.

Independent Measurement of Femoral Cortical Thickness and Cortical Bone Density using Clinical QCT. Graham Treece*[1], Andrew Gee[2]. [1]University of Cambridge, United Kingdom, [2]University of Cambridge, United Kingdom

Purpose: There is growing evidence that local features of cortical bone are a contributor to fracture risk. Both drug treatment and exercise regimes also result in cortical changes which are focused in particular regions rather than dispersed over the whole proximal femur. Accurate measurement of local cortical parameters is hence of importance in assessing both risk and intervention strategies. We have previously noted that both thresholding and full-width half-maximum (FWHM) techniques are incapable of measuring thickness or density for cortices less than 3 mm thick. Cortical bone mapping (CBM v1) can produce a much more accurate assessment of cortical thickness and mass (per unit cortical surface area), based on an estimate of cortical density which is presumed to be constant for each hip. However, although density varies much less than thickness, we would also like to be able to estimate the variation of density over the cortex.

Methods: A new CBM technique (v2) has been developed which makes use of the locally measured imaging blur to correct the initially global density estimate. This blur is overestimated when the initial density is too large, and underestimated when it is too small. The resulting local re-estimate of density can also be used to improve cortical thickness measurement. Performance was assessed with 70 ex vivo scans of proximal femurs (two each from 18 males and 17 females, aged from 56 to 96) from a study ethically approved by the Medical University of Vienna. True values were derived from calibrated HRpQCT data (cubic voxels of 0.082 mm) and estimates were made from QCT scans (0.33x0.33x1.0 mm) of the same femurs, each containing a BDC calibration phantom. Cortical thickness and density estimates were derived from over 700,000 matching measurements.

Results: Figure 1 shows the measurement errors for the FWHM, original CBM v1 and novel CBM v2 techniques. For thickness (in mm), range 1 to 3 mm, bias ± std was 0.48 ± 0.37 (FWHM), -0.24 ± 0.32 (CBM v1) and 0.12 ± 0.39 (CBM v2), and for 0.3 to 1 mm was 1.10 ± 0.37 (FWHM), -0.24 ± 0.12 (CBM v1) and -0.15 ± 0.23 (CBM v2). Density estimation (in mg/cm³) was less precise, but for range 1 to 3 mm cortex, results were -170 ± 137 (FWHM), 195 ± 217 (CBM v1) and -26 ± 178 (CBM v2). Cortical density estimation for CBM v2 was relatively unbiased above 800 mg/cm³.

Conclusion: It is possible to estimate both cortical density and thickness from clinical QCT, locally over the femur, though density estimation is less precise.

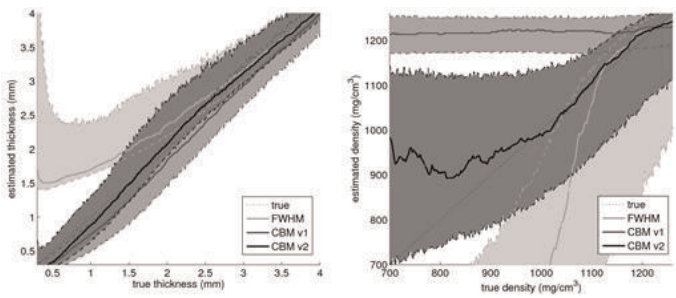

Figure 1. Estimated cortical thickness and density from QCT data compared to true values from HRpQCT data. Results are shown for FWHM, the original CBM v1 and the novel CBM v2 algorithms. The shaded regions show ± one standard deviation of many measurements from ex vivo scans of proximal femurs.

Lower matrix bound water is related to compromised skeletal mechanical properties in an animal model of chronic kidney disease. Matthew Allen[1], Christopher Newman*[2], Neal Chen[1], Sharon Moe[1], Jeffry Nyman[3], Mathilde Granke[3]. [1]Indiana University School of Medicine, USA, [2]Indiana University School of Medicine, USA, [3]Vanderbilt University Medical Center, USA

Chronic kidney disease (CKD) results in an increased fracture risk, partially due to declines in bone mass and increased cortical porosity. But, bone loss alone does not fully explain the compromised mechanical properties associated with the disease. The goal of this study was to assess the impact of CKD on skeletal tissue hydration, which is known to have significant effects on bone mechanical properties. At 35 weeks of age (approximately 80% reduction in kidney function), male rats with progressive CKD and their normal littermates (NL) were examined. Key biochemical outcomes, BUN (+199%), phosphorus (+122%), PTH (+1196%), and FGF23 (+1074%) were all significantly higher in rats with CKD compared to NL. Skeletal hydration (bound and free water) of the femoral diaphysis was determined using 1H NMR spectroscopy with T2 signals normalized by bone volume as determined by Archimedes' principle. Free water was significantly higher (+58%), whereas bound water was significantly lower (-12%) in CKD compared to NL. Cortical porosity, measured by microCT, was significantly higher in CKD animals (4.16%) compared to NL (0.12%) and was significantly correlated with free water (r = 0.87). Structural mechanical properties (determined by three-point bending) were significantly reduced with CKD (ultimate strength = -31%; stiffness = -17%; energy to fracture = -26%). These properties were negatively correlated to free water (ultimate strength, r = -0.80; stiffness, r = -0.87; energy to fracture, r = -0.72), but positively related to bound water (ultimate strength, r = 0.70; stiffness, r = 0.62; energy to fracture, r = 0.70). Previous work in this same model revealed microscale and nanoscale differences in mechanical properties between CKD animals and their normal counterparts, despite similarities in composition (mineral-to-matrix ratio and mineral crystallinity) and collagen cross-linking. The results of the current work suggest that changes in tissue hydration may be driving the compromised mechanical properties associated with the disease. These data also identify bound water, which can be enhanced by agents such as raloxifene, as a new potential therapeutic target for reversing the biomechanical deficits associated with CKD.

Multidirectional Poroelastic-Ultrasound and Structural-Anisotropy Predict Multidirectional Yield Behavior of Trabecular Bone. Paolo Palaciomancheno*[1], Mohamad Souzanchi F[2], Sankha Ghatak S[2], Stephen Cowin C[2], Luis Cardoso[2]. [1]The City College of New York, USA, [2]The City College of New York, USA

Bone fragility increases with decreasing Bone Mineral Density (BMD) and altered bone micro architecture. While BMD is the gold standard for bone fragility assessment, it neglects the evaluation of direction-dependent mechanical behavior, which strongly contributes to bone fracture. In this study, we investigated whether multidirectional poroelastic ultrasound (PEUS) can predict direction-dependent yield properties of trabecular bone. To evaluate the direction-dependent bone fragility, bone structural-anisotropy was defined by the Fabric tensor. For this purpose, seven human calcanei were scanned by micro-CT and single volume of interests (VOIs) obtained (Fig.1a). For each VOI, structural-anisotropy magnitudes and directions were obtained from the Fabric tensor ellipsoid (Fig.1b). 31 Fabric components (Fcomp) were analyzed per VOI. New VOIs were created according to the direction of each Fcomp (Fig.1c), and then converted to numerical models. These models were uniaxially tested to yield in compression, and interrogated ultrasonically. A total of 434 simulations were completed. Quadratic fittings were evaluated against directionality (Fcomp), bulk structural mechanical properties (Young's modulus (E), yield stress (σ_y), and yield strain (ε_y)) and Ultrasonic Parameters (fast-wave speed of sound (FW-SOS), slow-wave speed of sound (SW-SOS), fast-wave velocity(FW-Vel), slow-wave velocity (SW-Vel), fast-wave attenuation (FW-BUA) and slow-wave attenuation(SW-BUA)), and correlation coefficients were quantified (Table.1). Results demonstrate that all ultrasound parameters (Fast-Wave and Slow-Wave) and Fcomp exhibited strong and statistically significant correlation with E and σ_y ($0.83<R^2<0.95$), indicating that multidirectional PEUS is a good predictor of anisotropic elastic and yield mechanical properties. However, all ultrasound parameters (Fast-Wave and Slow-Wave) and Fcomp weakly predicted ε_y due to low correlation coefficients, indicating independence of yield strain to anisotropy. These results show that when bone mass structural directionality is taken into account, the anisotropic elastic and yield behavior of trabecular bone can be predicted by multidirectional ultrasound. In conclusion, multidirectional ultrasound can be used as a low cost, non-invasive, and non-radiating diagnostic tool for the assessment of direction-dependent bone fragility.

Reduced Growth-Related Trabecular Corticalization and Increased Age-Related Cortical Trabecularization: Determinants of Forearm Fragility Fractures. Yohann Bala*[1], Minh Bui[2], Sandra Iulliano[3], Tamara Rozental[4], Quinju Wang[3], Xiao-Fang Wang[5], Tara Sepehrizadeh[3], Ali Ghasem-Zadeh[6], Mary Bouxsein[7], Roger Zebaze[8], Ego Seeman[6]. [1]University of Melbourne, Dept. of Medicine, Australia, [2]Mega Center for Epidemiology, Australia, [3]Dept. Of Medicine, University of Melbourne, Australia, [4]Harvard Medical School, Beth Israel Deaconess Medical Cente, USA, [5]University of Melbourne, Austin Health, Australia, [6]Austin Health, University of Melbourne, Australia, [7]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [8]Austin Health, University of Melbourne, Australia

During growth, trabeculae emerging from the growth plate thicken. Peripherally placed trabeculae coalesce forming metaphyseal compact-appearing cortical bone (CC) while centrally placed trabeculae form cancellous bone with a transitional zone (TZ) between. Deficits in trabecular number or reduced thickening may delay corticalization leaving an enlarged and porous TZ. In adulthood, a negative bone balance and accelerated intracortical remodeling cavitates cortex. We hypothesized that these processes result in a higher porosity in women with forearm fractures across life.

We quantified microarchitecture using high resolution-peripheral quantitative computed tomography at the non-dominant or non-fractured distal forearm in cases with, and age-matched controls without, distal radius fractures with a ratio 1:2. After exclusions due to movement artefacts, we analysed: i) 110 girls (12 ± 3 yrs, range:7-18), ii) 100 pre-menopausal women (28 ± 6 yrs, range:18-44) (1) and iii) 164 post-menopausal women (65 ± 8 yrs, range:51-89). Bone compartment cross sectional areas (CSA), trabecular architecture and porosity of the, TZ and total cortex (TC) were assessed using StrAx1.0 (2) and expressed as a function of the total CSA to control for bone size.

Girls with fractures had a 3% smaller CC-CSA and a 3% reciprocally higher TZ-CSA that were 12% and 4% more porous than controls respectively (all $p \leq 0.03$). Trabecular BV/TV was 21% lower (8% fewer, 4% thicker, all $p<0.05$). Pre-menopausal cases had normal CC- and TZ-CSA but TZ porosity was 2% higher and trabecular BV/TV was 30% lower (7% fewer, 3% thinner) (all $p<0.05$). Post-menopausal cases had normal CC- or TZ-CSA that were respectively 25% and 5% more porous and 39% lower BV/TV (37% fewer, 10% thicker) (all $p<0.0001$). By multivariate regression analyses, CC and TZ porosity was associated with fracture independent of trabecular vBMD in girls. In pre-menopausal women, trabecular vBMD was associated with fracture independent of porosity. In post-menopausal women CC and TZ porosity was associated with fracture independent of trabecular vBMD.

At all ages, cases had higher cortical porosity and deficits in trabecular number. Metaphyseal fragility is the result of the incomplete corticalization of fewer trabeculae emerging from the growth plate early in life leading to higher peak porosity producing more surfaces for unbalanced and rapid remodelling after menopause.

SU0032

Relationship of Cortical and Endocortical-Trabecular Bone Structure to Femoral Strength in a Sideways Fall Configuration. Fjola Johannesdottir*[1], Kenneth Poole[1], Graham Treece[1], Mary Bouxsein[2]. [1]University of Cambridge, United Kingdom, [2]Beth Israel Deaconess Medical Center, Harvard Medical School, USA

The relative contribution of cortical and trabecular bone to fragility of the femur is unclear. Our goal is to determine the relationship of cortical and endocortical-trabecular bone structure to proximal femur strength during a sideways fall impact in order to improve current understanding of hip fracture etiology. We hypothesize that the relationship is stronger in areas considered 'at risk' of high load during simulation of fracture.

We obtained 70 human cadaveric proximal femurs (45 women, 25 men, range 55-98 years), scanned both using DXA and QCT, and mechanically tested the femurs to failure in a sideways fall configuration. Using a previously published method (Treece 2012), we applied a bone mapping technique (Stradwin, wxRegSurf and Surfstat) to identify regions where bone structure in the hip was significantly related to femoral strength. We spatially aligned the bone measurements onto an average femur surface and used statistical parametic mapping to analyse the results. Covariates were sex, age, height, weight and phantom type. The results are presented as percentage variation in cortical bone mass (Fig. 1A) and endocortical-trabecular density (Fig. 1B) per 1000N of failure load.

Femoral strength is predictive of both cortical bone mass and endocortical-trabecular density over large areas of the proximal femur (Fig. 1A & 1B). The increase in cortical bone mass was quite uniform (Fig. 1A), about 10-20% per 1000N of failure load. The range in increase of endocortical-trabecular density was more variable (Fig. 1B), with the strongest effect located at the femoral neck. Interestingly, both bone variables showed strong association with failure load in the regions that have been predictive of hip fractures in clinical case-control studies (marked with *). The strong relationship between endocortical-trabecular density and failure load in the femoral neck (Fig. 1B) is noteworthy because the current clinical standard for fracture prediction is femoral neck aBMD with clinical risk factors. The association between surface derived bone measurements and failure load was strongest in regions considered be 'at risk' of hip fracture.

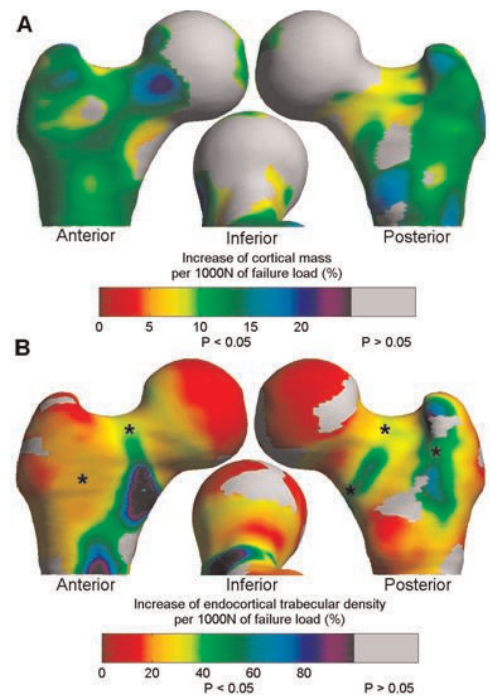

Figure 1: Relationship of cortical bone mass (A) and endocortical-trabecular density (B) to failure load. *: Locations which have been predictive of hip fractures in clinical case-control studies (Johannesdottir Bone 2011; Carballido-Gamio JBMR 2013; Poole ASBMR 2013). Only associations which were significant at p <0.05 are shown.

The role of type 2 Diabetes on fracture healing in an experimental rat model. Javier La Fontaine[1], Chris Chen*[2], Lawrence Lavery[2], Ed Jude[3]. [1]UT Southwestern Medical Center, USA, [2]UT Southwestern Medical Center, USA, [3]Tameside General Hospital, United Kingdom

BACKGROUND: Persons with diabetes have a higher incidence of fractures compared to persons without diabetes. However there is very little published information concerning the deleterious effect of late stage diabetes on osseous structure and bone healing. The purpose of the study was to evaluate the role of diabetes on fracture healing in a rat femur-repair model.

Methods: 36 Lean and diabetic Zucker rats used in this study were subdivided into three groups: 1) 12 Lean rats as control (Lean), 2) 12 Diabetic rats without blood glucose control (DM), and 3) 12 Diabetic rats treated with 300mg/kg metformin to reduce blood glucose (DM+Met). The animals at the age of 14-week-old age were fractured at the right femur using a customized apparatus as previously described where the contralateral femur was sham-operated. Animal recovery, activities, and blood glucose were monitored everyday where the body weight and cytokines in serum were measured every 3-5 days. X-ray was taken every week to determine bone repair/delayed union. All the animals were sacrificed at 6-week after surgery for serum biomarkers and biomechanical properties which were evaluated using three points bending at mid-shaft diaphysis to determine Stiffness, Fracture-Load, Ultimate-Strength, and Fracture-Load/Weight.

Results: VGEF, MIP-1α and IL-2 levels were significantly elevated in all 6 weeks in the diabetic animals (DM vs. Lean). This was consistent with significant decreases of biomechanical properties in the DM. In both the sham-operated and fracture/repaired femurs, significant decreases of Fracture-load/Weight (30.3-32.3%, p=0.004, 0.02, respectively) and marginally decreases of Fracture-load (24.9-31.4%, p=0.08, 0.055, respectively) between Lean and DM groups were found. There was a delay in fracture healing found in the DM (42% vs. 83%-Lean) group at the 3 week time point. The treatment of metformin significantly reduced blood glucose and body weight after 12days post-op (DM+Met vs. DM). To our surprise, further decreases of Fracture-load (44.8%, p=0.004) and Fracture-load/Weight (21.5%, p=0.03) in the repaired femurs was also found in the DM+Met (vs. DM) group, but the factor(s) contributed to this decrease was not clear.

CONCLUSIONS: Diabetes impairs bone fracture healing. The treatment of metformin reduces blood glucose and body weight but has an adverse effect in fracture repair in diabetic rats.

Toward non-invasive monitoring of bone infection in diabetic foot ulcers by Raman spectroscopy. Karen Esmonde-White*[1], Francis Esmonde-White[2], Michael Morris[3], Blake Roessler[4]. [1]University of Michigan, USA, [2]University of Michigan, USA, [3]University of Michigan, USA, [4]University of Michigan Medical School, USA

Introduction: Diabetics account for 8 in 10 non-traumatic amputations, and more than 80% of these amputations are preceded by foot ulcers. Diagnosis of osteomyelitis (bone infection) in diabetic foot ulcers is a challenge, especially in a point-of-care environment. Our pilot study used Raman microspectroscopy to measure composition in osteomyelitis and we discovered pathological crystals. The pathological crystals are unique to osteomyelitis and may serve as compositional markers of bone infection. We present our ongoing research in transcutaneous Raman spectroscopy (TRS) for intra-wound bone measurements. Methods: Feasibility studies were performed in human cadaveric tissue and a healthy human volunteer. Human cadaveric foot specimens were obtained from either the University of Michigan (UM) Medical School Anatomic Donations program or the UM Orthopaedic Research Laboratory. Near infrared Raman spectra were collected using our portable Raman instrument equipped with either a non-contact (~10 inch offset) or a contact (<1 cm offset) fiber optic probe. Transcutaneous measurements were collected on the plantar surface of cadaveric specimens and a healthy human volunteer. Simulated wounds were created in cadaveric specimens and examined either by the contact or non-contact probe. Results: Feasibility studies demonstrate rapid (<60s) intra-wound measurements using either a non-contact or contact probe. Probes are compatible with a single-use sterile sheath and/or hospital autoclaving protocols. No laser-induced tissue damage or localized heating was observed in the healthy human volunteer. Preclinical studies indicate that the non-contact probe is the most compatible with our clinical workflow and represents minimal risk to the patient. Conclusions: We present data from ongoing studies to translate TRS for intra-wound bone measurements, with the eventual aim of a point-of-care TRS diagnostic for osteomyelitis. Several probe designs have been evaluated in cadaveric tissue. At the time of abstract submission, we are awaiting IRB approval for a longitudinal TRS study in patients with diabetic foot ulcers. In addition to technology development, we have developed a unique clinical research workflow for the longitudinal TRS study. Co-localization of the wound clinic with clinical research facilities enables incorporation of TRS measurements into a patient's clinical visit and facilitates "bedside to bench" feedback on the TRS instrument.

Vertebral Fracture Discrimination in Postmenopausal Women using a Subject-Specific Finite Element Model of the Disc-Vertebra-Disc Unit. Chuhee Lee*[1], Miguel Debono[2], Richard Eastell[2], Priyan Landham[3], Michael Adams[3], Patricia Dolan[3], Lang Yang[2]. [1], United Kingdom, [2]University of Sheffield, United Kingdom, [3]University of Bristol, United Kingdom

Bone Mineral Density (BMD) assessed by dual-energy X-ray absorptiometry (DXA) is low in vertebral fracture patients. In recent years, patient-specific finite element (FE) models of the vertebral body based on quantitative computed tomography (QCT) have been used to estimate vertebral strength and assess fracture risk. We developed a new patient-specific FE model of the Disc-Vertebra-Disc unit (DVD) that incorporates the vertebra and adjacent intervertebral discs. The purpose of this study was to investigate whether vertebral strength derived from the DVD FE model could discriminate between women with and without vertebral fracture.

This cross sectional case-control study included 74 postmenopausal women (age 59-82) in 3 groups: a case group (n=17) with osteopenia/osteoporosis (total hip or vertebral BMD T-score < -1) and prevalent vertebral fracture, an age- and BMD-matched control group (n=26), and an age-matched non-osteopenia/osteoporosis control group (n=31). QCT scans of L1 to L3 were used to generate DVD FE models of the L2 vertebra. Transverse-isotropic, elastic-perfectly plastic material properties were assigned to the vertebra whereas linear-elastic properties were used for the nucleus pulposus and annulus ground matrix with 4 fibre layers embedded in the annulus fibrosus. A pure compressive loading condition was simulated. Vertebral strength was defined using a 0.2% offset method in the load-displacement curve. The 2 control groups were combined to form a single control group for statistical analysis. Odds ratio (OR) for vertebral fracture for 1 SD decrease in covariates was derived from logistic regression, and area under the curve (AUC) from analysis of receiver operating characteristics.

Compared with the controls, the cases had significantly ($p<0.0001$) lower vertebral BMD (0.80 ± 0.02 v. 0.94 ± 0.02 g/cm^2, Z-score -0.98 ± 0.66) and FE strength (1231 ± 79 v. 1822 ± 62 N, Z-score -1.28 ± 0.69). FE strength discriminated vertebral fracture (OR 11.6, 95% CI 3.0-44.7) and after adjustment for BMD (OR 9.3, 95% CI 2.2-39.0). The AUC for FE strength (0.86, 95% CI 0.77-0.96) was higher than that for BMD (0.78, 95% CI 0.67-0.88). In a model in which we added FE strength to BMD, AUC increased to 0.88 (95% CI 0.80-0.96), significantly ($p<0.05$) larger than that of BMD alone.

In conclusion, vertebral strength derived from the *in vivo* DVD FE model was able to discriminate between women with and without vertebral fracture independent of BMD by DXA.

What is the bilateral asymmetry of radius and tibia bone microarchitecture by HR-pQCT?. Erin Hildebrandt*, Sarah Manske, David Hanley, Steven Boyd. University of Calgary, Canada

Asymmetry is well established in human long bones on a macro scale. For example, right-side upper limbs tend to be longer and wider, regardless of hand dominance. Bone area by x-ray imaging has been shown to be significantly larger in dominant hands compared to non-dominant, presumably from an increase in mechanical loading. However, while bone microarchitecture clearly adapts to mechanical loading, scans from peripheral quantitative computed tomography (pQCT) have not found that dominance has an effect on cortical or trabecular bone mineral density (BMD) at the radius. The purpose of this study is to compare bone microarchitecture between the dominant and non-dominant radius and tibia as measured using high-resolution pQCT (HR-pQCT).

Healthy participants (average age 32.4 yrs, 43 women, 27 men) were recruited from Calgary and surrounding area and scanned at both radii and tibiae using HR-pQCT (XtremeCT, Scanco Medical). Dominance for hand and foot was determined by participant self-report. Scans were assessed using the manufacturer's standard protocol. Results were analyzed using a paired t-test and a Two-Way ANOVA of sex and limb dominance effects.

The majority of participants were right hand dominant (92.8%) and right foot dominant (94.2%). Overall, dominance was associated with an increase in cortical area (CtAr) at the radius ($p=0.049$) and cortical thickness (CtTh) at the tibia ($p=0.04$). For females, there were no microarchitectural differences at the radius, but trabecular area (TbAr) was greater at the dominant tibia ($p=0.02$). At the radius, males had greater CtAr ($p=0.005$), CtTh ($p=0.001$) and total BMD (TtBMD, $p=0.03$). Additionally, males had a greater CtAr at the dominant tibia ($p=0.02$). As has been previously reported, males had significantly greater TtBMD, CtAr and TbAr at the radius and tibia when compared to females ($p<0.05$).

This study found that dominance had an effect on structural cortical bone parameters at both the radius and tibia in a normal, healthy population. This is consistent with previous x-ray studies, but contrasts the results of pQCT studies. Our data suggest that dominance has a significant effect on cortical bone size but no significant effect on trabecular bone microarchitecture at the ultradistal radius and tibia. This work emphasizes that it is important to be consistent in the selection of either dominant or non-dominant limbs for HR-pQCT cohort studies at the ultradistal radius and tibia skeletal sites.

Bisphosphonate Treatment During an Initial Unloading Period also Protects Against Bone Loss for a Second Unloading. Scott Lenfest*[1], Jessica Brezicha[2], Ray Boudreaux[1], Cameron Schaefer[2], Susan Bloomfield[1], Matthew Allen[3], Harry Hogan[4]. [1]Texas A&M University, USA, [2]Texas A&M University, USA, [3]Indiana University School of Medicine, USA, [4]Texas A&M University, USA

Bone response to multiple exposures of microgravity remains a concern for astronauts as more are making repeat flights, and some have taken bisphosphonates (BP) to prevent bone loss during flight. Given the long-lasting effects of these drugs it is possible that protection may persist for subsequent flights. The current study used the adult hindlimb unloaded (HU) rat model to test the hypothesis that the beneficial effects of BP treatment given during an initial HU period would also extend to a second HU. We further hypothesized that Zoledronic Acid (ZA) would be more effective than Alendronate (ALN) due to their differences in binding affinity.

Adult male rats (6 mo.) were block assigned to aging control (AC) and HU groups by body weight. HU animals were exposed to 28d of HU, followed by 56d of recovery, and then a second 28d HU exposure. Subsets of HU animals were administered ALN (HU+A), ZA (HU+Z), or no drug (HUC). ALN (2.4 μg/kg) was given 3x/week for 5 weeks, starting the week before the initial 28d of HU. ZA (60 μg/kg) was given in a single dose immediately prior to the first HU. *In vivo* pQCT scans of the proximal tibia metaphysis (PTM) were taken at baseline (BL) and every 28d. The study is ongoing, and there will ultimately be 15 animals per group. For results presented here, N varies from 3 to 15.

During the first HU, HUC showed expected losses in both total bone mineral content (BMC) and volumetric bone mineral density (vBMD) relative to BL (-10.6%, -6.7%, resp.). Total BMC and vBMD for HU+A were not different from BL or AC at day 28, indicating protection against losses. For HU+Z animals, total BMC was significantly higher than AC (+6.2%) and HU+A (+10%) at day 28, and total vBMD was significantly higher than BL (+8.5%), AC (+8.8%), and HU+A (+6.3%). This potency of ZA continued throughout the 56d recovery period, with both total BMC and vBMD significantly higher for HU+Z compared to BL, AC, and HU+A. For the second HU, total vBMD was unchanged for HU+Z and remained significantly higher than BL (+13.1%), AC (+13.8%), and HU+A (+13.2%). Total vBMD for HU+A was similar to AC at the start and end of the second HU. Total BMC was lower for HU compared to AC at the end of the second HU, but HU+Z and HU+A were not different from AC.

In summary, both ALN and ZA protected against disuse-induced losses in total BMC and vBMD for both bouts of disuse, but ZA was more potent as evidenced by enhanced mass and density above age-matched control values.

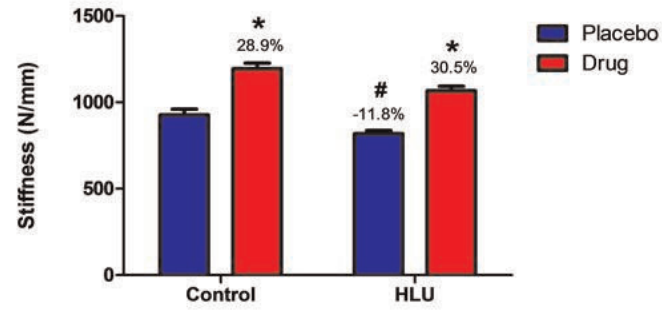
Effects of Hind Limb Unloading and Sclerostin Antibody on Femoral Neck Strength Estimated by Finite Element Analysis. Lindsay Sullivan*[1], Eric Livingston[2], Rachel Ellman[3], Jordan Spatz[4], Louis Stodieck[5], Mary Bouxsein[6], Virginia Ferguson[5], Ted Bateman[7], Anthony Lau[1]. [1]University of North Carolina at Chapel Hill, USA, [2]University of North Carolina-Chapel Hill, USA, [3]Beth Israel Deaconess Medical Center, USA, [4]Harvard-MIT Division of Health Sciences & Technology (HST), USA, [5]University of Colorado, USA, [6]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [7]Univesity of North Carolina, USA

Skeletal unloading during spaceflight reduces bone volume and bone mineral density. Hind limb unloading is a ground based technique developed to mimic the effects of microgravity on bones. The relationship between bone loss seen in the ground based model and during spaceflight has not been extensively characterized. This study uses finite element modeling (FEM) to assess changes in femoral neck stiffness due to hind limb unloading and sclerostin antibody treatment (Scl-Ab).

Thirty mice were suspended by their hind limbs for 13-days (HLU). Half the mice were treated with placebo (n=15) and half were treated with a Scl-Ab (n=15). Corresponding control (GC) groups were similarly treated. In this study, subject specific FE models were meshed from microCT images from the same mice (down sampled from 10 to 20μm resolution) for a 3.25mm segment of the proximal femur, which was taken from the top of the femoral head. All bone elements were modeled as linear elastic (E=10GPa, v=0.3). A downward displacement of 50μm was applied to the entire femoral head and the femoral neck bending stiffness was calculated from the measured load at 50μm.

FEM of the proximal femur found a 12% decrease in stiffness in the HLU mice compared to the GC mice. Scl-Ab treatment resulted in an increased stiffness by 31% in the HLU and 29% in the GC. When compared to the results for mice flown on STS-135, the HLU mice exhibited a similar trend. However, the HLU mice had a larger response to the sclerostin antibody than the STS-135 mice. The increased response seen in the hind limb unloaded mice may occur due to the fact that the mice still experience some gravitational force.

Conclusion: The unloading of the mouse hind limbs caused a significant loss of femoral neck stiffness in the proximal femur. Scl-Ab prevented the loss of bone strength, and increased femoral neck stiffness in both HLU and GC mice. The results of FEM from the hind limb unloading study showed the same trend as the previous STS-135 study in the proximal femur region



Changes in Femoral Neck stiffness caused by the sclerostin antibody(*) and HLU(#)

Bone morphology in 46 BXD Recombinant Inbred Strains and femur-tibia correlation. Yan Jiao*[1], Yueying Zhang[2], Jinshong Huang[3], Valentin David[2], Weikuan Gu[1]. [1]University of Tennessee Health Science Center, USA, [2]UTHSC, USA, [3]UTHSC.edu, USA

Osteoporosis is recognized as the most common bone disease in the world. It is characterized with a reduction in bone mass and an alternation of bone micro-architecture, which have been approved to be the major determinants of bone strength. The inbred strains of mice have proven to be useful models for studies of genetic effects on bone structure. In current study, we evaluated the bone mass and microstructure of femurs and tibias in BXD RI mouse strains.

We examined the bone properties of BXD RI mice using High-resolution μCT by analyzing femur and tibia and compared their phenotypes of different compartments. 46 BXD RI mouse strains were analyzed including progenitor C57BL/6J (n=16) and DBA/2J (n=15), and two first filial generations (D2B6F1 and B6D2F1). Strain differences were observed in bone quality and structural properties ($p<0.05$) in each bone profile (whole bone, cortical bone, or trabecular bone). Additionally, strains differences were revealed in bone stiffness ($p<0.0001$).

It is well-known that skeletal phenotypes are largely affected by genetic determinants and genders, such as bone mineral density (BMD). While genetics and gender appear expectedly as the major determinants of bone mass and structure, significant correlations were also observed between femur and tibia. More importantly, positive and negative femur-tibia associations indicated that genetic makeup had an influence on skeletal integrity. We conclude that a) femur-tibia association in bone morphological properties significantly vary from strain to strain, which may be caused by genetic differences among strains; b) strain-wise variations were seen in bone mass, bone morphology, bone micro-architecture along with bone structural property.

Key words: Bone mineral density, Femur, Tibia, Mouse, Recombinant inbred strain

Cx43 Scaffolding C-Terminus Intracellular Domain Is Required for Achieving Proper Bone Architecture and Strength, but It Does Not Mediate the Effect of Osteocytic Cx43 on Cortical Bone. Rafael Pacheco*[1], Iraj Hassan[2], Chad Sorenson[2], Hannah Davis[2], Max Hammond[3], Rejane Reginato[4], Eduardo Katchburian[4], Joseph Wallace[5], Teresita Bellido[6], Lilian Plotkin[6]. [1]Indiana University School of Medicine, Federal University of São Paulo, USA, [2]Indiana University School of Medicine, USA, [3]Purdue University, USA, [4]Federal University of São Paulo, Brazil, [5]Indiana University Purdue University Indianapolis (IUPUI), USA, [6]Indiana University School of Medicine, USA

Connexin (Cx) 43, a transmembrane protein abundantly expressed in bone cells, forms gap junction channels and hemichannels responsible for intercellular communication among osteocytes, osteoblasts and osteoclasts. The C-terminus intracellular domain (CT) of Cx43 acts as scaffold for structural and signaling proteins hence impacting intracellular signaling; and its phosphorylation status regulates Cx43 channel activity. Earlier *in vitro* studies demonstrated that channels formed by a mutant lacking the CT ($Cx43^{DCT}$) remains open; and that Cx43 promotes osteocyte viability but $Cx43^{DCT}$ does not, demonstrating the requirement of the CT for survival signaling in osteocytes. Here we examined the function of this CT domain in bone *in vivo* using mice in which CT was removed, rendering a truncated $Cx43^{DCT}$. First, we generated mice in which one allele of Cx43 was replaced by $Cx43^{DCT}$ ($Cx43^{fl/DCT}$). Compared to $Cx43^{fl/fl}$ littermate controls, $Cx43^{fl/DCT}$ mice exhibit low BV/TV and

trabecular number and high trabecular spacing in the distal femur, measured by μCT. In contrast, cortical thickness in the femoral mid-diaphysis was increased, and mechanical testing by femoral 3-point bending revealed increased mechanical strength (stiffness, yield force, and ultimate force). The macro-scale toughness measured by 3-point bending was not changed; however, the micro-scale toughness index average energy dissipation was increased, measured in the tibia by reference point indentation (RPI). These findings indicate that in the presence of one allele encoding full length Cx43, the truncated $Cx43^{DCT}$ has a dominant effect, affecting cancellous and cortical bone architecture in opposite ways and increasing cortical bone strength. We next generated mice in which the truncated $Cx43^{DCT}$ was expressed in osteocytes in the absence of endogenous Cx43, by crossing mice lacking Cx43 in osteocytes ($Cx43^{fl/fl}$;DMP1-8kb-Cre) with $Cx43^{fl/DCT}$ mice. Expression of the truncated $Cx43^{DCT}$ reversed the cortical thinning measured by μCT and the defective material strength, measured at the macro- and micro-scale levels by 3-point bending and RPI, exhibited by $Cx43^{fl/fl}$;DMP1-8kb-Cre mice to levels similar to $Cx43^{fl/fl}$ littermate controls. We conclude that the Cx43CT domain is required for acquisition of normal cancellous bone volume and architecture, but negatively affects cortical bone strength. Moreover, the Cx43CT is dispensable for the maintenance of cortical bone dependent on Cx43 expression in osteocytes.

Do African-Americans and Caucasians build long bones in fundamentally different ways. Stephen Schlecht*[1], Karl Jepsen[2]. [1]University of Michigan, USA, [2]University of Michigan, USA

Ethnic differences in bone morphology and BMD are well documented and often used to identify traits contributing to fracture susceptibility. On average, African-Americans (AA) have wider, thicker cortices compared to Caucasians (CN). However, it remains unclear whether AA and CN build bones in fundamentally different ways. Cortical area (Ct.Ar) correlates positively and tissue mineral density (TMD) correlates negatively with the natural variation in robustness (total bone area/length) in both populations. We tested whether these interactions explain ethnic differences in bone structure and composition.

Cross-sectional morphology and TMD were assessed for 7 long bone mid-diaphyses of 125 CN and 115 AA adult men and women (20-40 yrs) using pQCT. AA had more robust (wider relative to length) bones compared to CN for all sites except the femora, in both sexes ($p<0.05$). Comparing linear regressions between Ct.Ar and robustness, AA had a slightly greater Ct.Ar for a given robustness compared to CN for all sites except the femora (Fig.1a-b) in both sexes (ANCOVA, y-int, $p<0.0001$). Differences in regressions were small, suggesting that the lower Ct.Ar of CN long bones was consistent with the differences in robustness. Comparing linear regressions between TMD and robustness revealed that AA bones had greater TMD for a given robustness (ANCOVA, y-int, $p<0.0001$) (Fig.1b-d). This was a novel finding since AA bones were expected to show reduced TMD, not increased, given that TMD correlates negatively with robustness. Finally, both ethnicities showed similar degrees of functional inequivalence, with slender bones being 1.5–2.8 times less strong compared to robust bones, independent of body size. This 50-180% natural variation in strength among individuals within each ethnicity is 5-10 times greater than the mean bone strength between ethnicities.Morphologically, CN bones are simply a more slender version of AA bones. However, AA bones have a proportionally greater TMD compared to CN, independent of robustness, which may result from reduced porosity arising from ethnic differences in intracortical bone remodeling (Cho et al., AJPA, 2006). Insignificant findings between femoral Ct.Ar and robustness among ethnicities suggest trait covariance is highly conserved within this bone. By taking the functional interactions among traits into consideration, we provide new insight into differences in bone strength that may contribute to ethnic differences in fracture incidence

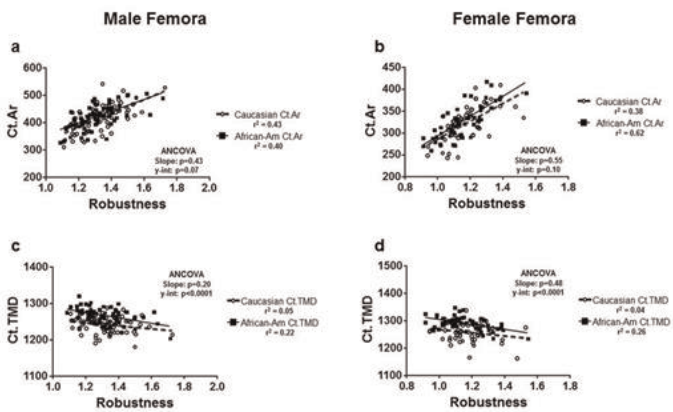

Figure 1a-d. Example of linear regressions between covarying traits for both African-American and Caucasian males and females. a) Ct.Ar versus robustness in male femora; b) Ct.Ar versus robustness in female femora; c) TMD versus robustness in male femora; d) TMD versus robustness in female femora.

Effects of Preventive Long Term Treatment with Strontium Ranelate and Zoledronic Acid to Ovariectomized Rats on Bone Biomechanics. Marta Martín-Fernández*[1], Marina Gómez-Chinchón[1], David Guede[2], Jose Caeiro[3], Manuel Díaz-Curiel[4], Concepcion De La Piedra Gordo[5]. [1]Bioquímica Investigación, Instituto de Investigación Sanitaria Fundación Jiménez Díaz, Spain, [2]Trabeculae,Technology Based Firm, Technological Park of Galicia, Spain, [3]Orthopaedic Surgeon, Spain, [4]Medicina Interna, Instituto de Investigación Sanitaria Fundación Jiménez Díaz, Spain, [5]Instituto de Investigación Sanitaria Fundación Jiménez Díaz, Spain

Many pharmacological treatments have been developed in order to prevent or treat postmenopausal osteoporosis. There is not any study in the literature comparing long-term treatments of osteoporosis. The aim of this work was to study the effects of long-term prevention treatment with Zoledronic Acid (ZA) and Strontium Ranelate (SrR) on biomechanical parameters in ovariectomized rats.

Sixty 6-month-old female Wistar rats were used in this study and divided into four groups: SHAM (n=15), simulated intervention; OVX (n=15), ovariectomized; OVX+ZA (n=15), ovariectomized and treated with ZA (0.08mg/kg i.v. at the begining of the study); OVX+SrR (n=15) ovariectomized and treated with SrR (0.033 g/kg/day by oral gavage). Treatments started one day after ovariectomy. Eight months later all rats were sacrificed and right femora were mechanically tested to failure in three-point bending to evaluate the mechanical properties of the midshaft. All mechanical tests were performed using a 1kN load cell on a material testing machine (Microtest EM1/10/FR/m) at a constant displacement of 10mm/min until the bone fracture. Extrinsic or structural properties: ultimate load, extrinsic stiffness and work to failure; and intrinsic or material properties: ultimate stress, Young's modulus and toughness were analyzed.

Young modulus was statistically decreased in OVX and SrR groups, without significant difference between them. Levels of ZA group were similar to those of SHAM group. Extrinsic stiffness was significantly higher in ZA treated rats as compared to all other groups. No significant differences between groups were observed in the other studied parameters.

SrR long-term preventive treatment is no capable of avoid the effects of ovariectomy on bone biomechanics. Long term treatment of ovariectomized rats with ZA prevented effects of ovariectomy preserving Young's modulus.

SU0044

New Tool for Accurate Cortical Bone Analysis in pQCT Images. Tomas Cervinka*[1], Lora Giangregorio[2], Deena Lala[3], Angela M. Cheung[4], Eva Szabo[5], Harri Sievanen[6], Jari Hyttinen[7]. [1]Tampere University of Technology, Finland, [2]University of Waterloo, Canada, [3]University of Waterloo, Canada, [4]University Health Network-University of Toronto, Canada, [5]University Health Network, Canada, [6]The UKK Institute for Health Promotion Research, Finland, [7]Department of Electronics & Communications Engineering, Tampere University of Technology, Finland

Peripheral quantitative computed tomography (pQCT) allows a reasonable option to assess the bone cross-sectional geometry and separation of the trabecular and cortical compartments. Although commonly used pQCT systems lack sufficient spatial resolution to capture specific structural traits compared with high-resolution pQCT (HR-pQCT) systems, they are cheaper and still widely used among bone researchers. However, the need for better accuracy in the detection of coarse bone structural traits in pQCT images is evident.

The aim of this study was to evaluate the agreement between pQCT and HR-pQCT measurements of cortical geometry at the distal tibia. More specifically, we addressed to what extend can our novel segmentation method, called OBS, improve the analysis of cortical CSA (CoA), thickness (CoTh) and density (CoD) from pQCT images. The OBS is a robust threshold free segmentation method developed for reliable cortical bone detection in pQCT images.

We used pQCT and HR-pQCT images of distal tibia obtained from 15 dry human tibia specimens. All scans for both modalities were taken from the same location (22.5 mm proximal to the endplate of the tibia). The pixel size of the pQCT image was 0.5x0.5 mm and the slice thickness was 2.2 mm. The HR-pQCT images were obtained with the standard acquisition approach and an isotropic voxel size of 82 μm. The performance of the OBS method, applied on pQCT data, was compared with results of standard analysis of HR-pQCT data. As descriptive statistics, the means and standard deviation (SD) of CoA, CoTh and CoD are given. In addition, we determined the mean error and its SD, and used Pearson correlations and Bland-Altman plots to describe the relationships between pQCT- and HRpQCT-derived variables.

The OBS method showed good performance for detection of CoA, CoTh and CoD in pQCT data when compared with HR-pQCT data (Table 1). The mean error and limits of agreement of these traits were $-2.8 \pm 16.7\%$, $4.9 \pm 16.2\%$ and $-0.6 \pm 7.9\%$, and correlation with HR-pQCT data was 0.94, 0.95 and 0.88, respectively.

In conclusions, this study showed that the OBS method offers a promising practical tool for more accurate evaluation of cortical bone geometry in pQCT images. Nevertheless, a comparison of the same volumes in pQCT and HR-pQCT data needs to be performed before the true accuracy of OBS analysis of cortical traits in pQCT images can be determined.

Table 1: Descriptive data of CoA, CoTh, and CoD (mean, SD) as obtained from analysis of pQCT and HR-pQCT images together with an agreement between obtained results:

	$pQCT_{OBS}$	HR-pQCT	Error
CoA [mm²]	139.0 (18.8)	144.8 (28.0)	-5.8 (12.1)
CoTh [mm]	1.31 (0.24)	1.26 (0.27)	0.05 (0.09)
CoD [mg/cm³]	838.1 (63.3)	844.1 (70.4)	-5.9 (34.0)

Once Daily and Once Weekly Regimens of Teriparatide have Different Effects on Cortical Bone. Roger Zebaze*[1], Ryoko Takao-Kawabata[2], Yu Peng[3], Ali Ghasem-Zadeh[4], Aya Shimomura[5], Hiroshi Yamane[5], Kyoko Hirano[5], Yukihiro Isogai[6], Toshinori Ishizuya[5], Ego Seeman[4]. [1]Austin Health, University of Melbourne, Australia, [2]Asahi Kasei Pharma Co., Japan, [3]StraxCorp Pty Ltd, Australia, [4]Austin Health, University of Melbourne, Australia, [5]Asahi Kasei Pharma Corporation, Japan, [6]Asahi Kasei Pharma Corporation, Japan

The pharmacokinetic profile of PTH determines its relative anabolic/resorptive effects. We hypothesized that less frequent administration of teriparatide may favor a lesser effect on resorption than daily administration. As cortical bone consists of a compact cortex (CC), and a more porous outer and inner transitional zone (OTZ, ITZ) with more surface area/matrix volume formed by varying degrees of corticalization of trabeculae, we proposed that the effects of teriparatide vary according to the cortical compartment.

We studied 17 female New Zealand white rabbits, aged 6 months treated for 1 month with teriparatide [human PTH(1-34)] (Asahi Kasei Pharma; Japan) as follows. (i.) Vehicle (DV; n=4); (ii.) 20 μg/kg/day (D20; n=3); (iii.) 40 μg/kg/day (D40; n=3); (iv.) Once weekly 140 μg/kg (W140; n=3); (v.) and once weekly 280 μg/kg (W280; n=4). Proximal femurs were imaged ex vivo using micro-CT (Scanco Viva CT-40) at 15 μm voxel size. Structure was quantified in a 10mm length ROI starting at the midshaft using StrAx1.0. StrAx1.0 segments the CC, the TZ (outer & inner) and, trabecular bone.

In rabbits treated with 20 μg/kg/d, CC porosity was unchanged. OTZ and ITZ porosity increased (9.0%; p=0.02, 5.4%; p=0.07 respectively). 40 μg//kg/d increased CC and OTZ porosity respectively by 49.9 and 19.3% ($p<0.05$) . The increase in porosity in CC and OTZ was greater than those in D20 group (all $p<0.05$). Porosity in ITZ was increased but not significantly so, (5.0%; p=0.13). Bone volume fraction decreased with 40 μg/kg/d (7.9%; p=0.005). Increments in bone volume fraction with 20 μg/kg/d and weekly therapies were modest respectively 0.76, 1.4 and 2.0% (NS).

By contrast, treatment with either dose of weekly teriparatide decreased CC porosity by 6.8% and 7.3% respectively (NS). Porosity was unchanged in TZs.

Teriparatide effects on the cortex depend on the treatment regimen and on the cortical region measured. Weekly regimens did not increase porosity. Daily regimens increased porosity in TZ, and the larger dose did so both in CC and TZ. We suggest that TZ porosity may be a 'pseudo-porosity' caused by bone formation on trabeculae abutting the cortex, which have not completely fused, and therefore this may not be associated with fragility as occurs with porosity due to remodeling imbalance.

Synchrotron mCT evaluation of peri-implant hard tissues -A review of the literature and preliminary results. Camilla Neldam*[1], Else Marie Pinholt[2], Niklas Rye Jørgensen[3]. [1]PhD student, Denmark, [2]DDS, M Sci, dr. odont, Professor & Head, Denmark, [3]MD, PhD, DMSc, Denmark

SRmCT is considered gold standard for evaluating bone microarchitecture, and it possess major advantages in comparison to laboratory-based microtomography due to its high resolution, high contrast, and excellent of high signal-to-noise-ratio. Hence, giving us the very highest spatial resolutions achieved today.

A review of the literature included 17 studies concerning animal, experimental and human studies, with SRmCT on bone substitutes and dental titanium implants. Reviewing the literature emphasizes the need, within dental practice, for more detailed evaluations in higher resolutions than previously obtained. SRmCT is required for evaluation of osseointegration of dental implants, comparison of osseointegration of different bone substitutes, and bone microarchitecture at the bone-to implant interface.

Using SRmCT at a voxel size of 5 μm in an experimental goat mandible model, bone-to-implant contact was found to around 5%, and the bone volume fraction increased at radial distance from the implant surface up to 50% and levelled out to approximately 70% at a 300 μm radial distance.

This method has been successful in depicting the bone and cavities in three dimensions thereby enabling us to give a much more precise answer to the fraction of the bone-to-implant contact compared to previous methods.

Matrix protein biglycan mediates suture expansion osteogenesis via potentiation of β-catenin. Hua Wang*[1], Wen Sun[2], Lin Wang[3], Wei-Bing Zhang[4]. [1]Institute of Stomatology, Nanjing Medical University, Peoples Republic of China, [2]Nanjing Medical UniversityThe Research Center for Bone & Stem Cells, Peoples Republic of China, [3]Institute of Stomatology, Nanjing Medical University, China, [4]School of Stomatology, Nanjing Medical University, Nanjing, China, USA

To investigate the involvement of extracellular matrix glycoprotein biglycan and β-catenin in bio-mechanical osteogenesis during suture expansion. We evaluated the changes in biglycan and β-catenin signaling over time using a mouse midpalatal suture expansion model in vivo. Furthermore, we examined the effect of tensile strain (2% magnitude, 0.5 Hz), which represents clinical expansion force on biglycan and β-catenin signaling in primary calvarial osteoblasts whose biglycan was silenced in vitro. Our data showed that expansive force significantly induced new bone formation at the edge of palatal sutures. The sutures prominently widened peaking on day 7. The immunopositive areas of biglycan peaked on day 7, showed a similar spatio-temporal pattern with ALP and Col-1. Biglycan, β-catenin, and osteogenic markers such as Runx2, ALP and Col-1 increased both at protein and mRNA levels together. Meanwhile, mechanical strain sufficiently induced up-regulation of biglycan and nuclear β-catenin in vitro. Silencing biglycan resulted in an attenuated up-regulation of nucleus β-catenin and Runx2 in response to mechanical strain; however, Wnt3a treatment was able to partly reverse this disruption. Our results demonstrated that biglycan as a component of extracellular matrix mediates suture expansion osteogenesis via potentiation of β-catenin.

A realistic musculoskeletal model of the thoracolumbar spine and ribcage produces spinal loading patterns that may help explain the non-uniform distribution of vertebral fractures along the spine. Alexander Bruno*[1], Dennis Anderson[2], Xiangjie Meng[3], Mary Bouxsein[4]. [1]Harvard-MIT, USA, [2]Beth Israel Deaconess Medical Center, USA, [3]Tsinghua University, China, [4]Beth Israel Deaconess Medical Center, Harvard Medical School, USA

Vertebral fractures (VFx) are the most common complication of osteoporosis, and occur most frequently in the mid-thoracic and thoracolumbar regions of the spine. However, the mechanisms underlying this site-specific occurrence of VFx are not known. Our working hypothesis is that the locations of VFx may be explained by the pattern of spine loading, such that during daily activities the mid-thoracic and thoracolumbar regions see preferentially higher mechanical loading compared to other spine regions. Prior estimates of vertebral loading are limited as they have used relatively simple models that did not incorporate explicit contributions of the ribcage and thoracolumbar trunk muscles. To address these limitations and test our hypothesis we developed a realistic musculoskeletal model of the thoracolumbar spine that includes the thoracic and lumbar vertebrae, ribs, sternum, arms, and head. The model, implemented in OpenSim musculoskeletal modeling software, uses 700 Hill-Type muscle fascicles to simulate major muscle groups affecting the trunk. Intervertebral and costovertebral joints are modeled as ball and pin joints, respectively. The ribs are connected to the sternum by actuators to account for the load transfer facilitated by the costal cartilage. We also examined whether incorporation of intra-abdominal pressure (IAP) into the model affects the magnitude or pattern of spine loading. To do so, we simulated abdominal pressure (10 kPa) by exerting forces on the diaphragm, pelvis, and abdominal wall, which the major abdominal muscle groups then had to balance. We used the model to simulate a lifting activity (10 kg weights in each hand with the elbows flexed 90°) with and without IAP present, and computed the compressive force in the axial direction of each vertebral body. We found that without IAP, vertebral compressive load increased progressively from upper to lower thoracic spine, peaking at T11 (Figure 1). Inclusion of IAP reduced vertebral compressive loading, with the largest reduction occurring at T10 and T11 (~38% reduction). The highest load in the model with IAP occurred at L1, with a smaller secondary peak at T8, corresponding to the locations of peaks in VFx occurrence. In sum, our realistic thoracolumbar spine model provides evidence that variations in spine loading may partly explain observed fracture patterns, and that intra-abdominal pressure plays an important role in vertebral loading.

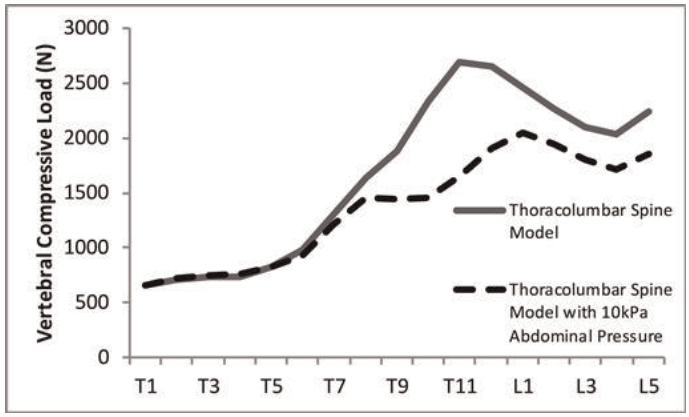

Figure 1: Vertebral compressive loading on T1 through L5 for standing with 10 kg weights

Four Year Vibration Therapy Reduces Age-related Bone Loss and Improves Lower Extremity Function. Belinda Beck*. Griffith University, Australia

Purpose: Whole body vibration (WBV) reduces fall risk in older adults and improves bone in animal models, however, human bone responses have been inconsistent. Some have suggested the inability to detect vibration-induced skeletal adaptation is a function of inadequate trial duration and that longer term stimulus is required. The study aim then was to determine the effect of 4 years of daily WVB on risk factors of hip fracture.

Methods: Four postmenopausal women (61.8 $\pm$ 9.8 y) with low bone mass (mean femoral neck [FN] t-score: -2.9 $\pm$ 0.92) undertook daily 10-20min WBV for 4 years (VIB) (Juvent, Parsippany). Four age-, sex-, and BMI-matched controls (58.8 $\pm$ 7.4 y) continued usual activities (CON). At baseline (T0) and annually to 4 years (T4), biometrics, whole body (WB), lumbar spine (LS) and FN BMD and BMAD (DXA, XR-800, Norland), parameters of tibial geometry (pQCT, XCT3000, Stratec), and lower extremity muscle function and balance were tested. Physical activity and calcium consumption were recorded. Effects were examined by repeated-measures ANOVA controlling for calcium, and by t-test comparison of measures taken at T0 and T4.

Results: The groups were similar at baseline, except VIB had lower LS and FN t-scores (p=0.005 and p=0.03, respectively). VIB maintained all measures between T0 and T4, with the exception of chair rise time, which improved (p=0.02), and tibial trabecular content and area, which decreased ($p<0.05$). CON did not improve any measure and lost FN BMC, BMD, BMAD and strength as well as tibial cortical bone content ($p<0.05$). Controlling for calcium, significant within-subject effects (time) were detected for LS BMC, (p=0.03) and tibial endosteal circumference (p=0.0001). Despite low participant numbers, power was adequate for significant outcomes (1-ß=0.73 and1-ß=0.99, respectively). Young's modulus of the LS (p=0.06, 1-ß=0.61) and tibial cortical density (p=0.06, 1-ß=0.62) approached significance. In all cases, CON lost more than VIB.Conclusion: Long term low intensity WBV tempers age-related skeletal loss and improves lower extremity function which may reduce the risk of falling

SU0050

Effectiveness of Community Group and Home Based Falls Prevention Exercise Programmes on Bone Health in Older People: the ProAct65+ Bone Study. Rachel Duckham[1], Katherine Brooke-Wavell*[2], Tahir Masud[3], Rachael Taylor[4], Denise Kendrick[5], Hannah Carpenter[5], Dawn A Skelton[6], Susann Dinan[7], Heather Gage[8], Richard Morris[7], Steve Iliffe[7]. [1]Deakin University, Aus, [2]Loughborough University, United Kingdom, [3]Nottingham University Hospitals NHS Trust, United Kingdom, [4]Nottingham University Hospitals NHS Trust, United Kingdom, [5]University of Nottingham, United Kingdom, [6]Glasgow Caledonian University, United Kingdom, [7]University College London, United Kingdom, [8]University of Surrey, United Kingdom

Exercise may reduce osteoporotic fracture risk through both increasing bone strength and reducing fall risk. Falls prevention exercise programmes can reduce fall incidence, and also include some strengthening exercises suggested to load bone but there is little information as to whether these programmes influence bone mineral density (BMD) and strength. The study compared home (Otago Exercise Programme, OEP) and group (Falls Management Exercise, FaME) falls prevention exercise programmes with usual care in older people to determine whether these interventions can improve bone strength.

Men and women aged over 65 years were recruited through primary care. They were randomised by practice to OEP, FaME or usual care. Bone mineral density (BMD) was measured by dual X-ray absorptiometry (GE-Lunar Prodigy) prior to randomisation and following the 24 week intervention. Comparisons between treatment arms were made using random effects linear regression models to allow for clustering by practice, adjusted for baseline values, gender, medication use and comorbidities.

Participants were 319 older people (193 women and 126 men), aged (mean + SD) 72 + 5 years. 92% of participants completed the trial. The OEP group completed 58 + 43 minutes/week of home exercise, whilst the FaME group completed 39 + 16 and 30 + 24 minutes/week of group and home exercise respectively. Femoral neck BMD changes did not differ between treatment arms, with mean effect sizes in OEP and FaME relative to usual care arms being -0.003 and -0.002 g/cm^2 respectively (P = 0.44 and 0.53). Effect sizes for section modulus were -8.5 and -6.9 mm^3 in OEP and FaME respectively (P=0.21 and 0.28). There were no significant changes at other skeletal sites, or in sensitivity analyses excluding those taking medication or poor compliers with exercise.

The OEP and FaME programmes did not influence bone mineral density in older people, although they have an important role in preventing fractures by preventing falls. To increase bone strength, programmes may need to incorporate exercise that exerts higher strains on bone and/or have a longer duration.

SU0051

Effects of Whole-Body Vibration Therapy on Bone, Muscle and Metabolism in Obese Adolescents. Rickard Zeijlon*[1], Bojan Tubic[2], Staffan Mårild[3], Göran Wennergren[4], Jovanna Dahlgren[4], Per Magnusson[5], Diana Swolin-Eide[6]. [1], Sweden, [2]Department of Pediatrics, Gothenburg University, Sweden, [3]The Queen Silvia Children's Hospital, Sahlgrenska Academy at the University of Gothenburg, Sweden, [4]The Queen Silvia Children's Hospital, Sweden, [5]Linkoping University,Sweden, Sweden, [6]Queen Silvia Children's Hospital, Sweden

Purpose: Mechanical loading is osteogenic and whole-body vibration therapy (WBV) is an emerging method for muscular training. WBV results in increased muscle power and decreased blood pressure in postmenopausal women. Previous WBV studies in obese women have demonstrated increased growth hormone levels, increased oxygen uptake, lowered BMI and increased muscular strength. This prospective pilot study is the first to investigate the effects of a 3-month WBV on bone mass, muscle, anthropometry and metabolic parameters in obese adolescents.

Methods: Seven obese patients, age 11-17 years (girls=3/boys=4), mean weight 92 kg (67-119 kg) and mean BMI 32 kg/m2 (26-39 kg/m2), were included and six completed 3 months of WBV. Three sessions (10-13 min per session) per week were performed on a side-alternating Galileo® (Stratec) vibration plate, frequency 18-24 Hz and amplitude +/-3.9 mm. Measurements were made at baseline and after 3 months of heel bone mineral density (BMD) and heel bone mineral content (BMC) by DXL (Demetech), muscle strength and balance with Leonardo Mechanography® (Stratec), weight and body fat with Tanita® (Tanita Corp.). Blood pressure, anthropometrics and metabolic parameters were followed.

Results: WBV was well tolerated but compliance varied and the reasons for skipping sessions were that patients regarded the WBV training to be boring or too strenuous. We observed decreased levels of total cholesterol (-0.76 mmol/L, p=0.046) and triglycerides (-0.39 mmol/L, p=0.028). A decrease was found for serum insulin in five patients, from pathological to normal levels, with a reduction with 10% to 72%. The decreased fasting insulin levels (mean -10.8 mU/L,) did, however, not reach statistical significance, p=0.12. There was a tendency of decreased abdominal girth (-2.4 cm, p=0.07) and decreased body fat (-1.6%, p=0.07). No change was observed for the Leonardo-measurements of muscle strength (single two leg jump, multiple one leg hopping and chair rising test). Calcaneal BMD and BMC, body weight, BMI, blood pressure and pulse did not change over the study period.

Conclusion: This prospective pilot study of whole-body vibration therapy demonstrated reduced fasting insulin levels for most patients and an improved lipid profile. There was, however, no effect on calcaneal bone mass. The number of patients was small and larger randomized studies are warranted.

Hand grip strength, leg extensor power and cardiorespiratory fitness are associated with bone mineral density in men aged 18-60 years: the Health2008 study. Peter Schwraz[1], Niklas Rye Joergensen[2], Barbara Rubek Nielsen*[3], Anne Sofie Dam Laursen[4], Allan Linneberg[4], Mette Aadahl[4]. [1]Research Centre of Ageing & Osteoporosis, Department of Medicine, Copenhagen University Hospital, Glostrup, Denmark.Faculty of Health Sciences, University of Copenhagen, Copenhagen,Denmark, Denmark, [2]Research Centre of Ageing & Osteoporosis, Department of Medicine & Diagnostics, Copenhagen University Hospital, Glostrup, Denmark, Denmark, [3]Research Centre of Ageing & Osteoporosis, Department of Medicine, Copenhagen University Hospital, Glostrup, Denmark, Denmark, [4]Research Centre for Prevention & Health, Denmark

Background & Purpose: Osteoporotic fracture represents a growing economical burden to society, not only caused by fractures in women, but also due to an increasing number of fractures in men.

In this cross-sectional study we aimed to investigate the association of muscular and cardio-respiratory fitness with BMD at the lumbar spine and hip in men.

Material & Methods: The association between independent variables VO_{2max}, leg power and hand grip, and dependent variables BMD at the lumbar spine and total hip, was explored in a series of linear regression models successively adjusted for age, weight and height, smoking, alcohol intake and leisure time physical activity level.

Results: In the fully adjusted model we found a significant association of VO_{2max} with BMD at the lumbar spine, $p<0.0089$. Furthermore we observed significant associations of VO_{2max} ($p<0.0022$) and leg power ($p<0.011$) with BMD at total hip.

Conclusion: We found that cardiorespiratory fitness was associated with BMD. Furthermore, hand grip strength and leg power were associated with increasing BMD at the lumbar spine and total hip, respectively. These results lend support to the mechanostat hypothesis. Further prospective studies are needed to further investigate the association between physical activity and BMD.

SU0053

Loading during Growth is Associated with Radius Marrow Density and Sector-specific Cortical Properties. Jodi Dowthwaite*[1], Tomas Cervinka[2], Charity Ntansah[3], Harri Sievanen[4], Tamara Scerpella[5]. [1]SUNY Upstate Medical University;Syracuse University, USA, [2]Tampere University of Technology, Finland, [3]Syracuse University, USA, [4]The UKK Institute for Health Promotion Research, Finland, [5]University of Wisconsin, USA

Purpose: Pediatric loading is considered osteogenic, but marrow and sector-specific cortical properties have not been evaluated. We hypothesized that extreme pediatric loading exposure and local lean mass and muscle strength would predict 33% radius marrow and cortical properties.

Methods: DXA (whole body) and non-dominant radius pQCT (33%) scans were performed, yielding data for 125 females, age 8 to 25 yrs. Cross-sectional moments of inertia (CSMImax, CSMImin), marrow density (MaD) and sector-specific cortical properties were evaluated: density (mean (CoD), medial (CoDmed)); cross-sectional area (mean (CoA), medial (CoAmed)); thickness (mean (CoTh), medial (CoThMed)). Annual mean non-aquatic physical activity and gymnastic training (h/wk) were calculated for the year prior. GYM were defined based on annual mean training $\geq$6 h/wk for $\geq$2 years (others= NON). Tanner breast stage was self-reported. Ipsilateral grip strength (GRIP) was recorded (n= 101/125). Continuous variables were log-transformed, except GRIP. Backward stepwise regressions were run, entering Tanner Breast stage, ln age (squared), ln ulna length, ln ipsilateral arm non-bone lean mass, ln ipsilateral arm fat mass, ln total body % fat, ln annual mean physical activity (lnPAL) and GYM history; separate regressions added GRIP (n=101).

Results: Subjects ranged from pre-puberty to early adulthood (mean age 15.7yrs, sd 4.3). Dependent variables increased with age ($p<0.05$), except MaD and CoAmed (positive trends); CSMI (max and min: no relationship). GYM was a negative predictor of MaD, CoD and CoDmed, but a positive predictor of CoA, CoAmed, CSMImax and CSMImin ($p<0.05$). PAL was a negative predictor of CoA, CoAmed, CoTh, CoThmed and CSMImax, whereas arm fat mass was positively related to CoA, CoAmed, CSMImax and CSMImin ($p<0.05$). Arm lean mass was positively related to all ($p<0.05$), except MaD, CoD and CoDmed. In the GRIP subsample, GRIP, GYM, lean and fat mass were positive predictors of CoA, CoAmed, CSMImax and CSMImin ($p<0.05$); in those 4 models, PAL was a negative predictor of all but CSMImin ($p<0.05$).

Conclusions: Gymnastic exposure during growth was associated with greater bone strength and geometry, except cortical thickness; GYM was negatively associated with mean and medial cortical density. As predicted, GRIP, local lean mass and GYM history were positively associated with bone area and strength indices. In contrast, marrow density was negatively associated with GYM loading history.

SU0054

Visceral adiposity is independently and inversely associated with bone mineral density. Mark Peterson*, Palak Choksi. University of Michigan, USA

Background

Despite ample evidence to confirm that increased visceral adipose tissue (VAT) deposition occurs with higher BMIs, the interrelationships between altered fat partitioning and regional bone quality is less understood. The purposes of this study were to examine the associations between adiposity and bone mineral density (BMD) across a large, heterogeneous cohort of adults, as well as to determine the mediating influences of age, race, sex, metabolic abnormalities, and objectively measured physical activity.

Methods

A population representative sample of 5,268 individuals, aged 20-85 years, was included from the combined 2003-2006 NHANES datasets. Body mass index, percent body fat and VAT as determined by dual energy X-ray absorptiometry (DXA), accelerometry-derived objectively measured physical activity, and markers of cardiometabolic risk were examined as potential predictors of whole body and lumbar BMD, after adjusting for sociodemographic data (i.e., age, race, sex, household income, etc.). Cardiometabolic abnormalities included elevated blood pressure, levels of triglycerides, fasting plasma glucose, C-reactive protein, home-ostasis model assessment (HOMA) of insulin resistance value, hemoglobin A1c (GHB), and low HDL-cholesterol level.

Results

Females had lower whole body (β=-0.10; $p<0.001$) and lumbar (β=-0.01; $p<0.001$) BMDs. Age was a negative predictor of whole body BMD among men (β=-0.001; $p<0.001$), and of both whole body (β=-0.003; $p<0.001$) and lumbar (β=-0.002; $p<0.001$) BMD in women. BMI was independently and positively associated with BMD at the whole body (β=0.01; $p<0.001$) and lumbar (β=0.007; $p<0.001$) levels. Conversely, after adjusting for all demographic variables and BMI, VAT was negatively associated with BMD at the whole body (β=-0.03; $p<0.001$) and lumbar (β=-0.02; $p=0.002$) levels. Moderate to vigorous physical activity (i.e., per 10 minute) was positively associated with BMD at the whole body (β=0.002; $p=0.02$), but not the lumbar level ($p=0.49$). Among women, elevated fasting glucose was inversely associated with whole body BMD (β=-0.02; $p=0.04$); yet, this became non-significant after controlling for VAT.

Conclusions

Our data demonstrate a significant negative association between VAT and BMD at the whole body and lumbar levels, even after adjustment for BMI, age, sex, and other sociodemographic predictors. Moreover, moderate to vigorous physical activity was a positive predictor of whole body BMD in both men and women.v

SU0055

The association of pediatric fractures with serum vitamin D25 [25(OH)D] levels compared to non-fracture community controls. Barbara Minkowitz*[1], Barbara Cerame[2], Eileen Poletick[3], Tim Leier[3], Sherri Luxenberg[3], Lior Fusman[3], Jonathan Chevinsky[3], Nicole Formoso[3], Renee Eng[3], Samantha Easton[3], Scott Musial[3], Ben Lee[2]. [1]Pediatric Orthopaedics, USA, [2]Goryeb Children's Hospital, USA, [3]Morristown Medical Center, USA

Background: There is growing concern over a relationship between severity of pediatric fractures and low 25(OH)D. Goals: Compare 25(OH)D levels and lifestyle of children with fractures to controls, determine if 25(OH)D is associated with fractures and determine the 25(OH)D fragility fracture threshold.

Methods: Pediatric fracture and community control patients included. Survey and medical data used. Parameters included 25(OH)D, calcium, PTH, age, gender, fracture history, severity, location, mechanism, ethnicity, skin tone, multivitamin, diet, sunscreen, outdoors time. Analyses performed, ANOVA with Tukey HSD, Chi Square test for fractures with 25(OH)D cut-off groups: 25(OH)D <12, <20, <30, and <40 ng/ml.

Results: 379 fracture patients, 754 controls $\leq$ 21 years. Fracture and controls mirrored comparable 25(OH)D (27.7 $\pm$9.3 ng/mL). Lower 25(OH)D in Hispanics (23.1 $\pm$ 7.3 ng/mL), African-American (20.76 $\pm$ 7.9 ng/mL), dark skinned (22.2 $\pm$ 8.7 ng/mL). Low 25(OH)D in "poor eater" children < 5 years (23.1 $\pm$ 9.2 ng/mL, p< .01). 25(OH)D higher with multivitamins (29.0 $\pm$ 9.3 ng/mL, p< .05), and in "healthy eater" < 5 years (30.7 $\pm$ 9.3 ng/mL). Sunscreen, outdoor time not correlated. Surgical fractures with lower 25(OH)D (24.1 $\pm$ 9.6 ng/mL, p< .001) vs. nonsurgical. Past history of fracture and mechanism not correlated to 25(OH)D. Femur fractures trended to lower 25(OH)D (Mean 24.4 ng/mL, +/- 9.5). Association 25(OH)D to fracture severity (surgical fractures) is seen. OR (odds ratio) for surgical fracture within fracture groups by 25(OH)D: <12 OR 5.3 (95% confidence Cl 1.3-22.7) p < .024, <20 OR 3.8 (95% confidence Cl 2.2-6.8) p < .001, <30 OR 2.7 (95% confidence Cl 1.5-4.6) p < .001 and <40 not significant (95% confidence Cl 0.8-4.7) p < 0.1. Not pathologic with VitD >30ng/mL.

Clinical Relevance: Occurrence of surgical pediatric fractures is associated with low 25(OH)D levels, a new target serum level of 25(OH)D of at least 30ng/mL (40ng/ml being more inclusive) was noted, which is associated with reduction in surgical severity of pediatric fractures.

SU0056

Distal one-third forearm bone mineral density of healthy young children is more highly related to lumbar spine than whole body bone mineral density. Catherine Vanstone[1], Jonathon Maguire[2], Hope Weiler[3], Paula Lavery[1], Neil Brett*[1]. [1]McGill University, Canada, [2]University of Toronto, Canada, [3]McGill University, USA

The recommended clinical assessment of bone density in children includes dual-energy x-ray absorptiometry (DXA) scans of lumbar spine or whole body bone mineral density (BMD). However, childhood fractures in otherwise healthy children are typically in the long bones, yet data on forearm DXA scans are limited. The objective was to examine whether distal one-third forearm BMD relates to whole body and lumbar spine BMD in healthy children (2-8 y). Participants were recruited through daycares and media advertisements in Montreal, Canada. Children with mobility problems or medical conditions affecting bone health were excluded. Body mass index Z-Scores for age (BAZ) were calculated using the WHO growth standard. Lumbar spine 1-4, distal forearm (non-dominant) and whole body BMD were acquired using DXA array mode (Hologic Discovery QDR series). All measurements were taken during winter months (January and February). Relationships among BMD values were tested using Pearson correlations for normal data and Bland Altman plots of agreement. Differences among age and sexes were tested using ANOVA; data are mean $\pm$ SD. Average age was 4.6 $\pm$ 1.9 y, BAZ 0.5 $\pm$ 0.8 kg/m^2 and $>$ 65% had at least one Caucasian parent. Distal one-third forearm BMD was more highly related (r=0.83, p$<$0.0001, n=68) to lumbar spine BMD than with whole body BMD (r=0.67, p$<$0.001, n=63). BMD at all sites varied according to age (p$<$0.05), but differences among one-year increments were not significant (table). From Bland-Altman plots, the bias between BMD values from whole body and distal one-third forearm was greater (0.367; 95% CI 0.212-0.521) than it was between lumbar spine and forearm (0.178; 95% CI 0.099-0.257). This study suggests that distal one-third forearm DXA scans offer an alternative assessment of BMD that is readily attainable in healthy children. Further work is needed to establish normative values.

Age (y)	Whole body BMD*	Lumbar spine BMD*	Forearm BMD*
2	0.628 ± 0.082 (10)	0.482 ± 0.073 (12)	0.298 ± 0.050 (11)
3	0.617 ± 0.082 (10)	0.501 ± 0.073 (11)	0.316 ± 0.050 (11)
4	0.714 ± 0.094 (12)	0.528 ± 0.080 (12)	0.319 ± 0.051 (12)

Effect of adiposity and trabecular bone microarchitecture on vibration transmission in the lower limb of children with spastic CP. Harshvardhan Singh*[1], Daniel Whitney[2], Freeman Miller[3], Christopher Knight[2], Christopher Modlesky[2]. [1]University of Delaware, USA, [2]University of Delaware, USA, [3]AI duPont Hospital for Children, USA

There is evidence that a high-frequency, low-magnitude vibration (HLV) stimulus has an anabolic effect on bone in children with cerebral palsy (CP). Whether the composition of the tissue in the lower extremities affects the transmission of HLV in children with CP is unknown. Children with spastic CP (n = 11; 4 to 11 y) with a gross motor function classification (GMFC) scale of I-III and able to stand participated in the study. Triaxial accelerometers (PCB Piezotronics Inc) were secured to the skin at the lateral condyle of the distal femur and at the medial malleolus of the distal tibia in the more affected limb. A uniaxial accelerometer was secured to the center of a plate (Juvent Inc) that was programmed to emit an HLV signal (0.3 g, 30 Hz). As the children stood on the plate, accelerations were sampled (2 kHz) at the plate, distal tibia and distal femur for 30 seconds while the plate was at rest and for 30 seconds while the plate was vibrating. Markers of trabecular bone microarchitecture [apparent trabecular bone volume to total volume (appBV/TV), trabecular number (appTb.N), trabecular thickness (appTb.Th) and trabecular separation (appTbSp)] at the distal femur and distal tibia (700 x 175 x 175 µm3) were estimated in the more affected limb using magnetic resonance imaging (1.5 T, GE). The concentration of fat in the more affected leg was estimated using dual-energy X-ray absorptiometry (Hologic Inc). Compared to the acceleration measured at the plate, the accelerations were 23 $\pm$ 9 % greater at the distal tibia and 41 $\pm$ 22 % lower at the distal femur. Distal tibia appBV/TV, appTb.Th and appTbSp were significantly related to transmission of HLV to the distal tibia (r = 0.664, 0.736 and -0.736, respectively, all p $<$ 0.05). Markers of trabecular bone microarchitecture were not significantly related to HLV transmission to the distal femur (p $>$ 0.25). Fat concentration in the leg was not significantly related to HLV transmission to the distal femur or the distal tibia (p $>$ 0.4). The findings suggest that the floor-based HLV plate evaluated in this study transmits higher signal to the distal tibia but only ~60 % of the signal to the distal femur in ambulatory children with spastic CP. The degree of amplification of HLV signal at the distal tibia in children with CP is less pronounced in children with less developed trabecular bone microarchitecture. Whether this amplification of HLV signal affects the adaptation of bone to HLV requires further investigation..

Effects of exposure to oral contraceptive use on bone mineral accrual and bone density between 12 and 30 years of age: A longitudinal study. Adam Baxter-Jones*[1], Stefan Jackowski[1], Ashlee McLardy[2], Carol Rodgers[3]. [1]University of Saskatchewan, Canada, [2]College of Kinesiology, University of Saskatchewa, Canada, [3]University of Saskatchewan, Canada

Introduction: Although genetic factors are a key determinant of bone mass accrual, hormonal levels are also documented to play a major role. Hormonal based oral contraceptives (OC) are primarily designed with the intention to regulate circulating endogenous estrogen and progesterone levels to maintain endometrial stability. However, the effects of OC use on bone mass development are controversial. The purpose of this longitudinal study was to investigate the long-term effect of OC exposure on bone mass accrual from adolescence to young adulthood.

Methods: One hundred and ten female participants were drawn from the University of Saskatchewan's Pediatric Bone Mineral Accrual Study (PBMAS) (1991-2011). Height, weight, body composition, maturation (years from peak height velocity (PHV - biological age [BA]), diet, physical activity (PA), bone parameters and OC use were measured annually between 12 and 30 years of age. DXA measures included total body (TB), lumbar spine (LS), femoral neck (FN) bone mineral content (BMC) and areal bone mineral density (aBMD). Site specific multilevel models were constructed for both BMC and aBMD development controlling for BA, size, body composition, PA and OC exposure.

Results: A significant negative independent OC use by biological age interaction (-4.94 $\pm$ 2.41 g, p$<$0.05) was found in the model of TB BMC but not TB aBMD (p$>$0.05). For the LS, significant BA by OC use interactions were observed for BMC (-0.29 $\pm$ 0.11 g, p$<$0.05) and aBMD (-3.07 $\pm$ 1.09 g/cm2, p$<$0.05). At the FN, no significant BA by OC use interactions were observed for either BMC or aBMD (p$>$0.05).

Conclusions: The effects of exposure to OC were site and age specific. When exposed to OC during the period 5 years post PHV, TB and LS BMC increased. However, from 6 years post PHV, TB and LS BMC decreased with increasing age. FN BMC showed no OC use effects. Only LS aBMD increased prior to 5 years post PHV in OC users and decreased thereafter. These results indicate that OC may be beneficial if taken within five years of obtaining PHV but thereafter may have negative effects on bone accrual and bone density.

SU0059

Is adolescent body composition development associated with bone structural strength at the proximal femur in males at 50 years of age?. Stefan Jackowski*[1], Donald Bailey[1], Joey Eisenmann[2], Lauren Sherar[3], Adam Baxter-Jones[1]. [1]University of Saskatchewan, Canada, [2]Michigan State University, USA, [3]Loughborough University, United Kingdom

Purpose: Although, body composition (fat and fat-free mass) is documented to influence skeletal strength throughout life, the potential role of fat mass accrual on bone structural strength remains controversial. Additionally, there is a paucity of information regarding the associations between adolescent body composition development and mid-adulthood bone structural strength. Therefore, the purpose of this study was to investigate whether adult bone structural strength at the proximal femur at 50 years of age was associated with the development of adolescent fat and fat-free mass.

Methods: Two hundred and seven males aged 7-17 years from the Saskatchewan Growth and Development Study (SGDS) had annual skinfolds measurements from 1964-1973. The sum of 5 skinfolds were used to estimate adolescent percent body fat (%BF) and percent fat free mass (%FFM). In adulthood (52.0 $\pm$ 0.5 years) 37 male participants were reassessed and hip bone strength measures which included cross sectional area (CSA) and section modulus (Z) at the narrow neck (NN) and femoral shaft (S) were determined using hip structural analysis (HSA). Adult bone strength measures were ranked and used to categorize individuals into low and high bone strength groupings. Multilevel models were constructed to examine the independent development of %FFM and %FM between adult bone strength groups.

Results: When age and body size were controlled, males with greater SZ in adulthood had developed significantly greater %BF during adolescence (1.65 $\pm$ 0.70 %, $p$$<$0.05). No significant differences in adolescent %FFM development were observed for NNCSA, NN Z and S CSA bone strength groupings ($p$$>$0.05).Conclusions: Males with greater bending strength at the femoral shaft in adulthood had significantly higher trajectories of fat mass development relative to overall body weight during adolescence. This suggests that the development of relative fat mass in adolescence may be associated with greater bending strength at the proximal femur in mid-adulthood. Further investigations are warranted to confirm the impact of adolescent body composition on adult bone structural strength.

Risk of vitaminD insuficiency and inadequate bone mineral status in newcomer immigrant and refugee children in Canada, data from Healthy Immigrant Children study. Hassanali Vatanparast*[1], Virginia Lane[2]. [1]University of Saskatchewan, Canada, [2]University of Saskatchewan, Canada

Nutrition and physical activity are two main important factors influencing bone mineral mass accumulation during childhood and adolescence. Newcomer immigrant/refugee children are at a high risk of poor nutritional status. Vitamin D deficiency, in particular, and its related diseases is a major concern due to minimal sun exposure in countries in high latitude and limited dietary sources. Using Healthy Immigrant Children (HIC) pilot data (n=72), we previously reported vitamin D and bone mineral status of sample of newcomer children. No large scale study is available in Canada to evaluate the relationship between nutrition, physical activity and bone mineral status on newcomer immigrant and refugee children. Objective: to evaluate the association between nutrition, physical activity and bone mineral status in immigrant and refugee newcomer children to Canada. Methods: In a cross-sectional design, we recruited 299 immigrant (n=133) and refugee (n=166) children aged 3-13 years who had been living in Saskatoon and Regina, Canada for no more than five years. Measurements included serum 25OHD using LC-MS/MS method, total body bone mineral content (TBBMC) using DXA, dietary assessment using three 24-h recalls, physical activity and USDA food security questionnaires. Results: The mean age of children was 8.0±2.8 y. The rate of childhood food insecurity was 18.8% and 32.3% in immigrants and refugees respectively. Most children (83.7%) were meeting the recommended level of physical activity (≥60 minutes/day). Over 40% of children had the TBBMC lower than the predicted optimal values for their age, sex and ethnicity. We found 63.7% of participants had inadequate levels of serum vitamin D (<50nmol/L) for bone health. Prevalence of inadequacy in vitamin D intake was 92%. In stepwise regression analyses, after controlling for all potential covariates; height and serum vitamin D status were found to be determinants of TBBMC (R^2=0.82, p<0.001). Children who were taller and had significantly greater serum vitamin D also had greater TBBMC with β=0.93 for height and β=0.12 for serum vitamin D. In accordance with HIC pilot data, a considerably high rate of vitamin D deficiency and insufficiency in newcomer immigrant and refugee children and its association with bone mineral mass during this important stage of life requires immediate preventive interventions to minimize the risk of serious vitamin D related diseases.

SU0061

Associations between Vitamin D Status, Undercarboxylated Osteocalcin, and Glucose Metabolism in American Children. Kelly Giudici*[1], Berdine Martin[2], Emma Laing[3], George McCabe[4], Linda McCabe[5], Dorothy Hausman[6], Ligia Martini[7], Richard Lewis[3], Connie Weaver[2], Munro Peacock[8], Kathleen Hill Gallant[2]. [1]Department of Nutrition, School of Public Health, University of São Paulo, Brazil, [2]Purdue University, USA, [3]The University of Georgia, USA, [4]Department of Statistics, College of Science, Purdue University, USA, [5]Department of Nutrition Science, College of Health & Human Sciences, Purdue University, USA, [6]Department of Foods & Nutrition, University of Georgia, USA, [7]University of São Paulo, Brazil, [8]Indiana University Medical Center, USA

Objective: We have previously reported a lack of relationship between total OC and insulin resistance in American children. However, there are suggestions in the literature that it may be undercarboxylated OC (ucOC) that is related to insulin resistance. The purpose of this study was to investigate the relationships among serum 25 hydroxyvitamin D [25(OH)D], ucOC, and insulin resistance in American children. Methods: This cross-sectional analysis included baseline data from 318 children who participated in a randomized controlled trial of vitamin D supplementation. Relationships among fasting serum 25(OH)D, HOMA-IR (insulin resistance), and ucOC were analyzed. Results: The prevalence of vitamin D deficiency and insufficiency was <1% and 14%, respectively, by IOM definitions, and 43.1% of participants were overweight/obese based on BMI-for-age percentiles. Serum 25(OH)D was positively associated with ucOC ($r = 0.46$, $p < 0.0001$), and this relationship persisted after adjusting for fat mass. However, a preliminary analysis of prospective data from a subset of subjects who were supplemented with 4000 IU/d vitamin D3 for 12 weeks and subjects who were given placebo for 12 weeks did not show an effect of increasing serum 25(OH)D on serum ucOC [12 week Δ25(OH)D = +132 ±16 ng/mL with 4000 IU/d and -24 ±8 ng/mL with placebo]. Additionally, while there was a weak negative relationship between serum 25(OH)D and HOMA-IR (r=-0.267 p<0.0001), there was no relationship between ucOC and HOMA-IR. Conclusions: This cross-sectional analysis agrees with some previous reports of associations between vitamin D status, bone, and energy metabolism. 25(OH)D was negatively associated with insulin resistance and positively associated with ucOC. However, the absence of association between ucOC and insulin resistance suggests that ucOC does not link vitamin D status, bone, and energy metabolism. Additionally, while there was a moderately strong cross-sectional association at baseline between serum 25(OH)D and ucOC, our preliminary prospective data analysis of the effect of increasing serum 25(OH)D on change in serum ucOC suggests that this is not a causal relationship.

SU0062

Effects of 2 years on treatment with Zoledronic acid given every 6 months on bone mineral density, bone turnover and skeletal architecture in children with secondary osteoporosis. Craig Munns*[1], Craig Coorey[2], Julie Briody[1], Andrew Biggin[2]. [1]The Children's Hospital at Westmead, Australia, [2]The Children's Hospital at Westmead, Australia

Background/Aims: Intravenous bisphosphonates are administered increasingly for treatment of childhood osteoporosis. Zoledronic acid (ZA) has potential advantages over pamidronate with a shorter infusion time and longer duration of action.

We aimed to evaluate the safety and efficacy of twenty-four months of ZA administered every six months to children with osteoporosis.

Methods: Retrospective cohort study of 28 patients (17 male, 11 female) with secondary osteoporosis treated with zoledronic acid (0.05mg/kg/dose) every six months for minimum of 24 months. Nineteen patients were immobile, 3 steroid induced osteoporosis, 3 idiopathic osteoporosis, 1 coelaic disease, 1 Girault syndrome and 1 neurofibromatosis type 1. Thirteen patients had vertebral fractures alone (vertebral wedging fractures defined as >20% reduction in anterior-posterior ratio), 9 had nonvertebral fractures alone and 6 had both vertebral and nonvertebral fractures. Mineral homeostasis, bone mineral density (BMD) via DXA and pQCT and vertebral shape were evaluated at baseline and 24 months. We compared these data to that of a similar cohort treated with zoledronic acid 0.025mg/kg every three months.

Results: Median age at start of treatment was 11.6 years (range 8.8-14.0). Following the first infusion, 2 developed asymptomatic hypocalcemia, 14 developed temperature >38℃, 13 aches/pain and 6 nausea. At 24 months, there was reduced bone turnover and improvement in BMD (DXA and pQCT) and vertebral shape. One patient fractured after starting ZA. Growth was normal. There was a significantly greater increase in lumbar spine BMD in those children who received 3 monthly zoledronic acid compared to 6 monthly zoledronic acid.

Conclusion: ZA administered six monthly was associated with acute phase reaction to the first dose and improvement in BMD, reduction in bone turnover and improved vertebral shape at 24 months. The 3 monthly zoledronic acid regimen resulted in a greater increase in BMD.

Osteocyte-mediated parathyroid hormone signaling restrains the long-term hematopoietic stem cell pool in the bone marrow. Benjamin Frisch*[1], Alexandra Goodman[2], Olga Bromberg[2], Xiaolin Tu[3], Teresita Bellido[3], Laura Calvi[4]. [1]University of Rochester School of Medicine & Dentistry, USA, [2]University of Rochester School of Medicine & Dentistry, USA, [3]Indiana University School of Medicine, USA, [4]University of Rochester School of Medicine, USA

The microenvironment, including osteocytes, is known to play a critical role in the regulation of hematopoiesis and hematopoietic stem cells (HSCs). Pharmacologic treatment with parathyroid hormone, PTH (1-34) increases HSCs in mice through microenvironmental signals, as HSCs do not express the PTH receptor (PTH1R). However, to date there is no evidence of a physiologic role for PTH in HSC regulation. To study the physiologic role of osteocyte-mediated PTH signaling to HSCs we utilized cre recombinase driven by the 8kb-DMP1 promoter and conditionally deleted PTH1R in osteocytes (OCy-PTH1Rko mice). There was no significant difference in PTH levels in OCy-PTH1Rko and WT mice. In 5-week-old OCy-PTH1Rko mice there was a significant decrease in long-term HSCs measured by flow cytometric analysis (.0029 ± 0..00028 vs. .0021 ± .00021 % of cells, WT vs. OCy-PTH1Rko p≤0.05 N≥19 mice/group). Confirming the phenotypic changes, OCy-PTH1Rko mice had a loss of long-term engraftment capacity, demonstrated by 12 weeks post-transplant myeloid cell engraftment was 10 fold lower than in WT littermate controls (32.68 ± 6.10 vs. 3.65 ± 1.02 % donor derived, WT vs. OCy-PTH1Rko donors p≤0.05 N≥3 mice/group). In contrast, short-term engraftment 4 weeks post-transplant was increased in OCy-PTH1Rko mice compared to WT littermate controls (10.81 ± 0.8904 vs. 25.13 ± 4.415 % donor derived, WT vs. OCy-PTH1Rko donors p≤0.01 N=9 mice/group) suggesting a shift from long to short-term HSC potential. The difference in engraftment was multilineage suggesting HSCs as the source. Five-month-old adult mice were also analyzed. At this age, OCy-PTH1Rko mice had decreased phenotypic multipotent progenitors (MPPs) compared to WT littermate controls measured by flow cytometric analysis (0.10 ± 0.01 vs. 0.07 ± 0.01 % of cells, WT vs. OCy-PTH1Rko donors p≤0.05 N≥19 mice/group). Despite this decrease, like the 5-week-old mice, at 5 months of age OCy-PTH1Rko mice showed an increase in levels of short-term engraftment 4 weeks post transplant (4.939 ± 1.367 vs. 14.34 ± 1.884 % donor derived, WT vs. OCy-PTH1Rko donors p≤0.001 N=10 mice/group). The difference in early engraftment was observed in both myeloid and lymphoid lineages, and was lost by 12 weeks post transplant. Our findings demonstrate a physiologic role of PTH signaling through osteocytes in the restraint of HSCs, indicating that osteocytes contribute to maintenance of the long-term repopulating pool.

Fibronectin from the Osteoblastic Niche Modulates Myelopoiesis and the Response to Cancer. Sabrina Kraft*[1], Carla Sens[1], Anja von Au[1], Inaam Nakchbandi[2]. [1]University of Heidelberg & Max-Planck Institute of Biochemistry, Germany, [2]Max-Planck Institute of Biochemistry & University of Heidelberg, Germany

Fibronectin (FN) is a matrix protein that stimulates osteoblast (Ob) differentiation and can bind to immune cells. The aim of this work is to characterize the role of osteoblast fibronectin in hematopoiesis.

Fibronectin was conditionally deleted in osteoblasts (cKO: colα1(I)-cre $FN^{fl/fl}$). In the bone marrow (BM) of cKO the precursors to myeloid cells (GMPs) were increased by 43% and the myeloid CD11b+ cells decreased by 53% ($p<0.05$). Culturing CT Ob with CT or cKO BM induced a comparable increase in the percentage of CD11b+ cells, while cKO Ob failed to induce an increase. Osteoblasts produce an isoform of fibronectin called EDA. Purified EDA, but not plasma-FN increased the percentage of CD11b+ cells *in vitro*. Thus EDA supports CD11b+ differentiation.

CD11b+ cells define a population called myeloid-derived suppressor cells (MDSCs) that inhibit the immune response to cancer. Induced subcutaneous B16 melanoma lesions were smaller in cKO (by 73%, $p<0.05$). Injection of MDA-MB-231B/luc+ in the tibia of T-cell deficient mice similarly resulted in hampered early tumor growth (68%, $p<0.05$). To establish a causal relationship between decreased CD11b+ in cKO and suppression of cancer growth we isolated CD11b+ cells from cKO and CT BM. Injection of equal numbers of these cells together with B16 cells subcutaneously in CT animals resulted in smaller lesions when CD11b+ cells from cKO animals were used. This suggests that CD11b+ cells already underwent epigenetic changes in the absence of EDA during their development. In line with this, isolated CD11b+ cells from cKO tumors showed a cytokine expression profile consistent with an immune active environment compared to cells originating from CT tumors (e.g. IFNγ increased 2x, $p<0.05$). Finally, in order to establish that EDA normalizes the response of CD11b+ cells, CT and cKO BM was depleted from CD11b+ cells and treated with EDA or plasma-FN for 24 hours. Developing CD11b+ cells were isolated, mixed with B16 and injected in CT mice. CD11b+ from cKO animals that were differentiated *ex vivo* in the presence of EDA normalized their response towards the tumor. Thus EDA exposure during early differentiation of myeloid cells affects their behavior.

In summary, EDA fibronectin originating from the osteoblasts controls the differentiation of myeloid cells in the bone marrow and affect their later response towards cancer. Our data also suggest the presence of myeloid cells that affect cancer growth without interacting with T-cells.

High plasma osteocalcin associates with low blood Hb and anemia in elderly men; The MrOS Sweden Study. Catharina Lewerin*[1], Helena Johansson[2], Ulf Lerner[3], Magnus Karlsson[4], Mattias Lorentzon[5], Elizabeth Barrett-Connor[6], Ulf Smith[7], Claes Ohlsson[8], Dan Mellstrom[9]. [1]Västra Götaland, Sweden, [2]Center for Bone & Arthritis Research, Sweden, [3]Sahlgrenska Univesity Hospital, Sweden, [4]Skåne University Hospital Malmö, Lund University, Sweden, [5]Geriatric Medicine, Center for Bone Research at the Sahlgrenska Academy, Sweden, [6]University of California, San Diego, USA, [7]Department of Molecular & Clinical Medicine, Sahlgrenska Academy, Sweden, [8]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden, [9]Sahlgrenska University Hospital, Sweden

Purpose

Osteoblasts have been suggested to be involved in the regulation and proliferation of hematopoetic stem cells. Blood hemoglobin (Hb) declines with age in healthy elderly men but the reason for this is not fully understood. Osteocalcin has previously been demonstrated to be associated with diabetes and blood glucose. The association between Hb and serum osteocalcin is unknown. Our aim was to determine whether serum osteocalcin is associated with anemia or low Hb in elderly men.

Methods

Men without diabetes participating in the Gothenburg part of the (cross-sectional), population-based MrOS (Osteoporotic Fractures in Men) Sweden cohort were included in the present study (n=821, median age 75.3 years, age range 69-81 years). Osteocalcin was evaluated in relation to Hb before and after adjustments for potential covariates (i.e. age, body mass index (BMI), erythropoietin (EPO), total estradiol, fasting insulin, adiponectin and cystatin C).

Results

Hb ($r=-0.12$, $p<0.001$), but not osteocalcin decreased with age. Hb correlated (age adjusted) negatively with osteocalcin ($r=-0.18$, $p<0.0001$). After adjusting for age, men with higher osteocalcin levels were more likely to have Hb in the lowest quartile of values (OR per SD decrease in osteocalcin = 1.35 (95% CI 1.15-1.59) and this was still significant after further adjustment for BMI, fasting insulin, EPO, and estradiol [OR per SD decrease in osteocalcin = 1.21 (95% CI 1.01-1.44)]. There was a negative linear trend (age adjusted) between quartiles of Hb and osteocalcin ($p<0.001$). Anemic men (age adjusted) (47/812) (Hb<130 g/L) had significantly higher mean osteocalcin than non anemic men (33.9 µg/L vs. 27.1 µg/L, $p<0.001$). In multiple stepwise linear regression analyses (adjusted for age, EPO, estradiol, fasting insulin, BMI, cystatin C, and adiponectin) osteocalcin was an independent predictor of Hb ($p<0.05$).

Conclusion

We present novel data showing that high osteocalcin is associated with low Hb and anemia in non-diabetic subjects. This association was unaffected by adjustment for age, BMI, EPO, estradiol, fasting insulin, cystatin C, and adiponectin. However, causality between osteocalcin and Hb cannot be assumed due to the cross-sectional design of the study.

Simultaneous Measurement of Changes in Bone Remodeling and Microvasculature in Response to Estrogen Deficiency-Induced Bone Loss and Intermittent PTH-Induced Bone Gain. Wei-Ju Tseng*[1], Chantal De Bakker[1], Tiao Lin[1], Wei Tong[2], Haoruo Jia[3], L. Scott Levin[4], Ling Qin[1], Xiaowei Liu[1]. [1]University of Pennsylvania, USA, [2]Perelman school of medicine, USA, [3]University of Pennsylvania, USA, [4]Hospital of the University of Pennsylvania, USA

The bone remodeling process works in conjunction with the microvascular network within bone marrow to regulate calcium and phosphate homeostasis. Because of their drastic effects on bone remodeling, it is likely that both ovariectomy (OVX) and intermittent parathyroid hormone (iPTH) treatment will also affect bone vasculature. However, simultaneous visualization of the effect of bone remodeling in the trabecular and vascular microstructures remains challenging. The objective was to investigate the changes in bone remodeling and microvasculature in response to estrogen deficiency-induced bone loss and iPTH-induced bone gain in rat tibiae.

6 intact and 9 OVX female SD rats (12-wk old) were purchased. Starting at 14-wk old, 3 intact rats (PTH group) received iPTH daily for 2 weeks (60µg/kg/day). At wk 15 and 16, 2 sequential scans of the proximal tibia were performed by *in vivo* µCT (Scanco, 10.5 µm) for 3 groups of rats: OVX (n=9), PTH (n=3), and control (CON, n=3). After the wk16 scan, rats were perfused with Microfil (MV122), a radiopaque contrast agent, to form a vascular cast inside bone. The tibiae were then harvested, fixed and scanned at 6-µm pre- and post- decalcification followed by a novel registration procedure to distinguish vessels from bone (Fig 1 Top). Finally, bone resorption and formation were identified and measured based on the sequential *in vivo* µCT scans (Fig 1 Bottom).

After 4-wk osteopenia development, OVX rats had 74% lower bone volume fraction (BV/TV, $p<0.05$), 80% lower trabecular number (Tb.N, $p<0.05$), 360% higher trabecular spacing (Tb.Sp, $p<0.05$) compared to the CON group; vessel volume fraction (Ves.V/TV) was 30% lower ($p<0.05$) than that of the CON group. After 2-wk iPTH treatment, Tb.Th and Ves.Th were 12% and 30% greater ($p<0.05$) than the CON group, respectively. µCT-based *in vivo* bone dynamic histomorphometry indicates that bone resorption rate was highly elevated after OVX (942%, $p<0.05$); bone formation rate increased 266% after iPTH treatment ($p<0.05$) compared to the CON group. The resorption and formation map with vessels (Fig 1) provides a platform for our future analysis between vessels and bone formation/resorption.

This study establishes a novel technique that simultaneously visualizes the 3D microstructures of bone and microvasculature using standard µCT. Combined with measures of bone formation and resorption, this may help improve our understanding of the effects of OVX and iPTH on the bone-blood vessel function unit.

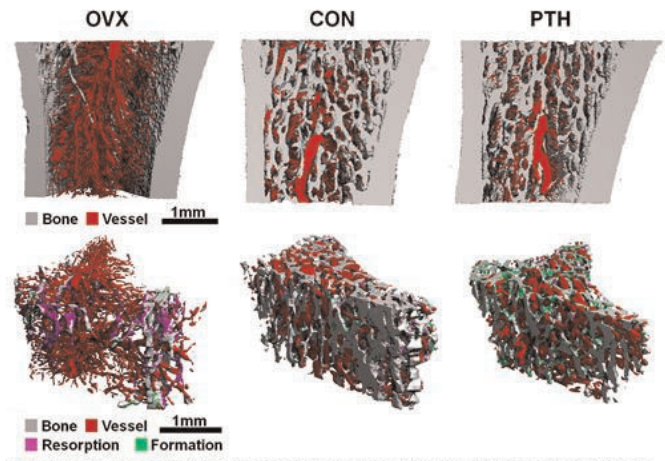

Fig 1. (Top) 3D representative bone and blood vessel images of the proximal tibia of OVX, control, and PTH groups. (Bottom) The 3D trabecular bone and blood vessel images with bone formation and resorption labeled in green and purple, respectively.

The Effect of Phosphate Deficiency on Callus Composition. Amira Hussein*[1], Kyle Lybrand[2], Anthony De Giacomo[2], Kamolnat Tabattanon[3], Brenna Hogue[2], Chantal De Bakker[4], Marie Demay[5], Elise Morgan[6], Louis Gerstenfeld[1]. [1]Boston University School of Medicine, USA, [2]Boston University School of Medicine, USA, [3]Boston University, USA, [4]Boston University, USA, [5]Massachusetts General Hospital & Harvard Medical School, USA, [6]Boston University, USA

Introduction: Fracture healing is a complex sequence that requires coordinated development of cartilage and bone, as well as tissue mineralization, to regain mechanical competence. Failure of these processes results in impaired healing. Phosphate is essential for bone growth and fracture repair; normal fracture healing is impaired in phosphate-deficient animals. This study's goal was to assess the effects of phosphate deficiency on cartilage development, cartilage resorption, and tissue mineralization.

Methods: Closed, stabilized fractures were generated in the right femora of C57BL/6J (B6) male mice. Phosphate deficiency was initiated in the diet two days prior to fracture and was maintained for 5 (5DR) or 20 (20DR) days post-fracture. Phosphate was then replenished and bone healing was allowed to continue until 14 or 21 days post-fracture. Control mice were provided with normal diet throughout the study. Cartilage volume was quantified with contrast-enhanced computed tomography using a cationic contrast agent. Cartilage volume, mineralized tissue volume, and tissue mineral density (TMD) were quantified.

Results: Phosphate deficiency impaired healing and resulted in lack of callus bridging for the longer period of diet restriction. The 20DR calluses had higher cartilage content, lower mineralized tissue volume and lower TMD than control calluses ($p<0.021$). The properties of the 5DR calluses were intermediate to those of the control and 20DR calluses. At 14 days post-fracture, the 5DR calluses had similar cartilage volume and TMD ($p>0.693$), but lower mineralized tissue volume than control calluses ($p<0.001$), and greater mineralized tissue volume compared to the 20DR calluses ($p<0.005$). At 21 days post fracture, the cartilage volume in the 5DR calluses was not different from that of the controls or 20DR ($p>0.113$). Further, the 5DR calluses had lower mineralized tissue volume and TMD than control calluses ($p<0.001$), and greater TMD than 20DR calluses ($p<0.001$).

Discussion: Phosphate restriction had an inhibitory effect on bone healing by impairing cartilage development and callus mineralization. More severe effects were seen with a longer duration of restriction. These results further showed that while cartilage tissues formed and resorbed, subsequent mineralization and bone replacement were progressively inhibited. The data suggest that long dietary restriction of phosphate can be used as a model of nutritionally induced delayed union.

Figure 1. For control and phosphate deficient (PI) calluses at 14 and 21 days post-fracture: (A) Representative 3-D rendering showing pre-existing bone (white) mineralized tissue (yellow), and cartilage (red); (B) Cartilage volume, mineralized tissue volume and tissue mineral density (*: $p<0.05$)

Engineering an Ex Vivo Analogue of Bone Tissue for Studies of Bone Metastasis. Eliza Fong*[1], Xinqiao Jia[2], Antonios Mikos[3], Daniel Harrington[3], Mary Farach-Carson[4]. [1]BioScience Research Collaborative, USA, [2]University of Delaware, USA, [3]Rice University, USA, [4]Rice University, USA

Elucidating the survival and growth mechanisms used by metastatic tumors in the bone/bone marrow microenvironment is key to the discovery of novel therapeutics specifically targeting bone metastasis. Currently, the study of cell-cell and cell-extracellular matrix (ECM) interactions that influence cancer cell adaptation and growth in bone is hampered by a lack of physiologically relevant ex vivo preclinical models. Hyaluronan (HA) is a major component of bone marrow ECM, and hydrogels made from HA reflect the low modulus of the tissue. Having previously demonstrated the ability of HA hydrogels to support the three-dimensional growth of bone metastatic prostate cancer cells, we next sought to modify the HA matrix further via the incorporation of other ECM moieties to enable the culture of bone marrow stromal cells (BMSC) or osteoblasts (OB) – critical cell types in the bone metastatic microenvironment. Given that hyaluronan-only hydrogels lack integrin-binding ECM motifs needed for the survival of mesenchymal cells, the cell binding domain present in many adhesive proteins such as osteopontin and fibronectin, GRGDS, was selected to confer adhesive properties to the hydrogel. Additionally, the matrix metalloproteinase 2 and 9 – sensitive peptide, PQGIWGQ, was chosen so that the resulting hydrogel matrix could be remodeled by cells expressing these proteases. Using thiolated HA, we conjugated acrylated GRGDS as pendant motifs, and crosslinked the HA chains using acrylated PQGIWGQ. By modulating the concentration of GRGDS and PQGIWGQ peptides, conditions that optimized the 3-dimensional spreading and growth of human bone marrow stromal cells and murine osteoblast-like cells within the hydrogels were identified. Figure 1 shows the ability of the modified hydrogels to support extensive spreading of MC 3T3 murine osteoblast-like cells encapsulated within. Additionally, this system is suitable for 3D co-cultures of bone metastatic cancer cells with bone resident cells. This engineered 3D system provides a suitable tool to study bone metastasis in a physiologically relevant, controlled, biomimetic system, overcoming many limitations of current models.

The Bone Microenvironment Modulates ERα Positive Mammary Cancer Cells Favoring Estrogen Independent Skeletal Metastasis. Aude-Helene Capietto*[1], Szeman Ruby Chan[2], Julie Allen[2], Robert Schreiber[2], Roberta Faccio[3]. [1]Washington University School of Medicine, USA, [2]Washington University School of Medicine, USA, [3]Washington University in St Louis School of Medicine, USA

Human breast tumors expressing the estrogen receptor-α (ERα) often develop osteolytic bone metastases. Despite successful therapeutic options for ERα+ breast cancer, resistance to endocrine therapy frequently occurs and leads to tumor recurrence at skeletal locations even in patients treated with anti-resorptive therapies. To further understand how the bone microenvironment modulates ERα+ breast cancer cells towards estrogen-independency, we generated a clinically relevant mouse model of bone metastasis. ERα+ SSM2 and SSM3 cell lines are derived from spontaneous mammary tumors in STAT1-/- mice. Both cell lines developed luminal mammary tumors when injected in the mammary fat pads of WT129S6 female mice and their growth is completely prevented by estrogen deprivation. When injected intratibially (i.t.), SSM2 and SSM3 cells developed lytic bone metastases within 30 days, as visualized by X-Rays, microCT and histology. Furthermore, if inoculated in the arterial system, SSM2 tumor cells showed high bone tropism, in particular to spine (60%), and developed lytic bone lesions by 56 days. The goal of endocrine therapies, including ovariectomy (OVX), is to deprive tumor cells of estrogen thus inhibiting their growth. To determine if ERα+ SSM cells could grow in bone independent of estrogen, cells were injected i.t. in sham-operated or OVX mice. Similarly to the orthotopic location, SSM3 tumor cells are sensitive to estrogen deprivation and fail to grow in OVX mice. Surprisingly, SSM2 cells develop osteolytic bone lesions within 2 months in 6/6 OVX mice indistinguishable to sham-operated controls. Because OVX induces bone loss through osteoclast activation, we injected SSM cells into male mice. Similarly to OVX, SSM3 cells did not grow in males, while 100% of males injected with SSM2 cells displayed osteolytic lesions. To gain more insights into the ability of SSM2 cells to become estrogen resistant once they reach the bone, we compared by gene array the genetic profile of SSM2 and SSM3 cells from in vitro cultures. Surprisingly, we found no differences in expression of genes modulating bone cell activation between the two lines. In conclusion our data highlight the crucial role of the bone environment in modulating permissive tumor cell growth and acquisition of estrogen insensitivity. Future inquiries at understanding mechanisms of hormonal resistance of ERα+ SSM2 cells may help define new therapeutic targets for breast cancer patients with skeletal metastases.

The role of Insulin-like growth factor-I and Focal adhesion kinase in angiogenesis of tumor induced bone metastasis. Naito Kurio*[1], Tsuyoshi Shimo[2], Hiromasa Kuroda[3], Kenichi Matsumoto[3], Tatsuo Okui[3], Akira Sasaki[4]. [1]Japan, Japan, [2]Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sci, Japan, [3]Okayama university, Japan, [4]Okayama University, Japan

Introduction: Insulin-like growth factors (IGFs), which are the most abundant growth factors stored in bone, have been involved in progression of many types of cancers. Recently we have reported thata novel dual inhibitor for Focal adhesion kinase (FAK) Tyr^{397} and IGF-IR, TAE226, inhibited breast cancer bone metastasis in vivo. However, the relationship between FAK Tyr^{397} and IGF-1 in angiogenesis of tumor bone microenvironment has not been revealed yet. Using both *in vivo* and *in vitro* approaches, we investigated how FAK Tyr^{397} and IGF-1 is involved in tumor progression in bone metastasis site.

Methods: A mouse model of bone metastasis was prepared by inoculating mice with tumor cell suspensions of breast cancer cell line MDA-MB-231 cells via the left cardiac ventricle. Oral administration of TAE226 was carried out at a dose of 30 mg/kg every day. A cell cycle was analyzed by flow cytometry. The expression of IGF-I and FAK related signals were confirmed by Western blot analysis. To evaluate the effects of IGF-I *in vitro,* proliferation, migration, and angiogenesis assays were performed.

Results: Oral administration of TAE226 in mice significantly decreased bone metastasis and CD31 positive endothelial cells in bone metastasis site. When the endothelial cells were exposed of 1uM of TAE226, the number of cells in sub-G_1 population increased to about 18% in flow cytometric analysis. Treatment of TAE226 increased TUNEL positive cells within 48h compared with control. IGF-I upregulated pFAK Tyr^{397} activity, and stimulated proliferation, migration and tube formation of endothelial cells *in vitro*, and these effects were inhibited in the presence of IGF-1R inhibitor.

Conclusion: IGF-I was critically involved in breast cancer progression in bone metastasis site through pFAK Tyr^{397} activation in endothelial cells.

Cell-to-Cell Crosstalk Between Multiple Myeloma Cells and Osteocytes Activates Notch Signaling and Triggers Osteocyte Apoptosis. Jesus Delgado-Calle*[1], Judith Anderson[2], Lilian Plotkin[1], G. David Roodman[3], Teresita Bellido[1]. [1]Indiana University School of Medicine, USA, [2]Indiana University, USA, [3]Indiana University, USA

Multiple myeloma (MM) is a malignancy characterized by accumulation of monoclonal plasma cells in the bone marrow, which grow in bone and weaken the skeleton. Hallmarks of MM bone disease are exacerbated resorption, reduced formation, and increased osteocyte apoptosis. Osteocytes regulate bone remodeling but their contribution to cancer in bone is unclear. We report that co-culture of murine osteocytic MLO-A5 cells with human JJN3 MM cells activated Notch signaling in MLO-A5 cells, with increased expression of the Notch target genes Hes/Hey1. This effect was suppressed by the Notch inhibitor GSIXX and did not occur when the MM and MLO-A5 cells were not in direct cell-to-cell contact. Similar activation of Notch signaling in osteocytic cells was induced by interaction of MLO-A5 or Y4 osteocytic cells with murine 5TGM1 MM cells or human MM.1S cells. Further, co-culture of JJN3 MM cells with MLO-A5 cells increased the percent of apoptotic MLO-A5 cells, which was inhibited by the caspase inhibitor DEVD. Importantly, human CD138+ MM cells purified from marrow aspirates from MM patients also induced MLO-A5 osteocytic cell apoptosis. MM-induced apoptosis of MLO-A5 osteocytic cells in co-culture as early as 8h and increased for up to 48h. Interestingly, inhibition of Notch signaling with GSIXX blocked MM-induced osteocyte apoptosis at 8-24h but not at 48h. Further, culture of MLO-A5 cells on plates coated with the Notch Delta ligand 1 fused to IgG2 increased the percentage of dead cells compared to cells cultured on IgG2 control, and the effect was inhibited by GSIXX. Overexpression of the Notch intracellular domains 1 or 2 known to be sufficient to activate Notch signaling also increased MLO-A5 cell apoptosis. In contrast, MM-derived conditioned medium (MM-CM) only induced apoptosis in MLO-A5 cells at 24 and 48h but not at 8h, and GSIXX did not prevent osteocyte apoptosis induced by MM-CM. These results demonstrate that 1) cell-to-cell crosstalk between MM and osteocytes induces osteocyte apoptosis, 2) MM-induced osteocyte apoptosis is triggered by activation of Notch signaling through direct cell-cell contact and maintained by MM-derived soluble factors, and 3) Notch activation per se is sufficient to trigger osteocyte apoptosis. Together with evidence presented in a separate abstract demonstrating MM-induced changes in osteocytic gene expression, these findings suggest a critical role of osteocytes in the initiation and development of MM bone disease.

Diagnostic microRNA Biomarkers Differentiate Benign Osteblastoma and Malignant Osteosarcoma. Scott Riester*[1], Amel Dudakovic[1], Eric Lewallen[2], Jorge Torres-Morra[2], Emily Camilleri[2], Peter Rose[2], Michael Yaszemski[3], Franklin Sim[2], Thomas Shives[2], Sanjeev Kakar[2], Andre Van Wijnen[1]. [1]Mayo Clinic, USA, [2]Mayo Clinic, USA, [3]Mayo Clinic College of Medicine, USA

The purpose of this investigation is to identify novel microRNA biomarkers that can reliably distinguish between osteoblastoma and osteosarcoma. Osteoblastoma is a benign primary bone tumor that is histologically very similar to malignant osteosarcoma. It is clinically difficult to distinguish between these two tumors using current techniques and misdiagnosis is common resulting in unacceptable clinical outcomes for patients.In this investigation next generation RNA sequencing was used to evaluate microRNAs expressed in fresh frozen and formalin fixed paraffin embedded (FFPE) tumor samples. RNA sequencing analysis included four fresh and four FFPE osteosarcoma samples, and two fresh frozen and five FFPE osteoblastoma specimens. A subset of microRNAs that showed differential expression in both the fresh frozen and formalin fixed paraffin embedded tumor specimens were selected for validation using TaqMan qPCR assays. In total, six microRNAs showed a statistically significant difference in expression between osteosarcoma and osteoblastoma by both RNA sequencing and qPCR. Two microRNAs showed higher expression in osteosarcoma, while four had higher expression in osteoblastoma. One of the FFPE samples examined in this study was from a case where an osteosarcoma was misdiagnosed as an osteoblastoma. These six microRNA biomarkers were able to correctly identify the FFPE tumor sample as an osteosarcoma demonstrating the potential clinical utility of these markers. MicroRNAs show differential expressed between osteoblastoma and osteosarcoma in both fresh frozen and formalin fixed paraffin embedded tumor samples by both RNA-sequencing and qPCR analysis. These differentially expressed microRNAs have the ability to clinically differentiate benign and malignant tumors which are frequently misdiagnosed in clinical practice. MicroRNA biomarkers are highly promising for the evaluation of bone tumors and have the potential to improve clinical outcomes for patients.

NELL-1 expression in benign and malignant bone tumors and correlation with malignant potential. Jia Shen[1], Kevork Khadarian[2], Greg Asatrian[2], Xinli Zhang[1], Sarah Dry[2], Kang Ting[1], Chia Soo[2], Aaron James*[1]. [1]University of California, Los Angeles, USA, [2]UCLA, USA

NELL-1 is a secreted osteoinductive protein that binds Integrinβ1 to activate Wnt/β-catenin signaling. Recent interest has grown in using recombinant NELL-1 as both a local or systemic agent to induce bone formation. However, the expression and role of NELL-1 in benign and malignant bone tumors is entirely unknown. Our purpose was to examine the expression patterns of NELL-1 in a comprehensive analysis of bone-forming skeletal tumors, accompanied by an examination of the effects of NELL-1 in osteosarcoma (OS) cells.

First, the expression of NELL-1 was assessed across a diverse set of human bone-forming skeletal tumors by immunohistochemistry. This included benign tumors (osteoid osteoma, osteoblastoma) and malignant tumors (osteosarcoma and its variants, including osteoblastic OS, chondroblastic OS, fibroblastic OS, periosteal OS, parosteal OS, telangiectatic OS). Semi-quantitation was performed to describe the distribution and intensity of immunostaining. Next, the Saos-2 OS cell line was treated with NELL-1, and the effects on osteogenic differentiation were assessed via standard methods.

Results showed that NELL-1 was expressed to some degree in all types of bone-forming tumors (Fig. 1). Diffuse, intense staining for NELL-1 was observed in all benign bone tumors, and was localized to bone-lining osteoblasts, osteocytes and bone matrix (Table 1). A relative loss of NELL-1 expression was observed in osteosarcoma specimens, with predominant weak, patchy NELL-1 immunostaining. Among OS subtypes, fibroblastic OS demonstrated the highest NELL-1 immunostaining. *In vitro*, NELL-1 significantly induced the osteogenic differentiation of Saos-2 OS cells by all markers examined ($*p<0.01$).In summary, NELL-1 is an osteoinductive protein that is widely expressed in both benign and malignant bone-forming skeletal tumors. NELL-1 is diffusely and robustly expressed in benign tumors, and its expression is much reduced in malignant bone tumors. NELL-1 induces osteodifferentiation of OS cells, and may represent a novel approach to induce the differentiation of sarcoma stem cells in combination with traditional chemotherapeutic regimens. Future areas of investigation include the specificity of NELL-1 in bone-forming tumors, and the *in vivo* effects of NELL-1 on osteosarcoma disease progression.

Serum Dickkopf-1 is a prognostic marker in prostate cancer. Tilman Rachner*[1], Stefanie Thiele[2], Andy Göbel[2], Susanne Füssel[2], Martina Rauner[3], Lorenz Hofbauer[4]. [1]University Hospital Dresden, Germany, [2]University Hospital Dresden, Germany, [3]Medical Faculty of the TU Dresden, Germany, [4]Dresden University Medical Center, Germany

Prostate cancer is the most prevalent malignancy in men and up to 80% of affected patients develop skeletal metastases in the course of their disease. Dickkopf-1 (DKK-1) is a secreted Wnt inhibitor that has been associated with the pathogenesis of bone lesions in multiple myeloma by impairing Wnt promoted osteoblast differentiation and activity. There is emerging evidence to suggest that DKK-1 also affects the biology of prostate cancer. However, detailed knowledge regarding the contribution of DKK-1 to prostate cancer biology remains elusive.

We determined the DKK-1 tissue expression in prostate cancer using a prostate cancer tissue microarray (n=400) by IHC and DKK-1 serum levels in 80 patients with prostate cancer. DKK-1 expression in prostate cancer tissue was significantly increased ($p<0.0001$) compared to BPH, with no differences between different tumor stages. Increased DKK-1 expression was also observed in healthy tissue adjacent to the tumor, with no apparent difference between the mean DKK-1 expression of malignant and adjacent normal cells. There was no correlation between Gleason score, PSA values, the presence of lymph node metastases, age and DKK-1 tissue expression. Furthermore, there was no correlation between tumor DKK-1 (high vs. low) and patient overall or disease specific survival.

Detectable DKK-1 serum levels were found in 76/80 prostate cancer patients. Patients were divided into two groups according to their DKK-1 serum levels. Mean DKK-1 serum levels of all patients were 33.9 ± 10.7 pmol/l. Patients with the higher 50% of DKK-1 levels (38.4 ± 7.2 pmol/l) were found to have a significantly lower overall ($p=0.015$) and disease specific survival ($p=0.031$) than those with low DKK-1 levels (16.2 ± 7.5 pmol/l). Univariate Cox regression analyses revealed significant associations between survival and T stage, lymph node involvement, Gleason score and DKK-1. There was no association for age and PSA. An additional stepwise multivariate Cox proportional hazard analyses revealed that high DKK-1 serum levels were independently associated with a poor survival ($p= 0.007$; HR 3.73; 95%CI 1.44-9.66).

In summary, these observations suggest that serum DKK-1 may serve as a prognostic marker in prostate cancer.

The protein tyrosine phosphatase Rptpz suppresses osteosarcoma development in Trp53-heterozygous mice. Christina Baldauf*[1], Anke Jeschke[2], Vincent Kanbach[2], Philip Catala-Lehnen[2], Peter Nollau[3], Michael Amling[4], Sheila Harroch[5], Thorsten Schinke[6]. [1]University of Hamburg, Germany, [2]Department of Osteology & Biomechanics, University Medical Center Hamburg Eppendorf, Germany, [3]Department of Clinical Chemistry, University Medical Center Hamburg Eppendorf, Hamburg, Germany, [4]University Medical Center Hamburg-Eppendorf, Germany, [5]Department of Neuroscience, Institute Pasteur, France, [6]Department of Osteology & BiomechanicsUniversity Medical Center Hamburg Eppe, Germany

Osteosarcoma (OS), an aggressive tumor derived from osteoblasts, belongs to the most common types of cancer in growing children. Since specific molecular targets for OS treatment remain to be identified, surgical excision combined with radiation and/or chemotherapy is still the only way to help affected individuals. We have previously identified the protein tyrosine phosphatase Rptpz as a marker of terminally differentiated osteoblasts, which negatively regulates their proliferation *in vitro*. Here we have addressed the question if Rptpz can function as a tumor suppressor protein inhibiting OS development *in vivo*. We therefore analyzed the skeletal phenotype of mice lacking *Ptprz1*, the gene encoding Rptpz, on a tumor-prone genetic background, i.e. *Trp53*-deficiency or *Trp53*-heterozygosity. Since we failed to detect any type of bony tumors in 12 weeks old mice lacking both, *Ptprz1* and *Trp53*, we screened a large number of 52 weeks old *Trp53*-heterozygous mice ($n \geqslant 20$ for each genotype) by contact radiography. In this context *Ptprz1*-deficiency significantly enhanced OS development with 25 % of the mice being affected, whereas *Trp53*-heterozygous littermates carrying two functional *Ptprz1* alleles did not display obvious skeletal abnormalities. The tumors in *Ptprz1*-deficient *Trp53*-heterozygous mice were present in various locations (spine, long bones, ribs), and their OS nature was confirmed by undecalcified histology. Likewise, cell lines derived from the tumors were able to undergo osteogenic differentiation *ex vivo*. An initial comparison between *Ptprz1*-heterozygous and *Ptprz1*-deficient cultures further revealed that the latter ones displayed increased proliferation together with a higher abundance of tyrosine-phosphorylated proteins. These findings underscore the relevance of Rptpz as an attenuator of proliferation in differentiated osteoblasts and raise the possibility that activating Rptpz-dependent signaling could specifically target osteoblastic tumor cells.

Effects of PGE2 receptor EP4 antagonist on breast cancer-induced bone metastasis and bone destruction in the metastasis region. Kenta Watanabe[1], Chiho Matsumoto[2], Michiko Hirata[3], Takayuki Maruyama[4], Masaki Inada[2], Chisato Miyaura*[2]. [1]Tokyo University of Agriculture & Technology, Japan, [2]Tokyo University of Agriculture & Technology, Japan, [3]Tokyo University of Agriculture & Technology, Japan, [4]Ono Pharmaceutical Co., Ltd, Japan

Prostaglandin E2 (PGE2) is a lipid mediator, and associated with local bone destruction with inflammation. We have reported that PGE2-induced bone destruction was mediated by increased RANKL expression in osteoblasts, and that EP4 is the most effective PGE2 receptor rather than the other EP subtypes (EP1, EP2 and EP3) in bone tissues. In bone metastasis of breast cancer, however, the functional role of EP4 is still unclear. In this study, we examined the effects of EP4 antagonist in case of *in vivo* administration on the model of breast cancer bone metastasis. When the cloned breast cancer cells with luciferase expression (4T1-Luc) were inoculated into mouse tail vein, the cells metastasized to the distal femur with severe bone destruction that was detected by both imaging of bioluminescence and soft X-ray. In tibial inoculation model of 4T1-Luc cells, the oral administration of EP4 antagonist clearly protected 4T1-induced bone destruction in both cancellous and cortical bone. To examine the further mechanism of 4T1-induced bone resorption, we invented the experimental system to evaluate the effects of cell-to-cell interaction. When bone marrow cells were co-cultured with osteoblasts on the fixated cancer cell layer, we detected numerous osteoclast formation, and the treatment of EP4 antagonist completely inhibited the osteoclast formation. In calvarial organ cultures with 4T1 cells, the number of osteoclasts and following bone resorption were elevated, and the resorbing trail was clearly detected on the surface of calvaria by 3D-micro CT analysis. The 4T1-induced osteoclastic bone resorption in calvarial organ culture was attenuated by the treatment of EP4 antagonist. These results suggest that the EP4-mediated signaling induces RANKL expression in osteoblasts that leads osteoclast differentiation and following osteolysis. EP4 antagonist is a possible candidate for the therapy of breast cancer with bone metastases.

Heparanase elicits a bone resident cell-like phenotype in multiple myeloma cells and promotes myeloma bone metastasis. Timothy Trotter*[1], Haiyan Chen[1], Patrick Rowan[2], Qianying Pan[2], Mei Li[2], Larry Suva[3], Amjad Javed[1], Yang Yang[4]. [1]University of Alabama at Birmingham, USA, [2]University of Alabama at Birmingham, USA, [3]University of Arkansas for Medical Sciences, USA, [4]The University of Alabama At Birmingham, USA

Multiple myeloma (MM) is a plasma cell malignancy that thrives in the bone marrow microenvironment and frequently metastasizes between bones. Heparanase (HPSE), an endo-β-D-glucuronidase that cleaves heparan sulfate chains on proteoglycans, is upregulated in MM. Indeed, MM cells expressing high levels of HPSE exhibit a significantly higher rate of bone metastasis. We hypothesized that this enhanced MM colonization of bone is related to bone marrow specific changes in the phenotype of MM cells. To test this idea, we transfected CAG MM cells that have low endogenous levels of HPSE with empty vector (HPSE-low) or with human HPSE cDNA (HPSE-high) and evaluated the expression levels of a series of bone markers in these cells. Western blots demonstrated increased expression of both the osteoblast marker Runx2 and the osteoclast marker RANK in HPSE-high cells compared to HPSE-low cells. In addition, using ELISA we detected higher levels of bone stroma growth factors VEGF and HGF in conditioned media of HPSE-high compared to HPSE-low cells. Similarly, HPSE-high cells secreted significantly higher levels of RANKL, MMP-9, osteocalcin, and DKK-1 – all of which are associated with the character and function of bone cells. We then investigated the consequences of Runx2 upregulation in HPSE-high cells by performing ChIP assays and found Runx2 occupancy of the promoters of both MMP-9 and RANKL genes was significantly increased in HPSE-high cells compared to HPSE-low cells. This directly implicates Runx2 as a mediator of HPSE induced changes in MM cell phenotype. Finally, immunohistochemical staining of HPSE-low and HPSE-high tumors harvested from *in vivo* models of myeloma revealed significantly higher expression of RANK, RANKL, Runx2, MMP-9, Osteocalcin, VEGF, HGF and DKK-1 in the HPSE-high tumors. Interestingly, this enhanced expression by HPSE-high tumors was observed at both primary and metastatic sites. These data demonstrate that the expression of HPSE induces a bone resident cell-like phenotype in MM cells. Such a change provides MM cells with the ability to avoid immune surveillance in the bone marrow, thereby facilitating tumor survival and growth in the bone (such as seen with HPSE-high cell tumors). Importantly, our data also suggest that MM cells expressing high levels of HPSE gain the ability to directly regulate the functions of osteoblasts (DKK-1), osteoclasts (RANKL), and stromal cells (HGF, VEGF), further supporting myeloma progression.

Osteocytes' Response to Mechanical Loading Supports Breast Cancer Cell Growth and Migration. Yu-Heng Ma*[1], Lidan You[2]. [1]University of Toronto, Canada, [2]Mechanical & Industrial Engineering, University of Toronto, Canada

Bone metastases are common and severe complications of cancers. It is estimated that 69% of patients died from breast cancer have developed bone metastases [1]. Cancer cells have such devastating impact on bones due to their ability to alter bone remodeling [2]. Exercise, often used as an intervention for patients suffering from breast cancer [3], regulates bone remodeling. Yet, information on the relationship between bone metastases and mechanical loadings is limited. Since osteocytes are mechanosensors of the bone that signals to reduce bone resorption in response to mechanical loading, this study focuses on the effect of this response on bone metastasis development. To achieve this, MLO-Y4 osteocyte-like cells were subjected to oscillatory fluid flow (1Pa 1Hz for 2 hours) and media from flow experiments were extracted (conditioned medium; CM). Controls were MC3T3 osteoblasts and glass slides with no cells. Migration of MDA-MB-231 breast cancer cells towards the CM was assayed with Transwell assay. Viability of MDA-MB-231 cells in the CM was measured with trypan blue, apoptosis with APOPercentage, and proliferation with CyQuant. It was observed that significantly more MDA-MB-231 cells migrated towards the CM from MLO-Y4 cells with exposure to flow in comparison to CM from MLO-Y4 cells not exposed to flow (figure 1). MDA-MB-231 cells apoptosis rate was significantly lower in CM from MLO-Y4 cells exposed to flow (figure 2). The current data (not reported) showed no difference in MDA-MB-231 cells viability and proliferation rate between any two groups. Overall, this study suggests that osteocytes subjected to mechanical loading can promote metastases. This gives insight on the potential effects of exercises on patients suffering from cancers. Further investigation on the mechanisms (figure 3) may provide potential targets for bone metastases.

Molecular Mechanisms of Bone Invasion by Oral Squamous Cell Carcinoma (OSCC). Jingjing Quan*[1], Nigel Morrison[2], Newell Johnson[3], Jin Gao[4]. [1]Guanghua Dental Hospital of Sun Yat-sen University, Peoples Republic of China, [2]Griffith University, Gold Coast Campus, Australia, [3]Griffith Univeristy, Australia, [4]James Cook University, Australia

Invasion of bone is a common complication of OSCC. This three-part study, aims to investigate signalling pathways involved in the crosstalk between OSCC cells, osteoblasts and osteoclasts. Firstly, conditioned medium (CM) was collected from OSCC cells (SCC15 and SCC25), and from osteoblasts of hFOB, then used for indirect co-culture: OSCC cells were treated with CM from osteoblasts and vice versa. Zymogenic activities of both MMP-2 and -9 were increased in OSCC cells following culture with CM from hFOB. The RANKL/OPG ratio, zymogen and protein expression of MMP-9 were increased in hFOB cultured with CM from OSCC cells. All targeted molecules were validated in clinical samples. Secondly, to determine which component of CM caused gene expression changes, OSCC cells of SCC25, HN5, and Tca8113 were artificially induced to display epithelial-mesenchymal transition (EMT) by adding 5 ng/mL of TGF-β to culture media for 1-3 days. Minimal immunochemical staining of VIM was found in SCC25 and HN5, while Tca8113 cells were strongly stained. In all cells assessed by real-time PCR, expressions of EMT markers Twist1 and N-cad were up-regulated; Snail1 and E-cad down-regulated. For osteoclast-related molecules, both MT1-MMP and RANKL were up-regulated while OPG down-regulated. CM of OSCC cells pre-treated with TGF-β could prolong the survival of mature osteoclasts up to 4 days. Thirdly, strong staining of MCP-1 protein was observed in OSCC cells and osteoclasts from clinical samples. SCC25 cells were found to have the highest expression of MCP-1 mRNA. A plasmid with the inhibitor of MCP-1 (7ND) was transfected into SCC25 cells, and stabilized SCC25 cells with 0.6 μg of 7ND vector (SCC25-7ND) were generated. 10% CM of SCC25-7ND cells efficiently inhibited the formation of human osteoclasts, comparing with 10% CM of SCC25 cells. Additionally, OSCC cells were injected onto the surface of calvariae of nude mice to establish an animal model of bone invasion. Well-differentiated SCC was formed in both groups of SCC25 and SCC25-7ND cell injections, with tumour cells invading bone, osteoclasts locating in typical resorption lacunae. TRAP staining indicated significantly fewer osteoclasts were found in calvariae with cells of SCC25-7ND in comparison to cells of SCC25. These studies prove that crosstalk between different types of cell appears to exist in invasion of bone by OSCC. Understanding, and ultimately interfering with these pathways, may provide therapeutic approaches.

PTHrP Abrogates CARP-1 Functional Mimetics (CFMs) Induced Growth Inhibition of Differentiated Osteoblasts. Sahiti Chukkapalli[1], Arun Rishi[2], Nabanita Datta*[3]. [1]Wayne State University School of Medicine, USA, [2]Wayne State University, USA, [3]Wayne State University School of Medicine, USA

The effectiveness of chemotherapeutic agents often limits their use due to negative effects on normal cells. Therefore development of new anti-cancer agents that have superior efficacy and minimal toxicity is warranted. Cell cycle and apoptosis regulatory protein (CARP)-1 (aka CCAR1) is a novel regulator of signaling by diverse agents including cell growth and differentiation factors, and chemotherapy-dependent apoptosis. CARP-1 functional mimetics (CFMs)-4 and -5 were previously shown to inhibit growth of human breast cancer (HBC) cells. In HBC, the over-production of parathyroid hormone-related peptide (PTHrP) and the bone forming osteoblasts play a critical role in facilitating colonization of metastatic cancer cells to bone. Our recent in vitro and in vivo studies revealed that CARP-1 was present in osteoblasts. PTHrP regulated CARP-1 expression in primary osteoblasts and in cultured MC3T3-E1 clone-4 (MC-4) cells. In this study we investigated the effects and mechanism of CFM-4 and -5 on growth and differentiation of MC-4 cells and the role of PTHrP in this process. Performing MTT assays our studies showed that the inhibitory effects of CFMs were dependent on the maturation stage of the MC-4 osteoblasts. While the growth of immature MC-4 cells was unaltered, CFMs suppressed growth of mature differentiated MC-4 cells. PTHrP (100 nM) abrogated MC-4 growth inhibition caused by 4 μM dose of CFM-4 and CFM-5 up to 98% and 75% respectively. Western blot analyses revealed that induction of CARP-1 protein by CFM-4 (60%) and -5 (35%) was partially attenuated by PTHrP. Importantly, while CARP-1 increase by CFM-4 or -5 correlated with activated caspase-3, PTHrP remarkably blocked caspase-3 activation (>50%). CFMs down-regulated (80-90%) cyclin D1 protein expression and was unaffected with PTHrP treatment. Together, CFM-4 and -5 induced G1-phase growth arrest as well as osteoblast apoptosis. We propose that PTHrP interferes with apoptosis signaling by CFMs in part by diminishing CARP-1 expression and caspase-3 inactivation. On the other hand PTHrP maintains G1-phase arrest of mature osteoblasts that permits continued extracellular matrix production. Thus elucidation of CARP-1 mediated osteoblast growth and differentiation mechanisms in the presence of CFMs and PTHrP will have a positive impact not only in the treatment of HBC but also in variety of other cancers which adversely affect bone.

The Mevalonate Pathway Inhibitors Atorvastatin and Zoledronic Acid Exhibit Synergistic Anti-Tumor Effects in Bone-Seeking Human Tumor Cells. Andy Goebel*[1], Stefanie Thiele[2], Andrew Browne[2], Martina Rauner[3], Lorenz Hofbauer[4], Tilman Rachner[5]. [1]University Hospital Carl Gustav Carus, Germany, [2]Division of Endocrinology, Diabetes & Metabolic Bone Diseases, Germany, [3]Medical Faculty of the TU Dresden, Germany, [4]Dresden University Medical Center, Germany, [5]University Hospital Dresden, Germany

Bone metastases are a frequent complication of breast and prostate cancer as well as melanoma. Aminobisphosphonates inhibit osteoclast function and are an established therapy for skeletal metastases. Similar to statins, they block the mevalonate pathway which is important for posttranslational protein modifications. Direct anti-tumor effects of amino-bisphosphonates have been described in preclinical models of bone metastases. However, concentrations required often exceeded those achievable in the clinical setting. Here, we report on the anti-tumor potential of a combined treatment with atorvastatin (ATO) and zoledronic acid (ZOL) in human bone-seeking cancer cell lines.

We treated MDA-MB-231 (breast), MDA-435s (melanoma) and PC3 (prostate) cell lines with ATO and ZOL, respectively. The combination of 10 μM ZOL and 1 μM

ATO induced at least a two-fold increase of caspases 3 & 7 activation and a decrease of vitality by 50% after 48 h, whereas no significant effects were observed with individual treatments. The apoptotic effect was further underlined by the induction of caspase 3 and poly ADP ribose polymerase (PARP) cleavage and a significant reduction of the anti-apoptotic genes *BCL-2* and *SVV* by 50%. The observed anti-cancer effects could be reversed by geranylgeranyl-pyrophosphate, but not by farnesyl-pyrophosphate highlighting that inhibited geranylgeranylation mediates the induction of apoptosis. As small Rho GTPases (RhoA, Rac1, and CDC42) need to be geranylated for being anchored in the cell membrane to exert their function, we assumed an inactivation by the ATO and ZOL treatment. Surprisingly, a concomitant treatment with a Rho/Rac/CDC42 activator which increases the levels of GTP-bound forms of the Rho GTPases led to an even higher induction of apoptosis. In accordance with this, a pull down assay revealed an accumulation of the GTP-bound forms of the Rho GTPases RhoA, Rac1 and CDC42 upon combined treatment with ATO and ZOL. Furthermore, this effect was accompanied by an increased phosphorylation of NFκB which points to a possible mechanism of the apoptosis induction by blocking the mevalonate pathway. In line, a pre-treatment with inhibitors of Rac1, CDC42 and NFκB partially rescued the anti-cancer effects elicited by ATO and ZOL.

Our results indicate the mevalonate pathway as a potential therapeutic target for the treatment of human cancer-induced bone metastases and warrant further research by using appropriate animal models.

The Pain Mediator NGF is Induced by Multiple Myeloma *in vivo*, and Relieved by Therapeutic Activation of Adiponectin Signalling. Sam Olechnowicz*[1], Megan Weivoda[2], Seint Lwin[3], James Edwards[4], Claire Edwards[3]. [1]University of Oxford, GBR, [2]Mayo Clinic, USA, [3]University of Oxford, United Kingdom, [4]University of Oxford, United Kingdom

Multiple myeloma (MM) is a plasma cell neoplasm characterised by osteolytic bone disease. Bone pain is the most common symptom of MM at diagnosis, yet the molecular mechanisms responsible are poorly characterised. Adiponectin (Adpn) is an adipokine expressed by adipocytes and osteoblasts that is protective against MM *in vivo*. Adpn has also been shown to negatively correlate with bone pain and the major pain mediator, Nerve Growth Factor (NGF), in osteoarthritis. We sought to determine the mechanism of NGF-regulation in MM, and the potential for Adpn-targeted therapies to reduce MM bone pain *in vivo*. We combined the 5TGM1 murine model of MM with activation of the endogenous Adpn pathway by an ApoAI-mimetic peptide, L-4F. Adpn signalling in osteoblasts was disrupted by molecular inhibition of Adpn receptors 1 and/or 2. KaLwRij or *Rag2*$^{-/-}$ mice were inoculated with 5TGM1 MM cells. In both strains, the resultant increase in tumour burden after 4 weeks was associated with a significant increase in serum NGF (KaLwRij: $p<0.001$; *Rag2*$^{-/-}$: $p<0.01$) as compared to baseline levels. Treatment of 5TGM1MM-bearing mice with L-4F, or existing therapeutics bortezomib or melphalan, resulted in an increase in serum Adpn in response to L-4F ($p<0.01$) and a similar reduction in tumour burden in response to all three treatments (L-4F; 36%, bortezomib; 34%, melphalan; 36%, $p<0.01$). Notably, only treatment with L-4F induced a significant 2-fold reduction in serum NGF ($p<0.01$). 5TGM1 MM cells did not express NGF mRNA, but high levels of NGF transcript were detected in osteoblasts and bone marrow stromal cells *in vitro*. Mimicking the *in vivo* findings, coculture of 2T3 osteoblasts with MM cells induced a significant 1.8-fold increase in NGF transcription from osteoblasts. Adpn inhibited an LPS-induced increase in NGF, while MM-derived cytokines such as TNFα induced a 3-fold increase in NGF expression in osteoblasts ($p<0.05$). Blockade of Adpn signalling by Adpn receptor 1 or 2 siRNA resulted in a significant 2-fold increase in NGF, which was further increased in combination with recombinant TNFα. Our results demonstrate that NGF is increased in MM *in vivo*, with osteoblastic NGF regulated by MM cells, TNFα and Adpn signalling. MM-induced NGF expression by osteoblasts is likely to be a cause of nerve dysregulation and bone pain. Adpn-based therapies may provide an improvement over traditional drugs by not only reducing tumour burden and bone disease, but also acting to reduce bone pain.

***In Vitro* Effects of Strontium on the Proliferation Process of Human Articular Chondrocytes.** Cecilia Romagnoli*[1], Roberto Zonefrati[2], Carmelo Mavilia[2], Anna Maria Carossino[2], Annalisa Tanini[3], Maria Luisa Brandi[4]. [1]University of Florence, Italy, [2]University of Florence, Italy, [3]University of Florence, Italy, [4]DIRETTORE MALATTIE DEL METABOLISMO MINERALE E OSSEOAZIENDA OSPEDALIERA UNIVERS, Italy

Purpose: Articular cartilage defects are characterized by the lack of spontaneous resolution because of the limited regenerative capacity of adult articular chondrocytes. Based on previous studies showing that Strontium (Sr^{2+}) modulates proliferation in some cell types, it could be hypothesized that this ion is also effective on human articular chondrocytes. Therefore, aim of this study was to investigate whether different concentrations of Sr^{2+} affect the proliferation process in primary culture of human articular chondrocytes.

Methods: Slices of articular cartilage were harvested from a patient undergoing to a knee arthroplasty, after an informed consent approved by the Local Ethical Committee. Cartilage specimens were minced and digested at 37℃ in 0.3 mg/ml collagenase type I in F12 nutrient mixture, overnight. Cell aggregates were mechanically dispersed, washed, resuspended in growth medium (Ham's F12 Coon's modification medium) with 10% FBS and 1% antibiotics and cultured at 37℃ and 5% CO_2. After verification of the expression of cartilage-specific genes (COL Type II, Aggrecan, Biglycan, COL Type X) in qPCR and the collagen type II protein in immunocytochemistry, expanded monolayers of human articular chondrocytes, at passages 2 and 3, were used in the experiments. The proliferation was evaluated in presence of scalar concentrations of $SrCl_2$ from 0.1 to 5 mM in growth medium containing 1% FBS by cell counting at 24-48-72 hours. Statistical analysis was performed by linearity test and parallelism test of the linear regressions of the obtained growth curves, using Student's t-test.

Results: Characterization of human articular chondrocytes was confirmed by the presence of cartilage-specific genes and the collagen type II protein. Cells proliferation analysis has shown that Sr^{2+} significantly increases chondrocyte proliferation at concentrations 1 mM ($p<0.025$) and, in particular, at 3 mM ($p<0.005$) with respect to the control group without Sr^{2+}, while no significant results were obtained using lower (0.1-0.5 mM) or the highest (5 mM) concentrations.

Conclusion: The present results have shown that articular chondrocytes at early passages can be used as models for *in vitro* studies in the field of cell therapy. Moreover, our results suggest that Sr^{2+} has the capacity to stimulate cell growth, opening future application in cartilage repair. Studies are in progress to evaluate the effect of Sr^{2+} on COL type II gene expression and cartilage matrix formation.

A potential role for TGFβ-RII/MCP-5/ PTHrP axis in post-traumatic osteoarthritis. Lara Longobardi*[1], Nunzia D'Onofrio[2], Tieshi Li[1], Joseph Temple[3], Huseyin Ozkan[4], Alessandra Esposito[3], Helen Willcockson[5], Timothy Myers[5], Ping Ye[1], Billie Moats-Staats[6], Lidia Tagliafierro[3], Marialuisa Balestrieri[2], Anna Spagnoli[1]. [1]University of North Carolina at Chapel Hill, USA, [2]Second University of Naples, Italy, [3]UNC-Chapel Hill, USA, [4]Gulhane Military Medical Academy, Etlik, Turkey, [5]University of North Carolina, USA, [6]University of North Carolina- Chapel Hill, USA

We have previously shown that increasing expression levels of the chemokine MCP5 correlated with osteoarthritis (OA) severity in a murine model of OA (DMM). By using a Tgfbr2-β-Gal-GFP-BAC reporter mouse, we characterized the TGFβ-Receptor II (TβRII) expressing cells as joint progenitors. We previously demonstrated that early blockage of MCP-5 signaling by using either a MCP-5-receptor antagonist or by intra-articular implants of isolated TβRII+ cells into DMM knees, were able to decrease articular cartilage lesions and bone sclerosis during OA (Longobardi et al., ASBMR 2013). Several studies support the hypothesis that TGF-β and PTHrP act in a common signaling cascade to inhibit the development of a calcifying phenotype in articular chondrocytes. The aim of this study is to determine the expression pattern of TβRII and PTHrP in articular cartilage during DMM and analyze whether PTHrP could mediate MCP-5 signaling.

Methods. 1)In vivo studies. Tgfbr2-β-Gal-GFP-BAC mice were subjected to DMM and euthanized 4, 8 and 12-weeks after DMM. Knees were decalcified and paraffin embedded for histological studies and OA grading. Adjacent sections were subjected to double-immunofluorescence for GFP(TβRII)/MCP-5 or PTHrP/MCP-5 proteins and in-situ hybridization for PTHrP mRNA. 2)In-vitro studies. FACS sorted TβRII+ cells from Tgfbr2-β-Gal-GFP-BAC limb buds were micromass cultured +/- MCP-5 for 3 days, cDNA was isolated and subjected to qRT-PCR.

Results. During DMM-induced OA, TβRII expression is increased 2 weeks after DMM but is abolished by 4 weeks, when MCP-5 starts to be expressed. Consistently with TβRII pattern, we found that PTHrP protein and mRNA expression levels in the periarticular chondrocytes increase 2 weeks after surgery but such expression is disorganized and decreased at later stages after DMM. Derangement of PTHrP expression is accompanied by increase in MCP-5 expression. In-vitro, we show that MCP-5 has a direct inhibitory effect on PTHrP mRNA in TβRII+ joint progenitors.

Conclusions. Our findings show that progression of OA after trauma is associated with derangement of TβRII-progenitors and PTHrP expressing cells in the periarticular chondrocytes, accompanied by increase of MCP-5 levels. In vitro data show a direct regulation of MCP-5 on PTHrP mRNA in joint progenitors. Taken together our results suggest that during post-traumatic OA, TβRII, MCP-5 and PTHrP may act together on articular chondrocytes, regulating their commitment toward mineralization.

Evaluation of cartilage based on second harmonic generation microscopy. Hiroshi Kiyomatsu*[1], Takeshi Imamura[2], Atsuhiko Hikita[3], Tadahiro Iimura[4], Tsuyoshi Miyazaki[5], Yusuke Ohsima[6], Takashi Saitou[7], Hiromasa Miura[8]. [1]Ehime University Hospital, Japan, [2]Ehime University Graduate School of Medicine, Japan, [3]Ehime University, Japan, [4]Ehime University, Proteo-Science Center (PROS), Japan, [5]Tokyo Metropolitan Geriatric Hospital & Institute of Gerontology, Japan, [6]Translational Research Center, Ehime University Hospital, Japan, [7]Department of Molecular Medicine for Pathogenesis, Ehime University Graduate School of Medicine, Japan, [8]Department of Orthopaedic Surgery, Ehime University Graduate School of Medicine, Japan

greatly restricts daily activities of patients. For the patients at the late stage of the disease, replacements of cartilages with prostheses are performed, because there is no method to regenerate articular cartilage and to detect early stage of disease. New methods to detect the affected lesions sensitively and to evaluate them quantitatively must be established for early detection of the disease and for the development of new treatments by understanding the mechanism of the disease. Second harmonic generation (SHG) imaging is useful tool at biological fields, because non-centrosymmetric molecular assemblies such as collagen fibers can be detected without staining. The SHG signal is affected by the minute changes in localization and orientation of the type II collagen fiber which is one of the major components of cartilage matrix, and thus degeneration of cartilages can be detected sensitively. To establish a new evaluation method for degeneration of articular cartilage in experimental and clinical setting, SHG and two-photon excited fluorescence imaging were performed for articular cartilage matrix and chondrocytes of H2B-GFP mice which express green fluorescence protein (GFP) in nuclei. At first, enzyme-induced degeneration of mouse articular cartilage was observed for the same samples in the same field of view. Reduction of SHG signals by collagenase treatment was observed, suggesting that SHG signal reduction is related to the degeneration of the cartilage. Chondrocytes were found to be dislocated from some region of articular cartilage, showing the destruction of the structures of extracellular matrices (ECM). We also observed the cartilages of the femurs of aged mice by using SHG imaging. We could divide those degenerative cartilages into 2 types. One of them showed rough surfaces of articular cartilage, and the other showed very strong SHG signals. We also developed OA model of H2B-GFP mice induced by destabilization surgery to evaluate the degeneration of cartilage, which were similar to human OA. In some samples, we observed empty lacunae with no GFP signal in cartilage matrix, rough surfaces of articular cartilage, and micro-cracks in ECM. In other samples showed very strong SHG signals running fibrous, suggesting hyperplasia of hyaline cartilage. The SHG imaging of cartilage matrix is promising technique for osteoarthritis study.

NFAT1 is an Upstream Regulator of Specific Anabolic and Catabolic Genes in Mouse Articular Cartilage. Mingcai Zhang*[1], Qinghua Lu[2], Andrew Miller[2], Clayton Theleman[2], Jinxi Wang[3]. [1]Department of Orthopedic Surgery, University of Kansas Medical Center, USA, [2]University of Kansas Medical Center, USA, [3]University of Kansas Medical Center, USA

Purpose: Despite that osteoarthritis (OA) is the most common form of joint disease, no disease-modifying pharmacologic therapy is currently available largely because the pathogenetic mechanisms of OA remain unclear. NFAT1 is a member of the nuclear factor of activated T-cells (NFAT) family of transcription factors. Our previous studies demonstrated that mice lacking *Nfat1* exhibited normal skeletal development but began to show OA-like changes at the age of 3-4 months. This study aimed to test our hypothesis that *Nfat1* deficiency causes OA-like changes in 3 to 4-month-old mice because the NFAT1 transcription factor regulates specific anabolic and catabolic genes in articular cartilage of young adult mice.

Methods: Total RNA was isolated from femoral head articular cartilage of 3 to 4-month-old wild-type (WT) or *Nfat1*-deficient (*Nfat1*$^{-/-}$) mice for gene expression analysis by quantitative real-time PCR (qPCR). Chromatins were isolated from the articular cartilage of femoral and humeral heads of 3 to 4-month-old WT BALB/c mice for chromatin immunoprecipitation (ChIP) assay. Normal mouse IgG was used as negative control.

Results: The expression levels of *Acan*, *Col2a1*, *Bmp7, Tgfb1* (anabolic genes) were down-regulated but the expression levels of *Admats5*, *Mmp13, Il1b, and Col10a1* (catabolic genes) were up-regulated in the articular cartilage of *Nfat1*$^{-/-}$ mice. NFAT1 ChIP assays were performed followed by qPCR analyses using specific primers encompassing the NFAT1 binding site in the promoters of selected genes (Table 1). The ChIP data demonstrated that NFAT1 directly binds to the promoter region of these candidate target genes whose expression was affected by *Nfat1* deficiency (Figure 1).

Conclusions: These results suggest that NFAT1 is an upstream factor regulating the expression of specific anabolic and catabolic molecules in articular cartilage of mice. *Nfat1* deficiency causes decreased expression of the anabolic genes and increased expression of the catabolic genes, leading to degradation of articular cartilage and OA-like changes. Thus, anti-OA agents that target NFAT1 could be more effective than drug candidates that target a single catabolic or anabolic molecule.

Role of estrogen and estrogen receptor beta signaling in mediating mandibular condylar growth in young male mice. Sunil Wadhwa[1], Jing Chen[2], Manshan Xu*[2], Helen Lu[2], Thomas Choi[2]. [1]Columbia University, USA, [2]Columbia University, USA

Abstract- Mandibular growth abnormalities approximately afflict 20 million Americans. There is a great need in the dental research community to develop alternative economical treatments for mandibular growth abnormalities. We have previously found that estrogen receptor beta deficiency caused increased mandibular condylar cartilage growth in female mice. The goal of this study was to determine the role of estrogen and estrogen receptor beta signaling in regulating the growth of the mandibular condyle in male mice. *Materials and Methods*- 21 day old male WT and ER beta KO mice were treated with placebo or estradiol (100ng/gram body weight) for 4 weeks. Histomorphometry, micro ct analysis, proliferation, and Col2 expression of the mandibular condyle was assessed. *Results*- There was no difference in the size of the mandibular condylar cartilage and microarchitecture of the subchondral bone between 49-day-old placebo treated male WT and ER beta KO mice. Estradiol treatment caused significant increases in condylar cartilage thickness, trabecular thickness and trabecular number in male WT mice but only trabecular thickness in male ER beta KO mice compared to placebo treated male mice. There was no difference in proliferation between estradiol treated male WT and ER beta KO compared to placebo treated male mice. Estradiol also caused superior localization of Col2 in the mandibular condylar cartilage in both male WT and ER beta KO mice. *Conclusion*- Estrogen via ER beta signaling pathway promoted increased mandibular condylar cartilage thickness, while estrogen independent of ER beta increased trabecular thickness in the mandibular condylar subchondral bone in male mice.

Effects Of Extracellular Calcium In Human And Porcine Adipose Derived Stem Cell Differentiation For Osteochondral Tissue Engineering. Liliana Mellor*[1], Elizabeth Loboa[2], Farshid Guilak[3], Jorge Piedrahita[2], Sehwon Koh[2], John Williams[2]. [1]North Carolina State University, USA, [2]North Carolina State University, USA, [3]Duke University, USA

Joint injury often leads to the onset of osteoarthritis (OA), a degenerative joint disease that limits mobility of the affected joint due to the degradation of articular

cartilage. The limited regenerative capacity of cartilage tissue presents significant challenges to repair or reverse the effects of damaged articular cartilage. Current methods for cartilage repair include autologous chondrocyte implantation, microfracture, and autograft and allograft osteochondral transplantation. Tissue engineering approaches using stem and/or primary cells have not been clinically proven. The majority of stem cell based approaches to cartilage or osteochondral tissue engineering, have used bone marrow derived mesenchymal stem cells (MSC) and have focused predominantly on cartilage regeneration as opposed to full osteochondral tissue regeneration.

Our goal is to use the more abundant and easily accessible adipose derived stem cell (ASC) to generate a full osteochondral construct using a gradient calcium concentration in a biodegradable poly-lactic acid (PLA) scaffold. Our laboratory has previously shown that elevated calcium concentration in human ASC induces osteogenesis and inhibits chondrogenesis. We have used this approach to seed hASC in a tricalcium phosphate (TCP) gradient scaffold, containing a 20% TCP concentration in the deep layers to induce osteogenesis, and 0%TCP in the superficial layers to induce chondrogenesis to mimic native osteochondral tissue. We are developing the same technique in a large animal model (porcine) to evaluate *in vivo* the ability to use our engineered osteochondral construct to replace damaged articular cartilage.

Our novel approach using hASC to create a full osteochondral construct would bring an alternative and less invasive treatment to patients suffering from osteochondral injuries, and would allow us to use stem cells from the patient's own fat tissue to create a full osteochondral construct designed to fit the size and shape of the injury. This technique would be less invasive as none of the healthy remaining cartilage tissue would be removed, and the use of autologous stem cells minimize tissue rejection.

Epigenetic Regulatory Role of KDM4B in TGFβ-Mediated Chondrogenic Differentiation of Human MSCs. Christine Hong*[1], HYELIM Lee[2], Cun-Yu Wang[3]. [1]UCLA School of Dentistry, USA, [2]SEOUL NATIONAL UNIVERSITY, South Korea, [3]UCLA, USA

The biomedical burden of arthritis and cartilage defects has grown over the past decades due to the inadequate treatment options currently available. While existing efforts in tissue engineering approaches utilizing human mesenchymal stem cells (MSCs) show enormous potential, a comprehensive understanding of the intricate mechanisms that govern the fate of MSCs is required for therapeutic applications of MSCs specific for cartilage regeneration. TGFβ is a potent inducer of chondrogenesis by activating the Smad signaling pathway and inducing chondrongenic genes such as SOX9, however, the involvement of epigenetic regulation in TGFβ-mediated induction of chondrogenic gene expression is not known. Recently, the histone demethylase, KDM4B, was shown to play a key role in promoting MSC osteogenic commitment by removing repressive epigenetic marks, H3K9me3. Therefore, we examined the role of KDM4B in TGFβ-mediated chondrogenic differentiation of MSCs. TGFβ significantly induced the expression of KDM4B by 70 fold. When KDM4B was overexpressed in MSCs, chondrogenic differentiation was induced more significantly as assessed by Alcian Blue staining and mRNA expression of chondrogenic marker genes, Collagen2a1, Sox9, and Aggrecan. Conversely, KDM4B depletion using shRNA technique led to a significant reduction in chondrogenic potential. When KDM4B expression was rescued in KDM4B-knockdown MSCs, chondrogenic differentiation was restored, further confirming the facilitating role of KDM4B in chondrogenic commitment. Mechanistically, upon TGFβ stimulation, KDM4B was recruited to the SOX9 promoter region and the subsequent epigenetic modulation by removal of silencing H3K9me3 marks led to the activation of this chondrogenic master gene. In addition, the occupancy of Smad3 was also increased in the SOX9 promoter region confirming Smad signaling dependent SOX9 induction. When KDM4B was knocked down, demethylation of H3K9me3 and occupancy of Smad3 in the SOX9 promoter region were significantly diminished, suggesting that TGFβ-mediated chondrogenic differentiation is directly regulated by KDM4B's epigenetic activity on the promoter of SOX9. Taken together, our results demonstrate the critical role of a histone demethylase, KDM4B, in the epigenetic regulation of chondrogenic differentiation of MSCs. Since histone demethylases are chemically modifiable, KDM4B may present as a novel therapeutic target in cartilage regenerative therapy.

Osteoclasts regulate chondrocyte metabolism through the inhibition of the Wnt canonical pathway. Chahrazad Cherifi*[1], Wafa Bouaziz[2], Martine Cohen-solal[3], Eric Hay[4]. [1]Inserm U1132, France, [2]INSERM U606, France, [3]Hôpital Lariboisière, France, [4]INSERM u1132, France

Purpose: Enhanced osteoclastogenesis is observed at early stages of osteoarthritis (OA). We have demonstrated that cartilage damage is prevented when osteoclastogenesis is inhibited in murine models. We speculate that Wnt activity, known to regulate the bone and chondrocyte cell function, might contribute to promote cartilage catabolism. Our purpose was to evaluate whether osteoclast-secreted molecules affect the chondrocyte metabolism and to assess the contribution of Wnt pathway.

Methods: Osteoclasts were obtained from RAW cells cultures in the presence of RANKL. Primary murine chondrocyte (Ch) were cultured in the presence of osteoclast conditioned medium (Oc-CM) for 48h. The gene and protein expressions of catabolism and anabolism were analyzed by RT-qPCR and western blot. To investigate the regulation of canonical Wnt pathway, transactivation assay was performed in primary chondrocytes derived from Topgal mice and cultured with Oc-CM. Western blot and immunocytochemistry were used to confirm the activation of β-catenin canonical Wnt signaling pathway. Finally, the role of Wnt canonical signaling was investigated through the b-catenin translocation in the presence of lithium chloride (LiCl) in addition to the Oc-CM.

Results: Oc-CM induced a marked decrease in proteoglycan release by chondrocytes. Oc-CM reduced the expression of anabolic genes (collagen type II, Aggrecan and Sox-9) while increased the expression of catabolic genes (MMP-3, -13, Adamts-4,-5). We then monitored the nuclear translocation of β-catenin induced by Oc-CM. Oc-CM abolished the translocation of β-catenin and subsequently the Topgal activity in line with the reduction of Wnt target genes (Axin, Wisp1 C-Myc). Moreover, LiCl reduces the expression of catabolic genes induced by Oc-CM, indicating the contribution of the canonical pathway in the regulation of catabolic genes.

Conclusion: We have here demonstrated that osteoclasts secrete soluble factors capable to disrupt chondrocyte metabolism and the anabolic / catabolic balance via the inhibition of the Wnt canonical signaling. Therefore, our data indicate that manipulating bone may affect chondrocyte function.

SU0092

Preferentially expressed genes in synovium derived stromal cells include atypical genes not expressed highly in mouse synovium but in embryonic cartilages. Yoichi Ezura*[1], Tadayoshi Hayata[2], Takuya Notomi[3], Ichiro Sekiya[4], Masaki Noda[5]. [1]Tokyo Medical & Dental University, Medical Research Insititute, Japan, [2]Organization for Educational Initiatives, University of Tsukuba, Japan, [3]Department of Pharmacology, Osaka Dental University, Japan, [4]Tokyo Medical & Dental University, Japan, [5]Tokyo Medical & Dental University, Japan

The synovium derived stromal cells (SSCs), also named as synovial mesenchymal stem cells (SMSCs) in human is a type of stromal progenitor cells resident in various adult tissues. We have reported that human SSCs are more potent for chondrogenesis in vitro than the other types of hMSCs. Gene expression profiles of the SSCs and bone marrow derived stromal cells (BMSCs) are consistently different in human and mouse, and thus a list of 113 genes significantly expressed more in SSCs than in BMSCs was made (ASBMR annual meeting 2013). To investigate if this expression profile of the signature genes in SSCs reflects the expression in adult synovial tissue, global gene expression was analyzed for adult and embryonic (E17.5) mouse synovium, menisci, epiphyseal and articular cartilage. Indeed, about 80% of these signature genes are expressed more in adult synovial tissue than in adult articular cartilage, whereas such preferential expression was not obvious when it was compared between the synovium and the meniscus. Preferential expression was also not clear between the embryonic synovial tissue and epiphyseal cartilage or the menisci. These results indicate that most synovial stromal signature genes preferentially expressed in SSCs may reflect their expressions in adult synovium, but not reflect their potential for expression in developing tissues. However, among the list of 113 genes, we could also detect several genes whose expression was paradoxically high in embryonic cartilaginous tissues i.e., epiphyseal cartilage and menisci compared to that in synovium. Those genes including *Prg4, Prelp*, *Comp,* and *Sfrp1* may be the candidate factors contributing to the higher potential of the SSCs for chondrogenesis than the other types of mesenchymal stromal cells.

The enzymatic activity of IRE1a modulates chondrocyte differentiation. Fengjin Guo*[1], Zhangyuan Xiong[2], Peng Zhang[3], Xiaofeng Han[3]. [1]Chongqing Medical University, Peoples Republic of China, [2]Department of Cell Biology & Genetics,Core Facility of Development Biology, Chongqing Medical University, China, [3]Department of Cell Biology & Genetics,Core Facility of Development Biology,Chongqing Medical University,Chongqing 400016,China, China

Growth and development of endochondral bones is controlled through the highly coordinated proliferation and differentiation of growth plate chondrocytes.BMP2 is known to activate UPR signaling molecules, such as BiP,ATF4 and IRE1α in chondrogenesis.IRE1a,as one of three unfolded protein sensors in UPR signaling pathways,can be activated during ER stress.GEP,also known as progranulin,is a 593–amino acid secreted glycoprotein with an apparent molecular weight of 80kDa.More evidence implicated that GEP is involved in the regulation of differentiation,development and pathological processes.We previously reported that GEP induced and promoted chondrocyte differentiation,endochondral bone formation and cartilage

repair.However,whether IRE1a influences GEP-mediated chondrogenesis remains undetermined.Specifically,the molecular mechanism by which IRE1a regulates chondrogenesis also remains unknown.Here we present evidences demonstrating that overexpression of IRE1a inhibits chondrocyte differentiation,as revealed by expression of Col?,SOX9,Col?,MMP-13,IHH,Runx2,PTHrP. Furthmore,IRE1a-mediated inhibition of chondrogenesis depends on its enzymatic activity,since its point mutant lacking enzymatic activity completely loses this activity.The RNase and Kinase domains of IRE1a C-terminal is necessary for its full enzymatic activity and inhibition of chondrocyte differentiation.Mechanism studies demonstrate that GEP induced IRE1a expression in chondrogenesis.The expression of IRE1a is depended on GEP signaling,and IRE1a expression is hardly detectable in GEP-/- embryos.IRE1a inhibits GEP-mediated chondrocyte differentiation as a negative regulator.Altered expression of IRE1a in chondrocyte hypertrophy was accompanied by altered levels of IHH and PTHrP.

Collectively,we report that IRE1α adversely mediates chondrocyte differentiation based on the following observations:(1)Overexpression expression of IRE1a dramatically inhibits the chondrocyte differentiation;(2)the enzymatic activity and the C-terminal RNase and Kinase domains of IRE1a are important for its full enzymatic activity and IRE1a-mediated inhibition of chondrogenesis;(3)IRE1α demonstrates prominent expression in proliferating and prehypertrophic chondrocytes in the wildtype embryonic growth plate,whereas its expression is hardly detectable in GEP-/- embryos;(4)IRE1a inhibits GEP-mediated chondrocyte differentiation as a negative regulator;(5)Promoting IHH/PTHrP signaling.

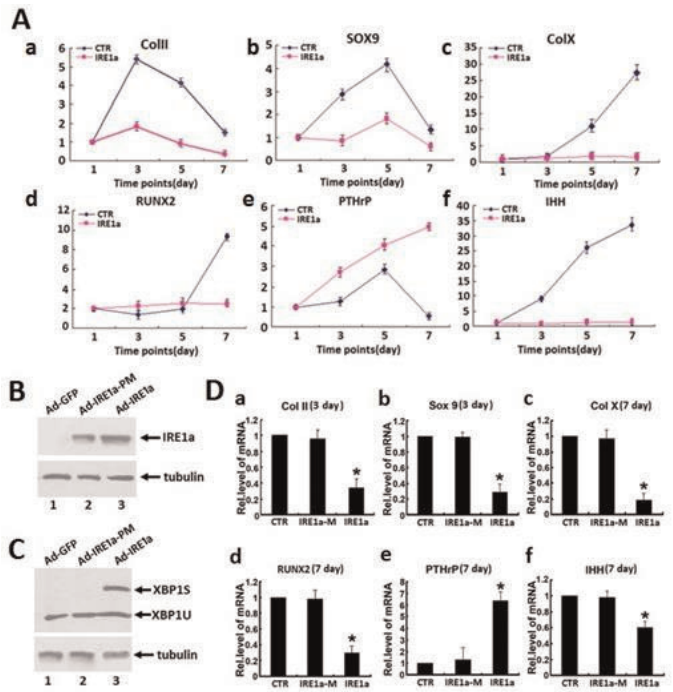

Figure 1.IRE1a inhibition of chondrogenesis is required for its enzymatic activity.

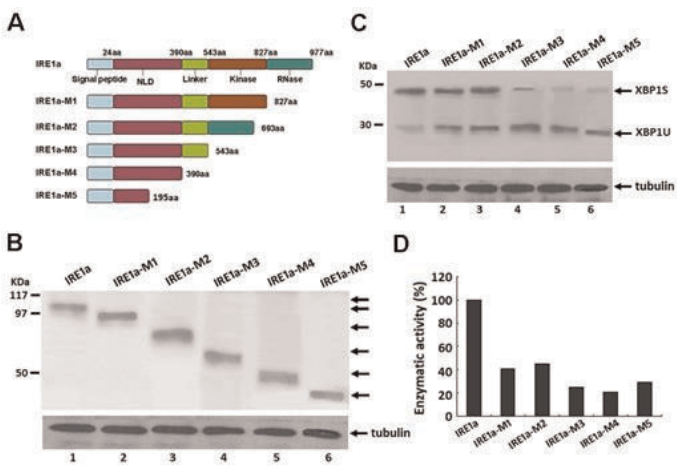

Figure 2. Effects of IRE1a functional domains and enzymatic activity.

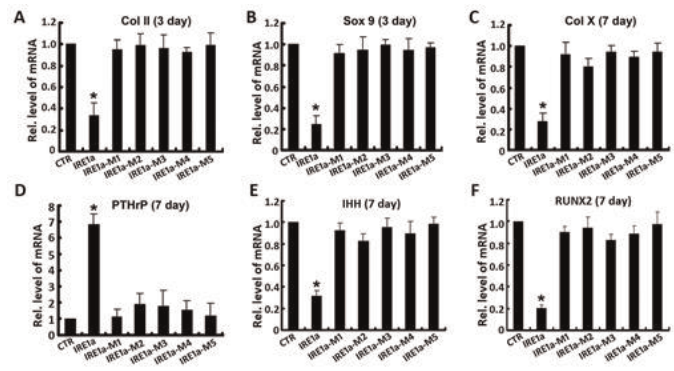

Figure 3.Kinase and Nuclease domain of IRE1a is important for its regulation of chondrogenesis.

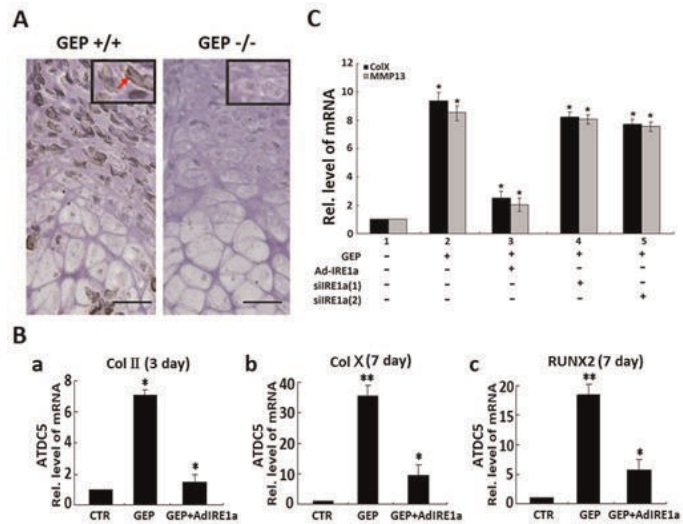

Figure 4. IRE1a expression depends on GEP signaling and inhibits the GEP-induced chondrogenesis.

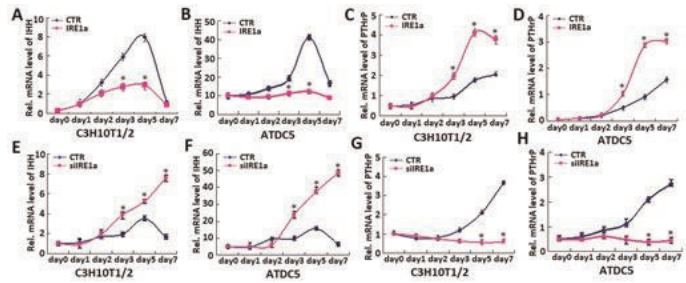

Figure 5. Altered expression of IRE1a affects the expression of IHH and PTHrP.

W9 peptide repaired full-thickness articular cartilage defects in rabbits. -Mechanism of chondrogenic differentiation by W9 peptide -. Yuriko Furuya*[1], Hisashi Mera[2], Maki Itokazu[3], Hiroaki Nakamura[4], Kohji Uchida[5], Shigeyuki Wakitani[2], Hisataka Yasuda[6]. [1]Oriental Yeast Co.,Ltd, Japan, [2]Mukogawa Women's University, Japan, [3]Osaka City University Graduate School of Medicine, Japan, [4]Osaka City University Gradulate School of Medicine, Japan, [5]Oriental Yeast Co., Ltd., Japan, [6]Oriental Yeast Company, Limited, Japan

WP9QY (W9) peptide is known to accelerate osteogenesis and inhibit osteoclastogenesis in vitro and in vivo. W9 inhibits osteoclastogenesis by binding receptor activator of NF-kB ligand (RANKL) as a RANKL antagonist. Recently we reported that short hairpin RNA (sh RNA)-mediated RANKL gene knock-down using lentivirus suppressed W9-induced calcification in mouse mesenchymal stem cells (MSCs), suggesting an important role of RANKL in osteogenesis by W9. We hypothesized that reverse signaling through RANKL regulated osteogenesis. We also

reported that W9 enhanced chondrogenesis in ATDC5 cells and human MSCs in this meeting previously. We observed robust matrix accumulation in three-dimensional pellet culture by W9 using human MSCs. Moreover, we ascertained that a feature of W9 in in vitro chondrogenesis was accelerating production of cartilage matrix in chondrocytes and their culture supernatants, but not proliferation of the cells.

Here we evaluated whether W9 had a chondrocyte differentiative effect in vivo using rabbit model of full-thickness articular cartilage defects. Full-thickness defects (5 mm width and 5 mm depth) in knee joints were created by a surgical drill in male Japan White rabbits (18-20 weeks of age, n=8). Two weeks after the formation of defects, W9 or PBS (vehicle) was administrated to rabbits intraarticularly once per week for 2 weeks. After formalin fixation and decalcification of knee joints, paraffin sections were stained by hematoxylin-eosin, toluidine blue, and safranin-O, respectively. Histological analysis revealed that W9 repaired the full-thickness defects. Histological grading was performed using the modified Wakitani score. Total score of W9 was lower than that of vehicle significantly.

Moreover, to clarify the mechanism of W9, we investigated its signaling pathway in C3H10T1/2 cells and ATDC5 cells with chemical or protein inhibitors and by western-blotting using phosphorylated antibody. Phosphorylated p38 MAP kinase enhanced in C3H10T1/2 cells and ATDC5 cells treated with W9, suggesting an involvement of p38 signal in the mechanisms. W9 peptide may be useful for and applicable to the treatment of chondropathy such as osteoarthritis and cartilage injury. By analogy with the important role of RANKL in W9-induced osteoblastogenesis, we will elucidate whether W9 stimulated chondrocytes differentiation via membrane RANKL on MSCs.

Leptin increases VEGF expression and enhances angiogenesis in human chondrosarcoma cells. Yi-chin Fong*[1], Wei-Hung Yang[2], Jui-Chieh Chen[3], Chih-Hsin Tang[4]. [1]China Medical University Hospital, Taiwan, [2] China Medical University Hospital, Taiwan, [3]China Medical University, Taiwan, [4]China Medical University, Taiwan

Leptin, a 16 kDa product of the obese gene, is an adipocytokine that plays a critical role in the regulation of body weight. In recent years, leptin is also defined as a potent angiogenic factor, which is involved in tumorigenesis, angiogenesis, and metastasis. However, it is unknown whether leptin regulates VEGF production in human chondrosarcoma and contributing the tumor-associated angiogenesis. In the present study, we found that both leptin and VEGF are highly expressed in human chondrosarcoma tissues, which are positively correlated with histopathological grade. Thus, we examined the effects of exogenous leptin on chondrosarcoma cells. In addition, the intracellular signaling pathways were also investigated by pharmacological and genetic approaches. Our data show that leptin increases VEGF production by activating OBRl receptor and MAPKs (p38, ERK, and JNK), which in turn enhances the binding of AP-1 transcription factor to the VEGF promoter, resulting in the transactivation of VEGF expression and subsequently promoting migration and tube formation in endothelial progenitor cells (EPC). Further, we have also evaluated the effect of leptin on angiogenesis and tumor growth using the *in vivo* models. The results show that knockdown of leptin attenuates neovessel formation and arrests chondrosarcoma tumor growth *in vivo*. These findings may provide a better understanding of the pathogenesis of chondrosarcoma and can utilize this knowledge to design a new therapeutic strategy.

Influence of Beta-Aminoproprionitrile on Morphology of Type I Collagen Produced by MC3T3-E1 Osteoblasts and Measured Using Atomic Force Microscopy. Silvia Canelon*[1], Joseph Wallace[2]. [1]Purdue University, USA, [2]Indiana University Purdue University Indianapolis (IUPUI), USA

Type I collagen can be morphologically characterized through measurements of the fibril D-spacing which can be used to detect differences in collagen structure across tissue types and disease. The D-spacing describes the axially repeating bands of gap and overlap regions of collagen fibrils arranged into a quarter-staggered array. This fibrillar structure is stabilized by enzymatic cross-links initiated by the lysyl oxidase enzyme, and disrupted by the beta-aminoproprionitrile (BAPN) toxin which inhibits lysyl oxidase. Murine *in vivo* studies have confirmed effects of BAPN on collagen nanostructure and the objective of this study is to evaluate the mechanisms of these effects *in vitro* by using atomic force microscopy (AFM) to measure D-spacing.

Osteoblastic cells (MC3T3-E1) were differentiated in culture, in the presence or absence of BAPN, resulting in the synthesis of extracellular matrix. Cells were grown in complete alpha-MEM medium and then cultured for 7 days at a density of 500,000 cells/60mm plate. Differentiation was induced by supplementing the medium with 50μg/mL, and also with 25mM BAPN for the BAPN-treated group. Medium was replaced every 2 days for both control (n=3) and treated groups (n=3). At the end of the 7 days, medium was removed from the plate and cells dissociated from the matrix with an EDTA buffer. The matrix was allowed to dry in the dish and imaged in air using AFM. The matrix was imaged in tapping mode using silicon cantilevers and 5 locations were imaged in each plate. The Fourier transform of 3.5μm x 3.5μm images was taken and D-spacing analysis was performed on 10 collagen fibrils per location for a total of 50 fibrils per plate and approximately 200 fibrils per group.

The D-spacing distribution of collagen produced in the presence of BAPN was found to be shifted toward higher D-spacing values by a statistically significant degree. These results indicate that BAPN indeed has an effect on morphology of collagen produced *in vitro* and support aforementioned *in vivo* experiments. Relevant future studies address further characterization of *in vitro* synthesized collagen by evaluating gene expression as well as biochemical and mechanical properties. In addition, studies are underway to analyze the effect of mechanical loading on collagen produced by osteoblasts under fluid shear stress, particularly relating to the recovery of properties altered by BAPN.

Sc65 is a novel ER protein and a regulator of bone mass homeostasis. Roy Morello*[1], Roberta Besio[1], Patrizio Castagnola[2], Milena Dimori[3], Yuqing Chen[4], Dana Gaddy[1], Larry Suva[1]. [1]University of Arkansas for Medical Sciences, USA, [2]IRCCS AOU San Martino – IST, Italy, [3]University of Arkansas for Medical Sciences, USA, [4]Baylor College of Medicine, USA

Members of the Leprecan family of proteins include enzymes, prolyl 3-hydroxylase 1 (P3h1), P3h2 and P3h3, and non-enzymatic proteins, Crtap and Sc65. Mutations in *CRTAP* and *LEPRE1* (encoding P3H1) are associated with human disease such as recessive osteogenesis imperfecta. However, the function of Sc65 which is closely related and highly homologous to Crtap is unknown. Sc65 was described as a synaptonemal complex protein, a nucleolar protein, and a cytoplasmic adapter protein. In light of its similarity with Crtap, an endoplasmic reticulum (ER)-associated protein and an important mediator of collagen post-translational modifications, we hypothesized that Sc65 was also an ER-resident protein with a potential role in bone homeostasis. Here we demonstrate that Sc65 is a previously unrecognized ER protein, and that it does not localize in the nucleus of somatic cells. Sc65 is expressed during mouse skeletal development and its loss due to a gene-trap insertion results in a progressive osteopenia that affects both trabecular and cortical bone. Low bone mass is due to increased osteoclastogenesis and bone resorption. Interestingly, Sc65 is highly expressed in chondrocytes and osteoblasts but not in osteoclasts or their precursors. Osteoblast/osteoclast co-culture experiments suggest that lack of Sc65 in osteoblasts is sufficient to mediate increased osteoclastogenesis, and point to a non-cell autonomous osteoclast defect. To assess if lack of Sc65 in osteoblasts is responsible for the observed bone phenotype we generated Sc65 floxed mice and crossed them with Osterix-Cre transgenic mice. Interestingly, micro-CT analysis of distal femur and spine (males, n=10) did not reveal significant architectural differences between Osterix-Cre and Osterix-Cre;$Sc65^{FL/FL}$ mice. However, volumetric bone density was significantly reduced in Osterix-Cre;$Sc65^{FL/FL}$ femurs (850 vs 810 mg HA/ccm, p=0.001), suggesting a potential material defect. Current studies are evaluating the distribution of collagen, the diameter of individual collagen fibrils in skin and bone at the ultra-structural level as well as characterizing specific Sc65 interactors within the ER.

Monoosteophils Accelerate Nonunion Bone Repair by Using Intracellular Apatite Formation. Zhifang Zhang*[1], Keith Le[2], Frances Chang[2], Zhuo Li[2], Ricardo Zerda[2], Marcia Miller[2], John Shively[2]. [1]City of hope, USA, [2]City of Hope, USA

BACKGROUND: Monoosteophils, derived from LL-37-treated monocytes, are a novel type of calcifying/bone forming cells. We have shown that monoosteophils have the ability to form bone-like nodules in vitro and ectopic bone in vivo and accelerate bone repair in a drilled bone repair model. Here, a critical-sized defect model was used to further investigate bone repair function of monoosteophils and mechanism of nodule formation of monoosteophils was studied.

Results: Critical-sized (5 mm) calvarial defects were created in the parietal bone of adult male NOD/SCID mice. Defects were treated with either 1 day human monocytes, 1 day human monoosteophils, or 1 day human monoosteophils with gel hydroxyapatite. Our results showed that significant healing was observed among monoosteophil engrafted calvarial defects with microCT scanning (Figure 1). In vitro study showed monoosteophils release 1-2 μm bone-like nodules on osteologic disc in low Ca2+ concentration 10% FBS RPMI1640 medium after 3 weeks by using scanning electronic microscopy. Transmission electron microscopy showed that monoosteophils, harvested from osteologic discs, express intracellular vesicles of calcium phosphate (Figure 2). When monoostophils were cultured in the 10% FBS αMEM medium with 2.5mM CaCl2 instead of osteologic disc for 3 weeks, significant intracellular calcium phosphate formations were observed by Alizarin Red S staining and elemental analysis by EDS/SEME (Figure 3). Furthermore, confocal fluorescence microscopy showed calcium phosphate vesicles of monoosteophils were positive for FAM labeled bisphosphonate or FITC labeled HABP19 staining and a small percentage of FAM-bisphophonate positive vesicles were colocalized with mitochondria, but not with Golgi, endosomes, endoplasmic reticulum, lysosomes, or autophagosomes (Figure 4), which suggest that calcium phosphate vesicles, as an unique vesicle in monoosteophil, may be associated with mitochondria.

Conclusion: Our observations highlight the bone repair function and the unique mechanism of bone formation of monoosteophils. These observations may have important implications in deciphering both how normal bone forms and in understanding pathological mineralization.

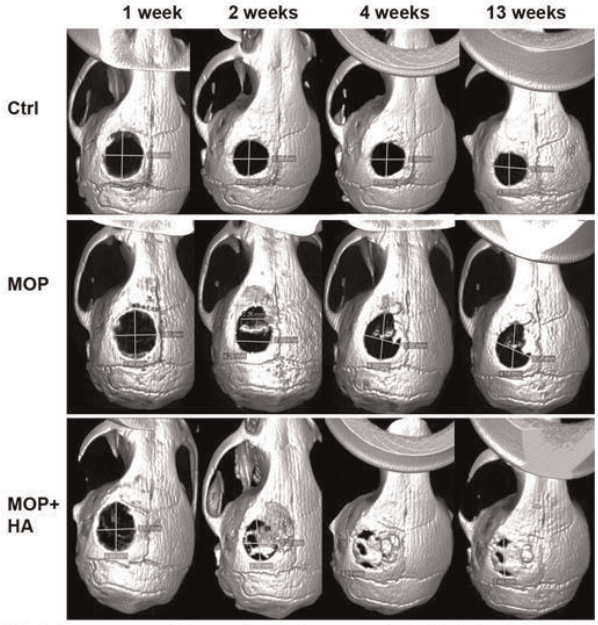

Fig 1. Monoosteophils accelerate bone repair. Critical-sized (5 mm) calvarial defects were created in the parietal bone of adult male NOD/SCID mice. Defects were treated with either 1 day monocytes (Ctrl) , 1 day monoosteophils (MOP), or 1 day monoosteophils with gel hydroxyapatite.(MOP+HA) and observed using micro CT.

Fig 1

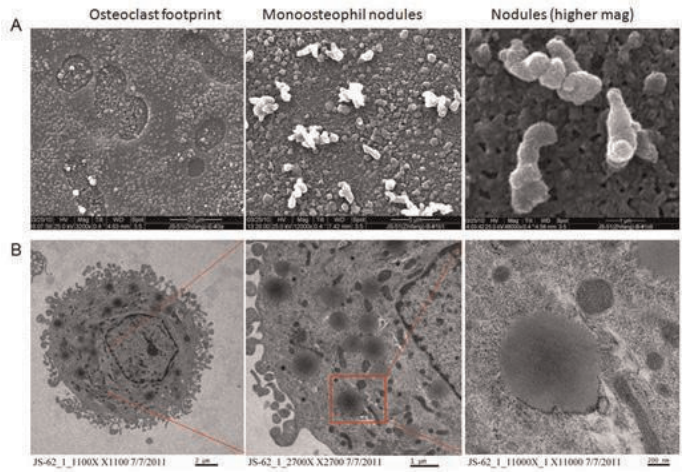

Fig 2. In vitro nodule formation of monoosteophils on BioCoat Osteologic Discs. Monocytes were incubated in the presence of M-CSF/RANKL (both at 25 ng/mL for osteoclast differentiation) or LL-37 (5μM for monoosteophil differentiation) in RPMI 1640 media on BioCoat Osteologic Discs in 5% CO2 atmosphere. After incubation for three weeks, cells were removed with bleach and observed by SEM (A) and monoosteophils were harvested and observed by TEM (B).

Fig 2

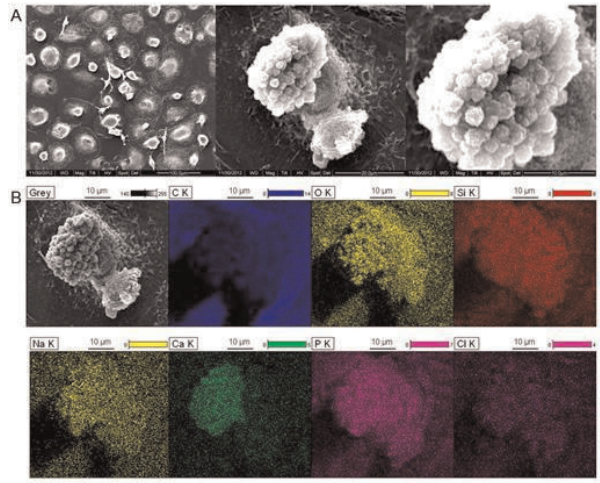

Fig 3. Intracellular nodules of monoosteophils consist of phosphorus, calcium, oxygen, and sodium. Monocytes were differentiated to monoosteophils using 5 μM LL-37 in plastic plate in αMEM with 2.5mM CaCl2 for three weeks. Elements of intracellular nodule were analyzed using SEM (A) and SEM/EDS (B).

Fig 3

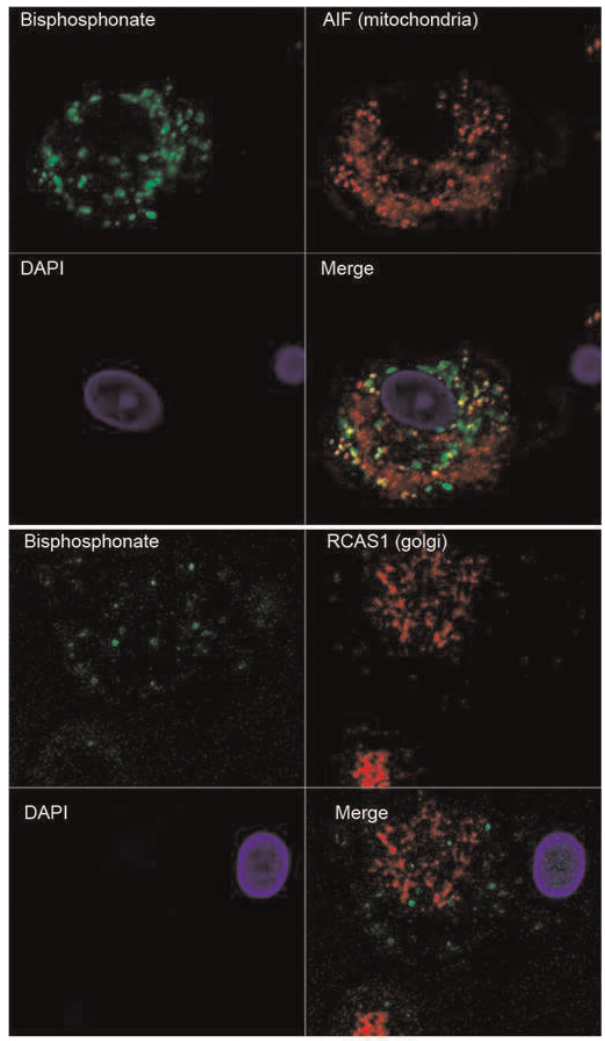

Fig 4. FAM-bisphophonate positive vesicles of monoosteophils were partly colocalizated with mitochondria, but not with Golgi. Monoostophils were cultured with aMEM with 2.5 mM CaCl2 for 3 weeks and fixed/permeablized and stained shown in the fugure.

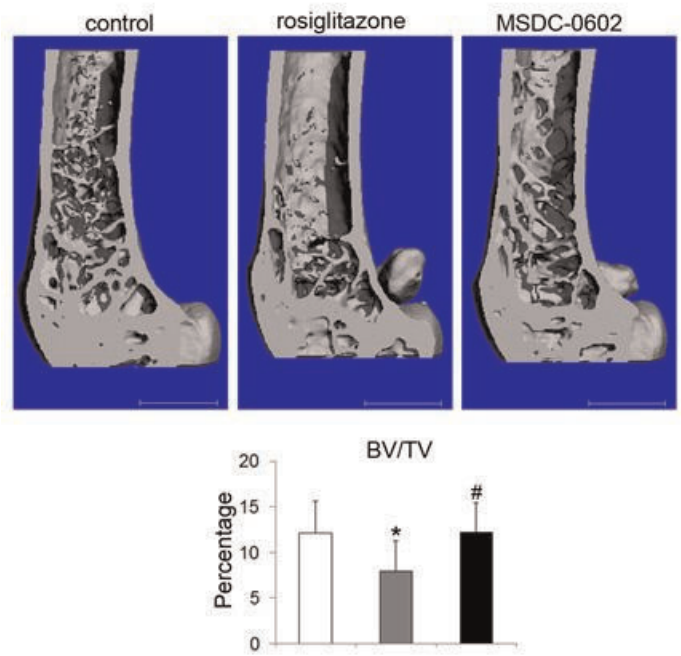
An insulin-sensitizing thioglitazone, which fails to activate PPARγ, does not cause bone loss. Tomohiro Fukunaga*[1], Wei Zou[2], Nidhi Rohatgi[3], Jerry Colca[4], Steven Teitelbaum[2]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University in St. Louis School of Medicine, USA, [3]Washington University in St. Louis, USA, [4]Metabolic Solutions Development Company, USA

Rosiglitizone (BRL) is an insulin-sensitizing thioglitazone (TZD) drug which exerts its effect by activating the transcription factor, PPARγ. While BRL is an effective oral treatment of type II diabetes mellitus, it carries substantial complications including increased fracture risk. This predisposition to fracture is consistent with the fact that PPARγ preferentially promotes formation of adipocytes at the cost of osteoblasts. Surprisingly however, BRL-activated PPARγ also stimulates osteoclast formation. Recently, a new TZD analog with low affinity for binding and activation of PPARγ has been developed whose insulin-sensitizing properties mirror those of BRL. In this study, we investigated the effects of this new TZD analog (MSDC-0602) on osteoclast function and differentiation, in vitro and in vivo. BRL dramatically increases PPARγ activity in a PPRE reporter assay system and enhances expression of the PPARγ target gene, CD36 in osteoclast. MSDC-0602, in contrast, minimally activates PPARγ and does not alter CD36 expression. Consistent with this finding, BRL increases RANKL-induced osteoclast differentiation and number but MSDC-0602 fails to do so. To determine if this new TZD analog is bone sparing, in vivo, we fed adult male C57BL/6 mice MSDC-0602 or BRL. 6-months of a BRL diet results in a 35% decrease in bone mass whereas that of MSDC-0602 fed mice is indistinguishable from control. Thus PPARγ-sparing TZDs could reduce the skeletal side effects of TZD drugs while maintaining their insulin-sensitizing properties.



MSDC-0602 does not Induces Osteoporosis

Dramatic effects of high and low glucose on osteocytes: A model for the effects of glucose on bone loss. Donna Pacicca*[1], Tammy Brown[2], Lynda Bonewald[3]. [1]Children's Mercy Hospital, USA, [2]Children's Mercy Hospital, USA, [3]University of Missouri - Kansas City, USA

Fluctuations in glucose have a detrimental effect on multiple tissues in patients with diabetes mellitus. While diabetic patients are known to have an increased fracture risk, the effect of glucose variability on bone tissue has not been as well-established. We hypothesized that high and low glucose levels regulate gene expression responsible for bone loss and lack of bone gain. We tested the effects of exposure to high and low glucose on the IDG-SW3 cell line which initially express an osteoblastic phenotype before transitioning to an osteocytic phenotype in culture. The IDG-SW3 cells were cultured under low (2.5 mM), normal (10mM), and high (25mM) glucose. A mannitol control was included for high osmolarity (glucose 10mM with mannitol 15mM). Media was changed daily and cells were harvested at 3, 7, 14, 21, 28 and 35 days. Glucose and lactate levels were measured, and LDH assay was used to evaluate cell viability. After RNA extraction, qPCR was performed on samples from the six time points to evaluate expression of glucose transport proteins, insulin receptor, E11, type 1 collagen, sclerostin, keratocan, RANKL and OPG. Glucose utilization and lactate production increased over time. PCR demonstrated expression of insulin receptor and glucose transport proteins 1 and 3 that increased under low glucose conditions and decreased with high glucose. Little or no GLUT2 and 4 was detected under any conditions (Ct values >36). Dramatic effects were observed on the osteocytic cells at days 21, 28, and 35. High glucose increased expression of sclerostin from day 21 to 35 by 3800%. RANKL was increased at days 28 and 35 in low glucose by 200%. Keratocan was increased in high glucose 350% but decreased in low glucose 65%. No significant differences were noted in E11, Col1, SOST or Kera at days 3 or 7 with either high or low glucose showing little effect on the early osteoblastic cells. In summary, high glucose increased sclerostin while low glucose induced the expression of RANKL. Keratocan was increased by high glucose but decreased by low glucose suggesting effects on differentiation and dedifferentiation. These data suggest that glucose variability may affect bone health through several mechanisms, including the anti-anabolic effect of sclerostin, the osteoclastic-stimulating effect of RANKL, and an interference with normal osteoblast/osteocyte differentiation. These mechanisms could be targets for treatment of fracture due to diabetes.

Glucose Intolerance Attenuates Bone Accrual in Young Growing Skeleton by Promoting the Maturation of Osteoblasts through Beclin1-Mediated Autophagy. Elizabeth Rendina-Ruedy*[1], Jennifer Graef[2], Stan Lightfoot[3], Jerry Ritchey[4], Stephen Clarke[2], Edralin Lucas[2], Brenda Smith[2]. [1]Vanderbilt University Medical Center, USA, [2]Oklahoma State University, USA, [3]Center for Cancer Prevention & Drug Development, University of Oklahoma Health Sciences Center, USA, [4]Department of Veterinary Pathology, Oklahoma State University, USA

Patients with type 2 diabetes mellitus (T2DM) have demonstrated a 1.5-3.5 fold increase in fracture risk, but the mechanisms responsible for these skeletal changes remain elusive. Macroautophagy, referred to hereafter as autophagy, is regulated by signaling downstream of the insulin receptor. Metabolic changes associated with the initiation and progression of glucose intolerance have been shown to alter autophagy in various tissues, but limited information is available in relation to bone cells. The aim of this study was to (1) investigate whether autophagy is altered in the bone during the initiation and progression of T2DM and (2) determine how autophagy impacts osteoblast differentiation, activity, and maturation. To accomplish this aim, 4-week old, male C57BL/6 mice were fed a control (Con) or high fat (HF) diet for 2, 8, and 16 wks. Consistent with reduced insulin sensitivity, mice on the HF diet demonstrated elevated fasting blood glucose and impaired glucose tolerance. Micro-computerized tomography (microCT) analyses revealed reduced trabecular bone at 8 and 16 wks in the femoral neck, which resulted in lower trabecular bone volume compared to Con mice. Histological evaluation of the tibia and characterization of osteoblast-related genes in the flushed femur suggested that hyperglycemia decreased bone mineralization and may promote terminal osteocyte differentiation. This shift of the osteoblasts towards a non-mineralizing, osteocyte phenotype appears to be coordinated by Beclin1 mediated autophagy during impaired glucose tolerance. However, long-term glucose intolerance resulted in an increase in apoptosis of the osteoblast based on an increase in *Casp3* mRNA. Consistent with changes occurring in the osteoblast *in vivo,* the induction of autophagy by rapamycin was able to direct MC3T3-E1 cells towards a more mature osteoblast phenotype. The current study provides evidence that glucose intolerance contributes to the skeletal dysregulation of bone metabolism by up-regulating autophagy in osteoblasts, directing this cell towards a non-mineralizing osteocyte, ultimately attenuating bone accrual. Further investigation is warranted to determine if Beclin1-mediated autophagy is essential for the terminal differentiation of the osteoblasts and whether autophagy is having a protective or deleterious effect on bone in T2DM.

mTOR-dependent Reactive Oxygen Species Contribute to Diabetic Bone Pathology. Nandini Ghosh-Choudhury*[1], Balakuntalam S Kasinath[2], Kavithalakshmi Sataranatarajan[3], Hanna E Abboud[3], Jameela Banu[4], Goutam Ghosh Choudhury[3]. [1]University of Texas Health Science Center at San Antonio, USA, [2]University of Texas Health Science Center at San Antonio, USA, [3]University of Texas Health Science Center, USA, [4]University of Texas-Pan American, USA

Diabetes is reaching an epidemic stage among people aged 20 years and older in the United States. Prolonged hyperglycemia significantly augments fracture risk and increases the healing time in diabetic patients. Role of mechanistic target of rapamycin (mTOR) and oxidative stress is established in many complications of diabetes. However, their role in diabetic bone pathology is not known. We probed the role of mTOR in compromised bone quality found in db/db mouse model of type 2 diabetes and in osteoblasts exposed to high glucose conditions. High glucose induced activation of mTORC1 (mTOR complex1) in preosteoblasts as measured by increase in phosphorylation of S6 kinase and 4EBP1, two downstream effectors of mTORC1. We show that mTORC1 is activated in bones of db/db mice with type 2 diabetes.

These mice were fed a diet containing rapamycin (2.24 mg/Kg/day), a pharmacological inhibitor of mTORC1, for 4 months starting at 7 months of age. Rapamycin blocked mTOR activation and reversed overall defect in mineralized bone formation. MicroCT analysis of the distal femur from db/db mice showed reduction in trabecular thickness, trabecular number and BV/TVand increase intrabecular separation compared to the control mice. Rapamycin treatment restored these bone parameters at this late stage of diabetes in mice. To identify the downstream effector of mTOR signaling in diabetic bone we investigated the involvement of reactive oxygen species (ROS). We detected increased production of ROS, as determined by DCF fluorescence, in osteoblasts incubated with high glucose. We also show that the NADPH oxidase activity, determined by lucigenin assay, is increased by high glucose in osteoblasts. Interestingly, rapamycin inhibited both ROS production and NADPH oxidase activity induced by high glucose. These results provide the first evidence for the presence of a cross-talk between mTORC1 and ROS in diabetic bone pathology.

Protective effect of ion zinc on bone strength and flexibility: Bone biomechanical and molecular analyses in type 1 diabetes model. Raul H Bortolin*[1], Marcela A G Ururahy[2], Flávio S Silva[2], Angelica A S Batista[3], Giselle Oliveira[3], Karla S C Souza[2], Melina B Loureiro[2], Valeria M G Duarte[4], Bento J Abreu[2], Maria G Almeida[2], Luciana A Rezende[3], Adriana Rezende[5]. [1]Federal University of Rio Grande do Norte, USA, [2]Federal University of Rio Grande do Norte, Brazil, [3]University of Ribeirão Preto, Brazil, [4]State University of Paraiba, Brazil, [5]Federal University of Rio Grande De Norte-UFRN, Brazil

Osteopenia is one of the diabetes-induced chronic complications. Studies have showed the importance of supplementation with minerals and vitamins in preventing bone loss. Thus, the aim of this study was to evaluate the protective effect of zinc on bone in a diabetic osteopenic model. Male Wistar rats were distributed in three groups (five rats per group): Control (C), Diabetic (D; STZ-induced; 40mg/Kg i.v.) and Diabetic supplemented with 500 mg/day of zinc during 90 days (DS). Serum glucose concentration, tibia biomechanical parameters (Maximum Load, Stiffness, Ultimate Strain and Youngs modulus) and femur mRNA expression of *RANKL, OPG, OC, COL1A, MMP2, MMP9* and *TGFB* were evaluated. Animals were considered diabetic by serum glucose concentration ($\geqslant$ 250 mg/dL) associated with polyphagia, polydipsia and polyuria. The Maximum Load, Stiffness, Ultimate Strain and Youngs modulus parameters were found decreased in the D group ($p<0.05$) when compared to C group. However, for DS group, all biomechanical parameters were similar to C group, except Stiffness parameter that was reduced ($p<0.05$). In relation to the molecular parameters the mRNA expression of the *OPG*, *OC*, *COL1A* and *MMP9* was increased (37, 17, 17 and 344 folds, respectively) in D group when compared to C Group ($p<0.05$). In addition, no differences were found for *RANKL, MMP2* and *TGFB* mRNA expression between the groups. Considering DS group, we also observed results similar to C group for molecular parameters, showing an important effect of the zinc ion in preventing bone loss in diabetes condition. Our results associated important analyses, such as Maximun load and Stiffness showing a decrease in the bone strength supported by the up regulation of *OPG* and *OC* mRNA as an attempt to avoid bone loss onset. When supplemented with zinc the DS group showed similar results with C group, suggesting the maintenance of bone strength. Considering Ultimate Strain and Youngs Modulus we may suggest a reduced bone flexibility associated with the up regulation of *COL1A* and *MMP9* mRNA expression, showing a tendency to try to compensate the alteration of bone architecture associated with collagen. Similarly to bone strength, bone flexibility was maintained in zinc-supplemented group. In conclusion, our results may suggest that zinc supplementation have a protective and benefic effect on preventing bone strength and flexibility reduction over a 90 days period.

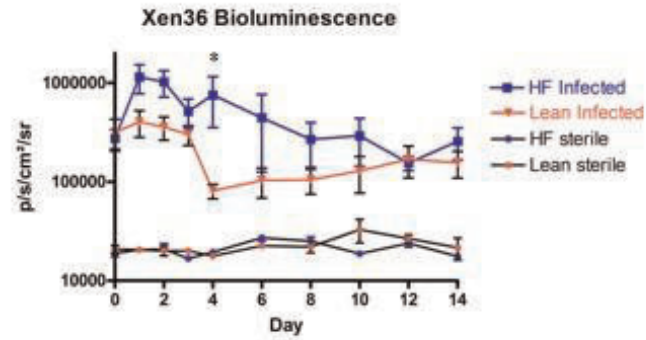
Type 2 diabetes increases infection severity, impairs humoral immunity, and alters bone remodeling following orthopaedic implant associated *S. aureus* infection. Christopher Farnsworth*[1], Robert Maynard[2], Edward Schwarz[1], Michael Zuscik[3], Robert Mooney[4]. [1]University of Rochester, USA, [2]University of Rochester, USA, [3]University of Rochester School of Medicine & Dentistry, USA, [4]University of Rochester Medical Center, USA

Purpose: Type 2 diabetes (T2D) is the greatest risk factor for infection following total joint arthroplasty. T2D is also a risk factor for osteoarthritis. With the number of type 2 diabetics expected to double by 2050, a dramatic increase in infection rates following total joint replacement is projected for the coming years. It is critical to determine the mechanism underlying increased infection rates in T2D. T2D is associated with both an impaired innate immune response and multiple bone diseases. Therefore we hypothesize that T2D increases the susceptibility of orthopedic implant recipients to infections, specifically by *Staphylococcus aureus,* by compromising immunity and altering bone remodeling.

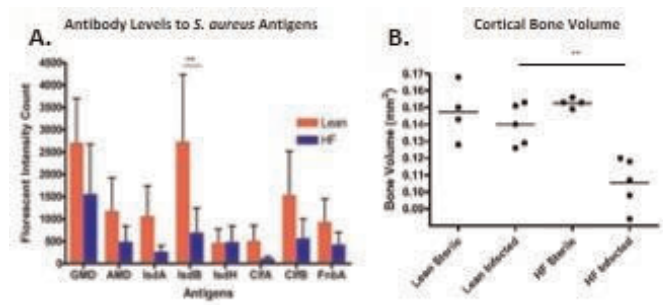
Methods: Animals: C57BL/6J mice were fed a high fat diet (60% Kcal from fat) or lean diet (10% Kcal from fat) for 12 weeks. Osteomyelitis model: tibiae were surgically exposed and pre-drilled medially to laterally with a 27G needle. A stainless steel wire was pre-coated with bioluminescent Xen36 *S. aureus* and was placed through the defect. Bioluminescent imaging (BLI): analyses were performed up to 14 days post infection using a Xenogen IVIS camera. Total IgG and IgM titers were determined by ELISA. Antibodies to eight *S. aureus* antigens were titered by Luminex-based assays. Cortical bone was measured using uCT and confirmed with histology.

Results: Mice fed a high-fat diet developed obesity and T2D. Following implantation of a *S. aureus*-coated implant through the tibia, diabetic mice had higher bacterial loads than control mice as indicated by BLI. These results were confirmed by isolating and counting colony forming units of *S. aureus* from both bone and muscle. Furthermore, diabetic mice had an impaired antibody response to *S. aureus* infection compared to control mice as indicated by a decrease in total IgG and an increase in IgM. Antibody titers to 8 *S. aureus* antigens were also decreased in infected diabetic mice. uCT and histology revealed impaired bone remodeling and cortical thinning at the surgical site in diabetic mice.Conclusion: These data indicate that T2D causes more severe *S. aureus* infections in a mouse model of joint arthroplasty. Diabetic mice have an impaired humoral immune response and impaired bone remodeling to *S. aureus* infection. These defects may underlie the susceptibility, severity, and pathogenesis of orthopedic implant- associated infections in diabetics.



Diabetic, infected mice have worse *S. aureus* infection than lean fed, control mice. Mice were given either a control diet, or a high fat (HF) diet to induce type 2 diabetes, and were infected through the right tibia with an orthopedic implant coated with bioluminescent Xen36 *S. aureus*. BLI was measured longitudinally over a 14 day experiment. Results were confirmed by counting colony forming units from infected tibiae.

Figure 1



Diabetic, HF-fed mice have an impaired antibody response and cortical thinning. A. Antibody levels were measured to 8 *S. aureus* antigens 14 d post infection by luminex based assay. **B.** Cortical bone thickness was measured by microCT 14 days post implantation of either a sterile pin or a pin coated with *S. aureus*.

Apolipoprotein E protects mice from osteoporosis by promoting osteoblasts differentiation and inhibiting osteoclasts induction. Takaaki Noguchi*[1], Kosuke Ebina[2], Masafumi Kashii[3], Yohei Matsuo[4], Tsuyoshi Sugiura[5], Jun Hashimoto[6], Hideki Yoshikawa[7]. [1]Osaka university, Japan, [2]Osaka University, Graduate School of Medicine, Japan, [3]Osaka University Graduate School of Medicine, Japan, [4], Japan, [5]Faculty of Medicine, Graduate School of Medicine, Osaka University, Japan, [6]National Hospital Organization, Osaka Minami Medical Center, Japan, [7]Osaka University Graduate School of Medicine, Japan

Purpose

It is well known that hyperlipidemia is frequently associated with osteoporosis, but its detailed mechanism remains unknown. Apolipoprotein E (ApoE) forms complex with lipids called lipoprotein and plays a major role in removing excess cholesterol from the blood, and its knockout mice presents severe lipidosis and arteriosclerosis. Meanwhile, effects of ApoE on bone metabolism still remains unkown.

Method

48-weeks olds ApoE knockout mice (ApoEKO) (n=8 females) and control wild type C57BL6 mice (WT) (n=8 females) which were fed with normal chaw were examined. 3D trabecular structure was measured by microCT, and the number of osteoclasts was evaluated by Tartrate-Resistant Acid Phosphatase (TRAP) staining. RNA was extracted by radius, and serum concentration of osteocalcin and CTX-1 was measured by ELISA. The effect of ApoE in osteoblasts differentiation was evaluated by using MC3T3-E1 cell, and its effect in osteoclasts differentiation was evaluated by using mice spleen cells with RANKL and M-CSF.

Results

MicroCT revealed that ApoE KO mice presents severe osteoporosis compared to wild type mice, which were evaluated by cancellous bone quantity (BV/TV) (3.3% v.s. 16.6% ; P <0.001), number of the trabecular (Tb.N) (1.2/mm v.s. 3.8/mm ; P<0.001), and cortical bone quantity (Cv/Av) (31.8% v.s. 37.9% ; P<0.01). In addition, ApoE KO mice showed larger number of osteoclasts (8.6/mm v.s. 4.5/mm ; P<0.05) and lower serum osteocalcin (52.7±13.5ng/ml v.s. 38.2±11.4ng/ml ; P=0.087) and CTX-1 (2.4±0.2ng/ml v.s. 2.0±1.5ng/ml ; P=0.58) . In vitro, human ApoE4 recombinant protein (0 v.s. 5μg/ml) inhibited osteoclasts formation(111.8±9.2 v.s. 84.8±11.3 ; P<0.05) and relative mRNA expression of c-Fos(1.1±0.07 v.s. 0.75±0.08 ; P<0.05), NFATc1(0.99±0.03 v.s. 0.92±0.07 ; P<0.05), TRAP(1.07±0.1 v.s. 0.83±0.02 ; P<0.05), and CathepsinK (0.98±0.04 v.s.0.59±0.05 ; P<0.05). In addition, human ApoE4 recombinant protein promoted ALP activity of MC3T3-E1 cell on day 7(0 v.s. 5μg/ml ; 1.0±0.03 v.s. 1.23±0.16 ; P<0.01).

Conclusions

Our findings revealed that ApoE plays a crucial role in connecting hyperlipidemia and osteoporosis by promoting osteoblasts differentiation and inhibiting osteoclasts differentiation, showing possibility as a dominant treating target of both desease.

Changes in Bone Marrow Fat During Gastric Bypass Surgery-Induced Weight Loss. Anne Schafer*[1], Ann Schwartz[2], Dennis Black[2], Amber Wheeler[2], Lygia Stewart[3], Stanley Rogers[4], Jonathan Carter[4], Andrew Posselt[4], Dolores Shoback[5], Xiaojuan Li[2]. [1]University of California, San Francisco & the San Francisco VA Medical Center, USA, [2]University of California, San Francisco, USA, [3]San Francisco VA Medical Center & the University of California, San Francisco, USA, [4]University of California, San Francisco, USA, [5]VA Medical Center, USA

Osteoblasts and adipocytes share a common mesenchymal stem cell precursor within the bone marrow, and greater marrow fat is associated with lower bone mineral density (BMD). Marrow fat may serve a metabolic role distinct from other fat depots. Longitudinal effects of weight loss on marrow fat in humans have not been studied. In young mice, caloric restriction increases marrow fat. In humans, women with anorexia nervosa have higher marrow fat than controls despite having much lower visceral and subcutaneous fat. We hypothesized that marrow fat increases after Roux-en-Y gastric bypass (RYGB) surgery, even while other fat depots decrease markedly.

In a pilot study of 11 morbidly obese women (6 diabetic, 5 nondiabetic), we measured vertebral marrow fat before and 6 months after RYGB using magnetic resonance spectroscopy (MRS) at 3T. Six healthy, normal weight control women also underwent MRS at baseline and after 6 months. Marrow fat as saturated lipid content (%) was calculated as $I_{methylene}/(I_{methylene}+I_{water})$ x100, where $I_{methylene}$ and I_{water} are the signal amplitudes of the bulk methylene and water peaks, respectively. Other measures included BMD and body composition by dual-energy X-ray absorptiometry (DXA).

Surgery patients had mean pre-op body mass index 40 kg/m^2. Median pre-op marrow fat was 49% and 46% among diabetic and nondiabetic patients, respectively. Older patients had higher pre-op marrow fat (p=0.04). By DXA, fat mass declined in all patients (mean 19 kg, a 36% decrease, p<0.001). Among those with diabetes, there was a trend towards decreased marrow fat after RYGB, with a median 8% decline (p=0.07; Figure). In nondiabetic women, marrow fat did not change (median change +4%, p=0.89). There was a trend for difference in change between diabetics and nondiabetics (p=0.10). Changes in marrow fat and fat mass by DXA were inversely correlated among nondiabetic (ρ=-0.90, p=0.04) but not diabetic patients. BMD declined at the spine and hip, but changes in marrow fat and BMD were not correlated. Normal weight controls had no 6-month change in marrow fat.

In conclusion, changes in bone marrow fat are variable after RYGB, despite consistent and dramatic declines in overall fat mass. Although more investigation is necessary, our results suggest that RYGB reduces marrow fat in women with, but not without, diabetes. Marrow fat may be subject to complex regulation and may have unique metabolic behavior and kinetic properties compared with other fat depots.

SU0107

Differences in the Associations of Obesity with Bone Density, Microarchitecture and Strength in Younger and Older Adults. Amy Evans*[1], Margaret Paggiosi[2], Richard Eastell[1], Jennifer Walsh[3]. [1]University of Sheffield, United Kingdom, [2]University of Sheffield, United Kingdom, [3]University of Sheffield, United Kingdom

Obesity is associated with lower risk of hip and vertebral fracture, but greater risk of lower leg and proximal humerus fracture. Obese adults have greater areal BMD (aBMD) by dual energy x-ray absorptiometry (DXA). It is not known whether greater BMD in obese adults is the result of greater bone acquisition or reduced bone loss. We investigated BMD, bone structure and strength in younger and older men and women to identify age-related effects of obesity on the skeleton. We studied 100 individually matched pairs of normal weight (BMI 18.5-24.9 kg/m^2) (NW) and obese (BMI>30 kg/m^2) (OB) adults aged 25-40 (n=80) and 55-75 years (n=120). We measured whole body, hip and lumbar spine aBMD by DXA, distal radius and distal tibia volumetric BMD (vBMD) by HR-pQCT and bone strength of the radius and tibia by micro FEA from HR-pQCT. Younger OB had greater hip, lumbar spine and tibia BMD than NW, while older OB had greater BMD than NW at all sites (all p<0.001). BMD was approximately 0 to 1 SD scores greater in younger OB than NW and 1 to 2 SD scores greater in older OB than NW (Table). There was greater trabecular density at the radius (younger p<0.05, older p<0.001) and tibia (younger and older p<0.001) in OB, due to greater trabecular number (younger and older p<0.001) and lower trabecular spacing (younger and older p<0.001) in OB than NW. Cortical density was also greater in older OB than NW (p<0.001). OB had thicker cortices at the tibia (young p<0.01, older p<0.001) and radius (older p<0.001). Univariate GLM showed an interaction of age and BMI on cortical density and cortical area at both sites and on vBMD, trabecular density and cortical thickness at the radius, with a larger difference between NW and OB in older adults. Bone size did not differ between OB and NW in younger or older adults. Bone strength was greater in OB at all sites (younger p<0.05, older p<0.001). There was no interaction of age and BMI on bone strength. Obesity is associated with higher BMD, favourable microstructure and greater bone strength in younger and older adults, but there is a greater difference in

BMD and microstructure between OB and NW in older adults than in younger adults. The higher BMD in obesity is explained by both higher peak bone mass and lower rates of bone loss

Relationships Between Total Body and Regional Adiposity and Cortical and Trabecular Architecture in Late Adolescent Females. Joseph Kindler*[1], Hannah Ross[2], Emma Laing[1], Christopher Modlesky[3], Norman Pollock[4], Clifton Baile[5], Mark Punyanitya[6], Richard Lewis[1]. [1]The University of Georgia, USA, [2]The University of Georgia, USA, [3]University of Delaware, USA, [4]Georgia Regents University, USA, [5]University of Georgia, USA, [6]Image Reading Center, Inc., USA

Adolescents who are obese are at increased risks for skeletal fractures. However, it is unclear whether general obesity rather than site-specific adiposity is implicated in higher fracture risk. The relationships between site-specific fat deposition and bone quality have been explored in older adults, but limited data exist in adolescents. We aimed to identify relationships between total body fat mass (FM), visceral (VAT) and subcutaneous adipose tissue (SAT) and bone architecture in obese and normal weight adolescent females (18-19 years old; N=24). Magnetic resonance imaging (MRI; 3.0 Tesla magnet) was used to measure VAT and SAT, as well as trabecular and cortical bone architecture at the non-dominant tibia and radius. Total body fat-free soft tissue (FFST) and FM were determined via DXA (Hologic Discovery A). FM and SAT were transformed for normality. Unadjusted Pearson's correlations and partial correlations controlling for FFST were used to examine relationships. Significant inverse correlations were observed between FM, SAT and VAT and trabecular thickness at the proximal tibia and bone volume/total volume at the distal radius. FM and SAT were positively related to trabecular separation at the distal radius (Table 1). After adjustment for FFST, FM was additionally inversely associated with bone outcomes at the mid-tibia and mid-radius, SAT at the mid-radius and VAT at the mid-radius only. These data support a potentially negative influence of adipose tissue on trabecular bone quality regardless of fat location at habitually loaded and unloaded skeletal regions in adolescents.

Skeletal response to caloric restriction differs in male vs. female mice. Maureen Devlin*[1], Miranda Van Vliet[2], Leeann Louis[3], Christine Conlon[3], Mary Bouxsein[4]. [1]University of Michigan, USA, [2]Beth Israel Deaconess Medical Center, USA, [3]Beth Israel Deaconess Medical Center, USA, [4]Beth Israel Deaconess Medical Center, Harvard Medical School, USA

Previously we showed that caloric restriction (CR) impairs bone acquisition and increases bone marrow adiposity in growing male mice, but effects of CR in female mice have not been well studied. The female skeleton may be more tolerant of CR due to females' metabolic flexibility during reproduction and/or the osteoprotective effects of estrogen. To test this hypothesis, male and female C57Bl/6J mice (N=8-13/grp) were fed normal (N) diet ad libitum or 30% calorie restricted diet from weaning (3 wks of age) to 12 or 20 wks of age. Outcomes included body mass and body length, %body fat, whole body bone mineral density (BMD), and cortical (Ct) and trabecular (Tb) bone architecture at midshaft and distal femur. Both male and female CR mice were lighter and shorter compared to N, but females were less affected than males (e.g. body mass 22-52% lower in female vs. 40-82% lower in male CR vs. N, $p<0.05$ for all). BMD was 10-21% lower in both male and female CR vs. N from 6-20 wks ($p<0.05$ for both). Body fat did not differ in CR vs. N females from 9-20 wks, but was 20-26% lower in CR males vs. N from 12-20 wks ($p<0.05$). In females, CR did not influence distal femur Tb.BV/TV (Figure), and led to higher Tb.N (+6-19%) and Conn.D (+32-44%) vs. N ($p<0.05$ for both). In contrast, male CR had markedly lower distal femur Tb.BV/TV (-75-77%, Figure), Conn.D (-24-41%), and Tb.N (-17-19%) vs. N ($p<0.05$ for all). Midshaft Ct.Th and polar moment of inertia did not differ in male or female CR vs. N after body mass adjustment, while mass-adjusted cortical bone area was lower in female CR vs. N ($p<0.05$). Thus, CR resulted in normal body fat and Tb.BV/TV and higher Tb.N and Conn.D in females, but lower body fat, Tb.BV/TV, Tb.N and Conn.D in males, suggesting that relatively higher body mass and body fat in CR females as compared to males may protect trabecular bone acquisition. These data support our hypothesis that females are more tolerant of caloric restriction than males, perhaps reflecting their higher estrogen levels or their metabolic flexibility during energetic stressors such as pregnancy and lactation.

Effect of dietary Fe on FGF23 level of adriamycin-treated mice. Masanori Takaiwa*[1], Kosei Hasegawa[2], Kunihiko Aya[3], Hiroyuki Tanaka[4], Yoichi Kondoh[5], Nobuyuki Kodani[5]. [1]Dept. of Pediatrics, Matsuyama Red Cross Hosp., Japan, [2]Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sciences, Japan, [3]Kurashiki Chuou Hospital, Japan, [4]Okayama Saiseikai General Hospital, Japan, [5]Dept. of Pediatrics, Matsuyama Red Cross Hosp., Japan

Parenteral Fe therapy for CKD patients could increase FGF23 and cause hypophosphatemia. However, Fe deficiency worsens FGF23 elevation in patients with inherited hypophosphatemia. It has been documented that FGF23 is associate with poor prognosis of CKD. Since FGF23 elevates during the early CKD, we created an early CKD model by intermittent administration of adriamycin (ADR) to C57BL/6J mice (C57) and examined the effect of dietary Fe on FGF23 during the early CKD. Using 6 groups (control and 0.6%-Fe-AN groups – fed a 0.6% Fe diet; 2%-Fe and 2%-Fe-AN groups - fed a 2.0% Fe diet; 0.02%-Fe and 0.02%-Fe-AN groups - fed a 0.02% Fe diet), 10-week-old male C57 were administered serine (the control, 2%-Fe and

0.02%-Fe) or ADR weekly (0.6%-Fe-AN, 2%-Fe-AN and 0.02%-Fe-AN) for 28 days. Data were expressed as the mean ± SEM. A value of $p<0.01$ was considered significant (Tukey's test). After treatment, Fe for 2%-Fe and 2%-Fe-AN (275 ± 9 and 280 ± 13μg/dl) were higher, and that of 0.02%-Fe-AN was lower (115 ± 10μg/dl) than the control (161 ± 6μg/dl). Hb of 0.02% Fe-AN (11.5 ± 0.1 g/dl) was markedly lower than the control (13.5 ± 0.1 g/dl). The kidneys of the ADR treated groups were smaller in size. Although not significant, Cr for 0.6%-Fe-AN, 2%-Fe-AN and 0.02%-Fe-AN were higher (1.8 ± 0.2, 2.3 ± 1.7 and 2.8 ± 0.3mg/dl) than the control (0.9 ± 0.1mg/dl). FGF23 tended to be higher among all ADR treated groups, only 0.02%-Fe-AN showed significant elevation (670 ± 134pg/ml) compared with the control (159 ± 10pg/ml). Ca, Pi and PTH showed no significant difference. The intermittent ADR injection caused the small kidneys associated with slight Cr increase. The ADR treatment caused mild increase in FGF23 without affecting Pi and PTH, hence serving as a reasonable early CKD model. Only the ADR treatment of the Fe depleted mice increased FGF23, hence the negative regulatory effect of Fe on FGF23 was significant during early CKD. Our results suggest that the initiation of oral Fe during early CKD suppresses FGF23 production and has a favorable effect on progression of CKD.

Impact of Common Variants in Type 2 Diabetes Genes on Fracture Risk and Measures of Bone Quality in African American Children. Courtney Sprouse*[1], Joseph Devaney[2], Heather Gordish-Dressman[2], Leticia Ryan[3], Laura Tosi[1]. [1]Children's National Medical Center, USA, [2]Children's National Health System, USA, [3]Johns Hopkins University, USA

Purpose: Type 2 Diabetes (T2D) is a serious health problem; morever the incidence rate of type 2 diabetes is twice as high in African Americans (AA) than those of European descent. It is associated with numerous complications, including reduced bone quality and increased fractures risk in adulthood. The purpose of our study was to determine if single nucleotide polymorphisms (SNPs) previously associated with increased risk of developing T2D are also associated with measures fracuture risk and bone quality in AA children.

Methods: DNA was isolated from 142 AA children, aged 5 to 9 years. Cases (n=71) had an isolated forearm fracture (radius, ulna or both) and age-matched control participants (n=71) had no prior fracture. Sixty-six SNPs previously found to be highly associated with pre-diabetic phenotypes or increased risk of developing T2D from genome wide association studies (GWAS) studies were selected for analysis. The 66 SNPs were then genotyped, using Taqman allelic discrimination assay or the Illumina Human Exome BeadChip. SNPs were analyzed for associations with Total Body minus head bone mineral density (BMD), Total Body minus head Z-score, Lumbar Spine BMD, and Lumbar Spine Z-score obtained from dual energy x-ray absorptiometry. Mean continuous phenotypes were compared among genotypes from each SNP using analysis of covariance models adjusted for gender and age. Associations between SNPs and fracture status were tested using logistic regression adjusted for gender. All regression models used a dominant genetic model.

Results: Significant associations with fracture status were found with rs17036101 located in the *SYN2* gene (OR= 3.54; 95% CI=1.21-10.34; p=0.021), rs896854 located in the *TP53INP1 gene* (OR= 1.98; 95% CI=1.02-3.86; p=0.045), and rs11634397 located in the *ZFAND6* gene (OR=0.40; 95% CI=0.19-0.85; p=0.018). Furthermore, significant associations were found between rs13266634 in the *SLC30A8* gene and total body minus head BMD [CC: 0.673 ± 0.015 g/cm^3; CT/TT: 0.711 ± 0.021 g/cm^3; p=0.020] and lumbar BMD [CC: 0.549 ± 0.018 g/cm^3; CT/TT: 0.593 ± 0.025 g/cm^3; p=0.020]; and rs7542900 in the *SYN2* gene with both total BMD [CC: 0.651 ± 0.018 g/cm^3; CT/TT: 0.681 ± 0.014 g/cm^3; p=0.019] and lumbar BMD [CC: 0.549 ± 0.018 g/cm^3 CT/TT: 0.518 ± 0.022 g/cm^3; p= 0.006].

Conclusion: Our study suggests that AA children possessing alleles associated with increased risk of developing T2D in adulthood also have reduced BMD and increased risk of fracture.

SU0112

A 'conditional-ON' mouse model of Fibrodysplasia Ossificans Progressiva (FOP). Sarah Hatsell*[1], Lily Huang[2], Liqin Xie[3], Trikaldarshi Persaud[2], Peter Yang[2], Lili Wang[4], Xialing Wen[2], Kalyan Nannuru[2], Vincent Idone[2], Aris Economides[5]. [1]Regeneron Pharmaceuticals, USA, [2]Regeneron Pharmaceuticals Inc, USA, [3]Regeneron Pharmaceutical company, USA, [4]Regeneron Pharmaceuticals Inc, USA, [5]Regeneron Pharmaceuticals, Inc., USA

FOP is an autosomal dominant disorder characterized by early onset, episodic and progressive ossification of skeletal muscle and associated connective tissue (Pignolo et al., 2011). FOP is driven by mutations in the intracellular domain of *ACVR1* (also known as *ALK2*), with the great majority altering Arginine 206 to Histidine (R206H). In order to enable the development of therapeutic approaches for FOP, as well as mechanistic studies of the disease process, we have engineered a Cre-regulated 'conditional-ON' allele of *ACVR1[R206H]* in the mouse – $ACVR1^{[R206H]COIN}$ – using a FlEx- (Schnutgen et al., 2003) or COIN-like design (Economides et al., 2013). (A conditional approach was necessitated because an unregulated *ACVR1[R206H]* knock-in allele cannot be transmitted through the germline in mice (Chakkalakal et al., 2012).)

$ACVR1^{[R206H]COIN}$ was generated by introducing the R206H mutation in exon 5 of *mmuACVR1*, placing the mutated exon and flanking intronic sequence in the antisense strand. The corresponding region from human *ACVR1* (Chr2:158628593-158632803) was inserted into in the sense strand of *mmuACVR1* upstream of the inverted exon. To enable Cre-dependent replacement of the wild type exon 5 with its R206H version, the introduced human sequence was flanked by a 'FlEx' array of Lox2372 and LoxP sites in parallel orientation, whereas the mutant exon is followed by Lox2372-LoxP placed in antiparallel orientation with the Lox2372 and LoxP sites flanking human exon 5. This arrangement allows Cre-mediated inversion of the mutant exon into the sense strand and simultaneous deletion of the wild type human exon 5.

We show that the $ACVR1^{[R206H]COIN}$ allele is wild type prior to activation of its mutant form by Cre. Body-wide activation of the FOP allele in $Acvr1^{[R206H]COIN/+}$;$Gt(ROSA26)Sor^{CreER t2/+}$ adult mice resulted in progressive ossification resembling that of FOP, evident radiographically as early as 2 weeks after dosing with tamoxifen. MicroCT analysis at 12 weeks after tamoxifen injection revealed dense heterotopic ossification of the axial skeleton, as well as long bones and thorax, whereas untreated $ACVR1^{[R206H]COIN/+}$;$Gt(ROSA26)Sor^{CreER t2/+}$ mice were normal in phenotype. The development of heterotopic ossification in tamoxifen-treated $ACVR1^{[R206H]COIN/+}$;$Gt(ROSA26)Sor^{CreER t2/+}$ mice was spontaneous, and did not require experimentally induced inflammation. The FOP phenotype was expressed in adult mice, uncoupling the process observed in these mice from development. Detailed studies deciphering the molecular and cellular mechanisms that underlie FOP are currently under investigation using this physiologic mouse model of FOP, along with testing of candidate therapeutic regimens.

A Transgenic Mouse Model of OI Type V Suggests the IFITM5 c.-14C>T Mutation Is Neomorphic. Ronit Marom*[1], Caressa Lietman[1], Ming Ming Jiang[2], Elda Munivez[2], Brian Dawson[2], Terry Bertin[2], Yuqin Chen[2], MaryAnn Weis[3], David Eyre[4], Brendan Lee[1]. [1]Baylor College of Medicine, USA, [2]Baylor College of Medicine, USA, [3]University of Washington, USA, [4]University of Washington Orthopaedic Research Labs, USA

Osteogenesis Imperfecta (OI) type V, characterized by increased bone fragility, long bone deformities, hyperplastic callus formation and calcification of interosseous membranes, is caused by a recurrent mutation in the 5' UTR of *IFITM5* gene (c.-14C>T). This mutation introduces a new start codon, adding 5 amino acid residues to the N-terminus of the protein. The mechanism whereby this novel IFITM5 protein causes OI type V – is yet to be defined. We present here a transgenic mouse model of OI type V that overexpresses the mutant *Ifitm5* allele.

The *IFITM5* transgenic construct, carrying either wild type (control) or mutant *Ifitm5* allele under the Col1a1 2.3kb promoter, was introduced into FVBN mice. The resultant transgenic mice carrying mutant *Ifitm5* exhibited perinatal lethality, whereas non-transgenic littermates and wild-type transgenic litters exhibited no lethality. Skeletal preparations and radiographs performed on E15.5 and E18.5 embryos revealed delayed/abnormal mineralization and skeletal defects including abnormal rib cage formation, long bone deformities and fractures. Primary osteoblast cultures, derived from mutant mice calvaria at E18.5, showed decreased mineralization by Alizarin-Red staining, as compared to non-transgenic littermates and wild-type mice calvaria cultures, consistent with the in vivo phenotype. Importantly, overexpression of wild-type *Ifitm5* did not result in significant bone phenotype, as evident by micro-CT studies of adult transgenic mice.

Collectively, our results suggest abnormal skeletal development, loss of bone mineralization and abnormal bone cell phenotype in this transgenic mouse model. Since overexpression of the mutant *Ifitm5* in bone resulted in perinatal lethality, we were unable to see the post-natal phenotype of hyper callus formation and interosseous membrane calcification. Given that neither overexpression of the wild type *Ifitm5*, as shown in our model, nor knock-out of *Ifitm5*, as previously published, were consistent with this overt bone phenotype, we suggest a neomorphic effect of *IFITM5* mutation as the cause of abnormal bone formation in OI type V.

Abnormal Bone Morphology in a Feline Model of Sandhoff Disease. Margaret McNulty*[1], Patricia Beadlescomb[2], Miguel Sena-Esteves[3], Ashley Randle[4], Aime Johnson[5], D. Ray Wilhite[6], Douglas Martin[2]. [1]Louisiana State University School of Veterinary Medicine, USA, [2]Auburn University College of Veterinary Medicine, Scott-Ritchey Research Center, Dept. of Anatomy, Physiology, & Pharmacology, USA, [3]University of Massachusetts Medical School, Department of Neurology & Gene Therapy Center, USA, [4]Auburn University College of Veterinary Medicine, Scott-Ritchey Research Center, USA, [5]Auburn University College of Veterinary Medicine, Department of Clinical Sciences, Scott-Ritchey Research Center, USA, [6]Auburn University College of Veterinary Medicine, Dept. of Anatomy, Physiology, & Pharmacology, USA

Lysosomal storage disorders are characterized by abnormal accumulation of molecular waste in all cells due to defects in lysosome function, however neurons are most affected. GM2 gangliosidoses, a subgroup of the disorders, including Sandhoff disease (SD), is caused by a deficiency in the enzyme β-N-acetylhexosaminidase (Hex) and presents with severe neurological effects in humans resulting in death at an early age. With advancements in treatments to prolong lifespan, research must be conducted on the potential effects of SD on other tissues that may impact quality of life. In this study, a feline model of infantile SD was used to evaluate boney changes secondary to the disease. Affected (known deficiency in Hex) cats received an intracranial injection of adeno-associated virus vector. This treatment has been shown to significantly increase the lifespan by reducing the neurological effects of the disease. As lifespan increased, skeletal abnormalities including dysplasias & luxations were clinically identified. Long bones from 21 cats (age: 3.9-37 months), both affected (treated & untreated) and normal (not deficient in Hex) were scanned with microCT. Trabecular architecture in the distal femur & proximal humerus, and cortical geometry in the midshaft of the femur was evaluated. Affected cats (treated & untreated) displayed abnormal skeletal changes. Overall morphology indicated a significant retardation in epiphyseal development. In young (<6 months) affected cats, there was severe lack of development of the epiphyses. The physes of older (>17 months) affected cats persisted, though the epiphyses appeared to be mostly developed. The boney articular surfaces of affected cats were roughened and had subchondral bone lesions. Periarticular osteophytes were also present. Trabecular bone volume was decreased in affected (treated & untreated) cats of all ages. This difference was significant in the young cats (BV/TV femur: p=0.03; humerus: p=0.023), but not other ages due to a small sample size. Other significant differences between affected & normal cats were found in structural model index, connectivity density, and degree of anisotropy. No significant differences were identified in cortical geometry. This study shows that Hex deficiency in cats has a significant effect on bone development, particularly secondary centers of ossification and may affect bone remodeling. This has implications for studies aimed to improve the lifespan of those affected with SD.

Activation of FGF/FGF Receptor Signaling in the Primary Osteocytes Isolated from Hypophosphatemic *Hyp* Mice. Kazuaki Miyagawa*[1], Miwa Yamazaki[2], Masanobu Kawai[3], Takao Koshimizu[2], Jin Nishino[4], Yasuhisa Ohata[5], Kanako Tachikawa[2], Yuko Mikuni-Takagaki[6], Mikihiko Kogo[7], Keiichi Ozono[8], Toshimi Michigami[9]. [1]Osaka University Graduate School of Dentistry, Japan, [2]Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, [3]Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, [4]Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, [5]Osaka University Graduate School of Medicine, Japan, [6]Kanagawa Dental University Graduate School of Dentistry, Japan, [7]Osaka University Graduate School of Dentistry, Japan, [8]Osaka University Graduate School of Medicine, Japan, [9]Osaka Medical Center & Research Institute for Maternal & Child Health, Japan

Osteocytes express multiple genes involved in mineral metabolism including PHEX, FGF23, DMP1 and FAM20C. In *Hyp* mice, a murine model for X-linked *Hyp*ophosphatemia (XLH), it has been established that *Phex* deficiency results in the overproduction of FGF23 in osteocytes, which leads to *Hyp*ophosphatemia and impaired vitamin D metabolism. However, the role of osteocytes in the pathogenesis of *Hyp* mice is still not fully understood. In this study, to further clarify the abnormality in osteocytes of *Hyp* mice, we obtained detailed gene expression profiles in osteoblasts and osteocytes isolated from 20-week-old *Hyp* mice and wild-type (WT) control mice, using cells freshly isolated from the long bones based on the differentiation stage by sequential digestion with collagenase and decalcification with EGTA. The expression of *Fgf23*, *Dmp1*, and *Fam20c* was higher in osteocytic cells than in osteoblastic cells in both genotypes, and was up-regulated in *Hyp* cells. Interestingly, the up-regulation of these genes in *Hyp* bones began before birth. On the other hand, the expression of *Slc20a1* encoding the sodium/phosphate (Na^+/Pi) co-transporter Pit1 was increased in osteoblasts and osteocytes from adult *Hyp* mice, but not in *Hyp* fetal bones. *Dmp1* expression in osteocytic cells was increased due to the 24-hour treatment with 10 mM Pi and was suppressed by 10^{-8} M $1,25(OH)_2D_3$ in WT. The up-regulation of *vitamin D receptor (Vdr)* by the treatment with $1,25(OH)_2D_3$ was smaller in *Hyp* cells than in WT cells, suggesting that the responsiveness to $1,25(OH)_2D_3$ might be reduced in *Hyp* cells. Previous studies suggest that induction of FGF23 in *Hyp* bone may be attributed to the activation of FGFR signaling. Therefore, we next examined the expression of the genes encoding Fgf1, Fgf2, Fgfr1–3, and a-Klotho in the osteocytic cells freshly isolated from WT and *Hyp* long bones. The expression of *Fgf1*, *Fgf2*, *Fgfr1,* and *Fgfr3* was significantly increased in *Hyp* cells, while that of a-*Klotho* was low in both genotypes. The expression of *Egr-1*, a target gene of FGF/FGFR signaling, was two-fold higher in *Hyp* osteocytic cells than in WT cells. These results provide the evidence for the activation of FGF/FGFR signaling in *Hyp* osteocytes, which might play a role in the pathogenesis of *Hyp* mice through the dysregulation of multiple genes. Since the expression of Fgf1 and Fgf2 was increased in *Hyp* osteocytic cells, these FGF ligands rather than Fgf23 might be responsible for the activation of the signaling.

Development of Refined Methods to Induce Heterotopic Ossification in the $Alk2^{Q207D}$ Mouse Model of Fibrodysplasia Ossificans Progressiva. Nicole Fleming[1], Satoru Hayano[2], Yuji Mishina[3], Charles Hong[4], Paul Yu[5], Daniel Perrien*[6]. [1]VUIIS, Vanderbilt University, USA, [2]Dept. of Biologic & Materials Sciences, University of Michigan School of Dentistry, USA, [3]Dept. of Biologic & Materials Sciences, University of Michigan School of Dentistry, USA, [4]Department of Cardiovascular Medicine, Vanderbilt University, USA, [5]Division of Cardiology, Harverd Medical School & Brigham & Women's Hospital, USA, [6]Vanderbilt University Medical Center, USA

Fibrodysplasia ossificans progressiva (FOP) is an untreatable rare congenital disorder characterized by progressive heterotopic ossification (HO) causing pain, immobility, and eventual death. FOP is caused by mutations in the *ACVR1* that produce constitutively active Alk2, a BMP Type 1 Receptor. Creating accurate and reliable animal models of FOP is a key step in developing therapies. Germline expression of activating mutations in Alk2 are embryonic lethal in mice, requiring a conditional approach. The $Alk2^{Q207D}$-floxed ($caAlk2^{fl/fl}$) mouse carrying a cre-inducible caAlk2 transgene was one of the first FOP models. However, it is unclear which methods and at what age HO can reliably induce HO in these mice. Hence, these studies sought to characterize multiple methods for inducing HO in $caAlk2^{fl/-}$ and $caAlk2^{fl/fl}$ mice. Local expression of caAlk2 was achieved by injection of adenovirus expressing cre recombinase (Ad-cre) into the calf muscles of mice with or without injections of cardiotoxin (CTX) at the same location to cause muscle damage. Weekly digital radiographs were acquired and the volume of HO was measured by *ex vivo* microCT. In the first study, 9-day old caAlk2 mice received i.m. injections of various titers of Ad-cre alone. HO was seen on x-ray at 2 wk only in the 10^9, $2x10^9$, and $5x10^9$ PFU groups, although the incidence of HO was lower with 10^9 PFU. The volume of HO at 3 wk was significantly greater with $5x10^9$ PFU ($p<0.05$). Induction of HO was significantly greater in $caAlk2^{fl/fl}$ mice vs. $caAlk2^{fl/-}$. The effect of CTX on HO in 9-11 day old $caAlk2^{fl/-}$ mice was tested using 10^9 PFU Ad-cre and injecting 0.3 μg of CTX per day for 3 days with Ad-cre on the 3rd day (3xCTX group), 1.0 μg CTX at same time of Ad-cre (1xCTX), or 1.0 μg CTX the day after Ad-cre (Delayed 1xCTX). The 3xCTX protocol significantly reduced HO vs. Ad-cre alone ($p<0.05$). The 1xCTX and Delayed 1xCTX protocols significantly enhanced HO, with lesions detectable within 1 wk and greater HO volume at 2-wk versus Ad-cre alone ($p<0.05$). Finally, 21-day old $caAlk2^{fl/-}$ mice were used to determine the reliability of HO induction in adolescent mice. Co-injection of $5x10^9$ PFU Ad-cre and 1.0 μg of CTX in the calf muscle resulted in rapid and aggressive HO detectable at 1 wk and maturing by 2 wk. These studies illustrate multiple methods for reliable induction of localized HO in the caAlk2 mouse model of FOP that should accelerate progress in research and drug development to treat this disease.

Dystrophic Systemic Milieu Plays an ImportantRole in the Muscle and Bone Abnormalities in Duchenne Muscular Dystrophy. Hongshuai Li*[1], Aiping Lu[2], Ying Tang[2], Bing Wang[2], Johnny Huard[3]. [1]University of Pittsburgh, USA, [2]University of Pittsburgh, USA, [3]Orthopaedic Surgery, USA

Background: Duchenne muscular dystrophy (DMD) is a degenerative muscle disorder characterized by a lack of dystrophin expression in the sarcolemma of muscle fibers. DMD patients acquire osteopenia, fragility fractures, and scoliosis indicating a deficiency in skeletal homeostasis; however, little is known about the mechanism of the degenerative changes in the bone tissues during the process of DMD pathogenesis. We hypothesized that the DMD systemic milieu is an influencing factor that contributes to the degenerative muscle and bone pathologies observed in a severely affected model of DMD, the dystrophin/utrophin double knockout (dKO) mouse. Materials: Three animal models of DMD were utilized: mdx (dystrophin-/-), dKO-homo (dystrophin-/-, utrophin-/-), and dKO-hetero (dystrophin-/-, utrophin+/-). A

parabiotic model was used to test the influence that the systemic milieu had on the pathologic changes in the bone and skeletal muscle of dKO-hetero and -homo mice. Results: The old dKO-hetero mice (12-14 months) were surgically paired with young mdx mice (3-5 months) to examine the influence that the young DMD systemic milieu had on the pathological changes in the muscle and bone. Significant improvements in the histopathological changes were observed in the skeletal muscle and bone. Healthier vertebral structures, epiphysis of proximal tibia, and mid-shaft of the femur were observed in the old dKO-hetero mice in the old/young pairings when compared with the old dKO-hetero mice in the old/old pairings (Fig. 1 &2). The dKO-homo mice were paired with WT mice to test the influence of the systemic milieu on the development of muscle pathology and bone healing. Significant improvements in the histopathological changes in the skeletal muscle and bone volumes in the defect areas were observed in both non-critical sized tibia and cranial defects created in the dKO-homo mice in the dKO-homo/WT pairings compared to dKO-homos in the dKO homo/homo pairings (Fig.3). The dKO-hetero mice were paired with WT GFP mice to examine the engraftment of circulating progenitor cells from the WT partner. None of the regenerating myofibers in the dKO-hetero mice were GFP-positive (Fig.4). Furthermore, the quantity of hematopoietic stem cells, not bone marrow-derived mesenchymal stem cells, was significantly increased in the dKO-homo mice in the dKO homo/WT pairings when compared to the dKO homo/homo pairings (Fig.5). These data indicate that improved muscle pathology and bone healing is due to circulating factors. Conclusion: These observations demonstrated that the systemic milieu is an influential factor that contributes to the degenerative muscle and bone phenotype observed in the dKO mice. These results indicate that the defect in the somatic cells in dKO mice could be driven by the dystrophic microenvironment and might be, in part, attributable to changes in blood-borne factors.

Enhanced TLR-MYD88 Signaling Stimulates Autoinflammation in SH3BP2 Cherubism Mice and Defines the Etiology of Cherubism. Teruhito Yoshitaka[1], Tomoyuki Mukai[2], Mizuho Kittaka[3], Bjorn Olsen[4], Ernst Reichenberger[5], Yasuyoshi Ueki*[6]. [1]University Missouri-Kansas CitySchool of Dentistry, USA, [2]University of Missouri - Kansas City, USA, [3]University of Missouri-Kansas City School of Dentistry, USA, [4]Harvard School of Dental Medicine, USA, [5]University of Connecticut Health Center, USA, [6]University of Missouri-Kansas City, School of Dentistry, USA

Cherubism (OMIM#118400) is a rare genetic disorder characterized by bilateral jawbone destruction due to proliferation of inflammatory/fibrous lesions that often regress after puberty. Heterozygous gain-of-function mutations in the adaptor protein SH3-domain binding protein 2 (SH3BP2) are responsible for the disorder. Analysis of the knock-in (KI) mouse model for cherubism revealed that, while heterozygous cherubism mice ($Sh3bp2^{KI/+}$) exhibit mild osteoporosis due to increased osteoclastogenesis induced by RANKL, homozygous mutant mice ($Sh3bp2^{KI/KI}$) spontaneously develop macrophage-rich inflammation in face, lung, stomach, and liver as well as inflammatory bone destruction in calvariae and joints in a TNF-α-dependent manner. Since $Sh3bp2^{KI/KI}$ mice deficient in T/B cells develop the inflammation, this inflammation is regarded as autoinflammation. However, these studies failed to explain the reason why human cherubism lesions are restricted to jaws and regress with age. We discovered that the elevation of serum TNF-α levels and the systemic inflammation in $Sh3bp2^{KI/KI}$ mice are MYD88-dependent and are rescued in the absence of toll-like receptor (TLR) 2 and TLR4 ($Tlr2^{-/-}/Tlr4^{lps\text{-}del/lps\text{-}del}/Sh3bp2^{KI/KI}$). IL-1R1-deficient $Sh3bp2^{KI/KI}$ mice exhibited only a partial reduction of liver lesions. Interestingly, germ-free $Sh3bp2^{KI/KI}$ mice still developed the inflammation. *In vitro* studies showed that bone marrow-derived M-CSF-dependent macrophages (BMMs) from mutant mice are hyper-responsive to PAMPs (pathogen-associated molecular patterns) and DAMPs (damage-associated molecular patterns) that activate TLRs, resulting in TNF-α overproduction. NF-κB pathway was more activated in $Sh3bp2^{KI/KI}$ BMMs stimulated with Pam3CSK4 and LPS than in $Sh3bp2^{+/+}$ BMMs. Tyrosine 183 residue in SH3BP2 was critical for TNF-α overproduction in RAW264.7 cells. Finally, SYK depletion in macrophages ($LysM\text{-}cre/Syk^{\Delta M/\Delta M}/Sh3bp2^{KI/KI}$) prevented the inflammation. These data suggest that presence of a large amount of oral bacteria and increased release of DAMPs during active jawbone remodeling phase resulting from, for example, tooth eruption that activate TLRs may cause the jaw-specific development of human cherubism lesions. Reduced levels of DAMPs after stabilization of jaw remodeling and potential maturation of MYD88-independent

immunity with age may contribute to the age-dependent regression. Therapeutically, our data suggest that SYK inhibitors may be effective in the treatment of cherubism.

Iroquois Homeobox Factors 3 and 5 Regulation of Skull Mineralization. Corey Cain*[1], Nathalie Gaborit[2], Wint Lwin[3], Edward Hsiao[1]. [1]University of California, San Francisco, USA, [2]Inserm 1087/CNRS UMR 6291, Institut du Thorax, France, [3]University of California, San Francisco, USA

Purpose: Osteoporosis affects over 10 million people in the United States and contributes to 1.5 million fractures each year. While osteoblast (OBC) dysfunction is thought to be one major contributor to osteoporosis, the genetic complexity of bone loss poses a major challenge to understanding how OBCs lose their ability to synthesize bone matrix. Iroquois homeobox transcription factors (IRX) are expressed early in bone tissues and facilitate patterning and mineralization of the skeleton. Recently, mutations in IRX5 have been associated with Hamamy syndrome, which presents in humans with osteoporosis, hip dysplasia, facial abnormalities, and cardiac malformations. Although *Irx5*$^{-/-}$ mice are asymptomatic, dual loss of both *Irx3* and *Irx5* in mice phenocopies the cardiac malformations found in humans with Hamamy syndrome, but causes embryonic lethality. Here, we used the *Sp7-Cre* to drive OBC-specific deletion of *Irx3 in Irx5*$^{-/-}$ mice to study the bone specific functions of the IRX genes.Methods: Newborn *Irx3*^{floxlflox}*; Irx5*$^{-/-}$*; Sp7-Cre*$^{+}$ mice were measured for body mass and length. 3D microCT image reconstruction was then performed on *Irx3*^{floxlflox}*; Irx5*$^{-/-}$*; Sp7-Cre*$^{+}$ mice to determine total body skeletal defects. *Irx3*^{floxlflox}*; Irx5*$^{-/-}$*; Sp7-Cre*$^{+}$ skeletons were stained with alizarin red and alcain blue to visualize bone and cartilage. We used histological analysis of sectioned skulls to determine mineralization and cartilaginous arrangement within the skull. Finally, qPCR analysis of mineralization and cartilaginous genes were performed on whole *Irx3*^{floxlflox}*; Irx5*$^{-/-}$*; Sp7-Cre*$^{+}$ calvaria.Results: Approximately 43% of newborn *Irx3*^{floxlflox}*; Irx5*$^{-/-}$*; Sp7-Cre*$^{+}$ mice die at birth. *Irx3*^{floxlflox}*; Irx5*$^{-/-}$*; Sp7-Cre*$^{+}$ mice had significant reductions in body mass even though body length was not significantly reduced. MicroCT, in conjunction with alizarin red and alcain blue staining, showed decreased mineralization in parietal, occipital, and mandible bones of *Irx3*^{floxlflox}*; Irx5*$^{-/-}$*; Sp7-Cre*$^{+}$ mice but relatively unaffected long bones. Furthermore, there were significant reductions in calvarial expression of Col1A1 and Aggrecan.Conclusion: Mineralization in the skulls of *Irx3*^{floxlflox}*; Irx5*$^{-/-}$*; Sp7-Cre*$^{+}$ mice was markedly reduced despite no major differences in cartilaginous formation in the skull. Our findings indicate that IRX3 and IRX5 are important for mineralization of mesenchymal-derived intramembranous bones.

Mechanisms of Mineral Metabolism During Pregnancy in Mice with X-Linked Hypophosphatemia (XLH). Steven Tommasini*[1], Meina Wang[1], Helen King[2], Catherine Skinner[1], Carolyn Macica[3]. [1]Yale University, USA, [2]Yale University, USA, [3]Frank H. Netter School of Medicine Quinnipiac University, USA

During pregnancy, maternal adaptations to high mineral demand include more than doubling intestinal calcium absorption by increasing vitamin D production. However, in patients with XLH, vitamin D production and intestinal calcium absorption are impaired. Previously, we showed that to accommodate the increased mineral demands of lactation, Hyp mice, a murine model of XLH, increase intracortical remodeling similar to that described in post-menopausal osteoporotic bone. As vitamin D biosynthesis is impaired in Hyp mice, we hypothesized that the skeletal contribution to mineral homeostasis begins during pregnancy. Serum analysis in Hyp and C57BL/6 (B6) mice revealed that maternal $1,25(OH)_2D$ levels were lower in Hyp compared to B6 at different time points across pregnancy ($p<0.05$, t-test). However, consistent with human data, both groups showed an increase in $1,25(OH)_2D$ early and then a decrease at E18.5. One possibility is that increases in levels of prolactin may drive the potentiation of vitamin D. Hyp and B6 maternal PTH levels also were consistent with normal human pregnancy where PTH is suppressed during the first trimester and then increases steadily to the mid-normal range by term. However, Hyp PTH levels remained consistently 50-100% higher than B6. Despite sustained elevated levels of PTH in pregnant Hyp mice, these levels are likely to be insufficient to overcome the inhibitory effect of increased FGF23 on vitamin D production. Analysis of the femoral diaphysis by high resolution μCT (resolution=1.55μm), revealed that at the end of pregnancy, Hyp porosity ($14.5\pm1.2\%$) was increased relative to virgin Hyp ($8.8\pm0.4\%$) and similar to lactating Hyp ($12.5\pm1.2\%$). This increase in porosity was due to an increase in large unmineralized spaces comprised of vasculature or demineralized matrix. Pregnant B6 mice had lower overall intracortical porosity ($0.9\pm0.2\%$) compared to Hyp including smaller lacunae ($176\mu m^3$ vs. $234\mu m^3$). We further characterized the matrix composition of cortical bone using FTIR and Raman spectroscopy. Compared to pregnant B6, pregnant Hyp cortical bone had similar collagen cross-linking (3.1 ± 0.2 vs. 3.6 ± 1.1), lower mineralization (4.1 ± 0.4 vs. 5.3 ± 0.3, $p<0.0001$), lower amounts of acid phosphate ($p<0.0001$), higher carbonate ion substitution (0.027 ± 0.001 vs. 0.020 ± 0.001, $p<0.0001$), and increased crystallinity (0.89 ± 0.01 vs. 0.87 ± 0.01, $p<0.05$). Taken together, these data suggest that increased intracortical remodeling also contributes in maintaining phosphate levels during periods of high mineral demand in patients with XLH.

Mouse Model with Mutant Type I Collagen C-propeptide Cleavage Site has Brittle Bones and Increased Osteoblast Mineralization. Aileen Barnes*[1], Joseph Perosky[2], M. Helen Rajpar[3], Kenneth Kozloff[4], Joan Marini[5]. [1]NICHD/NIH, USA, [2]University of Michigan, USA, [3]NICHD/NIH, USA, [4]University of Michigan Department of Orthopaedic Surgery, USA, [5]National Institute of Child Health & Human Development, USA

Classical dominant osteogenesis imperfecta (OI) is caused by mutations in type I collagen. Mutations in the C-propeptide cleavage site of both *COL1A1* and *COL1A2* were shown to cause high bone mass OI, characterized by bone hypermineralization and normal to increased DXA Z-scores. We generated a mouse with a heterozygous C-propeptide cleavage site defect (high bone mass, HBM) in which the Ala-Asp residues of the COL1A1 cleavage site were mutated to Thr-Asn to prevent cleavage by BMP1. We utilized this mouse to elucidate the role of type I procollagen C-propeptide processing in bone formation.

Collagen from newborn HBM calvarial osteoblasts had normal biochemistry and the collagen was incorporated normally into trimers. However, osteoblasts deposited only about 50% of WT matrix. Additionally, an *in vitro* mineralization assay showed that calvarial HBM osteoblasts had a 15% increase in mineralization ($p=0.006$), ± BMP2 treatment. Conditioned media from newborn HBM fibroblasts showed decreased processing of the C-propeptide. Dermal fibril diameters were smaller and more homogeneous in HBM than WT, with a loss of large fibrils.

At 2 months of age, male HBM mice are significantly smaller in weight (77%) and length (92%) and have shorter femurs (92%). Femoral areal BMD in HBM mice is decreased 25% ($p<0.001$), but vertebral BMD is normal. All 2 month HBM mice have pelvic deformities, and 40% have kyphosis. On μCT, HBM femora have a thinner cortex with decreased cortical area; the distal femoral metaphysis is notably thinner. Four point bending revealed an extremely brittle phenotype; post-yield displacement is only ~10% of WT (0.23 vs 0.03, $p<0.001$). HBM femoral stiffness, yield load, and ultimate load are also significantly decreased.

The bone phenotype of the HBM mouse is similar to that of the *Bmp1*$^{-/-}$*/Tll1*$^{-/-}$ mouse (Muir, et al, *Hum Mol Genet*, 2014, doi:10.1093/hmg/ddu013), in which cleavage of types I, II, III and V procollagen as well as bone-related factors such as DMP1, biglycan, lysyl oxidase, and TGFβ1 are defective. The *Bmp1*$^{-/-}$*/Tll1*$^{-/-}$ mouse has small size, thin cortices, reduced failure energy and maximum load and a dramatic decrease in post-yield displacement. The HBM mouse demonstrates that the essential elements of the broader enzyme deficiency can be reproduced by a substrate defect in type I C-propeptide cleavage. These data show the importance of the type I procollagen C-propeptide to both collagenous and mineral properties of bone.

The Collaborative Cross, a Next-Generation Genetic Analysis Platform for Complex Skeletal Traits. Charles Farber[1], Larry Mesner*[2], Gina Calabrese[3], Steven Tommasini[4], Mark Horowitz[5], Clifford Rosen[6]. [1]University of Virginia, USA, [2]University of Virginia, USA, [3], USA, [4]Yale University, USA, [5]Yale University School of Medicine, USA, [6]Maine Medical Center, USA

Complex skeletal traits such as bone mineral density (BMD), trabecular microarchitecture and biomechanical strength are primarily determined by genetic factors. Genome-wide association studies (GWAS) in human cohorts have begun to identify large numbers of genetic variants associated with bone traits; however, due to the need for large cohorts (tens of thousands), GWAS is only capable of investigating the genetics of clinically accessible traits, such as areal BMD. The Collaborative Cross (CC) is a new, next-generation mouse genetic mapping population designed to facilitate gene discovery for complex phenotypes. The CC provides a platform for ultra-high resolution mapping of traits that cannot be feasibly interrogated using GWAS. The CC consists of a set of inbred strains derived from eight genetically diverse founder strains. As a result of the CC breeding design, full genome sequences on the founders and advanced analytics, the mapping resolution in the CC is sufficient to identify quantitative trait loci (QTL) containing single genes. Here, we utilized the CC to investigate the genetic basis of ~60 skeletal traits, including trabecular and cortical microarchitecture, histomorphometry, marrow adiposity and biomechanics. To date, we have phenotyped 40 CC strains (N=6, 12-week old males per strain) and across these strains high levels of variation were observed for all traits. For example, trabecular bone volume fraction (BV/TV) of the distal femur varied from 1.5% to 34.8% between the strains with the lowest and highest trait values, respectively. Heritability (H^2) estimates were significant ($P<0.05$) for all traits, ranging from $H^2=0.20$ ($P=3.6\times10^{-4}$) for marrow adiposity to $H^2=0.76$ ($P=6.8\times10^{-42}$) for BV/TV of the distal femur. QTL scans revealed a number of significant loci, many of which implicated a small number of candidate genes. Thus, the CC is a powerful new genetic mapping population in the mouse with the potential to significantly increase our understanding of the genetics of a wide-range of complex skeletal phenotypes.

A Peptide-functionalized delivery system to target osteoclasts. Ge Zhang[1], Lei Dang*[2], Baosheng Guo[2], Defang Li[3], Jin Liu[2], Chao Liang[2], Xiaojuan He[4], Heng Wu[2], Zhijun Yang[2], Zicai Liang[3], Aiping Lu[2]. [1]Ge Zhang' S Lab, Hong Kong, [2]Hong Kong Baptist University, China, [3]Kunshan Industrial Technology Research Institute, China, [4]China Academy of Chinese Medical Sciences, China

Introduction: The dyregulated miRNAs in osteoclasts could contribute to osteoclastic dysfunction and even cause skeletal disorders[1]. Synthetic miRNAs antagomir could modulate the endogenous miRNAs in targeted cells. But there is lack of systems for delivering therapeutic miRNAs to osteoclasts *in vivo*[2]. Thus, it is desirable to develop a delivery system selectively targeting osteoclasts for therapeutic modulation of miRNAs.

Objective: To develop a delivery system specifically approaching bone resorption surfaces to target osteoclasts.

Methods: The D-Asp_8 can selectively bind to bone resorption surfaces for meeting osteoclasts nearby and miR-29a antaogmir can suppress osteoclastogenesis[3]. The D-Asp_8 was conjugated to the surface of liposome confirmed by HPLC. (D-Asp_8)-modified liposome encapsulated the miR-29a antagomir. Its hydrodynamic diameter and zeta potential were detected by the Delsa® Nano HC Particle Analyzer. Its encapsulation efficiency was measured by Quant-iT™ RiboGreen® RNA assay and serum stability was determined by agarose gel electrophoresis. Its tissue-selective delivery and cell-selective delivery of miR-29a antagomir *in vivo* were analyzed by biophotonic imaging system and immunohistochemistry, respectively[4].

Results: The D-Asp_8 was successfully conjugated to the liposome surfaces, as confirmed by HPLC (Fig. A & B). The delivery system has a average diameter of 150 nm (Fig. C), zeta potential of -10 mV and encapsulation efficiency of 80%. The miR-29a antagomir in (D-Asp_8)-liposome was detectable at 24 hours after incubation in serum, while the free miR-29a antagomir was vanished at 1 hour after incubation in serum. The fluorescence signals of the labeled miR-29a antagomir were relatively stronger in bone tissues and lower in liver and kidney, but barely detected in heart, spleen and lung from the (D-Asp_8)-liposome group in comparison with liposome group (Fig. D). More instances of co-localization of the labeled miR-29a antagomir with $OSCAR^+$ cells were found in (D-Asp_8)-liposome group compared with liposome group (Fig. E).

Conclusion: The D-Asp_8 could facilitate miR-29a antagomir encapsulated within liposome to selectively target osteoclasts (HKBU479111 and HKBU261113).

Improvement of enamel and skeletal defects in murine hypophosphatasia via lentiviral gene therapy. Seiko Yamamoto*[1], Carmen Huesa[2], Eri Yokoi[3], Chika Endo[4], Yumi Obi[4], Kei Ogawa[5], Takehiko Shimizu[3], Takashi Shimada[6], Jose Luis Millan[7]. [1]Nihon University, Japan, [2]University of the West of Scotland, United Kingdom, [3]Nihon University School of Dentistry at Matsudo Department of Pediatric Dentistry, Japan, [4]Nihon University School of Dentistry at Mastudo Department of Pediatric Dentistry, Japan, [5]Nihon University School of Dentistry at Mastudo Department of Pediatric Dentistry, Japan, [6]Nippon Medical School, Japan, [7]Sanford-Burnham Medical Research Institute, USA

Hypophosphatasia (HPP) is an inherited skeletal disease caused by mutations of the gene (*ALPL* in humans, *Alpl* in mice) encoding tissue-nonspecific alkaline phosphatase (TNAP). Although TNAP is expressed in various tissues, the HPP symptoms appear primarily in bones and teeth. The clinical severity of HPP is varies widely; the most severe to the mildest forms are perinatal, infantile, childhood, adult, and odonto-hypophosphatasia. There is no established treatment. We reported that enzyme replacement therapy (ERT) using daily injections of bone-targeted TNAP is effective in preventing all the skeletal and dental manifestations of HPP in TNAP knockout mice ($Alpl^{-/-}$ mice) (Millán *et al.,* 2008; Yadav *et al.,* 2012). We also showed that a single injection of either a lentiviral vector (Yamamoto *et al.,* 2011) or an adeno-associated viral vector (Matsumoto *et al.,* 2011) harboring bone-targeted TNAP (TNAP-D_{10}) was equally effective in preventing all the manifestations of HPP.

Objectives: In this study we evaluated improvement of the hard tissues of $Alpl^{-/-}$ mice using a lentiviral vector to administer bone-targeted TNAP. We also investigated the feasibility of using mineral-targeting placental alkaline bone (PLAP-D_{10}), instead of TNAP-D_{10}.Methods : $Alpl^{-/-}$ mice develop skeletal disease at day 6-8 and usually die of their disease at postnatal day 20. We injected 1 day-old $Alpl^{-/-}$ mice with 100 ul of lentiviral vector expressing TNAP-D_{10} or PLAP-D_{10} (5.0 x 10^7 TU) via the jugular vein and collected and examined their tissues after 20 days of treatment and compared them to those of WT and untreated $Alpl^{-/-}$ mice. The tibias were used for histomorphometrical analysis. μCT imaging and analyses were used to evaluate the effect of treatment on the enamel, dentin, cementum and surrounding alveolar bone.

Results: Bone growth rates were improved compare with untreated $Alpl^{-/-}$ mice using TNAP-D_{10}. The mineral content, enamel, cementum layer and bone volume of the mandible were also improved. PLAP-D_{10} was less effective than TNAP-D_{10}, but still provided benefit over vehicle-treatment.

Conclusion : These results indicate that targeted delivery of alkaline phosphatase(s) to dental tissues mediated via a lentiviral vector can correct the dental defects and enhance bone growth in this murine model of infantile HPP.

Identification of a novel PCSK5 frameshift mutation in a patient with the VACTERL association. Yukio Nakamura*[1], Shingo Kikugawa[2], Hidehito Inagaki[3], Tatsuya Kobayashi[4], Hiroki Kurahashi[3], Hiroyuki Kato[5]. [1]Dept of Orthopaedic Surgery Shinshu University School of Medicine, Japan, [2]DNA Chip Research Inc., Japan, [3]Fujita Health University, Japan, [4]Massachusetts General Hospital, USA, [5]Shinshu University School of Medicine, Japan

The VACTERL association is a sporadic, non-random collection of congenital anomalies that includes vertebral defects, anal atresia, cardiac defects, tracheoesophageal fistula, renal anomalies, and limb abnormalities. Although several chromosomal aberrations and gene mutations have been reported as disease-causative, these findings have not been replicated to date. In the present study, whole exome sequencing of 2 families with the VACTERL association and 2 unrelated patients uncovered a novel frameshift mutation in the PCSK5 gene in 1 patient that was confirmed by Sanger sequencing. This mutation is suspected to disrupt PCSK5 function either by producing an abnormal protein that is missing an essential cysteine-rich motif (CRM) or by leading to nonsense-mediated mRNA decay. As several other non-synonymous variants in the CRM domain of the PCSK5 gene have been detected in patients with the VACTERL association, our finding further implicates loss-of-function mutations of PCSK5 in disease etiology.

New Lessons From An Old Disease – What Alkaptonuria Teaches Us About Cartilage and Bone Remodelling. Craig Keenan*[1], Alan Boyde[2], Lakshminarayan Ranganath[1], James Gallagher[3], Nathan Jeffery[1], Jonathan Jarvis[1], Adam Taylor[4]. [1]University of Liverpool, United Kingdom, [2]Barts & The London School of Medicine & Dentistry, Queen Mary University of London., United Kingdom, [3]University of Liverpool, United Kingdom, [4]Lancaster University, United Kingdom

Alkaptonuria (AKU) was the first human disorder recognised to conform to Mendelian inheritance by Sir Archibald Garrod in 1901. AKU is characterised by deposition of pigmented polymers in connective tissues, a process called ochronosis. Cartilage is most severely affected causing early onset arthropathy in weight bearing joints. We investigated the origin and progression of arthropathy in AKU patient tissue samples obtained at joint replacement surgery and in an AKU mouse model. Light and electron microscopy studies reveal collagen fibres are initially resistant to pigmentation but become susceptible through organisational and compositional changes, including proteoglycan loss. Onset of ochronosis appears to be associated with high mechanical loading. In joint tissues the first pigment is laid down in the pericellular matrix of hypertrophic chondrocytes in calcified articular cartilage. The hypertrophic lacunae are surrounded by previously unrecognised concentric lamellae. Ochronosis then spreads to the non-mineralised hyaline cartilage causing it to stiffen. This phase is accompanied by development of classical osteoarthritic lesions including erosions, tidemark duplication and osteophytes. The increased stiffness in cartilage also elicits a spectrum of changes in the subchondral plate and underlying bone. Some areas are subjected to aggressive local resorption possibly a mechanotransduction response to stress shielding. This can lead to complete subchondral plate resorption by osteoclastic action. In other areas there is cracking of the subchondral plate and extrusion of an unknown matrix, which becomes hypermineralised, into the hyaline cartilage. Finite element analysis predicts that this and other changes in microarchitecture in the deep cartilage have a profound effect on the strain distribution throughout the hyaline cartilage leading to the generation of potentially damaging loads. The underlying trabeculae undergo non-Frostian remodelling with areas of hypo- and hyper-mineralised deposition which we have named trabecular excrescences. These latter structures are templated by adipocytes. All these features, which except ochronosis per se, were first identified in the severe AKU phenotype have subsequently been observed at lower frequency in aged and osteoarthritic joints. These findings demonstrate that studying syndromes with extreme phenotypes can help elucidate the pathophysiological mechanisms in more common diseases of cartilage and bone.

Relationship between SQSTM1 mutations status and severity of Paget disease of Bone (PDB). Manuel Diaz Curiel*[1], m jesus moro alvarez[2], marjorie andrade[3], M Jose Trujillo[4], Ignacio Mahillo Fernandez[5], Camilo Velez[6], Nerea Carvajal[7]. [1]Jimenez Diaz Fundacion, Spain, [2]Department of Internal Medicine. Metabolic Bone Disease. Hospital Infanta Leonor., Spain, [3]Bone Diseases Service. IIFJD., Spain, [4]Genetic Department IIFJD, Spain, [5]IIFJD. Epidemiology Research, Spain, [6]Genetic Department. IIFJD, Spain, [7]Genetic Department, Spain

Paget disease of bone (PDB) is a common disorder characterized by increased bone turnover at one of more sites throughout the skeleton. Genetic factors play an important role in the pathogenesis of PDB, and the most important predisposing gene is SQSTM1.

We investigated the relationship between SQSTM1 mutation status and disease severity in 50 patients who took part in a retrospective analysis.

Mutations of SQSTM1 were detected in 5 of 50 (10 %) patients. Mutation carriers had a similar age at diagnosis (75.4 $\pm$ 11.5 versus 70.0 $\pm$ 10.1 years) and a similar rate in bone turnover with CTX 0.840 $\pm$ 0.259 versus 0.730 $\pm$ 0.429 (n.s.), alkaline phosphatase (AP) 206.80 $\pm$ 127.024 versus 168.00 $\pm$ 130.430 (n.s.), P1NP 109.75 $\pm$ 30.527 versus 140.66 $\pm$ 142.217 (n.s.).

Only one of these five patients with positive mutation of SQSTM1, presented a monostotic Pagets disease and 4 patients corresponded to poliostotic Pagets disease. In the total population 20 patients had a monostotic Pagets disease and 30 patients had a poliostotic Pagets disease. Bisphosphonate therapy was not more commonly required (86.3% versus 75.2%, p = .01) than those without mutations. Genetic testing for SQSTM1 mutations may be not of value in identifying individuals at risk of developing severe disease, therefore a program of genetic testing and early intervention in these individuals couldn ot be cost-effective.

Conclusions: We did not found a relationship between SQSTM mutation and severity of Paget disease.

***Bicc1* Regulates the Expression of *Pkd2* in Osteoblasts and Genetic Variants in both are Associated with BMD.** Larry Mesner[1], Yi-Hsiang Hsu[2], Ani Manichaikul[3], Elizabeth Bryda[4], Guanqing Wu[5], Stephen Rich[3], Clifford Rosen[6], Michael Criqui[7], Matthew Allison[7], Matthew Budoff[8], Thomas Clemens[9], Charles Farber*[10]. [1]University of Virginia, USA, [2]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, [3]University of Virginia, USA, [4]University of Missouri, USA, [5]Vanderbilt University, USA, [6]Maine Medical Center, USA, [7]University of California at San Diego, USA, [8]Los Angeles Biomedical Research Institute at Harbor-UCLA Medical Center, USA, [9]Johns Hopkins University, USA, [10]University of Virginia, USA

Bicaudal C homolog 1 (*Bicc1*) is an RNA-binding protein implicated in the post-transcriptional regulation of gene expression. Recently, we identified *Bicc1* as a novel genetic determinant of BMD in the mouse. Here, we sought to determine how *Bicc1* influences BMD and whether *BICC1* plays a role in the regulation of BMD in humans. To elucidate *Bicc1* function, we used a network-based approach to determine that *Bicc1* was a member of a co-expression module enriched for genes involved in osteoblast function. The network connections between *Bicc1* and genes with a known role in osteoblastogenesis were stronger than its connections with other module genes, suggesting a role for *Bicc1* in osteoblast differentiation. Consistent with this prediction, knockdown of *Bicc1* in primary calvarial osteoblasts decreased osteogenic gene expression, alkaline phosphatase activity and mineralized nodule formation. In the co-expression network, *Bicc1* was most strongly connected to the polycystic kidney disease 2 (*Pkd2*) gene. *Pkd2* encodes Polycystin-2 (PC2), a calcium channel located on the surface of primary cilium in a complex with PC1, a protein implicated in the regulation of BMD. Knockdown of *Bicc1* decreased *Pkd2* transcript levels and, similar to perturbation of *Bicc1*, *Pkd2* knockdown also decreased markers of osteoblast differentiation. Overexpression of *Pkd2* in *Bicc1* null osteoblasts rescued impaired differentiation, whereas overexpression of *Bicc1* in *Pkd2* null osteoblasts did not, suggesting that *Bicc1* acts upstream of *Pkd2*. Lastly, in two human BMD genome-wide association study (GWAS) meta-analyses, single nucleotide polymorphisms (SNPs) in *BICC1* and *PKD2* were associated with BMD. These results identify *Bicc1* as a genetic determinant of BMD and osteoblastogenesis, and suggest that it does so by regulating *Pkd2* transcript levels.

hiPSCs from Patients with Craniometaphyseal Dysplasia are Refractory to *in vitro* Osteoclast Differentiation. I-Ping Chen*[1], Zhifang Hao[2], Ernst Reichenberger[1]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut Health Center, USA

Craniometaphyseal dysplasia (CMD), characterized by progressive hyperostosis of craniofacial bones and widening metaphyses, is one of more than 500 rare genetic bone disorders (NIH Office of Rare Disease Research). Molecular mechanisms and treatment for these rare bone diseases are mostly unknown. Major obstacles for studying rare genetic bone disorders are the lack of animal models and human specimens. Our group generated a knock-in (KI) CMD mouse model carrying a Phe377del *Ank* mutation and integration-free hiPSCs from CMD patients and healthy controls. We showed that defective osteoclastogenesis is the major reason for the CMD phenotype in $Ank^{KI/KI}$ mice. To study the osteoclast defects in the human system, we developed protocols to differentiate hiPSCs into osteoclasts (OC).

We differentiated hiPSCs into OCs using a previously published hiPSC/OP9 coculture method or via embryoid body (EB) formation. Briefly, 3 control and 3 CMD hiPSCs were grown on matrigel-coated plates for 5 days. EBs were developed by plating 10,000 cells/well on Lipidure-coated 96 well plates for 4 days to promote primitive streak induction. EBs cultured for 1, 2, 3 and 4 days in various media under ambient or low O2 conditions were selected for expression of *hT*, *hSCL*, *hCD34, hCdx2 and hHand1*. EBs were then cultured with cytokines under various conditions to induce hematopoiesis. A $CD43^{+}CD45^{+}CD14^{+}$ population was enriched with magnetic beads and cultured in the presence of hM-CSF, hRANKL and hTGF-β to form mature OCs, defined as $TRAP^{+}$ multinucleated cells.

Expression of *hSCL*, *hCD34* and *hCdx2* genes were lower in EBs derived from CMD hiPSCs when compared to EBs from control hiPSCs suggesting reduced mesoderm induction of CMD hiPSCs. Mature OCs could be differentiated from control hiPSCs but not from CMD hiPSCs using hiPSCs/OP9 cocultures or EB methodologies. Control OCs were capable of resorbing hydroxyapatite-coated plates and showed intact actin rings. We concluded that CMD hiPSCs were refractory to *in vitro* OC differentiation. Differentiated OCs from hiPSCs will help to study bone disorders caused by defective osteoclastogenesis in a human system.

SU0133

Menaquinone-4 (Vitamin K_2) in Bone Originates from Menadione (Vitamin K_3) Released from Oral Phylloquinone (Vitamin K_1) During Intestinal Absorption. Kimie Nakagawa*[1], Yoshihisa Hirota[2], Naoko Tsugawa[3], Yuri Uchino[2], Yoshitomo Suhara[4], Toshio Okano[1]. [1]Kobe Pharmaceutical University, Japan, [2]Kobe Pharmaceutical University, Japan, [3]Kobe Pharmaceutical University, Japan, [4]Shibaura Institute of Technology, Japan

Aims: Vitamin K plays an important role in bone metabolism. Mice have the ability to convert dietary vitamin K_1/phylloquinone (PK) into vitamin K_2/menaquinone-4 (MK-4) and store the latter in many tissues. Previously, we identified a novel enzyme UbiA prenyltransferase domain containing 1 (UBIAD1) that catalyzes this conversion. Our previous study showed that UBIAD1 has a weak side chain cleavage activity for PK but a strong prenylation activity for vitamin K_3/menadione (MD) that has long been postulated as an intermediate or catabolic product of PK in this conversion process. Further evidence indicates that when intravenously administered in mice, PK can enter into tissues, but is not converted further to MK-4. These findings raise the question whether dietary PK is absorbed in the intestine, delivered to tissues in its original form, and converted to MK-4 or whether the phytyl side chain of PK is cleaved to release MD in the intestine, followed by delivery of MD to tissues via a mesenteric lymphatic system and subsequent conversion to MK-4. At present, the locations where release of MD from PK occurs and where MD is converted to MK-4 remain unclear. To elucidate this, it is necessary to identify PK-derived MD generated in the course of the intestinal absorption of PK and elucidate the relationship between the concentrations of MD in the mesenteric lymphatic system and blood circulation and the concentrations of MK-4 in tissues.

Methods: Cannulation experiments were conducted using stable isotope tracer technology in rats. Rats were divided into 2 groups of 4 animals and each group was used for either portal vein cannulation or thoracic lymph duct cannulation after oral administration of deuterium-labeled PK (PK-d_7) as a single dose of 10 μmol/kg body of weight. We measured the concentration of PK-d_7 and deuterium-labeled MK-4 (MK-4-d_7) in tissues, and conducted structural assignments and measurements of PK-derived MD using high-resolution MS (HR-MS) analysis and a bioassay using recombinant UBIAD1 protein.

Results and Discussion: We confirmed that the phytyl side chain of PK is cleaved off to release MD in the intestine, followed by delivery of MD via a mesenteric lymphatic system to tissues, where it is converted to MK-4. These results provide unequivocal evidence that MD is not only a catabolic product of PK but also a circulating precursor of tissue MK-4.

Regulation of Osteocytic Osteolysis by the Calcitonin Receptor During Lactation in Mice. Rachel Davey*[1], Michele Clarke[2], Patricia Russell[2], David Findlay[3], Jeffrey Zajac[4]. [1]University of Melbourne, Australia, [2]Department of Medicine, Austin Health, University of Melbourne, Australia, [3]University of Adelaide, Australia, [4]Austin Hospital, Australia

We have shown previously, that the calcitonin receptor (CTR) plays a physiological role to protect against induced hypercalcemia in mice. In order to determine whether the CTR also protects the skeleton from excessive resorption in times of high calcium demand, we assessed the maternal skeleton of global-CTRKO and littermate control mice following pregnancy and lactation.

Viable Global CTRKO mice were generated by breeding floxed CTR mice with CMV-Cre mice, resulting in >94% but <100% global deletion of the CTR. Global-CTRKO and littermate control females were time-mated to C57BL/6 males at 8 weeks of age and their bone phenotype assessed by microCT and histomorphometric analyses at the end of pregnancy (E18) and at the end of lactation (P21). For the lactation group, following the birth of pups, litter sizes were made equal (n=4) by sacrificing the necessary number of pups in order to normalize the requirements of breast milk from each mother.

MicroCT analyses showed no effect on trabecular and cortical bone in the distal femur and L5 vertebra by global CTR deletion during pregnancy and lactation in the Global CTRKOs, compared to controls, at a resolution of 6.5μm. However, global CTRKO mice were hypercalcemic following pregnancy (Control: 2.17 ± 0.22mmol/L; Global CTRKO: 3.34 ± 0.30mmol/L; $P<0.05$), indicating a role for the CTR to regulate calcium homeostasis during pregnancy. In the absence of any changes in osteoclast number or activity, cathepsin K mRNA levels were elevated 2 fold in the bone of lactating Global-CTRKO females compared to controls ($P<0.05$). Given the recently identified function of osteocytes to resorb their surrounding bone matrix during lactation, together with their reported expression of the CTR, we assessed osteocytic osteolysis in the Global-CTRKOs and controls by determining osteocyte lacunae area in cortical bone. The top 20% of osteocyte lacunae area was increased by 10% following lactation in global-CTRKOs compared to controls ($P<0.05$). Consistent with the increased osteocytic osteolysis, serum calcium was elevated in global-CTRKOs following lactation compared to controls (Control: 2.43 ± 0.21mmol/L; Global CTRKO: 3.00 ± 0.17mmol/L; $P=0.05$). These data provide strong evidence for a significant physiological role of the CTR to protect the maternal skeleton during lactation by a direct action on osteocytes to inhibit osteolysis.

Fibroblast growth factor 23 impairs aortic relaxation: role of reactive oxygen species. Neerupma Silswal*[1], Chad Touchberry[1], Jon Andresen[1], Michael Wacker[2]. [1]University of Missouri-Kansas City School of Medicine, USA, [2]University of Missouri-Kansas City School of Medicine, USA

Recent clinical studies of chronic kidney disease (CKD) patients have demonstrated associations between increased plasma fibroblast growth factor 23 (FGF23) levels and impaired flow-mediated dilation of the vasculature, impaired vasoreactivity, reduced ejection fraction, and heart failure. CKD patients also have elevated levels of reactive oxygen species (ROS) which is a risk factor for the development of endothelial dysfunction by reducing nitric oxide (NO) bioavailability. However, there have been no mechanistic studies to connect these clinical observations. Recently, we have found that FGF23 directly impairs vasorelaxation of mouse aorta by inhibiting endothelial NO bioavailability. Based on the high levels of ROS found during CKD, we hypothesize that FGF23 directly increases vascular ROS which leads to impaired endothelial function. To test this hypothesis, intracellular ROS was measured by dihydroethidium-based epifluorescence microscopy of primary endothelial cells isolated from mouse aorta as well as lucigenin chemiluminiscence assay of isolated aortic rings. Pretreatment of aortic endothelial cells with FGF23 (9000 pg/ml) increased superoxide levels by an average of 78% vs vehicle ($p<0.05$, n=3) compared to only a 15% increase after pretreatment with the superoxide scavenger, tiron ($p>0.05$, n=3). Similarly, FGF23-treated aortic rings resulted in increased ROS levels that were inhibited by tiron pretreatment ($p<0.05$, n=3). To further define the physiological role of increased ROS in FGF23-mediated impairment of vascular function, we preincubated mouse aortic rings with tiron prior to FGF23 incubation for isometric tension myography experiments. Specifically, endothelium-dependent relaxation to acetylcholine was determined after precontraction with $PGF_{2\alpha}$ (10^{-5} M). Tiron treatment was able to rescue the impaired endothelium-dependent vasorelaxation caused by FGF23 ($p<0.05$, n=5). Therefore, our data suggest that FGF23-mediated increases in ROS impair NO-mediated aortic relaxation and that the antioxidant, tiron, can rescue these effects. These findings have clinical implications for therapeutic intervention to prevent cardiovascular disease in CKD patients.

SU0136

MEPE-ASARM, a Substrate of Phex, Decreases Bone Volume Independently of Serum Phosphate Levels. Kaoru Sakurai*[1], Tomoko Minamizaki[2], Yoko Fujino[1], Yuichiro Takei[3], Hirotaka Yoshioka[4], Mitsugi Okada[3], Katsuyuki Kozai[3], Yuji Yoshiko[3]. [1]Hiroshima University Graduate School of Biomedical & Health Sciences, Japan, [2]Hiroshima University Institute of Biomedical & Health Sciences, Japan, [3]Hiroshima University Institute of Biomedical & Health Sciences, Japan, [4]Hiroshima University Graduate School of Biomedical Sciences, Japan

Matrix extracellular phosphoglycoprotein (MEPE), a member of the small integrin-binding ligand N-linked glycoprotein (SIBLING) family, is originally identified in tumor-induced osteomalacia and involved in bone mineralization and phosphate metabolism. This polypeptide contains the acidic serine- and aspartate-rich motif (ASARM) that exhibits high affinity to hydroxyapatite and inhibits matrix mineralization *in vitro*. Some of ASARM peptides are phosphorylated at several sites (pASARM), which appear to be relevant to its biological activities. pASARM is released in MEPE processing and presumably degraded by the phosphate regulating endopeptidase homolog, X-linked (Phex), suggesting that the accumulation of pASARM in bone may cause mineralization defects in X-linked hypophosphatemic rickets. Recently, we showed that pASARM is accumulated in bone in Klotho mutant (*kl/kl*) mice with osteopenia. pASARM had no detectable effects on rat calvaria cell proliferation and differentiation and the generation of osteoclasts from RAW 264.7 cells, which differed from results in a mouse bone marrow stroma cell model. To clarify the effects of pASARM on bone and phosphate metabolism in normal mice, C57BL/6 male mice (6-week-old) were implanted with osmotic pumps releasing pASARM for two weeks. pASARM did not impinge on body weight, serum calcium and phosphate levels, and renal *Slc34a3* and *Cyp27b1* mRNA levels; *Slc34a1* in kidney was slightly downregulated by pASARM. Neither gene expression profiling in bone nor serum markers showed significant effects of pASARM on bone formation and resorption. μCT analysis indicated that pASARM decreased tissue volume, bone volume, tissue surfaces, bone surfaces and trabecular thickness and increased trabecular bone pattern factor, with a concomitant decrease in calcein labeling of bone surfaces. Mice treated with pASARM also exhibited an increase in TRAP-positive multinucleated cells. Because non-phosphorylated ASARM has little effect on bone, the phosphorylation is necessary for ASARM to exert its actions in bone. Taken together, these results suggest that pASARM may inhibit bone mineralization independently of serum phosphate levels and increase bone resorption through an undefined mechanism.

Role of renal phosphate excretion in the pathogenesis of renal stone disease and nephrocalcinosis: insights from the Npt2a knockout mouse model. Yuwen Li[1], Chuanlong Zhu[1], Jun Guo[2], Marie Demay[3], Harald Jueppner[2], Clemens Bergwitz*[3]. [1]Massachusetts General Hospital, USA, [2]Massachusetts General Hospital, USA, [3]Massachusetts General Hospital & Harvard Medical School, USA

Mutations in the sodium phosphate co-transporters, NPT2a and NPT2c have been reported in kindreds with renal stone disease and nephrocalcinosis. These individuals have phosphate-wasting, high circulating levels of $1,25(OH)_2D$ and hypercalciuria. Since hypophosphatemia is often observed in hypercalciuric stone formers this raises the possibility that allelic variants in NPT2a and NPT2c might contribute to the pathogenesis of calcium stone disease in the general population. Oral phosphate supplementation is thought to reduce risk for renal calcifications. As in humans, a high phosphate/normal calcium diet (HP, 0.6% calcium, 1.20% phosphate) reverses hypercalciuria in Npt2a-null mice when administered from age two to four months. However, despite this treatment, these mice develop nephrocalcinosis, albeit to a lesser degree than animals fed a high phosphate/high calcium diet (HPC, 20% lactate, 2% calcium, 1.25% phosphate). Nephrocalcinosis is not observed in wild-type animals on the HPC diet, or in Npt2a-null mice fed a normal phosphate/normal calcium diet (CO, 0.6% calcium, 0.4% phosphate). These findings suggest that oral phosphate supplementation can contribute to renal calcification despite a reduction in urine calcium at least in the setting of impaired proximal tubular function. Excessive phosphaturia even with normal or low urinary calcium can cause nephrocalcinosis in humans as is seen in XLH or after treatment with phosphate enema, and Npt2a-null mice on HP diet may serve as a model to better understand its pathophysiology. We are currently evaluating the hypothesis that phosphate supplementation causes (possibly transient) increases in PTH and FGF23. Either hormone could be targeted to reduce the phosphaturia when Npt2a is absent in mice or mutated in humans.

Table 1: All diets are egg-white based: SEM, standard error of mean; WT, wild-type; BUN, blood urea nitrogen; sCa, serum calcium; sP, serum phosphate; CEI, urine calcium excretion index; PEI, urine phosphate excretion index; calc. area, calcified area in kidney sections.

Chronic Inhibition of RANKL Induces an Osteoclast-Independent Mechanism of PTH-induced Calcium Mobilization. Hila Bahar*[1], Akira Maeda[2], Monica Reyes[3], Thomas Dean[3], Ernestina Schipani[4], Paola Divieti Pajevic[1], Robert Neer[2], Paul Kostenuik[5], John Potts[2], Thomas Gardella[2]. [1]Massachusetts General Hospital & Harvard Medical School, USA, [2]Massachusetts General Hospital, USA, [3]Massachusetts General Hospital, USA, [4]University of Michigan, USA, [5]Amgen Inc., USA

Acute administration of Parathyroid Hormone (PTH) into animals or humans is well known to induce rapid (within 30 minutes) and robust (>10%) increases of blood ionized calcium (Ca). The rise in blood Ca is likely due in large part to the actions of PTH on bone, as this is the largest store of Ca in the body. PTH is known to induce the release of Ca from bone via the indirect activation of bone-resorbing osteoclasts (OCs) by RANKL. Whether or not other mechanisms and cell types can also contribute to the PTH-induced release of Ca from bone is currently unclear. This question has relevance not only to basic understanding of how PTH modulates bone and Ca metabolism, but also to patients being treated with anti-resorptive drugs, such as denosumab, that target the RANKL/OC pathway, and their capacities to maintain Ca homeostasis. We reported last year that a single co-injection of the RANKL inhibitor, osteoprotegerin-Fc (OPG-Fc) in mice markedly blunted the acute (within 1-2 hours) calcemic response to co-injected PTH(1-34), suggesting that the RANKL/OC pathway of bone-resorption can be rapidly activated by PTH. Surprisingly, however, when mice were pre-treated with OPG-Fc for seven days to deplete OC populations, their acute calcemic response to PTH(1-34) was not blunted but rather was equivalent to that observed in OPG-Fc-naive mice. The results suggest that in the absence of OCs, PTH may induce Ca mobilization from bone into blood via a novel RANKL/OC-independent mechanism. Ocsteocytes (Ocys) were recently suggested to have the capacity to mediate bone resorption in response to PTH ligands under certain conditions. To assess the potential role of Ocys in this putative novel mechanism of PTH-induced Ca release, we are utilizing mice that lack the PTH receptor (PTHR1) specifically in Ocys via the DMP1(10kb promoter)-Cre/PTHR1(exonE1)-floxed alleles. The acute calcemic response to PTH(1-34) injection will be assessed in these OcyPTHR1^{KO} mice following seven days of OPG-Fc pre-treatment. If the above hypothesis is correct, then the calcemic response to PTH in the OPG-Fc-pre-treated OcyPTHR1^{KO} mice should be blunted, as compared to that in vehicle-pre-treated OcyPTHR1^{KO} mice. Such findings would suggest that an adaptive mechanism by which PTH mediates Ca mobilization from bone via actions on Ocys is induced under conditions of OC depletion. The results could help explain how patients treated with OC-targeted anti-resorptive drugs generally maintain normocalcemia.

Localization of parathyroid hormone-related protein and its receptor in MIN6 cells, a mouse insulinoma cell line. Syu Mi Sam*[1], Kristi Milley[2], Peter Little[1], Jeffrey Zajac[3], Mathis Grossmann[4], Janine Danks[5]. [1]School of Medical Sciences, RMIT University, Australia, [2]RMIT University, Australia, [3]Austin Hospital, Australia, [4]The University of Melbourne, Department of Medicine, Australia, [5]School of Medical Sciences, RMIT University, Australia

Parathyroid hormone-related protein (PTHrP) is a protein first discovered in the 1980's in the search to find the cause of humoral hypercalcemia of malignancy (HHM). Since then, this molecule has been shown to be involved in many physiological roles in the body. These functional roles include calcium homeostasis, a smooth muscle relaxant and its role in cellular proliferation, survival and differentiation in tissues such as skin, mammary gland, skeleton and the islets of the pancreas. The binding of PTHrP to its receptor, the parathyroid hormone-related protein receptor 1 (PTHR1), a G-protein coupled receptor, allows PTHrP to have its many functions in the body.

The mouse insulinoma cell line MIN6 is derived from a transgenic mouse expressing the large T-antigen of SV40 in pancreatic beta cells. PTHrP has been demonstrated previously in this cell line but localization patterns have not been performed on these cells. Based on this, the aim of this project is to localize both PTHrP and PTHR1 in the MIN6 cell line and examine whether PTHR1 is functional.

The presence of PTHrP and PTHR1 protein and mRNA in MIN6 cells were localized using immunohistochemistry (IHC) and chromogenic *in situ* hybridization (CISH) on formalin-fixed agar-embedded cell blocks, respectively. IHC for glucagon and insulin were also carried to characterize the MIN6 cells. Cyclic adenosine monophosphate (cAMP) assay has been performed on cultured MIN6 cells to examine PTHR1 functionality with UMR106 cells used as an assay control.

PTHrP and PTHR1 protein have been localized in the MIN6 cells using IHC. The localization pattern of PTHrP and PTHR1 mRNA was observed using CISH. A combination of nuclear and cytoplasmic staining was observed for PTHrP and PTHR1 in both methods of detection. Preliminary cAMP data from cultured MIN6 cells indicate that PTHR1 is not functional, as there is no cAMP production after stimulation with PTH.

PTHrP and its receptor proteins and mRNA were shown to be present in the MIN6 cell line. PTHrP has been suggested to play a role in growth and differentiation of b-cells (Sawada et al Mol Cell Endocrinol 182:265, 2001) with a responsive PTHR1. So far we have demonstrated that the MIN6v cells contain both PTHrP and PTHR1 protein and mRNA but not been able to show a functional PTHR1 in these cells. PTHrP may play in glucose regulation but further characterization of this cell line is required.

Mechanisms controlling duration of signaling at the PTH receptor 1. Tomoyuki Watanabe*[1], Alexandre Gidon[2], Thomas Dean[3], John Potts[1], Jean-Pierre Vilardaga[4], Thomas Gardella[1]. [1]Massachusetts General Hospital, USA, [2]University of Pittsburgh, School of Medicine, USA, [3]Massachusetts General Hospital, USA, [4]University of Pittsburgh, School of Medicine, USA

We have recently reported a series of PTH analogs that bind to the PTHR1 with high affinity and induce sustained cAMP signaling responses in PTHR1-expressing cells, as wells as prolonged calcemic and phosphaturic responses in animals (Maeda, A. et al., PNAS 2013). To understand better the mechanisms by which such analogs mediate prolonged signaling responses, we investigated the functional properties of one of the long-acting analogs, LA-PTH, in GP-2.3 cells, which are HEK-293-derived cells that stably express the hPTHR1 along with a Glosensor cAMP reporter. The cAMP response to LA-PTH persisted for several hours after ligand wash-out, and was thus considerably prolonged, as compared to PTH(1-34). Cell internalization patterns were assessed using confocal microscopy and fluorescently labeled FAM-LA-PTH and FAM-PTH(1-34). By 30 minutes after addition, each ligand was observed mainly in cytoplasmic vesicles. To further assess the relationship between ligand internalization and signal duration/termination, we treated cells with Bafilomycin A1 (Baf), a specific inhibitor of the vacuolar-type H^+-ATPase, which mediates vesicle acidification. Short-term (15') Baf treatment blocks endosomal acidification but not internalization, whereas long-term (24 hr) Baf treatment also blocks vesicle internalization due to inhibition of membrane lipid recycling. FAM-LA-PTH

internalized normally in cells treated with Baf for 15', whereas it remained surface-associated in cells treated for 24hr. Short-term (15') treatment with Baf prolonged cAMP signaling by PTH(1-34) but did not affect signal duration by LA-PTH. Longer-term (24hr) treatment with Baf shortened cAMP signal duration by PTH(1-34), as well as by LA-PTH, such that signaling duration was similar for the two ligands. Cell membrane-based binding assays revealed that PTH(1-34)-PTHR1 complexes were unstable at the low pH levels found in endosomes (~pH 6.0), whereas LA-PTH-PTHR1 complexes were stable. The data suggest that LA-PTH forms complexes with the PTHR1 that are more acid-resistant than those formed by PTH(1-34), and that this acid-resistance contributes to the capacity of LA-PTH to mediate more prolonged signaling responses by enabling active signaling complexes to be maintained within endosomes.

Osteoblast number is dependent and bone formation independent of osteoblast-specific CaSR and calcium availability. Saja Al-Dujaili*[1], Amy Koh[2], Ming Dang[3], Xue Mi[4], Wenhan Chang[5], Peter X. Ma[3], Laurie McCauley[6]. [1]University of Michigan, USA, [2]University of Michigan, USA, [3]University of Michigan, USA, [4]Tianjin University, China, [5]Endocrine Unit, VA Medical Center, University of California, San Francisco, USA, [6]University of Michigan School of Dentistry, USA

While the mechanisms of PTH anabolic actions in bone are not yet entirely clear, calcium availability and the calcium sensing receptor (CaSR) are potential cofactors. *We hypothesize that bone formation depends on calcium availability, and the CaSR plays a critical role in the anabolic actions of PTH.*

Calvarial osteoblast numbers increased dose-dependently with calcium chloride administration in vitro. In vivo *bioluminescent imaging of scaffolds seeded with luciferase-tagged bone marrow stromal cells showed similar trends with a 2.5-fold increase in bone volume in scaffolds containing 0.6mg Ca vs. 0mg Ca via microCT ($p<0.05$) and histologic analyses.*

To determine the role of the CaSR in cell proliferation, osteoblasts were cultured from osteoblast-specific CaSR knock-out (KO) and wildtype (WT) mice. No difference in the number of WT and KO cells was observed initially. However, after confluence, WT cells increased and KO plateaued (33% increase in WT vs. KO; $p<0.05$). *In vitro* treatment of WT cells with calcimimetic (R-568) or calcilytic (NPS 2143) did not affect osteoblast number during early stages, but after 14 days a 32% reduction of cells was seen with calcilytic versus vehicle ($p<0.05$) and no difference with calcimimetic. Increased apoptosis with calcilytic treatment (1.7-fold vs. vehicle, 6-fold vs. calcimimetic; $p<0.05$) suggested that the CaSR is critical for protection against cell death at later stages in culture.

When vertebral bodies from CaSR KO and WT pups were implanted in athymic mice, no difference in bone volume was found via microCT or histological analyses at 4wks. Intact CaSR KO mice had 58% lower serum P1NP levels vs. WT ($p<0.05$). PTH treatment of young WT and KO mice increased P1NP levels in WT mice by 43% ($p<0.05$). In KO mice, PTH increased P1NP by 127%, normalizing the levels to WT. MicroCT and radiographic analyses were similar to P1NP trends, where basal differences between vehicle-treated CaSR KO and WT mice were rescued with PTH treatment.

In summary, osteoblast numbers *in vitro* and bone volume *in vivo* depend on calcium suggesting the CaSR is important for proliferation and protection from apoptosis in mature osteoblasts. Osseous implants from CaSR KO mice developed normally in WT hosts suggesting the CaSR is dispensable for bone formation. Intact mice with osteoblast-specific CaSR KO had a compromised bone phenotype which was rescued by PTH suggesting that the CaSR is part of a larger pathway involving PTH and endocrine feedback.

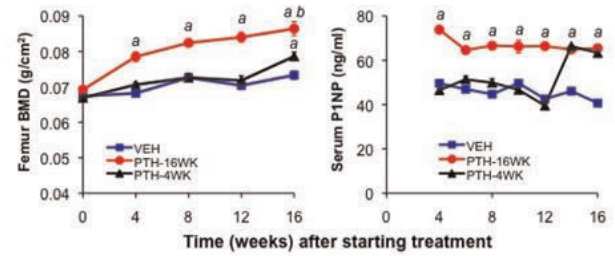
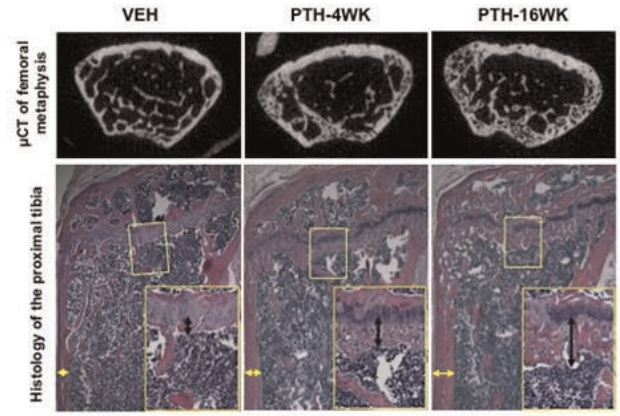
Reduced Differentiation of Bone Marrow Stromal Cells May Contribute to Attenuated Response to Long-term Intermittent Administration of PTH. Jun Guo*[1], Forest Lai[2], Daniel Brooks[3], Joel Finkelstein[1], Mary Bouxsein[4], Henry Kronenberg[1]. [1]Massachusetts General Hospital, USA, [2]Massachusetts General Hospital, USA, [3]Beth Israel Deaconess Medical Center, USA, [4]Beth Israel Deaconess Medical Center, Harvard Medical School, USA

Intermittent administration of teriparatide (hPTH 1-34) is currently the only approved anabolic agent for the treatment of osteoporosis. In humans, teriparatide stimulates bone formation dramatically for 6-12 months after which, for unknown reasons, bone formation declines, presumably limiting the anabolic potential of teriparatide. To investigate potential explanations for this phenomenon, we attempted to create an animal model that mimicked the decline in bone formation during long-term teriparatide administration and then assessed selected cellular and molecular mechanisms that may contribute to this pattern. 10-wk old C57BL/6J male mice (n=10/group) were treated with vehicle (VEH) or PTH (60 μg/kg/d; 5x/wk) for 16 wk, or VEH for 12 wk and then PTH for 4 wk. Long-term iPTH increased BMD progressively, though the increase was more robust in the initial 4-wk of iPTH administration (13.5 ± 1.3%) than in the 2nd (5.0 ± 0.6%), 3rd (1.9 ± 1.9%), or 4th (2.9± 2.7%) 4-wk period. BMD increased 9.5 ± 1.6% in mice given iPTH only in the last 4 wk. Peak serum P1NP and CTX levels were observed at 2 or 4 wk of iPTH administration after which levels declined or remained steady. μCT analysis and histological examination revealed that long-term iPTH dramatically increased metaphyseal bone mass, associated with substantial increases in primary spongiosa and in cortical bone with increases in cortical porosity. iPTH increased the number of osteoblasts and osteoclasts per trabecular bone surface. Urine cAMP stimulation by acute PTH was not attenuated in mice with long-term iPTH, indicating no generalized desensitization or downregulation of PTH1R by long-term iPTH. iPTH administration increased levels of mRNAs encoding Runx2, osterix, Col1a1, osteocalcin, Bsp, MMP9 and TRAP in bone after16 or 4 wk, suggesting that long-term iPTH promotes osteoblast and osteoclast differentiation. After 16-wk iPTH, bone marrow cells formed fewer colonies of fibroblastic cells and, under osteogenic conditions, incorporated less calcium into osteoblastic colonies, than after VEH or 4-wk iPTH; such reduced differentiation of BMSCs may contribute to the attenuated response to long-term iPTH. Our results provide an insight into the reduced response to PTH after long-term therapy.





Bone Volume (% TV)	VEH	PTH-4WK	PTH-16WK
Femoral metaphysis (μCT)*	38.61 ± 0.96	45.99 ± 1.03[a]	51.01 ± 1.91[a,b]

Segment specific role of Gsα in mediating parathyroid hormone actions in the renal proximal tubule. yan zhu*[1], Cumhur Aydin[2], Isabelle Rubera[3], Michel Tauc[3], Min Chen[4], Lee Weinstein[5], Vladimir Marshansky[6], Murat Bastepe[7]. [1]Massachusetts General Hospital, Harvard Medical School, USA, [2]Endocrine Unit, Massachusetts General Hospital & Harvard Medical School, USA, [3]LP2M CNRS 7370 Université de Nice Sophia Antipolis, France, [4]National Institute of Diabetes & Digestive & Kidney Diseases, USA, [5]National Institute of Diabetes & Digestive & Kidney Diseases, USA, [6]Program in Membrane Biology, Massachusetts General Hospital & Harvard Medical School, USA, [7]Massachusetts General Hospital, Harvard Medical School, USA

The paternal promoter of the alpha-subunit of the stimulatory G protein (Gsα), is silenced in the renal proximal tubule (PT), and this silencing, together with maternal inactivating mutations in the Gsα gene, lead to Gsα deficiency and proximal tubular PTH resistance, as seen in pseudohypoparathyroidism type-I characterized by hypocalcemia, hyperphosphatemia, and elevated serum PTH. PT consists of three

functionally and anatomically distinct segments, but the spatial distribution of allelic Gsα silencing and the roles of Gsα along PT have remained unknown. We thus examined allelic Gsα expression in S1 and S3 segments in mice heterozygous for maternal ($E1^{m-/+}$) or paternal ($E1^{+/p-}$) *Gnas* exon 1 ablation, in which Gsα expression is exclusively paternal or maternal, respectively. We have shown that Gsα mRNA levels were $65 \pm 6\%$ of wild-type ($p<0.05$) in kidneys of $E1^{+/p-}$ mice when analyzing all PT segments isolated by laser cut microdissection. We now analyzed S3 segments only and showed that the levels were not significantly different from that in wild-type littermates ($83 \pm 3.5\%$; p=0.50). Moreover, immunostaining of kidney sections from $E1^{m-/+}$ mice indicated that, whereas Gsα protein levels in outer cortical PT, populated mostly by S1, were similar in $E1^{m-/+}$ and wild-type littermates, the levels in S3 were significantly lower in $E1^{m-/+}$ mice than wild-type littermates ($51.6 \pm 4.7\%$;$p<0.05$). These results indicate that the allelic silencing of Gsα is more prominent in S3 than the other segments. In addition, we ablated Gsα conditionally in S1 segments ($S1rptE1^{-/-}$ mice) by using *Gnas* exon 1 floxed mice and Cre driven by the promoter of type 2 sodium glucose transporter (Sglt2-Cre). Western blot analysis of PT-enriched renal cortices, which include all PT segments and other contaminating tubules and blood vessels, showed that Gsα levels were diminished by ~50% in $S1rptE1^{-/-}$ mice compared to controls. Offspring of Sglt2-Cre and *mTmG* reporter mice showed strong Cre activity in S1 segments. However, $S1rptE1^{-/-}$ mice and control littermates did not appear to have significantly different ionized calcium (1.15 ± 0.02 [n=6] vs 1.18 ± 0.01 [n=13] mmol/l, respectively; p=0.12) or serum PTH (227 ± 62 [n=5] vs 165 ± 36 [n=12] pg/ml, respectively; p=0.41), suggesting that Gsα may be dispensable for PTH actions in S1. Together, our findings indicate that the allelic Gsα silencing and the role of Gsα in mediating PTH actions in PT differ in a segment-specific manner.

The Calcium-Sensing Receptor Supports the Growth of Breast Cancer Cells in High Calcium Environments By Stimulating Parathyroid Hormone-related Protein Production. Wonnam Kim*[1], Joshua VanHouten[2], Karena Swan[3], John Wysolmerski[2]. [1]Yale School of Medicine, USA, [2]Yale University School of Medicine, USA, [3]Yale School of Medicine, USA

Bone metastases from breast cancer cause pain, hypercalcemia, pathologic fractures and, ultimately, death. In order for breast cancer cells to grow in the bone microenvironment, they must adapt to high levels of extracellular calcium. Cells respond to extracellular calcium by activating the calcium-sensing receptor (CaSR), a G protein-coupled receptor that binds and signals in response to extracellular calcium. Previous reports have demonstrated that the CaSR is expressed in the lactating mammary gland and regulates parathyroid hormone-related protein (PTHrP) production and calcium transport into milk. In addition, the CaSR has been shown to be expressed in many breast cancer cell lines and its expression has been shown to be higher in bone metastases than in primary tumors in patients. Therefore, we studied the role of the CaSR in breast cancer cell behavior. First, we identified that activation of the CaSR with high extracellular calcium stimulated proliferation in human BT474 breast cancer cells. Knocking down expression of the CaSR inhibited proliferation in response to extracellular calcium. In addition, BT474 cells treated with the CaSR antagonist, NPS2143, showed decreased proliferation in a dose dependent manner. Furthermore, activation of the CaSR increased intracellular cyclic adenosine monophosphate (cAMP) levels and increased the production of PTHrP. Since PTHrP has been reported to increase proliferation in some breast cancer cell lines, we also knocked down PTHrP expression in BT474 cells, which reduced proliferation in response to increasing doses of calcium. Interestingly, BT474 cells treated with NPS2143 showed dramatic increase in apoptosis in response to increasing doses of extracellular calcium. Knocking down either the CaSR orPTHrP also dramatically increased apoptosis in response to extracellular calcium in BT474 cells. These studies suggest that the CaSR promotes the survival and proliferation of breast cancer cells under calcium-rich conditions such as those found in the bone microenvironment, and that PTHrP acts as an important mediator of these effects. Ongoing studies are examining the consequences of altering CaSR expression on the growth of breast cancer cells in bone in vivo, but our preliminary studies suggest that the CaSR-PTHrP axis may be a useful therapeutic target to treat bone metastases in breast cancer.

The transcription factor, Mef2c participates in PTH stimulated MMP-13 gene expression in osteoblastic cells through the AP-1 site and c-Fos. Teruyo Nakatani*[1], Nicola Partridge[2]. [1]New York University College of Dentistry, USA, USA, [2]New York University College of Dentistry, USA

Parathyroid hormone (PTH) regulates transcription of many genes in osteoblasts. One of these is matrix metalloproteinase-13 (MMP-13), which is involved in bone remodeling and early stages of endochondral bone formation. Previously we reported that PTH induces MMP-13 transcription by causing the repressor, histone deacetylase 4 (HDAC4), to dissociate from Runx2 bound to the MMP-13 promoter. It is known that as well as Runx2, HDAC4 associates with the transcription factor, Mef2c, and represses its activity. To determine whether Mef2c is involved in the transcriptional regulation of MMP-13 by PTH, Mef2c expression was transiently knocked down in UMR cells by siRNA transfection. Knockdown of Mef2c decreased MMP-13 mRNA expression and promoter activity with or without PTH treatment. ChIP assays showed that Mef2c associated with the MMP-13 promoter and this increased after 4 h of PTH treatment. ChIP-reChIP results indicated that endogenous Mef2c was shown to associate with HDAC4 at the promoter region and after PTH treatment this association was found to be decreased. Gel shifts showed that Mef2c associated with the AP-1 site and not the Runx2 binding site (RD) of the MMP-13 promoter. Mutation of the AP-1 site, but not the RD site, abolished the stimulatory effect of Mef2c in MMP-13 promoter-reporter assays. Immunoprecipitation demonstrated that Mef2c associated with c-Fos (but not c-Jun). In conclusion, Mef2c is necessary for PTH-induced MMP-13 gene transcription and acts by increased binding to the AP-1 site through c-Fos. This is the first description of Mef2c interaction with c-Fos and an AP-1 element.

High Estradiol to Testosterone Ratio is Associated with Higher Baseline Bone Mineral Density but Poorer Response to Testosterone Treatment in Hypogonadal Males. Lina Aguirre*[1], Irum Jan[2], David Robbins[3], Dennis Villareal[4], Reina Armamento-Villareal[4]. [1]New Mexico VA Health Care System, USA, [2]New Mexico VA Health Care System, USA, [3]New Mexico VA Health Care System, USA, [4]University of New Mexico School of Medicine, USA

Estrogen has been recognized as the more important hormone to the male skeleton than testosterone. Despite higher levels of testosterone, deficiency in the enzyme aromatase (which is responsible for the conversion of testosterone to estradiol) is associated with low bone density which readily responds to estrogen supplementation. In this study we evaluated the role of estradiol to testosterone ratio on the response to testosterone in hypogonadal males participating in a genetic study of the enzyme aromatase. Bone mineral density (BMD) by DXA and serum total testosterone, estradiol sex hormone binding globulin and sclerostin by ELISA were measured at baseline and at six months. All participants were treated with testosterone cypionate with a starting dose of 200 mg every 2 weeks to achieve normal testosterone levels.

Results: To date, 90 patients have been enrolled in the study, with a mean age of 59.7 ± 8.6 years, and mean body mass index (BMI) of 31.4 ± 6.1 k/m^2. There were no correlations between free testosterone, free estradiol and sclerostin levels with baseline BMD at any skeletal site. However, baseline BMD of the lumbar spine increased with increasing tertiles of estradiol to testosterone ratio (1.063 ± 0.04, 1.098 ± 0.04, and 1.209 ± 0.04, for first, second and third tertiles respectively (p=0.04). In sixty patients with 6 month follow-up data to date, those in the lower tertiles for estradiol to testosterone ratio actually experienced a significant increase in the femoral neck BMD relative to the upper 2 tertiles (Fig. 1). A similar trend was observed for BMD at the trochanter and intertrochanter althought the difference did not reach statistical significance (p=>0.05). There was no correlation between changes in BMD and changes in estradiol levels or testosterone levels. Furthermore estradiol/testosterone ratio did not correlate with sclerostin levels at baseline and at 6 months.

Conclusion: While a higher estradiol to testosterone ratio may have a positive influence on BMD in hypogonadal men at baseline, our results suggest that with testosterone treatment those in the lower tertile of estradiol/testosterone ratio actually experience greater increases in BMD relative to those in the upper tertiles. Our findings need confirmation in a larger sample size of men on testosterone treatment.

A Common Polymorphism in the *CYP2R1* Gene Reduces Promoter Activity: Relevance to GWAS for 25(OH)D. Jeff Roizen*[1], Alex Casella[2], Michael Levine[3]. [1]The Childrens Hospital of Philadelphia, USA, [2]1Division of Endocrinology & Diabetes, The Children's Hospital of Philadelphia, Philadelphia, PA, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, United States, 19104, USA, [3]Children's Hospital of Philadelphia, USA

Optimal bone and mineral metabolism, as well as immune and cardiovascular function, depend on normal vitamin D metabolism. Ineffective sunlight exposure and inadequate dietary vitamin D intake each have well understood roles in the pathophysiology of vitamin D deficiency; however, the extent to which common variations or polymorphisms in genes encoding vitamin D metabolizing enzymes contribute to vitamin D homeostasis remains undefined. Several recent genome wide association studies (GWAS) have identified significant associations between serum [25(OH)D] and single nucleotide polymorphisms (SNPs) in or near the locus for *CYP2R1,* the gene encoding the principal vitamin D 25-hydroxylase enzyme. To examine whether common SNPs in the human *CYP2R1* gene promoter affect transcriptional activity, we generated a reporter construct in which expression of firefly luciferase was under the control of the proximal 5 kb of the *CYP2R1* promoter. The wild type *CYP2R1* promoter reporter or reporter constructs containing one of five promoter SNPs (rs2060793, rs10741657, rs1562902, rs16930609 and rs7949459) plus a Renilla luciferase reporter (to correct for transfection efficiency) were used to transfect LnCap cells, a human prostate carcinoma cell line previously shown to express CYP2R1 in a regulated fashion. The wild-type promoter showed significantly ($p < 0.001$ one way ANOVA) greater activity than a promoterless luciferase reporter (3.58 ± 0.51 vs 1.00 ± 0.00, mean $\pm$ SD). Four of the five polymorphic promoters (rs2060793, rs10741657, rs1562902, and rs16930609) showed luciferase activity (2.73 ± 0.35 to 3.51 ± 0.29) that was similar to the wild-type promoter. By contrast, SNP rs7949459 showed markedly reduced luciferase activity compared to the wild type promoter (0.58 ± 0.07 vs 3.58 ± 0.51, $p < 0.001$). *In silico* analysis of the promoter sequence using ENCODE revealed that the rs7949459 SNP is located in a DNase I hypersensitivity site, indicating that SNP rs7949459 may play a role in transcription factor binding to the *CYP2R1* promoter. Because the 1000 Genomes database indicates that this SNP occurs in more than 10% of the population, our results provide evidence that common genetic variations in *CYP2R1* may influence expression of 25-hydroxylase activity and thereby play a role in vitamin D homeostasis. Moreover, our results provide a functional context for interpreting GWAS that show relationships between circulating 25(OH)D and *CYP2R1*.

SU0148

Anabolic Bone Effect Of PGE_1 On The Rabbit Orthodontic Palate Disjunction. Francisco Valasquez-Forero*. Hospital Infantil De Mexico Federico Gomez, Mexico

Purpose: The purpose of this study was to evaluate, the PGE_1 anabolic effects on the rabbit orthodontic palate disjunction.

Methods: To evaluate the effects of the PGE_1 on the rabbit orthodontic disjunction, 30 rabbits were divided into 3 groups for study, ten control, 10 sham and ten PGE_1 subjects. Basal Rx evaluation was repeated on day 3 and 22. Using an orthodontic appliance sham and PGE_1 groups were subject to palate disjunction for five days, after wich it was filed with a steel bar. All animals received double tetracycline bone labeling. Control and sham groups received a daily IV dose of vehicle solution, and the third group, vehicle with 50 mg of PGE_1 in vehicle and orthodontic appliance. On day 22 blood and urine samples were taken to all animals to analyze hormones, electrolytes and bone biochemical remodeling markers and the animals were sacrificed. Bone palate samples were taken and processed, undecalcified and the sutural bone modelation was histomorphometric evaluated using a digitalizing table with Osteomesure software parameters, following the recommendations of the American Society for Bone and Mineral Research. Data were statistically analyzed.

Results: Radiology verified the suture palate disjunction. In the PGE_1 group, blood exhibited significant calcitriol increments. The other calciotropic hormones and calcemia were normal (Table 1). In the urine the hypercalciuria was significantly high and the resorption bone marks (N-telopeptides) were normals (Table 1). Histomorphometric modelation on sutural bones was analyzed. It is exhibiting a significant increase percentage on structural formation parameters (SBWi: 142%, SBAr: 66%, SbTh:123%, SBV/TV;86%) when compared with control. The mineralization parameters (Omt,MLT) accelerated their function and the modelation activity (BFR/BS) is increased. Table 2. On the contrary, the resorption indexes (ES/BS and OcS/BS) showed decreased activity table 2.

Conclusions: This model suggests that PGE_1 can be an important osseous anabolic molecule. An ideal anabolic molecule is one that can optimize bone formation while producing no resorption, as we have observed in the present model. Hopefully this finding guide research to options for osteopenies treatment.

Effect of Dietary Calcium and Sodium on Blood Pressure and Its Related Gene Expression in *Cyp27b1* Knockout Mice. Naoko Tsugawa*[1], Shiho Hiraiwa[2], Kanako Ohara[2], Kimie Nakagawa[2], Toshio Okano[3]. [1]Kobe Pharmaceutical University, Japan, [2]Kobe Pharmaceutical University, Japan, [3]Kobe Pharmaceutical University, Japan

Introduction: Based upon the observation that vitamin D receptor knockout mice exhibit high blood pressure, 1,25-Dihydroxyvitamin D (1,25-D) is thought to play a role in controlling blood pressure. To clarify the role of 1,25-D in the regulation of blood pressure, we examined the effect of dietary calcium (Ca) and sodium (Na) on blood pressure and its related gene expression in *Cyp27b1* knockout mice (*Cyp27b1*-KO). Methods: [Experiment 1] Wild-type (WT) and *Cyp27b1*-KO littermates were divided into two groups. After weaning (3-week-old), they were fed a normal Ca diet (N-Ca) or a high Ca containing rescue diet (2% Ca, 1.25% phosphorus, and 20% lactose: H-Ca) for 32 weeks (age: 35-week-old). In this feeding condition, *Cyp27b1*-KO fed N-Ca and *Cyp27b1*-KO fed H-Ca showed hypocalcemia and normocalcemia, respectively. Blood pressure was measured using a noninvasive computerized tail-cuff system. [Experiment 2] Mice raised in experiment 1 were subsequently fed a high Na diet (8% NaCl: N-Ca&H-Na) or a rescue diet with 8% NaCl (H-Ca&H-Na) for further 4 weeks, respectively. Animals were sacrificed and mRNA levels of brain natriuretic peptide (BNP) in hearts and renin in kidney were measured by real-time PCR. Results: [Experiment 1] No significant difference of blood pressure was observed between *Cyp27b1*-KO and WT fed N-Ca or H-Ca for 32 weeks. [Experiment 2] Blood pressure of *Cyp27b1*-KO fed N-Ca&H-Na was significantly higher than that of WT fed the same diet. On the other hand, no significant difference of blood pressure was observed between *Cyp27b1*-KO and WT fed H-Ca&H-Na. Renal renin mRNA expression of *Cyp27b1*-KO was higher than that of WT in both feeding of N-Ca&H-Na and H-Ca&H-Na. BNP mRNA expression in the heart of *Cyp27b1*-KO fed N-Ca&H-Na was lower than that of WT fed the same diet, but no significant

difference was observed between WT and *Cyp27b1*-KO fed H-Ca&H-Na. Both WT and *Cyp27b1*-KO fed H-Ca&H-Na showed the tendency of high blood pressure and low expression of BNP. Conclusion: These results suggest that *Cyp27b1*-KO fed N-Ca&H-Na is likely susceptive to high Na containing diet. However, the susceptibility to high Na diet was not observed in *Cyp27b1*-KO fed H-Ca&H-Na, which suggests that susceptibility to high Na diet was due to hypocalcemia. Low BNP expression observed in *Cyp27b1*-KO fed N-Ca&H-Na was thought to associate partly with high susceptibility to dietary Na. However, further investigations will be needed to clarify the mechanism of these phenomenon.

SU0150

Alterations of volumertic bone density, bone microarchitecture and bone strength in patients with ankylosing spondylitis: a case-control study using high-resolution peripheral quantitative computerized tomography. Nisha Nigil Haroon*[1], Eva Szabo[2], Janet Raboud[3], Robert Josse[4], Robert. D. Inman[5], Angela M. Cheung[6]. [1]University of Toronto, Canada, [2]Osteoporosis Program, University Health Network, Canada, [3]Dept of Biostatistics, University of Toronto & Toronto General Research Institute, Canada, [4]St. Michael's Hospital, University of Toronto, Canada, [5]Department of Medicine, University of Toronto, Canada, [6]University Health Network-University of Toronto, Canada

Background: Patients with ankylosing spondylitis (AS) have high fracture risk. Bone mineral density (BMD), bone microarchitecture and bone strength determine fracture risk. However, in AS, DXA-based BMD measurements of the lumbar spine may be falsely normal due to the presence of syndesmophytes. Also, DXA cannot differentiate between trabecular and cortical bone. The effect of AS on bone microarchitecture and bone strength is unknown.

Objectives: To assess bone microarchitecture and strength in patients with AS and to compare these parameters with non-AS controls.

Methods: AS was defined by the modified New York criteria. Disease activity of AS was measured by BASDAI (clinical severity), mSASSS (radiological severity), serum ESR and CRP levels. Volumetric BMD (vBMD) and microarchitecture were measured using HRpQCT, and bone strength was estimated using finite element analysis (FEA). Multivariable linear regression was used to analyze the effect of AS on HRpQCT parameters.

Results: There were 44 cases (82% Caucasian). The mean (+SD) age and BASDAI were 44+2 and 6.3+ 1.8 respectively. Median (IQ) disease duration was 20 (7.3-27.8 years). Twenty-three subjects had mSASSS >0. Four cases (9%) reported a history of fragility fracture. Use of TNF inhibitors (none), bisphosphonates (n=2) and corticosteroids (n=2) was negligible. Mean serum ESR, CRP and SAP levels were 22.0+23.6, 12.6 +15.6 and 96.2 +43.2 IU respectively. In multivariable linear regression models adjusted for age and gender, cases (n=44) had lower vBMD (trabecular, cortical and total), cortical thickness, BV/TV, bone stiffness and stress, and higher cortical porosity and trabecular separation at the radius (Table 1) when compared to non-AS controls (n=85). Tibial vBMD, BV/TV and cortical porosity were also abnormal in cases. But trabecular architecture at tibia was not different between cases and controls.

Conclusions: This study documents abnormalities of bone structure and bone strength in patients with AS. Patients with AS had lower volumetric BMD and worse microarchitecture at the trabecular and cortical regions compared to controls. Bone stiffness and stress at the radius and tibia, as estimated by FEA, also tended to be lower in cases than controls. These abnormalities might partly explain the high fracture risk in patients with AS.

Table 1: Multivariable linear regression showing abnormal bone microarchitecture and strength in patients with AS (44 cases and 85 controls).

Circulating Osteoblast Precursors in Peripheral Blood Were Decreased after TNF-α Blocker Therapy in Patients with Ankylosing Spondylitis. Seong-Ryul Kwon*[1], Won Park[1], Min-Jung Son[2], KoWoon Joo[2], Mie-Jin Lim[2], Kyoung-Hee Jung[2]. [1]INHA University Hospital, South Korea, [2]INHA University Hospital, South Korea

Background

The relationship between inflammation and new bone formation is unsolved question in area of spondylitis. First hypothesis is that inflammation is the process that sets in motion the chain of events that leads to ankylosis; an opposite one has proposed that an unknown pathogenic trigger simultaneously induces both inflammation and activation of new bone formation.

Objective

We investigated the circulating osteoblast precursors in peripheral blood with cell culture technique before and 14 weeks after infliximab therapy in patients with ankylosing spondylitis.

Methods

Male Fifteen individuals with ankylosing spondylitis were enrolled. They met the modified New York criteria and the candidates of infliximab therapy, refractory to non-steroidal anti-inflammatory drugs or disease modifying anti-rheumatic drugs. Peripheral blood mononuclear cells were collected and cultured in osteoblast growth medium. Once cell multilayering has been observed (about 7 days later), cells were moved to osteoblast differentiation medium and cultured for 3 weeks more. Then, cells were fixed and stained with alizarin S red to detect any calcified nodules. The optic density measurement of alizarin S red was performed to quantitative analysis.

We evaluated the changes of 1) the number of circulating osteoblast precursors, 2) the optic density of alizarin S red staining of circulating osteoblast precursors, 3)the osteocalcin, c-terminal telopeptide (CTX-1), receptor activator of NFkB ligand (RANKL) with enzyme linked immunosorbent assay (ELISA) in peripheral blood before and after 14 week infliximab therapy in patients with ankylosing spondylitis.

Results

The number of osteoblast precursor cells (Figure-1) and optic density of alizarin S were decreased after infliximab therapy ($p = 0.018$ for optic density of alizarin S, Figure-2). The serum level of osteocalcin was increased after infliximab therapy ($p = 0.01$); but, that of CTX and RANKL was not changed significantly.

Conclusion

The circulating osteoblast precursors in peripheral blood were decreased significantly after 14 weeks of infliximab therapy. This result can support inflammation and activation of new bone formation occurs simultaneously in patients with ankylosing spondylitis.

SU0152

Serum Sclerostin in Juvenile Idiopathic Arthritis. Jan Stepan*[1], Kristyna Brabnikova Maresova[2], Katerina Jarosova[3], Karel Pavelka[3]. [1]Charles University, Czech Republic, [2]Institute of Reheumatology, Czech Republic, [3]Institute of Rheumatology, Czech Republic

Background: The study was aimed to evaluate the clinical value of serum sclerostin in adult patients with active juvenile idiopathic arthritis (JIA) treated with biologicals. This group of young patients was used to avoid an overlap of changes in serum sclerostin due to disease and aging. JIA is the most common chronic rheumatic multifactorial autoimmune disorder of childhood. Sclerostin is a potent antagonist of bone morphogenetic proteins critical for osteoblastogenesis. Serum sclerostin levels are higher in males and increase in both sexes across the adult lifespan. Although widely thought to be an osteocyte-specific protein, the SOST mRNA is expressed by other cells including articular chondrocytes.

Methods: Adult patients (12 male and 19 female, age 25 $\pm$ 6.1 years) with active JIA (DAS 28, 6.36 $\pm$ 0.64, hsCRP, 18.36 $\pm$ 16.95 mg/l) and 84 healthy age- and gender- matched controls were enrolled into the study. Before the initiation of treatment with biologics, the patients were treated with DMARDs, and 12 patients were on glucocorticoids (6.6 $\pm$, 4.3 mg/day). After baseline evaluation, the patients were treated for 2 years with biologics (18 infliximab, 8 etanercept, 5 adalimumab). Areal bone mineral density (BMD) at the lumbar spine, proximal femur, and femoral neck was assessed using DXA, and correlated with clinical and laboratory characteristics of the disease. Sclerostin was measured using the Human SOST ELISA, Uscn Life Science Inc.

Results: At baseline, compared to healthy controls, BMD in JIA patients was lower at all measured sites ($p<0.001$), and serum sclerostin was increased ($p<0.001$). An increase in lumbar spine BMD after 2 years of therapy (Table) was predicted by decrease in DAS28 during the first year ($p=0.003$, after adjustment for sex, age, height, glucocorticoid therapy and disease duration). Serum sclerostin was decreased after 12 and 24 months of therapy as compared with baseline values (Table). A significant positive correlation was found between DAS28 and serum sclerostin concentrations ($r=0.32$, $p=0.002$), and between number of swollen joints and sclerostin ($r=0.33$, $p=0.001$). However, no correlation was found between sclerostin and hrCRP ($r=0.01$, $p=0.92$).

Conclusion. The association between serum sclerostin concentrations and number of swollen joints rather than CRP suggests that circulating sclerostin is a reflection of the number of sclerostin-producing cells, either subchondral bone or chondrocytes.

Table. Disease activity, BMD and serum sclerostin in patients with JIA during biologics treatment and in controls. Median and 75% CI

Comparison of the effect of 18-months daily teriparatide administration on patients with rheumatoid arthritis and postmenopausal osteoporosis patients. Kosuke Ebina*[1], Jun Hashimoto[2], Masafumi Kashii[3], Takaaki Noguchi[4], Yohei Matsuo[5], Tsuyoshi Sugiura[6], Hideki Yoshikawa[7]. [1]Osaka University, Graduate School of Medicine, Japan, [2]National Hospital Organization, Osaka Minami Medical Center, Japan, [3]Osaka University Graduate School of Medicine, Japan, [4]Osaka Univiersity, Graduate school of medicine, Department of Orthopaedic Surgery, Japan, [5], Japan, [6]Faculty of Medicine, Graduate School of Medicine, Osaka University, Japan, [7]Osaka University Graduate School of Medicine, Japan

Purpose

The aim of this study is to clarify the effect of 18 months daily Teriparatide (TPTD; 20μg/day) administration on osteoporosis patients with rheumatoid arthritis (RA; n=70) by comparing with that of postmenopausal osteoporosis patients (Porosis; n=62).

Methods

RA group (age 68.4, prior bisphosphonate (BP) 77.1%, lumbar spine (LS) T-score -2.5, femoral neck (FN) T-score -2.7, previous vertebral fracture 72.9%, DAS28-CRP 2.8, 84.3% taking prednisolone (PSL) 4.4mg/day, 25.7% taking biologics) and Porosis group (age 71.3, prior BP 77.4%, LS T-score -3.0, FN T-score -2.5, previous vertebral fracture 71.0%) were enrolled. BMD and Bone metabolism markers including PINP, bone ALP, TRAP-5b, uDPD, and ucOC were monitored. The relationship between baseline and changes in these markers and 18-months BMD changes in LS and FN were evaluated using Spearman correlation analysis and multivariate logistic regression analysis.

Results

Absolute increase of bone formation markers at 1-month were significantly greater in RA group compared to Porosis group, which were 101.8 v.s. 50.2 μg/L for PINP ($P=0.0001$), and 5.6 v.s. 2.1 U/L for bone ALP ($P=0.007$). Increase in FN BMD from baseline at 18 months were significantly greater in RA group compared to Porosis group, which was 4.7% v.s. 0.7% ($P=0.035$), while increase in LS BMD were 9.7% v.s. 7.9%, which did not reached significant difference. In RA group, increase in 18-months BMD was positively correlated with baseline ucOC ($P<0.05$ for LS; $P<0.01$ for FN) and change in PINP at 3-months ($P<0.05$ for LS; $P<0.01$ for FN) and 6-months ($P<0.05$ for LS ; $P<0.01$ for FN). The increase in FN BMD at 18-months was negatively correlated with baseline PSL dose ($P<0.05$), although prior use of BP, disease duration, disease activity, autoantibody titers, and combined biologics didn't show significant correlation with 18-months BMD increase. There was no significant difference between RA and Porosis group in the incidence of vertebral fractures (3.7% versus 3.9%) and nonvertebral fractures (1.9% versus 2.0%). Multivariate logistic regression analysis revealed that significant indicator of 18-months BMD change of LS and FN was baseline and 3-months change (Δ3) of ucOC in RA group, whereas Δ1 bone ALP in Porosis group.

Conclusions

Our findings indicate that RA group showed grater response to TPTD administration, especially in increase of 1-month bone formation markers, and increase of 18-months FN BMD compared to Porosis group.

Role of the A2B Adenosine Receptor in the Degradation of Bone in Rheumatoid Arthritis. Lauren Mangano*[1], Dana Daukss[2], Shannon Carroll[3], Katya Ravid[4], Louis Gerstenfeld[5], Elise Morgan[6]. [1]Boston Univeristy, USA, [2]Boston University, USA, [3]Boston Univerisyt, USA, [4]Boston University School of Medicine, USA, [5]Boston University School of Medicine, USA, [6]Boston University, USA

Introduction: Adenosine receptors are known to mediate the activity of cytokines involved in the inflammatory processes of rheumatoid arthritis (RA) and have been connected to production of matrix metalloproteinases and differentiation of osteoblasts. The goal of this study is to determine the role of the A2B adenosine receptor (A2BAR) in degenerative changes to cartilage and bone using a mouse model of collagen antibody-induced arthritis (CAIA).

Methods: A2BAR knockout (KO) mice (n=11) were bred into a C57BL6/J background. C57BL6/J mice (n=12) were used as a wild type (WT) reference. At 16 weeks of age, female mice were injected with a collagen antibody cocktail (ArthritoMab, MD Bioproduts) and lipopolysaccharide (LPS) to induce arthritis (CAIA) or with saline (control). Ankle width, as a measure of joint swelling, was recorded on days 4, 8, and 10. Mice were sacrificed after 8 and 10 days. The forepaws and hindpaws were imaged with μCT (μCT40, Scanco Medical, Brüttisellen Switzerland) at resolution of 16 μm/voxel. The bone mineral density (BMD) and bone fraction (BV/TV) of the 2nd-4th metatarsal phalangeal (MTP) joints were measured. The distal femora and proximal tibiae were imaged with contrast-enhanced μCT (6 μm/voxel), a technique involving performing a μCT scan both before and after a 14-hourincubation in an iodinated contrast agent (CA4+) that labels cartilaginous tissues.

Results: Ankle width was higher at days 8 and 10 vs. day 4 in both WT CAIA ($p<0.05$), but not KO CAIA mice ($p>0.05$). As compared to control mice, CAIA mice—both WT and KO— showed increased porosity and roughness of the endosteal surface in the distal metatarsal metaphyses (Fig 1). Correspondingly, tissue mineral density (TMD) and bone volume fraction (BV/TV) in these regions were lower with CAIA ($p<0.0001$, $p<0.005$). TMD was also lower in the entire metatarsal-phalangeal (MTP) joints in CAIA ($p<0.0001$) and trended higher in KO vs. WT mice ($p=0.0962$).

Contrast-enhanced μCT indicated a greater loss of articular cartilage in WT vs. KO CAIA mice at day 10 (Fig 2).

Discussion: Evidence of increased bone resorption in MTP joints was seen with CAIA irrespective of genotype. Loss of articular cartilage in the knee was also seen in both genotypes with CAIA but to a lesser extent in A2BAR KO mice, suggesting a protective effect of the loss of this receptor. Pharmacological antagonism of this receptor may be a potential treatment to mitigate the destruction of bone and cartilage associated with RA.

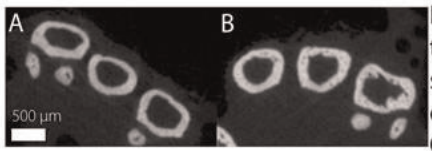

Figure 1. μCT scan of the 2nd-4th metatarsal of WT mice. A) control day 10, B) CAIA day 10.

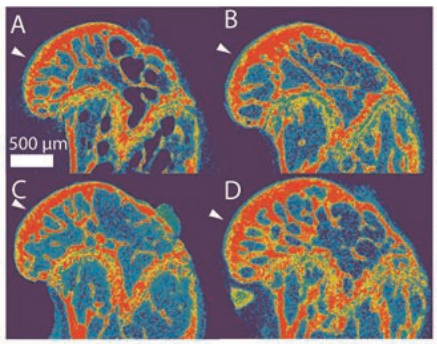

Figure 2. Contrast-enhanced μCT scan of the distal femur of CAIA mice. A) WT day 8, B) KO day 8, C) WT day 10, D) KO day10. Arrowheads indicate the articular surface.

***In Vivo* Fatigue Damage in Bone Linked to Cytokine Expression.** Travis McCumber*[1], Bryan Hackfort[2], Mohammed Akhter[3], Diane Cullen[2]. [1]Creighton University, USA, [2]Creighton University, USA, [3]Creighton University Osteoporosis Research Center, USA

Long bone fractures result in cytokines that regulate the formation and/or remodeling of fracture callus; however, cytokine production is not associated with typical mechanical loading and exercise. Repetitive ulna compression that causes bone fatigue in rats induces tissue microdamage with subsequent remodeling. This project examines the cytokine response to *in vivo* fatigue loading. We have reported that IL-2 is elevated in serum and bone blood spaces after fatigue loading. IL-2 is produced by T cells and increases T cell number, suggesting that T-cells may play a role in the bone response to tissue damage and repair. We hypothesize that overloading of bone to cause fatigue damage, activates cytokines and osteoclastogenesis leading to bone resorption. In Sprague Dawley female rats (6 mo) the right ulna was fatigue loaded in compression (< 4000 με, < 20,000 cyc, 4 Hz) to 40% loss of ulna stiffness. Right and left ulnae were collected at 48 hrs post-fatigue, fixed, decalcified, and embedded in paraffin (N=8). Immunohistochemistry was used to identify Th17 cells (IL-23 receptor) and TRAP staining was used to identify osteoclasts. IL-23r was expressed strongly in *bone* blood spaces in load and nonload legs at 48 hours similar to the IL-2 pattern. TRAP stained osteoclasts were numerous in fatigue loaded bone, located in blood spaces, periosteum, and tissue in the vicinity of microcracks. Compared to loaded, the nonloaded legs had fewer osteoclasts that were randomly distributed in the tissue. The up-regulation of IL-2 and IL-23r are novel findings that implicate inflammatory signals in the bone response to fatigue damage. IL-2 is not known to be produced by osteocytes or osteoblasts. While IL-2 is a non-specific T-cell signal, it demonstrates that T-cells in the loaded limb are activated and that the response can be detected at the serum level. Th17 cells can stimulate osteoclastogenesis via IL-17. Unlike complete fracture, an inflammatory response with an influx of white blood cells typically is not associated with microdamage. These data are the first to show a rapid increase in cytokines in blood and bone tissue following ulnar fatigue damage in rats. If T cell activation and subsequent cytokines contribute to remodeling of bone tissue damage, this would provide a new paradigm for studying tissue damage and repair.

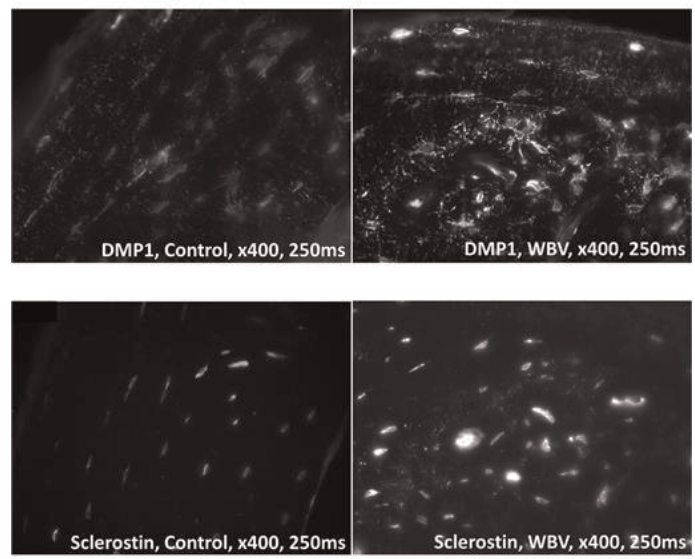
Continuous and intermittent hypergravity induce a bone compartment-specific anabolic response and affect differently osteocyte Sclerostin expression. Vasily Gnyubkin*[1], Alain Guignandon[2], Norbert Laroche[2], Arnaud Vanden-Bossche[2], Fiona Louis[2], Marie-Helene Lafage-Proust[3], Laurence Vico[4]. [1]INSERM U1059, LBTO, Faculty of Medicine, University of Lyon, France, [2]INSERM U1059, LBTO, Faculty of Medicine, University of Lyon, France, [3]INSERM Unit 1059, France, [4]University of St-Etienne, France

Bone fragility is a major obstacle to the long-term spaceflights. Adequate mechanical loading is necessary for bone status preservation. Possible countermeasure can be exposure to hypergravity (hyperG) either continuous by centrifugation or intermittent by whole body vibration (WBV). We investigated how the bones reacted to different modes of G-load and which G level was the most effective. Firstly, we studied effects of 21-d continuous hyperG at 2 and 3G on the skeleton of 7 w-old male C57/BL6 mice. We analyzed the structural parameters by μCT and cellular activities by histomorphometry in femur. At 3G, significant difference ($p<0.05$) vs control group were found for femoral cortical thickness (-6%). Although trabecular bone was maintained, resorption activity (TRAcP+ Oc.S/BS,%) increased by 41% whereas bone formation activity decreased (OS/BS,%:-42%; dLS/BS,%:-20%; MAR, μm/d:-16% and BFR, μm3/μm2/day:-30%). In contrast, 2G exposure improved trabecular volume (BV/TV, %:+18%), number (Tb.N, mm-1:+15%) and connectivity density (Conn.D,1/mm3:+32%). In 2G, resorption activity decreased by 36% and osteoblast recruitment increased (OS/BS:+33%; dLS/BS:+31%). Because 3G caused negative effects and 2G was beneficial we repeated 2G experiment to investigate osteocyte Sclerostin and DMP1 levels, and bone vascularization (Roche B. et al, Bone. 2012). In femur cortex DMP1 increased by 7.2%, Sclerostin decreased by 15% (automated image analysis, 7500 osteocytes p/group, $p<0.02$). In distal metaphysis of femur the number and area of vessels/mm2 of bone marrow increased by 22% and 44%, respectively ($p<0.02$). Secondly, we studied effects of intermittent hyperG at 90Hz,15 min/d,5 d/wk, 9 wks, 3 WBV modes: 0.5G, increment from 0.5 to 2G, and 2G. Because PIXImus BMD showed 11% ($p<0.02$) increase in femur of 2G group only, this mode was selected for a 21-d experiment. After 21-d of WBV cortical thickness (μm) increased by 5%, area (μm2) by 6%, and porosity (%) decreased by 6% ($p<0.05$). Both resorption and formation activities increased (Oc.S/BS:+41%; OS/BS:+47% and BFR:+124%, $p<0.02$). Sclerostin and DMP1 increased by 26% and 33% respectively ($p<0.001$). Also, WBV led to 23% increase of vessels number ($p<0.02$). In summary: while continuous 2G improved trabecular, intermittent 2G improved cortical bone and both stimulated angiogenesis. Resorption activity and Sclerostin decreased after continuous 2G and increased after WBV. DMP1 increased in both cases although much more after WBV.



IHC of DMP1 and Sclerostin, Control vs WBV

Deficit in the Adaptation of Old Bone to Loading is Associated with Reduced Retention of Wnt Activity. Nilsson Holguin*[1], Michael Brodt[2], Matthew Silva[3]. [1]Washington University Department of Orthopaedic Surgery, USA, [2]Washington University in St Louis, USA, [3]Washington University in St. Louis School of Medicine, USA

Tibial compression increases bone mass in mice but aging reduces the response. Wnt signaling is a key anabolic pathway in bone, where suppression of antagonist Sost is necessary for load-induced bone formation. We hypothesized that aging diminishes the activation of Wnt signaling by mechanical loading. First, we subjected a range of adult (5-, 12- and 22-month; n=5-8/age/time) C57Bl/6 mice to 1-5 days of tibial compression (1200 cycles, peak compressive strain -2200 με). Multiple days of loading enhanced the gene expression of matrix production (Col1a1) (Fig. 1a), osteoblast-differentiation (Osx), late-osteoblast (Osc), and Wnt-related markers (Wnt1, Dkk1, Sost) (Fig. 1b) towards activation of the pathway. The enhanced expression of Col1a1 was age-dependent at day 5, which corroborates the age-dependent decline in mineralizing surface at day 5. Next, noting suppression of all the common bone formation markers after a single bout of loading, we determined the kinetic profile for the same above-mentioned genes. Following a single day of loading, the expression of bone formation markers and Sost (Fig. 1c) remained down-regulated for longer in young-adults than older mice (n=5-7/age/time). In order to account for control levels of Sost with aging, we ran a three-way ANOVA to demonstrate an interaction between age and loading. A post-hoc test removing time as a factor showed that aging diminished the Sost expression in control tibiae and the loading response, suggesting that heightened suppression of Sost may not be as necessary in old age (Fig. 1d). Lastly, we determined the activation of Wnt signaling in osteocytes from Wnt-reporter mice (TOPGAL, n=7-10/age/time) after 1 and 5 d of anabolic loading. We confirmed that aged TOPGAL have an age-related decline in loading-induced bone formation. Two weeks of tibial compression at -650 με increased periosteal MS/BS in 5-month and 12-month mice (n=4-7/age), and the periosteal response was 5-fold greater in 5-month mice (Fig. 1e). Following tibial compression of young-adults, 1 and 5 d of loading doubled the percentage of Wnt-active cells. By contrast, 1 d of loading activated Wnt signaling in cells of 12-month mice, but 5 d of loading did not (Fig. 1f). Tibial compression at a higher strain (-2200 με) similarly increased activation of Wnt signaling. In conclusion, the reduced bone formation response of aged mice to tibial compression may be due to a reduced retention of Wnt activity.

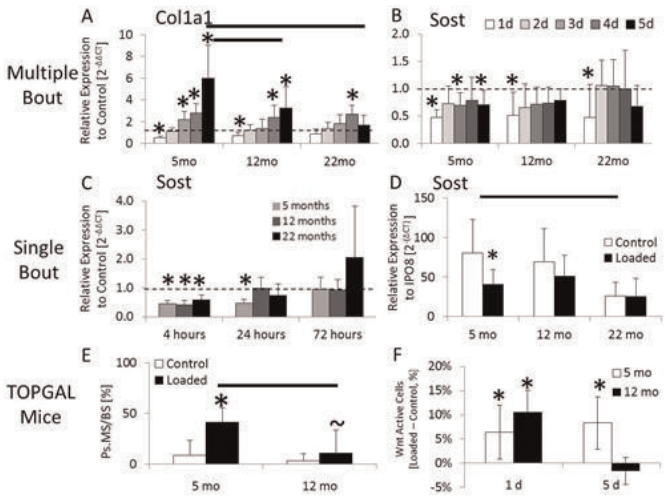

Fig. 1 Multiple bouts of loading increased (a) Col1a1 expression in a range of adult mice, with the greatest response determined in young-adult 5-month mice at day 5. (b) Similarly, Sost expression was down-regulated in 5-month mice up to the 5th day, but not reduced in older mice following multiple bouts. (c) A single session of tibial compression reduced Sost expression for longer in 5-month mice than older mice. (d) When the 4, 24 and 72 hour time points were pooled, loading did not suppress Sost expression in 22-month mice as it had in younger mice but the expression in the control tibiae of these old mice declined compared to younger mice. Tibial compression in TOPGAL mice increased (e) periosteal MS/BS more so in 5-month mice than 12-month mice. (f) Similarly, loading increased activation of Wnt in osteocytes from 5 month mice following both 1 and 5 days, whereas 12-month old mice had greater activation after 1 day but not 5 days. *: vs control, Bar: between ages, p<0.05; ~:vs control, p<0.1.

Differential effects of involuntary running on bone structure of high-fat diet-induced obese rats. Jay Cao*[1], Matthew Picklo[2]. [1]USDA ARS, USA, [2]Grand Forks Human Nutrition Research Center, USA

The aim of the study was to examine how exercise and exercise plus anti-oxidant supplementation with vitamin E and vitamin C alter bone structural properties at different skeletal sites and markers of bone metabolism in a high-fat diet induced obese rat model. Fourteen 5-wk old obese prone Sprague Dawley rats were fed a normal-fat diet (NF, 10% kcal as fat), and 41 rats were fed a high-fat diet (HF, 45% kcal as fat from lard) *ad libitum* for 15 wks. Then, rats on the high-fat diet were assigned randomly to three treatment groups for additional 12 wks: (1) high-fat diet (n=14); (2) high-fat diet + exercise (HF-Ex, n=14); (3) high-fat diet with vitamin E (0.4 g α-tocopherol acetate/kg diet) and vitamin C (0.5 g ascorbate/kg diet) supplementation + exercise (HF-Ex-Aox, n=13). Animals were forced to exercise by running wheel for 5 days/wk for 8 wks at a graduated rate until reaching 1.2 km/ 2 hr session and maintained at the same rate by another 4 wks. Body weight and fat (%) were similar among NF, HF-Ex, and HF-Ex-Aox whereas HF had greater body weight and fat (%) than other groups. Compared to NF, HF had elevated serum leptin, tartrate-resistant acid phosphatase (TRAP), and IGF-1, increased trabecular separation, and structural model index, decreased bone mineral density, trabecular connectivity density, and trabecular number in distal femur, while HF-Ex and HF-Ex-Aox had elevated serum TRAP, decreased bone volume/total volume and trabecular number of distal femurs. Compared to HF, HF-Ex and HF-Ex-Aox had decreased serum TRAP and osteocalcin, and improved bone structural properties of distal femur but similar bone parameters of 2nd lumbar vertebrae (L2) and cortical variables of mid-shaft femurs. HF-Ex and HF-Ex-Aox had similar bone structural properties at distal or mid-shaft femurs, or L2. These findings suggest that exercise improves but does not fully protect against negative skeletal effects of excessive adiposity induced by a high-fat diet at certain skeletal sites and that vitamin E and C supplementation has no additional benefits on bone structural properties during exercise.

Prolonged Performance of A High Repetition High Force Task Induces Bone Degradation in Young Adult Rats. Vicky Massicotte[1], Michele Harris[2], Paul W Fisher[3], Steven Popoff[1], Mary Barbe*[1]. [1]Temple University School of Medicine, USA, [2]Temple University School of Medicine, USA, [3]Temple University, USA

Overuse injuries are the most reported types of athletic and occupational disorders. Only a few studies have examined changes occurring in upper extremity bones as a consequence of occupational tasks, although it is well known that chronic cyclical tissue over-load affects bone quality and morphometry. We have reported, using a rat model of repetitive grasping and pulling, that high repetition high force (HRHF) task for 12 weeks leads to bone loss. We have also shown that pro-inflammatory cytokines (TNF-α, IL1-β and IL-6) are increased in 6 and 12 weeks HRHF rats, but that inflammation resolves thereafter. These cytokines are known to affect osteoblasts (bone forming cells) and osteoclasts (bone resorbing cells) homeostasis. Although not yet investigated with occupational overuse injuries, RANKL is another cytokine linked to osteoclast activation during remodeling and increases in bone after osteocyte apoptosis due to microdamage. We hypothesized that performance of HRHF task for 18 weeks will induce detrimental bone remodeling, increase RANKL and osteoclast numbers. Thus, using micro-computed tomography, we investigated the impact of HRHF task performance for 18 weeks on young adult rat bones. We observed detrimental trabecular bone remodeling in the radius due to impaired bone formation and increased resorption observed as decreased bone volume, trabeculae number and thickness, increased bone surface and trabeculae separation, increased anisotropy and rod shaped trabeculae in HRHF 18W rats, compared to food restricted control rats (FRC). Osteoblast cell numbers decreased and osteoclasts increased, concomitant with an increase in empty osteocytes lacunae due to augmented apoptosis (increased TUNEL staining) in HRHF 18W, compared to FRC. Serum osteocalcin (a bone formation biomarker) was reduced ($p<0.01$) while CTX1 (a bone resorption biomarker) increased ($p<0.01$), compared to FRC. ELISA and qPCR show increases in both RANKL protein and mRNA levels. Immunohistochemistry show increased cartilaginous matrix with augmented diffused RANKL staining in HRHF 18W rat radii, while FRC rats had lower levels of RANKL that was concentrated to osteocyte's lacunae only. We can conclude that HRHF prolonged task performance leads to detrimental histomorphometric changes due to increased RANKL-mediated bone resorption.

Congenic Strains Confirm a Pleiotropic Bone QTL on Mouse Chromosome 4. Jasmin Kristianto*[1], Michael Johnson[2], suzanne litscher[3], Forum Patel[3], Robert Blank[4]. [1]University of Wisconsin–Madison, USA, [2]University of Wisconsin, USA, [3]University of wisconsin Madison, USA, [4]Medical College of Wisconsin, USA

Osteoporosis is an important health problem that affects more than 75 million people worldwide. Although the etiology of osteoporosis is multifactorial, genetics contribute ~70% to its development. We and others previously identified a pleiotropic quantitative trait locus (QTL) on mouse chromosome 4 that affects bone size, shape, and strength. The QTL includes *Ece1*, the gene encoding endothelin converting enzyme 1 and in recombinant congenic HcB-8 and HcB-23 mice having widely divergent femoral biomechanical performance, *Ece1* is differentially expressed. To study the QTL in isolation from other segregating loci, we bred two congenic strains carrying overlapping segments of chromosome 4 from C57BL/10ScSnA (B10) within the locus on a C3H/DiSnA (C3H) background. The long and short congenic strains harbor a ~10 Mb and a ~1 Mb B10-derived chromosome segment, respectively. We tested femoral diaphysis biomechanical performance by quasi-static 3-point bending and measured bone geometry in (C3H x congenic) F2 mice. We analyzed the results via 2-way ANOVA, using sex and genotype as factors. In the long congenic, C3H/C3H male (M) and female (F) mice have greater shape factor (M= 1.42 $\pm$ 0.05, F= 1.38 $\pm$ 0.02) than C3H/B10 (M=1.40 $\pm$ 0.02, F=1.35 $\pm$ 0.02) and B10/B10 (M=1.40 $\pm$ 0.02, F=1.33 $\pm$ 0.02) mice, $p < 0.001$. Both M and F C3H/C3H mice also have greater cross-sectional area (CSA) (p= 0.022) than C3H/B10 and B10/B10 mice. C3H/C3H mice have greater total displacement relative to B10/B10 mice (p=0.023) but not C3H/B10. In the short congenic, C3H/C3H F mice (1.05 $\pm$ 0.03) and C3H/B10 F mice (1.07 $\pm$ 0.03) have greater CSA than B10/B10 F mice (0.95 $\pm$ 0.05), p=0.045. Both M and F C3H/C3H and C3H/B10 mice also have greater maximum load (p=0.015) and yield load (p=0.041) than M and F B10/B10 mice. We have also shown that autocrine endothelin signaling by osteoblasts *in vitro* and in organ culture increases IGF1 secretion, providing a mechanism that could account for the development of these phenotypes. Our findings confirm our prior intercross results and motivate further study of *Ece1*'s biological role in bone development and modeling.

Interleukin-11 is an important factor for mechanical stress-induced osteoblast differentiation and bone formation. Takeshi Kondo*[1], Bingzi Dong[1], Takashi Omatsu[1], Yukiyo Ohnishi[1], Itsuro Endo[2], Masahiro Abe[3], Shinichi Aizawa[4], Hiroshi Sakaue[5], Toshio Matsumoto[2]. [1]Department of Medicine & Bioregulatory Sciences, University of Tokushima Graduate School of Medical Sciences, Japan, [2]University of Tokushima Graduate School of Medical Sciences, Japan, [3]University of Tokushima, Japan, [4]not yet, Japan, [5]Department of Nutrition & Metabolism, Institute of Health Biosciences, University of Tokushima Graduate School, Japan

Background: We have previously reported that interleukin (IL)-11 expression is markedly enhanced by mechanical stress, and plays a role in mechanical stress-induced stimulation of osteoblast differentiation and bone formation. Increased IL-11 down-regulates dikkopf 1/2 (Dkk1/2) expression and stimulates canonical Wnt signaling in primary osteoblasts. The present study was undertaken to clarify the physiological role of IL-11 in osteogenesis in response to mechanical stress by creating IL-11 deficient (IL-11KO) mice.

Methods: We measured bone mineral density (BMD) and performed bone morphometric analysis of IL-11KO and WT mice. Mechanical unloading by tail suspension for 2 weeks and reloading by forced running were performed in both IL-11 KO and wild-type (WT) mice. Expression of osteoblastic and osteoclastic marker genes, and Wnt inhibitors including Dkks and sclerostin was also examined.

Results: IL-11 KO mice exhibited low BMD in weight-bearing bones such as femurs and vertebrae after weaning, which was aggravated with aging. In contrast, BMD of non-weight bearing calvarial bone was slightly increased in IL-11 KO mice. Serum osteocalcin was lower in IL-11KO than in WT mice, while serum TRAP5b was similar in both groups. Bone morphometric analysis revealed that Tb.Th, Ob.S/BS, N.Ob/BS and BMR were reduced in IL-11KO mice, but there was no significant difference in N.Oc/BS or Oc.S/BS between IL-11KO and WT mice. Expression of osteocalcin and Runx2 mRNA was reduced, while SOST and Dkk1/2 mRNA expression was elevated in bones of IL-11KO mice. Up-regulation of sclerostin expression in bones of IL-11KO mice was confirmed by immunohistochemical analysis. After unloading, BMD of weight-bearing bone and osteocalcin mRNA expression decreased in both IL-11KO and WT mice. After reloading, increase in BMD and osteocalcin mRNA was significantly lower in IL-11KO mice. SOST mRNA was higher in both unloading and reloading conditions in IL-11KO mice compared with that in WT mice. Furthermore, bone morphometric analysis revealed that bone formation parameters after reloading was significantly lower in IL-11KO mice than in WT mice.

Conclusion: IL-11 is an important factor for mechanical stress-induced osteoblast differentiation and bone formation by suppressing the expression of Wnt inhibitors in response to mechanical stress.

M1/M2-like Macrophage Polarization Contributes to Mechanical Force-induced Orthodontic Root Resorption. Danqing He*[1], Xiaoxing Kou[2], Yanheng Zhou[3]. [1]Department of Orthodontics, Peking University School & Hospital of Stomatology, Peoples Republic of China, [2]Orthodontic Department, Peking University School of Stomatology, Beijing, China, [3]Orthodontic Department, Peking University School of Stomatology, China

Mechanical force-induced orthodontic root resorption is a major clinical challenge in orthodontic treatment, but the underling mechanism remains largely unknown. In this study we show that M1/M2-like macrophage polarization affects root resorption accompanied with orthodontic tooth movement.

Mechanical force was applied to the upper first molars of rats using NiTi springs for 14 days and then maintained for 14 days by placing resin between first and second molars. Root resorption was observed from day 3 to day 14 after force application (active resorption stage), then showed a resting stage from day 3 to day 14 of retention. Meanwhile, $CD68^+/iNOS^+$ M1-like macrophages persistently increased in the compression side of the roots from day 3 to day 14 after force application, matching the active resorption stage, while $CD68^+/CD163^+$ M2-like macrophages were detected upregulated in the resorption resting stage. In addition, increased expression of IFN-γ, a major M1 activator, was detected in the periodontal ligament cells (PDLCs) after force application both *in vivo* and *in vitro*, while M2 activator IL-4 was mainly observed in the resorption resting stage. Besides, M1-associated pro-inflammatory cytokine TNF-α was highly expressed during active resorption stage and persisted to the resting stage, while M2 associated anti-inflammatory cytokine IL-10 was upregulated in the resorption resting stage. Furthermore, systemic injection of TNF-α inhibitor etanercept or systemic injection of IL-4 attenuated the severity of root resorption, along with decreased numbers of $iNOS^+$ M1-like macrophages and increased numbers of $CD163^+$ M2-like macrophages, respectively.

These data imply that the balance between M1/M2-like macrophages may influence orthodontic root resorption, M1-like macrophages promote orthodontic root resorption in the active resorption stage and M2-like macrophages inhibit it in the resting stage.

Streptomycin inhibits effects of electrical stimulation-induced muscle force on reducing disused bone loss. Hiroyuki Tamaki*[1], Kengo Yotani[2], Hikari Kirimoto[3], Kazuhiro Sugawara[4], Atsuhiro Tsubaki[4], Hideaki Onishi[4], Noriaki Yamamoto[5], Norikatsu Kasuga[6]. [1]Niigata University of Health & Welfare, Japan, [2]National Institute of Fitness & Sports in Kanoya, Japan, [3] Niigata University of Health & Welfare, Japan, [4]Niigata University of Health & Welfare, Japan, [5]Niigata Rehabilitation Hospital, Japan, [6]Aichi University of Education, Japan

Limb disuse due to denervation causes musculoskeletal atrophy accompanied by a large reduction in bone mass and changes in trabecular architecture. Findings from animal studies suggest that electric muscle stimulation (ES)-induced muscle force with an appropriate regimen reduces muscle deterioration caused by disuse and bone loss caused by denervation; however, whether these effects of ES are associated with mechanosensors in bone tissue or with stimulated skeletal muscle mass remains unknown. We tested the hypothesis that streptomycin, a stretch-activated channel (SAC) blocker, can essentially abolish the reduction in bone loss elicited by ES.

Direct ES with an intensity of 16 mA and a frequency of 10 Hz for 30 min/day for 6 consecutive days was applied to the tibialis anterior (TA) muscle after unilateral sciatic denervation in 7-week-old male rats as follows: control (CON); denervation (DN); DN with direct ES (DN-ES); and DN with ES treated with streptomycin (DN-ES-Str). The weight of the TA muscle and the tension force induced by ES were determined, and the metaphyseal trabecular regions of the tibiae were analyzed using micro CT and histomorphometry.

Significant losses in trabecular bone in the tibiae and TA muscle were evident in the DN rats. Trabecular bone volume fraction (BV/TV), thickness (Tb.Th), and number (Tb.N.), as well as connectivity density (Conn.D.) and osteoid thickness were increased in DN-ES compared with DN rats at 1 week after denervation. However, these parameters were lower in the DN-ES-Str than in the DN-ES group, without the differences in TA muscle weight and tension force induced by ES at 10 Hz.These findings suggest that streptomycin inhibits the ability of ES-induced muscle force to reduce the loss of disused bone. Activation of SACs might thus explain why ES-induced muscle tension applied to bone reduces bone loss in the denervated rat hindlimb.

Structured Fibronectin Surfaces to Guide Migration of Mesenchymal Stem Cells. Annika Kasten[1], Rolf Brenner[2], Tamara Naser[2], Jörg Fiedler[2], Petra Müller[1], Jürgen Groll[3], Joachim Rychly*[4]. [1]Rostock University Medical Center, Germany, [2]Department of Orthopaedics, Germany, [3]Department of Functional Materials in Medicine, Germany, [4]University of Rostock, Germany

Design of chemical as well as physical modification of implant surfaces to control functions of mesenchymal stem cells (MSC) is a great challenge in regenerative medicine. Fibronectin (FN) or RGD peptides as ligands for integrins are often used to coat surfaces for controlling adhesion mediated mechanisms in cells. Beside proliferation and osteogenic differentiation, migration of MSC to a defect site is critical for regeneration of bone. We generated lines of FN with varying width and distances between them to explore migration of MSC and a number of cell parameters involved in mechanisms of cell adhesion.

The material surfaces were prepared by coating cover slips using NCO terminated six armed star shaped polymers (NCO-sP (EO-stat-PO) to prevent protein adsorption and cell adhesion. Using a microprint technique, FN was immobilized to this surface, forming lines of 10-80 µm and gaps between them of 5-20 µm. Bone marrow derived human MSC were used in the experiments. Speed and directionality of cell migration were tested and correlated with a number of cellular parameters, like morphology of cells and nuclei, cell spreading, formation of the actin cytoskeleton, as wells as size and shape of focal contacts.

With decreasing line width, cells migrated faster with a stronger directionality. On 80 µm lines, two or three cells were able to adhere in parallel and formed cell-cell contacts, which enable a collective migration. On smaller FN lines, single cells adhered in a line and at smaller gaps between the lines of 10 or 5 µm, cells were able to bridge the lines, which mimic the situation of matrix fibrils in vivo. With reducing the width of FN lines, the actin cytoskeleton formed few strongly aligned fibers. Characteristic alterations in the formation of focal adhesions were also measured in dependence on the sizes of FN lines. On lines with lower width, focal adhesions became smaller and formed a round shape.

In conclusion, using lines of FN with varying sizes and gaps between them we were able to tune speed and directionality of stem cell migration. Further, the geometry of the adhesion substrate was translated into an internal organization of significant components of cell adhesion. The generation of defined adhesive surface patterns, like lines of FN, is suitable to control the biological responses of MSC for applications in regenerative engineering.

β2-adrenergic Receptor Plays an Important Role in Sympathetic Nervous System-regulated Orthodontic Tooth Movement. Haifeng Cao*[1], Xiaoxing Kou[2], Yanheng Zhou[3]. [1]Peking University School & Hospital of Stomatology, Peoples Republic of China, [2]Peking University School & Hospital of Stomatology, China, [3]Department of Orthodontics. Peking University School & Hospital of Stomatology, China

Sympathetic nervous system (SNS) may regulate skeletal homeostasis, but whether and how SNS contributes to the mechanical force-induced orthodontic tooth movement (OTM) remains unclear. In this study, we showed that β2-adrenergic receptor (Adrb2) mediated the enhancing capacity of SNS on OTM. We first confirmed that blocking SNS activity in jawbones by sympathectomy of superior cervical ganglion ectomy (SCGx) was capable of significantly reducing OTM. We next revealed that Adrb2$^{-/-}$ mice displayed significantly reduced OTM when compared to the control group. Adrb2 agonist isoproterenol (ISO) treatment accelerated OTM. Histopathological analysis showed that the number of Adrb2 positive cells increased in compressive region of periodontal ligament (PDL) after application of orthodontic force in rats. We further confirmed that the expression of Adrb2 in periodontal ligament cells (PDLCs) was upregulated by mechanical force through increase of intracellular Ca^{2+} concentration ($[Ca^{2+}]_i$). Furthermore, activation of Adrb2 in PDLCs promoted osteoclastogenesis via elevating RANKL/OPG ratio thus accelerated OTM. In summary, this study suggested that mechanical force-induced Adrb2 expression in PDLCs contributed to SNS-regulated OTM.

Anti-sclerostin Antibody Treatment of Renal Osteodystrophy. Sharon Moe*[1], Neal Chen[1], Christopher Newman[2], Jason Organ[1], Vincent Gattone[3], Michaela Kneissel[4], Ina Kramer[4], Matthew Allen[1]. [1]Indiana University School of Medicine, USA, [2]Indiana University, USA, [3]Indiana University School of Medicine, USA, [4]Novartis Institutes for Biomedical Research, Switzerland

Chronic Kidney Disease (CKD) is associated with abnormalities in bone quantity and quality leading to increased fractures. Recent studies suggest abnormalities of wnt signaling in animal models of CKD and elevated sclerostin levels in patients with CKD. The goal of this study was to evaluate the effectiveness of anti-sclerostin antibody treatment in an animal model of progressive CKD with low and high parathyroid hormone (PTH) levels. Cy/+ male rats (CKD) were treated without or with calcium in the drinking water at 25 weeks of age to stratify the animals into high PTH and low PTH groups, respectively, by 30 weeks. Animals were then treated with anti-sclerostin antibody at 100 mg/kg IV weekly for 5 doses, a single 20 ug/kg subcutaneous dose of zoledronic acid, or no treatment and sacrificed at 35 weeks. As a positive control, the efficacy of anti-sclerostin antibody treatment was also evaluated in normal littermates. The results demonstrated that the CKD animals with high PTH had lower calcium, higher phosphorus, and lower FGF23 compared to the CKD animals with low PTH. Treatment with anti-sclerostin Ab had no effect on any of the biochemistries, while zoledronic acid lowered dkk-1 levels. The anti-sclerostin antibody increased trabecular BV/TV in animals with low, but not high, PTH. Neither anti-sclerostin antibody nor zoledronic acid improved biomechanical properties in the animals. Cortical porosity was severe in high PTH animals and unaffected by either treatment. In contrast, in normal animals treated with anti-sclerostin antibody, there was an improvement in bone volume and biomechanical properties.

In summary, this is the first study to test the efficacy of anti-sclerostin Ab treatment on animals with advanced CKD. We found efficacy in improving bone volume only when the PTH levels were low.

Dabigatran etexilate, a new direct thrombin inhibitor, enhances bone mass, inhibits bone resorption and stimulates bone formation in mice. Judy Kalinowski[1], Sandra Jastrzebski[1], Hee Yeun Won[1], Faryal Mirza[2], Sun-Kyeong Lee[2], Joseph Lorenzo*[2]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut Health Center, USA

Thrombin converts fibrinogen to fibrin to form a fibrin clot. The commonly used anticoagulants, heparin and warfarin, act as direct or indirect thrombin inhibitors. Heparin therapy is a well-known risk factor for osteoporosis. Warfarin's effects are variable with studies showing either no effect or an increased osteoporotic risk. Recently, a newer class of thrombin inhibitors was approved for clinical use. Dabigatran etexilate (DE) is a direct inhibitor of thrombin's catalytic activity. We investigated the effects of DE on bone mass, bone turnover and osteoclast precursor cell number in mice. Eight-week-old male C57BL/6 mice were injected intraperitoneally with DE (8.5/mg/Kg twice daily) for 6 weeks. Control mice were injected with vehicle. Bone mass in the femurs of the DE-treated mice increased by 10% ($p<0.05$) as measured by DXA. Using µ-CT analysis, we found that trabecular bone mass in the femurs increased by 71% ($p<0.01$) with no change in cortical bone mass. We also found that serum CTX was decreased by 43-53% at 3 and 6 weeks ($p<0.01$ for both) and serum P1NP was increased by 52% in DE-treated mice ($p<0.01$). In addition, we found that DE-treatment significantly decreased the number of precursors of osteoclasts in the bone marrow of the mice as measured in two assays: in vitro culture, and flow cytometry. In the in vitro culture assays bone marrow macrophage cultures were treated with M-CSF (30 ng/ml) and either 10 or 30 ng/ml of RANKL for 4 days and TRAP-stained. We found that for both RANKL concentrations, the number of osteoclasts that formed in the cultures was decreased in cultures of cells from DE-treated mice (by 42 or 35%, respectively, $p<0.01$ for both). The percentage of osteoclast precursor cells in bone marrow was identified by flow cytometry (CD45R-, CD3-, CD11b-/lo, CD115+) and was decreased by 36% in DE treated mice ($p<0.01$). We also measured the serum levels of stromal cell-derived factor 1 (SDF-1) by ELISA in the mice since this cytokine regulates osteoclast migration and resorption as well as osteoblast formation. Surprisingly, DE treatment decreased serum SDF-1 levels by 74% ($p<0.01$), which may be one mechanism for its effects on bone resorption and bone formation. We conclude that DE-treatment in mice markedly stimulated bone formation and inhibited bone resorption, resulting in a significant net gain in bone mass. These results imply that DE may also enhance bone mass in treated patients who are at high risk for osteoporosis.

Dose response study of the effects of sclerostin antibody on cortical bone mass and strength in Brtl/+ mouse. David Barton*[1], Benjamin Sinder[1], Yuchen Yang[2], Joan Marini[3], Michelle Caird[2], Kenneth Kozloff[4]. [1]University of Michigan, USA, [2]University of Michigan, USA, [3]National Institute of Child Health & Human Development, USA, [4]University of Michigan Department of Orthopaedic Surgery, USA

In a number of animal studies, sclerostin antibody (Scl-Ab) has demonstrated its effectiveness for increasing bone mass and strength. Potential uses may be expanded beyond osteoporosis to other diseases including osteogenesis imperfecta (OI). We previously demonstrated a significant bone forming response of Scl-Ab in Brtl/+ mice, a model for OI, when administered for 2 weeks at 25 mg/kg, twice weekly (Sinder et al, JBMR 2013 28:73). To better understand the impact of dose on the response to Scl-Ab, a dose-response study was done to determine what dose(s) affect Brtl/+ such that

both geometric and mechanical characteristics of bone strength are sufficient to match those of untreated wild-type (Wt) mice.

In this study, 100 mice (50 WT; 50 Brtl/+) were separated into 5 dose-response cohorts and compared to a control group administered saline. Scl-Ab was administered twice per week from 3 weeks of age to 14 weeks at doses of 3, 6, 12.5, 25, and 50 mg/kg (n= 8-9 per group). Following euthanasia, femora were dissected and scanned by μCT. Mid-femoral cortical regions of interest were assessed for cross sectional geometric parameters. Femora were then tested to failure in 4-point bending, from which mechanical properties were assessed.

Brtl/+ and WT mice both showed a significant dose response in geometric measures including total area, cortical area and thickness, and bending moment of inertia (Fig 1). No significant difference in dose response between genotypes was found for these measures by linear regression models. Cortical thickness and cross-sectional area in Brtl/+ significantly exceed untreated Wt at doses of 25 and 50 mg/kg respectively. Mechanically, dose responses were found both in pre-yield measures of stiffness and yield load, and post-yield measures of ultimate load (Fig 2) and energy. Similarly, no significant dose response differences were found between genotypes by linear regression models. Brtl/+ stiffness, yield load, and ultimate load all significantly exceeded untreated Wt at 25 mg/kg.

In this study, doses less than 25 mg/kg, 2x/week for 11 weeks were sufficient to provide restoration of Brtl/+ function to untreated WT levels. These studies provide data supporting the dose response of Scl-Ab in a mouse model of OI.

The authors gratefully acknowledge Amgen and UCB Pharma for providing Scl-Ab and the NIH for providing funding (Grant AR062522).

MVNP Expression in Osteoblast Induces IGF1 to Increase EphrinB2/EphB4 and Osteoblast Differentiation. Jumpei Teramachi[1], Yukio Kitagawa[2], Jolene Windle[3], Laetitia Michou[4], Jacques P. Brown[5], Noriyoshi Kurihara*[6], G. David Roodman[6]. [1]The University of Tokushima, Japan, [2]Indiana University, USA, [3]Virginia Commonwealth University, USA, [4]Université Laval, Canada, [5]CHU de Québec Research Centre, Canada, [6]Indiana University, USA

We reported that 70% of patients with Paget's bone disease (PD) expressed measles virus nucleocapsid protein (MVNP) in their osteoclasts (OCLs) and that MVNP is not expressed in their osteoblasts (OBs). Further, transgenic mice with targeted expression of MVNP to cells in the OCL lineage form pagetic-like bone lesions that display both increased bone resorption and rapid new bone formation. In contrast, mice with $p62^{P394L}$ mutation ($p62^{MUT}$) linked to PD have increased bone resorption but do not have increased bone formation *in vivo*. EphrinB2/EphB4 were identified as key coupling factors for OCL/OB. EphrinB2 is produced by OCL and enhances OB function and bone formation through specific interactions with EphB4 on OB. We previously demonstrated by immunohistochemistry that EphrinB2 expression in OCL, and EphB4 expression in OB were dramatically increased in MVNP mice compared to WT mice. Further the gene-expression profiling studies by highly purified OCLs derived from MVNP, $p62^{MUT}$ and WT mice revealed that IGF1 expression was significantly enhanced in MVNP expressing OCL precursors compared to the other genotypes. We hypothesized that MVNP expressing OCL play a crucial role in the promotion of bone formation in PD via IGF1 signaling and EphrinB2/EphB4 coupling. We found that MVNP expressing OCL from patients with PD and MVNP transduced human OCL highly expressed EphrinB2 and IGF1 as compared to normal or EV transduced OCLs. To examine how IGF1 signaling contributes EphrinB2 expression in MVNP expressing OCL, we treated MVNP expressing OCL with anti-IGF1 which decreased their EphrinB2 levels. The expression level of EphrinB2 in MVNP OCL was decreased by anti-IGF1 (5μM). Further the PI3K inhibitor (LY294002) (5μM) and MEK inhibitor (V112A) (10μM) completely blocked EhrinB2 expression in OCL. We tested if purified mature OCL from MVNP or WT mice stimulated mesenchymal cell migration and differentiation toward the OB lineage from MVNP or WT mice bone as measured by EphB4 and osteocalcin levels by Western blot. Co-cultures of mature OCL and mesenchymal cells from MVNP mice bone significantly increased Eph4 and osteocalcin levels compared to co-cultures of WT OCL with WT mesenchymal cells or MVNP OCL with WT mesenchymal cells. Eph4 expression in co-cultures with MVNP OCL/mesenchymal cells were blocked with anti-mouse IGF1 (5μM). These results suggest that IGF1 contributes to increased bone formation induced by MVNP by enhancing EphrinB2 expression.

Bone turnover markers in a 24-month treatment study comparing efficacy of a cathepsin K inhibitor, MK-0674, to alendronate and denosumab in ovariectomized cynomolgus monkeys. Maureen Pickarski*[1], Mary Belfast[2], Brenda Pennypacker[3], Le Duong[3]. [1]Merck & Co., Inc., USA, [2]Merck & Company, USA, [3]Merck Research Laboratories, USA

Odanacatib (ODN), a selective and reversible inhibitor of cathepsin K (CatK), is currently in development for the treatment of postmenopausal osteoporosis. Here, we compared the effect of MK-0674, a highly orally bioavailable CatK inhibitor with similar potency and selectivity to ODN, to that of alendronate (ALN) and denosumab (Dmab) on bone turnover markers in ovariectomized (OVX) monkeys in treatment mode.Cynomolgus monkeys (10-27 yrs. old) were OVX-d 2 yrs prior to randomization into one of five groups (N=14-16/group): untreated control, MK-0674 at 0.6 mg/kg or 2.5 mg/kg (p.o., q.d.), ALN (30μg/kg; wkly, s.c.) or Dmab (2.5 mg/kg, wkly, s.c.) for 24 mo. A cohort of age-matched sham-operated animals was also included. Both doses of MK-0674 and ALN rapidly reduced bone resorption markers uNTX and sCTX to 70 to 90% vs. untreated control at month 5, and the reduction of these markers was maintained between 55 to 90% vs. control for the duration of the study. Dmab initially reduced uNTx and sCTx by 50-60% up to month 5; yet, these markers returned to baseline levels by study termination. Anti-Dmab antibody was confirmed to develop in 10 out of 14 monkeys treated with Dmab at month 12. As expected, ALN consistently reduced serum bone formation markers, BSAP and P1NP, by 60% and 70% relative to control, respectively. Dmab also reduced BSAP (30-50%) and P1NP (45-55%) compared to control. However, treatment with MK-0674 at both doses trended towards less reduction of BSAP and P1NP compared to ALN or Dmab. Trap-5b levels, a marker of osteoclast number, were reduced by ALN by 60% within 5 months post-dosing and levels remained suppressed for the duration of the study. In contrast, Trap-5b levels in animals treated with the low and high doses of MK-0674 continuously increased from 10-60% and 55-100% above control, respectively. Detectable Trap-5b levels in the Dmab group were consistent with the progressively reduced efficacy of this drug in monkeys. In summary, ALN reduced both bone formation and resorption markers in OVX-monkeys, while the modest effects of Dmab on bone turnover markers may be due to anti-drug antibody developed in this species. In treatment mode, MK-0674 reduced bone resorption markers similarly to ALN. Consistent with previous preclinical and clinical reports with ODN, MK-0674 showed less reduction of bone formation markers in these estrogen-deficient monkeys in treatment mode, suggesting that the bone formation sparing effects of CatK inhibitors differentiate this mechanism from those of currently available inhibitors of bone resorption.

Comparison of the Efficacy of Cathepsin K inhibitor MK0674 versus Alendronate and Denosumab in Restoring Bone Mass in the Treatment of Estrogen-deficient Cynomolgus Monkeys. Brenda Pennypacker*[1], Maureen Pickarski[2], Nancy Doyle[3], Aurore Varela[4], Le Duong[1]. [1]Merck Research Laboratories, USA, [2]Merck & Co., Inc., USA, [3]Charles River Laboratories, Canada, [4]Charles River Laboratories, Canada

Selective inhibitors of cathepsin K (CatK) are currently developed for the treatment of postmenopausal osteoporosis. The aim of this study was to evaluate efficacy of MK-0674 (MK), a highly orally bioavailable CatK inhibitor with similar potency and selectivity profile as odanacatib, compared to alendronate (ALN) and denosumab (Dmab) in ovariectomized (OVX) cynomolgus monkeys in treatment mode. Adult monkeys (10-27 yrs-old) were sham- (N=12) or OVX'd for 2-years prior to randomizing the OVX animals (N=14-16/group) into 5 groups: untreated-control, treated with MK (0.6 or 2.5mg/kg, q.d., p.o.), alendronate (ALN, 30μg/kg, wkly, SC) or denosumab (Dmab, 2.5mg/kg, weekly, SC) for 24-mo. DXA scans (Hologic Discovery A) for acquiring bone mineral density (BMD) of the whole body (WB), lumbar vertebrae (LV1-4), distal radius, hip and distal femur were performed at baseline, 6, 12, 18, and 24 mo. of treatment. Cortical and cancellous BMD were also examined concurrently in the distal radius by pQCT (XCT Research SA). LVBMD loss of 13% was observed in OVX- versus Sham-animals prior to the start of treatment. MK at both doses and ALN significantly increased LVBMD by mo.-6 vs. untreated controls. By mo.-18, MK at 0.6 or 2.5 mg/kg restored BMD of all sites to the respective levels of sham animals. At mo.-24, MK at both doses and ALN significantly increased BMD (8, 11, and 5% at WB; 11, 14, and 9% at LV; and 9, 18, and 13% at total hip, respectively vs. untreated-controls). MK at both doses significantly increased BMD in femoral neck (15 and 22%), distal femur (5 and 9%), and distal radius (7 and 11%), respectively, while BMD at these sites in ALN group were not different from controls. MK 0.6 mg/kg and ALN showed equivalent efficacy at most bone sites. However, MK at 2.5 mg/kg resulted in superior BMD gains at WB ($p<0.05$), femoral neck ($p<0.05$), and distal femur ($p<0.05$) compared to that in ALN. Due to anti-drug antibodies developed in 10 of 14 monkeys by mo.-12, the Dmab group showed only modest increases in LVBMD by 4% ($p<0.05$) and total hip BMD by 6% ($p<0.05$) vs. controls at mo.-24. Total and cortical BMD in the distal radius was significantly increased with MK 2.5 mg/kg compared to ALN and Dmab by pQCT at mo.-24. In conclusion, treatment with this CatK inhibitor rapidly and dose-dependently restored cortical and cancellous bone mass to Sham levels. The accrued BMD gains by MK-0674 at the high dose were generally greater than that achieved by ALN or Dmab in OVX-monkeys in treatment mode.

SU0172

Increased Periostin in Cortical Bone of Cathepsin K Knock-Out Mice is Responsible for Higher Cortical Bone Mass and Strength. Nicolas Bonnet*[1], Le Duong[2], Serge Ferrari[3]. [1]University Geneva Hospital (HUG), Switzerland, [2]Merck Research Laboratories, USA, [3]Geneva University Hospital & Faculty of Medicine, Switzerland

Cathepsin K (CatK, Ctsk) inhibition in preclinical models results not only in lower bone resorption but also in higher bone formation (BF) on both remodeling and modeling surfaces. The mechanisms for greater BF at modeling surfaces, including the periosteum, remain unexplained. Periostin (Postn) is a matricellular protein expressed in periosteum and osteocytes that mediates inhibition of sclerostin, beta-catenin signaling and skeletal response to loading. In vitro data suggest that periostin is a substrate for proteolytic degradation by CatK. We hypothesized that higher BF at modeling surfaces in Ctsk-/- mice might be related to high periostin levels in cortical bone. For this purpose, BMD, microstructure and cortical strength were evaluated in the progeny of Postn-/- x Ctsk-/- mice. Periostin protein and gene expression were analyzed by immunocytochemistry and qRT-PCR, respectively, on femur samples. Postn protein by immunostaining was more intense in Ctsk-/- osteocytes and periosteum surfaces vs WT, whereas Postn mRNA levels were similar in presence and absence of CatK. Postn-/-;Ctsk +/+ have lower femoral BMD, cortical volume (CtBV) and thickness (CtTh) whereas Postn+/+;Ctsk-/- have higher BMD, BV/TV, CtBV and CtTh compared to WT. Double heterozygous mice present similar phenotype as of Postn+/+;Ctsk+/- which tend to increase cortical and trabecular bone (NS). Removing both Postn alleles in Ctsk-/- mice, i.e. Postn-/-;Ctsk-/-, restored a WT cortical bone phenotype. Hence, the increases in ultimate force, stiffness and elastic energy in Postn+/+;Ctsk-/- (+15.9%, +19.2% and +40.5% vs WT, $p<0.01$) were absent in Postn-/-;Ctsk-/-. Plastic energy was significantly decreased in the double KO (-24.6% vs WT, $p<0.05$). In contrast, trabecular parameters at the distal femur and vertebrae were not affected by the ablation of periostin in Ctsk-/- mice. For example, at the vertebrae, Postn-/-;Ctsk-/- and Postn+/+;Ctsk-/- exhibit high BV/TV, respectively $25.1\pm1.1\%$ and $27.2\pm2.4\%$ vs 18.2 ± 1.8 for WT, both $p<0.001$. In conclusions, Cstk-/- mice present high levels of periostin in periosteum and in osteocyte. Postn deletion abrogates the high cortical structure of Cstk-/- mice without affecting the high trabecular bone phenotype. This implies that periostin could be a novel CatK-mediated physiological substrate in the periosteum, and in the absence of this protease, high periostin levels enhance the cortical bone adaptation to loading.

Osteoactivin/Gpnmb, A Negative Regulator of Osteoclastogenesis. Hilary Stinnett*[2], Samir Abdelmagid[1], Fouad Moussa[2], Gregory Sondag[2], Matthew Matthew Khol[2], Kimberly Novak[2], Nagat Frara[3], Fayez Safadi[1]. [1]Northeast Ohio Medical University, USA, [2]Northeast Ohio Medical University, USA, [3]Temple University, USA

Osteoactivin (OA/*Gpnmb*) was first identified by differential gene display in mutant osteopetrotic rats. The role of OA/*Gpnmb* in osteogenesis has been characterized and reported by our group. A recent study reported on OA/*Gpnmb* expression during osteoclastogenesis. To specify the critical role and mechanism of action of OA/Gpnmb in osteoclastogenesis, we characterized osteoclast phenotype of three genetically modified mouse models for OA/*Gpnmb*. These mice are: *D2J*, mutant for OA/*Gpnmb* characterized with nonsense loss-of-function mutation generating a truncated protein sequence; *D2J* wild-type (WT), *D2J*/*Gpnmb*+, generated by knocking in OA/*Gpnmb* alleles into *D2J* mouse; OA-null mouse (OA-KO), where OA is disrupted within the coding exons; and OA/*Gpnmb* transgenic mice (OATg), where OA/*Gpnmb* is overexpressed under the CMV-promoter. We hypothesized that OA/*Gpnmb* is a negative regulator of osteoclastogenesis. Osteoclastic phenotype examined by μ-CT analysis revealed a decrease in bone mass in the *D2J* and an increase in bone mass in OA-KO mice and OATg mice. Cortical thickness of *D2J* was significantly increased compared to *D2J*/*Gpnmb*+ WT mice. Cortical thickness of OATg mice was decreased, and no difference was observed between OA-KO and their wild-type littermates. Serum ELISA of CTX-1 was significantly lower in *D2J*, however, RANKL/OPG ratio were not different. In contrast, in OATg mice there was a decrease in RANKL/OPG ratio. Whereas, OA-KO mice displayed an increase in RANKL/OPG ratio. Bone marrow-derived osteoclast-progenitors (BM-OCP) isolated from mouse femurs and tibiae were differentiated into osteoclasts using RANKL and MCSF. In *ex vivo* cultures, number and surface area of TRAP-positive multinucleated osteoclasts were substantially increased in *D2J* and OA-KO compared to their WT counterparts. q-PCR analysis show increased expression of osteoclast markers in *D2J* and OA-KO compared to WT. Additionally, in *ex vivo* cultures, osteoclasts of *D2J* and OA-KO show increased ability to survive in the absence of MCSF due to delayed onset of apoptosis. RANKL signaling is enhanced in *D2J* and OA-KO osteoclasts as determined by increased phosphorylation of ERK, P38 and JNK in MAPK pathway. Most interestingly, AKT and GSK-3β phosphorylation in *D2J* and OA-KO osteoclasts were up-regulated, suggesting that mutation or lack of OA/*Gpnmb* results in increased osteoclast survival. Taken together, these data suggest that OA/*Gpnmb* works as a negative regulator of osteoclastogenesis.

Skeletal Retention and Urinary Excretion of Nitrogen-Containing Bisphosphonates Including Fluorescently-labeled Bisphosphonates in Rats. Mark Lundy*[1], Shuting Sun[2], Xuchen Duan[3], Charles McKenna[4], Gwyn Jeans[5], Roy Dobson[5], Michael Quijano[5], James Triffitt[6], R Graham Russell[7], Frank Ebetino[8]. [1]Indiana University School of Medicine, USA, [2]BioVinc LLC, USA, [3]Department of Developmenta Biology, Harvard School of Dental Medicine, USA, [4]Department of Chemistry, University of Southern California, USA, [5]Procter & Gamble, USA, [6]University of Oxford Nuffield Orthopaedic Centre, United Kingdom, [7]University of Oxford, United Kingdom, [8]University of Rochester, USA

InThe antiresorptive mechanism of action of nitrogen-containing bisphosphonates (N-BPs) used in the treatment of osteoporosis is comprised of a combination of bone affinity characteristics, which target BPs to bone, and inhibition of farnesyl pyrophosphate synthase (FPPS) within osteoclasts and osteoclast precursor cells. Their prolonged presence in bone is related to their affinity for hydroxyapatite (HAP) (Ebetino). Differences in distribution of BPs have been demonstrated in vivo using fluorescent BPs encompassing a range of mineral affinities (Roelofs, Turek). Fluorescent-BPs provide information on localization of BPs in cortical and cancellous bone, as well as penetration at bone surfaces and within osteocyte canaliculi. We have determined the mineral affinity of both parent BPs and fluorescent-BPs by measuring their binding on HAP columns and disks. The mineral affinity was determined relative to risedronate (RIS = 1.0). Zoledronate (ZOL) had higher affinity than RIS, while minodronate (MIN) was similar. The addition of fluorescent groups to RIS can increase (rhodamine 2 (RhR) = 1.45) or decrease (alexafluor 647 (AF647) = .75) mineral affinity relative to RIS in the order: ROX-RIS > ZOL > RhR-RIS > RIS = MIN > fluorescein (FAM)-RIS = 800CW-ZOL > FAM-ZOL > AF647-RIS > deoxyRIS > NE10790, although high affinity to HAP is retained for the entire group.

We further explored the impact of bone affinity in vivo on 24 hour urinary excretion after iv administration. Compounds were simultaneously injected in rats in one of the first reported head to head studies of N-BPs. This non-radioactive study was facilitated by LC-MS techniques. Approximately 90% of the amount excreted within 24 hours of both parent and fluorescent-BPs was excreted within 4 hours. The excretion within a 24 hour period relative to RIS, in order from high to low in vivo retention, was: alendronate > ZOL > RIS > etidronate > MIN > Ox-14 > neridronate > ibandronate = FAM-RIS > clodronate = AF647-RIS >> NE-10790. There was a similar but inverse relationship between urinary excretion and affinity to HAP, indicating that binding of BPs to HAP strongly influences their in vivo distribution and excretion profiles. The ability to alter bone affinity among BPs using fluorescent tags is a useful tool for exploring the localization and pharmacology of BPs.

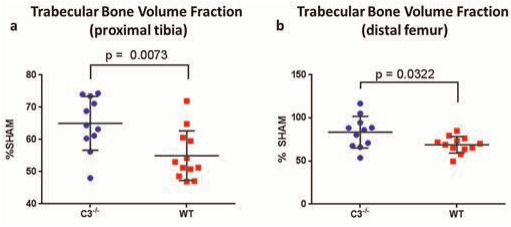
Absence of Complement Component 3 Protects Against Bone Loss in a Murine Model of Postmenopausal Osteoporosis. Danielle MacKay*[1], Thomas Kean[2], Kristina Bernardi[2], Feng Lin[3], Jim Dennis[4]. [1]Benaroya Research Institute, USA, [2]Benaroya Research Institute, USA, [3]Cleveland Clinic Foundation, USA, [4]Baylor College of Medicine, USA

Recent studies indicate that crosstalk between the immune system and bone extends far beyond what occurs during primary lymphopoiesis. Notably, we and others have demonstrated that differentiation of osteoblasts or osteoclasts, the two cell types maintaining bone homeostasis, is regulated by complement, an important part of the innate immune system. It is hypothesized that deficiency of complement component 3 (C3), the central part of the complement activation cascade, will reduce bone loss that results from estrogen deprivation in a model of postmenopausal osteoporosis. In addition to its contribution to our understanding of the role of complement in bone remodeling, this study points to a potential new target for osteoporosis therapy. Wild type and $C3^{-/-}$ mice on a C57BL/6 background were obtained from The Jackson Laboratory and bred and housed in accordance with the guidelines of the ACUC of Benaroya Research Institute. Only mice born on site were used in this study. At 6 weeks of age, ovariectomy or sham surgeries were performed under isoflurane anesthesia. At 12 weeks of age (6 weeks post-surgery), animals were sacrificed by CO_2 asphyxiation, and their uteri, hindlimbs, and vertebrae were harvested. Uterine mass validated successful ovariectomies. Hindlimbs and vertebrae were fixed for 72 hours in 10% formalin before being processed for micro-computed tomography or histomorphometry, respectively. The former was performed on a Scanco vivaCT 40 desktop scanner with a threshold of 300. Data are presented as a percentage and standard deviation with calculations made by dividing individual ovariectomized values by the mean sham operated value. Significance was calculated by unpaired Student's t-test. Micro-computed tomography revealed that the trabecular bone volume fraction retained in both proximal tibia metaphyses and distal femurs of ovariectomized $C3^{-/-}$ mice is significantly greater than that of their wild type counterparts (a, b). The increased trabecular number is clearly visible in 3-dimensional reconstructions from distal femur scans of ovariectomized $C3^{-/-}$ animals (c). This protection against bone deterioration is also evident in the lumbar vertebrae

of C3$^{-/-}$ mice, as reflected by significantly greater osteoid content and mineral apposition rates (d, e). Using a murine model of postmenopausal osteoporosis, our results demonstrate that absence of C3 protects against bone loss in key anatomical locations.



Figs a, b

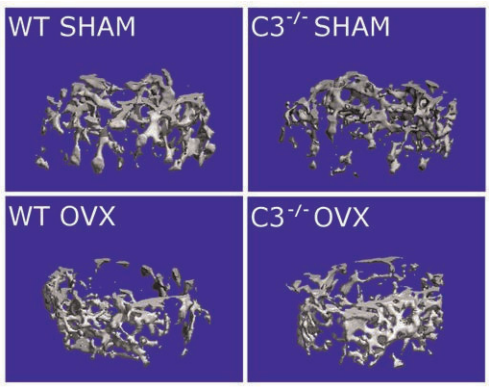


Fig c

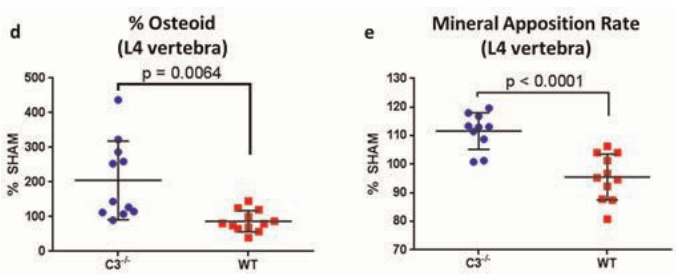

Figs d, e

For all graphs, data are presented as % sham, with each data point representing the value for each ovariectomized C3$^{-/-}$ mouse (blue circles) and each ovariectomized wild type mouse (red squares). Horizontal lines indicate the mean ± SD. (a) µCT values for the trabecular bone volume fraction as a percentage of mean sham values in the proximal tibia (b) µCT values for the trabecular bone volume fraction as a percentage of mean sham values in the distal femur (c) Images of 3D reconstructions of distal femur µCT scans (d) Histomorphometry values for the osteoid portion of the measured region of lumbar vertebra 4 as a percentage of mean sham values (e) Histomorphometry values for the mineral apposition rate in lumbar vertebra 4 as a percentage of mean sham values

Chronic administration of Liraglutide, a glucagon-like peptide-1 receptor agonist, improves trabecular bone mass and architecture in ovariectomised mice. Marie Pereira*[1], Jeshmi Jeyabalan[1], Mark Hopkinson[1], Mark Cleasby[1], Pascale Chavassieux[2], Jean Paul Roux[3], Chantal Chenu[4]. [1]Royal Veterinary College, United Kingdom, [2]INSERM UMR1033, Université De Lyon, France, [3]INSERM UMR1033 & Universite de Lyon, France, [4]Royal Veterinary College, United Kingdom

The increased incidence of type 2 Diabetes Mellitus among the aged is associated with an impaired skeletal structure and a higher prevalence of bone fractures. In addition, anti-diabetic therapies can also negatively affect bone mass. In this study, we tested the skeletal effects of chronic administration of two Glucagon-like peptide-1 receptor (GLP-1R) agonists and examined the expression of GLP-1R in bone tissue and cells. Twelve week-old female C57Bl/6N mice were ovariectomised (OVX) to induce bone loss. Four weeks after OVX, mice were treated with either: Liraglutide (LIR) 0.3 mg/kg/d, Exenatide (Ex-4) 10 µg/kg/d or saline for four weeks (n=10/group). Mice were injected with calcein and alizarin red at days 8 and 3 respectively, prior to euthanasia, to label bone-forming surfaces. Tibiae were harvested from these mice, bone micro-architecture determined by micro-CT and bone formation and resorption parameters measured by histomorphometric analysis. Serum was collected for evaluation of sclerostin levels, an inhibitor of bone formation. RNA was extracted from bone, bone marrow and bone cells for detection of GLP-1R using RT-PCR. GLP-1R distribution in bone was also examined using immunohistochemistry. Our results show that LIR significantly increases bone mass compared to controls, manifested by higher trabecular bone volume percent (+61%, $P<0.01$) and trabecular number (+46%, $P<0.05$). Trabecular pattern factor (-15%, $P<0.05$) and structure model index (SMI) (-9%, $P<0.05$) were significantly decreased, reflecting improvement in trabecular bone structure and connectivity, respectively. The cortical indexes were not significantly affected by LIR. Ex-4 treatment induced a similar tendency for improvement of trabecular mass and architecture, although the effects were non-significant, except for SMI (-9%, $P<0.05$). We found no significant effect of LIR on bone-forming and resorption surfaces, suggesting that bone turnover is not affected by LIR. We did not detect GLP-1R mRNA in bone devoid of bone marrow, osteoblasts and osteocyte cell lines, but it was expressed in bone marrow cells and mouse primary osteoclasts. The expression of GLP-1R in those cells was confirmed by immunocytochemistry. Serum sclerostin levels were significantly decreased by Ex-4 (-23%, $P<0.05$) but not by LIR. Our data suggest that GLP-1R agonists have beneficial effects on bone although their effects may be indirect. Further studies will determine their mechanisms of action in bone.

Combination Treatment of 1-34 PTH and Eldecalcitol Showed Synergistic Effect on BMD without Severe Hypercalcemia. Sadaoki Sakai*[1], Satoshi Takeda[2], Tomomaya Yamamoto[3], Tomoka Hasegawa[4], Norio Amizuka[5], Koichi Endo[6]. [1]Chugai Pharmaceutical Co., Ltd., Japan, [2]Chugai Pharmaceutical Co., Ltd., Japan, [3]Hokkaido University, Japan, [4]Hokkaido University, Japan, [5]Hokkaido University School of Dentistry, Japan, [6]Chugai Pharmaceutical Co., Ltd., Japan

Teriparatide and eldecalcitol (ELD, active vitamin D_3 derivative) have been used in osteoporosis treatment. It is suggested that teriparatide increases immature osteoblasts and ELD enhances differentiation into mature osteoblasts. On the basis of these actions of teriparatide and ELD on osteoblast differentiation, a combination treatment of teriparatide and ELD for osteoporosis may have additional effect on bone formation compared to mono-therapy of these drugs. However, combination treatment is possibly associated with a risk of hypercalcemia. In this study, we examined the effect of combination treatment of 1-34 PTH (PTH) and ELD on BMD, osteoblast number, bone histomorphometry and serum calcium concentration using a rat osteoporosis model.

Nine-week-old rats were ovariectomized (OVX) and either vehicle, PTH (10 µg/kg, s.c.), ELD (20 ng/kg, p.o.) or both were administered 5 days a week for 8 weeks from 4 weeks after surgery. Femur and serum were collected after 4 and 8 weeks treatment.

BMD of distal femur was lower than sham in vehicle treated group (vehicle) at 4 and 8 weeks. PTH, ELD and combined therapy (combination) increased BMD at 4 and 8 weeks and combination was higher than both PTH and ELD at 8 weeks. ES/BS was increased in vehicle and recovered in both PTH and ELD at 4 and 8 weeks, and further decreased in combination than PTH at 8 weeks. Ob.S/BS was increased in vehicle. PTH showed additional increase but ELD is lower than vehicle. Combination is comparable as vehicle. Meanwhile, MS/OS in ELD was higher than vehicle. The number of osteoblast, especially cuboidal-shaped osteoblasts, was increased in PTH. ELD decreased the total number of osteoblast but the ratio of flat-shaped osteoblasts was increased. Serum calcium was increased in ELD but there was no difference between ELD and combination.

In conclusion, combination treatment of PTH and ELD had aditive effect on BMD upregulation in OVX rats without hypercalcemia. These two drugs had different actions on regulation of osteoblast maturation. Further investigations are required but we suppose that PTH increases cuboidal-type osteoblasts and upregulates bone matrix production, whereas ELD normalizes bone remodeling cycle

and helps to mineralize the matrix through controlling the ratio of flat-shaped osteoblasts.

Effect of Sclerostin Depletion on Fracture Healing in the Mouse Model. Mohammad Alzahrani*[1], Frank Rauch[2], Reggie Hamdy[3]. [1]McGill University, Canada, [2]Shriners Hospital for Children, Montreal, Canada, [3]Shriners Hospital for Children, Canada

Purpose: Sclerostin is a secreted glycoprotein that interacts with LRP5 receptor on osteoblasts and inhibits the intracellular Wnt signaling pathway, leading to decreased bone formation activity by osteoblasts. When sclerostin is inactivated bone formation is therefore stimulated. This stimulation has been proven in fracture studies showing that sclerostin deficient mice have larger and stronger calluses with accelerated fracture healing. Also sclerostin antibody (Scl-Ab) injection has been studied in its ability to promote fracture resulting in accelerated and enhanced bone volume.These observations suggest that sclerostin inhibition and depletion show improved and accelerated fracture healing, but the effect of these two mechanisms have not been compared to asses the accurate effect of Scl-Ab. Therefore we designed a study to compare the effect of sclerostin depletion (sclerostin knockout) and inhibition (Scl-Ab injection).

Methods: 10-week-old male SOST knockout (KO) (N=40) and Wild-type (WT) (N=80) mice underwent insertion of a tibial intramedullary pin after which a tibial osteotomy was performed. The mice were divided into three groups: SOST KO (N=40), WT with Scl-Ab injection (N=40) and WT with saline injection (control) (N=40). The Scl-Ab group received an intravenous dose of 100mg/kg weekly starting on day 7. Each group was managed and sacrificed according to the specified protocol (Fig.1).

Results: The Scl-Ab group showed similar callus formation and density to the sclerostin KO group, especially on microCT results. At 28 days post-fracture there was no significant difference in callus BV/TV ratio (p=0.1) between both groups. Amount of trabecular thickness between the Scl-Ab group and KO group showed no significant difference at both 28 and 35 days post-fracture (p=0.16 and p=0.92, respectively). In addition the bone surface density (BS/TV) was comparable between the two groups (Scl-Ab group mean= 15.7 and KO group mean=17.5, p=0.06) at day 28 post-fracture, a similar result was apparent also at day 35 post-fracture. Also at day 28 post-fracture Bone Mineral density difference was not significant between the two groups (p=0.32).

Conclusion: Scl-Ab injections showed promising results, which were comparable to the complete depletion of sclerostin in this model. This may be implicated in management of different types of fractures in humans and also be applied in the treatment of fracture nonunions in combination with other management options.

Estrogen replacement but not dietary antioxidants from beetroot juice preserves alveolar bone in ovariectomized rats. Bryan D. Johnston*, Amanda B. Longo, Wendy E. Ward. Centre for Bone & Muscle Health, Faculty of Applied Health Sciences, Brock University, St. Catharines, Ontario, L2S 3A1, Canada

Introduction: Tooth loss is correlated with a greater decrease in whole body and femoral neck bone mineral density (BMD) in postmenopausal women. The loss of hip and vertebral BMD are likely mirrored by the loss of tooth-supporting, alveolar bone. Individuals with fewer teeth have limited food choices, compromising nutritional status and thereby may be at higher risk of chronic disease development, such as osteoporosis. While estrogen replacement is known to attenuate deterioration of bone tissues in postmenopausal women, the response of alveolar bone has not been studied. Moreover, given concerns with estrogen replacement, dietary approaches to maintain bone mass are of interest. Such dietary approaches could involve foods that are rich sources of antioxidants and nitrates as both are individually associated with higher BMD in postmenopausal women. Beetroot juice is an abundant source of dietary antioxidants and nitrates and thus may preserve alveolar bone. The objective of this study was to determine the potential bone sparing effect of estrogen replacement as well as a dietary strategy (beetroot juice) on alveolar bone in the well-characterized ovariectomized rat model.

Methods: Sprague Dawley rats were ovariectomized at 12 weeks and randomized to one of three groups (n = 14 per group): ovariectomy alone (OVX), estrogen replacement (E2) (17-β estradiol, 1.5 mg, 90-day, subcutaneous pellet from Innovative Research of America), and beetroot juice (BR) (provided as gelatinized beetroot juice containing 18.75 mg/day nitrates from James White Drinks). Rats were fed semi-purified diet (AIN93M) for 12 weeks at which time mandibles were collected. Hemimandibles were scanned at a 9µm resolution using micro-CT (Skyscan 1176). The following scanning parameters were used: 2 mm aluminum filter, 180˚ scanning rotation and 0.20˚ rotation step at 82 kV/298 µA. The region analyzed was the alveolar bone supporting the first mandibular molar.

Results: The E2 but not the BR group had a higher ($p<0.001$) bone volume fraction (BV/TV) than the OVX group. Trabecular separation was lower in the E2 group compared to both the OVX ($p<0.05$) and BR ($p<0.01$) groups. Trabecular thickness was higher ($p<0.01$) in the E2 group compared to the BR group alone. Trabecular number did not vary among groups.

Conclusion: E2 but not a beetroot intervention prevented deterioration of alveolar bone. The ability of other dietary components to preserve alveolar bone is an area of future study.

Maintenance of Proximal Tubule Phosphate Homeostasis Requires the Transcription Factor Ebf1. Jackie Fretz*[1], Tracy Nelson[2], Yougen Xi[2], Mark Horowitz[1]. [1]Yale University School of Medicine, USA, [2]Yale School of Medicine, USA

The transcription factor Early B Cell Factor 1 (Ebf1) is not only important for maturation of B lymphocytes, but has also been revealed to be integral for maturation of several cell lineages from mesenchymal progenitors. Whole body knockout mice have many problems including low bone mineral density and are severely runted. While there is a significant *in vivo* differentiation and mineralization defect in Ebf1-deficient BM cells, recent reports using Runx2- and Osx-cre specific deletions of Ebf1 have no bone phenotype. Our investigations have revealed that Ebf1-deficient mice have deficient renal maturation and function. Urine analysis revealed that Ebf1-deficient mice waste phosphate and calcium. While the ionized serum calcium level is normal, the mice are hypophosphatemic, have reduced expression of proximal tubule phosphate transporters, and alterations in proximal tubule maturation in the peripheral cortex. Administration of a high phosphate diet (1.5%) was able to partially reverse the runting present in these animals, increase bone density and quality (as assessed by micro-CT, histomorphometry, and biomechanical testing), as well as improve survival of the KO mice. Ebf1 deficient mice are also lipodystrophic (mediated by a direct role of Ebf1 in adipocyte maturation), and a combination diet of high fat (45%) and high phosphate improved survival, bone quality, and growth better than either high phosphate or high fat diet alone. These results identify a role for Ebf1 in the complex system of renal phosphate homeostasis and provides a mechanism for Ebf1 action in kidney to explain the mineralization deficiency seen *in vivo*.

Methylphenidate Impairs Skeletal Development In Female Rats. David Komatsu*[1], Lisa Robison[2], Melissa Vitale[2], Junho Lee[2], Michalis Michaelos[2], Jason Gandhi[3], Soyeh Paeng[2], Panayotis Thanos[2], Michael Hadjiargyrou[4]. [1]Stony Brook University, Dept. of Orthopaedics, USA, [2]Department of Psychology, Stony Brook University, USA, [3]Department of Physiology & Biophysics, Stony Brook University, USA, [4]New York Institute of Technology, USA

Methylphenidate (MP) is widely used to treat Attention Deficit Hyperactivity Disorder (ADHD), the most commonly diagnosed adolescent psychological disorder with a US incidence of ~9.5%. We previously showed MP to be detrimental to skeletal development in male rats. This study was conducted to test the hypothesis that MP adversely affects skeletal development in female rats. Four-week old female Sprague-Dawley rats were randomized to 5 groups ($n=12/T_x$): Water, Low-Dose MP (LD MP), High-Dose MP (HD MP), Water Pair-Fed to LD MP (Water LD PF), and Water Pair-Fed to HD MP (Water HD PF). Water groups received no MP. LD and HD MP received MP via their drinking water. Pair-fed groups had food restricted to their corresponding treatment groups' ad-lib consumption. After 13 weeks of treatment, HD MP rats gained less weight than Water (16%), LD MP (23%), and Water HD PF (19%) rats. Open field behavioral testing showed that HD MP rats were more active, with increases in movement time, distance, and velocity compared to Water, LD MP, and Water HD PF rats from 25 to 310%. LD MP rats were 10-52% more active than Water and Water LD PF. Length, anterior-posterior (AP) and medial-lateral (ML)

diameter were measured in tibiae, femora, and L5 vertebrae using calipers. Only tibiae showed differences with HD MP 4% shorter than LD MP and wider than Water on AP (10%) and ML (8%) axes. LD MP was 8% narrower than Water on the AP axis. Water HD PF showed ML increases of 9% and 7% compared to Water and Water LD PF, respectively. Femora were assessed by microCT at cortical (mid-diaphysis) and trabecular (distal metaphysis) regions. A 6% reduction in cortical thickness was seen for HD MP as compared to LD MP. Trabecular bone mineral density (BMD) was reduced by 2% in HD MP rats compared to both LD MP and Water. Water HD PF rats showed a similar 2% reduction in BMD compared to Water LD PF and Water. Compared to Water, trabecular volume was increased by ~12% in LD MP, Water HD PF, and HD PF. Three-point bending tests of femora revealed no differences. Overall, the effects of MP on skeletal development in adolescent female rats were mild. Pair-feeding removed body weight as a confounding variable at the low dose, but not at the high dose. This is likely due to the tremendous increases in activity seen in the high dose rats. This increase in activity was significantly higher than seen previously in male rats and may account for milder skeletal phenotype seen in female rats exposed to MP.

Osteoclastogenesis–inhibiting peptide W9 delivery stimulates new bone formation in expanded mid-palatal suture. Wei-Bing Zhang*. School of Stomatology, Nanjing Medical University, Nanjing, China, USA

Objective – The aim of the present study was to assess the effects of the WP9QY peptide on bone formation in the expanded palatal suture model.

Materials and Methods – Expanded palates of 6-week-old male C57BL 6 mice were either unstimulated or stimulated with W9 for 7 days. Histological observations and the Raman microspectroscopy assessments of the palatal bone as well as bone mineral density measurements were performed.

Results – Raman microspectroscopy analysis demonstrated that W9 (%increase = 35.33 $\pm$ 1.82, p = 0.007) formed significantly more bone at the palatal suture compared with vehicle samples at day 7. Alkaline phosphatase activity along the bone edges was markedly greater in the W9 groups compared with that in vehicle group at day 7. The levels of Trap activity of vehicle group were higher than of W9 group.

Conclusion-These results suggest that W9 delivery stimulates new bone formation in expanded mid-palatal suture.

PEGylation of NELL-1 Improves Pharmacokinetics and Systemic Osteogenic Therapy. Yulong Zhang*[1], Jin Hee Kwak[2], Juyoung Park[3], Chirag Chawan[3], Omar Velasco[4], Kambiz Khalilinejad[5], Jia Shen[1], Eric Chen[3], Pia Bayani[3], Sepideh Dolatyar[3], Greg Asatrian[3], Xinli Zhang[1], Chia Soo[6], Benjamin Wu[7], Kang Ting[1]. [1]University of California, Los Angeles, USA, [2]Department of Craniofacial Research Institute, School of Dentistry, University of California, Los Angeles, USA, [3]Department of Craniofacial Research Institute, School of Dentistry, University of California, Los Angeles, USA, [4]UCLA & Orthopaedic Hospital Department of Orthopaedic Surgery & the Orthopaedic Hospital Research Center, University of California, Los Angeles, USA, [5]Division of Associated Clinical Specialties & Section of Orthodontics, School of Dentistry, University of California, Los Angeles, USA, [6]Division of Plastic & Reconstructive Surgery, Department of Surgery, David Geffen School of Medicine, University of California, Los Angeles, USA, [7]Weintraub Center for Reconstructive Biotechnology, School of Dentistry, University of California, Los Angeles, USA

NEL-like molecule-1(NELL-1) is a pro-osteogenic secretory molecule shown to successfully prevent osteoporosis through intramedullary injection in ovariectomy-induced osteoporotic rats. However, the short half-life of native NELL-1 limits its application as a systemic therapy. Thus, the purpose of this study was to modify the structure of NELL-1 by PEGylation technology in order to improve its pharmacokinetics while maintaining its bioactivity and osteogenic potential *in vitro* and *in vivo*. PEGylated NELL-1 was prepared using three different types of polyethylene glycols (PEG):linear 5KDa, 20KDa, and branched 40KDa.First, when characterized by GPC and fluorometric assay, NELL-PEG-5K was found to yield the greatest amount of PEGylation (PEG degree increased from 14.2% up to 72.6%) and the most thermally stable conjugate (denature temperature increased from 49.75ºC to 63.42ºC) while maintaining a bioactivity *in vitro* comparable to that of unmodified NELL-1.Next, the pharmacokinetics and biodistribution of PEGylated NELL-1 was examined in CD-1 mice. The half-life of PEGylated NELL-1 *in vivo* was significantly improved from 5.5h to 15.5h, up to 31.3h(6-fold), while the biodistribution of NELL-PEG-5k at 48h revealed that more than 2-3 times amount of protein was distributed into bone tissue (femur, tibia, vertebrae, calvaria) compared to controls. Next, the systemic osteogenic capacity of NELL-PEG-5k was investigated by systemic administration in B6 mice(n=16, 1.25 mg/kg, q4d and q7d schedules) for 4 weeks. The femoral bone mineral density (BMD) measured by DXA showed a gradual and significant increase (16% for q4d, 17% for q7d) in the NELL-PEG-5k group compared to the baseline. Live-microCT and F-18 microPET revealed increased BMD and bone turnover rate in the NELL-PEG-5k group. MicroCT analysis revealed significant improvements in trabecular BMD volume(BV/TV), and structural values(Tb.Th, Tb.N, Tb.Sp) compared to control. In addition, H&E staining confirmed increased bone formation and trabeculation.OCN and TRAP immunostaining demonstrated increased osteoblastic and decreased osteoclastic activities in the NELL-PEG-5k group. These data suggest that PEGylation of NELL-1 not only improves its pharmacokinetics, but also preserves its bioactivity and systemic osteogenic effect *in vitro* and *in vivo*. The current findings hold promise for developing an effective systemic therapy of various osteodeficient disorders including osteoporosis and dysostosis syndromes.

Sharpin-deficient *Cpdm* mice display cortical thinning due to loss of osteoblasts and osteal macrophages. Anke Jeschke*[1], Philip Catala-Lehnen[2], Sabrina Sieber[3], Michaela Schweizer[4], Kristofer Wintges[2], Thomas Bickert[2], Michael Amling[5], Hans-Jürgen Keienkamp[3], Thorsten Schinke[6]. [1]Department of Osteology & Biomechanics, Germany, [2]Department of Osteology & Biomechanics, University Medical Center Hamburg Eppendorf, Germany, [3]Department of Human Genetics, University Medical Center Hamburg Eppendorf, Germany, [4]Center of Molecular Neurobiology, University Medical Center Eppendorf, Germany, [5]University Medical Center Hamburg-Eppendorf, Germany, [6]Department of Osteology & BiomechanicsUniversity Medical Center Hamburg Eppe, Germany

Cpdm mice, carrying a mutation of the *Sharpin* gene, are primarily known as a model of multi-organ inflammation. A previous study additionally revealed a low bone mass phenotype, yet the underlying causes remained to be identified. Here we have applied non-decalcified histology and histomorphometry to perform a thorough skeletal phenotyping of *Cpdm* mice. We show that defects of bone formation, but not increased osteoclastogenesis, are causative for osteopenia and thinning of cortical bone in *Cpdm* mice. This phenotype is associated with a near absence of osteal macrophages, a cell type identified recently as a positive regulator of endocortical bone formation. *Ex vivo* experiments demonstrated that calvarial osteoprogenitor cells from *Cpdm* mice lack osteal macrophages and fail to differentiate into osteoblasts. Likewise, bone marrow cells from *Cpdm* mice display impaired osteogenic differentiation, also confirmed by genome-wide expression analysis. Here we additionally found that *Cpdm* bone marrow stromal cells produce higher levels of Cxcl5 and lower levels of IL1-ra, an IL1 receptor antagonist preventing chronic inflammation. Taken together, these data do not only identify Sharpin as a physiological regulator of bone formation, they also provide additional evidence for the critical role of bone and immune cell interactions in skeletal remodeling. In particular, the *Cpdm* mice represent the first model, where a spontaneous deficiency of osteal macrophages is associated with cortical thinning, thereby further underscoring the physiological relevance of this particular cell type.

Soy Protein Isolate Inhibits High Fat Diet-Induced Senescence Pathways in Osteoblasts to Maintain Bone Acquisition in Rats. Jin-Ran Chen*[1], Oxana P. Lazarenko[2], Michael L. Blackburn[3], Thomas M. Badger[3], Martin J. J. Ronis[3]. [1]University of Arkansas for Medical Science, Arkansas Children's Nutrition Center, USA, [2]Arkansas Children's Nutrition Center, & The Department of Pediatrics, University of Arkansas for Medical Sciences, USA, [3]Arkansas Children's Nutrition Center, & The Department of Pediatrics, University of Arkansas for Medical Sciences, USA

Chronic consumption by experimental animals of a typical Western diet high in saturated fats and cholesterol during postnatal life has been demonstrated to impair skeletal development. However, the underlying mechanism by which high fat, energy dense diets affect bone forming cell phenotypes is poorly understood. Using peripheral quantitative computerized tomography (pQCT) analysis of the proximal tibial and vertebrae compression testing, we show that male weanling rats fed a diet containing 45% fat and 0.5% cholesterol made with casein (HF-Cas) for 6 weeks displayed lower bone mineral density and strength compared to AIN-93G-fed dietary controls. Substitution of casein with soy protein isolate (SPI) in the high fat diet (HF-SPI) prevented these effects. The bone sparing effects of SPI were associated with prevention of HF-Cas-induced osteoblast senescence pathways through suppression of p53/p21 signaling pathways. HF-Cas-fed rats had increased caveolin-1 and down-regulated Sirt1 leading to activation of PPARγ and p53/p21; whereas, rats fed HF-SPI suppressed caveolin-1and activated Sirt1 to de-acetylate PPARγ and p53 in bone. Treatment of osteoblastic cells with non-esterified free fatty acid (NEFA) (a mixture of NEFA with individual NEFA ratio and concentration similar to their appearance in HF rat serum) increased cell senescence signaling pathways. An isoflavone mixture

(at concentrations identical to that found in SPI diet rat serum) significantly blocked activation of senescence-associated β-galactosidase (SA-β-gal) and PPARγ/p53/p21 by NEFA. Over expression of PPARγ in osteoblastic cells triggered p53/SA-β-gal senescent signaling. Finally, replicative senescent osteoblastic cells and bone marrow mesenchymal ST2 cells exhibited similar behavior to cells treated with NEFA and bone cells *in vivo* in rats fed HF-Cas diet. These results suggest that: 1) high concentrations of NEFA occurring with HF intake are mediators of osteoblast cell senescence leading to impairment of bone development and acquisition; and 2) the molecular mechanisms underlying the SPI-protective effects involve isoflavone-induced inhibition of osteoblastic cell senescence to prevent HF-induced bone impairments. *Supported in part by ARS CRIS #6251-51000-005-03S (JRC).*

Staphylococcal lipoprotein is a potent inhibitor of osteoblast differentiation. Ok-Jin Park*[1], Jiseon Kim[2], Cheol-Heui Yun[2], Seung Hyun Han[1]. [1]Seoul National University School of Dentistry, South Korea, [2]Seoul National University, South Korea

Streptococcus aureus can cause osteomyelitis and septic arthritis resulting in the bone destruction where its lipoprotein is considered as a major bone-resolving component by stimulating osteoclast formation. We previously demonstrated that synthetic diacylated lipopeptide, Pam2CSK4 mimicking Gram-positive bacterial lipoproteins, increased osteoclast differentiation through up-regulation of RNAKL and down-regulation of osteoprotegerin in osteoblasts. In order to further elucidate the action mechanism, we investigated whether the bacterial lipoprotein affects osteoblast differentiation using Pam2CSK4 together with *S. aureus* wild-type (WT) and the lipoprotein-deficient mutant (*S. aureus*-Δ*lgt*). When mouse osteoblast cell line MC4 was treated with *S. aureus*-WT or Pam2CSK4, the osteoblast differentiation was significantly attenuated which such effect was not observed in the cells treated with *S. aureus*-Δ*lgt* under the same condition. Furthermore, Pam2CSK4 decreased the transcriptional activity of Runx2 and β-catenin, which are important transcriptional activators for osteoblast differentiation. In addition, Pam2CSK4 attenuated the expression of osteogenic marker genes, including alkaline phosphatase and bone sialoprotein. In contrast, IL-6 negatively affecting osteoblast differentiation was increased in the cells treated with *S. aureus*-WT or Pam2CSK4, but not with *S. aureus*-Δ*lgt*. In conclusion, these results suggest that lipoprotein is an important component of *S. aureus* for the attenuation of osteoblast differentiation through down-regulation of the Runx2 and β-catenin.

Velcade Inhibits the Ubiquitin Proteasome System in Mesenchymal Stem Cells to Enhance Fracture Repair. Xing Li*[1], Hengwei Zhang[2], Hani Awad[3], Matthew Hilton[4], Zhenqiang Yao[5], Michael Zuscik[6], Brendan Boyce[3], Lianping Xing[5]. [1]University of Rochester, USA, [2]Univeristy of Rochester, USA, [3]University of Rochester Medical Center, USA, [4]Duke University Musculoskeletal Research Center, USA, [5]University of Rochester, USA, [6]University of Rochester School of Medicine & Dentistry, USA

The Ubiquitin Proteasome System (UPS) regulates osteoblast (OB) differentiation from mesenchymal stem cells (MSCs) by promoting ubiquitination and proteasomal degradation of OB positive regulators, including Runx2, JunB and b-catenin, but it is not known if it or agents affecting its activity regulate fracture repair. To test this, we used an open tibial fracture model in C57B6 WT mice and found significantly increased expression of the ubiquitin E3 ligases, Smurf1, Itch and Wwp1 (fold increase vs day 0: 26±2, 17±3, 4±0.4, respectively) and of ubiquitinated proteins in callus tissues at day 7 post-fracture. We treated fractured mice with VELCADE (a proteasome inhibitor used to treat patients with multiple myeloma) or vehicle and found that VELCADE significantly increased callus volume (3.5±1.1 vs 1.1±0.4 mm^3 by mCT), bone area within callus (1.2±0.3 vs 0.7±0.2 mm^2 by histomorphometry), and bone strength (torsional rigidity: 1017±215 vs 688±214 N.mm/rad/mm; maximum torque: 28±4 vs 21±3 N.mm by biomechanical testing). We also fractured Nestin-GFP mice and found large numbers of $Nestin^+$ cells in tissue sections of fracture calluses and a >10-fold increase in $Nestin^+$ cells isolated from calluses compared to non-fractured tibial bone. FACS analysis showed that 70% of $Nestin^+$ cells from calluses are $CD105^+Sca1^+$ (surface markers of MSCs) and 80% of the $CD105^+Sca1^+$ cells are $Nestin^+$. VELCADE increased the % of $Nestin^+$ cells in fractured Nestin-GFP mouse calluses by 4-10-fold, but it had no effect on the % of $CD3^+$ T cells, $B220^+$ B cells or $CD11b^+$ macrophage/monocytes. Finally, we treated OB/myoblast progenitor C2C12 cells with VELCADE and found that it had no effect on cell migration to a CXCL12 gradient or on apoptosis, but it significantly increased cell growth (2±0.13-fold increase vs Ctl) and % of cells in the G2 phase of cell cycle (13±2 vs 8±0.6). Cells from calluses of mice or C2C12 cells treated with VELCADE had higher levels of ubiquitinated proteins and proteins known to be degraded via the proteasome, such as Runx2, JunB, and β-catenin, consistent with proteasome inhibition. In conclusion, our findings reveal a novel role for the UPS system in fracture repair to regulate MSC proliferation and OB differentiation. Thus, VELCADE or other UPS inhibitors may have utility as potential new therapeutic agents to enhance fracture repair in patients with impaired bone healing.

The Role of LXR in Glucocorticoid-Induced Muscle Wasting and Bone Loss. Jasmine Williams-Dautovich*[1], Rucha Patel[2], Carolyn L. Cummins[2]. [1]University of Toronto, Canada, [2]University of Toronto, Canada

Background: Glucocorticoids (GCs) have profound anti-inflammatory properties that are critical for the treatment of a wide range of diseases. Unfortunately, major metabolic side-effects, including osteoporosis and muscle wasting, remain a key limitation for the long-term therapeutic use of GCs. The glucocorticoid receptor (GR) and liver X receptor (LXR) are members of the nuclear receptor superfamily that regulate distinct but overlapping transcriptional programs. Our lab has found that LXRα/β-/- mice are resistant to developing hyperglycemia and hepatic steatosis, two detrimental side effects of long-term GC therapy, while retaining their therapeutic anti-inflammatory effect. The aim of this study was to determine whether LXRs are also involved in modulating GC-induced bone loss and muscle wasting.

Methods: Wildtype and LXRα/β-/- mice were given Dexamethasone (Dex, 50μg/day) in drinking water for 14 days and plasma osteocalcin and Trap-5b were measured. In vitro studies were performed with mouse myotube (C2C12), osteocyte (MLO-Y4), and osteoblast (MC3T3-E1) cell lines treated with Dex (100nM, 1μM) ± LXR antagonist (GSK2033, 100nM). Wildtype and LXR knockout mice were treated in vivo with Dex (5mg/kg), ± GSK2033 (40mg/kg) for 10 days. Gene expression was measured by QPCR for MuRF1, MAFbx and myostatin (muscle); and RANKL, OPG, osteocalcin, Col1a1 and TRAP (bone).

Results: The osteoblast marker osteocalcin was decreased with Dex treatment in both WT mice and LXRα/β-/- mice; whereas, the osteoclast marker TRAP-5b was increased only in Dex-treated WT mice. When cultured in the presence of LXR antagonist, in vitro cultured osteocytes were not protected against Dex-induced changes in osteocyte gene expression. Analysis of bone markers from Dex ± GSK2033 treated mice found no protective role for LXR antagonists on bone markers. However, it was found that the exposure of bone to the LXR antagonist was minimal, likely due to extensive hepatic metabolism of GSK2033. In vitro and in vivo studies in muscle found that the LXR antagonist treated groups were slightly protected from GC-induced muscle wasting, however, the effect did not reach statistical significance. Together, these data suggest that LXRs may play a role in modulating Dex-induced osteoclastogenesis (in vivo) but does not appear to significantly modulate GR target genes in osteocyte or muscle cell lines. Future studies are aimed at assessing the contribution of LXRs to GC-induced osteoclastogenesis.

Wnt3a potentiates myogenesis in C2C12 myoblasts through changes of signaling pathways including Wnt and NFκB. Jian Huang*[1], Chenglin Mo[2], Lynda Bonewald[3], Marco Brotto[3]. [1]University of missouri kansas city, USA, [2]University of Missouri-Kansas City, USA, [3]University of Missouri - Kansas City, USA

As bone cells produce Wnt3a, we postulated that Wnt3a might be a candidate molecule signaling from bone cells to muscle cells. To test this hypothesis, we have conducted a series of studies with concentrations of Wnt3a ranging from 0.1 to 10ng/ml on C2C12 myogenesis. A concentration as low as 0.5ng/ml can consistently increase both the number and the size of myotubes during differentiation, a finding that was confirmed morphologically (4,299 ± 594 μm2 untreated, vs.7,957 ± 1,269 μm2 for Wnt3a treated myotubes, $p < 0.001$) and also with the concomitant double staining of myosin heavy chain (MHC) and nuclei. When C2C12 myoblasts were exposed to 10ng/ml Wnt3a in differentiation media, this led to a 2-fold increase in the translocation of β-catenin to the nucleus compared to control suggesting that Wnt3a might stimulate the activation of the β-catenin signaling pathway in muscle cells. Under these conditions, increased number and size of myotubes (4,319 ± 642 μm2 untreated, vs. 9,833 ± 1,013 μm2 for Wnt3a treated C2C12, $p < 0.001$) was also observed. Furthermore, these potent effects of Wnt3a strongly correlated with the appearance of intracellular calcium oscillations (ranging from 150-500nM free calcium) in myotubes measured with Fura-2. To study the potential molecular signaling mechanism of Wnt3a function in C2C12 myoblast differentiation, we used the Mouse Signal Transduction PathwayFinder PCR Array which monitors the activity of 10 signaling pathways to quantitate changes in gene expression between the control and the Wnt3a-treated C2C12 cells. In Wnt3a treated C2C12 cells, compared to control, the expression of Axin2, Wnt5a, Gata3 and Adm was increased by 7.05 fold, 2.53fold, 2.85fold and 2.35 fold, respectively, while the expression of Hey2, Ifng, Icam1, Tnf and Lrg1,Tnf decreased by 2.23 fold, 4.56 fold, 2.79 fold, 2.79 fold and 4.85 fold, respectively. Genes that were increased with Wnt3a were components of the Wnt signaling pathway (Axin2, Wnt5a), JAK1, 3/Stat6 signaling pathway (Gata3) and Hypoxia signaling pathway (Adm). Genes that were decreased include the Notch

signaling pathway (Hey2), NFκB signaling pathway (TnF, Ifng, Icam1), and the Stat3 signaling pathway (Lrg1). These results suggest that Wnt3a may function through these pathways to regulate C2C12 myoblast differentiation.

Longitudinal Changes in Distal Lower-Extremity Muscle Area and Density after Chronic Spinal Cord Injury. Cameron Moore[1], B. Catharine Craven[1], Lehana Thabane[2], Jonathan Adachi[3], Alexandra Papaioannou[4], Lindsie Blencowe[5], Milos Popovic[6], Lora Giangregorio*[7]. [1]Toronto Rehabilitation Institute, Canada, [2]McMaster University, Canada, [3]St. Joseph's Hospital, Canada, [4]Hamilton Health Sciences, Canada, [5]Toronto Rehabilitation Institute, Canada, [6]University Health Network - Toronto Rehabilitation Institute, University of Toronto, Canada, [7]University of Waterloo, Canada

Background: Lower-extremity skeletal muscle atrophy and fatty-infiltration are linked to poor bone quality after spinal cord injury (SCI) and may offer potential therapeutic targets for treating osteoporosis. This study prospectively measured lower-extremity skeletal muscle cross-sectional area (CSA) and muscle density in a group of adults with chronic SCI and diverse impairment. Methods: Seventy individuals [50/20 m/f, mean (± standard deviation) age 48.9 ± 11.5 years; duration of injury 15.5 ± 10.0 years] with chronic (>2 years post-injury) SCI (C1-T12, AIS A-D) had a pQCT scan of the 66%-site of the calf at baseline and annually for 2 years. Mixed-effects models were used to examine longitudinal changes in muscle CSA and density. Linear regression models were created to identify baseline characteristics associated with 2-year muscle CSA and density change. Possible correlates selected *a priori* included: gender, age, height, weight, waist circumference (WC), age at injury, level of injury, injury duration, leg spasm frequency and severity scale score, calf-muscle lower-extremity motor score, wheelchair use, serum vitamin D level, and physical activity level. Results: Significant reductions in muscle CSA and density were observed over a 2-year period (adjusted mean difference ± standard error: -1.8±0.8 cm^2, $p<0.05$ and -1.2±0.5 mg/cc, $p<0.01$, respectively). High individual variability in 2-year muscle CSA change (range: -22.6 to 8.5 cm^2) and 2-year muscle density change (range: -8.6 to 6.4 mg/cc) were observed. A greater WC at baseline was associated with a reduction in CSA ($R^2 = 0.14$, $p<0.05$), and a lower weight and WC at baseline were associated with a reduction in muscle density ($R^2 = 0.26$, $p < 0.001$ and $R^2 = 0.20$, $p < 0.01$, respectively). Conclusion: Muscle CSA and density do not reach a "steady-state" after chronic paralysis. Continued atrophy and fatty-infiltration of skeletal muscle may have adverse implications for bone quality. Rehabilitation or pharmacological interventions able to prevent progressive declines in muscle status may have therapeutic potential for augmenting bone quality. We were able to explain a small proportion of the variability in muscle change; continued investigation to determine the cellular mechanisms responsible for ongoing changes in muscle CSA and density are warranted.

SU0193

Lower Extremity Muscle Size, Density and Function Is Associated with Indices of Bone Quality in Individuals with Chronic Spinal Cord Injury. Jenna Gibbs*[1], Catharine Craven[2], Cameron Moore[3], Lehana Thabane[4], Alexandra Papaioannou[5], Jonathan Adachi[6], Milos Popovic[2], Neil McCartney[7], Lora Giangregorio[1]. [1]University of Waterloo, Canada, [2]University Health Network - Toronto Rehab - Lyndhurst Centre, Canada, [3]University of Waterloo, Canada, [4]McMaster University, Canada, [5]Hamilton Health Sciences, Canada, [6]St. Joseph's Hospital, Canada, [7]Brock University, Canada

Individuals with spinal cord injury (SCI) experience substantial losses in muscle cross-sectional area (CSA), density and function in the lower extremities, which may have significant implications for bone quality several years post-injury. Purpose: To examine the association between muscle CSA, density and function, and indices of bone quality among a sample of adults with chronic SCI. Methods: Baseline data from sixty-five participants (45 men and 20 women) with chronic SCI (C2-T12 ASIA Impairment Scale [AIS] A-D; ⩾2 years post-injury) in a two-phase prospective, observational study were examined. Calf muscle CSA (adjusted for tibia length, cm^2m) and density (mg/cm^3), and indices of bone quality (trabecular bone mineral density (BMD) (mg/cm^3) at the distal tibia (4% tibia length) and cortical thickness (CTh) (mm), cortical CSA (mm^2), cortical BMD (mg/cm^3) and polar moment of inertia (PMI) (mm^4) at the tibial shaft (66% tibia length)) were measured using peripheral quantitative computed tomography. Plantar flexor lower extremity motor scores (pf-LEMS) were used as clinical measures of muscle function. Pearson's correlations and linear regression were performed to determine the strength of the muscle-bone relationships. Results: Participants had a mean age of 49.2±11.9 years and were 15.3±9.8 years post-injury (LEMS: 11.8±16.1; 30.8% LEMS>20). Positive correlations were found between indices of bone quality and muscle CSA (r=0.458-0.563, $p<0.001$), muscle density (r=0.245-0.473, $p<0.05$), and pf-LEMS (r=0.410-0.678, $p<0.001$). Muscle density was the only muscle variable associated with cortical BMD (r=0.383, p=0.002). When controlling for gender and duration of injury, pf-LEMS had the strongest associations with trabecular BMD (b=7.21 [5.06, 9.37], $p<0.001$) and CTh (b=0.08 [0.04, 0.13], $p<0.001$). When controlling for gender, duration of injury, and injury completeness, muscle CSA had the strongest association with PMI (b=744.7 [240.6, 1248.7], p=0.004) and cortical CSA (b=2.53 [0.43, 4.62], p=0.019); whereas, muscle density had the strongest association with cortical BMD (b=1.87 [0.70, 3.05]). Conclusion: Our findings demonstrate that lower extremity muscle CSA is more strongly associated with bone geometry and cortical CSA at the tibial shaft; whereas, muscle density and function are more strongly associated with tibial BMD and structure. Future prospective research is needed to assess the role of muscle atrophy in the manifestation of osteoporosis in SCI.

Mechanical Stimulation Induced Musculoskeletal Adaptations Are Responses to Manner of Loading via Oscillatory Electrical Muscle Contraction and Dynamic Hydraulic Flow Stimulation. Minyi Hu*[1], Hoyan Lam[2], Robbin Yeh[2], Morgan Teeratananon[2], Yi-Xian Qin[3]. [1]Stony Brook University, USA, [2]Stony Brook University, USA, [3]State University of New York at Stony Brook, USA

Mechanotransductive signals through fluid flow stimulation, e.g., intramedullary pressure (ImP), have been shown effective in bone adaptation. Muscle compressions may increase vessel pressure gradient that can directly increase ImP. To elucidate the bone-muscle relationship aided by mechanical loading, the aim of this study was to evaluate the effects of oscillatory electrical muscle stimulation (MS) and dynamic hydraulic flow stimulation (DHS) on musculoskeletal adaptation in a rat functional disuse model. For MS, 6-months-old female SD retired breeder rats were divided to groups with n=8: 1) baseline, 2) age-matched, 3) hindlimb suspended (HLS), 4) HLS+1Hz, 5) HLS+20Hz, 6) HLS+50Hz, and 7) HLS+100Hz. For DHS, 5-month-old female SD virgin rats were assigned to 5 groups: 1) baseline (n=15), 2) age-matched (n=12), 3) HLS (n=10), 4) HLS+static (n=10); 5) HLS+DHS (n=14). Stimulations were given to right quadriceps (MS) and tibiae (DHS) of the experimental rats for 10min/day (MS) and 20min/day (DHS), 5 days/week for 4 weeks. Distal metaphysis of the femur (MS) and proximal metaphysis of the tibia (DHS) were scanned for trabecular bone morphology using a microCT. Right quadriceps (MS), soleus and gastrocnemius (DHS) were cross-sectioned and H&E stained. Muscle fiber areas were determined by Image J. HLS significantly reduced trabecular bone quantity and quality. MS at 20Hz and 50Hz led to increases in BV/TV by 143% ($p<0.05$) and 147% ($p<0.01$), respectively. Stimulation at 100 Hz showed an 86% increase in BV/TV. Conn.D, Tb.N and Tb.Sp were also significantly affected by MS at 20Hz, 50Hz and 100Hz (Figure 1A). Animals with DHS at 2Hz showed an increase in BV/TV by 83% ($p<0.001$). Conn.D, Tb.N, and Tb.Sp were also significantly affected by DHS at 2Hz (Figure 1B). HLS led to muscle atrophy and strongly reduced muscle fiber cross-sectional areas compared to age-matched control. Load-induced improvements on muscle fiber growth were observed with MS treatment at 50Hz (Figure 2B), but not with DHS (Figure 2A). DHS provides a relatively passive stimulation on muscle compared to MS, and was insufficient to reduce muscle atrophy. Moreover, as a relatively more active stimulation, MS was only effective at certain optimal loading condition. The current effective DHS loading parameters may be suitable for bone cell responses but not for muscle fiber responses. Further investigations are needed to optimize loading conditions and to determine downstream mechanisms.

Dkk-1 secreted by bone cells prevents mice against osteoarthritis. Thomas Funck-Brentano*[1], Wafa Bouaziz[2], Caroline Marty[1], Valerie Geoffroy[3], Eric Hay[4], Martine Cohen-solal[5]. [1]Inserm U1132, France, [2]INSERM U606, France, [3]INSERM Unit 1132, France, [4]INSERM u1132, France, [5]Hôpital Lariboisière, France

Objective: Characteristics of osteoarthritis (OA) are cartilage loss and subchondral bone changes. The regulation of Wnt pathway is crucial for bone and cartilage metabolism and homeostasis. We have previously shown that the Wnt/β-catenin pathway is activated mainly in bone structures and in articular cartilage in mice with OA. As a crosstalk takes place between bone and cartilage, we here investigated the impact of the inhibition of the Wnt pathway specifically in bone cells during the development of OA.

Methods: OA was triggered in mice by joint instability by induced partial meniscectomy (MNX). We investigated the impact of the inhibition of bone Wnt pathway in mice overexpressing Dkk1 in bone cells (2.3 Col1-Dkk1Tg) at baseline and 6 weeks after MNX. Moreover, we tested the effects of Dkk-1 in chondrocyte metabolism using the supernatant transfer assays and the expression of matrix metalloproteinases.

Results: The Wnt/β-catenin pathway was activated in both bone and cartilage, predominantly in osteocytes of subchondral bone and in osteophytes, and in articular cartilage throughout the development of OA. The number of Dkk1(+) chondrocytes was high at baseline (84.2 ± 3.1%) and decreased markedly during the course of OA from week 4 (14.4 ± 3.8%) to week 6 (5.7 ± 1.6%). At baseline, Dkk1-Tg mice had lower bone volume which was further reduced in MNX knees. Dkk1-Tg experienced a lower OA score than WT mice (5.1 ± 0.63 vs 8.4 ± 0.6, p=0.002) independently of the expression of Dkk1 in chondrocytes. This was accompanied by a reduction of the subchondral bone and osteophyte volume. However, addition of rhDkk1 or of supernatant of osteoblasts derived from Dkk-1-Tg mice in chondrocyte cultures promoted the chondrocytic expression of MMP-3, -13 and ADAMTS-4. In contrast, a decreased expression of proteases was observed in the supernatant of pre-exposed osteoblasts with Dkk1. Because Dkk1-Tg osteoblasts produced low VEGF, we tested whether VEGF could mediate the anti-catabolic effect observed in vivo. We found that blocking VEGF in the supernatant of osteoblast cultures reversed the expression of MMPs by chondrocytes.

Conclusion: We here confirm that Wnt is mainly activated in bone of OA joints. Inhibition of Wnt pathway by Dkk1 overexpression in bone decreased the severity of OA by reducing VEGF production. Our data show that targeting bone could be an efficient approach for the treatment of OA.

Early Diagnosis of Osteoarthritis through Detecting Articular Chondrocyte Apoptosis Using a Minimally Invasive Fluorescent Peptide Probe. Xiang-Guo Che*[1], Lian-Hua Chi[1], Gyoung-Ho Cho[1], Na-Rae Park[2], Min-Su Han[1], Clara Park[3], Seung-Hee Han[1], Gyoung-Hwa Kim[1], Byung-Heon Lee[1], Je-Yong Choi[4]. [1]Kyungpook National University, School of Medcine, South Korea, [2]Kyungpook National University School of Medcine, South Korea, [3]Kyungpook National University School of Medicine, South Korea, [4]Kyungpook National University, School of Medicine, South Korea

Early diagnosis of osteoarthritis (OA) at a reversible period of disease progression is essential to prevent further cartilage degeneration and for treatment of OA. However, current methods of OA diagnoses depend on radiography or MRI, which can only detect late-stage OA or is costly for popular use. As apoptosis of articular chondrocytes occurs during the early phase of OA, detection of early chondrocyte apoptosis may allow for the diagnosis of OA within its reversible period. ApoPep-1 is a peptide that binds to apoptotic and necrotic cells and seldom binds to live cells. The receptor for ApoPep-1 is the histone H1.2 that is exposed on the surface of apoptotic cells. Here we test the use of ApoPep-1 to serve as a specific and easily accessible diagnostic tool for early, reversible OA. *In vitro* analyses of ApopPep-1 resulted in its binding to staurosporine-induced apoptotic chondrocytes.For *in vivo* analyses, C57BL/6 mice (*n*=6/group) received sham or destabilization of the medial meniscus surgery. In the latter mice, OA is considered to be reversible between 1 and 4 weeks post-surgery based on the OARSI criteria. Mice were injected a Cy7.5-labeled ApoPep-1 probe or control substance intravenously at 1, 2, 4, and 8 weeks after surgery. In vivo imaging was performed at 0.5, 2, 4, 8, 12, 24 hours post injection. Higher levels of ApoPep-1 signals were detected in the knees of OA mice as early as 2 weeks post surgery and intensified with OA progression. Signals were detectable in OA mice from 30 minutes post-injection, and disappeared within 12 hours of injection. No signals in the kidney or liver were detected by 12 hours after injection, indicating the rapid removal of ApoPep-1 from the body. TUNEL and immuno-fluorescence staining at 2 weeks post-surgery revealed that ApoPep-1 signals were strongly correlated with degenerative cartilage areas and reduced type II collagen, and were co-localized with MMP13, a marker of cartilage degradation. These results suggest that the ApoPep-1 probe binds to apoptotic chondrocytes even at early stages of OA, which indicate that ApoPep-1 may be used as a novel imaging probe to detect OA at its reversible state.

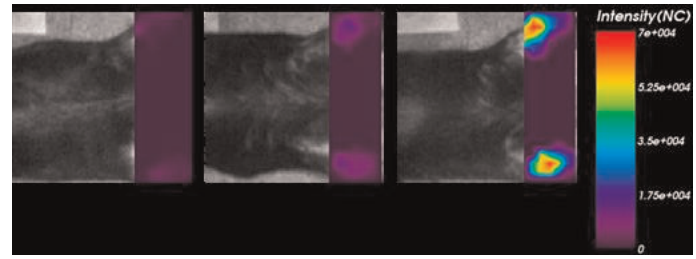

Figure. Early osteoarthritis (OA) is detected in mice 2 weeks after OA surgery by the ApoPep-1 probe

Estrogen status in experimental osteoarthritis determines extent of chondrocyte apoptosis following injury. Paul Fanning*[1], Linda Xie[2], Christopher Raskett[2], David Ayers[3]. [1]University of Massachusetts Medical School, USA, [2]UMass Medical School, USA, [3]UMass Memorial Medical Center, USA

Small animal models of osteoarthritis (OA) have shown that female mice develop less OA than males, and that ovariectomized (OVX) female mice develop worse OA than female mice with intact ovaries. One hypothesis is that estrogen (E2) may be a chondro-protective molecule. We have tested this hypothesis by surgical induction of OA in female mice and quantified articular chondrocyte apoptosis using the TUNEL methodology. The following experimental conditions were combined with surgical induction of OA (destabilization of the medial meniscus; DMM) and ovariectomy surgery (OVX) or sham-OVX and/or 17beta-estradiol 3- benzoate (E2) injections as follows: 1) OVX was performed on female mice 2 weeks prior to the DMM surgery (n=7). 2) OVX were performed on mice 2 weeks prior to DMM and treated with E2 injections (s.c.) of 1.92mg/kg every 4 days following OVX (n=7). 3) The control group consisted of sham-OVX performed 2 weeks prior to DMM (n=7). All mice were sacrificed at 4 days after DMM surgery. Results showed that female mice with intact ovaries developed significantly less apoptosis (TUNEL positive cells) than OVX-DMM females (34% reduction; $p<0.01$). There were significantly less total apoptotic cells in the superficial-middle zone as well as less apoptotic cells in a clearly defined lesion area within the superficial-middle zone. Additionally, mice with intact ovaries developed smaller cross sectional OA lesion areas (48% reduction; $p<0.01$), as well as smaller width (36% reduction; $p<0.01$) and height (24% reduction; $p<0.01$) of the lesion margins compared to OVX-DMM mice. There was significantly less apoptosis (31% reduction; $p<0.01$) in OVX-DMM mice with E2 injection as compared to OVX-DMM mice without E2 injection. There was no significant difference in apoptosis between the intact ovaries group and OVX-DMM + E2 treatment group. E2 treatment did have a modest but significant reduction in lesion width (9% reduction; $p<0.05$). These results indicate that estrogen presence results in significantly less numbers of apoptotic chondrocytes following DMM compared to OVX-DMM mice. These data suggest that estrogen may have direct anti-apoptotic effects after an induction of injury to the joint. We also propose that since early estrogen intervention in OVX-DMM mice can reduce apoptosis in OA mice, more acute anti-apoptotic based medical interventions following knee injury can be made that may alter the progression of later OA stages.

Subchondral Bone Health is Compromised in Post-Traumatic Osteoarthritis. Brett Tonkin[1], Natasha Jansz[2], Evange Romas[3], Natalie Sims[4], Nicole Walsh*[5]. [1]St Vincent's Institute of Medical Research, Australia, [2]St Vincent's Institute of Medical Research, Australia, [3]St. Vincent's Hospital Melbourne, Australia, [4]St. Vincent's Institute of Medical Research, Australia, [5]St Vincent's Institute of Medical Research, Australia

Purpose: The destabilisation of the medial meniscus (DMM) mouse osteoarthritis (OA) model is a commonly used model of post-traumatic OA. We sought to determine how DMM-induced joint injury impacts tibial subchondral bone, and how this relates to onset and progression of articular cartilage damage.

Methods: 12-week old male C57BL/6 mice underwent DMM or sham surgery on the right knee; left knees served as contra-lateral controls. In vivo micro-CT was performed prior to surgery and at 4, 8, and 12 weeks post-surgery. Bone volumes were quantified using novel a method optimized to assess bone of varying mineralization states. Limbs from separate groups of mice were also collected for OARSI histologic assessment.

Results: Pre-surgery bone volume/tissue volumes (BV/TV) were similar in all limbs. Consistent with increased loading, a focal increase in medial subchondral bone BV/TV was observed in DMM-OA tibiae compared to sham from 4 weeks post-surgery. BV/TV in the lateral subchondral bone and tibial metaphyseal trabecular bone were similar in all limbs, indicating no systemic effect of DMM-OA on bone structure.

However, medial subchondral BV/TV of DMM-OA tibiae and contra-lateral tibiae were similar, suggesting an influence of altered gait on the contralateral limb. Aggrecan loss and cartilage erosion was evident in the medial compartment of DMM-OA tibiae from 4 weeks post-surgery. Interestingly, the medial subchondral bone in DMM-OA tibiae from 4 weeks post surgery was not healthy: it resembled osteonecrotic bone with many empty osteocyte lacunae present. Furthermore, the number of empty osteocyte lacunae at this site, negatively correlated with the width of overlying aggrecan-positive (healthy) cartilage suggesting a relationship between aggrecan loss and subchondral bone health in DMM-OA.

Conclusions: Focal accrual of medial subchondral bone occurs early in DMM-OA tibiae alongside cartilage damage. Similar to human OA, osteocyte cell death in subchondral bone is a feature of DMM-OA and may be in part a result of mechanical changes or biochemical signals induced by aggrecan loss in articular cartilage. This osteocyte cell death could also contribute to local changes in bone integrity, vascularization or cartilage. Finally altered bone structure in the contra-lateral tibiae of DMM-OA mice, suggests that increased subchondral bone per se does not affect overlying cartilage, and serves to highlight the need to include sham-operated mice when using this model.

Novel high-throughput molecular techniques have the potential to enhance our understanding of the mechanisms underlying tissue differentiation and musculoskeletal disease. The purpose of this investigation is to characterize variation within and among different types of musculoskeletal tissues, including both normal and diseased states. With this information, novel biomarkers can be identified and used directly for tissue engineering and molecular therapeutic applications. In this investigation, RNA sequencing was performed on 118 primary musculoskeletal tissues including bone, cartilage, muscle, ligament, and tendon. Multiple disease states, including but not limited to diabetes, degenerative rotator cuff, osteoporosis and osteoarthritis are represented. Molecular findings based on RNA-seq data were correlated with clinical grades of diseased osteoarthritic cartilage. Cartilage specimens were graded using a modified 5-point scale of Collins. Grade 0 tissues were considered normal non-arthritic tissues, while grades 1 through 4 reflected increasing levels of degeneration. Normal and diseased cartilage tissues were prepared using a novel zero-gravity digestion method. RNAseq profiles for each grade of osteoarthritis were subjected to a series of quality control and data filtering measures to reduce the potential impact of any sampling artifacts. Both uni- and multi-variate statistical approaches (ANOVA, Bayesian Inference, hierarchical clustering, and PCA), assisted by recent and versatile software packages (PVClust, EdgeR, DESeq, BaySeq, Bioconductor, and Partek) were used to resolve gene expression differences between grades of osteoarthritis. Our data confirms the known validity of osteoarthritic biomarkers, and identifies novel therapeutic targets for the treatment of osteoarthritis. These techniques can be applied to the identification of novel therapeutic targets for the treatment of other musculoskeletal disease states beyond osteoarthritis. High-throughput RNA-seq has important implications for the fields of tissue engineering and therapeutic drug discovery because of the ability to rapidly conduct comprehensive assessments of the molecular mechanisms that define tissue-specific phenotypes.

Elevated Mean Arterial Pressure Is Associated With Higher Rate of Subchondral Bone Turnover in Patients With Knee Osteoarthritis. Yan Chen*[1], Min Guan[2], Frankie Leung[3], Xu Cao[4], Xiaohua Pan[5], William Lu[6]. [1]The University of Hong Kong, Hong Kong, [2]Center for Human Tissues & Organs Degeneration, Shenzhen Institutes of Advanced Technology, CAS, China., China, [3]Department of Orthopaedics & Traumatology, Faculty of Medicine, the University of Hong Kong, Hong Kong; China, China, [4]Johns Hopkins University, USA, [5]Department of Joint Surgery, Shenzhen People's Hospital, Jinan University Second College of Medicine, China., China, [6]The University of Hong Kong, Hong Kong

Purpose: Epidemiologic data showed that frequency of OA is much higher (40%) in hypertensive patients than in non-hypertensive individuals (25%). We previously demonstrated that hypertensive patients displayed bone loss at subchondral plate, indicated possible association between blood pressure and subchondral bone turnover. Furthermore, our animal study found that elevated level of TGF-ß1 signaling in subchondral bone induced higher rate of subchondral bone turnover and OA progression. However, the pathological relationship between hypertension and OA is still not clear. Therefore, this study investigated the association between mean arterial pressure (MAP) and subchondral bone turnover in knee OA patients.

Methods: Seventy patients undergoing total knee arthroplasty (TKA) for primary OA were recruited and divided into two groups according to their MAP: normal (n=33) and elevated (n=37). The tibial plateaus removed during TKA were collected and evaluated using micro-CT, histology and immunohistochemistry. Patients' clinical data were also collected and analyzed.

Results: No significant differences were detected in patients' age, gender, BMI, etc. between OA patients with normal or elevated MAP (table 1). Patients with elevated MAP presented lower bone volume fraction(BV/TV) and trabecular number(Tb.N) while higher structure model index(SMI) of medial subchondral bone than normal MAP group. However, the results were reverse on lateral side. (Fig.1 & table 2). Histology showed more obvious formation of new bone and osteoid islets in subchondral bone marrow in elevated MAP group(Fig.3). Compared with normal MAP group, elevated MAP group showed higher number of $TRAP^+$ osteoclasts on the medial side. However, the numbers of $TRAP^+$ osteoclasts showed no significant difference on lateral side between the two groups (Fig.4). Immunohistochemistry revealed that the number of $pSMAD2/3^+$, $Osterix^+$ and $Osteocalcin^+$ cells were significantly lower in medial subchondral bone in elevated MAP group than normal MAP group. Nevertheless the inverse results were observed on lateral side.

Conclusions: Our data show that elevated MAP is associated with higher rate of subchondral bone turnover in patients with advanced knee OA. Moreover, uneven local distribution of osteoprogenitors in subchondral bone marrow mediated by TGF-ß1 signaling may be involved in this pathogenesis. These findings provide a possible mechanism by which hypertension may correlate with OA progression.

Table 1. Demographic, radiological and clinical data of OA patients with normal or elevated MAP

Parameters		OA patients with normal MAP (n=33)	OA patients with elevated MAP (n=37)	P

Individuals with Primary Osteoarthritis Have Different Musculoskeletal Phenotypes Depending on Affected Joint. Magnus Karlsson*[1], Caroline Karlsson[2], Håkan Magnusson[3], Maria Cöster[4], Jan-Åke Nilsson[3], Bjorn Rosengren[1]. [1]Skåne University Hospital Malmö, Lund University, Sweden, [2]Department of Clinical Sceinces, Lund University, SUS, Sweden, [3]Department of Orthopedics & Clinical Sciences, Lund University, SUS, Sweden, [4]Department of Orthoepdics & Clinical Sciences, Lund University, SUS, Sweden

Purpose: Primary osteoarthritis (OA) in the hip in associated with high BMD and obesity. It has then been postulated that the obesity will confer a high joint surface load and the high BMD a stiff skeleton that transfer an abnormal proportion of the mechanical load to the cartilage. If the same phenotype applies to patients with OA in all joints and if the obesity is the result of high fat or high lean mass is unclear. We therefore evaluate if primary OA, independent on affected joint, is associated with same abnormal musculoskeletal phenotype as in patients with hip OA.

Method: We included 30 women and 32 men (mean age, 66 years; range, 42–84) with primary hip OA, 38 women and 74 men (mean age 61 years; range 34–85) with primary knee OA, 42 women and 19 men (men age 64 years, range 42–87) with primary ankle or foot OA, 20 women and 19 men (mean age 66 years, range 47-88) with primary hand or finger OA and 122 women and 118 men as controls. We measured total body BMD (g/cm^2) and proportion fat and lean mass (%) with DXA and height, weight and BMI (kg/m^2) by standard equipment.

Results: Individuals with hand OA and controls had similar phenotype in respect of BMD, weight, height, BMI, fat and lean body mass. Individuals with OA in hip, knee and ankle/foot joint had all similar weight, BMI and BMD, but these values were significantly higher than in individuals with hand/finger OA and controls (all $p<0.05$). Individuals with OA in hip, knee and ankle/foot had also higher fat mass and lower lean mass than individuals with hand OA and controls (all $p<0.001$).

Conclusions: A higher BMD may lead to stiffer bone, a higher BMI to a greater joint load and a lower lean body (muscle) mass to lower joint-protective capacity, all conditions predisposing for OA in the lower extremity. There seem to be different pathophysiological pathways for primary OA in the upper and lower extremity.

Osteoclast Regulatory Factors in Human Osteoarthritic Chondrocytes. Julie Glowacki*[1], Shuanhu Zhou[1], Thomas Thonhill[2]. [1]Brigham & Women's Hospital, USA, [2]Brigham & Women's Hospital, USA

Articular chondrocytes have capacity for anabolic and catabolic activities. Osteoarthritis (OA) is associated with increases in lytic proteinases, aggrecanases, and cytokines. We used tissue discarded during arthroplasty to partition zones of cartilage by disease severity/Grade and to identify the molecular signature of human cartilage representing OA progression.

With IRB approval, discarded tissue was obtained during knee replacement. Zones with sufficient homogeneity were ranked and partitioned according to the Outerbridge classification from Grade 0 (normal-appearing) to Grade 3 (significant fragmentation/fissuring). Chondrocytes were isolated by sequential digestions with 0.1% hyaluronidase, 0.25% trypsin, and 0.3% collagenase. The influence of OA grade on constitutive gene expression was tested with RT-PCR and was compared with the *in vitro* effect of Interleukin (IL)-1b in normal human chondrocytes.

Clinical grade was correlated with histological score, p=0.043. Expression analysis showed expected and unexpected Grade-dependent differences. Genes encoding lytic enzymes [Adamts-5, cathepsin K (catK), and matrix metalloproteinases (MMP-8, MMP-13)] showed low/no expression in Grade 0 and upregulation in advanced Grades. There was Grade-associated upregulation of TNF-a, IL-1b, -6, and -11, and TNF receptors RI and RII. Finding CatK, a known marker of typical osteo/chondroclasts, in OA cartilage stimulated our analysis for tartrate-resistant acid phosphatase (TRAP) and for regulators of osteoclastogenesis, including Receptor Activator of Nuclear factor-kB (RANK), Receptor Activator of Nuclear factor kB Ligand (RANKL), and osteoprotegerin (OPG). There was no or low expression of TRAP, RANK, and RANKL in Grade 0 chondrocytes, but all three were dramatically upregulated in advanced Grades. OPG was expressed similarly for all Grades. Brief treatment (24 h) of normal human chondrocytes with IL-1β upregulated RANK, RANKL, CatK and the expected lytic enzymes. These *in vitro* data support the conclusion that osteoclastogenic regulatory factors play a cell-autonomous role in cartilage pathology. In sum, these studies identified differences in constitutive gene expression in human chondrocytes based upon regional OA disease severity. Beside the expected upregulation of lytic enzymes and mediators/receptors, we found OA Grade-dependent induction of RANK, RANKL, CatK, and TRAP, proteins that are involved in typical osteoclast differentiation and function.

Subchondral Bone Underlying Degenerated versus Normal Cartilage Has Greater Bone Mineral Density but No Difference in Structural Stiffness.

James Johnston*[1], Saija Kontulainen[1], Tuhina Neogi[2], Bassam Masri[3], David Wilson[3]. [1]University of Saskatchewan, Canada, [2]Boston University, USA, [3]University of British Columbia, Canada

Introduction: Thickening of subchondral bone as a part of the osteoarthritis (OA) disease process has been proposed to increase bone's overall structural stiffness, leading to higher internal cartilage stresses, and eventual cartilage breakdown. However, the proposed role of bone stiffness in OA has been primarily based upon isolated analyses of excised tissues samples (e.g., subchondral cortical or trabecular bone), typically after complete cartilage erosion. It is unclear if altered subchondral bone properties are associated with a) overlying cartilage degeneration prior to complete cartilage erosion, or b) overall structural stiffness—a measure most closely reflecting bone's response to cartilage loading. The purpose of this study was to compare regional proximal tibial bone mineral density and structural stiffness at subchondral bone sites underlying normal and degenerated cartilage. Methods: Thirteen proximal tibia compartments (4 medial, 9 lateral) from 10 male donors (age: 73+/-11 years) were scanned using Quantitative CT. Cartilage was intact with both normal (International Cartilage Repair Society (ICRS) grades 0-1) and degenerated regions (ICRS 2-3). After removing cartilage, indentation stiffness testing was performed directly at the subchondral surface (3.5mm diameter flat indentor, 3-6 sites per compartment, 51 sites in total). Each site was characterized as having minimal cartilage degeneration (ICRS 0-1, n=26) or moderate degeneration (ICRS 2-3, n=25). At each site, average subchondral bone density within a 3.5mm diameter region of interest was assessed at depths of 0-2.5, 2.5-5, and 5-10mm from the subchondral surface. Multivariate analysis of variance with Bonferroni adjustment was used to compare subchondral bone density and structural stiffness between normal and degenerated sites. Results: Density across the 0-2.5mm depth did not differ between sites (95% CI: -29 to 101 mg/cm3; p=0.27). In degenerated sites, density was 25% higher across the 2.5-5mm depth (+59 mg/cm3; 95% CI: 11-107 mg/cm3; p=0.018) and 34% higher across the 5-10mm depth (+39 mg/cm3; 95% CI: 5-72 mg/cm3; p=0.026). Structural stiffness did not differ between sites (95% CI: -132 to 1070 N/mm, p=0.12). Conclusion: Subchondral bone underlying degenerated versus normal cartilage had greater bone density at depths beyond 2.5mm from bone surface. No structural stiffness differences were observed; though, a larger sample size is likely needed to account for high mechanical testing variability.

TBRII/IL36α Axis is Involved in the Osteoarthritic Process in Mice and Humans.

Tieshi Li*[1], Joseph D. Temple[2], Lara Longobardi[1], Susan Chubinskaya[3], Helen Willcockson[4], Timothy Myers[4], Ping Ye[1], Billie Moats-Staats[5], Alessandra Esposito[6], Arnavaz A Hakimiyan[3], Daniel J. Del Gaizo[6], Christopher W. Olcott[6], Anna Spagnoli[1]. [1]University of North Carolina at Chapel Hill, USA, [2]University of North Carolina-North Carolina State University Joint Department of Biomedical Engineering, USA, [3]GME, Graduate College, Rush Medical College, USA, [4]University of North Carolina, USA, [5]University of North Carolina- Chapel Hill, USA, [6]University of North Carolina at Chapel Hill, USA

The interplay between TGF-beta type II receptor (TBRII) signaling and cytokines in osteoarthritis (OA) is complex. We have reported that the conditional inactivation of TBRII signaling in embryonic mesenchyme limb progenitors (TBRIIPrx1KO) leads to failure of joint development and its inducible postnatal inactivation (TBRII-ER-Prx1KO) to progressive OA that was associated with an increase of IL36α. To determine the interplay between TBRII and IL36α signaling in OA, we have performed intra-articular injections of IL36α or IL36Ra (receptor antagonist) in TBRII mutants and control mice starting at postnatal age 3 months (P3M). In TBRII mutants, sacrificed at P4M and P6M, injection of IL36Ra halted the loss of Safranin O staining and also the increase of Collagen10 and Mmp13 expressions. By contrast, injection of IL36α exacerbated the OA development in TBRII mutants. To determine if the TβRII/ IL36α axiswas also involved in human cartilage degeneration, histological sections of full-thickness articular cartilage from knee joints obtained from human tissue donors (Collins grade 0-1 defined as normal and grade 2-4 as asymptomatic degenerative) and from subjects with end-stage OA undergoing total joint replacement surgery were subjected to IL36α, IL36R and TBRII immunohistochemistry and Safranin O staining analyses. Our results revealed a consistent increase of IL36α expression within the degenerative lesions (from grade 0 to 3) that was associated with a parallel decrease of TBRII expression. Results were confirmed by RT-PCR analyses of isolated RNA from shaved cartilage from human tissue donors. In severely damaged articular cartilage of subjects with end-stage OA, we found high expression of IL36α in the cell clusters which is a histological hall mark of arthritic cartilage but low expression in deep-zone chondrocytes. Our studies provide a novel perspective for the prevention and treatment of cartilage degeneration by manipulating the TBRII/IL36α axis.

SU0205

The development of articular cartilage thickness, impeded by obesity in high weight bearing regions, is protected by daily exposure to low intensity vibration.

Tee Pamon*[1], M. Ete Chan[1], Vincent Bhandal[2], Clinton Rubin[3]. [1]Stony Brook University, USA, [2]Stony Brook University, USA, [3]State University of New York at Stony Brook, USA

Obesity is a risk factor for osteoarthritis (OA), a degenerative joint disease characterized by the thinning of articular cartilage (AC), abnormal subchondral bone (SB) remodeling, joint pain, and reduced mobility. Considering that obesity has been associated with the suppression of bone formation, it is possible that cartilage formation is also impeded, contributing to relatively thin AC. Recent evidence has shown that low intensity vibration (LIV) protects mesenchymal stem cell (MSC) lineage selection towards the formation of higher order connective tissues such as bone—we sought to determine if LIV could enable the formation of AC despite the obese phenotype. C57BL/6 male, 5w mice were separated into 3 groups (n=9): Regular diet (RD), High fat diet (HF), and High fat diet + LIV (HFv). Part I of the protocol consisted of 2w of high fat diet for HF and HFv. In part II, HFv were also subject to LIV for 6w (90Hz, 0.2g, 30 m/d, 5 d/w). At end of protocol, the R tibial condyles were extracted, and the AC and SB were scanned using contrast agent enhanced μCT. The medial condyle was separated into 2 equal areas: the high-weight bearing region (HWB), adjacent to the midline of the plateau, and the lower weight bearing region (LWB), towards the joint periphery. Bone marrow from the R hindlimb was flushed and FACS used to quantify MSC number. After 8w of high fat diet, HF & HFv were 17.2% heavier than RD (p=0.006). AC thickness of the HWB of HF mice was 28.2% below RD (p=0.02). LIV had a protective effect on AC in this region, as evidenced by a 26.7% thicker AC compared to HF (p=0.13). While there was nsd between RD and HF mice in AC thickness of the LWB, LIV resulted in a 50% increase in AC thickness compared to HF (p=0.002). Despite increases in AC thickness, LIV did not compromise SB mineralization or thickness. Within the bone marrow, LIV increased MSCs by 14.2% compared to HF (p=0.16), and 17.7% compared to RD mice (p=0.03). Given that MSCs have the ability to differentiate into chondrocytes, the increase in MSCs in the HFv group could contribute increased cartilage thickness. Since the HF and HFv groups did not differ in weight, these results suggest that the OA associated with obesity may be, to an extent, the result of suppressed cartilage formation rather than excessive joint loading. The protective effect of LIV appears to be the restoration of cartilage development, due to elevated chondrocyte activity or increased MSC differentiation to chondrocytes.

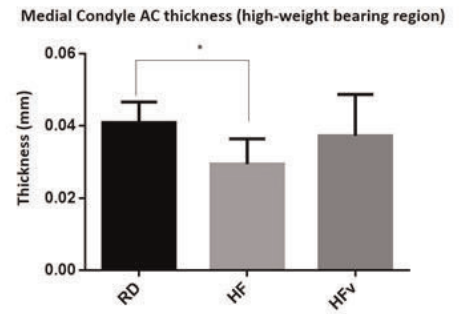

Fig 1: Articular cartilage thickness is reduced in HF with a trend towards recovery in the LIV treatment group. *p<0.05 compared to RD. Mean ± SD shown.

Cortical Expansion in Connexin43 (Cx43) Deficient Bones: Potential Role of Reduced *Sost* Expression. Susan Grimston*, Marcus Watkins, Roberto Civitelli. Washington University in St. Louis School of Medicine, USA

We and others have shown decreased *Sost* expression in mice with a conditional deletion of the connexin43 (Cx43) gene (*Gja1*) specifically in osteogenic lineage cells (cKO). Similar to germline *Sost* deletion (*Sost*$^{-/-}$), *Gja1* cKO bones exhibit cortical expansion secondary to accentuated periosteal bone formation. Unlike *Sost*$^{-/-}$ mice, marrow area of *Gja1* cKO is expanded rather than reduced, the consequence of increased endocortical osteoclast activity. To explore whether *Sost* down-regulation and Wnt signaling activation may in part explain periosteal expansion in *Gja1* deficient bone, we tested a genetic interaction between *Gja1* and *Sost*. We generated double *Gja1*$^{+/-}$;*Sost*$^{+/-}$ heterozygotes (double Hets), and compared their cortical structure and strength to *Gja1* and *Sost* heterozygous mice, which are phenotypically normal. In vivo microCT studies at 3 months demonstrated a trend towards increased Tissue Area in the double Hets, although not as evident as in the *Sost*$^{-/-}$. Marrow Area was similar among all groups and Cortical thickness (Ct.Th) was significantly larger in *Sost*$^{-/-}$. Nonetheless, Polar Moment of Inertia (pMOI) a geometric index of bone strength, in the double Hets tended to increase implying a changed cortical geometry compared with other genotypes. pMOI was significantly higher in *Sost*$^{-/-}$. Ultimate Force (index of bone strength) by 3-point bending was not significantly changed in the double Hets relative to single Hets, whereas it was 40% higher in *Sost*$^{-/-}$ bones, as expected. While the modestly expanded Tt.Ar and pMOI in the double Hets would be consistent with a genetic interaction between *Gja1* and *Sost*, the contribution of decreased sclerostin in the mechanism leading to cortical expansion in *Gja1* deficient bones would be modest, based on these data.

Variable	*Gja1*$^{+/-}$;*Sost*$^{+/+}$	*Gja1*$^{+/-}$;*Sost*$^{+/+}$	*Gja1*$^{+/-}$;*Sost*$^{-/-}$	*Gja1*$^{+/-}$;*Sost*$^{-/-}$	*Sost*$^{-/-}$

Sphingomyelin Synthase 2 Promotes Osteoclast Differentiation by Enhancing retinoid X receptor a Expression. Yoshihiro Yoshikawa*[1], Eisuke Domae[2], Seiji Goda[2], Isao Tamura[2], Aiko Kamada[1], Takashi Ikeo[3]. [1]Osaka Dental University, Japan, [2]Osaka Dental University, Japan, [3]Osaka Dental University, Japan

For treatment with implants, long-term survival and rapid recovery of the socket bone are necessary, and determining the mechanism of alveolar bone regeneration is important. 1,25-dihydroxyvitamin D_3 ($1,25(OH)_2D_3$) plays a central role in bone regeneration. A deficiency in this compound has profound negative effects on implant osseointegration and stimulates osteoclastogenesis through osteoblasts. In addition, several studies have reported that $1,25(OH)_2D_3$ induces turnover of sphingomyelin, which plays vital roles in stabilizing the membrane structure and in cell-cell recognition. However, whether sphingomyelin is involved in osteoclast differentiation is unclear.

To examine the effects of sphingomyelin on osteoclast differentiation, we cocultured bone marrow cells isolated from mouse tibia and sphingomyelin synthase 2 (SMS2) siRNA-transfected primary osteoblasts (POB) isolated from calvaria of newborn mice and performed tartrate-resistant acid phosphatase (TRAP) staining. We evaluated expression of genes with real-time PCR and proteins with western blotting in the presence of 10^{-8} M $1,25(OH)_2D_3$ in POB transfected with SMS2 siRNA.

Formation of TRAP-positive multinucleated osteoclasts was significantly suppressed by SMS2 siRNA. In addition, mRNA expression of the Vitamin D receptor (VDR) target gene receptor activator of nuclear factor-κB ligand (RANKL) was significantly suppressed by SMS2 siRNA in POB in the presence of $1,25(OH)_2D_3$.- Next, we examined whether SMS2 affected nuclear translocation of VDR and retinoid X receptor a (RXRa), which play a profound role in VDR genomic signaling. SMS2 siRNA did not affect VDR expression but reduced RXRa expression in POB.

We suggest that SMS2 is important for osteoclast differentiation by regulating RANKL expression via RXRa.

Biomechanical Analysis of Fibronectin Fibril Assembly Dynamics in Living Osteoblasts. Bhargav Javvaji*[1], Sarah Dallas[2], Ganesh Thiagarajan[2]. [1]University of Missouri Kansas City, USA, [2]University of Missouri - Kansas City, USA

Fibronectin (FN) is an extracellular matrix (ECM) protein expressed in bone and connective tissues. We have shown that FN regulates osteoblast differentiation and controls assembly of multiple bone ECM proteins. Therefore, understanding its mechanism of assembly is key to understanding how bone matrix is formed. To gain new insight into the kinetics of FN assembly, we have used time lapse imaging of FN assembly in living osteoblasts. This was combined with biomechanical analysis to determine the strains experienced by FN fibrils during assembly and maturation of the matrix and to quantify their motions.

FN assembly was imaged in 2T3 osteoblasts over 48hr by time lapse imaging using an alexa555 labeled FN probe, which enabled imaging from a baseline of no FN fibrils to formation of a well organized fibril network. FN assembly was highly dynamic and was associated with extensive cell motion, which subjected FN fibrils to tensile and compressive forces. 6 independent movie fields were analyzed using a previously validated cross correlation based Digital Image Correlation algorithm developed in Matlab. The 0-12h movie segment shows rapid FN deposition, generation of many new fibrils and abundant cell and fibril motion. The 12-24h segment shows some new fibrils and continued cell and fibril motion. The 24-36h and 36-48h segments show fewer new fibrils and reduced cell motion. Analysis of 20 fibrils in the 12-24h movie segment showed average strains ranging from -42,000 to 36,000 με and analysis of 30 fibrils in the 24-36h segment showed average strains from -32,000 to 29,000 με. Fibrils in the 36-48h segment showed average strains from -23,000 to 24,000 με. Individual fibrils had unique strain profiles, driven by the underlying cell motion and experienced both tension and compression. Maximum strains were higher in shorter vs. longer fibrils and the average fibril strains decreased as a function of time, suggesting that fibril strains decrease with ECM maturation. This may be due to reduced cell motility and/or increased ECM crosslinking. Together these data show that ECM assembly is more dynamic than previously known and suggest that FN fibrils are subjected to significant strains and displacements during assembly due to cell motion. Mechanical stretching of ECM fibrils may expose binding sites for other ECM molecules, may result in shedding of ECM bound growth factors and may physically organize/reshape the ECM.

Ciliary protein Bbs3 positively regulates the induction of ALP activity by Hedgehog signaling in MC3T3-E1. Makiri Kawasaki*[1], Tadayoshi Hayata[2], Yoichi Ezura[3], Masaki Noda[1]. [1]Tokyo Medical & Dental University, Japan, [2]Organization for Educational Initiatives, University of Tsukuba, Japan, [3]Tokyo Medical & Dental University, Medical Research Insititute, Japan

Primary cilium (PC), a hair-like organelle protruding from cell surface, is known to exist in most of the mammalian cells. The recent intensive studies revealed that this organelle plays an important role in signal transduction in osteoblasts. To date there are about 600 genes identified to be involved in the formation and function of PC. The deletion of proteins engaged to the transportation inside PC frequently causes disappearance of this structure and thus prevents us from systematic analysis. We focused on BBS3 (ADP ribosylation factor-like 6), one of the causative genes of Bardet-Biedl Syndrome, since this protein doesn't intervene in the formation of PC, while its lack disturbs the proper translocation of some GPCRs in/to PC. However, function of Bbs3 in osteoblasts is largely unknown. So, in this study we examined the effect of Bbs3 depletion in the differentiation of osteoblastic cell line MC3T3-E1.

First we examined the mRNA level of Bbs3 in skeletal tissues. Among bone tissues, Bbs3 was expressed the most highly in calvaria and less in bone marrow. We extracted bone marrow cells and cultured them in osteogenic medium for 3 weeks. The expression of Bbs3 was gradually increased along with the differentiation of bone marrow cells to osteoblasts. To know the role of Bbs3 in osteoblasts, we depleted Bbs3 in MC3T3-E1 using RNAi system (siControl/siBbs3). We performed immunocytochemistry and observed the PC in MC3T3-E1. We found that the knockdown of Bbs3 in MC3T3-E1 didn't affect the ratio of ciliated cells. Then we evaluated the differentiation of MC3T3-E1 on ALP activity in cells transfected with siControl or siBbs3. In the cells cultured in osteogenic medium, the induction of ALP activity was significantly suppressed in Bbs3-silenced cells, while the induction of ALP activity by BMP2 treatment wasn't suppressed in those cells, suggesting that the suppressed ALP activity was not due to the disturbed BMP2 signaling. Indeed, BRE-luc activity was comparably induced by BMP2 in Bbs3-silenced cells. PC is well known to be a signal center of Hedgehog signaling, so we cultured MC3T3-E1 in the presence of SAG, Smoothened agonist, and examined the ALP activity. In control cells, the SAG treatment up-regulated the ALP activity but this effect was diminished in the Bbs3-silenced cells.

Our data indicates that Bbs3 is positively involved in the induction of ALP activity by Hedgehog signaling during the differentiation of MC3T3-E1.

Dock7 is a Novel Regulator of Osteoblast Differentiation and Function. Kathleen Bishop*[1], David Maridas[1], Katherine Motyl[1], Clifford Rosen[2]. [1]Maine Medical Center Research Institute, USA, [2]Maine Medical Center, USA

Dock7 is a guanine nucleotide exchange factor (GEF) involved in the activation of the small GTPases Rac1 and Cdc24. While Dock7 is best known for its role in neuronal cell function, mice lacking the Dock7 protein, the *Misty* mice, have low bone mass and accelerated age-related bone loss. Uncoupled bone remodeling was also observed, with decreased osteoblast and increased osteoclast numbers. However, it is unclear whether the *Misty* bone phenotype is a direct result of loss of Dock7 in bone remodeling cells or an indirect effect from other cell types. In order to elucidate the role of Dock7 in the osteogenic lineage and bone formation process, proliferation and differentiation markers were analyzed. Calvarial osteoblasts (COBs) displayed a decrease in the proliferation marker *Cyclin D1* and osteoblast markers *Runx2*, *Osteocalcin*, and *Alkaline Phosphatase* when compared to wild type controls. Cell proliferation is currently being assessed by Brdu staining *in vivo*. Furthermore, COBs isolated from *Misty* mice demonstrated decreased osteogenic differentiation and mineralization as well as reduced Wnt3a-induced β-catenin nuclear localization. These data suggest that decreased osteoblast numbers observed in the *Misty* mice may be a result of decreased proliferation and impaired differentiation, potentially through modulation of Wnt signaling. Additionally, we hypothesized that if Dock7 controlled GTPase activation, GTPase-dependent processes such as cell mobility may also be affected. *Misty* bone marrow stromal cells (BMSCs) had a pronounced decrease in migration and increase in adhesion onto a collagen I matrix when compared to wild type; however, mobility in *Misty* COBs was only minimally reduced. Changes in BMSC mobility suggest an alteration in adhesion complex proteins such as integrins whose actions are dependent on the activation of small GTPases. Modulation of Rac1 and Cdc42 signaling would provide a strong rationale for the altered proliferation, differentiation, and migration observed in the osteoblast progenitors. These data indicate a direct role for Dock7 in the osteogenic lineage, specifically in the MSC to early osteoblast transition. To further determine if Dock7 deficiency in the osteogenic lineage contributes to the bone pathophysiology observed in *Misty* mice, we have generated a Dock7 conditional knockout using CRISPR, which will be used to elucidate the cell type-specific role for Dock7 modulating the bone formation and remodeling processes.

Hira, a histone chaperone, regulates bone mass. Pablo Roman-Garcia*[1], Virginia Piombo[2], Vijay Yadav[2]. [1]Systems Biology of Bone, Wellcome Trust Sanger Institute, United Kingdom, [2]Systems Biology of Bone, Wellcome Trust Sanger Institute, United Kingdom

Deletions of chromosome 22q11.2 also known as diGeorge or Velocardiofacial syndrome affect nearly one in 3000 births with an autosomal dominant inheritance. A region of at least 20 genes is lost and many clinical features, including low bone mass, are associated with this deletion. However, the genes in 22q11.2 underlying the skeletal disorders are not known.

In this study, we investigated the effect of loss of function of genes implicated in "22q11 syndromes" on osteoblast lineage and bone mass.

siRNA was used in OB6 cells to test if the silencing of genes involved in 22q11 deletion affects osteoblasts proliferation and/or differentiation. Gene expression was measured by qRT-PCR. Proliferation was measured as DNA synthesis (BrDu incorporation) and differentiation as alkaline phosphatase activity. Knockout mice generated using EUCOMM resources were used to investigate the implications of the deletion of candidate gene(s). Embryonic bone development was evaluated using whole mount skeletal preparations. Serum osteocalcin and glucose levels were measured using ELISA. Bone histology and histomorphometry was performed on undecalcified vertebral sections in adult mice using osteomeasure analysis system.

Ten genes involved in 22q11.2 deletion, with detectable levels in tibia, were silenced in OB6 osteoblastic cells. Gene expression was significantly decreased to ⩾20% in all of the genes. Out of these genes only loss of function in *Hira*, which codes for a histone chaperone, was found to have a negative effect on both the proliferation (-25.5%) and differentiation (-30.2%) of osteoblasts. Generation of knock out mice for *Hira* revealed that homozygous mice were embryonically lethal, and heterozygous mice had normal skeletal mineralization during embryonic development. Analysis of 8 week-old *Hira*+/- mice showed a significant decrease in bone mass: 34% less bone volume/total volume compared to wild-type littermates. This low bone mass was caused by a severe suppression in the number and function of osteoblatsts associated with a major decrease in serum osteocalcin levels. *In vitro* osteoblast cultures showed that *Hira*+/- primary osteoblasts have impaired ability to proliferate and differentiate (-40% and -42% respectively).This study identifies a role for *Hira* in regulating osteoblast functions and bone mass, and suggests that this gene is likely involved in the low bone mass observed in diGeorge syndrome patients.

Lack of Wnt16 Exerts Gender-Specific Effects on Cortical Bone Diameter in Mice. Chandrasekhar Kesavan*[1], Jon Wergedal[1], Robert Brommage[2], Subburaman Mohan[1]. [1]Jerry L. Pettis Memorial VA Medical Center, USA, [2]Lexicon Pharmaceuticals, USA

Periosteal bone formation (BF) is the primary determinant of bone diameter and canonical Wnt signaling is a major pathway regulating periosteal BF. Recent studies in our and other laboratories have shown that targeted knockout (KO) of the Wnt16 gene in mice results in reduced cortical bone thickness and strength. The C57BL6/J – 129SvEv hybrid Wnt16 KO mice examined in our laboratory have small cortical bone diameters and reduced periosteal BF. Since estrogen receptor α (ERα) can physically interact with β-catenin and genetic interactions between ERα and β-catenin signaling occur in vivo, we determined if Wnt16 exerts gender-specific effects on cortical bone size. As expected, cross-sectional area (CSA) of the tibia mid-diaphysis was significantly lower in female than male mice in both wild type (WT) and Wnt16 KO genotypes at 12 weeks of age. Compared to WT mice, lack of Wnt16 caused a greater reduction in tibia CSA in female mice (25%, $P < 0.01$) versus male mice (8%, $P < 0.05$). Similarly, cortical thickness was reduced by 10% and 20%, respectively, in male and female Wnt16 KO mice. Two-way analyses for genotype-gender interactions revealed a "p" value of 0.09 and 0.11, respectively, for CSA and cortical thickness. To examine mechanisms for the Wnt16-estrogen interaction, we evaluated the effect of estrogen on Wnt16 expression. 17β-estradiol treatment for 21 days using time release pellets (0.05 mg/21 days) implanted subcutaneously to three week-old WT ovariectomized C57BL/6J mice increased expression levels of both Wnt16 and β-catenin in the femur more than 6-fold ($P < 0.01$) compared to placebo treatment. Since estrogen effects on BF are mediated in part via upregulation of IGF-I signaling, we evaluated the effects of IGF-I treatment on Wnt16 expression in cultured (serum free) WT periosteal cells. IGF-I treatment at 10 ng/ml increased Wnt16 expression 10-fold but did not affect expression of Wnt4 and Wnt5a. Consistent with these in vitro data, Wnt16 mRNA level was reduced 50% ($P < 0.05$) in femur shafts from osteoblast-specific IGF-I conditional KO mice compared to control mice. We conclude that Wnt16 is required for the maximal effects of estrogen on cortical bone diameter and the estrogen dependence of Wnt16 expression may be mediated via IGF-I signaling.

Mechanisms for Specificity of Wnt16 Actions on the Periosteum. Jon Wergedal*[1], Chandrasekhar Kesavan[1], Karthikeyan Muthusamy[2], Robert Brommage[3], Subburaman Mohan[1]. [1]Jerry L. Pettis Memorial VA Medical Center, USA, [2]Alagappa University, India, [3]Lexicon Pharmaceuticals, USA

Human genome-wide association and mouse genetic studies revealed that Wnt16 is an important determinant of bone strength and fracture risk. Recent studies in our and other laboratories have shown that targeted knockout (KO) of the Wnt16 gene in mice results in reduced cortical bone thickness and strength. The C57BL6/J – 129SvEv hybrid Wnt16 KO mice examined in our laboratory have small cortical bone diameters and reduced periosteal bone formation. Furthermore, at the 2013 ASBMR meeting, we demonstrated that mechanical strain-induced periosteal bone formation was abrogated by a lack of Wnt16 in mice. Since numerous Wnts are expressed in bone and act via modulation of canonical β-catenin signaling, we examined the specificity of Wnt16 signaling in the periosteum. By RT-PCR, total RNA extracted from periosteal tissue of 5 week-old female wild-type (WT) mice showed several-fold higher expression of Wnt16 compared to Wnt1, Wnt2a, Wnt5a, Wnt7a, Wnt9a and Wnt10b. There were no differences in periosteal expression of Wnt1, Wnt2a, Wnt7a, Wnt9a and Wnt10b between WT and Wnt16 KO mice. Expression of Wnt5a was 30% higher ($P < 0.05$) in KO compared to WT mice. Wnt receptors Fzd1 and Fzd8 showed higher expression than other Frizzled receptors (Fzd3, Fzd4, Fzd5 and Fzd7), with Fzd8 expression upregulated in periosteum from Wnt16 KO mice. These findings, and structural modeling studies with two protein docking program, GRAMM-X, showing a Fzd8 binding pocket for Wnt16, suggest Fzd8 mediates Wnt16 canonical β-catenin signaling in bone. Proliferation of cultured periosteal cells obtained from Wnt16 KO mice is reduced and addition of exogenous Wnt16 but not Wnt3a rescued this defect. Supporting the importance of muscle – bone interactions, Wnt16 expression was observed to be high in muscle and elevated in both muscle (2-fold, $P < 0.05$) and periosteum (4-fold, $P < 0.01$) of mice subjected to increased mechanical strain (9N force producing 4800 με strain was applied to the right tibia using a four-point bending loading method for 2 weeks [6 days/week] at 2 Hz frequency, for 36 cycles). Together, these studies demonstrate that the anabolic action of Wnt16 on periosteal bone formation results from high expression of Wnt16 in periosteal and surrounding muscle cells as well as high expression of the Wnt16 receptor Fzd8.

Mechanisms Underlying the Effect of Melatonin, Strontium citrate, Vitamin D3 and Vitamin K2 on Bone Marrow Stem Cells and Peripheral Blood Monocytes Grown as Co-cultures. Sifat Maria*[1], Holly Lassila[2], Christine O'Neil[3], Mark Swanson[4], Paula Witt-Enderby[5]. [1]Duquesne University Division of Pharmaceutical Sciences, USA, [2]Duquesne University Division of Clinical, Social & Administrative Science, USA, [3]Duquesne University Division of Clinical, Social & Administrative Sciences, USA, [4]Private practice, Heart Preventics, LLC, USA, [5]Duquesne University,School of Pharmacy, USA

The bone remodeling system preserves the integrity of bone by balancing the activities of bone-forming osteoblasts and bone-resorbing osteoclasts. A shift in this equilibrium towards bone resorption could lead to bone loss. A clinical trial, the Melatonin-micronutrients Osteopenia Treatment Study (MOTS), was designed to assess the efficacy of a combination of bone tropic agents: melatonin, strontium citrate, vitamin D_3 and vitamin K_2 (MSDK) on bone health and quality of life in post-menopausal osteopenic women to address the rise in osteopenia-induced fracture. One aspect of this translational study examined the mechanisms underlying MSDK's effects on osteoblasts and osteoclasts using a co-culture system containing human bone marrow stem cells (hMSCs) and human peripheral blood monocytes (hPBMCs). Using a novel treatment paradigm that closely mimics the *in vivo* condition, hMSC/hPBMC co-cultures were exposed to vehicle or MSDK in osteogenic (OS+) or growth medium (OS-) for 21 days. These effects of MSDK on osteoblast and osteoclast differentiation were measured by alizarin red and TRAP staining, respectively. Co-cultures grown in OS+/MSDK enhanced osteoblast differentiation but inhibited osteoclast differentiation when compared to OS-/MSDK. To identify potential signaling mechanisms underlying MSDK's action, osteoprotegerin (OPG) and RANKL levels were measured in both hMSC/hPBMC co-cultures and in hMSC monocultures by ELISA and western blot analyses. In hMSC/hPBMC co-cultures exposed to OS+/vehicle or OS+/MSDK, the ratio of secreted OPG:RANKL decreased compared to cells grown in OS-/MSDK; this was due to an increase in RANKL secretion since secreted RANKL levels but not OPG levels increased when compared to OS-/MSDK. Interestingly, in hMSC monocultures, the ratio of secreted OPG:RANKL as measured by ELISA, decreased due to increases in RANKL with a concomitant decrease in OPG vs. OS-/MSDK; however, as measured by western blot, this ratio of OPG:RANKL increased in hMSC monocultures due to increases in OPG. From these data, we conclude that MSDK has dual actions on bone cells in-vitro to enhance osteoblast differentiation while inhibiting osteoclast differentiation through a modulation of OPG and RANKL expression and release from the osteoblast. These findings also suggest that the presence (co-culture) or absence (hMSC monoculture) of the osteoclast plays a significant role in MSDK-mediated expression and release of RANKL and OPG from the mature osteoblast.

PEPTIDE-MEDIATED α5β1 INTEGRIN ACTIVATION INTEGRATES WNT/β-CATENIN SIGNALING TO PROMOTE MESENCHYMAL CELL OSTEOGENIC DIFFERENTIATION. Zuzana Saidak*[1], Sofia Azzi[1], Caroline Marty[1], Sophie Da Nascimento[2], Pascal Sonnet[2], Isabelle Dupin-Roger[3], Pierre J. Marie[1]. [1]UMR-1132 Inserm, Paris, France, Université Paris Diderot, Sorbonne Paris Cité, France, [2]Equipe Théra, Laboratoire des Glucides-UMR-CNRS 6219, Université de Picardie Jules Verne, France, [3]Institut De Recherche Servier, France

Identifying mechanisms upregulating mesenchymal skeletal progenitor cell (MSC) osteogenic differentiation is an important issue for promoting bone formation during aging. We previously showed that the integrin α5β1 is essential for osteogenic differentiation in MSCs. However, the mechanisms underlying this effect are poorly understood. We thus investigated the mechanisms induced by α5β1 activation by CRRETAWAC, which interacts specifically with this integrin, and by two related peptides (GACRRTAWACGA, GACRETAWACGA) lacking the full RRET sequence that is believed to play a role similar to RGD to activate integrin signaling. These two peptides were less active than CRRETAWAC at reducing MSC attachment to fibronectin. All peptides significantly increased FAK activity (+10% in the presence of Mn2+), Runx2 transcriptional activity (+ 50-130%), osteoblast gene expression (1.2-4-fold) and in vitro matrix mineralization, showing promotion of in vitro osteogenic differentiation, irrespective of the RGD-like RRET sequence. Mechanistically, all peptides enhanced β-catenin-dependent TCF/LEF transcriptional activity by ~50% in MSCs, an effect that was abolished by α5 integrin siRNA. Western blot analysis showed that the activation of Wnt/β-catenin signaling by the peptides was related to PI3K and GSK3 phosphorylation. To investigate the in vivo effects of the selected peptides, the purified cyclic peptides, or an inactive peptide used as negative control were coupled to $(Asp\text{-}Ser\text{-}Ser)_6$ which binds to active bone surfaces, and were administered (i.v., 100 mg/kg body weight/day, 5 days/week, 6 weeks) to 8-week old senescent osteopenic mice (SAMP6). Histological analysis showed that the peptide that was the most efficient at increasing Wnt/β-catenin signaling in vitro increased femoral bone volume (15%) and trabecular number (17%) in SAMP6 mice. This effect did not result however from increased bone formation rate but was associated with decreased trabecular separation (17%), suggesting decreased bone resorption. Overall, the data indicate that RRET-independent activation of α5β1 integrin promotes MSC osteogenic differentiation in vitro in part by activating Wnt/β-catenin signaling, and increases bone mass in senescent osteopenic mice possibly through decreased osteoclastogenesis. This reveals a novel cross-talk between α5β1 integrin and Wnt/β-catenin signaling, which may serve as a basis for increasing bone mass in age-related bone disorders.

Pre-clinical screening of novel two-photon photopolymerized biomaterials for bone implantation. Oskar Hoffmann[1], Tristan Fowler*[2], Carina Kampleitner[3], Leander Poocza[4], Andrea Markus[5], Christian Dullin[5], Gerhard Hildebrand[4], Frauke Alves[5], Klaus Liefeith[4]. [1]University of Vienna, Austria, [2]Universität Wien, Aut, [3]Universität Wien, Austria, [4]Institute for Bioprocessing & Analytical Measurement Techniques (iba), Germany, [5]University Medical Center Göttingen, Germany

The development of biomaterials for bone repair is essential for non-healing large bone lesions. We sought to investigate the effects of novel scaffolds consisting of lactide (LA), caprolactone (CL), and methacrylate (MA) using 2-photon photo-polymerization (PP) on *in vitro* osteoblast (OB) function and osteoclast (OC) development and *in vivo* bone healing. We evaluated 3 formulations comprised of varying [LA : CL] ratio and different MA% as follows:

1) LCM3 contains 8 LA : 2 CL and 85% MA
2) LCM4 contains 9 LA : 1 CL and 90% MA
3) LCM6 contains 9 LA : 1 CL and 40% MA

To determine the effect on OB differentiation, proliferation, and mineralization, we tested murine calvarial-derived OBs in MTT and alkaline phosphatase assays and stained them with alizarin red. We found that LCM3 and LCM4, but not LCM6, supported OB attachment, proliferation, and matrix mineralization when compared to cells plated on plastic. We then tested murine co-culture-derived OCs and human blood-derived CD14+ OC precursors and observed that mouse and human OCs attached and differentiated on LCM3 and LCM4, but not on LCM6 compared to tissue culture plastic. To evaluate *in vivo* scaffold integration, we implanted the scaffolds into 5mm calvarial defects in 3-month old BALB/c mice. We observed that all implants were well tolerated and all recipients survived without weight loss. At 12 weeks post-implantation, Quantum FX μCT and histological sections demonstrated that OVF and scaffolds enabled cellular integration and attachment. In animals re-implanted with syngeneic calvarial bone, there was a mean bone re-growth of $77.3 \pm 0.75\%$ compared with $25.7 \pm 4.29\%$ in animals without implant. Implantation of LCM3, LCM4 and LCM6 scaffolds led to a net change in mean bone re-growth of $20.1 \pm 2.76\%$, $23.7 \pm 4.17\%$, and $-7.5 \pm 1.42\%$, respectively. Thus, animals implanted with LCM3 and LCM4 scaffolds had normal bone re-growth which was identical to animals without implant, whereas LCM6 caused a significant reduction in bone formation. Using this pre-clinical screening approach, our results illustrate that LCM biomaterials with greater than 40% MA promote *in vivo* and *in vitro* OB and OC function leading to normal bone re-growth. In conclusion, these data suggest that novel 2-PP LCM biomaterials provide new opportunities for the treatment of non-healing large bone lesions.

RANKL-binding peptides increased bone formation in a murine calvarial defect model. Yasutaka Sugamori*[1], Masashi Honma[2], Genki Kato[3], Yukihiko Tamura[3], Yuriko Furuya[4], Hisataka Yasuda[5], Yasuhiko Tabata[6], Nobuyuki Udagawa[7], Keiichi Ohya[8], Hiroshi Suzuki[9], Kazuhiro Aoki[8]. [1]Tokyo Medical & Dental University, Japan, [2]The University of Tokyo Hospital, Japan, [3]Tokyo Medical & Dental University, Japan, [4]Oriental Yeast Co.,Ltd, Japan, [5]Oriental Yeast Company, Limited, Japan, [6]Kyoto University, Japan, [7]Matsumoto Dental University, Japan, [8]Tokyo Medical & Dental University, Japan, [9]The University of Tokyo Hospital, Japan

Back ground

We have shown that the RANKL binding peptide W9 (MW: 1226.4) promotes bone formation as well as inhibiting bone resorption. We hypothesized that the increase of bone formation by the peptide is RANKL dependent since the anabolic effects of W9 on bone formation by the peptide was blunted in the RANKL deficient mice.

Purpose

In this study, we compared anabolic effects of W9 with another RANKL-binding peptide X (MW: 1448.7), which has been already known as an inhibitor of osteoclastogenesis, on local bone formation, and investigated the mechanism of the anabolic effects.

Materials and Methods

For *in vitro* study, we used calvarial osteoblasts and ST-2 cells to compare W9 with peptide X on osteoblast differentiation. For *in vivo* study, we used murine

calvarial defect model. Gelatin hydrogel sheets were used as a carrier for these peptides. The mice were sacrificed 4 weeks after the operation, and the local bone formation was analyzed radiologically and histologically. In order to elucidate the signal transduction pathway upon the stimulation of peptide after binding to RANKL, we used ST-2 cells and investigated the phosphorylation of Akt and S6K1, which was considered as the RANKL downstream signaling molecules, by Western blotting.

Results

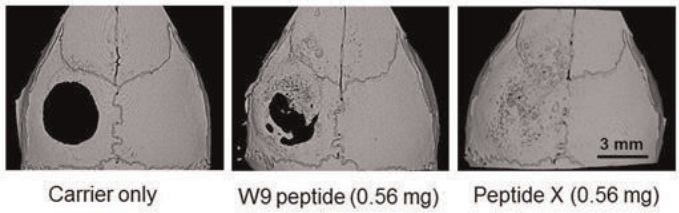
Peptide X could promote osteoblast differentiation more than W9 *in vitro*. Micro-CT analyses at the calvarial defects showed that peptide X (0.56 mg) could promote local bone formation to almost fully repairing extent, whereas W9 (0.56 mg) could only recover partially at the defects (See attached figure). The BMD measurement and histomorphometric analysis confirmed these Micro-CT data. Interestingly, peptide X could stimulate Akt and S6K1 phosphorylation more than W9.

Discussion

Since the phosphorylation of S6K1 is known as a signal-indicator of mTORC1 activation and mTORC1 activation is also known to lead the increase of Runx2 expression in osteoblasts, our data suggest that RANKL-binding peptides bind to the membrane-bound RANKL on the surface of osteoblasts and stimulate osteoblasts directly, promoting bone formation.

Conclusion

A RANKL-binding peptide may be a useful template to develop a therapeutic reagent for promoting local bone formation.



Anabolic effects of the RANKL-biniding peptides in the murine calvarial defects model

Runx2 Deficiency in Committed Osteoblasts Impairs Postnatal Skeletogenesis. Mitra Adhami*[1], Harunur Rashid[2], Haiyan Chen[3], Amjad Javed[3]. [1]UAB, USA, [2]University of Alabama Birmingham, USA, [3]University of Alabama at Birmingham, USA

Runx2 transcription factor is critical for mesenchymal cell commitment to the osteoblast lineage and skeletogenesis. Mice with global deletion of Runx2 exhibit a complete absence of osteoblasts and mineralized tissue. However, early lethality of Runx2-null mice precludes identification of cell and tissue-specific requirements of Runx2 in postnatal bone development. Moreover, it remains unclear if Runx2 is necessary after mesenchymal cell commitment to the osteoblast lineage. We specifically deleted the Runx2 gene in committed osteoblasts using 2.3kb collagen1-Cre transgenic mice. Surprisingly, homozygous mice were born alive and indistinguishable from WT littermates. Runx2 deficiency did not alter chondrocyte differentiation, cartilage growth and proliferative capacity of osteoblasts during embryonic development. However, histological analysis revealed a poorly calcified skeleton and severely disrupted cranial development in mutant mice. Runx2 mutants showed progressive retardation in postnatal growth and exhibited significantly low bone mass in cortical and trabecular bones by 1 month of age. Poor bone synthesis was associated with decreased gene expression of osteoblast markers BSP, OC and OSX and impaired collagen assembly in the extracellular matrix. In addition, 3-point bend testing revealed a 35% decrease in stiffness and 37% decrease in the ultimate force displacement of mutant femurs. Interestingly, TRAP staining showed a decrease in both osteoclast number and activity; thus, the low bone mass in mutant mice is not associated with increased bone resorption. Consistent with this observation, Runx2 mutant bones showed a decrease in RANKL, along with an increase in expression of OPG, an inhibitor of osteoclastogenesis. The altered RANKL/OPG ratio is consistent with loss of osteoclast differentiation. By 3 months of age, bone acquisition in mutant mice was roughly half of WT littermates. We also noted a 60% decrease in osteoclast number and 55% decrease in osteoclast activity. Interestingly, the number of osteoblasts was unchanged but the osteoblast surface to bone surface ratio was decreased in mutants. Our result indicate that osteoblast function, and not number, is disrupted in Runx2 mutant mice. Consistent with these findings, we observed a 50% decrease in the bone formation rate of 3-month old homozygous mice. In conclusion, Runx2 activity is critical for function after commitment to the osteoblast lineage and postnatal bone development.

Static Magnetic Fields Affect Biological Behaviors of Bone Cells. Peng Shang*[1], Jian Zhang[2], Chong Ding[2], Airong Qian[3], Zhe Wang[2], Lifang Hu[2]. [1]Northwestern Polytechnical University, Peoples Republic of China, [2]Key Laboratory for Space Bioscience & Biotechnology, Institute of Special Environmental Biophysics, School of Life Sciences, Northwestern Polytechnical University, China, [3]Northwestern Polytechnical University, Peoples Republic of China

All the living beings live and evolve under geomagnetic field (25~65 μT). Besides, opportunities for human exposed to different intensities of static magnetic fields (SMF) in the workplace have increased progressively from hypo-magnetic field (HpMF, < 5 μT) environment, weak magnetic field (WMF, 5 μT~1 mT), moderate SMF (MMF, 1 mT~1 T) to high SMF (HiMF, > 1 T). Numerous studies have indicated that magnetic fields can influence our skeleton systems. However, the mechanisms of SMF environment on bone tissue are still poorly understood till now. In this study, HpMF of <500 nT, MMF of 0.2~0.4 T and HiMF of 16 T were used to investigate the effects of SMF on bone cells including osteoblasts, osteocytes and osteoclasts.

Our results showed that HiMF did not affect the morphology of osteocyte like cells of MLO-Y4, but increased cell viability. Accordingly, MLO-Y4 apoptosis decreased in MMF, but increased in the HpMF. HiMF promoted the expression of cox-2, Cx43 and some differentiation markers such as osteocalcin, sclerostin. In osteoblasts, the morphology and proliferation of osteoblastic MC3T3-E1 cells was influenced by SMF with different responses. HiMF promoted the differentiation of MC3T3-E1 cells at both early and mineralization stages. Besides, HiMF altered neither the height nor the distribution of both cytoskeleton and cytoskeleton-associated proteins. However, lots of cytoskeleton-associated genes in osteoblastic MG63 cells were sensitive to strong SMF identified by cDNA microarray. As for osteoclast, SMFs decreased the survival of preosteoclasts Raw264.7. Besides, Raw264.7 cell showed elevated osteoclastogenesis in HpMF and MMF, but reduced in HiMF.

These results suggest that exposure to the environments with magnetic intensity far away the geomagnetic field was harmful to bone metabolism such as HyMF and MMF. On the contrary, HiMF had positive effects on bone remodeling. It indicated that HiMF may be a potential physical therapy to for both maintenance and treatment of bone health. Above all, these results will improve our further understandings of the exact mechanisms of bone tissues under SMF and have potential application value in treating or preventing human bone disorders on the Earth or in outer space.

Tension force-induced ATP promotes osteoblast differentiation-related transcription factors and osteogenesis through P2X7 receptor in osteoblasts. Natsuko Tanabe*[1], Taro Kariya[2], Chieko Shionome[2], Takayuki Kawato[2], Masao Maeno[2], Noriyoshi Shimizu[2], Naoto Suzuki[1]. [1]Nihon University School of Dentistry, Japan, [2]Nihon University School of Dentistry, Japan

Orthodontic tooth movement induced alveolar bone resorption and formation by mechanical stimuli. In particular, the force exerted on the traction side promotes bone formation. Nucleotides, such as adenosine triphosphate (ATP), are thought to be key mediators in the response of bone cells to mechanical stimuli. It has been reported that Fluid shear stress induces ATP release in the osteoblastic MC3T3-E1 cells, and also has been reported that ATP promotes bone formation through P2X7 receptor in rat calvarial cells (Panupinthu et. al., J.Cell.Biol, 181, 2008, Genetos et. al., J.Bone.-Miner.Res, 20, 2005). However, the effect of Tension force (TF) -induced ATP in osteogenesis is poorly understood. Thus, our purpose was to determine the effect of TF on ATP release, the expression of differentiation related-factors and extracellular matrix, ALPase activity and osteogenesis in osteoblasts. MC3T3-E1 cells were plated on flexible-bottom plate, incubated in the presence or absence of P2X7 antagonist A438079, then stimulate with cyclic TF (6 or 18%, that is 6 cycles/min: 5 sec strain, 5 sec relaxation) for maximum 24hs using a Flexercell Strain Unit 3000. ATP release is from the culture medium was measured by the luciferin/luciferase assay. The expression of osteogenesis-related transcription factors, P2X7, and extracellular matrix proteins was determined by real-time PCR, Western blotting or ELISA. ALPase activity was estimated by ALP staining is assessed as red stains indicating the products of enzyme activity.The calcium content in mineralized nodules was determined by using a calcium E-test kit. 6% TF induced ATP production, the gene expression of P2X7, and the expression of osteogenesis-related transcription factor and extracellular matrix protein. 6% TF also significantly increased the calcium content in mineralized nodules and ALP activity staining. Moreover, P2X7 antagonist A438079 was blocked these increases of 6% TF stimulation. These results suggest that the production of ATP which is stimulated by 6% TF promotes differentiation and osteogenesis through P2X7 in osteoblasts.

Regulation of bone formation and mineralisation by ATP-induced ATP release from osteoblasts. James Gallagher*[1], Jane P Dillon[2], Lakshminarayan R Ranganath[2], Peter JM Wilson[2]. [1]University of Liverpool, United Kingdom, [2]University of Liverpool, United Kingdom

Extracelluar ATP appears to play a major role in the regulation of bone physiology, signalling through P2 purinergic receptors. There are almost certainly more receptor subtypes responsive to ATP expressed in bone than for any other single ligand and the receptors are expressed on osteoblasts, osteoclasts and osteocytes. Despite the dominant presence of this complex signalling system in bone, the physiological role is relatively unelucidated. Polymorphisms in several P2 receptors including P2X7 are associated with bone mass. Osteoblasts are known to release ATP both constitutively and in response to stimuli including shear stress, indicating that purinergic signalling plays a role in mechanotransduction. In this study we investigated if activation of P2 receptors influences the subsequent release of ATP from human osteoblasts in vitro. We investigated primary human osteoblasts and three osteosarcoma cell lines MG-63, TE-85 and Saos-2, which represent different stages of osteoblastic differentiation. We used the luciferin/luciferase assay to measure ATP in conditioned medium. When exogenous ATP was added to osteoblastic cells at concentrations below 10^{-5} M it was rapidly broken down with a half life of less than 1h. However when we raised the concentration of exogenous ATP above 10^{-4} M, in cultures of primary osteoblasts or MG-63 and Saos-2 cells, there was a massive release of ATP from the cells into the conditioned medium. The concentration of ATP reached millimolar level, which could only be achieved by an almost complete depletion of ATP in the cells. This release of ATP was not associated with cell death. ATP-induced ATP release was not observed in the Te-85 cells which are devoid of functional P2X7 receptors, indicating that this ionotropic, pore forming receptor might be the conduit for release of ATP. However, we could not completely replicate the effects of ATP in primary osteoblasts, or the other two osteosarcoma cell lines with BzATP, a prototypical P2X7 agonist. Taking into account the large dilution effect of tissue culture medium, the ATP released from osteoblasts could reach concentrations where it would have a significant effect on mineralisation as a source of local phosphate ions or through degradation to the mineralisation inhibitor pyrophosphate. In summary ATP-induced ATP release from osteoblasts is an unusual example of positive feedback in bone homeostasis and may play a major role in regulating formation and mineralisation of bone.

Vitamin B_{12}-dependent liver taurine synthesis regulates growth and bone mass. Isabel Quiros-Gonzalez*[1], Pablo Roman-Garcia[2], Liesbet Lieben[3], Vijay K. Yadav[3]. [1]Wellcome Trust Sanger Institute, United Kingdom, [2]Systems Biology of Bone, Wellcome Trust Sanger Institute, United Kingdom, [3]Wellcome Trust Sanger Institute, United Kingdom

Purpose: Vitamin B_{12} (B_{12}) is an essential water-soluble vitamin that regulates a multitude of cellular processes. Absortion of B_{12} from the gut lumen into the blood stream requires gastric intrinsic factor (Gif), a stomach-specific protein, and following absorption B_{12} is stored in the liver. A decrease in the production of functional Gif therefore causes B_{12} deficiency. In humans, B_{12} deficiency is associated with lower bone mineral density and increased fracture risk. In the present study we investigated the importance of B_{12} in the regulation of bone mass homeostasis.Methods: A mouse genetic model of B_{12} deficiency was generated by deleting *Gif* gene. Liver and bone tissues or cell lines were studied for mRNA and protein expression. Liver HepG2 cell line with alterations in B_{12} levels [Transcobalamin-oleosin (TCOL) based B_{12} sequestration] or in GH signaling pathway (shSTAT5) was used as an *in vitro* model to investigate effect of B_{12} deprivation on in hepatocytes by metabolomic analysis. In addition, pre-osteoblast cell line MC3T3 was used to investigate the direct effect of B_{12} on osteoblast proliferation and differentiation.Results: *Gif*-/- mice showed growth retardation and early onset osteoporosis during post-weaning period. Analysis of GH-Igf1 axis that regulates grwoth and bone mass revealed a major decrease in Igf1 levels and an increase in GH levels in mutant mice. These results suggested that B_{12} deficiency in *Gif*-/- mice results in a block in GH signaling pathway. Consistent with this hypothesis, phosphorylation levels of STAT5 the major mediator of GH signaling showed a drastic decrease in the liver of *Gif*-/- mice. Similarly, sequestration of B_{12} by TCOL transfection in HepG2 cells caused a decrease in STAT5 phosphorylation mimicking shSTAT5 transfected HepG2 cells. Both TCOL and shSTAT5 transfected cells showed disruption of Igf1 expression in response to GH. Metabolomic analysis in HepG2 cells transfected with TCOL or *Gif*-/- liver samples showed that taurine, produced mainly in the liver, is a critical metabolite affected upon B_{12}/GH signaling disruption. Further experiments showed that taurine increases osteoblast proliferation directly by increasing IGF1 signaling in osteoblast and when given *in vivo* can rescue growth retardation and osteoporosis observed upon B_{12} deficiency.Conclusions: Together these results show that liver B_{12}/Taurine pathway is essential for normal functioning of GH/Igf1 axis in the regulation of growth and bone mass

Analysis of Runx2 and LRP5 Along the hFOB Differentiation. Susana Balcells*[1], Behjat Gholami[1], Judith Garcia-Gonzalez[1], Roser Urreizti[1], Natalia Garcia-Giralt[2], Robert Guerri Fernandez[3], Leonardo Mellibovsky[4], Xavier Nogues[5], Adolfo Diez-Perez[6], Daniel Grinberg[7]. [1]Dept. Genetics, Univ. Barcelona, CIBERER, IBUB, Spain, [2]IMIM, Spain, [3]Fundacio IMIM, Spain, [4]Institut Municipal d'Investigació Mèdica, Spain, [5]Institut Municipal D'Investigació Mèdica, Spain, [6]Autonomous University of Barcelona, Spain, [7]The University of Barcelona, Spain

Osteoblasts are bone-forming cells, derived from mesenchimal progenitors through differentiation in which Runx2 plays a crucial role. LRP5 is a Wnt coreceptor, which has been involved in determining bone mass, both in humans and in mice. Gain of function mutations in *LRP5* determine high bone mass and loss of function mutations cause osteoporosis. Five Runx2 binding sites have been described in the upstream region of *LRP5*, one of which –BS1- contains the SNP rs312009, associated with bone mineral density. The aim of this study was to characterize the expression of these genes in the human fetal osteoblast cell line hFOB, along 21 days of differentiation.hFOB cells were grown in Ham's medium with G418 and 10%FBS at 33.5℃. At 80% confluence, they were shifted to 39.5° to promote osteoblast differentiation. Viability (MTT test) and mineralization (Alizarin staining) were monitored at days 0, 3, 7, 14 and 21. Protein, RNA and fixed chromatin samples were collected at each time point. Proteins were screened by western blot and mRNAs by RT-qPCR using GAPDH as normalizer. Saos2 cells were grown in standard conditions and protein, RNA and fixed chromatin was obtained and analyzed in parallel.At day 0, hFOBs underwent rapid cell division. Upon temperature shift, cell division slowed down and at day 3 they stained positive for mineralization. Cells, initially elongated and fusiform (day 0-3), changed to a planar rectangular aspect and with pseudopodes at the borders (day 14-21). Concomitantly, viability decreased starting at day 7 and at each subsequent time point was reduced about 50%.At mRNA level, Runx2 was almost undetectable in hFOB at d.0, when compared to the very high levels present in Saos2. Along differentiation, Runx2 transcript levels raised 6.5 x at day 3 and stayed stable up to day 21. LRP5 mRNA was 3.7 x higher in hFOB d.0, when compared to Saos2, and it increased moderately along differentiation. Between d.3 and d.14, levels were 1.5 x and at d.21 they were 2 x higher than at d.0. Runx2 and LRP5 proteins were detected in hFOB at any day of differentiation. Runx2 was very abundant in Saos2, and very low, although detectable, in hFOB (any day), paralleling the mRNA profile. ChIP with anti-Runx2 in Saos2 chromatin showed occupancy of all 5 BS sites of the *LRP5* promoter.In conclusion, both Runx2 and LRP5 were detected at mRNA and protein levels along the hFOB differentiation. A ChIP assay is underway to test the occupancy of the 5 BSs in hFOB chromatin.

Bio-active silica nanoparticles promote osteoblast differentiation though stimulation of autophagy and direct association with LC3 and p62. Shin Ha[1], M. Neale Weitzmann[2], George Beck*[2]. [1]Emory University, USA, [2]Emory University School of Medicine, USA

Nanotechnology is a multidisciplinary field involving the development of engineered ''devices'', including particles, at the nanometer size (typically 1-200 nm). Recent advances in nanotechnology have raised exciting possibilities for use of nanoparticles as therapeutic interventions. Silica based nanoparticles have been demonstrated to alter biological processes in the nano form, dependent on size, and are generally thought to be non-toxic in vivo. Consequently, they are good candidates for use in biomedical applications. We have engineered a novel 50 nm silica-based fluorescent nanoparticle (designated herein as NP1) that potently stimulates in vitro differentiation and mineralization of osteoblasts, the cells responsible for bone formation, and increases bone mineral density in young mice in vivo. The results demonstrate that these nanoparticles have intrinsic biological activity, however the intracellular fate and a complete understanding of the mechanism(s) involved remains to be elucidated. Here we investigated the cellular mechanism(s) by which NP1 stimulates differentiation and mineralization of pre-osteoblasts. We determine that NP1 enters the cells through a caveolae mediated endocytosis followed by stimulation of the mitogen activated protein kinase ERK1/2 (p44/p42). Our findings further revealed that NP1 stimulates autophagy including the processing of LC3β-I to LC3β-II, a key protein involved in autophagosome formation, which is dependent on ERK1/2 signaling. Using a variant of NP1 with cobalt ferrite magnetic metal core (NP1-MNP) to pull down associated proteins, we demonstrate direct binding of LC3β and p62, two key proteins involved in autophagosome formation, with silica nanoparticles. Interestingly, NP1 specifically interacts with the active and autophagosome associated form of LC3β (LC3β-II). Taken together, the stimulation of autophagy and associated signaling provides a cellular mechanism for the stimulatory effects of our nanoparticles on osteoblast differentiation and mineralization.

Indirubin-3'-oxime Reverses Bone Loss in Ovariectomized and Hindlimb-Unloaded Mice via Activation of the Wnt/β-Catenin Signaling. Muhammad Zahoor*[1], Pu-Hyeon Cha[2], Kang-Yell Choi[2]. , [2]Yonsei University, South Korea

Osteoporosis is a major global health issue in elderly people. Increasing evidence suggests that current anti-osteoporosis agents have adverse effects, including high risk of cancer, micro-fracture, and jaw osteonecrosis. Because Wnt/β-catenin signaling plays a key role in bone homeostasis, we screened activators of this pathway through cell-based screening, and investigated indirubin-3'-oxime (I3O), one of the positive compounds known to inhibit GSK3β, as a potential anti-osteoporotic agent. Here, we show that I3O activated Wnt/β-catenin signaling via inhibition of the interaction of GSK3β with β-catenin, and induced osteoblast differentiation *in vitro* and increased calvarial bone thickness *ex vivo*. Intraperitoneal injection of I3O increased bone mass and improved microarchitecture in normal mice and reversed bone loss in an ovariectomized mouse model of age-related osteoporosis. I3O also increased thickness and area of cortical bone, indicating improved bone strength. Enhanced bone mass and strength correlated with activated Wnt/β-catenin signaling, as shown by histological analyses of both trabecular and cortical bones. I3O also restored mass and density of bone in hindlimb-unloaded mice compared to control, suspended mice, demonstrating bone-restoration effects of I3O in non-aged–related osteoporosis as well. Overall, I3O, a pharmacologically active small molecule, could be a potential therapeutic agent for the treatment and prevention of osteoporosis.

Figure lagend:

(A): ALP staining of I3O treated murine primary osteoblasts. (B) Alizarin red stainin of I3O treated murnine primary osteoblasts. (C) I3O treated calvaria. (D). TRAP stained RANKL and I3O treated RAW264.7 cells. (E). Micro CT images of I3O treated ovarectmized mice femur. (F). Micro CT images of I3O treated hind-limb-unloaded mice femur.

MAPK-Mediated Epigenetic Regulation of Gene Expression During Osteoblast Differentiation. Yan Li*[1], Chunxi Ge[2], Guisheng Zhao[3], Renny Franceschi[1]. [1]University of Michigan, USA, [2]Pom Univ of Michigan School of Dentistry, USA, [3]University of Michigan School of Dentistry, USA

BMPs, FGF2, mechanical loading and cell-ECM contact stimulate osteoblast differentiation in part by activating the ERK/MAP kinase pathway, which subsequently phosphorylates a number of substrates including the Runx2 transcription factor. However, the relationship between MAP kinase activation and epigenetic regulation of chromatin has not been previously examined. In this study, we used chromatin immunoprecipitation (ChIP) to examine early histone modifications during osteoblast differentiation and compared these changes with chromatin occupancy by p300 histone acetyltransferase, AOF1 histone demethylase, P-ERK and phosphorylated Runx2. Studies focused on chromatin regions containing Runx2 binding sites present in osteocalcin (Bglap2) and bone sialoprotein (Ibsp) genes. Osteoblast differentiation was induced in MC3T3-E1c4 cells using ascorbic acid (AA) and gene expression measured with quantitative RT-PCR. Initial AA-dependent induction of Bglap2 and lbsp mRNAs was seen at 3 days and continued to increase at 6 days. Chromatin was isolated at 6 days for ChIP analysis using antibodies specific to AcH3k9, AcH4K5, H3K4dm, H3K9m, P-ERK, Runx2, P-Runx2 (S319-P), Pol II, p300 histone acetyltransferases and AOF1 histone demethylase. Osteogenic stimulation increased histone H3K9 and H4K5 acetylation near the two Runx2-binding elements of Bglap2 (OSE2a, OSE2b) and at a proximal Runx2 binding region of Ibsp. The level of H3K4 di-methylation, another gene activation-associated histone marker, was also increased in both genes. However, the level of H3K9 mono-, di-, and tri-methylation in the same regions was reduced. Similarly, chromatin-bound P-ERK, P-Runx2, p300 and RNA polymerase II all increased. In contrast, no changes were observed in total Runx2 and AOF1. Inhibition of MAP kinase signaling blocked chromatin modifications and Bglap2 and Ibsp induction. To evaluate the role of Runx2 phosphorylation, Runx2-deficient C3H10T1/2 cells were transduced with adenovirus encoding wild type or phosphorylation-deficient Runx2 (S301A/S319A mutant). Wild type Runx2 increased H3K9 and H4K5 acetylation as well as chromatin-associated P-ERK, p300 and polymerase II. In contrast, the phosphorylation-deficient Runx2 mutant had much less activity. Taken together, this study reveals a molecular mechanism through which osteogenic genes are epigenetically controlled by a MAPK-mediated, Runx2-requiring complex associated with specific promoter regions.

Sp7 is Obligatory for Stability and Function of Runx2 Protein During Bone Formation. Harunur Rashid*[1], Haiyan Chen[2], Ching-Fang Chang[3], Krishna Sinha[4], Benoit DeCrombrugghe[4], Amjad Javed[2]. [1]University of Alabama Birmingham, USA, [2]University of Alabama at Birmingham, USA, [3]University of Alabama at Birmingham, USA, [4]UT MD Anderson Cancer Center, USA

Targeted disruption of specificity protein-7 (Sp7) and Runx2 genes results in complete failure of bone formation. Molecular reasons for surprisingly similar phenotype from two structurally unrelated proteins remain unknown. Sp7 is not expressed in Runx2-null mice reflecting a compound phenotype of both Runx2 and Sp7 loss. Sp7-null mice, however fail to form bone, despite normal levels of Runx2 mRNA in skeletal tissues. Here we identified molecular mechanisms underlying the functional incompetency of Runx2 in Sp7 null model. Human and mouse osteoblasts expressing both proteins were treated with Sp7 specific siRNA. We observed a dose dependent inhibition of Sp7 protein. To our surprise, a concomitant reduction of Runx2 protein was also noted. To assess if decrease in Runx2 protein is due to transcriptional regulation of Runx2 by Sp7, we isolated RNA. The siRNA treatment only decreased Sp7 mRNA but the levels of Runx2 mRNA remain unchanged. Thus regulation of Runx2 protein by Sp7 is post-transcriptional. We next determine if Sp7 is necessary for stability of Runx2 protein by co-transfecting cells with fixed amount of Runx2 and increasing concentration of Sp7 plasmid. We observed a dose dependent increase in Sp7 protein. Surprisingly, a progressive increase in Runx2 protein ~20 fold was also noted. Importantly, the half-life of Runx2 protein was significantly extended in the presence of Sp7. Interestingly, Co-IP studies revealed that in osteoblasts, endogenous Sp7 protein forms a molecular complex with Runx2. The physical interaction requires RHD of Runx2 and transactivation domain of Sp7 protein. Moreover, MAPK mediated phosphorylation of both Runx2 and Sp7 protein is essential for their interaction. Reciprocal interaction between Sp7 and Runx2 protein prompted us to examine how Sp7 stabilizes Runx2 protein. We found both ubiquitination and degradation of Runx2 protein by smurf1 is strongly inhibited by the presence of Sp7. Runx2-Sp7 physical interaction is an integral component of this process, as mutant Sp7 that lack Runx2 interaction domain, fail to block degradation of Runx2 protein by smurf1. Importantly, phosphorylated Runx2 and Sp7 functionally cooperate for maximal induction of osteoblast genes. Finally, we demonstrate that Runx2 protein is highly unstable and rapidly degrade in both intramembranous and endochondral bones of Sp7 null mice. In conclusion Sp7 regulate Runx2 protein stability and function through molecular interaction in bone cells.

Suppression of p38alpha MAPK Signaling in Mature Osteoblasts Impairs PTH-Induced Bone Anabolism. Cyril Thouverey*[1], Joseph Caverzasio[2]. [1]University Hospital of Geneva, Switzerland, [2]Division Bone Diseases, Switzerland

Intermittent PTH administration (iPTH) increases bone mass in humans and animals. PTH exerts its effects by binding to PTH type 1 receptor (PTHR1) predominantly expressed by osteoblasts, resulting in activation of multiple downstream signaling pathways. *In vitro* investigations have suggested that p38 mitogen-activated protein kinase (MAPK) signaling is an important mediator of PTH-induced osteoblast functions. To evaluate the contribution of p38alpha MAPK signaling in iPTH-induced bone anabolism, 3-month-old male mice lacking *p38alpha* in osteoblasts (*Ocn-Cre;p38alpha$^{f/f}$*) and their control littermates (*p38alpha$^{f/f}$*) were treated with daily subcutaneous injections of either 40 μg/kg PTH (1-34) or its vehicle. After 4 weeks of treatment, bone phenotypes were assessed by dexa, microCT, histomorphometry and quantitative gene expression analyses (n=7 per group). Data were analyzed by two-way ANOVA and *post hoc* analyses were performed using the Holm-Sidak method. iPTH treatment increased total bone mineral density (+8.5 %, p=0.003 versus Veh), femoral cortical thickness (+10.9 %, p=0.005), femoral cancellous bone volume (+35.4 %, p=0.007) and trabecular thickness (+21.9 %, p=0.008) in control mice but did not induce significant changes of those parameters in *Ocn-Cre;p38alpha$^{f/f}$* mice. Consistent with this, iPTH significantly stimulated mineralizing surfaces (1.5-fold), mineral apposition rate (1.9-fold) and bone formation rate (2.8-fold) in control animals, whereas it only enhanced mineralizing surfaces (1.5-

fold) in *Ocn-Cre;p38alpha$^{f/f}$* mice, indicating a functional defect of *p38alpha*-deficient osteoblasts in response to iPTH. Furthermore, iPTH significantly increased osteoblast marker gene expressions (*Col1a1*, *Alp*, *BspII* and *Ocn*) in control mice but not in *Ocn-Cre;p38alpha$^{f/f}$* mice. Finally, *p38alpha*-deficient osteoblasts exhibited normal *Pthr1* gene expression in comparison to control osteoblasts, but displayed reduced elevations of *Alp*, *BspII* and *Ocn* expressions and matrix mineralization in response to PTH *in vitro*. Our findings indicate that the p38alpha MAPK in osteoblasts plays an important role in PTH-induced bone anabolism in mice.

Transcription factor SP1 regulates Frizzled 1 expression in osteoblasts. Shibing Yu*[1], Laura Yerges-Armstrong[2], Yanxia Chu[3], Joseph Zmuda[4], Yingze Zhang[5]. [1]University of Pittsburgh Medical Center, USA, [2]University of Maryland School of Medicine, USA, [3]University of Pittsburgh Department of Medicine, USA, [4]University of Pittsburgh Graduate School of Public Health, USA, [5]University of Pittsburgh, USA

Frizzled 1 (FZD1) is a co-receptor for Wnts and plays a role in osteoblast differentiation and mineralization. The expression of FZD1 is regulated by multiple transcription factors including Egr1 and E2F1. Promoter variants of FZD1 affect its transcriptional regulation and are associated with bone mineral density (BMD) in humans. Specificity protein 1 (Sp1) is an important transcription factor regulating gene expression in different tissues including bone. We performed in silico analysis of the promoter variant rs2232158 and identified putative differential binding of Sp1 with the G and C alleles. To assess the potential regulatory role of Sp1 in FZD1 expression in osteoblasts, we cloned the FZD1 promoter luciferase reporter plasmid containing the rs2232158 variant G or C alleles and transfected the reporter constructs into Saos2 cell lines with Sp1 or control expression plasmids. Our experiments demonstrated that Sp1 significantly increases FZD1 promoter activity, but this regulation was not affected by rs2232158 allelic variants. Overexpression of a loss-of-function Sp1 mutant plasmid did not affect the FZD1 promoter activity, indicating Sp1 specifically up-regulates FZD1 expression in Saos2 cells. Moreover, quantitative PCR and Western blot results showed that overexpression of Sp1 leads to higher FZD1 mRNA and protein expression. Further studies are needed to ascertain the specific Sp1 binding site(s) in FZD1 promoter region. Taken together, our study demonstrates that Sp1 is a transcriptional activator of FZD1 in osteoblasts.

Transcriptional Profiling of Laser Capture Microdissected Subpopulations of the Osteoblast Lineage Provides Insight Into the Molecular Mechanism of Action of Sclerostin Antibody. Paul Nioi*, Scott Taylor, Rong Hu, Efrain Pacheco, Yudong He, Hisham Hamadeh, Chris Paszty, Ian Pyrah, Mike Ominsky, Rogely Boyce. Amgen Inc., USA

Sclerostin antibody (Scl-Ab) increases bone formation that is dependent upon activation of canonical Wnt signaling, though the specific in vivo signaling in the osteoblast lineage is largely unknown. To gain insight into the signaling pathways acutely modulated by Scl-Ab, the acute transcriptional response of subpopulations of the osteoblast lineage was assessed by microarray analysis of mRNA isolated from laser capture microdissection (LCM)-enriched samples from the vertebrae of aged ovariectomized (OVX) rats following exposure to Scl-Ab.

Six-month-old rats were OVX, and after 2 months, received a single dose of vehicle or 100 mg/kg Scl-AbVI (n=20/group). Rats were administered fluorochrome labels at 72h predose and 48h and 120h postdose to label active forming surfaces. At 6h, 24h, 72h, and 168h postdose, 5 rats/group were euthanized. Lumbar vertebrae were collected, snap-frozen, and cryosectioned undecalcified for LCM. Osteoblasts and lining cells (LC) from cancellous bone were enriched by capturing bone surfaces with and without fluorochrome label, respectively, and osteocytes were enriched by capturing bone matrix. mRNA was isolated from the LCM samples, amplified, and profiled by microarray.

Analyses revealed that Scl-Ab resulted in a strikingly similar transcriptional profile in all 3 cell types, evident as early as 6h and sustained through 168h. A limited number of Wnt target genes were found to be upregulated, with *Wisp1, Twist1, connexin 43, osteocalcin,* and *Mmp2* being the most responsive. These genes have known functions in bone including regulation of osteoblastogenesis, cell-to-cell communication, mechanotransduction, and bone matrix production and remodeling. There was coincident upregulation of numerous extracellular matrix (ECM) genes, heralding the onset of bone matrix synthesis. Several of the ECM genes have a consensus Wnt response element, suggesting these are potential canonical Wnt target genes in bone. The acute and sustained upregulation of transcripts related to bone matrix synthesis in LC supports activation of quiescent LC into matrix-producing osteoblasts consistent with modeling-based bone formation. This same transcriptional profile in osteocytes may indicate that Scl-Ab stimulates perilacunar/pericanalicular matrix deposition.

These data demonstrate the focused nature of canonical Wnt signaling in bone in response to Scl-Ab that is acutely shared by all the mature osteoblast subpopulations.

Hippo pathway in cranial neural crest is required for normal cranial bone and suture growth. Jun Wang*[1], Yang Xiao[2], Jianning Tao[3], Margarita Bonilla-Claudio[4], Brian Dawson[4], Eric Olson[5], Brendan Lee[3], James Martin[4]. [1], USA, [2]Baylor College of Medicine, USA, [3]Baylor College of Medicine, USA, [4]Baylor College of Medicine, USA, [5]University of Texas Southwestern Medical Center, USA

Cranial neural crest (CNC) contributes to multiple cells types including cartilage, bone, neurons, and glia. CNC defects cause different congenital defects such as craniosynostosis. The function of Hippo signaling, an ancient organ size control pathway, in CNC is poorly understood. To investigate Hippo signaling in CNC derivatives such as calvarial bones and sutures, we specifically inactivated the Hippo component *Salv*, as well as downstream Hippo pathway effectors *Yap* and *Taz* in CNC using the Wnt1 Cre driver. Our observations reveal that 1) *Wnt1^{Cre}; Salv$^{f/f}$* mutants had dramatically enlarged calvarial bones and cranial sutures with increased calvarial bone density; 2) *Wnt1^{Cre}; Taz$^{f/+}$; Yap$^{f/f}$* and *Wnt1^{Cre}; Taz$^{f/f}$; Yap$^{f/f}$* mutants were embryonic lethal and had severe frontonasal and mandibular structural defects; 3) *Wnt1^{Cre}; Taz$^{f/f}$; Yap$^{f/+}$* mutants had a range of survival times from E14.5 to postnatal 8 weeks with a range of calvarial bone defects with Wormian bones and decreased calvarial bone density; 4) *Taz$^{f/f}$; Yap$^{f/f}$* CKO mutant CNC had reduced cellular proliferation but no obvious change in apoptosis as compared to controls; 5) Yap expression level and subcellular location changed in response to matrix stiffness. Together, our findings indicated the crucially important requirement for Hippo pathway in normal cranial bone and suture growth.

Bmp2 Gene in Stem Cell Biology of the Periodontium. Stephen Harris*[1], Audrey Rakian[2], Jelica Gluhak-Heinrich[1], Marie Harris[1], Yong Cui[3], Ivo Kalajzic[4]. [1]University of Texas Health Science Center at San Antonio, USA, [2], USA, [3]UTHSCSA, USA, [4]University of Connecticut Health Center, USA

Understanding how stem cells in the periodontium differentiate into the 3 major components of the periodontium, alveolar bone, periodontal tendon like ligament (PDL), and cementum (links PDL to teeth), will lead to new paradigms to regenerate this lost tissue in disease. Cells labeled by a-smooth muscle actin (aSMA+) in the periodontium have recently been found by lineage tracing studies to be a major class of stem cells that differentiate into these 3 major periodontium components (Roguljic et al, 2013, J. of Dental Res.). Using the conditional knock-out of the Bmp2 gene with the αSMACreERt2 model, we discovered major defects in formation of the alveolar bone, cementum, both cellular and acellular, as well as formation of periodontal ligaments or PDL in the absence of the Bmp2 gene in these stem cells. We observed decreased expression of Scleraxis, Tenomodulin, and Periostin, as well as Osterix in the Bmp2 cKO model. Utilizing Ai9 allele, (Rosa26-loxP-stop-loxP-tdTomato), we have demonstrated by lineage tracing methods, in the absence of the Bmp2 gene, that there are major defects in growth and expansion of these stem cells noted as early as 17 days after a single Tamoxifen injection (Cre activation at 6 days). By 1 month, we quantitated colocalization (Fiji/coloc2 program) of bone/cementum marker, Osterix (green FITC labeled antibody), and the td-Tomato+ (red) cells, and find a 60-70% reduction in aSMA+ cells differentiating to either alveolar osteoblasts or cellular cementoblasts. We used the Periostin antibody for periodontal ligament (PDL) cells, to also quantitate a 50% reduction in tdTomato+ stem cells capable of differentiating to mature PDL cells. Sirius red histology demonstrated that major regions of the PDL and cellular cementum are lacking or dysmorphic at 3 months of age. Purified αSMA+ periodontal stem cell differentiation, with and without the Bmp2 gene is now being used to characterize the transcriptome using RNA-seq methods. Thus, the Bmp2 gene in the periodontal stem population is required for expansion and differentiation of all three major mesodermal derived components of the periodontium.

Connectivity Map-Based Discovery Of Parbendazole As A Novel Osteogenic Compound. Andrea Brum*[1], Jeroen van de Peppel[2], Cindy van der Leije[2], Marco Eijken[3], Johannes Van Leeuwen[4], Bram Van Der Eerden[5]. [1]Erasmus MC, The Netherlands, [2]Erasmus MC, Netherlands, [3]Arcarios, Netherlands, [4]Erasmus University Medical Center, The Netherlands, [5]Erasmus MC, The Netherlands

Osteoporosis is a common skeletal disorder characterized by low bone mass leading to increased bone fragility and fracture susceptibility. Little is currently known about what specific factors stimulate osteoblast differentiation from human mesenchymal stem cells (hMSCs). Our aim was therefore to determine novel factors and mechanisms involved in human bone production, which can be targeted to treat osteoporosis, using gene expression profiling and bioinformatic analyses, including the Connectivity Map (CMap), as an *in silico* approach.

The gene signature of osteogenic hMSCs (top significantly regulated genes 6 hours after induction by dexamethasone as assessed by Illumina microarrays) was uploaded into CMap (www.broadinstitute.org/cmap/). Osteogenic differentiation was assessed by analyses of alkaline phosphatase (ALP) activity and mineralization by calcium assay and alizarin red staining. Gene expression was determined by qPCR and BMP activity was assessed by reporter assay. Immunofluorescent analyses were performed to examine changes in the cytoskeleton.

The CMap identified parbendazole as a compound with the most significantly correlating gene signature to osteogenic hMSCs. Parbendazole stimulated osteogenic hMSC differentiation as indicated by increased ALP activity, mineralization and upregulation of ALP, osteopontin, and bone sialoprotein II, which interestingly occurs independent of the presence of glucocorticoids (GC). Moreover, strong upregulation of GC receptor (GR) target genes by GC is absent in parbendazole-treated cells and the effect was not inhibited by GR antagonist mifepristone. Parbendazole caused profound cytosketetal changes including strong inhibition of microtubules and increased number of focal adhesions. Stabilization of microtubules by pretreatment with taxol abolished osteoblast differentiation. Additionally, BMP-2 gene expression and activity is upregulated by parbendazole. Treatment of hMSCs with the BMP antagonist DMH1 in combination with parbendazole limited mineralization.

By combining genomic and bioinformatic tools against the backdrop of highly characterized human osteogenic MSCs we have identified a novel bone anabolic candidate that induces osteoblast differentiation through a combination of cytoskeletal changes and increased BMP-2 activity, and independent of GC stimulation. In addition, the results demonstrate the significance of cytoskeletal organization in osteogenic differentiation and the power of the CMap.

Cross-Species Transcriptomic Analysis Reveals Conserved Osteogenic Signatures During Zebrafish and Rat Bone Regeneration. Ronald Kwon*[1], Amarjit Virdi[2], D. Rick Sumner[2]. [1]University of Washington, USA, [2]Rush University Medical Center, USA

Modern advances in large-scale biological research underscore the potential impact of novel in vivo models of bone disorders that are genetically tractable, optically transparent, and amenable to high-throughput approaches. By virtue of its capacity to recapitulate the major phases of mammalian bone formation, the regenerating zebrafish tail fin provides a compelling system for such studies. In this investigation, our goal was to utilize cross-species transcriptomic analysis to quantify the extent to which gene expression signatures underlying mammalian bone formation are conserved during zebrafish fin regeneration. We compared genome-wide gene expression during zebrafish tail fin regeneration (d1, d3, and d5; GEO accession # GSE3667) and rat marrow ablation-induced intramembranous bone formation (d0, d1, d3, d5, d7, d10, d14, d28, and d56; GSE22321) using custom meta-analysis software that mapped zebrafish and rat protein sequence homology pairings to their respective genome microarray probe sets. Analysis revealed 1778 and 14,845 significantly altered genes during zebrafish and rat bone regeneration, respectively, between which 720 were identified as orthologous gene pairs. Genome-wide correlations (Fig 1) during zebrafish and rat initial healing ($r=0.31$ for d1 in zebrafish & d1 in rat, $p<1e-16$) and early osteogenesis ($r=0.33$ for d5 in zebrafish & d10 in rat, $p<1e-16$) were highly significant, approaching the 95% confidence interval for inter-sample correlations within each species ($r=0.36$-0.87 in zebrafish and $r=0.51$-0.64 in rat). Lower correlations were observed during zebrafish blastema formation ($r=-0.15$ to 0.17 for d3 in zebrafish and d1-d10 in rat), suggesting zebrafish and rat bone regeneration occur through distinct transcriptomic trajectories that converge during osteogenesis. Analysis of ortholog gene pairs revealed a number of genes implicated in disorders of bone mineralization (phex, lemd3, fkbp10, crtap, mmp2, sost, col1a1, col1a2, sparc, periostin), craniofacial disorders (msx2, twist1), and skeletal dysplasias (col10a1 ,col11a1, col11a2, fgr3), suggesting the potential to map gene regulatory networks underlying these disorders through cross-species strategies. Collectively, these studies identify genome-wide correlations and conserved gene expression signatures in zebrafish and rat intramembranous bone formation, an essential step toward cross-species examinations of bone anabolic pathologies in the zebrafish and mammalian skeletons.

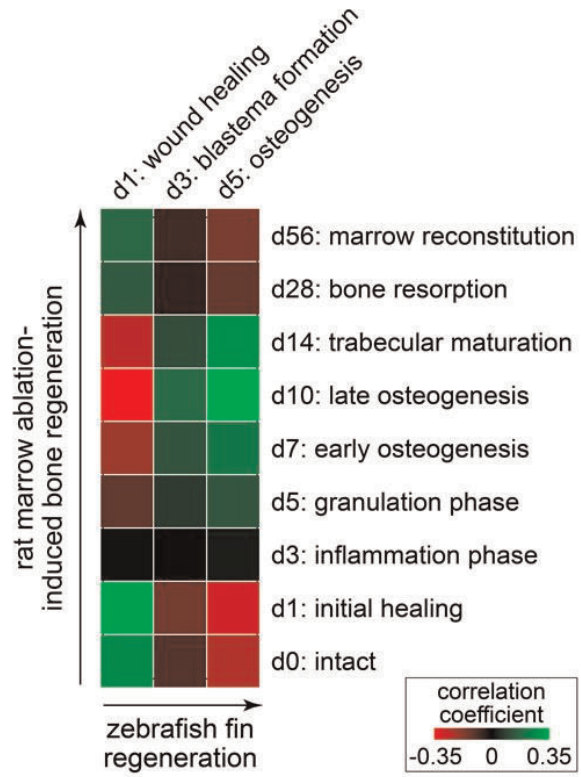

Fig 1: Correlation coefficients for genome-wide gene expression during zebrafish fin regeneration and rat marrow ablation-induced bone regeneration. Transcriptomes converge during initial healing (d1 in zebrafish and d1 in rat) and osteogenesis (d5 in zebrafish and d10 in rat).

Evaluation of Potential Dried Plum Bioactive Components and their Effects on Osteoblast and Osteoclast Differentiation and Activity. Jennifer Graef*[1], Elizabeth Rendina-Ruedy[2], Jarrod King[3], Robert Cichewicz[4], Edralin Lucas[1], Brenda Smith[1]. [1]Oklahoma State University, USA, [2]Vanderbilt University Medical Center, USA, [3]Natural Products Discovery Group, University of Oklahoma, USA, [4]Natural Products Discovery Group, Department of Chemistry & Biochemistry, University of Oklahoma, USA

Osteoporosis treatment strategies utilizing naturally occurring phytochemicals that are abundant in certain functional foods may provide cost-effective alternatives with fewer side effects. Previously, we reported a biphasic effect of dried plum (DP) treatment *in vivo*, characterized by an initial suppression of osteoblast and osteoclast number followed by a rebound of osteoblast activity occurring later. The purpose of this study was to begin to identify the bioactive components in DP and to examine their effects on osteoblast and osteoclast differentiation and activity under normal and inflammatory conditions. A polyphenolic extract from DP was fractionated via chromatography using HP-20 resin and increasing concentrations of methanol to yield 8 fractions of interest. Toxicity was determined by evaluating the dose-escalating effects of the fractions on the viability of RAW 264.7 (monocytes/macrophages) and MC3T3-E1 (osteoblast precursor) cells using the MTT (3-[4,5-dimethylthiazol-2-yl]-2,5 diphenyl tetrazolium bromide) assay. Doses that were not detrimental to cellular growth/viability were studied. Osteoblast differentiation and activity were determined by assessing extracellular alkaline phosphatase (ALP) and quantifying ALP staining density and an Alizarin Red stain for mineralization. Osteoclast differentiation was assessed by culturing RAW 264.7 cells in the presence of receptor activator NF-kappa B ligand (RANKL) and quantifying the large, multi-nucleated TRAP-positive stained cells. Under normal conditions, there was no change in osteoblast activity at day 1 of treatment, but by day 3, suppression of extracellular ALP was occurring with most of the fractions. Osteoclastogenesis, as indicated by the number of TRAP-positive cells, was reduced. Mineralization by osteoblasts was not affected by treatments under normal conditions, but certain fractions were able to restore mineralization under inflammatory conditions to that of the control. In contrast, the fractions did not

restore the LPS-induced increase in osteoclast differentiation to that of the control. Together, these data support the notion that compounds within these fractions initially suppress bone turnover, similar to that observed in our previous *in vivo* study. Certain fractions have a more robust response in the osteoblast cell line, and these fractions will be further studied to determine how they alter osteoblast and osteoclast activity using primary cells cultures and *in vivo* models.

Foxp1 Regulaes Osteogenic/Adipogenic Cell Fate Commitment in Bone Marrow Mesenchymal Stem Cell. Xizhi Guo[1], Hanjun Li*[2], Sixia Huang[2]. [1]Shanghai Jiao Tong University, Peoples Republic of China, [2]Bio-X Institutes, Shanghai Jiao Tong University, China

Mesenchymal stem cells (MSCs) in bone marrow are capable to differentiate into osteoblasts and adipocytes. And more, the differentiative preference of MSCs between osteoblastic and adipogenic lineages is dynamic as bone aging. However, the molecular mechanisms underlying the determination process is not fully clarified. Here we showed that the transcription factor Foxp1 plays an important role in the cell fate determination of bone marrow MSCs. Elevated fat formation and decreased bone formation bone marrow was observed in mice with MSC-targeted deletion of Foxp1. Foxp1-deficient MSCs in both Nestin-Cre; Foxp1c/c and Prx1-Cre; Foxp1c/c mice differentiated into adipocytes at expense of osteoblasts in CFU assays. Conversely, over-expression of Foxp1 in C3H/10T1/2 cells resulted in a severe blockage of adipocyte differentiation, accompanied by an increase of osteoblast differentiation. Molecularly, Foxp1 suppressed the transcactvation of Pparg (one of the master activators in adipogenesis) through interacting with and antagonizing Cebpβ/δ proteins, which are two important inducers during early adipogenic commitment. In addition, Foxp1 repressed adipogenic differentiation in its synergistical association with another adipogenic suppressor Hdac7. Taken together, Foxp1 modulates MSC differentiation as a novel switch between adipogenic and osteoblastic commitment.

IGBBP-2-Regulated Sequential Activation of AMP-Activated Protein Kinase is Required for Osteoblast Differentiation. Gang Xi*[1], Christine Wai[1], Victoria Demambro[2], Clifford Rosen[3], David Clemmons[1]. [1]Department of Medicine, University of North Carolina at Chapel Hill, USA, [2]Maine Medical Center Research Institute, USA, [3]Maine Medical Center, USA

AMP-activated protein kinase (AMPK) regulates skeletal muscle differentiation but studies analyzing its role in osteoblast differentiation have given contradictory results therefore, we determined the temporal sequence of AMPK activation during differentiation using mouse calvarial osteoblasts. The results showed that differentiation medium stimulated AMPK activation at the early stages of differentiation (e.g. days 3-9) but this change was significantly attenuated at the later stages of differentiation (e.g. days 12-21). To definitively determine the role of AMPK, we manipulated AMPK activation using chemical compounds and mutagenesis. Addition of compound C (an AMPK inhibitor) on day 0 or 3 significantly reduced differentiation but had no effect at later time points. In contrast overexpression of constitutively activated AMPK (T172D) dramatically inhibited cell differentiation (e.g., 88 $\pm$ 10% suppression compared to control cells, $p<0.01$) and this inhibition could be rescued by addition of compound C on days 9 or 12. In contrast stimulation of AMPK activation on days 9 and 12 with Metformin significantly inhibited differentiation. Therefore there appears to be a critical window of AMPK activation between days 3-9 that is required for differentiation.

Since our previous studies have shown that IGFBP-2 stimulates osteoblast differentiation, we determined whether IGFBP-2 regulates AMPK activation. Analysis of IGFBP-2 expression showed that it was increased on days 3-6 and declined days 9 - 12, which paralleled the decline in AMPK activation. Overexpression of IGFBP-2 enhanced AMPK activation (e.g., 35 $\pm$ 6% and 87 $\pm$ 9% increases on days 3 and 6, respectively, $p<0.05$). A peptide containing the heparin binding domain of IGFBP-2, a sequence that mediates the effect of IGFBP-2 on osteoblast differentiation, enhanced AMPK activation at the early stage (e.g., 76 $\pm$ 18% increase on day 6, compared to control cultures, $p<0.05$). The inhibitory effect of compound C added on days 0 or 3 was less effective in IGFBP-2 overexpressing cells compared to control cells. Consistently, AMPK activation was significantly impaired from days 3 to 9 in IGFBP-2 knockdown cells and in calvarial osteoblasts isolated from IGFBP-2 -/- mice. We conclude that AMPK activation followed by its down regulation after day 9 is required for osteoblast differentiation and that IGFBP-2 stimulation of AMPK activation is one of the mechanisms by which regulates osteoblast differentiation.

Parathyroid Hormone (1-34) Increases the Numbers and Differentiation of Osteoblast Progenitor Cells *in Vivo*. Deepak Balani*[1], Noriaki Ono[2], Henry Kronenberg[3]. [1]Massachusetts General Hospital & Harvard Medical School, USA, [2]University of Michigan School of Dentistry, USA, [3]Massachusetts General Hospital, USA

A once daily injection of hPTH (1-34) to mice increases trabecular and cortical bone by prolonging the lifespan of osteoblasts by suppressing their apoptosis and activating quiescent lining cells. However, very little is known about the effects of PTH on progenitors of osteoblasts *in vivo*. We investigated whether once daily injections of PTH have effects on osteoblast progenitors. In col2α1-creERT mice, shortly after tamoxifen administration, Rosa26-tomato reporter expression is observed in chondrocytes, perichondrial cells and cells in primary spongiosa. After a prolonged chase, the tomato label is found in mature osteoblasts and adipocytes. We hypothesized that this system could be used to study the effects of hPTH (1-34) on early cells of the osteoblast lineage *in vivo*. 6-8 week old triple transgenic mice carrying col2α1-creERT, Rosa26-tomato reporter, and osteocalcin (Ocn)-GFP received 2 mg tamoxifen once. After 24h, once daily subcutaneous injections of 100 and 500ug/kg hPTH (1-34) or vehicle was begun. Mice were sacrificed 3, 7 and 21d after the tamoxifen injection and hind limbs were dissected. Long bones were utilized for flow cytometry or processed for histology. Flow cytometry analysis showed a dose dependent increase of tomato+ cells on day 3, 7 and 21. We chose mice treated with 500ug/kg hPTH (1-34) for all subsequent experiments. Compared to control mice PTH-treated mice showed a 6-fold increase in the number of tomato+ cells. After 3d there was no tomato/GFP+ cell, suggesting that no tomato+ cell had differentiated into Ocn-GFP+ osteoblast yet. After 7 and 21d in PTH-treated mice, tomato+ cells showed a 3- and 7-fold increase respectively over control mice. We also observed a 6-fold increase in the number of GFP/tomato+ cells after 7 and 21d. Assessment of tomato+ cells using epifluorescent/ confocal microscopy was consistent with the observations from flow cytometry. After 3w of daily PTH injections, compared to control mice, a 6-fold higher number of tomato+ cells were seen throughout the metaphyseal region extending towards the diaphysis. Counting of tomato/GFP+ cells showed a 4-fold increase in the PTH-treated mice compared to the control mice. These data suggest that the col2α1-creERT promoter is active in 6-8 week old mice in osteoblast progenitor cells. Administration of once daily injections of PTH to such mice significantly increases the number of tomato-positive cells that, over time, become Ocn-GFP expressing osteoblasts.

PDGF-AA promotes osteogenic differentiation and migration of mesenchymal stem cell by down-regulating PDGFRa and derepressing BMP-Smad1 signaling. Qian Cong*[1], James Yeh[2], Xuechun Xia[3], Yuji Mishina[4], Aijun Hao[5], Baojie Li[6], Huijuan Liu[3]. [1]Bio-X institute, Key laboratory for the Genetics of Developmental & neuropsychiatric Disorders, Ministry of Education, Shanghai Jiao Tong University, China, [2]Winthrop University Hospital, USA, [3]The Bio-X Institutes, Key Laboratory for the Genetics of Developmental & Neuropsychiatric Disorders, Ministry of Education, Shanghai Jiao Tong University, China, [4]University of Michigan School of Dentistry, USA, [5]Key Laboratory of the Ministry of Education for Experimental Teratology, Shandong University, China, [6]Shanghai Jiao Tong University, Peoples Republic of China

Platelet-derived growth factors (PDGFs) play important roles in skeletal development and bone fracture healing, yet how PDGFs execute their functions remains incompletely understood. Here we show that PDGF-AA, but not -AB or -BB, could activate the BMP-Smad1/5/8 pathway in mesenchymal stem cells (MSCs), which requires BMPRIA as well as PDGFRa. PDGF-AA promotes MSC osteogenic differentiation through the BMP-Smad1-Runx2/Osx axis and MSC migration via the BMP-Smad1-Twist1 axis. Mechanistic studies show that PDGF-AA activates BMP-Smad1 signaling by feedback down-regulating PDGFRa, which frees BMPRI and allows for BMPRI-BMPRII complex formation to activate smad1/5/8, using BMP molecules in the microenvironment. This study unravels a physical and functional interaction between PDGFRa and BMPRI, which plays an important role in MSC differentiation and migration and establishes a link between PDGF-AA and BMPs pathways, two essential regulators of embryonic development and tissue homeostasis.

Comparative Multi-lineage Differentiation of Mandible and Femur Canine Mesenchymal Stem Cells. Juan Bugueno[1], Weihua Li[1], Pinky Salat[1], Sunday Akintoye*[2]. [1]University of Pennsylvania School of Dental Medicine, USA, [2]University of Pennsylvania School of Dental Medicine, USA

BACKGROUND: Mesenchymal stem cells (MSCs) are promising donor grafts for tissue regeneration. MSCs are phenotypically and functionally skeletal site-specific based on extensive studies using human and rodent MSCs but there is paucity of information on canine MSCs (cMSCs) and their regenerative applications in veterinary care. We hypothesized that cMSCs are functionally skeletal-site specific and that canine mandible MSCs (cmMSCs) are highly osteogenic relative to femur MSCs (cFMSCs).

Methods: Trabecular bone samples were obtained from mandible and femur of normal healthy dogs. Primary cmMSCs and cFMSCs were established in culture. Using early passage cells, colony-forming units (CFU), cell proliferation and population doubling capacity were assessed. Using established induction culture conditions, *in vitro* osteogenesis, chondrogenesis, and adipogenesis were assessed. Western blotting and real time PCR were used to assess the following osteogenic markers: alkaline phosphatase (ALP), bone sialoprotein (BSP), osteocalcin (OCN) and osteopontin (OPN). Chondrogenesis was assessed using pellet culture method and histologic sections were stained with Alcian blue; adipogenically induced-cultures were stained with Oil Red O. Furthermore, *in vivo* osteogenesis was assessed using the mouse model of *in vivo* bone regeneration. Transplants were harvested at 6, 8 and 12 weeks for histological analysis.

Results: The cmMSCs demonstrated 1.5 to 2 fold increases in CFU, proliferation and population doublings relative to cFMSCs. Similar pattern was displayed by cmMSCs based on expression levels of BSP, ALP and OCN but OPN levels were not significantly different. Adipogenesis based on number of stained lipid droplets per unit area in cmMSCs were also moderately higher than cFMSCs but chondrogenic response were similar in both cell types. Evaluation of *in vivo* bone formation by transplanted cells is still pending.

CONCLUSIONS: cmMSCs are apparently more responsive to multi-lineage differentiation relative to cFMSCs and can potentially serve as donor graft materials for oral bone regeneration.

BMP2 induced *de novo* bone formation utilizes different progenitors in rats versus mice and humans. Corinne Sonnet*[1], Eleanor Davis[2], ZaWaunyka Lazard[1], Eric Beal II[2], Elizabeth Salisbury[1], Alan Davis[1], Elizabeth Olmsted-Davis[1]. [1]Baylor College of Medicine, USA, [2]Baylor College of Medicine, USA

We developed a cell-based gene therapy approach for inducing *de novo* bone formation at a targeted site as a means of rapidly inducing spine fusion. We tested this therapy through direct injection into the paraspinous musculature in a murine model of posterolateral spine fusion and observed stable fusion as early as 2 weeks. To further suppress any immunological response and provide the ability to re-inject the materials, we have encapsulated the cells in a PEG-DA hydrogel. Studies in which control adenovirus transduced cells were injected prior to delivery of the AdBMP2 transduced cells (therapy), demonstrated the ability of the hydrogel encapsulation to rescue the bone formation. In these studies, bone formation was similar in the primed animals with the encapsulated therapy as those without priming and no encapsulation. Surprisingly, unlike the mouse *de novo* bone formation did not occur in rat spine, without inclusion of periosteal cells. Characterization and comparison of the bone formation in mice and rats showed that they utilize a different source of osteogenic progenitors. Further, studies which included either the mouse osteogenic cells or mesenchymal stem cells (MSCs) did not result in rescuing the bone formation although the MSCs did incorporate into bone when included in the mouse. Detailed analysis of the mechanism of the two systems reveals significant differences. Further, comparison of human osteogenic cells observed in patients with early heterotopic ossification, showed more similarities to the mouse progenitors. In conclusion, rats may not accurately reflect human physiology with respect to BMP2 induced *de novo* bone formation. Thus significant biological consideration may be required for selecting an appropriate preclinical model for these types of therapies.

Culture of Human BM-MSC in Physiological O2 Improves Robustness of Bone Formation in a Mouse Calvarial Defect Model. Xiaonan Xin*[1], Xi Jiang[2], Liping Wang[1], Paiyz Mikael[3], Kyle Shin[3], Syam Nukavarapu[3], David Rowe[1], Alexander Lichtler[1]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut Health Center, USA, [3]University of Connecticut Health Center, USA

Human bone marrow derived mesenchymal stem (or stromal) cells (hBM-MSC) are a valuable source of cells with bone-forming potential for basic science and for therapy of human bone disease. However, their bone forming potential has often been found to be inconsistent, with dependence on passage number, age and medical condition of the bone marrow donor, and, in the case of in vivo bone formation assays, the scaffold used. It has been reported that cell culture under 5% O_2 produces a dissolved O_2 concentration that is more similar to physiological O_2, and that this decreases the production of reactive oxygen species, which decreases cell stress and genetic damage. We have compared the ability of hBM-MSC cultured under 5% O_2, to cells grown under ambient O_2 for their ability to form bone in our calvarial defect model. hBM-MSC were obtained from 20-30 year old commercial donors, or from 50 to 60 year old patients. We also tested cells that had been plated directly from whole bone marrow under standard bone marrow culture conditions, and cells that were enriched for white blood cells using the Magellan automated cell separator (Arteriocyte Medical Systems). We tested cells cultured for 1, 2 and 3 passages, and whole, uncultured bone marrow. We also tested hBM-MSCs from a commercial source that had been passaged 2-3 times before we obtained them. Cells were tested in our calvarial defect model. In some cases, cultured cells were transduced with a ubiquitin promoter driven RFPcherry expressing lentiviral vector to aid in identifying human cells. The implants were harvested after 8 weeks, and analyzed using our frozen section tape transfer method. Human bone formation was indicated by cells staining for human nuclear antigen that were alkaline phosphatase positive, associated with newly formed bone that contained human antigen positive osteocytes and stained with a human specific bone sialoprotein antibody. Our results were that uncultured bone marrow, and commercial passaged cells, never formed bone. Cultured cells from older surgical patients formed bone at passage 1 but not after 3 passages in ambient O_2, but formed bone robustly after 3 passages in 5% O_2. Cells from younger BM donors formed bone after 3 passages in both 5% and ambient O_2, although the bone formed by 5% O_2 cells had a more mature appearance. Thus low O2 culture seems to improve the robustness of in vivo bone formation.

Early reversal cells: osteoblastic nature, catabolic function and interaction with osteoclasts. Mohamed Essameldin Abdelgawad[1], Jean-Marie Delaisse*[2], Maja Hinge[1], Ragad Walid Hamid[1], Lars Rolighed[3], Lars H Engelholm[4], Niels Marcussen[5], Thomas Levin Andersen[1]. [1]Department of Clinical Cell Biology (KCB), Vejle Hospital – Lillebaelt Hospital, IRS, University of Southern Denmark, Denmark, Denmark, [2]Vejle Hospital, IRS, University of Southern Denmark, Denmark, [3]Aarhus University Hospital, Denmark, [4]The Finsen Laboratory, Rigshodpitalet/Biotech Research & Innovation Centre (BRIC), University of Copenhagen, Denmark, [5]Department of Clinical Pathology, Odense University Hospital, Odense, Denmark, Denmark

The reversal phase is an intermediate phase in the bone remodelling process, needed to prepare the eroded surfaces vacated by the osteoclasts for bone formation. The reversal cells colonizing the vacated eroded surfaces during the reversal phase are mononuclear cells that are immunoreactive for osteoblastic markers, and whose function and interaction with the osteoclasts remains poorly investigated. Herein, we studied the reversal cells in human cancellous bone biopsies from 25 controls, confirming that reversal cells are of osteoblastic nature, even though they sometimes are immunoreactive for TRAcP, which in comparative immunostainings and in situ hybridisations was shown to be taken up from neighbouring TRAcP-expressing osteoclasts. The early osteoblastic reversal cells were also shown to have direct cell-cell contacts with the neighbouring osteoclasts, and shown to interact with the demineralised resorption debris left behind by the osteoclasts. Collectively, these data supports that early osteoblastic reversal cells interact both directly and indirectly with the neighbouring osteoclasts. The early reversal cells appear to have a catabolic/collagenolytic function, involving: extracellular collagenases of the MMP family generating defined ¾-collagen fragments, including MMP-13 (collagenase-3), and to some extent the endocytic collagen receptor uPARAP/Endo180, supporting the notion that they clean the eroded surfaces from resorption debris. Interestingly, the presence of MMP-13 in reversal cells decreased with age, indicating that the cleaning activity of reversal cells may become less efficient with age. Late reversal cells next to osteoid surfaces are functionally and phenotypically different from early reversal cells next to osteoclasts, as they show less immunoreactivity for the ¾-collagen fragment, MMP-13 and uPARAP and have a morphological resemblance to mature bone forming osteoblasts, supporting that the reversal cells gradually change during the reversal phase. Collectively, this study stresses that the early osteoblastic reversal cells as a privileged partner of the osteoclasts in the bone resorption-bone formation coupling mechanism during the bone remodelling.

Intravital Multiphoton Imaging of Skeletal Progenitor Cells in Bone Tissue-Engineered Constructs. Pieter-Jan Stiers*[1], Nick Van Gastel[1], Karen Moermans[2], Ingrid Stockmans[2], Geert Carmeliet[3]. [1]Laboratory of Clinical & Experimental Endocrinology, KU Leuven, Belgium, Belgium, [2]Laboratory of Clinical & Experimental Endocrinology, KU Leuven, Belgium, Belgium, [3]Katholieke Universiteit Leuven, Belgium

Bone tissue engineering using scaffolds, skeletal progenitor cells and osteogenic growth factors is a promising therapy for non-healing bone defects, but still largely depends on a trial and error approach. A major reason is that the in vivo behavior of the implanted cells and the response of the host tissues are still poorly understood. Insight in the early stages of the healing process are crucial because once the bone formation process is started it will largely recapitulate the bone development pathways. Analysis of these early time points using conventional techniques however does not provide dynamic information on cell behavior and on the interactions with the host tissue. To obtain insight in these processes, we developed an intravital imaging setup based on an established model for ectopic bone formation.

First, we analyzed whether the imaging windows had any influence on bone formation using microCT and histological analysis. There was only a small delay in the formation of cartilage and mineralized matrix compared to ectopically implanted scaffolds after 21 days of implantation. In addition, the inflammatory reaction at early time points was comparable between the imaging windows scaffolds and the ectopically implanted scaffolds. Next, scaffolds seeded with fluorescently labeled murine periosteum-derived cells were implanted and repeatedly imaged with a multiphoton microscope. A procedure was developed to trace the same cell population over a 2 week implantation period in relation to the collagen matrix, visualized through second harmonics generation. Seeded cells displayed diverse behavior and fate across scaffold types, which correlated to different outcomes at later time points. Changes in host blood vessels, perfused with FITC-dextrans, were observed within 6 days after implantation, but vascularization of the scaffold did not occur until day 11. Further optimization of this technique and use of reporter constructs will provide new insight into the mechanisms of bone regeneration and of therapeutic growth factors.

In conclusion, multiphoton intravital imaging is a promising technique that will allow us to study cell behavior and scaffold-host interactions non-invasively inside an implanted tissue engineered construct.

LARG GEF and ARHGAP18 GAP Control Cytoskeletal Dynamics to Influence MSC Lineage Allocation. William Thompson*[1], Sherwin Yen[2], Gunes Uzer[1], Zhihui Xie[2], Buer Sen[3], Maya Styner[4], Keith Burridge[5], Janet Rubin[4]. [1]University of North Carolina, USA, [2]University of North Carolina, USA, [3]University of North Carolina At Chapel Hill, USA, [4]University of North Carolina, Chapel Hill, School of Medicine, USA, [5]University of North Carolina, USA

Bone density depends on mesenchymal stem cell (MSC) lineage allocation where adipogenic commitment depletes the pool available for osteogenesis. Cell architecture influences lineage decisions, as the cytoskeleton aligns critical elements that underwrite cellular responses to the mechanical and physical environment. Disruption of the actin cytoskeleton and RhoA activity tip MSC fate in favor of adipogenesis. We have shown that application of mechanical strain suppresses MSC adipogenesis by enhancing cytoskeletal structure through activation of RhoA via Fyn/mTORC2/AKT signaling. RhoA activity is directed by two distinct protein families, GEFs (RhoA activators) and GAPs (RhoA deactivators). In fibroblasts, ARHGAP18, a little studied GAP, suppresses RhoA leading to decreased actin stress fiber formation and motility, while the GEF LARG regulates RhoA activation in response to force. We hypothesized that ARHGAP18 and LARG determine MSC commitment by altering RhoA and cytoskeletal architecture. We observed no alteration in MSC lineage following siRNA knockdown of LARG; however, basal RhoA activity was significantly decreased and mechanical activation of RhoA was almost entirely prevented. This implicates LARG as the major GEF responding to substrate strain in MSCs. In contrast, stable shRNA knockdown of ARHGAP18 both increased basal RhoA activity and enhanced the response to mechanical strain. Additionally, actin stress fiber formation was enhanced in ARHGAP18 knockdown cells. As the actin cytoskeleton is known to modulate MSC fate, we reasoned that ARHGAP18 should affect MSC differentiation. In ARHGAP18 null MSCs adipogenesis was significantly suppressed, as assessed by Oil-Red-O staining and Western blot. Additionally, when cultured in osteogenic media, ARHGAP18 knockdown enhanced osteogenic commitment, confirmed by alkaline phosphatase staining and PCR. This suggests that ARHGAP18 is a critical tonic inhibitor of MSC cytoskeletal assembly, returning RhoA to an "off state". In contrast, LARG is recruited during active mechanical strain, and as such its absence has less effect on the resting RhoA state. In summary, control of RhoA cycling between on and off states relies on ARHGAP18 when quiescent, with LARG playing a predominant role in the active mechanical control of actin remodeling. Thus, both of these GTP exchangers converge on RhoA to regulate the MSC response to static and dynamic physical factors, influencing lineage allocation.

Temporal Nocturnin expression leads to impaired peak bone acquisition. Anyonya Guntur*[1], Phuong Le[1], Jeremy Stubblefield[2], Carla Green[2], Clifford Rosen[3]. [1]Maine medical center research institute, USA, [2]Department of Neuroscience, University of Texas Southwestern Medical Center, USA, [3]Maine Medical Center, USA

Osteoporosis is associated with an increase in marrow adiposity and reduced bone mass resulting in increased fracture risk. Allocation of bone marrow mesenchymal stromal cells towards the adipogenic lineage is one potential mechanism for age-related bone loss. Nocturnin (*Noc*), a circadian deadenylase induced by *Pparg* activation, can regulate lineage allocation. Previously, we showed that *Noc*-/- mice have higher bone mass compared to controls and are protected from Rosiglitazone induced bone loss. To test whether activation of *Noc* results in bone loss, we utilized a Doxycycline (Dox) inducible (Tet-ON) mouse model to overexpress *Noc in vivo.* In this model, the tetracycline responsive element (TRE) is fused to the *Noc* open reading frame (with a C-terminal 3x FLAG-Tag), and a Rosa promoter fused to the reverse-tetracycline trans-activator (rtTA) was used for regulating expression. Male mice were put on either 2mg/mL of Dox supplemented with 1mg/mL of saccharin (Dox+Sacch) or saccharin (Sacch) water starting at 4 weeks of age. Areal bone mineral density (aBMD) and bone mineral content (aBMC) were measured by DEXA; femur trabecular and cortical microarchitecture were measured using MicroCT. DEXA revealed that the *Noc* overexpressing mice on Dox+Sacch had a significant decrease in total aBMD and aBMC (n=6-8, p=0.001 and p=0.02 respectively) compared to Sacch mice at 12 weeks. MicroCT analysis (n=3) showed that trabecular BV/TV and trabecular thickness was significantly lower in the Dox+Sacch treated group (p=0.01 and p=.0009 respectively) although there was no difference in trabecular number or trabecular spacing. In addition, cortical thickness was significantly decreased in the Dox+Sacch treated group (p=0.0007). To determine if Dox or Sacch has an effect on the skeleton, we treated male C57BL/6J (B6) mice with Dox+Sacch and Sacch in similar manners. DEXA revealed no skeletal differences between the two groups (n=10-12). In conclusion, temporal *Noc* expression results in impaired peak bone acquisition, in part due to changes in lineage allocation.

Dibenzazepine, a gamma-secretase inhibitor, inhibits osteoclastic bone resorption by suppressing c-Src activation. Bong Jun Kim*[1], Won Jong Jin[1], Hong-Hee Kim[2], Hyunil Ha[3], Zang Hee Lee[4]. [1]Department of Cell & Developmental Biology, School of Dentistry, Seoul National University, South Korea, [2]Seoul National University, South Korea, [3]Korean Medicine-Based Herbal Drug Development Group, Korea Institute of Oriental Medicine, South Korea, [4]Seoul National University School of Dentistry, South Korea

Tyrosine kinase c-Src plays an important role in actin ring formation and bone resorption activity in osteoclast. Therefore, c-Src has been targeted for the treatment of osteolytic disorders. In the present study, we found that dibenzazepine (DBZ), one of the γ-secretase inhibitors (GSIs), has bone protective effect against osteoclast-mediated excessive bone resorption both in vitro and in vivo. Although DBZ did not affect osteoclast differentiation, DBZ significantly suppressed non-receptor tyrosine kinase c-Src phosphorylation at tyrosine 416 and proline-rich tyrosine kinase 2 (PYK2) phosphorylation at tyrosine 402. Moreover, c-Src binding ability as a adaptor protein also suppressed by DBZ treatment. Therefore, inhibitory effects of DBZ on osteoclast exhibited abnormal spreading and disturbed actin ring formation with inhibition of resorption activity. Competitively treatment of Src family activator rescued the anti-resorptive effects of DBZ, suggesting that DBZ mainly attributed to the c-Src-mediated bone resorption. Consistent with the *in vitro* results, interleukin-1 (IL-1) induced bone destruction was strongly suppressed by administration of DBZ. Collectively, we demonstrated that DBZ has inhibitory effects on bone resorptive activity by targeting disruption of c-Src activity in osteoclast and our results suggest that DBZ may serve as a useful agent for osteoclast-mediated excessive bone resorption.

Effect of IL-4 on mechanical loading-induced osteoclastogenesis and bone resorption. Hideki Kitaura*[1], Zaki Hakami[2], Keisuke Kimura[3], Masahiko Ishida[4], Jafari Saeed[2], Haruki Sugisawa[2], Teruko Takano-Yamamoto[5]. [1]Tohoku University, Japan, [2]Tohoku University, Japan, [3]Tohoku university, Japan, [4]Tohoku UniversityGraduate School of Dentistry, Japan, [5]Tohoku University, Japan

Mechanical loading exerts important effects on the skeleton by controlling bone mass and strength. Osteoclasts are required for bone resorption and remodeling. Two cytokines are required for osteoclasts formation, M-CSF and RANKL. TNF-α has also been recognized as important factor for osteoclastogenesis. It also been reported

that TNF-α plays an important role in mechanical loading-induced osteoclastogenesis and bone resorption. IL-4 is a recognized immunomodulatory cytokine that regulates bone hemostasis. However, its influence on mechanical loading-induced osteoclastogenesis and bone resorption is still unknown. Orthodontic tooth movement is a good model for exploring the mechanism underlying the mechanical loading-induced bone changes. Thus, the purpose of this study was to investigate the effect of IL-4 on orthodontic movement and associated root resorption in mice model. Mouse orthodontic tooth movement model was established, and investigate whether IL-4 inhibit osteoclastogenesis and bone resorption on mechanical loading. The maxillary first molars of male mice were subjected to mesial force by A Ni-Ti coil spring. Varying doses of IL-4 from 0 to 1.5 μ/day were injected locally adjacent to the first molar every other day. After 12 days of experimental tooth movement, the amounts of orthodontic movement and the number of tartrate-resistant acid phosphatase (TRAP)-positive cells along the loaded alveolar bone and root surface was counted as osteoclasts and odontoclasts, respectively, in histological sections. The root resorption associated orthodontic movement was also evaluated by scanning electron microscope. Orthodontic tooth movement and the number of osteoclasts were significantly decreased in IL-4 treated mice. IL-4 inhibited tooth movement in dose-dependent manner. IL-4 significantly suppressed the mechanical loading-induced odontoclasts and root resorption. These results suggest that IL-4 might be a useful adjunct to regulate the extent of orthodontic tooth movement and control root resorption.

Estrogen does not Facilitate Apoptosis, but Inhibit Bone Resorption by Regulation of V-ATPase in Avian Medullary Bone Osteoclasts. Shinji Hiyama*[1], Yumiko Kadoyama[2], Mineo Watanabe[2], Takashi Uchida[2]. [1]Hiroshima University Institute of Biomedical & Health Sciences, Japan, [2]Hiroshima University, Japan

Medullary bone (MB) of female birds acts as a calcium reservoir of egg-shell formation and is remodeled in the bone marrow cavity under the control of circulating estrogen. MB forms by a single injection of estrogen even in the male bird and is resorbed vigorously by osteoclasts with diminished circulating estrogen level. In this process, increased circulating estrogen does not facilitate apoptosis of osteoclasts, while this hormone induces mammalian osteoclasts apoptosis, which may be implicated in postmenopausal bone loss. Clarifying the role of estrogen in avian osteoclasts may be helpful to identify additional roles of estrogen in bone. We previously reported that estrogen had not effect on apoptosis of MB osteoclasts, while their activity and morphology were affected. Therefore, focusing on the effects of estrogen to bone resorption activity, we examined the expression of vacuolar H^+-ATPase (V-ATPase) by use of the osteoclastogenesis induced by estrogen in the male avian *in vivo* and *in vitro*. Five days after first injection of estrogen (E2) into male Japanese quails, second injection of E2 was given to same quails. The femurs of these quails were analyzed histochemically. After second E2 injection, osteoclasts on the MB surface became smaller and flat-shaped and the immunoreactivity of V-ATPase was reduced in these cells progressively. Following this, after 3 days of single injection of E2, bone marrow cells were collected and cultured with or without 17β-estradiol (17β-E) in the presence of RANKL/M-CSF for a week. The expression of V-ATPase in these cells was examined by RT-PCR analysis and immunocytochemistry. The expression level of V-ATPase mRNA was decreased in the presence of 17β-E. Correspondingly, although V-ATPase immunoreactivity was also observed in these cultures, the immunereactivity was reduced in 17β-E-exposed cells. These results suggest that estrogen may inhibit bone resorption activity by the decrease of V-ATPase activity in avian osteoclasts. Further studies are needed to reveal the relationship between estrogen and the regulation of bone resorption including V-ATPase in avian osteoclasts.

Stromal cell-derived factor-1 (SDF-1) Elevations are Associated with Increased Osteoclast Formation and Bone Resorption in Transgenic or Ovariectomized mice. Philip Osdoby[1], Patricia Collin-Osdoby*[1], Linda Rothe[2], Xuefeng Yu[3]. [1]Washington University in St. Louis, USA, [2]Washington University, USA, [3]Tongji Hospital, China

SDF-1 (CXCL12), a multifunctional chemokine constitutively expressed by bone marrow stromal cells, has essential roles in lymphocyte, hematopoietic stem cell, and vascular biology through regulating cell homing, survival, mobilization, and angiogenesis. Previously, we and others have shown that SDF-1 promotes the chemotactic recruitment, fusion and development of avian, murine and human osteoclast precursors, as well as the survival of mature resorptive osteoclasts in vitro. To further examine SDF-1 roles in bone physiology or pathology in vivo, we have utilized three different model systems. First, in a chick chorioallantoic developmental model, focally administered SDF-1 dose-dependently increased avian osteoclast formation (numbers) and bone pit resorption on implanted bone chips concurrent with stimulating localized angiogenesis. Second, transgenic mice overexpressing SDF-1 (under an RSV promoter) demonstrated 2-fold more TRAP+ osteoclasts in metaphyseal regions of tibial bone sections compared to wild-type mice. Third, microarray gene expression analyses of ovariectomized (OVX) mice, which undergo rapid bone loss following estrogen depletion, revealed increased expression of SDF-1 and its signaling receptor, CXCR4, for at least 4 months following OVX. Estrogen supplementation to prevent OVX-induced bone loss was found to also reduce OVX-stimulated SDF-1 expression. Moreover, an alternative receptor, CXCR7, that binds SDF-1 to sequester it away from CXCR4 and potentially interfere with SDF-1/CXCR4 responses, was downregulated by OVX but not if estrogen supplementation was provided. Finally, preliminary data suggest that elevated SDF-1 expression occurs in another murine bone osteolytic condition characterized by increased osteoclasts, bone resorption, and osteopenia. These and other findings lead us to conclude that elevated SDF-1 levels may be linked to pathological bone loss. If so, targeting the SDF-1/CXCR4 axis may be a novel therapeutic approach for the treatment of bone loss in osteoporosis or other osteolytic disorders.

BMP Responsive Smads Are Required for Osteoclast Differentiation. Amy Tasca*[1], Melissa Stemig[2], Aaron Broege[3], Brandon Huang[1], Eric Jensen[3], Kim Mansky[3], Raj Gopalakrishnan[3]. [1]University of Minnesota, USA, [2]University of Minnesota School of Dentistry, USA, [3]University of Minnesota, USA

Osteoclasts are regulated by numerous cytokines and growth factors including bone morphogenetic proteins (BMPs). BMPs bind to type I and type II receptors. Type I receptors then phosphorylate the receptor activated Smads (R-Smads), SMADs 1, 5 and 8 in the case of BMP signaling. The R-SMADs then bind Smad 4, a common Smad (co-Smad) and alter transcription. Our recent work indicates that osteoclasts express BMP receptors, BMP ligands, and that BMP signaling directly stimulates osteoclast formation in vitro and in vivo. Most recently we reported that loss of expression of BMP receptor type II (BMPRII) in osteoclasts results in an osteopetrotic phenotype primarily due to a change in noncanoncial signaling by BMP receptors. While our BMPRII null osteoclasts confirmed the importance of BMPs in osteoclast differentiation, they did not allow us to address the importance of Smad 1, 5 and 8 expression and activation during osteoclast differentiation. In our current study intended to evaluate the role of SMADs, osteoclasts were isolated from Smad 1/5 or Smad 4 floxed mice and infected with control or CRE-expressing adenoviruses. Loss of either Smad 1/5 expression or Smad 4 expression resulted in fewer and smaller multinuclear osteoclasts compared to control infected cells. Smad 1/5 and Smad 4 null osteoclasts had less *DC-STAMP* and *cathepsin K* expression; however, *Nfatc1* expression was only changed in Smad 4 null osteoclasts and not in Smad 1/5 null cells. Lastly, we detected a significant decrease in resorption pits and area resorbed in both the Smad 1/5 and Smad 4 null osteoclasts. From this we conclude that SMAD signaling in required for osteoclast differentiation. Since osteoclast differentiation is inhibited in the Smad 1/5 and Smad 4 null osteoclasts, to better test SMADs' functional role in bone resorption, we treated fully mature wild-type osteoclasts with BMP2 with and without dorsomorphin, a chemical inhibitor that selectively blocks canonical BMP signaling. We found that BMPs stimulated resorption by mature osteoclasts whereas treatment with dorsomorphin blocked BMP's enhancement of osteoclast activity. Thus our work shows that the canonical BMP/SMAD pathway regulates both the formation and resorptive activity of osteoclasts and suggests that this pathway might be a novel target for antiresorptive therapies.

Ligand-mediated Notch Signaling Enhances Osteoclastogenesis and Resorption. Jason Ashley*[1], Jaimo Ahn[2], Kurt Hankenson[3]. [1]University of Pennsylvania, USA, [2]University of Pennsylvania, USA, [3]University of Pennsylvania, USA

Regulated Notch signaling is required for bone growth and healing. There are, however, conflicting reports on the role of Notch signaling in osteoclasts and their precursors. There is evidence for both stimulatory and inhibitory roles for Notch signaling in osteoclast differentiation. Based on studies by others using Notch activating antibodies, we hypothesized that Notch signaling can promote osteoclastogenesis. To address this, we investigated the effects of two Notch ligands, Jagged1 (JAG) and Delta-like1 (DLL), and two Notch inhibitors, DAPT and SAHM1, on the differentiation and function of osteoclasts.

Notch signaling was stimulated by culturing marrow-derived osteoclast precursors in tissue culture plates coated with immobilized goat anti-human Fc IgG (control), JAG-Fc, or DLL-Fc. Notch signaling was inhibited by adding DAPT or SAHM1 to the culture medium. Under M-CSF/RANKL-stimulated osteoclastogenesis, JAG, but not DLL, promoted a significant increase in osteoclast size and TRAP-stained well area compared to IgG. Conversely, both DAPT and SAHM1 significantly reduced osteoclast size and stained area compared to DMSO control. As measured by quantitative RT-PCR, JAG stimulation resulted in a significant increase in TRAP, cathepsin K, and MMP9 expression, while DAPT significantly decreased in cathepsin K expression.

To assess the function of osteoclasts under Notch stimulation and inhibition, osteoclasts were differentiated on hydroxyapatite-coated surfaces, and resorbed area was measured after 4 and 6 days. Both JAG and DLL significantly increased resorbed area compared to IgG control at day 4. At this time, DMSO control, DAPT, and SAHM1

groups were similar. At 6 days, however, IgG resorption matched JAG resorption, though DLL stimulation still showed significantly higher resorption than IgG control. DAPT and SAHM1 groups had significantly less resorption than DMSO control. In partial explanation for the enhanced osteoclast size and resorption seen in JAG and DLL stimulated osteoclasts, JAG and DLL both significantly increased expression of pro-fusion genes CD200 and DC-STAMP. DAPT significantly reduced expression of both CD200 and DC-STAMP, and SAHM1 significantly reduced expression of CD200.

These data indicate that Notch signaling is necessary for normal osteoclast differentiation and function, and Notch stimulation by JAG and DLL can increase osteoclast formation and function potentially by enhancing the fusion of osteoclast precursors.

Bone substrate and Integrin beta 3 regulate critical pathways of cell cycle progression, proliferation and survival during terminal osteoclast differentiation. Ed Purdue*[1], Jonathan Hill[2], Steven Goldring[1], Tania Crotti[3], Gerald Nabozny[2], Kevin McHugh[4]. [1]Hospital for Special Surgery, USA, [2]Boehringer Ingelheim Pharmaceuticals, Inc., USA, [3]University of Adelaide, Australia, [4]University of Florida, USA

Background. Multiple lines of evidence have established that osteoclasts are required for physiologic bone resorption and pathological bone loss in inflammatory disorders. In vivo, analysis of osteoclasts at sites of bone resorption reveals that functionally activated osteoclasts are almost exclusively localized to the immediate bone surface, indicating that cell-substrate interactions contribute to terminal osteoclast differentiation. However, in vitro approaches to the delineation of osteoclastogenesis have almost always neglected to take into account the role of bone substrate in this process, and have been limited to the differentiation of multinucleated osteoclasts from myeloid precursor cells on tissue culture plastic substrate. In this study, we have employed a unique in vitro osteoclastogenesis system using authentic bone substrates coupled with expression profiling and pathway analysis to identify critical bone substrate-mediated pathways of osteoclast formation and activation. To further dissect the signaling pathways involved, we have also characterized the involvement of integrin beta 3 (itgb3), a critical cell surface mediator of osteoclast-bone interaction, in this process.

Methods Murine bone marrow derived macrophages from wildtype and itgb3 deficient mice were cultured in the presence or absence of RANKL on plastic, hydroxyapatite, or calvarial bone discs. RNA was isolated at different stages of osteoclast generation and subjected to microarray analysis. Pathway analysis was performed using GSEA and Ingenuity pathway analysis.

Results Of 1490 genes identified as upregulated by RANKL in differentiated osteoclasts, 5.4% were further upregulated by culture on the bone substrate; an additional 8.5% were downregulated. Pathway analysis identified that several key pathways including those regulating cellular function, death, survival, growth and proliferation, were profoundly impacted by the choice of substrate, and were further modulated by the presence or absence of itgb3 in cells growing on bone substrate.

Conclusions. Interaction of osteoclasts with the bone surface regulates multiple critical pathways of osteoclast formation and activation. Most notably, bone substrate regulates the transition from proliferation to activation during late stages of osteoclastogenesis. This suggests that developing osteoclasts can sense and respond to signals derived from bone substrate, and that these signals regulate the life cycle of the cell.

The microRNA-26a regulates RANKL- induced osteoclast differentiation. Kabsun Kim*[1], Jung Ha Kim[2], Nacksung Kim[3]. [1]Chonnam National University Medical School, South Korea, [2], South Korea, [3]Chonnam National University Medical School, South Korea

Osteoclasts are multinucleated giant cell resulting from cell-cell fusion of monocyte/macrophage osteoclast precursor cells. Osteoclast fusion process is critical for osteoclast function. MicroRNAs (miRNAs) are small, noncoding ribonucleic acids (ncRNAs), which regulate gene expression by binding the 3'-untranslation region (3'UTR) of their target mRNAs, leading to translational repression or mRNA degradation. The role of miRNAs in osteoclastogenesis has not yet been understood. In this study, we examined the role of miRNA-26a in RANKL-induced osteoclastogenesis. The expression of miR-26a was extremely upregulated by RANKL at late stage of osteoclastogenesis. Ectopic expression of miR-26a mimic in osteoclast precursor cells suppressed osteoclast formation, actin-ring formation, and bone resorption. On the other hand, overexpression of miR-26a inhibitor slightly enhanced RANKL-induced osteoclastogenesis. Through a bioinformatics approach, we identified CCN family 2 /connective tissue growth factor (CCN2/CTGF), which can promote osteoclast differentiation via upregulation of DC-STAMP, as a candidate target gene of miR-26a. Overexpression of miR-26a mimic decreased the protein level of CTGF, whereas overexpression of miR-26a inhibitor increased the protein level of CTGF. In addition, we found putative target sites of miR-26a in the 3'-UTR of CTGF mRNA. The inhibitory effect of miR-26a on osteoclastogenesis was prevented by the treatment with recombinant CTGF. Taken together, our results suggest that miR-26a is involved in the last stage of osteoclast formation and function through regulation of CTGF.

Inherent Activation of Apoptosis is a Determinant of Osteoclast Lifespan. Robert Jilka*[1], Toshifumi Fujiwara[1], Kanan Vyas[2], Michela Palmieri[2], Haibo Zhao[1], Stavros Manolagas[1]. [1]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [2]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

Because of their destructive potential, the lifespan of osteoclasts must be under strict control; however the mode of osteoclast death is poorly understood. We therefore investigated death pathways in cultures of murine bone marrow macrophage-derived osteoclasts. We report that the number of TRAP-positive multinucleated osteoclasts reached a maximum between 5 and 6 days of culture, and then declined to less than 25% of initial number between day 7 and 10 of culture. This occurred despite the continuous presence of RANKL and M-CSF, which activate anti-apoptotic pathways in osteoclasts. The decrease in osteoclasts coincided with a 5-10-fold increase in caspase-8 and caspase-3 activity, and a 10-fold increase in the number of ghost-like osteoclast remnants attached to the substratum. Live cell imaging of multinucleated osteoclasts by time lapse microscopy distinguished two morphologic modes of death. Some exhibited classic features of apoptosis, notably retraction of cells from the substratum, extensive blebbing of the entire plasma membrane, and phagocytosis of the small cellular remnant by macrophages. Others exhibited highly localized transient blebbing of the plasma membrane followed by rapid necrosis-like death, accounting for the formation of the osteoclast ghosts. The pan-caspase inhibitor z-VAD-fmk caused a 40% reduction in the number of osteoclast ghosts, indicating that caspases initiate this form of death, despite their necrotic appearance. Apoptosis often depends on activation of either Bak or Bax – pro-apoptotic proteins that increase mitochondrial outer membrane permeability, leading to activation of caspases. We investigated this pathway using Bak/Bax-deficient osteoclasts generated from bone marrow macrophages obtained from $Bak^{-/-}$ mice bearing a floxed Bax gene, followed by infection with adeno-Cre. Western blotting confirmed absence of Bax in these cells. Bak/Bax-deficient osteoclasts failed to exhibit increased caspase-3 activity during prolonged culture, and the number osteoclast ghosts was reduced, compared to adeno-Cre infected $Bak^{-/-}$ control osteoclasts. Based on these findings, we propose that the survival signaling initiated by M-CSF and RANKL during osteoclast differentiation is overwhelmed by inherent programmed death cues that ensure a limited osteoclast lifespan. Among these cues are activation of Bak and Bax leading to activation of caspases.

A critical role of *Tet2* in osteoclastogenesis by maintaining the level of 5-hydroxymethylcytosine in the genome. Mingjiang Xu*[1], Ling Li[2], Zhigang Zhao[3], Feng-Chun Yang[4]. [1]Indiana University School of Medicine, USA, [2]Indiana University School of Medicine, USA, [3]Indiana University, USA, [4]Indiana University, USA

As an epigenetic landmark, DNA methylation plays an important role in regulating gene expression. TET protein family members enzymatically convert 5-methylcytosine into 5-hydroxymethylcytosine and play a critical role in active DNA demethylation pathway, thus, regulating gene expression. We and others have reported that deficiency of Tet2 altered myelogenesis, leading to the development of myeloid malignancies in mice. Osteoclasts, the progeny of myeloid lineage play an important role in maintaining the bone remodeling and the physiologic integrity of the skeleton. However, the role of Tet family in bone remodeling remains unknown. In this study, using both qPCR and a Tet2:GFP reporter knock-in murine model, we found that Tet2 is expressed in preosteoclasts (pre-OCLs) at high levels. Deletion of Tet2 led to dramatic reduction in the 5-hydroxymethylcytosine levels and increase in the 5-methylcytosine levels in the genomic DNA of pre-OCL. Interestingly, Tet2-/- mice are slightly smaller is size and gradually develop osteosclorosis with significantly higher BMD, increased trabecular BV/TV, conn D and direct Tb N as compared to WT littermates. Macrophages of Tet2-/- mice exhibited impaired osteoclastogenesis as shown by less osteoclast formation following tartrate-resistant acid phosphatase staining. To delineate if deletion of Tet2 alters the expression levels of critical gene that are critical for osteoclastogenesis and differentiation, RNA-Seq was performed and genomic 5-hmC profiling were surveyed in Tet2-/- pre-OCLs compared to their respective WT counterparts. Several differentially expressed genes were found in Tet2-/- pre-OCLs (Gata2, Sin3a). In addition, genome-wide 5-hmC distribution in WT and Tet2-/- pre-OCLs allowed us to correlate expression levels of selected genes with their promoter 5-hmC/5-mC status. In addition, the genomic distributions of Tet2 were mapped by Chip-Seq in pre-OCLs derived from a Tet2:Flag/V5 Tag knock-in mouse model with well-tested anti-Tag antibodies. These data indicate that deletion of Tet2 in mice leads to dysregulated hydroxylation of 5-methylcytosine and gene expression profiling in pre-OCLs, which subsequently altered cellular functions of osteoclasts, which eventually altered skeletal development. These results indicate an important role of DNA demethylation in the regulation of bone homeostasis.

Activation of G protein-coupled receptor 84 with capric acid inhibits RANKL-induced osteoclast differentiation via the suppression of NF-κB signaling and blocks cytoskeletal organization and survival in mature osteoclasts. Hyun Ju Kim*[1], Hye-Jin Yoon[2], Shin-Yoon Kim[3], Young-Ran Yoon[2]. [1], South Korea, [2]Kyungpook National university, South Korea, [3]Kyungpook National University Hospital, South Korea

Osteoclasts are bone-resorbing cells that are generated by the differentiation of myeloid lineage progenitors. To evaluate new regulators of osteoclast development, we performed a microarray analysis, and we found that G protein-coupled receptor 84 (GPR84), a molecule known to function as a specific receptor for medium-chain fatty acids, was down-regulated by 10-fold in osteoclasts compared to their precursors. In this study, we investigated the impact of GPR84 activation on osteoclast development and addressed its possible mechanisms. Activation of GPR84 with a potent ligand, capric acid, inhibited RANKL-mediated osteoclast differentiation from bone marrow-derived macrophages. Capric acid suppressed the RANKL-induced phosphorylation of IκBα, p65 nuclear translocation, and NF-κB transcriptional activity. Capric acid further blocked the RANKL-stimulated activation of ERK without affecting JNK or p38. The induction of NFATc1 in response to RANKL was also attenuated by capric acid. In addition, GPR84 activation abrogated M-CSF and RANKL-stimulated cytoskeleton reorganization, which is crucial for efficient bone resorption of osteoclasts, and increased apoptosis in mature osteoclasts through the induction of Bim expression and the suppression of ERK activation by M-CSF. Together, our data demonstrate that GPR84 activation inhibits osteoclast differentiation and function. We therefore suggest that GPR84 may be a potential therapeutic target for the treatment of bone resorption-associated disorders.

C-reactive protein inhibited TRAP-positive multinucleated cell formation and induced cytokine expression through TLR signaling. Ho-Yeon Chung[1], In-Jin Cho*[2], Kyung Hee Choi[2], Yoo-Chul Hwang[2], In-kyung Jeong[2], Kyu Jeung Ahn[2], Hyoung-moo Park[3]. [1]Kyung Hee University, South Korea, [2]Kyung Hee University, South Korea, [3]Chung-ang University, South Korea

Inflammatory processes play a role in osteoclastogenesis. C-reactive protein (CRP), an acute phase reactant that reflects different degree of inflammation. More recently, accumulating evidence suggest that CRP is not only an inflammatory marker but also direct cause of diseases. Therefore, we examined the direct effects of CRP on osteoclast formation using mouse bone marrow cells or RAW 264.7 cells. CRP significantly inhibited RANKL-induced TRAP-positive multinucleated cell formation in RAW 264.7 cell cultures in a dose-dependent manner (1 ug/ml to 30 ug/ml). We observed suppression of ERK and p38 mitogen-activated protein kinases induced by RANKL in Western blotting after CRP treatment in RAW 264.7 cells. Furthermore, CRP increased TNFa and IFNb expression in RAW 264.7 cells. OxPAPC, inhibitor of toll-like receptor signaling, decreased CRP-induced TLR signaling and expression of TNFa and IFNb. Furthermore, OxPAPC reduced CRP-induced inhibition of TRAP-positive multinucleated cell formation. These data indicated that CRP may have a direct role on osteoclastogenesis via MAPK and TLR-dependent pathway.

Feedback regulation of osteoclastogenesis by exosomes. Lexie Holliday*[1], Lindsay VonMoss[2], Nancy Huynh[2], Pooja Patel[2], Wellington Rody[2], Kevin McHugh[3]. [1]University of Florida College of Dentistry, USA, [2]University of Florida College of Dentistry, USA, [3]University of Florida, USA

Exosomes are 30-120 nm secreted vesicles that function in intercellular signaling. Exosomes have been shown to be involved in cell-cell communication in the immune system, nervous system and are a mechanism by which cancer cells trigger angiogenesis. The purpose of this study was to characterize changes in the composition of exosomes produced by osteoclasts as they differentiate, and to test whether exosomes regulate osteoclastogenesis by adding them to calcitriol-stimulated mouse marrow cultures.

Exosomes were isolated from CSF-1/RANKL-stimulated primary hematopoetic cell cultures or RANKL-stimulated RAW 264.7 cells either by filtration and differential centrifugation or by ExoQuick TC^{TM} (System Biosciences). Exosomes were characterized by positive/negative contrast transmission electron microscopy and Western and Lectin blots. Various concentrations of exosomes were added to calcitriol-stimulated mouse marrow cultures on Days 1 and 4 of a 6 Day culture period. After 6 Days, cells were fixed and osteoclasts were identified as multinuclear cells expressing tartrate-resistant acid phosphatase (TRAP) activity.

Exosomes isolated from primary osteoclasts or RAW 264.7 osteoclast-like cells displayed characteristic exosome size and morphology by electron microscopy and expressed the exosome marker proteins CD63 and EPCAM. The peanut agglutinin binding proteins in exosomes changed dramatically as osteoclasts differentiated from precursors. Only exosomes from resorbing osteoclasts contained V-ATPase subunits. When added to calcitriol-stimulated mouse marrow cultures, exosomes from osteoclast precursors increased osteoclast numbers in the mouse marrow up to 4-fold. Exosomes from mature osteoclasts decreased osteoclast numbers up to 3-fold.

Conclusions: Osteoclast precursors and osteoclasts produce exosomes that vary compositionally and functionally depending on the differentiation and activation state of the cells. Exosomes are involved in positive and negative feedback regulation of calcitriol-stimulated osteoclastogenesis in mouse marrow cultures.

Identification and analysis of function of a novel splicing variant of receptor activator of NF-kB. Riko Kitazawa*[1], Ryuma Haraguchi[2], Yosuke Mizuno[3], Sohei Kitazawa[1]. [1]Ehime University, Japan, [2]Ehime University, Japan, [3]Ehime University Hospital, Japan

Receptor activator of NF-κB (RANK) is a member of the tumor necrosis factor receptor (TNFR) family expressed in osteoclast precursors, and RANK-RANK ligand (RANKL) signaling is a key system for differentiation, activation and survival of osteoclasts. We have identified a novel alternative splicing variant of mouse RANK gene (vRANK) that contains a new intervening exon between exons 1 and 2 of mouse full-length RANK (fRANK) mRNA. Since this novel exon contains the stop codon, vRANK encodes truncated 45 amino acids that have a portion of the signal peptide of fRANK and an additional 19 amino acids that show no homology to previously reported domains. By transient transfection with vRANK-GFP and -Flag expressing constructs, vRANK was found localized mostly in the cytoplasm and partly in the cell membrane, but was not secreted into the culturesupernatant. Under the stimulation of various factors, the expression of mouse vRANK mRNA was almost parallel to that of fRANK in RAW264 cells. Overexpression of vRANK in RAW cells decreased the formation of TRACP-positive multinucleated giant cells and negated the anti-apoptotic effect of sRANKL. The human RANK gene also contains an intervening exon that yields vRANK mRNA containing 38 amino acids. In the presence of Vitamin D3, PMA or TGF-b induced vRANK mRNA in HL60 cells through the ERK-dependent pathway. To examine the *in vivo* effect of mouse vRANK, we generated a systemically overexpressed CAGcre+/svRANK mouse that showed high fatality before weaning; a 13-week survivor displayed bronchopneumonia and cardiac dilatation with cardiomyopathy. Taken together, these results suggest that vRANK is a novel bioactive peptide that not only reduces the number of RANKL-induced mature osteoclasts, but also exhibits profound systemic cytopathic effects.

Iron Homeostasis is Critical for Osteoclast Differentiation. Toshifumi Fujiwara*[1], Jian Zhou[2], Shiqiao Ye[1], Stavros Manolagas[1], Haibo Zhao[1]. [1]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [2]UAMS, USA

Iron is essential for osteoclast (OC) differentiation, and iron overload in a variety of hematologic diseases is associated with excessive bone resorption. Iron uptake by OC precursors, via the transferrin (Tf) cycle, has been shown to increase mitochondrial biogenesis, reactive oxidative species (ROS) production, and activation of CREB – a critical transcription factor downstream of RANKL-induced calcium signaling. However, the molecular mechanisms regulating cellular iron metabolism in OC lineage cells remain largely unknown. Most mammalian cells acquire iron from the extracellular fluid through the Tf cycle, in which ferric iron (Fe^{3+})-loaded Tf binds to TfR on the cell surface, and the complex is then internalized via receptor-mediated endocytosis. Fe^{3+} is released from Tf due to acidic pH in endosomes. Fe^{3+} is then reduced to ferrous iron (Fe^{2+}) by the six-transmembrane epithelial antigen of prostate (Steap) family of ferrireductases. Fe^{2+} is transported across the endosomal membrane to the cytosol by divalent metal transporter 1 (DMT1). Fe^{2+} is mainly utilized by mitochondria and the rest of Fe^{2+} is pumped out of the cell by Ferroportin at the plasma membrane. Mammalian cells can also obtain iron by non-Tf-dependent mechanisms through uptake of Hemes and Ferritins which are transported by Flvcr2-Slc46a1 and Scara5-Timd2, respectively. In order to identify the molecular mechanisms of iron metabolism in OC we examined the expression of major regulators of iron homeostasis in bone marrow macrophages, pre-OCs, and mature OCs by quantitative real-time PCR. The expression of both TfR1 and TfR2 increased during OC differentiation, with TfR1 being the major isoform. Of 4 Steap family members, Steap4 was the highest expressed isoform and was increased 5-fold during OC differentiation. An increase in DMT1 expression with a simultaneous reduction of Ferroportin may be a mechanism by which OCs raise intracellular Fe^{2+}. The expression of genes involved in other iron uptake pathways such as Scara5, Timd2, Flvcr2, Slc46a1 is either undetectable or there is no significant change during OC differentiation. These results indicate that Tf-dependent iron uptake plays an essential role in iron homeostasis in OCs. Consistent with this scenario, knockdown of Steap4 and DMT1 in macrophages by lentivirus-mediated shRNAs markedly inhibits iron uptake and OC formation. Hence, iron homeostasis regulated by Steap4 and DMT1 is critical for osteoclastogenesis.

Psychosine inhibits osteoclastogenesis and bone resorption via G-protein coupled receptor 65 by regulating intracellular cAMP levels in osteoclasts. Eun-Hee Ha*[1], Seong Hee Ahn[2], Hyeonmok Kim[3], Sun-Young Lee[4], Ji-Eun Baek[4], Sook-Young Park[5], Su-Youn Lee[4], Young-Sun Lee[5], Beom-Jun Kim[6], Seung Hun Lee[2], Jung-Min Koh[6], Ghi Su Kim[2]. [1]Asan Institute for Life Sciences, South Korea, [2]Asan Medical Center, University of Ulsan College of Medicine, South Korea, [3]Division of Endocrinology & Metabolism, Asan Medical Center, University of Ulsan College of Medicine, South Korea, [4]Asan Institute for Life Science, South Korea, [5]Asan Institute for Life Sciences, South Korea, [6]Asan Medical Center, South Korea

Recently, the inhibitory effects of G-protein coupled receptor 65 (GPR65) on ovariectomy induced bone resorption have been demonstrated. Psychosine, a lysosphingolipid, has been reported to be a ligand for the GPR65. We investigated a role of psychosine on osteoclastic differentiation and bone resorption via GPR65. Osteoclasts were differentiated from mouse bone marrow macrophages. Tartrate-resistant acid phosphatase-positive multinucleated cells were considered as osteoclasts, and the resorption area was determined by incubating the cells on dentine discs. The expression levels of markers for osteoclast differentiation were assessed by qRT-PCR. GPR65 siRNA and scrambled RNA were transfected with lipofectamine reagent (Invitrogen). The intracellular cAMP levels were determined using a direct enzyme immunoassay. Psychosine inhibited both osteoclastogenesis and in vitro bone resorption, without any significant effect on the viability of preosteoclasts. Consistently, the expressions of osteoclast differentiation markers were significantly decreased by psychosine. The knockdown of GPR65 by its siRNA ameliorated the psychosine-suppressed osteoclastogenesis, and expressions of osteoclast differentiation markers. Psychosine increased the levels of intracellular cAMP, with reversal by the knockdown of GPR65. Psychosine inhibited osteoclastogenesis by increasing intracellular cAMP levels via GPR65.

Serum calcium-decreasing factor, caldecrin, suppresses osteoclastogenesis by regulation for the RANKL-mediated Src family kinase. Akito Tomomura*[1], Mineko Tomomura[2]. [1]Meikai University, School of Dentistry, Japan, [2]Meikai University School of Dentistry, Japan

We have reported that caldecrin inhibits osteoclast differentiation by inhibition of RANKL-mediated Ca^{2+} oscillation, leading to suppression of NFATc1 activation. We have also reported that caldecrin inhibits RANKL-mediated actin ring formation and bone resorptive activity of mature osteoclasts. Caldecrin inhibits RANKL-stimulated c-Src kinase activity and c-Src-Syk association of mature osteoclasts, leading to inhibition of phosphorylation of c-Src, Syk, PLC, SLP-76, and Pyk2, and inhibition of transient receptor potential vanilloid channel 4-mediated Ca^{2+} entry. These results suggest that caldecrin inhibits RANKL-stimulated c-Src activation in mature osteoclast. C-Src is critical to the function of mature osteoclasts, but not osteoclastogenesis. Other Src family including Fyn, and Lyn are regulate osteoclast differentiation.

Here, we investigated the effects of caldecrin on the RANKL-stimulated Fyn and Lyn activation of the pre-osteoclasts. Immunoprecipitation studies indicated that caldecrin inhibited the phosphorylation of Fyn stimulated by RANKL treatment, but not those of Lyn in the pre-osteoclasts. These results suggest that caldecrin inhibits osteoclast differentiation by suppression of RANKL-stimulated Fyn phosphorylation.

The Effect of Vascular Endothelial Growth Factor (VEGF) on Osteoclastogenesis in Rheumatoid Arthritis. Sang-Heon Lee*[1], Hae-Rim Kim[2], Youngil Seo[3]. [1]Konkuk University Medical Center, South Korea, [2]Konkuk University Medical Center, South Korea, [3]Hallym University Sacred Heart Hospital, South Korea

Objective. This study was aim to determine the specific role of VEGF, which is originally known to be involved in the angiogenesis, on the osteoclastogenesis in RA.

Methods. The expression of VEGF, receptor activator of nuclear factor κB ligand(RANKL) and CD55 in RA synovial tissues was analyzed using confocal microscopy. VEGF and RANKL concentrations in synovial fluid and their correlation were determined by ELISA. VEGF-induced RANKL expression was determined in RA synovial fibroblasts using RT-PCR, luciferase assay and ELISA, Peripheral blood CD14+ monocytes were cultured with VEGF, and then osteoclastogenesis was assessed by counting tartrate-resistant acid phosphatase(TRAP)-positive multinucleated cells. Osteoclastogenesis was also determined after co-culutre of monocytes with VEGF-pretreated synovial fibroblasts.

Results. We found co-expression of VEGF, RANKL and CD55 in lining and sublining areas of RA synovium. RANKL concentration correlated with VEGF concentration in synovial fluid of RA patients. VEGF stimulated the expession of RANKL mRNA and protein in RA synovial fibroblasts, and RANKL promoter activity was upregulated by VEGF in the synovial fibroblasts transfected with RANKL reporter plasmids. The VEGF-induced RANKL expression was decreased by the inhibition of Src and PKC pathways. VEGF induced osteoclast differentiation from monocytes in the absence of RANKL. When monocytes were co-cultured with VEGF-prestimulated RA synovial fibroblasts, monocytes were differentiated into osteoclasts, which was downregulated by Src and PKC inhibtion.

Conclusion. VEGF plays dual roles on osteoclastogenesis in RA: direct induction of osteoclastogenesis from the precursors and indirect stimulation of RANKL producing synovial fibroblasts, which may mediate Src and PKC pathway. The axis of VEGF and RANKL could be a potential therapeutic target to prevent bone destruction in RA.

SU0266

A bacterial artificial chromosome-based SOST-Cre transgene is active in mature osteocytes as well as an early hematopoietic progenitor. Jinhu Xiong*[1], Marilina Piemontese[2], Priscilla Baltz[3], Stavros Manolagas[1], Charles O'Brien[1]. [1]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [2]University of Arkansas for Medical Sciences, USA, [3]University of Arkansas for Medical Sciences, USA

RANKL is essential for osteoclastogenesis and RANKL expressed in Dmp1-Cre transgene-expressing cells is required for cancellous bone remodeling in adult mice. However, the Dmp1-Cre transgene used to obtain these findings is active in both osteocytes and matrix-synthesizing osteoblasts, leaving open the possibility that RANKL produced by osteocytes, osteoblasts, or bone lining cells contributes to osteoclast formation in cancellous bone. To distinguish between osteocytes, osteoblasts, and lining cells as sources of RANKL, we created transgenic mice expressing the Cre recombinase under the control of regulatory elements of the Sost gene contained in a bacterial artificial chromosome. Activity of the Sost-Cre transgene in vivo was determined by crossing Sost-Cre mice with Rosa26R reporter mice, which express LacZ only in cells expressing Cre recombinase or their progeny. X-gal staining of bones of these mice, which had also been injected with calcein to identify surfaces with active bone formation, showed that the Sost-Cre transgene is active in osteocytes but not osteoblasts. However, we also observed lacZ positive cells in the bone marrow. To determine the identity of these cells,we crossed Sost-Cre mice with another Cre reporter strain that expresses tandem dimer (td)-Red fluorescent protein upon Cre-mediated recombination and then analyzed bone marrow cells by flow cytometry. Due to the large number of lacZ positive cells in the bone marrow of Sost-Cre;R26R mice, we focused the sorting on hematopoietic cells using anti-CD3 to identify T cells, anti-CD19 to identify B cells, anti-CD11b to identify monocyte/macrophage lineage cells, and anti-TER119 to identify erythroid progenitors. Flow cytometry revealed that 27.3 percent of the cells in the bone marrow expressed the tdRed reporter gene. Among those tdRed-positive cells, 1.6 percent were T cells, 20.5 percent were B cells, 48.2 percent were monocytes, and 33.3 percent were erythroid cells. The distribution of each cell type within the tdRed-positive population is similar to that in total bone marrow population suggesting that Sost-Cre transgene activity is restricted to a subpopulation of early hematopoietic progenitors. Consistent with this, endogenous Sost mRNA was undetectable in T cells, B cells, or monocytes. Whether the activity of the transgene accurately reflects the activity of the endogenous Sost gene in hematopoietic progenitors will require further analysis.

A Novel Bone Metabolic Role for the Acute Phase Protein A-SAA/Saa3. Roman Thaler*[1], Monika Rumpler[2], Ines Sturmlechner[2], Silvia Spitzer[2], Klaus Klaushofer[3], Amel Dudakovic[4], Andre Van Wijnen[4], Franz Varga[2]. [1]Mayo Clinic, USA, [2]Ludwig Boltzmann Institute of Osteology at the Hanusch Hospital of WGKK & AUVA Trauma Centre Meidling. 1st Medical Department, Hanusch Hospital, Austria, [3]Hanusch HospitalLudwig Boftzmann Institute of Osteology, Austria, [4]Mayo Clinic, USA

Collagen triple helix disruption in osteoblasts significantly stimulates expression of the acute-phase protein Serum Amyloid A (A-SAA/Saa3), which is known to be elevated in cardiovascular diseases, rheumatoid arthritis or insulin resistance. We have previously shown that induction of SAA3 affects bone metabolism by modulating the expression of genes involved in bone matrix remodeling, inflammation and apoptosis. Here, we further investigated the regulatory role of *Saa3* during osteogenic differentiation and bone turn-over.

We observed that C3H10T1/2 mesenchymal progenitor cells do not express appreciable amounts of SAA3 protein levels. However, pre-osteoblastic MC3T3-E1 osteoblasts, late osteoblastic MLO-A5 cells and MLO-Y4 osteocytes each exhibit detectable expression of SAA3. Each of these cell types represent models for osteogenic differentiation at progressive stages of lineage-commitment. Our results

suggest that SAA3 expression positively correlates with increased cellular maturation towards the osteocyte phenotype. These findings with immortalized bone cell lines were validated with primary pre-osteoblasts, osteoblasts and early osteocytes from newborn mouse calvaria. Functionally, administration of recombinant SAA3 protein significantly reduces expression of mature osteoblast markers *Bglap2 (osteocalcin)*, *Runx2*, *Col1a1* or *Alpl* expression during osteoblasts differentiation. In contrast, SAA3 protein treatment of primary mouse macrophages/monocytes increases the number of multinuclear cells (>5 nuclei/cell), and in RAW264.7 pre-osteoclasts the number of TRAP positive cells and *Calcr* mRNA expression. Thus, SAA3 is suppressive of osteoblast differentiation and promotes osteoclast differentiation. siRNA mediated depletion of *Saa3* in MLO-Y4 osteocytes down-regulates the osteocyte biomarkers *Dmp1*, and *Mepe*. Remarkably, administration of recombinant osteocalcin, a key extracellular matrix protein produced by osteoblasts, decreases *Saa3* expression in MLO-Y4 osteocytes. These data suggests that SAA3 may function as a coupling factor between osteoblasts, osteoclasts and osteocytes to control their biological properties. We demonstrate that SAA3 produced by MLO-Y4 osteocytes is clearly deposited and integrated into the extra cellular matrix of MC3T3 osteoblasts. Importantly, mineralization is significantly decreased in newborn mouse calvaria treated for 12d with recombinat SAA3.

We propose that A-SAA/Saa3 is a novel regulator of bone metabolism and homeostasis.

Expression of c-fms in osteocytes is differentiation-dependent and plays an important role in regulating Tissue Mineral Density *in vivo*. Meiling Zhu[1], Joanne Walker*[2], Benhua Sun[3], Steven Tommasini[1], Christine Simpson[3], Joshua VanHouten[3], Karl Insogna[3]. [1]Yale University, USA, [2]Yale School of Medicine, USA, [3]Yale University School of Medicine, USA

Selective deletion of c-fms in osteocytes results in a marked increase in tissue mineral density (TMD) *in vivo*. TMD is an intrinsic property of bone that makes an important contribution to fracture risk. Toluidine blue staining and FTIR analyses demonstrated focal areas of hypermineralization in knock out cortical bone. This occurred despite unaltered serum levels of CTX in the knock out mice indicating that a change in the rate of skeletal remodeling was not the basis for the change in TMD. Besides altering the rate of skeletal remodeling osteocytes can influence TMD by regulating osteocyte lacunar size and the density of the perilacunar bone. Indeed, in an initial study using high-resolution microCT osteocyte lacunae size tended to be smaller. Since we have not observed expression of c-fms protein in osteoblasts we wondered if its expression in osteocytes was differentiation-dependent. When cultured in mineralizing media, primary murine osteoblasts form mineralized extracellular matrix that is reminiscent of bone and contains cells that have an osteocyte phenotype. We found that mineralizing but not non-mineralizing osteoblast cultures express c-fms protein and coincident with that mineralized cultures evidenced a marked increase in expression of DMP1 and sclerostin, two key osteocyte markers. Further, we found using the osteocyte cell line IDG-SW3, that undifferentiated IDG-SW3 cells do not express c-fms protein but when these cells were induced to differentiate to an osteocytic phenotype they also express c-fms protein. Interestingly, in both the mineralization experiments and during IDG-SW3 differentiation, the levels of c-fms transcript did not change, indicating that the expression of c-fms protein during the transition from osteoblasts to osteocytes is post-transcriptionally regulated. Phosphotyrosine western blotting of cell lysates from CSF-1-treated differentiated IDG-SW3 cells demonstrated selective phosphorylation of certain proteins indicating that c-fms was functional in these cells. Taken together with the *in vivo* data summarized above, our findings indicate that c-fms plays a direct and important role in osteocyte biology and in regulating Tissue Mineral Density.

Gender specific effects of β-catenin on trabecular bone with unloading. Delphine Maurel*[1], Peipei Duan[2], Ning Zhao[3], Mark Johnson[4], Lynda Bonewald[5]. [1]Department of Oral & Craniofacial Sciences, USA, [2]Oral & Craniofacial Sciences, USA, [3]univ of missouri kansas city, USA, [4]University of Missouri, Kansas City Dental School, USA, [5]University of Missouri - Kansas City, USA

Deletion of both alleles of β-catenin in bone cells results in a fragile skeleton highly susceptible to fracture. In contrast, deletion of one allele using Dmp1-Cre results in a relatively normal skeleton at 8 weeks of age with minor reductions in trabecular bone but no effect on bone density or other properties. Interestingly, anabolic response to ulnar mechanical loading was absent in Dmp1-Cre x β-catenin heterozygote (cKO) animals at 6 months of age, suggesting that β-catenin also plays a role in the response of bone to mechanical loading. In this study we asked whether β-catenin could also play a role in the response of bone to unloading.

In 18 week old female mice, tibial cortical bone volume was significantly less by a modest amount in cKO mice compared to controls (Con/cKO: Ct. BV/TV = 91.2±0.2/90.5±0.1%, Ct. Th. = 0.206±0.004/0.193±0.002mm), but no differences in trabecular bone. In contrast, in 18 week old male mice, no differences were observed in cortical bone, but tibial trabecular bone volume was significantly less in cKO mice compared to controls (Con/cKO: Tb. BV/TV = 14.4±1.2/9.1±0.5%, Tb. N. = 4.97±0.23/3.81±0.09/mm, Tb. Sp. = 0.20±0.01 /0.26±0.01mm, a 37%, 23% and 30% change respectively), suggesting that β-catenin is essential for maintaining normal bone mass in males under normal ambulatory conditions (SPSS 21.0, independent t-test). To test the effects of unloading, mice were either suspended (SUS) or attached but not suspended (NS) using a tail ring starting at 14 weeks of age for 4 weeks. Male control mice lost significant amounts of trabecular bone with unloading (NS/SUS: BV/TV = 15.7±1.8/8.1±0.8%, Tb. Th. = 0.053±0.004/0.039±0.002mm), however the cKO mice did not (One-way ANOVA with Tukey post-hoc test). The lack of bone loss in male mice may have been due to the fact that their trabecular bone mass was much less than control prior to unloading. As expected, female control mice lost significant tibial trabecular bone with unloading (NS /SUS: Tb.Th. = 0.055±0.003/0.048±0.002mm), but female cKO mice had greater trabecular bone loss with unloading (Con/cKO: Tb. N = 2.30±0.06/1.82±0.08/mm, Tb. Sp. = 0.46±0.01 / 0.57±0.03 mm). These differences of a 9% decrease for controls and a 21% decrease for cKO for Tb. N. and a 12% increase for controls and a 27% increase for cKO for Tb. Sp. suggests that β-catenin is protective against the effects of unloading in females. In males, β-catenin appears necessary for normal bone mass.

IGF-1 induces the differentiation of mouse and human osteoblasts in 3D culture to mature osteocytes expressing sclerostin and FGF-23. Nicole Scully*[1], Sam Evans[2], Carole Elford[2], Deborah Mason[3], Bronwen Evans[3]. [1]Cardiff University, United Kingdom, [2]Cardiff University, United Kingdom, [3]Cardiff University, United Kingdom

Osteocytes differentiate from osteoblasts, are mechano-sensitive, and are difficult to isolate with a dependence on cell lines for *in vitro* studies of osteocyte biology. Recent publications have indicated that osteoblasts maintained in *in vitro* 3D collagen gels may differentiate to osteocytes. We have developed a novel, 3D, mineralised culture system enabling the differentiation of osteoblasts to osteocytes, which can then be applied to the study of osteocyte biology and function, including responses to mechanical loading. Since IGF-1 plays a key role in bone homeostasis and regulates osteoblast differentiation from osteoprogenitor cells, we hypothesised that IGF-1 added to our 3D model in basal and/or mineralising medium regulates osteoblast differentiation and function.

We maintained osteoblasts (mouse MC-3T3; human primary hOB) in 3D type I collagen gels (48-well plates; 15 days) in basal or mineralising medium ± IGF-1 (50 ng/μl). Cell number, viability and phenotype (IHC, confocal), IL-6, VEGF and FGF-23 secretion (ELISA), and gene expression (*e.g.* sclerostin, FGF-23; qRTPCR) were measured. Results presented are combinations of at least 2 independent experiments.

Both cell types appeared more dendritic in mineralising medium compared to basal medium, and cell viability was >92% throughout. IGF-1 treatment did not affect cell number in MC-3T3s or hOBs in basal medium. MC-3T3 cells in basal medium with IGF-1 significantly increased RANKL (~43-fold; $p<0.01$) DMP-1; ($p<0.01$), Cx43 ($p<0.01$) and FGF-23 (~15-fold; $p<0.001$) expression from day 11. FGF-23 secretion was only detected with IGF-1 treatment from day 11. In mineralising medium with IGF-1 cell number increased ($p<0.05$), E11 ($p<0.05$) and MEPE ($p<0.05$) expression decreased, and VEGF secretion increased ($p<0.01$) at day 15. hOBs in basal medium with IGF-1 increased ($p<0.05$) DMP-1 and sclerostin expression from day 11, whereas VEGF, IL-6 and RANKL secretions were reduced with days in culture.

IGF-1 modulated cell differentiation and secretion, with broadly similar results obtained with both cell types tested. FGF-23 and sclerostin production, as well as the large increase in RANKL expression, in the presence of IGF-1 highlights the possible role of IGF-1 in osteocyte differentiation and function. This novel 3D *in vitro* system provides a tool to further study the role of IGF-1 in osteocyte function, especially those related to the mechano-sensing signaling pathways.

Multiple tissue targets revealed in a transgenic mouse model for inducible and specific osteocyte ablation. Ahmed Aljazzar*[1], Andy Pitsillides[2]. [1], United Kingdom, [2]Royal Veterinary College, United Kingdom

Many approaches highlight a potential for osteocyte-mediated control of bone remodeling. Direct in vivo support for this pivotal role stems mostly from osteocyte-selective ablation achieved following diphtheria toxin (DT) injection in mice harbouring a DMP1 promoter-regulated human diphtheria toxin receptor (hDTR) transgene. These DTR-DMP1 mice have been to support multiple osteocyte roles: in mechanical unloading responses and in regulating primary lymphoid organs, fat metabolism and hematopoietic stem cell mobilization. To explore osteocyte roles more fully we sought to confirm the selectivity of DT effects and DMP1-driven hDTR expression in bone.

Fifty-three 8-50wk-old WT and DTR-DMP1 mice were DT-injected (50ng/g), calcein double-labelled and sacrificed within 8days. hDTR, DMP1 and endogenous murine-DTR mRNA levels were assessed in multiple tissues by standard- and qRT-PCR. Tibia/femur were processed for histomorphometric analysis and samples collected for histology and assessment of EF-2 activity (DTR activation target). Health status was evaluated daily for signs of modified welfare.

hDTR (and DMP1) mRNA was detected in muscle, spleen, marrow, heart, liver, brain, lung, kidney and bone in DTR-DMP1, but not WT mice, and levels correlated with histopathology (mDTR did not). Histopathological changes included liver vacuolation, acute kidney necrosis and splenic/thymic atrophy in DTR-DMP1 only after DT-treatment within 3days. Marked DT-induced distension and congestion of bone marrow sinusoids was also evident in DTR-DMP1. Histomorphometry revealed significantly reduced bone formation rate on endosteal, not periosteal, surfaces in DTR-DMP1 mice (not WT) after DT-treatment. This was not, however, linked with expected widespread osteocyte ablation (<20% in DTR-DMP1 mice 6days after single DT (WT, <6%) and only 50% after five daily DT-doses). Whilst DT-treated WT showed little ill-health, surprisingly marked deterioration was observed (condition score, weight loss, low temperature, rough coat, staggered gait and signs of pain) in all DTR-DMP1 mice after DT-treatment.

Our data question the utility of DTR-DMP1 mouse model for inducible and specific osteocyte ablation. We find hDTR expression in multiple tissues and ill-health in response to DT treatment, suggesting that conclusions regarding osteocyte function, based solely on this model, are premature.

Mutual Enhancement of Differentiation of Osteoblasts and Osteocytes Occurs Through Direct Cell-cell Communication. Qian Xing[1], Koji Fujita[2], Sundeep Khosla[3], David Monroe*[4]. [1]Mayo Clinic, USA, [2]Mayo Clinic, USA, [3]Mayo Clinic College of Medicine, USA, [4]Mayo Foundation, USA

There is increasing evidence that osteocytes regulate multiple aspects of bone remodeling through communication with osteoblasts. This bi-directional communication may occur through the secretion of specific factors or through direct cell-cell contact, via osteocytic dendritic processes. We used a novel transwell model whereby calvarial osteoblasts were co-cultured (but physically separated) with IDG-SW3 osteocytes, or each cell type cultured on either side of a permeable membrane that allows direct cell-cell contact. Both conditions permit crosstalk between the osteoblastic and osteocytic cells via secreted factors, with the latter also allowing for direct cellular communication. The SW3 cells were allowed to differentiate under osteogenic conditions for 3 weeks before being placed into the transwell model with the osteoblasts, and both were allowed to continue differentiation for 1 week. At that point, the cells were separated and analyzed for specific osteoblastic and osteocytic gene expression signatures using RT-QPCR. Direct cell contact resulted in a marked upregulation of osteoblast differentiation markers, such as *Col1a1*, *Runx2*, *osterix*, *osteocalcin* (*Ocn*) and *alkaline phosphatase*, when compared to osteoblasts cultured with osteocytes without cell contact. Interestingly, the SW3 osteocytes exhibited increased osteocyte differentiation markers, such as *Phex*, *Mepe*, *Sost* and *Dmp1* expression, when in direct contact with osteoblasts. These data suggest that physical contact mutually enhances both the osteoblastic and osteocytic character of each respective cell type. We also found that *connexin 43* (*Gja1*) expression was increased in the osteoblasts only when in direct contact with the SW3 cells, suggesting that Gja1 may mediate some of the phenotypic effects of direct cell contact. To test this, we treated the direct contact system with the gap junction inhibitor 18-alpha-glycyrrhetinic acid (AGA) and found that *Ocn* expression was significantly inhibited, suggesting that osteocytes may regulate late osteoblast differentiation via Gja1. These data indicate that the pro-differentiative effects of direct osteoblast/osteocyte contact are mostly likely mediated through both gap junction signaling and presumably through cytokine secretion. Identification of the specific factors involved in the enhancement of osteoblastic/osteocytic differentiation will uncover new biology concerning how these bone cells communicate and respond to direct cell contact.

Pannexin 1 Knockout Mice Have Reduced RANKL Expression Following Focal Microinjury: Possible Mechanism Involving Pannexin 1 Channels for Osteoclast Recruitment?. Wing-Yee Cheung*[1], Eliana Scemes[2], David Spray[2], Jelena Basta-Pljakic[3], Robert Majeska[4], Mitchell Schaffler[1]. [1]City College of New York, USA, [2]Albert Einstein College of Medicine, USA, [3]City College of New York, USA, [4]City College of New York, USA

Osteocyte apoptosis is essential to recruit osteoclasts to bone microdamage sites. However apoptosis only occurs near the damage sites, while viable osteocytes surrounding the dying cells upregulate their RANKL expression to promote osteoclastogenesis. How apoptotic cells communicate with their surviving neighbors to induce pro-osteoclastogenic signal expression is unknown.

In cardic and brain ischemia, Pannexin 1 (PANX1) channels mediate the release of "find-me" signals that recruit phagocytes to clear apoptotic debris. To test whether PANX1 channels might play similar roles in recruiting osteoclasts to damaged bone, we assessed the patterns of osteocyte apoptosis and RANKL expression in mice lacking PANX1 (PANX-/-, n=4) and in C57/BL6 wild-type (WT) controls following focal microinjury in vivo.

A microindentation probe (5N, 10 cycles) was used to create a single microcrack in mouse tibiae at the indent apex. After 24 hours, bones were harvested, fixed, decalcified and analyzed by immunohistochemistry (Fig 1A). Apoptotic (cleaved caspase-3-positive) and RANKL-expressing osteocytes were counted as a function of distance from the microcrack sites. Non-damaged regions from the same tissue sections were used to assess baseline levels of osteocyte apoptosis and RANKL expression. Differences between groups were determined by Mann-Whitney U tests ($p<0.05$).

In WT mice, focal microinjury induced osteocyte apoptosis and osteocyte RANKL expression near microdamage sites (Fig 1B; 3 to 4 fold above baseline), consistent with previous fatigue-loading studies. In PANX1 deficient mice, the numbers of apoptotic osteocytes near focal microinjury were the same as WT. However, numbers of osteocytes expressing RANKL were indistinguishable from baseline (Fig 1B, $p<0.05$). These results indicate that deficiency of PANX1 channels prevents dying osteocytes near microdamage sites from inducing their surviving neighbors to express RANKL. How PANX1 channels mediate this signaling process remains unclear, but PANX1 channels have been implicated in nucleotide release during apoptosis. Moreover, ATP has been shown to upregulate RANKL experssion in osteoclasts. Thus, PANX1 channels are likely candidates to mediate "find-me" signaling needed to activate osteoclast recruitment.

Strontium Ranelate is more efficient when combined with *physical* activity. Priscilla Aveline[1], Eric Lespessailles[2], Claude Laurent Benhamou[3], Thomas M Best[4], Hechmi Toumi*[1]. [1]Univ. Orléans, I3MTO Laboratory, EA 4708, Hospital of Orleans, 1 rue Porte Madeleine, F-45032 Orléans, France, France, [2]Centre Hospitalier Regional Orleans, France, [3]CHR ORLEANS, France, [4]3-
Division of Sports Medicine, Department of Family Medicine, Sports Health And, USA

Physical exercise is known to exert beneficial effects on bone status. Strontium Ranelate (SrRan) on the other hand has been shown to have anti-osteoporotic properties in both animal models and clinical trials. PURPOSE: Investigate the effects of SrRan, physical exercise (E) and a combination of SrRan and E on bone formation in sedentary and ovariectomized rats. METHODS: Ninety six female Wistar rats, aged 6 weeks, were randomly assigned to 8 groups: (1) (Sham): sedentary rats + saline, (2) (SH/ SrRan): sedentary rats + SrRan, (3) (SH/E): sedentary rats + saline + E, (4) (SH/SR/E): sedentary rats + SrRan + E, (5) (OVX): ovariectomized rats + saline, (6): (OVX/SR): ovariectomized rats + SrRan, (7) (OVX/E): ovariectomized rats + saline + E and (8) (OVX/ SrRan /E): ovariectomized rats + SrRan + E. Exercise involved 10 impacts drop landing exercises per day from 45 cm, 5 days a week over 8 weeks.

SrRan treatment consisted of 625 mg/kg of SrRan per gavage in 0.5 % carboxymethylcellulose daily. Body composition, whole body, and left femur BMDs were analysed using µCT. Bone strength was assessed at the femur mid-shaft in 3-point bending. Osteocyte apoptosis was studied by cleaved caspase-3 immunostaining. RESULTS: Jump exercises and SrRan increased Bone/Tissue ratio in the left femur of the OVX and control groups. Similarly, a cumulative effect was observed when SrRan was combined with physical exercise. The same results were mirrored for trabeculea thickness except only the OVX rats benefited from cumulative effects when SrRan was combined with exercise. Ultimate strength increased with SrRan in the control rats, however it decreased with exercise in the OVX groups. In the OVX rats, both exercise and SrRan increased Osteocalcin expression. However, in control rats, osteocalcin increased only when SrRan was combined with exercise. Exercise and SrRan decreased amino-terminal telopeptide of type I collagen only in the OVX rats and the effect of SrRan was more prominent. Both jump exercise and SrRan decreased Osteocyte apoptosis in the OVX and control groups. SrRan decreased lipid cells in OVX rats, however in control rats, this effect was observed only when SrRan was combined with exercise. CONCLUSION: Our findings demonstrate that both jump exercise and SrRan have a positive influence on bone status, however the SrRan effects were more substantial. SrRan could have an important role in postmenopausal osteoporosis particularly when combined with jump exercise.

Extracellular Inorganic Phosphate Functions as a Potent Inducer of the *Dmp1* Expression and Facilitates the Transition of Osteoblasts to Osteocytes. Jin Nishino*[1], Kazuaki Miyagawa[2], Masanobu Kawai[3], Miwa Yamazaki[4], Kanako Tachikawa[4], Yuko Mikuni-Takagaki[5], Mikihiko Kogo[6], Keiichi Ozono[7], Toshimi Michigami[8]. [1]Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, [2]Osaka University Graduate School of Dentistry, Japan, [3]Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, [4]Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, [5]Kanagawa Dental University Graduate School of Dentistry, Japan, [6]Osaka University Graduate School of Dentistry, Japan, [7]Osaka University Graduate School of Medicine, Japan, [8]Osaka Medical Center & Research Institute for Maternal & Child Health, Japan

Several molecules responsible for hypophosphatemic rickets, including FGF23, PHEX, DMP1 and FAM20C, are highly expressed in osteocytes, indicating the critical roles of osteocytes in phosphate metabolism. In the current study, to elucidate how the extracellular inorganic phosphate (Pi) modulates the osteocyte function, we first examined the direct effects of Pi on the gene expression in primary osteocytes isolated from mouse long bones. The expression of *Dmp1* was markedly increased by 24-h treatment with high (10 mM) Pi, which suggests that osteocytes are responsive to the alteration in extracellular Pi concentration. However, the expression of *Fgf23*, *Phex*, and *Fam20c* was not obviously changed by 24-h treatment with 10 mM Pi. Then, we next examined whether high extracellular Pi induced the expression of *Dmp1* in osteoblasts as well, using a murine osteoblastic cell line MC3T3-E1. We treated the cells with various concentrations (1-10 mM) of Pi for 48 h, and found that the *Dmp1* expression and phosphorylation of ERK1/2 were induced by the increased Pi in a dose-dependent manner. Interestingly, treatment with U0126, an MEK inhibitor, abolished the up-regulation of *Dmp1* by the increased Pi. Treatment with phosphonoformic acid (PFA), an inhibitor of Na^+/Pi co-transporter cancelled the increase in the *Dmp1* expression by the elevated Pi, either. These results suggest that the signaling triggered by extracellular Pi leads to an increased expression of *Dmp1* via Na^+/Pi co-transporter and MEK/ERK pathway. Since these findings indicate that Pi functions as a potent inducer of the *Dmp1* expression, we further examined the effects of longer treatment with Pi. To recapitulate the bone microenvironment, MC3T3-E1 cells were embedded in type I collagen gel and cultured in the presence of various concentration of Pi. In addition to *Dmp1*, the expression of *Fgf23*, *Fam20c*, *Hif1α*, *Connexin43*, *Fgf1*, *Fgf2*, and a Na^+/Pi co-transporter *Pit1,* was increased in the presence of 10 mM Pi compared to 1 mM Pi after 2 weeks of culture. The increase in the *Fgf23* expression was preceded by that in the *Dmp1* expression, implying that it may take long before Pi induces the expression of *Fgf23*. The expression of an osteoblastic marker *Keratocan* was decreased in the presence of 10 mM Pi. Taken together, these results indicate that Pi directly exerts its effects on osteoblast/osteocyte lineage cells to induce the expression of *Dmp1* and facilitates the differentiation of osteoblasts to osteocytes.

Further Characterization of a Novel Cell Line Expressing a Membrane Targeted GFP in Osteocytes, Which Forms "Mini-bone"Structures in vitro. Kun Wang*[1], Brad Chun[2], Richard Campos[3], Vladmir Dusevich[2], Sarah Dallas[1]. [1]University of Missouri - Kansas City, USA, [2]University of Missouri - Kansas City, USA, [3]University of Missouri - Kansas City, USA

With the increasing interest in osteocytes as multifunctional regulators of both osteoblast and osteoclast activity, as well as their role as endocrine cells, there is a need for new tools to study their biology and function. We have previously described the generation of a novel immortalized cell line, OmGFP66, which has the unique property of forming highly organized "mini-bone" structures in culture that closely mimic osteocytes and trabecular bone structure in normal bone tissues. Here we describe the further characterization of this novel cell line.

The OmGFP66 cell line was derived from calvarial cells isolated from transgenic mice expressing a membrane targeted GFP variant driven by the 10kb dentin matrix protein-1 promoter for selective expression in osteocytes. The cells were immortalized by stable transfection with SV40T antigen and clone OmGFP66 was found to have the unique property of forming well organized mini-bone structures in long term culture with highly dendritic GFP-positive osteocytes embedded in well defined lacunae. We have previously shown by western blotting that over a 28 day time course these cells progress from expressing early osteocyte markers E11/gp38 and dentin matrix protein-1 to expressing the late osteocyte marker, sclerostin. The cells also express alkaline phosphatase, suggesting that they represent a late osteoblast/early osteocyte cell line that can be differentiated to mature embedded osteocytes. qPCR analysis confirmed expression of these early and late osteocyte marker genes and showed that omGFP66 cells also express other osteocyte marker genes, such as FGF23, MEPE and PHEX, which increased over the 28 day time course. Expression of Cx43 was also detected as well as high expression of HIF-1α. Transmission electron microscopy revealed a highly organized mineralized matrix that appeared very similar to bone structure in vivo, with mineral deposited on collagen fibrils. Embedded cells resembling in vivo osteocytes were observed within mineralized lacunae and canaliculi containing dendrites were observed throughout the mineralized matrix. This novel cell line provides a useful tool for examining osteocyte function in vitro within a mineralized microenvironment that closely resembles the osteocyte microenvironment in vivo.

Prevention of Osteocyte Apoptosis and the Increase in Osteocytic RANKL Are Not Sufficient to Restrain Osteoclastic Bone Resorption and Stop Bone Loss Induced by Reduced Mechanical Forces. Lilian Plotkin*[1], Arancha Gortazar[2], Keith Condon[3], Hugo Gabilondo[3], Marta Maycas[4], Teresita Bellido[1]. [1]Indiana University School of Medicine, USA, [2]Universidad San Pablo-CEU School of Medicine Madrid Spain, Spain, [3]Indiana University School of Medicine, USA, [4]Indiana University School of Medicine, USA

Apoptosis of osteocytes precedes osteoclast-mediated resorption and bone loss induced by reduced mechanical forces, and RANKL expression is increased with unloading in mice. Because osteocytes are the major producers of RANKL, we hypothesized that apoptotic osteocytes signal to neighboring cells to increase RANKL expression, which in turn increases osteoclast formation and bone resorption. We tested herein whether inhibition of osteocyte apoptosis alters osteocytic RANKL expression and stops resorption and bone loss induced by unloading. Female 4 month old C57Bl/6 mice were tail-suspended for 28d and received daily injections of the bisphosphonates (BPs) alendronate (Aln) or IG9402 at 2.3µmol/kg/day, or placebo, starting 3d before unloading. Earlier studies showed that Aln inhibits both osteocyte apoptosis and resorption, whereas IG9402 only prevents osteocyte apoptosis. Unloading increased the prevalence of apoptotic, TUNEL+ osteocytes by 2-fold compared to ambulatory controls; and Aln and IG9402 prevented this increase. Unloading also increased the number of RANKL+ osteocytes by 2-fold, detected by immunohistochemistry with sc-7628 antibody; and both BPs equally prevented this effect. Further, unloaded mice exhibited elevated osteoclasts on cancellous vertebral bone surfaces, increased osteoclastogenesis in *ex vivo* bone marrow cultures (plus RANKL/M-CSF), and increased levels of the bone resorption marker CTX in serum. Aln prevented all these effects, whereas IG9402 was ineffective. Unloaded mice also exhibited a reduction in spinal and femoral BMD (-11%) by DXA; spinal BV/TV (-25%) and trabecular thickness (-14%) by micro-CT; and mechanical strength (-46% ultimate load, N) as well as material strength (-62% maximum stress, MPa). Aln treatment prevented the loss of both bone mass and strength. In contrast, IG9402 did not prevent the loss of bone mass, but partially prevented the loss of both mechanical and material strength (-38%) suggesting a contribution of osteocyte viability to strength independent of bone mass. These results demonstrate that inhibition of osteocyte apoptosis and prevention of the increase in osteocytic RANKL are not sufficient to restrain osteoclastic bone resorption and stop bone loss induced by unloading. We conclude that osteocyte apoptosis is not the main cause of increased resorption and that osteocytic RANKL is not the sole mediator of osteoclastogenesis and bone loss induced by lack of mechanical forces.

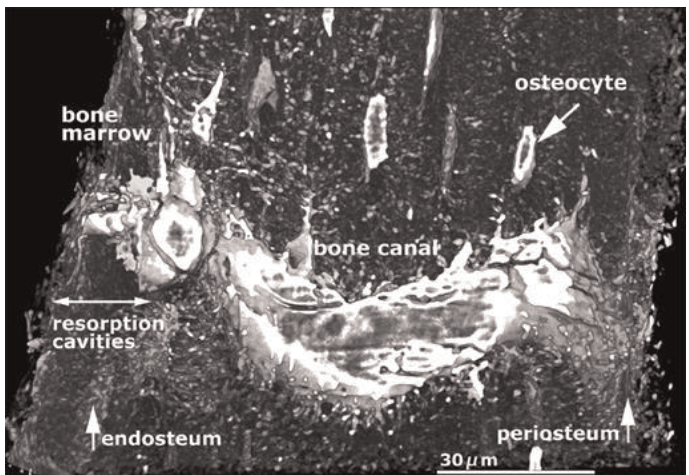
Continuous PTH Administration Stimulates Osteoclasts and Leads to Increased Cortical Bone Resorption at the Endosteal Surface, Widening of the Porosities, and Osteoclasts Contact with Osteocytes. Nobuhito Nango*[1], Shogo Kubota[2], Wataru Yashiro[3], Atsushi Momose[3], Makoto Morikawa[4], Koichi Matsuo[5]. [1]Ratoc System Engineering Co., Ltd., Japan, [2]Ratoc System Engineering Co., Ltd., Japan, [3]Institute of Multidisciplinary Research for Advanced Materials, Tohoku University, Japan, [4]Laboratory of Cell & Tissue Biology, School of Medicine, Keio University, Japan, [5]School of Medicine, Keio University, Japan

With age, cortical bones tend to become more porous and thinner, which may lead to a higher risk of bone fracture. A similar phenomenon occurs by continuous PTH administration. However, the mechanism of porosity increasing in cortical bone remains unclear. We previously reported that osteocytes dissolve bone mineral through bone canaliculi, and cement lines and calcified cartilage matrices appear because of the formation of a high mineral wall (HMW) following a single administration of PTH. In this report, the effects of continuous PTH administration were evaluated to clarify the mechanism of increased porosity in cortical bone. We examined responses of microstructures and bone cells such as osteoclasts. Seven-week-old mice with implanted osmotic pumps were continuously dosed with PTH at 40 μg/kg/day for 12, 24, 48, and 144 h to maintain serum PTH levels. The tibial bones were isolated prior to and after administration. We scanned the tibial diaphysis using μCT with a voxel size of 7 μm (N = 4). Furthermore, we built a multi-scan synchrotron X-ray microscope at the SPring-8 (Hyogo, Japan) to observe the bone microstructures at 9 keV (N = 1–3). This method enables three-dimensional observation (0.2-μm voxel size) of the canaliculi and degree of bone mineralization. In the group that received continuous PTH administration for 144 h, the bone marrow volume was increased by 1.5-fold and the cortex was thinned by 28% compared with controls. Moreover, the bone canal was extended and porosity volume increased by 2.2-fold. A HMW was formed, which suggests that the osteocytes reacted to continuous PTH administration. Following continuous PTH administration, deep and wide resorption cavities were observed at the endosteum rather than the periosteum. This finding suggested that osteoclast activity was enhanced at the endosteum by continuous PTH administration. Therefore, the number of porosities on the endosteum extended the bone marrow and made cortical bone thinner. The bone canal ran through cortical bone from the endosteum (left) to the periosteum (right), and deep resorption cavities were formed on the endosteum (Fig.). Osteoclasts in the bone canal made contact with canalicular networks of osteocytes and made cell-cell contact with the osteocytes. The formation of this structure suggested that the osteoclasts may find the location of osteocytes within bone.



Bone canal obtained from synchrotron X-ray microscope (negative contrast image).
The bone canal ran through cortical bone from the endosteum (left) to the periosteum (right), and deep resorption cavities were formed on the endosteum.

Circulating sclerostin as a predictor of cardiovascular events in Type 2 diabetes patients. Manuel Muñoz-Torres*[1], Cristina Novo-Rodriguez[2], Rebeca Reyes-Garcia[3], Pedro Rozas-Moreno[4], Antonia Garcia-Martin[5], Veronica Avila-Rubio[2], Sonia Morales-Santana[2], Beatriz Garcia-Fontana[2], Fernando Escobar-Jimenez[2]. [1]Bone Metabolic Unit (RETICEF), Endocrinology Division, Hospital Universitario San Cecilio, Instituto de Investigación de Granada., Spain, [2]Bone Metabolic Unit (RETICEF), Endocrinology Division, Hospital Universitario San Cecilio, Instituto de Investigación de Granada, Spain, [3]Bone Metabolic Unit (RETICEF), Endocrinology Division, Hospital Universitario San Cecilio, Instituto de Investigación de Granada. Endocrinology Unit. Hospital General Universitario Rafael Mendez, Lorca, Murcia., Spain, [4]Bone Metabolic Unit (RETICEF), Endocrinology Division, Hospital Universitario San Cecilio, Instituto de Investigación de Granada. Endocrinology. Hospital General de Ciudad Real, Spain, [5]Bone Metabolic Unit (RETICEF), Endocrinology Division, Hospital Universitario San Cecilio, Instituto de Investigación de Granada. Endocrinology. Hospital Comarcal de Moroeste, Caravaca de la Cruz, Murcia., Spain

Background: Sclerostin is an osteocyte-secreted protein, which acts as an endogenous inhibitor of Wnt/ β-catenin pathway. Recent studies have shown that type 2 diabetes patients have high sclerostin concentrations, and in type 2 diabetes sclerostin concentrations are related to prevalent atherosclerotic disease.

Aims: To evaluate the predictive ability of circulating sclerostin on the incidence of cardiovascular events in type 2 diabetes patients.

Patients and methods: We performed a prospective study with a follow-up of seven years (2007-2014). We included 133 subjects: 77 with type 2 diabetes (mean age 57 ± 6 years), and 56 subjects without diabetes (mean age 55 ± 7 years). We measured baseline sclerostin concentrations by ELISA (Biomedica), and we evaluated cardiovascular events (acute myocardial infarction, unstable angina, stroke and peripheral vascular disease) and cardiovascular event-related admissions during the follow-up.

Results: Subjects with incident cardiovascular events showed higher baseline sclerostin concentrations. Further, we found a significant difference in sclerostin concentrations ($p<0.025$) when we considered subjects with cardiovascular event-related admissions. The incidence of cardiovascular event-related admissions was 36.5% in the diabetic group and 14.3% for non-diabetic group. In the entire group, sclerostin concentrations above the percentile 50 ($\geqslant$ 43.6 pmol/L) were associated with an increase of cardiovascular events ($p<0.065$) and also with cardiovascular event-related admissions ($p<0.001$). The relative risk of suffering a cardiovascular event in patients with sclerostin concentrations above 43.6 pmol/L was 1.4 (CI 95%: 1.01-1.95). The relative risk of a cardiovascular event-related admission was 1.74 (CI 95%: 1.36-2.2).

Conclusions: Serum concentrations of sclerostin are associated with an increase of the risk of cardiovascular events in type 2 diabetes patients. According to these results, the determination of sclerostin may help in the identification of high-risk patients.

Higher serum carcinoembryonic antigen level is associated with increased development of incident fractures in Korean women: a longitudinal study using the national health insurance claim data. HyeonMok Kim*[1], Seong Hee Ahn[2], Beom-Jun Kim[3], Seung Hun Lee[2], Ghi Su Kim[2], Jung-Min Koh[3]. [1], South Korea, [2]Asan Medical Center, University of Ulsan College of Medicine, South Korea, [3]Asan Medical Center, South Korea

Pro-inflammatory cytokines play important roles in bone metabolism, and several studies revealed that carcinoembryonic antigen (CEA) has a pro-inflammatory feature. We aimed to investigate the relationships of serum CEA with osteoporosis and incident fracture risk.

We performed a small cross-sectional study in the 302 Korean women and a large, longitudinal study in the 7,192 Korean women with an average 3-years. Bone mineral density (BMD) and bone turnover markers (BTMs) were measured in the cross-sectional study. Incident fractures were identified using selected ICD-10 codes in the nationwide claims database of the Health Insurance Review and Assessment Service of Korea in the longitudinal study. In the cross-sectional study, serum CEA negatively correlated with BMD at lumbar spine (γ = -0.023, P = 0.029), and positively correlated with BTMs (γ = 0.122 to 0.138, P = 0.002 to <0.001). In the longitudinal study, 254 (3.5%) women developed incident fractures. After adjustment for potential confounders, the hazard ratio (HR) per 1 ng/mL increment of the baseline CEA level for the development of incident fracture was 1.22 [95% confidence interval (CI) = 1.05 - 1.42]. The HR was markedly higher in subjects in the highest CEA quartile category compared with those in the lowest CEA quartile category (HR = 1.54, 95% CI = 1.04 – 2.28).

These findings suggest that serum CEA may be a biomarker for the risk of incident fracture in Korean postmenopausal women.

How accurate is your sclerostin measurement? Comparison between two commercially available sclerostin ELISA kits. Isabelle Piec*[1], Emily Fisher[2], Christopher Washbourne[3], Jonathan Tang[4], William Fraser[3]. [1]BioAnalytical Facility, University of East Anglia, United Kingdom, [2]University of East Anglia, United Kingdom, [3]University of East Anglia, United Kingdom, [4]University of East Anglia, Norwich, UK, United Kingdom

Introduction: Sclerostin (SOST), osteocyte-secreted soluble antagonist of the Wnt/β-catenin signaling pathway, is a potent inhibitor of osteoblastogenesis. Circulating SOST levels have been measured in a plethora of disorders such as ankylosing spondylitis, chronic kidney disease, diabetes, fractures, hypercortisolism, multiple myeloma and spinal cord injury. SOST is a crucial regulator of the skeletal anabolic action of PTH and as so, anti-sclerostin antibodies are being investigated as potential therapeutic molecules for metabolic bone diseases. Accurate measurement of SOST is therefore of utmost importance for the diagnosis of bone disorders and therapy effectiveness. However, reports so far suggests further study is needed before SOST measurements are introduced into routine clinical practice.

Objective: To compare two commercially available assays for measurement of circulating SOST.

Method: EDTA-plasma samples from 36 anonymised healthy individuals were analyzed using ELISA kit for circulating SOST from Biomedica (Vienna, Austria) and TecoMedical (TECO, Sissach, Switzerland). Both assays are based on immuno-capture using two antibodies which have been raised against human recombinant SOST and are highly specific for this molecule.

Results: Circulating SOST levels in EDTA plasma samples were found to be significantly different between TECO and Biomedica assays (36.9 $\pm$ 2 and 21.3 $\pm$ 1pmol/L, respectively, $p<0.001$) with discrepancies of up to 32pmol/L. The TECO assay demonstrated less variability between duplicates (2.6$\pm$2.4 % and 7.4$\pm$6.3 % respectively) and dilution study showed that the biomedical kit over-recovered diluted samples by up to 60%. When samples containing various concentrations of endogenous sclerostin were spiked with a known amount of SOST, recovery was 88.5% and 104% respectively.Conclusion: The variability in values generated from Biomedica and TECO assays has raised questions regarding the specificity of antibodies used by the two manufactures, and whether there is possible interference affecting one of the assays remains unclear. Cross-reactivity experiments are being conducted to determine the source of variation between the two kits. Until such issues are resolved, measurement of sclerostin remains invaluable for understanding the mechanism by which osteocytes regulate bone turnover but should be used in discretion and interpretation should be carried out with guided clinical evidence.

LC-MS/MS Measurement of Urine Free Collagen Crosslinks Pyridinoline and Deoxypyridinoline: Urine Markers of Bone Resorption. Jonathan Tang*[1], John Dutton[2], Darrell Green[3], Isabelle Piec[4], Emily Fisher[5], Christopher Washbourne[3], William Fraser[3]. [1]University of East Anglia, Norwich, UK, United Kingdom, [2]Royal Liverpool & Broadgreen University Hospital, United Kingdom, [3]University of East Anglia, United Kingdom, [4]BioAnalytical Facility, University of East Anglia, United Kingdom, [5]University of East Anglia, United Kingdom

Background: The pyridinium cross-links Pyridinoline (PYD) and Deoxypyridinoline (DPD) are markers of bone resorption. Primarily found in bone and cartilage, PYD and DPD are the major stable cross-links only present in mature Type I collagen. Breakdown of cross-links are a result of osteoclast resorption, normally excreted in the urine, and in larger quantities when bone resorption is increased. In contrast, when bone resorption is inhibited by bisphosphonate, oestrogen or calcitonin therapy, the excretion of PYD and DPD is decreased. The main application for DPD and PYD is in assessing and monitoring response to osteoclast inhibitory treatment (mainly bisphosphonates) in osteoporosis and Paget's disease of bone. A decrease in value obtained pre-treatment is indicative of a good response in osteoporosis. Normalisation of DPD and PYD is the ultimate goal when treating Paget's disease of bone.

Objective: To develop a sample clean up protocol to extract PYD and DPD from urine and quantify by LC-MS/MS. The method was used to assay urine samples from healthy individuals and patients samples requested for bone turnover markers.

Method: PYD and DPD were measured by reversed-phase, ion-paired high performance liquid chromatography with MS/MS detection. Solid phase extraction was carried out by passing acidified urine mixed with cellulose slurry through a column containing a frit, then washed with butanol and tetrahydrofuran then followed by elution with heptafluorobutyric acid. Mass detection and quantification were performed by a triple quadrupole tandem mass spectrometer.

Results: The method was able to fully resolved PYD and DPD. The intra assay and inter assay CVs for PYD and DPD were <10%. PYD was linear up to 2000 nmol/L, DPD up to 1000 nmol/L. Typical standard curve fit $r^2 \geq 0.998$. Spiked recovery was determined by adding a known quantity of PYD/DPD urine samples containing different levels of endogenous PYD/DPD, percentage recovery were ranged between 98.4-116.5%. The method was compared with two commercial immunoassays for urine total PYD and DPD, with correlation coefficients r^2 of 0.862 and 0.832 respectively.

Conclusion: The presented LC-MS/MS method have been fully validated and showed excellent assay characteristics that is suitable for routine clinical hospital laboratory. Ratio of PYD:DPD is also a valuable diagnostic tool for Ehlers-Danlos Syndrome (EDS), where a reverse ratio is specific and diagnostic for the kyphoscoliotic type of EDS.

Using Bone Turnover Markers to Predict Changes in BMD After Alendronate Therapy in Postmenopausal Women. Brian Mcnabb*[1], Eric Vittinghoff[2], Ann Schwartz[3], Douglas Bauer[3], Kristine Ensrud[4], Elizabeth Barrett-Connor[5], Richard Eastell[6], Dennis Black[3]. [1]San Francisco VA Medical Center, University of California, San Francisco, USA, [2]University of California, San Francisco, USA, [3]University of California, San Francisco, USA, [4]University of Minnesota & Minneapolis VA Health Care System, USA, [5]University of California, San Diego, USA, [6]University of Sheffield, United Kingdom

Context: Many women with osteoporosis are candidates for therapy cessation after 5 years of alendronate. Little information exists to guide monitoring women who stop alendronate with bone turnover markers (BTMs).

Objective: To determine if BTMs measured early after alendronate discontinuation can predict subsequent loss of bone mineral density (BMD).

Methods: We analyzed women who had received an average of 5.1 years of alendronate during the Fracture Intervention Trial (FIT) and were subsequently followed for 5 treatment-free years (on placebo) during the FIT Long Term Extension (FLEX) trial. Repeated measures analysis of annual BMD measurements was used to estimate 5-year changes in total hip and femoral neck BMD during the 5-year treatment-free period following alendronate use (FLEX). BMD was measured by 2D dual-energy X-Ray absorptiometry (DXA). The BTMs bone specific alkaline phosphatase (bone ALP) and N-propeptide of type-I collagen (NTX) were measured at baseline, year-1, and year-3 of FLEX. Linear regression was used to assess the associations of BTM values with 5-year changes in BMD. Models were adjusted for age, body mass index (BMI), vertebral fracture status, calcium intake, walking for exercise, smoking status, alcohol intake, general health status, and falls history.

Results: There were 392 women with analyzable BMD and BTM data. Bone ALP measured at FLEX baseline, year-1, and year-3 predicted 5-year changes in total hip BMD (Table 1), explaining 6.5% or less of the variability. Femoral neck BMD was only predicted by baseline and year-1 bone ALP measurements (data not shown), explaining 11% or less of the variability. NTX predicted total hip BMD change (Table 1), but only when measured at year-1 and year-3, and explained 6.3% or less of the variability. NTX did not predict femoral neck BMD change (data not shown). Models assessing BTMs over multiple time-points or changes in BTMs did not improve prediction over measuring at a single time-point. Measuring both BTMs improved prediction at the total hip, but not the femoral neck.

Conclusions: Bone ALP and NTX measured after alendronate discontinuation are associated with future BMD losses. However, because these BTMs only explain a small amount of the variability of BMD losses, their predictive ability is modest. Assessing changes in BTMs provides no added value over a single measurement at 1 year off therapy.

Table 1: Difference in 5-year % Change in Total HIP BMD per SD Increase in Bone ALP or NTX Measured at Different Time-points After ALN Discontinuation.

BTM (SD)	Change in BMD (Percentage Points)	P	CV-R^2 (%)
Bone ALP, ng/mL			
Years Post-ALN			
0 (2.4)	-0.53	0.001	6.5
1 (4)	-0.43	0.002	6.1
3 (4.1)	-0.4	0.004	3.0
NTX, nmol BCE/mmol Cr			
Years Post-ALN			
0 (16.3)	-0.12	0.41	2.5
1 (12.8)	-0.51	0.001	6.3
3 (12.8)	-0.46	0.002	3.2

Abbreviations: ALN, alendronate; BMD, bone mineral density; SD, standard deviation; Bone ALP, bone specific alkaline phosphatase; NTX, N-propeptide of type 1 collagen; BTM, bone turnover marker; CV-R^2, 10 times cross-validated R^2.

Factors Involved in Cortical Porosity Formation in Males: Analysis of Distal Radius by HR-pQCT. Ko Chiba*[1], Andrew Burghardt[2], Narihiro Okazaki[3], Makoto Osaki[4], Sharmila Majumdar[2]. [1]Nagasaki University School of Medicine, Japan, [2]University of California, San Francisco, USA, [3]University of California, San Francisco, USA, [4]Nagasaki University, Japan

[Introduction]

Cortical porosity at the distal radius was measured using HR-pQCT in males aged between 50 to 78, and the factors involved in its formation were analyzed.

[Methods]

The subjects were 49 healthy males (60 ± 8 year-old, 50 ~ 78 year-old).

The ultradistal radius was scanned by HR-pQCT at 82 μm in voxel size, and the volume density of cortical porosity (Ct.Po) was measured. Correlations with the following factors were analyzed: age, height, weight, body mass index, smoking/drinking habits, serum calcium, vitamin D and testosterone value, bone mineral density value of the lumbar vertebra, proximal femur, distal radius measured by dual-energy x-ray absorptiometry (DXA), and bone microstructural parameters at the ultradistal radius measured by HR-pQCT.

[Results]

The factors that significantly correlated with Ct.Po were age and height, and each of them had a weak correlation ($P<0.01$, $R=0.39, 0.40$).

[Conclusion]

The cortical porosity of the distal radius tended to be seen with aging. However, cortical porosity does not have a significant correlations to local bone loss as indicated by DXA or HR-pQCT. Rather, it can be caused by general factors.

Microarchitectural Deterioration of Lumbar Spine Estimated by Trabecular Bone Score (TBS) is Associated with Vertebral Fractures Independent of Bone Mineral Density in Patients with Type 2 Diabetes Mellitus. Masahiro Yamamoto*[1], Toru Yamaguchi[2], Nobuaki Kiyohara[3], Noriko Nakata[3], Toshitsugu Sugimoto[4]. [1]Shimane University Faculty of Medicine, Japan, [2]Shimane University Faculty of Medicine, Jpn, [3]Shimane University Faculty of Medicine, Japan, [4]Shimane University School of Medicine, Japan

Purpose: Patients with type 2 diabetes mellitus (T2DM) have an increased risk of vertebral fractures compared to non-T2DM controls independent of bone mineral density (BMD) (JBMR 2009), suggesting that increased bone fragility is caused by poor bone quality. Bone quality consists of bone material properties and bone structural properties. Exacerbation of bone material properties such as accumulation of advanced glycation end-products in bone tissue and aggravation of bone structural properties such as increased porosity of cortical bone are associated with bone fragility in patients with T2DM. However, impact of structure of trabecular bone on bone fragility still remains unclear in these patients. The aim of this study is to investigate whether deteriorated bone microarchitecture estimated by trabecular bone score (TBS) which is a DXA-derived index that focuses on the cancellous architecture is attributed to bone fragility in these patients.

Methods: We compared parameters of bone metabolic markers including TBS and lumbar spine BMD between Japanese T2DM patients with and without vertebral fractures [278 postmenopausal women and 334 men over 50 years old, whose creatinine levels were within normal range].

Results: There was no significant difference in TBS values between the sexes. Multiple regression analysis including independent variables of HbA1c, creatinine, BAP and duration of T2DM showed that TBS values were significantly and positively correlated with lumbar spine BMD and inversely related with age and BMI in both genders (women: $r = 0.44$, $P < 0.04$, $r = -041$, $P < 0.01$, $r = -0.17$, $P < 0.01$; men: $r = 0.50$, $P < 0.01$, $r = -0.31$, $P < 0.01$, $r = -0.28$, $P < 0.01$, respectively). Logistic regression analysis adjusted for age showed no relationship between spine BMD and the presence of vertebral fractures. In contrast, TBS values were significantly associated with vertebral fractures after adjustment for age, BMI, HbA1c, creatinine, phosphate, duration of T2DM and spine BMD [women: odds ratio (OR) 0.67 (95%CI 0.45-0.93), $P = 0.02$; men: OR 0.70 (0.50-0.99), $P = 0.04$, per 0.1 increase in TBS].

Conclusion: This study demonstrated that TBS values were associated with vertebral fractures independent of BMD in both genders. This finding suggested that microarchitectural deterioration of trabecular bone may cause poor bone quality and result in elevated fracture risk in patients with T2DM.

Multi-Row Detector CT Imaging with Image Analysis using an Advanced Tensor Scale Algorithm Provides a Robust Assessment of Trabecular Bone Micro-Architecture for Human Studies. Punam K. Saha*[1], Yinxiao Liu[2], Chadi Calarge[1], Ryan Amelon[2], Cheng Chen[2], Elena Letuchy[2], Trudy Burns[2], James Torner[2], Steven Levy[1]. [1]University of Iowa, USA, [2]University of Iowa, USA

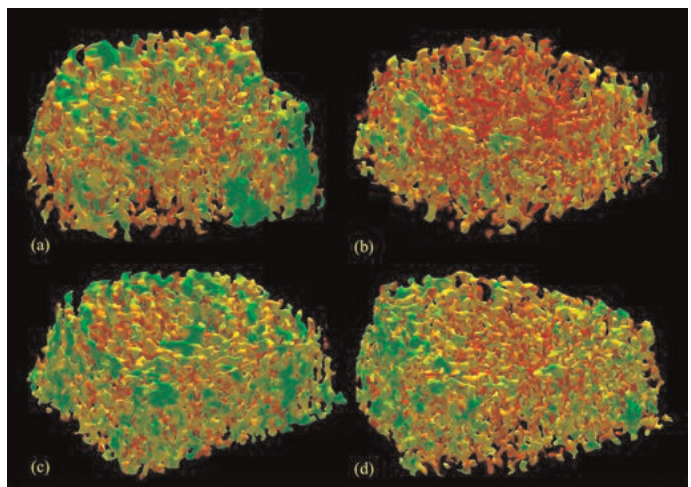
Recent evidence implicates serotonin in bone metabolism and selective serotonin reuptake inhibitors (SSRIs) in bone-loss and increased fracture-risk. Low bone mineral density (BMD) is the hallmark of osteoporosis, a leading cause of low-trauma fracture. However, increasing evidence suggests that the micro-architectural quality of trabecular bone (TB) is an important determinant of bone strength and fracture risk. This makes robust and sensitive measures of TB micro-architecture at *in vivo* resolution of significant interest in early detection and characterization of bone loss. Thus, a tensor scale-based *in vivo* characterization of TB micro-architecture at the distal tibia using multi-row-detector CT (MD-CT) imaging was developed.

Tensor scale provides an optimized ellipsoidal approximation of individual trabeculae, assessing their micro-architecture on the continuum between a perfect plate and a perfect rod, as well as their orientation. Repeat MD-CT scan reproducibility and the sensitivity of the method were examined by evaluating its ability to predict bone strength of cadaveric specimens. Additionally, the method was evaluated in a pilot human study involving healthy young-adult participants from the Iowa Bone Development Study (IBDS) (19 to 21 Y; 51 F, 46 M) and age-similar patients treated with SSRIs (6 F, 6 M).

Observed repeat scan intraclass correlation coefficients were greater than 95% for regional MD-CT TB measures (VOI diameter$\geqslant$1.05mm). Tensor scale-based TB measures demonstrated stronger linear association with bone strength (correlation coefficient $r=0.96$) than did volumetric BMD (vBMD) ($r=0.89$). Results of the pilot human study showed that SSRI-treated participants had 8% (inner region) and 14% (peripheral region) reduced TB plate-width and also 5% (inner) and 4% (peripheral) reductions in tensor scale-measured transverse BMD as compared to healthy controls (Figure 1, Table 1). In contrast, only a 4% reduction in whole body BMD was observed in the SSRI-treated participants, suggesting that DXA is much less sensitive than TB micro-architectural measures.

In vivo MD-CT imaging, together with the advanced algorithm of tensor scale, is suitable for robust assessment of plate-rod micro-architecture and orientation of TB at a peripheral site. Long-term SSRI treatment may be associated with skeletal effects more sensitively captured by MD-CT imaging.

This study was funded by NIH grants: R01-AR054439, R01-DE012101, UL1-RR024979, and UL1-TR044206.



Color-coded illustration of trabecular bone (TB) plate/rod classification for a healthy female IBDS control (a) and a female patient on continuous treatment with a selective serotonin reuptake inhibitor (b). (c,d) A male control and a male SSRI-treated patient. Male and female IBDS participants have more TB plates (colored in green) as compared to the two patients.

Figure 1. Color-coded illustration of trabecular bone (TB) plate/rod classification.

Paired comparisons for selected trabecular bone measures (over an axial VOI covering 4-6% of tibia) computed using MD-CT imaging and tensor scale and the whole body BMD from DXA.

	Matched (min=1, max= 4 controls /1 case)[a]			
	Paired (N=12)		t-test	Wilcoxon
Variable	Diff (μm)[b]	% Diff[b]	p-value	p-value
TB plate-width (peripheral)	-183	-13.6	0.03	0.04
TB plate-width (central)	-92	-8.1	0.15	0.20
Transverse BMD (peripheral)	-17.17	-3.9	0.20	0.15
Transverse BMD (central)	-23.00	-5.2	0.14	0.18
Whole body BMD (DXA)	-0.048	-4.0	0.07	0.08

[a] Matching algorithm with variable number of controls per case subject (1 to 4 controls) was used for optimal matching by sex, height, and weight. Paired t-test and non-parametric Wilcoxon signed ranks test were used for comparison.
[b] Mean value of differences between SSRI participants and average value for matched controls (across all pairs). Percent difference is calculated the same way relative to average value for matched controls.

Non-invasive assessment of longitudinal changes in bone microarchitecture and bone strength over eighteen months in lung transplant recipients using high-resolution peripheral quantitative computed tomography (HR-pQCT). Daniela Kienzl[1], Lukas Fischer[1], Thomas Gross[2], Matthew DiFranco[3], Michael Weber[1], Alexander Valentinitsch[4], Peter Jaksch[1], Walter Klepetko[1], Rodrig Marculescu[5], Peter Pietschmann[6], Claudia Schueller-Weidekamm[1], Franz Kainberger[1], Georg Langs[1], Janina Patsch*[3]. [1]Medical University of Vienna, Austria, [2]Vienna University of Technology, Austria, [3]Medical University of Vienna, Austria, [4]Klinikum rechts der Isar, Technische Universität München, Germany, [5]Medical university of Vienna, Austria, [6]Department of Pathophysiology & Allergy Research, Medical University of Vienna, Austria

With additive effects of pre-existing secondary bone disease and post-transplantion bone loss, lung transplant (LuTX) recipients are highly susceptible to fragility fractures. Using HR-pQCT, we have previously reported cross-sectional data on poor cortical and trabecular microarchitecture and deficits in bone strength in LuTX recipients after surgery [1]. Bearing in mind the particularly high fracture risk in the first year after transplantation, we hypothesized to find significant longitudinal bone loss. To gain insight into structural and biomechanical changes at the ultradistal radius over time, we have thus followed up LuTX recipients (n=18) over eighteen months after surgery. We performed densitometric and morphometric standard HR-pQCT analyses for baseline and follow-up scans. We carried out extended cortical analyses including quantification of cortical porosity, 3D-texture-based clustering of trabecular bone [2] and micro-finite element analyses. Serum markers of bone turnover were analyzed along with clinical data including incident fractures and episodes of graft rejection. Paired t-tests were used to compare mean differences between baseline and follow-up. LuTX patients exhibited significant decreases in total bone mineral density (BMD; -3.1%,p=0.001), trabecular BMD (-2.9%,p=0.027) and cortical BMD (-2.1%,p=0.003). Cortical area decreased (-3.2%,p=0.015) and trabecular area increased (+0.6%,p=0.020). Changes in cortical porosity were not statistically significant (+9.4%,p=0.419). Trabecular heterogeneity (+5.6%,p=0.023) and intermediate trabecular quality cluster size (TMAC2;+7.6%,p=0.015) increased. Vice versa, the size of the trabecular high quality cluster (TMAC1) decreased by 7.1% ($p<0.001$). There were pronounced decreases in stiffness (-6.8%,p=0.004), failure load (-5.9%,p=0.004), and bone strength (-5.2%,p=0.001). Serum osteocalcin and P1NP increased (+254.8%,p=0.006;+123.5%,p=0.001), changes in CTX were not significant (+23.8%,p=0.348). Patients with incident fractures (17%; 3/18) had significantly greater declines in BMD than those without (p=0.034). Densitometric and microarchitectural changes did not differ between patients with (22%; 4/18) and without severe rejection episodes. Our results indicate significant bone loss, declining biomechanical properties, and increasing bone turnover in LuTX recipients in the first eighteen months after surgery.

Systemic and local bone loss in Psoriasis and Psoriatic Arthritis. Roland Kocijan*[1], Matthias Englbrecht[2], Arnd Kleyer[2], Judith Haschka[3], David Simon[2], Stephanie Finzel[2], Sebastian Kraus[2], Christian Muschitz[4], Heinrich Resch[5], Klaus Engelke[6], Juergen Rech[2], Georg Schett[2]. [1]St. Vincent Hospital Vienna, Austria, [2]Department of Internal Medicine 3 & Institute of Clinical Immunology, University of Erlangen-Nurnberg, Germany, [3]University Hospital Erlangen-Nuremberg, Deu, [4]St. Vincent's Hospital, Austria, [5]Medical University Vienna, Austria, [6]University of Erlangen, Germany

Purpose: Psoriatic arthritis (PsA) is a chronic inflammatory joint disorder characterized by local bone loss. However, data on systemic bone loss and bone mineral density (BMD) in PsA as well as in psoriasis are inconsistent. Moreover, data on bone quality are missing. The aim of this study was to evaluate bone microstructure and volumetric bone mineral density (vBMD) in patients with PsA and psoriasis by HR-pQCT (high resolution peripheral quantitative computed tomography).

Methods: HR-pQCT scans were performed at the periarticular and the non-periarticular radius in patients with PsA (n=50), patients with psoriasis without any signs of arthritis (n=30) and healthy, age- and sex-related controls (n=70). We assessed vBMD and parameters of microstructure including trabecular bone volume (BV/TV), trabecular number (Tb.N), inhomogeneity of the trabecular network, cortical thickness (Ct.Th) and cortical porosity (Ct.Po). Moreover, HR-pQCT scans of the metacarpophalangeal joints (MCP) were performed to detect bone erosions.

Results: At the non-periarticular radius trabecular BMD (p=0.009), cortical BMD (p=0.031), BV/TV (p=0.009) and Tb.N (p=0.0013) were significantly decreased in PsA patients compared to healthy controls. In addition, Tb.Sp (p=0.014) and inhomogeneity of the network (p=0.040) were increased in PsA. No differences were found regarding cortical thickness and cortical porosity between the three subgroups.

Similar results were found at the periarticular radius. Patients with psoriasis without arthritis had a bone phenotype comparable to healthy controls. Nonetheless, duration of skin disease was found to be associated to low BV/TV and Tb.N in patients with PsA. Bone erosions were detected in 70% of patients with PsA, 47% of patients with psoriasis and 30% of healthy controls.

Conclusion: Trabecular and cortical vBMD as well as trabecular bone microstructure are decreased in PsA. Our data suggest a skin-bone-axis linked to duration of psoriasis and a pre-PsA status in patients with psoriasis without arthritis. However, systemic bone loss seems to be triggered by additional factors linked to arthritis.

Trabecular Bone Microarchitecture of lumber spine is Deteriorated in Patients with Type 2 Diabetes Mellitus. Kenichiro Matsuzaki*[1], Toshihide Kawai[2], Takeshi Miyamoto[3], Kensuke Mio[4], Hironori Kaneko[5], Keisuke Horiuchi[6], Morio Matsumoto[6], Koichi Nemoto[4]. [1]National Defense Medical College, Japan, [2]Dept. of Internal Medicine, Keio Univ., Japan, [3]Keio University School of Medicine, Japan, [4]Dept. of Orthopaedic Surgery, National Defense Medical College, Japan, [5]Keio University, Japan, [6]Dept. of Orthopaedic Surgery, Keio Univ., Japan

Introduction: Fracture risk is increased in type 2 diabetes mellitus, although areal bone mineral density is elevated. There is a possibility that some aspect of bone quality plays a role here. These include bone turnover, material property such as cross-links of collagen, cortical and trabecular microarchitecture. We investigated the trabecular microarchitecture of lumber spine of patients with type 2 diabetes mellitus (T2DM).

Methods: 33 postmenopausal women with BMD < 80%-YAM with T2DM and 33 control postmenopausal women with BMD < 80%-YAM without T2DM were evaluated in a cross-sectional study. Clinical multi-detector row CT (MDCT) was applied to capture differences in three-dimensional (3D) trabecular bone architecture and cortical or trabecular volumetric density in lumber supine. We measured/calculated 3D trabecular bone architecture parameters. Statistical significance was set at $P<0.05$.

Results: Trabecular and cortical vBMD significantly increased in T2DM patients. On the other hand, BV/TV was lower in T2DM patients significantly compared with control patients. V*tr, which indicates the connectivity of trabecular, was significantly decreased inT2DM compared with control. All other parameters did not reach significance but showed the tendency related to decreased bone strength in T2DM patients. These tendencies were greater at upper part of vertebra than at middle part.

Discussion: It is suggested that deterioration of trabecular bone microarchitecture may be one of the reasons why fracture risk is elevated despite high BMD in T2DM patients.

SU0290

Trabecular bone score (TBS), vitamin d and biochemical measures of bone metabolism in men. Mário Rui Mascarenhas*[1], Ana Paula Barbosa[2], Didier Hans[3], Manuel Bicho[4]. [1]Lisbon's Faculty of Medicine, Santa Maria University Hospital, CHLN,EPE, Portugal, [2]Endocrinology, Santa Maria Hospital & Faculty of Medicine, Portugal, [3]Lausanne University Hospital, Switzerland, [4]Genetic Laboratory, Lisbon's Medical School, Portugal

Despite the use of DXA, biomarkers and fracture clinical risk factors, many older people are at risk for fractures, as the BMD does not provide total info on bone quality; the TBS is a diagnostic tool developed recently and at the moment is used to supplement DXA and may provide information about bone quality; together, TBS and DXA may evidence the strength of bone, which is determined by material composition and configuration. The BMD and vitamin D decline with age. Inadequate vitamin D levels may be associated to the high prevalence of osteoporosis and low vitamin D concentration may be related to an increased falls number and subsequent fragility fractures among older persons. The role of microarchitecture of bone tissue in relation to Vitamin D and PTH is relatively unkown. The TBS (trabecular bone score) may allow to estimate bone microarchitectural texture.

OBJECTIVES: To evaluate the BMD at L1-L4, the TBS at the spine and their associations with some biochemical bone and inflammatory markers and in men and post-menopausal women.

MATERIAL AND METHODS: The BMD (g/cm^2) and the BMC (g) at the L1-L4 in a group of 106 ambulatory men and post-menopausal women of were evaluated by DXA and the spine TBS was derived from each spine DXA scan.

The blood osteocalcin (ng/ml), bone alkaline phosphatase (mcg/l), 25(OH)D_3 (ng/ml), iPTH (pg/ml) and reactive C-protein or RCP (mg/dl) concentrations were measured.

Adequate statistical tests were used.

Results: The means($\pm$SD) obtained in men were: L_1-L_4 TBS= 1.310 ($\pm$0.1), BMC= 68.8 ($\pm$12.8) and BMD= 1.032($\pm$0.2), 25(OH)D3= 22.6($\pm$8.6), iPTH= 52.9($\pm$23.1) and RCP= 0.19 ($\pm$0.17) and the means($\pm$SD) in the post-menopausal women were: the L_1-L_4 TBS= 1.3172($\pm$0.1), L_1-L_4 BMC= 49.0 ($\pm$10.8), BMD= 0.928($\pm$0.2), 25(OH)D3= 20.3($\pm$8.8), iPTH= 57.1($\pm$34.7) and RCP= 0.34 ($\pm$0.47).

The significant correlation coefficients were detected, in men, between the spine TBS and the BMC at L_1-L_4, the osteocalcin, 25(OH) vit. D_3 and the PCR blood levels. In women significant correlation coefficients were observed between the spine TBS and the BMC at L_1-L_4, the 25(OH) vit. D_3 and the PCR blood levels.

CONCLUSIONS: The vitamin D3 may play a role on the bone quality, as normal men and post-menopausal women with low 25(OH)D_3 may have TBS and thus worse bone quality; it is possible that RCP may also act in the bone quality.

Further studies are needed on a larger cohort and it might be worth to investigate also patients with osteomalacia.

SU0291

Comparison between normative spine TBS data for men and women: LAVOS Mexican Cohort. Patricia Clark*[1], Renaud Winzenrieth[2], Margarita Deleze[3], Fidencio Cons-Molina[4], Jorge Morales[5], Didier Hans[6], Bruno Muzzi Camargos[7]. [1]Hospital Infantil Federico Gomez-Facultad de Medicina UNAM, Mexico, [2]Med-imaps, Hôpital X. Arnozan, PTIB, Pessac, France, France, [3]Hospital Angeles Puebla, Mexico, [4]Centro de Investigacion en Artritis y Osteoporosis, Mexico, [5]Hospital Aranda de la Parra, Mexico, [6]Lausanne University Hospital, Switzerland, [7]Densimater Hospital Mater Dei, Brazil

Introduction: Analyzing the Mexican site of the LAVOS Cohort and the mexican men vertebral fracture study, we have investigated the difference between age related changes of the lumbar vertebrae micro-architecture in women and men assessed by TBS.Methods: Subjects in the study were Mexican women and men (LAVOS, Mexican centers) aged 50 and older with a BMD Z-score at spine L1-L4 within $\pm$ 2SD. Individuals were excluded if they had fractures or were on any osteoporosis treatment and/or had any illness that would be expected to impact bone metabolism. All data have been obtained from Prodigy DXA devices (GE-Lunar, Madison, WI, USA). BMD and TBS (TBS insight v2.1, Med-Imaps, France) were evaluated at spine L1-L4.

Results: A database of 370 men and 339 women ages 50 to 90 years was created. TBS value at L1-L4 was not correlated with BMI r=0.05 and r=0.06 in women and men respectively. TBS values obtained for at lumbar spine decreased significantly with age (see figure below at L1L4) in both gender. There was a linear decline of 17% (-2.7 SD) and of 7.9% (-1SD) in the micro-architectural texture at L1-L4 between 45 and 90 years of age in women and men respectively. Similar results were obtained for other ROIs of the lumbar spine.

Conclusion: A TBS bone microarchitectural texture impairement with ageing has been observed in both women and men. As expected, TBS decrease is more marked in women than in men to reach -1.7 SD difference at 90 years old. Results in women are consistent with previously published data.

Glucocorticoid-induced osteoporosis in patients with pulmonary diseases, 4-year observation of treatment compliance. Vaclav Vyskocil*[1], Monika Honnerova[2]. [1]Center for Metabolic Bone Diseases, Czech Republic, [2]Metabolic Bone Disease Center, Czech Republic

Authors observed the group of 207 patients treated by oral corticoids indicated for pulmonary diseases within the period of last 5 years. Authors retrospectively evaluated the rate of patients where DEXA measurement was performed before corticoid therapy and who were supplemented by either calcium plus vitamin D or treated with bisphosphonates (oral as well as i.v.)

115 pateints (75 women and 40 men) out of the study group of 207 were observed further in the 5 year period. 40 patients died (24 women and 16 men) and 48 patients (28 women and 20 men) did not come back for examination after corticoid therapy cessation. This group of patients (115) who were exposed to corticoids for the whole study period was split based on corticoid equivalent $>$ 7,5 mg Prednison and $<$ 7,5 mg daily. BMD increased in patients with lower dose by 3,25% (female); 2,3 % (male) in spine and changed by -0,72% (female); +0,51 (male) in femur in comparison with higher dose group where change of BMD was 0,57% (female); 1,75% (male) in spine and decrease 0,38%(female); 0,62 % (male) in femur.

Authors discus the reason of low treatment compliance of pneumology patients as well.

Subject Position on Accuracy of Vertebral Measurement. Bo Fan*[1], Meng Lian[2], Cassidy Powers[2], Neda Sarafrazi Isfahani[3], Mita Patel[4], John Shepherd[1]. [1]University of California, San Francisco, USA, [2]University of California San Francisco, USA, [3]Nutritional Epidemiologist National Health & Nutrition Examination Survey National Center for Health Statistics Centers for Disease Control & Prevention, USA, [4]Westat, USA

Background: Advanced vertebral morphometry is an attempt to describe the projected shape of the vertebral body using many peripheral points (i.e. $>$ 14). Vertebral shape can be assessed on lateral views of dual-energy X-ray absorptiometry (DXA) scans, either by using a rotating arm (Hologic QDR 4500 A, QDR Delphi) or by placing the patient on their side (Lunar Prodigy, Hologic Discovery W). Because all of these are fan beam systems, the inaccurate position of the subject may result in image amplification and geometric distortion.

Purpose: To investigate effect of subject's position on vertebra morphometric shape measurements.

Methods: Using the Hologic spine phantom, we tested three different positions: normal (at center of scanner table), 5 cm away from table edge of technologist (Away) and 5 cm toward the table edge of technologist (Toward). The same scanning protocol was used for the phantom scans as is used participant scans. The individual vertebra's posterior height, mid height, anterior height, superior depth and inferior depth were measured using Optasia SpinalAnalyer software. Multiple tests with bonferroni adjustments were used to test the measurement difference between three different phantom positions.

Results: Five scans in normal position and 3 scans in each of off centered position were acquired on the same DXA scanner at an NHANES examination center. The vertebra height differences between the normal and off center scans were not consistent across the individual vertebrae. Differences ranged from 0.03 (0.05%) to 1.52 (2.28%) mm (Table 1). However, the superior and inferior depth differences were consistent across individual vertebrae and between normal to off centered scans (Table 1, Figure 1, 2). The average difference was 1mm/per cm change of position from Toward to Away. The difference could be up to 8.5%.

Discussion and Conclusion: DXA equipment allows quantitative morphometric vertebral analysis with very low exposure to ionizing radiation. However, our study results show that careful positioning of the subject is a must. Otherwise, the accuracy of the measurement will be reduced.

Table 1: The absolute and percent difference between the Normal, 5cm Away and 5cm Toward.

Position/Measures	Difference (mm) (% difference)			
Normal to Away	**L1**	**L2**	**L3**	**L4**

A Comparison of Trabecular Bone Microarchitecture as Determined by Quantitative MRI in Caucasian versus Asian American Young Adults at Peak Bone Mass. Albert Shieh*[1], Jacqueline Hollada[2], Edgar Rios Piedra[2], Ameer Elbuluk[2], Alex Bui[2], John Adams[1]. [1]University of California, Los Angeles, USA, [2]University of California, Los Angeles, USA

Purpose: Trabecular microarchitecture is not well characterized in young adults at peak bone mass. The primary aim of this study was to use quantitative MRI to characterize and compare trabecular microarchitecture in Caucasian (CA) versus Asian American (AA) young adults. The secondary aim was to determine the effects of correcting vitamin D deficiency on trabecular microarchitecture.

Methods: Healthy CA and AA female and male subjects between 21 and 30 years of age were recruited. Baseline evaluation included: 1) collection of demographic and anthropomorphic data [age, gender, BMI], 2) serum biochemical evaluation [metabolic panel, 25-hydroxyvitamin D (25D), immunoactive parathyroid hormone (iPTH)], and 3) trabecular microarchitecture evaluation by calcaneal MRI [apparent bone volume/total volume (app.BV/TV), trabecular thickness (app.Tb.Th, mm) and trabecular separation (app.Tb.Sp, mm)]. Subjects with baseline 25D levels <20 ng/mL received 500,000 IU of vitamin D3 over 10 weeks, after which calcaneal MRI was repeated.

Results: Trabecular microarchitecture was not significantly different between 17 CA versus 17 AA subjects with 25D levels >20 ng/mL matched by age, gender, and BMI [structural parameter: mean (SD) (CA) vs. mean (SD) (AA), p-value; app.BV/TV: 0.479 (0.037) vs. 0.478 (0.034), p=0.534; app.Tb.Th (mm): 1.304 (0.271) vs. 1.237 (0.132), p=0.368; app.Tb.Sp (mm): 1.247 (0.267) vs. 1.189 (0.184), p=0.467]. Five AA subjects had baseline 25D levels <20 ng/mL [25D: 16.2 (2.3) ng/mL; iPTH: 39.8 (16.5) pg/ml]. 25D increased to 34.4 (3.8) ng/mL following vitamin D repletion. Trabecular microarchitecture at follow-up was not significantly different than that at baseline [structural parameter: mean (SD) (follow-up) vs. mean (SD) (baseline), p-value; app.BV/TV: 0.479 (0.047) vs. 0.468 (0.069), p=0.775; app.Tb.Th: 1.417 (0.276) vs. 1.369 (0.337) mm, p=0.812; app.Tb.Sp: 1.191 (0.236) vs. 1.237 (0.301), p=0.796]. Neither baseline 25D nor iPTH levels were significant predictors of percent change in trabecular structural parameters.

Conclusions: Trabecular microarchitecture as assessed by quantitative MRI was not significantly different between CA and AA subjects with 25D levels >20 ng/mL; this may help explain why AA women do not fracture more than CA women despite having lower areal bone mineral density. Correction of vitamin D deficiency did not elicit, in the short term, a change in trabecular microarchitecture in AA subjects with baseline 25D levels <20 ng/mL.

A New Method for Peripheral 3D QCT of the Distal Forearm using Clinical Whole Body CT Scanners: Preliminary Results. Bastian Gerner*[1], Dominique Töpfer[1], Oleg Museyko[1], Alexander Mühlberg[1], Wolfgang Kemmler[1], Klaus Engelke[2]. [1]University of Erlangen, Germany, [2]University of Erlangen, Germany

Introduction: For peripheral QCT typically dedicated scanners are used. However, scan times of the XtremeCT (Scanco Medical AG, Switzerland) are long and with the XCT2000 device (Stratec Medizintechnik GmbH, Germany) single slices can be acquired, only. In contrast, with clinical whole-body CT scanners, which are widely available, a scan of both distal forearms with a length of 10 to 20 cm covering the trabecular rich ultra distal region to the mid region containing pure cortical bone can be acquired in seconds. Here we developed a new 3D analysis approach based on the MIAF (Medical Image Analysis Framework, University of Erlangen) concept using 3D segmentation, anatomic coordinate systems (ACS) and an automatic placement of analysis volumes of interest (VOIs). The VOIs are adapted to the individual anatomy of the radius, for determining integral, cortical and trabecular BMD, BMC and volume as well as cortical thickness.

Material und Methods: CT datasets of both distal forearms of 16 professional male climbers (26 ± 5 years) were scanned on a SIEMENS VolumeZoom (80 kV, 122 mAs, 24 cm FOV, 15 cm scan length, 1.0 mm slice thickness, convolution kernel B60s). The Siemens Osteo Phantom was used for BMD calibration. Endosteal and periosteal surfaces of radius and ulna were segmented for both arms using a multi step local adaptive thresholding procedure. The ACS of the radius is determined as follows: (1) In each CT slice the center of mass (CM) of the radius is determined. (2) A center curve (CC) is fitted to the CMs. (3) A plane perpendicular to the CC is moved from proximal to distal direction. (4) A distinct increase in area marking the transition into the tapered part of the distal radius together with the CC is used to define the ACS origin.

Results: The figure shows periosteal and endosteal segmentation of radius and ulna along with the 4 VOIs (ultra-distal, distal, mid and proximal) defined relative to the ACS. The table shows mean BMD and BMC values for various bone compartments of the 16 subjects along with inter-operator analysis precision results (3 operators).

Discussion: A new 3D QCT analysis program for the distal forearm was developed that specifically exploits the advantages of clinical whole-body CT scanners and can be used to determine integral cortical and trabecular BMD at any position along the radius or ulna (data not shown) included in the scan. Preliminary findings show good results for inter-operator analysis precision.

Bindex® Technology for Osteoporosis Diagnostics in US Primary Care. Janne Karjalainen*[1], Ossi Riekkinen[2], John Schousboe[3]. [1]Bone Index Finland Ltd., Finland, [2]Bone Index Finland, Ltd., Finland, [3]Park Nicollet ClinicUniversity of Minnesota, USA

Currently, majority of the osteoporotic patients are not diagnosed (1). A new ultrasound based point of care device (Bindex®) has been recently introduced for osteoporosis (OP) screening and diagnostics at primary healthcare (2). Bindex measures cortical thickness and determines parameter called density index (DI). Thresholds for DI (90% sensitivity and specificity for OP) in OP assessment have been determined in Finnish Caucasian population (n= 448) along the International Society of Clinical Densitometry (ISCD) guidelines (3). In this study, these thresholds are tested in American-Caucasian population.

Elderly American-Caucasian females under osteoporosis suspicion were examined (n = 430, age = 67.7 $\pm$ 9.7 years). Subjects were measured with dual energy x-ray absorptiometry (DXA) to determine bone mineral density (BMD) at proximal femur. Further, the cortical thickness was measured at three locations (distal radius, distal and proximal tibia) with Bindex®. Subjects were diagnosed with OP when T-score at femoral neck or total proximal femur was below -2.5 (NHANES III reference database). Density index was calculated either by using measurement at one location (DI_1, proximal tibia) or all three locations (DI_3). By using the diagnostic thresholds, subjects were classified as healthy, osteoporotic or in need of DXA examination to verify diagnosis.

A total of 69.0% and 71.6% of the subjects could be directly diagnosed by using Bindex® measurement, with DI_1 and DI_3, respectively. Both parameters showed significant linear correlation with total proximal femur BMD (r = 0.60 - 0.65, $p <$ 0.001). Sensitivity in OP diagnostics was 81.4% and 84.3% for DI_1 and DI_3, respectively. Specificity was 86.4% and 84.0% for DI_1 and DI_3, respectively. Positive predictive values were 81.9% and 80.0% and negative predictive values were 86.1% and 88.1% for DI_1 and DI_3, respectively. OP was diagnosed in 185 subjects in total. Average reproducibility of 2.0% in DI_3 was observed with two ultrasound operators.

The correlation between BMD and DI was similar than previously observed. These results suggest that Finnish-Caucasian thresholds may be applicable for American-Caucasian population. The use of triage approach and the pocket size technology with no ionizing radiation the treatment of OP would significantly increase.

Can identification of vertebral fractures on lateral spine x-rays be improved by workflow software?. Jeri Nieves*[1], Peter Steiger[2], Patricia Garrett[3], Marsha Zion[3], Robert Lindsay[4], Felicia Cosman[4]. [1]Columbia University & Helen Hayes Hospital, USA, [2]Paroxel, United Kingdom, [3]Helen Hayes Hospital, USA, [4]Helen Hayes Hospital, USA

Background: Both the number and severity of vertebral fractures predict the risk of future fractures. Therefore, their identification is key to comprehensive risk assessment and development of an appropriate treatment plan. Objective: The purpose of this study was to evaluate the consistency of reporting of a dedicated vertebral fracture workflow tool that measures vertebral deformity and directs the reader to record location, type and severity of vertebral fractures (SpineAnalyzer, Optasia Medical Ltd.), compared to clinical radiology reports. Methods: 49 postmenopausal women with osteoporosis were evaluated on 2 or 3 different occasions, resulting in 123 pairs of lateral lumbar and thoracic x-rays. All x-rays were read by a physician (FC) using SpineAnalyzer and compared to the clinical radiology reports. Results: Overall, there was excellent agreement with a kappa of 0.74 in thoracic region (32 fractures by radiologist / 30 by SpineAnalyzer) and a kappa of 1.00 in the lumbar region (22/22). Severity was frequently not noted by the radiologist (31% thoracic / 8% lumbar), while where severity was noted by both approaches, SpineAnalyzer tended to grade fracture more severely (17%/33%) than vice-versa (3%/5%). Longitudinal consistency of fracture evaluation was better by SpineAnalyzer than by radiology reading. In one case the radiologist noted several lower thoracic mild compressions of 3 adjacent vertebrae that were followed by a reading of "no compression fractures" two years later. In this patient no fractures were identified using SpineAnalyzer at either time. In another case, the radiologist noted no fracture in the first x-ray and then a fracture at T10 two years later. Again SpineAnalyzer found that neither of the x-rays had evidence of a fracture. The fractures found by SpineAnalyzer, but not by the radiologist, included a mild wedge at T7 and a mild biconcave at T10. Conclusion: We found that the workflow discipline imposed by using SpineAnalyzer and the clarity of the resulting report helps consistently quantify number and severity of vertebral fractures, thereby improving risk assessment and treatment of patients with osteoporosis.

Clinical Ultrasonic Bone Assessment of the 1/3 Radius. Emily Stein*[1], Fernando Rosete[2], Gangming Luo[3], Mariana Bucovsky[2], Jonathan Kaufman[4], Elizabeth Shane[1], Robert Siffert[5]. [1]Columbia University College of Physicians & Surgeons, USA, [2]Columbia University College of Physicians & Surgeons, USA, [3]CyberLogic, Inc., USA, [4]CyberLogic, Inc., USA, [5]The Mount Sinai School of Medicine, USA

The objective of this study was to evaluate a new clinical ultrasound device (*UltraScan 650*, CyberLogic, Inc., NY, USA, Fig. 1) in terms of its ability to estimate BMD at the 1/3 radius (1/3R), as well as to investigate its ability to discriminate fracture and non-fracture cases. The device (Fig. 1) rests on a desktop and is portable, and permits real-time evaluation of the radial bone mineral density (BMD). The device measures in thru-transmission two (2) net time delay (NTD) parameters, NTD_{DW} and NTD_{CW}. NTD_{DW} is defined as the difference between the transit time of an ultrasound pulse through soft-tissue, cortex and medullary cavity, and the transit time through soft tissue only of equal overall distance. NTD_{CW} is defined as the difference between the transit time of an ultrasound pulse through soft-tissue and cortex only, and the transit time through soft tissue only, again of equal overall distance. The square root of the product of these two parameters is a measure of the BMD at the 1/3R as would be measured by DXA. A clinical IRB-approved study was carried out in which 77 adults (age range 21-83, 75% female) were measured at the 1/3R using ultrasound and DXA (range = 0.45-0.92 g/cm^2). An age and sex-matched subset (28 fracture cases and 16 controls) of these subjects was used to determine the capability of DXA and ultrasound to discriminate between fracture and non-fracture cases. A linear regression showed that $BMD_{US}{}^{TM} = 0.19 * \{NTD_{DW} * NTD_{CW}\}^{1/2} + 0.28$ and that the linear correlation between BMD_{US} and BMD_{DXA} was 0.93 ($P<0.001$, Fig. 2). We found that forearm ultrasound measurements yield results that are very closely associated with those from DXA. These results are consistent with previous computer simulation and *in vitro* studies, in terms of the ability to estimate radial bone mass. In the case-control cross-sectional fracture study, we found a small decrease in mean BMD_{DXA} (1/3R) for the fracture cases (P=0.20) but a somewhat greater decrease in mean BMD_{US} (P=0.05). This latter result raises the possibility that BMD_{US} may contain additional information on fracture risk. In conclusion, although x-ray methods can estimate BMD, osteoporosis remains one of the world's most undiagnosed diseases. This research should enable significant expansion of the identification of bone loss as occurs in osteoporosis using an ultrasonic desktop device that can serve as a proxy for BMD_{DXA} at the 1/3R and may ultimately provide further data on fracture risk as well.

Diagnostic performance for identifying osteoporotic postmenopausal women without prevalent fractures by dental panoramic radiographs. Akira Taguchi*[1], Noriyuki Sugino[2], Shinichiro Yamada[2], Yae Iwamoto[2], Keiichi Uchida[2], Mikio Kamimura[3]. [1]Matsumoto Dental University, Japan, [2]Matsumoto Dental University, Japan, [3]Center of Osteoporosis & Spinal Disorders, Japan

Purpose: Cortical shape and trabecular pattern of the mandible on dental panoramic radiographs (DPRs) may be useful indices for identifying asymptomatic postmenopausal women with osteoporosis. The aim of this study was to clarify the diagnostic performance in identifying postmenopausal women, who visited medical practitioners and was diagnosed as osteoporosis without prevalent fractures, by DPRs.

Methods: Of 739 women age ⩾ 50 years who visited our hospital and underwent DPRs, 250 women participated in this study with informed consent. A structured questionnaire including a history of several diseases, lifestyle, and food consumption was mailed to all subjects. The ethics committee reviewed and approved the study protocol. Cortical shape was categorized as normal, moderately eroded, or severely eroded. The trabecular pattern was categorized as sparse, mixed, or dense. An experienced oral radiologist evaluated them. Since observer agreements for cortical shape were good in many previous studies, 3 oral radiologists assessed trabecular pattern on 30 DPRs twice with 1 week interval to calculate observer agreements by weighted Kappa. Logistic regression analysis adjusted for covariates was used to calculate the odds ratios for identifying subjects who had osteoporosis without prevalent fractures, compared to normal cortex and dense trabecular pattern. Diagnostic performances were calculated for both DPR measures when normal cortex and mixed/dense trabeculations were considered normal.

Results: Thirty-three (13.2%) had osteoporosis without prevalent fractures. Mean intra- and inter-observer agreement for trabeculation was 0.74 and 0.063, respectively. The odds ratio for identifying subjects associated with moderately and severely eroded cortices was 1.98 (95% CI, 0.59 to 6.66) and 7.85 (95% CI, 2.41 to 25.5). That for identifying subjects associated with mixed and sparse trabeculations was 1.75 (95% CI, 0.63 to 4.87) and 0.54 (95% CI, 0.19 to 1.59). Positive and negative likelihood ratios were 1.42 (95% CI, 1.15 to 1.59) and 0.32 (95% CI, 0.12 to 0.73) for cortical shape and 1.57 (95% CI, 1.01 to 2.23) and 0.75 (95% CI, 0.51 to 1.00) for trabeculation.

Conclusions: There was no significant difference in diagnostic performance between cortical shape and trabeculation. However, inter-observer agreement for trabeculation suggests that this may not be used for identifying women who will visit medical practitioners and be diagnosed as osteoporosis.

SU0300

QCT as a problem-solving diagnostic tool for individuals other than post-menopausal Caucasian females. Bruno Camargos*[1], Marlon de Faria[2], Renata Diniz[2], Alan Brett[3], Keenan Brown[4]. [1]Hospital Mater Dei, Brazil, [2]Hospital Mater Dei, Brazil, [3]Mindways Software, Inc., USA, [4]Mindways Software, USA

Introduction: Compared to DXA, QCT has a number of advantages including true volumetric measurements that have no bone size dependency, less susceptibility to degenerative spine changes and higher sensitivity to changes in bone mass. Disadvantages include the higher radiation doses and less experience with fracture prediction and therapy monitoring. QCT may be utilized in situations where the availability of DXA is restricted and it is not infrequently used as a problem solving technique for a number of clinical indications.

Methods: A male, Caucasian, 42 yo, 170cm height, 106.9kg weight, complained of back pain. No evidence of fractures on MRI, CT or plain X-Ray screening. History of high trauma fractures (car accident and sports): clavicles, left tibia, ribs, fingers. No clinical fracture risk issues other than central obesity. No surgeries. No family history of fragility fractures. Biochemical screening included liver, renal and thyroid, cortisol, testosterone, 24h urine calcium, serum minerals (Pi, Mg, Na, Ca, Cl), vitamin D > 35 ng/mL, CBC and others. All of them were normal. DXA performed on a LUNAR Prodigy Advance (GE, Madison, WI) showed L1-L4 BMD 0.904 g/cm^2 with T-score and Z-score of -2.6 (both); Femoral Neck BMD 1.075 g/cm^2 T-score = 0.0 and Z-score = -0.1; Total Femur 1.065 g/cm^2 T-score = -0.3 and Z-score = -0.5; Left forearm 33% Radius 0.791 g/cm^2 T-score = -0.2 and Z-score = -0.2. QCT at L1-L2 was then performed using QCT Pro 5.1 (Mindways, Austin, TX) according to manufacturer's instructions.

Results: QCT results showed no signal of low bone density (vBMD = 128.0 g/cm^3), despite low T and Z-scores at lumbar spine by DXA. The QCT results show better correlation to forearm and femur DXA results.

Discussion: DXA results may be influenced by excessive overlying soft tissue. This may cause high soft tissue attenuation values compromising the bone results. Male obese patients may be specifically more affected than normal weight female patients who comprised the majority part of the normal DXA reference curves available on DXA devices' software. It may act as a background "noise" and cause an abnormal low bone density reading at the involved region.Conclusion: QCT is helpful on selecting individual patients, other than female Caucasian subjects, whose lumbar DXA might be influenced by adipose and soft tissue concentration at this site. Further research is needed to determine what DXA patients should be considered for a QCT evaluation.

Self-directed Training for Recognition of Vertebral Fractures. Sharon Chou*[1], Jessica Hwang[2], Peter Steiger[3], Tamara Vokes[1]. [1]University of Chicago, USA, [2]University of Chicago, USA, [3]PAREXEL International, USA

Although vertebral fractures (VFx) are common and associated with increased mortality and morbidity[1], only 1/3 of vertebral fractures are clinically recognized[2]. Chest x-rays are frequently performed for other indications, but as few as 18% of VFx on x-rays are mentioned in the radiology report[3,4]. Increased recognition of VFx by disciplines such as Endocrinology would improve the diagnosis and care of osteoporosis. We assessed the effect of self-directed training in VFx recognition. The training included a web-based, self-study of VFx (www.iofbonehealth.org/vertebral-fracture-teaching-program), a 60-minute lecture summarizing key points, and a demonstration of SpineAnalyzer™, a commercially available software application that generates multi-point outlines of vertebral bodies. The training did not stress the controversy of equivocal VFx (e.g. short vertebral height versus mild morphometric fracture). Two Endocrinology fellows completed the training. Fellow A is a third-year fellow familiar with VFx diagnosis. Fellow B is a second-year fellow who has not had prior training. Both fellows evaluated the same 55 images (45 chest x-rays, 10 spine x-rays) twice in random order before and after training. Among these 55 images, 26 had clear VFx, 14 had no VFx, and 15 had equivocal VFx. The first reading of each image was compared before and after training using area under the receiver operator curves. Intra- and inter-rater reliability were assessed by percent agreement and Cohen's kappa statistic. Both fellows had similar intra-rater reliability for pre-training and post-training. Training showed a trend for improvement in the recognition of clear VFx for Fellow B (p=0.13), and concordance between Fellow A and Fellow B improved from 80% (?=0.56) to 93% (?=0.83). Thus, this training program tended to improve the inexperienced fellow's ability to recognize VFx. Our findings suggest that self-directed learning tools can be used to teach VFx recognition and ultimately improve the quality of the osteoporosis care. However, additional instruction regarding the classification of equivocal VFx should be included in the training.

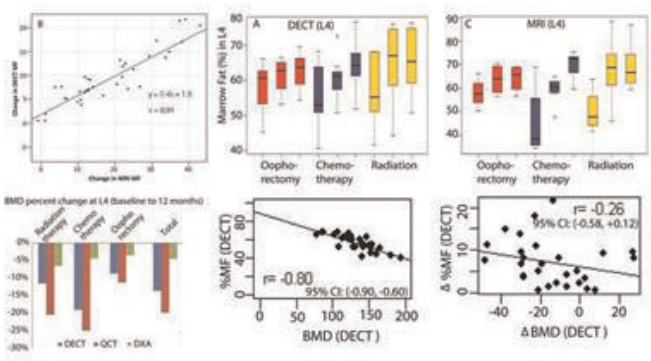
Why we should think differently about cancer survivors'bone health - multi-modality imaging reveals gradual decreased bone mineral density but rapid and heterogeneous expansion of marrow fat from cancer therapy. Susanta Hui*[1], Luke Arentsen[2], Keenan Brown[3], patrick Bolan[2], Rahel Ghebre[2], Levi Downs[2], Ryan Shanley[2], Karen Hansen[4], Anne Minenko[2], Yutaka Takahashi[2], Masashi Yagi[2], Yan Zhang[5], Sharon Allen[1], Bruno Beomonte Zobel[6], Chap Le[2], Jerry Froelich[2], Clifford Rosen[7], Douglas Yee[8]. [1]University of Minnesota, USA, [2]University of Minnesota, USA, [3]Mindways Software, USA, [4]University of Wisconsin, USA, [5]Medtronic, USA, [6]Campus Bio-Medico University, Italy, [7]Maine Medical Center, USA, [8]University of Minnesota, USA

Cancer survivors have a high risk of fractures, but the effect of cancer treatments on marrow fat (MF) and bone mineral density (BMD) are poorly understood. The purpose is to develop multimodality imaging for quantitative monitoring of bone and marrow damage and repair over time. We used dual energy CT (DECT), water-fat MRI (WF-MRI), quantitative CT (QCT) and DXA to measure one-year changes in MF and BMD associated with three cancer treatments: oophorectomy, radiotherapy or chemotherapy. We also measured changes in circulating adiponectin levels. Twenty-nine patients with gynecologic malignancies underwent DECT and DXA at 0, 6 and 12 months after initial treatment; 15 were also imaged by WF-MRI. BMD and MF percent and distribution were quantified in lumbar vertebrae (L3, L4, and L5) and the right femoral neck (FN). We observed a high overall correlation (r = 0.77, 95% CI: 0.69, 0.83) between DECT and WF-MRI based MF quantification at L3, L4, and L5 for 15 subjects (Figure A) with r = 0.80 (95% CI: 0.65, 0.89) at baseline; r = 0.68 (95% CI: 0.47, 0.81) at 6 months; r = 0.66 (95% CI: 0.44, 0.80) at 12 months. Likewise, changes in MF from 0 to 12 months were highly correlated by both imaging methods (r = 0.91, 95% CI: 0.84, 0.95). MF increased significantly from 0 to 12 months ($p<0.002$ at L3, L4, L5, and FN). All three treatments increased MF ($p<0.032$), but chemotherapy and radiation caused greater increases than oophorectomy (Figure B &C). L4 BMD measured by DECT decreased the most after chemotherapy (p=0.01), followed by radiation (p=0.09) and oophorectomy (p=0.24). L4 BMD decreased 14% by DECT, 20% by QCT, but only by 5% by DXA ($p<0.002$ for all) (Figure D). At baseline, we observed a statistically significant, inverse association between MF and BMD. By contrast, at 12 months the inverse association between MF and BMD was dramatically attenuated (Figure E &F). Adiponectin increased from 0 to 12 months without changes in total body fat. Our study demonstrated rapid increases in MF following radiotherapy and chemotherapy. Additionally, DECT detected much greater changes in BMD than did conventional DXA. Our results suggest that, contrary to the general population, MF and BMD cannot be used interchangeably to monitor skeletal health following cancer therapy. Longitudinal studies in larger population are needed to determine if increases in MF and adiponectin are associated with long-term sustained bone damage and ultimate ability to predict fracture risk.



Rapid marrow and bone damage

Association between polymorphisms of the tissue non-specific alkaline phosphatase gene with serum alkaline phosphatase and fragility fractures in Italian population. Laura Masi*[1], Gigliola Leoncini[2], Francesco Franceschelli[3], Maria Luisa Brandi[4]. [1]University of Florence, Italy, [2]Department of Surgery & Translational Medicine, University Hospital of Florence, Italy, [3]Department of Surgery & Translational Medicine, University Hospital of Florence, Italy, [4]DIRETTORE MALATTIE DEL METABOLISMO MINERALE E OSSEOAZIENDA OSPEDALIERA UNIVERS, Italy

The process of bio mineralization that occurs in bone tissue takes place throughout an individual's life. Complex biological systems carefully orchestrating the crosstalk between skeletal tissue and modulator of mineralization. The physiological role of Alkaline Phosphatase (ALP) is not fully understood, and a useful model is provided by the rare genetic disease hypophosphatasia (HPP), an inherited disorder characterized by a defect in skeletal mineralization caused by Tissue Non Specific ALP (TNSALP) deficiency due to TNSALP gene mutations. It is highly variable in its clinical presentation and patients with the adult form present with osteomalacia, chondrocalcinosis, non-healing fractures, and premature tooth loss. Bone mineral density is often osteopenic, and the disease is misclassified as primary osteoporosis. In the present study, the clinical records of a population of 2850 patients referring to the Bone and Mineral Diseases Unit at the University of Florence Hospital is revisiting in order to mark subjects with low serum ALP before any osteoporotic treatment, with history of non-healing fractures, with metatarsal fractures, premature tooth loss, periodontal diseases Additional clinical symptoms: fatigue, chronic pain, nephrocalcinosis, hypercalciuria. As the osteoporosis patients referred to our Unit undergo blood withdrawal to be stored for genetic analysis when informed consent is obtained. TNSALP gene was evaluated. Of the populations we have so far analyzed 276 subjects with a mean age 62,3 yrs. (min 21 and max 82 yrs.). The biochemical investigations of these patients showed serum and urine calcium and phosphate in the normal range. The levels of serum vitamin D (25 OH D3) were below the optimal range (mean: 15.6 $\pm$ 6.1 ng /ml, n.v. 30-70). The mean value of Total and Bone Alkaline Phosphatase before to start any osteoporotic fracture were in the normal range (54$\pm$6 IU/L n.v.: 50-126 IU/L and 12$\pm$4 mcg/l n.v: 4-22.5 mcg/L). Bone resorption markers were in the normal range. BMD measured at the lumbar spine and femoral neck by DXA showed an osteopenia or osteoporosis. From the fracture's history we observed 12 women with metatarsal , 18 with wrist, 69 with spine and 5 with ''other '' fractures. The results of the genetic analysis showed the presence of a variant in exon 5 codon 152 (CGC > CAC , Arg > His) in heterozygosity in 16 patients , a variant of exon 9, codon 292; (CCA > GCC; Pro > Pro) in 2 patients , an intronic deletion IVS5 +14 ex 5 in 81 patients. Applying Anova analysis we found that patients with intronic deletion and exon 5 polymorphisms had a significantly lower Total and Bone Alkaline Phosphatase (45 vs. 59 IU/L and 6 vs.12 mcg/L respectively). These preliminary data, open up to the possibility that polymorphic variants of the ALP gene may be associated with a low BMD with a tendency to spontaneous fractures and insufficient response to drugs used to date in the treatment of osteoporosis.

Association of *C6orf97* and *ESR1* region with Bone mineral density in postmenopausal Mexican women. Alma Parra-Torres[1], Humberto García-Ortiz[2], Manuel Castillejos-López[3], Rogelio Jiménez-Ortega[4], Nelly Patiño[5], Quiterio Manuel[6], Lorena Orozco[7], Jorge Salmerón[8], Rafael Velazquez-Cruz*[4]. [1]Laboratorio Genómica del Metabolismo Óseo, Instituto Nacional de Medicina Genómica, Mexico, [2]Laboratorio de Inmunogenómica y Enfermedades Metabólicas, Instituto Nacional de Medicina Genómica, Mexico, [3]Unidad de Vigilancia Epidemiológica Hospitalaria, Instituto Nacional de Enfermedades Respiratorias, Mexico, [4]Laboratorio de Genómica del Metabolismo Óseo, Instituto Nacional de Medicina Genómica, Mexico, [5]Subdirección de Desarollo de Aplicaciones Clínicas, Instituto Nacional de Medicina Genómica, Mexico, [6]Centro de Investigación en Salud Poblacional,Instituto Nacional de Salud Pública, Mexico, [7]Laboratorio de Inmunogenómica y Enfermedades Metabolicas, Instituto Nacional de Medicina Genómica, Mexico, [8]Unidad de Investigación Epidemiológica y en Servicios de Salud, Instituto Mexicano del Seguro Social, Mexico

Mexican population is admixed with a complex genetic structure including genes of Native American, European and a small percentage of African ancestries. Osteoporosis, a disease characterized by low bone mineral density (BMD), is a common health problem in Mexican population. To date, few genes affecting BMD variation in the Mexican population have been identified. The aim of this study was to investigate the possible association of single-nucleotide polymorphisms (SNPs) of *C6orf97* and *ESR1* region with BMD variation in postmenopausal Mexican-Mestizo women. Four hundred unrelated postmenopausal women were included in the study. Risk factors were recorded and BMD was measured in total hip, femoral neck and lumbar spine using dual-energy X-ray absorptiometry. Seven SNPs in *C6orf97* (rs9479055, rs7753676, rs4870044, rs712219, rs851993, rs3020331 and rs851982) and four in *ESR1* genes (rs1999805, rs2504063, rs3020404, and rs2228480) were studied. Real time PCR and TaqMan probes were used for genotyping. The pattern of association and linkage disequilibrium data in this region is very similar to previously observed in European population, suggesting four LD blocks. Each LD block was associated with total hip and/or neck femoral. Linear regression analyses adjusted by age, body mass index, blood glucose levels and ancestry showed that five SNPs were significantly associated with BMD: rs9479055, rs7753676, rs4870044, rs3020331, rs2504063 in the *C6orf97* gene ($p<0.0004$). In addition, rs3020331 and rs851982 SNPs of the *ESR1* gene were associated with BMD of the total hip and neck femoral under dominant and recessive models, respectively ($P=0.006$ and $P=0.008$). Our data replicate previous associations found between SNPs in the *C6orf97* and *ESR1* region and BMD and suggest that this region may contribute to variation in BMD across multiple ethnic groups.

Association of $P2Y_2$ Receptor Single-Nucleotide Polymorphism with Bone Mineral Density in Elderly Men. Maria Ellegaard*[1], Magnus Karlsson[2], Mattias Lorentzon[3], Claes Ohlsson[4], Dan Mellstrom[5], Osten Ljunggren[6], Peter Schwarz[7], Niklas Jorgensen[1]. [1]Copenhagen University Hospital Glostrup, Denmark, [2]Skåne University Hospital Malmö, Lund University, Sweden, [3]Geriatric Medicine, Center for Bone Research at the Sahlgrenska Academy, Sweden, [4]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden, [5]Sahlgrenska University Hospital, Sweden, [6]Uppsala University Hospital, Sweden, [7]Glostrup Hospital, Denmark

Background and aim: The $P2Y_2$ receptor is a G-protein-coupled receptor, which is activated by adenosine 5-triphosphate and involved in signalling between bone cells. The $P2Y_2$ receptor single-nucleotide polymorphism (Leu46Pro) has been shown to be associated with high BMD in women. As gender-specific effects of P2 receptors have been suggested, the aim of this study was to investigate whether $P2Y_2$ receptor polymorphisms are associated with BMD and fracture prevalence in elderly men.

Materials and Methods: A total of 3014 men (age 69-81 years) from the MrOS Sweden study were genotyped for three $P2Y_2$ receptor polymorphisms (Leu46Pro, Ser359Pro and Arg312Ser). Genotyping was performed using Sequenom MassARRAY platform. BMD of lumbar spine, total hip and femoral neck was measured by DXA. Vertebral fractures were analyzed by spinal x-ray in 1428 of the participants. Furthermore, previous sustained fractures (any type) were recorded from questionnaires. Differences in BMD and fracture prevalence in wildtype allele carriers, heterozygous and homozygous variant allele carriers were assessed using analysis of covariance (covariates: BMI and age) and Chi Square test. Data are presented as mean (SD).

Results: At baseline the study population presented with an age of 75.4 (3.2) years; BMI of 26.4 (3.6) kg/m^2; spine BMD of 1142 (201) mg/cm^2; femoral neck BMD of 831 (132) mg/cm^2 and total hip BMD of 936 (144) mg/cm^2. Fifteen percent (of the 1428) had experienced one or more vertebral fractures. Age and BMI was compared within genotypes of each polymorphism and no significant differences were found between the genotypes ($p>0.05$). BMD of the femoral neck was significantly different between genotypes for the Leu46Pro polymorphism, with hetero- and homozygous variant allele carriers showing higher BMD compared to wildtype allele carriers (wildtype: 827 (132) mg/cm^2; heterozygous: 850 (131) mg/cm^2; homozygous: 848 (95) mg/cm^2; $p=0.018$). The Arg312Ser and Ser359Pro polymorphisms showed no significant difference in BMD at any site between the different genotypes ($p>0.05$). None of the polymorphisms were significantly associated with prevalent vertebral fractures or all reported fractures ($p>0.05$).

Conclusion: The Leu46Pro polymorphism of the human $P2Y_2$ receptor was in our cohort associated with BMD of the femoral neck in elderly men. Further experimental studies are required in order to establish the effect of the polymorphism on receptor and bone cell function.

SU0306

Associations Between Polymorphisms in ALOX12 and ALOX15 and Bone Properties in Young and Elderly Women. Maria Herlin*[1], Fiona McGuigan[2], Holger Luthman[3], Kristina Akesson[4]. [1]University of Lund, Malmö, Skane University Hospital, Malmö, Sweden, [2]University of Lund, Malmö, Skane University Hospital, Malmö, Sweden, [3]Medical Genetics Unit, Department of Clinical Sciences, Malmö, Lund University, Sweden, [4]Skåne University Hospital, Malmö, Sweden

Purpose: The ALOX12 and ALOX15 genes encode arachidonate lipoxygenases, which produce endogenous ligands for PPARγ. Activation of the PPARγ pathway stimulates adipogenesis at the expense of osteoblastogenesis. Arachidonate lipoxygenases also produce leukotrienes with pro-inflammatory effects, and may be involved in inflammatory bone loss. In this study, genetic variation at the ALOX12 and ALOX15 loci were analyzed for associations with bone properties in two population based cohorts of Swedish women.

Methods: The PEAK-25 cohort consists of 1061 women aged 25 years, and the OPRA cohort consists of 1044 women aged 75 years and prospectively followed for 10 years. Bone mineral density (BMD) was measured with dual-energy x-ray absorptiometry (DXA) at femoral neck, lumbar spine, hip and total body. Quantitative ultrasound (QUS) measurements (SoS, BUA and stiffness) were performed on the right calcaneus. Fractures were assessed in OPRA only. Three SNPs in ALOX12 (rs1126667, rs2292350, rs312466) and five SNPs in ALOX15 (rs8074545, rs748694, rs9894225, rs2619112, rs916055) were genotyped in both cohorts. Differences between genotypes were analyzed by ANOVA and linear regression analysis, and the Chi-Square test was used to analyze genotype differences in fracture incidence.

Results: Genotype frequencies of ALOX12 and ALOX15 were similar in both cohorts. rs2292350_ALOX12 was associated with lumbar spine BMD (AA: 1.224 vs. GG: 1.240, p = 0.023) in PEAK-25, but this association did not remain significant after adjustment for weight, height and smoking. There were no associations observed for ALOX12 with BMD, QUS or fracture in OPRA. rs748694_ALOX15 was associated with QUS parameters SoS (CC: 1573.5 vs. TT: 1580.7, p = 0.024) and stiffness (CC: 98.6 vs. TT: 102.0, p = 0.017) in PEAK-25, and remained significant after adjustment for weight, height, femoral neck BMD and smoking (p = 0.022 and p = 0.026, respectively). Further, a trend for higher total BMD with the rare allele of rs748694_ALOX15 was observed. In OPRA, rs2619112_ALOX15 was associated with incident fracture (p = 0.014), while there were no associations with BMD or ultrasound parameters.

Conclusions: A common variant in ALOX15 was associated with ultrasound parameters, indicating a role in bone microarchitecture independent of BMD, in young women. In elderly women, ALOX15 was associated with fracture independent of BMD in this cohort.

Common and Rare Variants in the Exons and Regulatory Regions of Osteoporosis-Related Genes Improve Osteoporotic Fracture Risk Prediction. Seung Hun Lee*[1], Moo Il Kang[2], Seong Hee Ahn[1], Kyeong-Hye Lim[3], Gun Eui Lee[4], Eun-Soon Shin[4], Jong-Eun Lee[4], Beom-Jun Kim[5], Eun-Hee Cho[6], Sang-Wook Kim[6], Tae-Ho Kim[7], Hyun-Ju Kim[8], Kun-Ho Yoon[2], Won Chul Lee[9], Ghi Su Kim[1], Jung-Min Koh[5], Shin-Yoon Kim[10]. [1]Asan Medical Center, University of Ulsan College of Medicine, South Korea, [2]Seoul St. Mary's Hospital, The Catholic University of Korea, South Korea, [3]Asan Medical Center, University of Ulsan College of Medicine, South Korea, [4]DNA Link, South Korea, [5]Asan Medical Center, South Korea, [6]Kangwon National University College of Medicine, South Korea, [7]Kyungpook National University School of Medicine, South Korea, [8]Skeletal Diseases Genome Research Center & Kyungpook National University School of Medicine, South Korea, [9]The Catholic University of Korea, South Korea, [10]Kyungpook National University Hospital, South Korea

Osteoporotic fracture risk is highly heritable, but genome-wide association studies have explained only a small proportion of the heritability to date. Genetic data may improve prediction of fracture risk in osteopenic subjects for early intervention and management. We aimed to detect common and rare variants in coding and regulatory regions related to osteoporosis-related traits, and to investigate whether genetic profiling improves the prediction of fracture risk. We performed targeted resequencing of 198 genes in 982 individuals with extreme phenotypes and then replicated sequencing of the promising variants in 3,895 participants. Genetic risk scores from common variants (GRS-C) and from common and rare variants (GRS-T) were calculated. Nineteen common variants in 17 genes (of the discovered 34 functional variants in 26 genes) and 31 rare variants in 5 genes (of the discovered 87 functional variants in 15 genes) were associated with one or more osteoporosis-related traits. Accuracy of fracture risk classification was improved in the osteopenic patients by adding GRS-C to fracture risk assessment models (6.8%, $P < 0.001$) and was further improved by adding GRS-T (9.6%, $P < 0.001$). GRS-C improved classification accuracy for vertebral and non-vertebral fractures by 7.3% ($P = 0.005$) and 3.0% ($P = 0.091$), and GRS-T further improved accuracy by 10.2% ($P < 0.001$) and 4.9% ($P = 0.008$), respectively. Our results suggest that both common and rare functional variants may contribute to osteoporotic fracture, and that adding genetic profiling data to current models could improve the prediction of fracture risk in an osteopenic individual.

SU0308

BMD Genome-Wide Association Studies (GWAS) loci are enriched in tissue-specific DNase I hypersensitive sites in human muscle, skin, blood and osteoblast cells. Wen-Chi Chou*[1], Gosia Trynka[2], David Karasik[3], Douglas Kiel[1], Yi-Hsiang Hsu[4]. [1]Hebrew SeniorLife, USA, [2]Broad Institute, USA, [3]Hebrew SeniorLife; Bar Ilan University, USA, [4]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA

Most reported genetic loci associated with BMD are located in non-coding regions, making it difficult to interpret their functions. DNase I hypersensitive sites (DHS) have been reported to overlap with tissue-specific regulatory elements (such as enhancers and promoters) in non-coding regions, suggesting DHS is a functional-genomic marker to predict tissue-specific regulatory activities. To determine whether BMD loci are enriched in tissue-specific regulatory elements, we performed a systematic enrichment analysis of DHS data across 26 cell types (see table).

Using an algorithm developed by Trynka et al. that assesses chromatin data enrichment of cell types for a given SNP set, we tested DHS enrichment of 26 non-cancer and non-stem cell lines selected from 97 cell lines in the ENCODE project for the top 56 reported significa-nt GWAS SNPs associated with BMD. DHS signals were captured by a SNP-DHS score defined as the height of a DHS peak closest to a SNP (a GWAS SNP or a SNP in LD, $r^2 > 0.8$, of the GWAS SNP) divided by the distance of the summit of the DHS peak to the SNP. A higher DHS-SNP score has greater probability of the SNP being closer to a higher DHS peak. To test for significant cell type enrichment, summary SNP-DHS scores of BMD SNPs in each cell were compared to a null distribution of

10,000 permutations of random SNPs sets that were required to have the same number of DHS peaks in LD across all cell types as the BMD SNPs.

Across a total 7,285 DHS peaks from 26 cell types, BMD loci were observed to be significantly enriched with DHS in aortic smooth muscle (P=1x10^{-5}), skin fibroblast (P=1x10^{-4}), ureter cell (P=6x10^{-4}), B cell (P=0.0011) and osteoblast (P=0.0015) after Bonferroni correction. Enriched BMD loci in aortic smooth muscle included *SFRP4*, *DNM3*, and *OPG*. Enriched BMD loci in osteoblast included *CCDC170*, *FAM210A,* and *MARK3*.BMD loci were found to be enriched with DHS data not only in osteoblast, but also in other cell types, suggesting genetic factors may contribute to the variation of BMD via bone cells and other tissues. In addition, 54% of 56 BMD GWAS loci were enriched in DHS in at least one enriched cell type, suggesting that the majority of non-coding GWAS loci are located in regulatory elements. This approach holds promise for characterizing the functional significance of GWAS findings located in non-coding regions.

Table: Identification of enriched cell types for BMD loci (significant P < 0.0019 = 0.05/26).

SU0309

Combined Hormonal Contraceptive Use Associated with Less Positive BMD Change in Adolescent Women in CaMOS Population-based Cohort—BMD loss significantly greater in women 20-24 using CHC at baseline. Jerilynn Prior*[1], Katharina Schlammerl[2], William Mercer[3], David Hanley[4], Jonathan Adachi[5], Christopher Kovacs[6]. [1]University of British Columbia, Canada, [2]Technical University of Munich, Germany, [3]Centre for Menstrual Cylce & Ovulation Research, Canada, [4]University of Calgary, Canada, [5]St. Joseph's Hospital, Canada, [6]Memorial University of Newfoundland, Canada

Combined hormonal contraception (CHC) is widely used by adolescent/ young women for birth control or treatment of menses related problems (PMS, heavy flow, cramps, irregular cycles or acne). Peak bone mineral density (BMD) is primarily attained by late adolescence. Baseline CaMOS BMD data in ages 25-45 found values 2.3-3.7% lower in CHC ever-users[1]. Prospective observational[2-4] and RCT data[5;6] show CHC use reduces adolescent age-appropriate BMD gain. No population-based prospective CHC BMD change data are available and no BMD change data related to contraceptive/ therapy indications for first CHC use are published. Methods—The CaMOS Youth Cohort included 527 women ages 16-24 recruited by random residential sampling in 9 Canadian centres (2004-6). Extensive interviewer-administered questionnaires and BMDs (L1-4, femoral neck, total hip [TH]) were obtained at 0 and 2-y. Results, due to sample size, are based on CHC ever/never use at baseline and y-2 and indication for first CHC use at y0. Ever CHC use was reported by 66% of women ages 16-24 at both y0 and y2. At baseline, CHC ever vs. never users were significantly older (20 vs. 18.5 y), similar in BMI (22.6 vs 23), not different in total calcium intake and vitamin D intakes or kcal exercise/d but were more likely to smoke (P=0.000). CHC was started for contraception by only 45% of 391 ever-CHC users (55% for therapy). Two year BMD change data were available for 326. L1-4 increased as age-expected in the 57 adolescents (16-19 y) who had never used CHC; those adolescent ever-CHC users tended to gain less BMD than never-users (+.0026 vs. +.0116g/cm^2, respectively; P=.204) (Figure). Women ages 20-24 who were ever (n=127) or never (n=24) CHC users had similar L1-4 2-y changes (+.0072 vs. +.0037g/cm^2; P=.653). BMD changes were also importantly different in ages 20-24 by current vs. no CHC use at y0. Although current contraceptive CHC users ages 20-24 at baseline were younger and smoked less, CHC users showed BMD loss. L1-4 (-.007 vs. +.011, P=.028) and TH (-.009 vs. +.007, P=.005) changes were significantly different in these CHC users. In conclusion, these population-based data support previous data showing CHC decreases optimal peak BMD in those 16-19. In addition, in 20-24 y olds y0 current use of CHC was associated with significant BMD loss. Different Relationships between Body Compositions and Bone Mineral Density According to Gender and Age in Korean Populations (KNHANES 2008–2010). Seong Hee Ahn*[1], Seung Hun Lee[1], Hyeonmok Kim[2], Beom-Jun Kim[3], Jung-Min Koh[3]. [1]Asan Medical Center, University of Ulsan College of Medicine, South Korea, [2]Asan Medical Center, University of Ulsan College of Medicine, South Korea, [3]Asan Medical Center, South Korea

Fat and muscle are linked to bone metabolism. We investigated the association of fat mass (FM) and lean mass (LM) with bone mineral density (BMD) according to gender and age. This is a population-based, cross-sectional study from Korea National Health and Nutrition Examination Surveys, including 15,036 Koreans (6,692 men and 8,344 women) aged 10–95 years. BMD and body compositions were measured using a dual-energy X-ray absorptiometry. BMD was determined at the femoral neck, total hip, and lumbar spine. Body compositions included total FM (TFM), percentage FM (PFM), truncal FM (TrFM), total LM (TLM), and appendicular skeletal muscle mass/weight (ASM/Wt). We categorized each man and woman into one of three age groups, based on changes in age-related BMD and the hormonal status. In all gender and age groups, TFM, PFM and TrFM associated inversely with BMD (P<0.001–0.034), while TLM and ASM/Wt associated positively (P<0.001–0.037) after adjusting for confounders. The negative contribution of FM (P=0.001–0.034), and the positive contribution of LM (P<0.001–0.035) on BMD were significantly stronger in men than in women. The associations were strongest in men of growing age (P=0.003–0.040). When we subdivided the subjects into four groups based on median values of PFM and TLM, FM had a greater effect than LM on BMD in men (P<0.001–0.024). These results demonstrate that the effects of FM and LM on BMD may be based on gender and age.

SU0311

Hip Structural Analysis Predicts Hip Fracture in Women Independent of BMD: A Meta-Analysis. Preeti Kohli*[1], Chia-Ho Cheng[2], Marian Hannan[3], Yi-Hsiang Hsu[4], Lisa Strano-Paul[5], Michael Lavalley[6], Thomas Beck[7], Douglas Kiel[8], David Karasik[9]. [1]Stony Brook University, USA, [2]Hebrew SeniorLife, USA, [3]HSL Institute for Aging Research & Harvard Medical School, USA, [4]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, [5]Stony Brook University, USA, [6]Biostatistics, Boston University Sch of Public Health, USA, [7]Beck Radiological Innovations, Inc., USA, [8]Hebrew SeniorLife, USA, [9]Hebrew SeniorLife; Bar Ilan University, USA

Objective: The current gold standard to identify patients at risk for hip fracture is to use bone mineral density (BMD) measurements by Dual Energy X-Ray Absorptiometry (DXA). Though there is a strong association between BMD and hip fractures (HFx), there is also a substantial overlap in BMD between individuals with and without HFx. The reason that BMD alone does not sufficiently differentiate fracture risks may be because BMD does not account for the cross-sectional distribution of bone mass, suggesting a role for factors such as femoral geometry. Measurements of femoral geometry by Hip Structural Analysis (HSA) may improve the prediction of HFx independently of BMD. Our aim was to combine systematically assembled published data with our own data, and through meta-analysis, understand the ability of HSA to predict HFx.

Methods: PubMed, Web of Science, and Embase databases were searched in accordance with the PRISMA Statement for publications on the association of femoral geometry and HFx using a combination of key terms. Criteria for eligible studies included the measurement of HSA by DXA, odds ratios for risk of HFx at proximal femur sites, and publication after 1999 in English language journals. We extracted bibliographic information, demographics, study design, number of HFx cases and controls, exclusion criteria, method of HSA calculations, bone parameters, type of hip fracture, and average years of follow up. Similar characteristics were derived for the Framingham Cohort (unpublished). Odds Ratios (OR) and 95% CIs, unadjusted and adjusted for hip BMD, were used as input data. We performed sex-stratified meta-analyses for each bone parameter using random effects meta-analysis and evaluated heterogeneity between studies using I^2.

Results: In men, none of the HSA measures were significantly associated with HFx (not shown). In women, the following bone parameters predicted HFx risk (see Table): hip axis length (HAL), neck shaft angle (NSA), femoral neck width (FNW), and buckling ratio (BR). After adjusting for BMD, ORs for FNW and BR became non-significant, while the femoral neck cortical thickness (CT) became significant. Heterogeneity was lower in the BMD-adjusted analyses than unadjusted.

Conclusions: Although limited by substantial heterogeneity, in women, HAL, NSA, and CT showed modest strength in HFx prediction independent of BMD. Therefore, HSA indices could potentially be used in addition to BMD, to screen high-risk patients for hip fractures.

TABLE 1 Results for Women

Bone Parameter	# studies	Unadjusted for BMD (OR, 95% CI)	I^2	Adjusted for BMD (OR, 95% CI)	I^2
HAL	10	1.39 [1.09, 1.77]	70.9%	1.42 [1.19, 1.68]	63.2%
NSA	5	1.52 [1.08, 2.14]	83.2%	1.58 [1.13, 2.20]	82.3%
FNW	5	1.30 [1.08, 1.57]	54.2%	1.17 [0.97, 1.40]	33.1%
BR	3	1.76 [1.04, 2.98]	94.4%	1.12 [0.98, 1.29]	0.0%

Idiopathic and Secondary Osteoporosis in Premenopausal Women. Alicia Bagur*[1], Silvina Mastaglia[2], Beatriz Oliveri[3], Diana González[4], Elizabeth Sarnacki[5], Candela Fernández[5], Carlos Mautalen[6]. [1]Mautalen Salud e Investigacion, Argentina, [2]Laboratorio De Enfermedades Metabólicas Oseas, CONICET-UBA, Argentina, [3]Mautalen, Salud e Investigación, Argentina, [4]Mautalen Salud e Investigación, Argentina, [5]Mautalen, Salud e Investigación, Argentina, [6]Centro de Osteopatías Médicas, Argentina

Premenopausal (preMP) osteoporosis (OP) may be idiopathic or due to diseases or treatments that affect bone mineral density (BMD). Aim: To identify the clinical characteristics and the evolution of BMD over two years in women with preMP OP. We reviewed the clinical records of 95 preMP women who were referred during the last 6 years for evaluation of BMD to an Institute of Metabolic Bone Diseases. Patients were either self-referred due to concern for the disease or referred from other physician. We analyzed personal and familiar history of fractures (Fx), BMD, biochemical bone markers, diagnosis and their treatments. BMD was considered normal as a Z score above -2.0 in the lumbar spine and/or total femur. Results: 41 out 95 (43%) were in the BMD osteoporotic values. In 22 out of 41 (54%) a diagnosis of idiopathic or primary (1♂) OP was made. Nineteen patients (46%) had secondary (2♂) OP due to the following diseases: pregnancy (6), anorexia nervosa (4), celiac disease (2), hypercalciuria (1), 1♂ hyperparathyroidism (1), hypothalamic amenorrhea (1), glucocorticoid (1), osteogenesis imperfecta (1), excess of T4 (1), and congenital adrenal hyperplasia (1). Two out 22 women (9%) with 1♂ OP had Fx (1 vertebrae and 1 wrist). Four out 19 women (21%) with 2♂ OP had Fx at the following site: wrist (1), vertebrae (2), and metatarsal (1). Eleven (50%) of the 1♂ OP women and 6 (32%) with 2♂ OP had a familiar history of Fx. Table 1 show the significant differences between 1♂ and 2♂ OP. The 1♂ OP patients received the following treatments: Calcium and vitamin D (Ca+D) (17), bisphosphonate (5). Secondary OP patients received: Ca+D and treatment according to the underlying disease.About fifty percent of preMP women with low BMD were idiophatic standing out less bone formation and vitamin D vs. 2♂ OP. In a preliminary analysis, follow up of this group showed an increase in bone mass.

Table1: Baseline Characteristic between 1ºOP and 2ºOP (X±SD)

The association of vitamin D and parathyroid hormone with bone mineral density in Korean adults. Seong-Woo Choi[1], Sun-Seog Kweon[2], Jin-Su Choi[2], Jung-Ae Rhee[2], Young-Hoon Lee[3], Hae-Sung Nam[4], Hee Nam Kim[5], Min-Ho Shin*[6]. [1]Department of Preventive Medicine, Chosun University Medical School, Gwangju, Republic of Korea, South Korea, [2]Department of Preventive Medicine, Chonnam National University Medical School, South Korea, [3]Department of Preventive Medicine & Institute of Wonkwang Medical Science, Wonkwang University College of Medicine, South Korea, [4]Department of Preventive Medicine, Chungnam National University Medical School, South Korea, [5]Center for Creative Biomedical Scientists, Chonnam National University, South Korea, [6]Chonnam National University Medical School, South Korea

The purpose of this study is to investigate the association of serum 25-hydroxyvitamin D(25(OH)D) and parathyroid hormone with bone mineral density in Korean general population. The study population consisted of 8,700 subjects (3464 men and 5236 women) aged 50 years and older who participated in the baseline survey of the Dong-gu Study conducted in Korea between 2007 and 2010. Bone mineral density (BMD) was measured by dual-energy X-ray absorptiometry at the spine and hip. Serum 25(OH)D and parathyroid hormone were measured by chemiluminescent microparticle immunoassay. Multiple linear regression analyses were used to evaluate the association of the quartiles of 25(OH)D and parathyroid hormone with BMD, after adjusting for age, height, smoking, alcohol intake, physical activity, education, medication of hypertension, and medication of diabetes. To evaluate the independent effect of parathyroid hormone and 25(OH)D levels on BMD, we further adjusted for 25(OH)D or parathyroid hormone. In multiple adjusted models, low 25(OH)D levels were associated with low BMD at both hip and spine in males and females. High parathyroid hormone levels were associated with low BMD at both spine and hip in males and females. Parathyroid hormone and 25(OH)D levels were associated with BMD independently of each other except for lumbar spine in females. In females, the association between 25(OH)D and lumbar spine BMD was attenuated and remained statistically non-significant after adjustment for covariates and parathyroid hormone. In conclusion, we found that vitamin D and parathyroid hormone were significantly associated with BMD in community-dwelling Korean adults.

Table Bone mineral density according to serum 25-hydroxyvitamin D

	25 (OH)D ng/ml	Male			Female		
		Model 1	Model 2	Model 3	Model 1	Model 2	Model 3

The trends in bone mineral density is reversed by body weight adjustment — a study of 12,401 Chinese women. Edith Lau*[1], Rick Chung[2], Peng Cheng Ha[3], Hai Tang[4], Dicky Lam[5]. [1]Center for Clinical & Basic Research (CCBR) (Hong Kong), Hong Kong, [2]Center for Clinical & Basic Research (CCBR) (Hong Kong), Hong Kong, [3]CCBR Beijing, China, [4]Department of Orthopedics, Friendship Hospital, Beijing, China, [5]CCBR Hong Kong, Hong Kong

Background and objective

The hip fracture incidence in Hong Kong (Southern Chinese) women is around two times that of Beijing (Northern Chinese) women. The objectives of the current study are to compare the bone mineral density (BMD) of Hong Kong Chinese and Beijing Chinese women, and to investigate how the trends were affected by adjustment for body weight. The prevalence of osteoporosis in these populations was also studied.

Subjects and materials

A total of 12,401 postmenopausal Chinese women were recruited from the community in Hong Kong and Beijing. BMD was measured by Lunar Dual X-ray Densitometry (DEXA) machines. Multiple regression was used to study the effects of adjustment for age, height and weight on the BMD comparison, and to deduce the variance in BMD accounted by the anthropomorphic factors in the two populations. The percentage prevalence of osteoporosis in the two populations was calculated using Asian normal values and the World Health Organization criteria for osteoporosis.

Results

Although the BMD of Beijing Chinese women was found to be higher than that of Hong Kong Chinese women; this trend was reversed once the body weight was adjusted for. Using the multiple analysis of ANCOVA, body weight accounted for 13.3% of the difference between lumbar spine BMD and 14.6% of the total hip BMD between Hong Kong Chinese and Beijing Chinese women respectively. The prevalence of osteoporosis at any site was extremely high: 24.9% in Hong Kong Chinese women and 20.3% in Beijing Chinese women.

Conclusion

We conclude that osteoporosis is a highly prevalent health problem in Hong Kong Chinese and Beijing Chinese women. It is extremely important to adjust for body weight when comparing BMD, even for subjects of the same ethnicity. The adjusted BMD of Hong Kong Chinese women was higher than that of Beijing Chinese women; implying that the higher hip fracture incidence in Hong Kong Chinese women could be due to factors related to bone strength and falls.

Site	Mean of BMD (g/cm²) (SD)			
	Hong Kong women (N=6099)		Beijing women (N=6302)	
	Unadjusted	Adjusted[1]	Unadjusted	Adjusted[1]
Lumbar Spine	0.956 (0.168)[2]	0.996(0.002)[3]	0.978 (0.166)	0.949(0.002)
Total hip	0.779 (0.123)[2]	0.835(0.001)[3]	0.850 (0.133)	0.813(0.001)
Femoral neck	0.732 (0.110)[2]	0.765(0.001)[3]	0.789 (0.122)	0.755(0.001)

SU0315

Obesity Was Not Protective Against Fractures in Post-Menopausal Women: a Cross-Sectional Study at Santa Maria, Brazil. Rafaela Copes[1], Felipe Langer[1], Karen da Costa[1], Luana Marchesan[1], Giovani Sartori[1], Aline Cocco[1], Jose de Carvalho[1], Rafael Moresco[1], Fabio Comim[1], Melissa Premaor*[2]. [1]Federal University of Santa Maria, Brazil, [2]Federal University of Santa Maria, Brazil

Recent studies have challenged the paradigm that high BMI is always protective against bone fractures. The prevalence of fractures has been reported similar between obese and non-obese people in the GLOW study[1]. Nevertheless, others did not reproduce this lack of association. In this study we aimed to evaluate the association between BMI/obesity and fractures in post-menopausal women. In order to do so, we carried out a cross-sectional study at Santa Maria (parallel 29º South), Brazil. Post-menopausal women aged 55 years or older who had at least one appointment at their GP practice in the two years prior the study were recruited from March 1st to August 31st, 2013. Women with cognitive impairment were excluded. The GLOW study questionnaire was applied with permission of The Center for Outcomes Research, University of Massachusetts of Medical School[1,2]. Height and weight were measured according the WHO protocol. Bone fractures (excluding hand, feet, and head) that occur after age 45 years were considered as the outcome. Overall, 1301 women were invited to participate of the study. In total, 1057 women completed the questionnaire; of whom, 973 had their BMI measured. The mean [mean (SD)] age and BMI were 67.2(7.6) years and 29,3(5,5) kg/m^2, respectively. The prevalence of fractures and obesity (BMI $\geq$ 30 kg/m^2) were, respectively, 17% and 39.6%. The BMI was not different in women with and without fractures [29.5(5.8) kg/m^2 vs. 29.2(5.5) kg/m^2, P=0.66]. The power of the study for this endpoint was 99%. Of the obese women, 17.4% presented a bone fracture; it was not different from the non-obese women prevalence of fractures (16.2%, P = 0.62). The odds ratio of fracture in obese women was 1.09 (95% CI 0.74,1.54; P = 0.56). There were no association between fracture site and BMI. Moreover, age and impaired mobility were associated with fractures in obese women. Although the BMI of this population was high, the study had sufficient power to evaluate its association with fracture. In conclusion, obesity was not protective against fracture in post-menopausal women in our study. Efforts to modify the misconception that obesity is always protective against fracture are needed.

Bone mineral density and association between BMI and fracture risk: a mediation study. Mei Chan*[1], Steve Frost[2], Jacqueline Center[3], John Eisman[3], Tuan Nguyen[3]. [1]Osteoporosis & Bone Biology, Australia, [2]Garvan Institute of Medical Research, Australia, [3]Garvan Institute of Medical Research, Australia

Aim The relationship between body mass index (BMI) and fracture risk is controversial. We sought to delineate the causal structure of the relationship between BMI, bone mineral density (BMD) and fracture risk by mediation analysis

Methods The study involved 2,199 women and 1,351 men aged 60 years or older. BMI was derived from baseline weight and height. Femoral neck BMD was measured by dual energy X-ray absorptiometry (GE-LUNAR, Madison, WI). The incidence of fragility fracture was ascertained by X-ray reports during 1991-2012. Mediation analysis was used to assess the direct and indirect effects of BMI, and the mediated effect of BMD, on fracture risk within the framework of the Cox's proportional hazards model.

Results Overall, 774 women (35% of total women) and 258 men (19%) had sustained a fracture. Approximately 21% of women and 20% of men were considered obese (BMI $\geq$ 30). In univariable analysis, greater BMI was associated with reduced fracture risk in women (HR 0.92; 95% CI, 0.85-0.99) and in men (HR 0.77; 95% CI, 0.67-0.88). After adjusting for femoral neck BMD, higher BMI was associated with greater risk of fracture in women (HR 1.21; 95% CI, 1.11-1.31) but not in men (HR 0.96; 95% CI, 0.83-1.11). However, in mediation analysis, the direct effect of BMI on fracture risk was not statistically significant, and the majority of BMI effect on fracture risk was mediated by femoral neck BMD. The overall mediated effect estimates were -0.048 (95% CI, -0.059 to -0.036; $P < 0.001$) in women and -0.030 (95% CI, -0.042 to -0.018; $P < 0.001$) in men.

Conclusion These analyses suggest that there is no significant direct effect of BMI on fracture, and that the observed association between BMI and fracture risk is mediated by femoral neck BMD in both men and women.

Degree of Trauma Differs for Major Osteoporotic Fracture Events in Older Men vs. Older Women. Kristine Ensrud*[1], Terri Blackwell[2], Peggy Cawthon[3], Dawn Mackey[4], Douglas Bauer[5], Howard Fink[6], John Schousboe[7], Dennis Black[5], Eric Orwoll[8], Deborah Kado[9], Jane Cauley[10]. [1]University of Minnesota & Minneapolis VA Health Care System, USA, [2]California Pacific Medical Center Research Institute, USA, [3]California Pacific Medical Center Research Institute, USA, [4]Simon Fraser University, Canada, [5]University of California, San Francisco, USA, [6]GRECC, Minneapolis VA Medical Center, USA, [7]Park Nicollet ClinicUniversity of Minnesota, USA, [8]Oregon Health & Science University, USA, [9]University of California, San Diego, USA, [10]University of Pittsburgh Graduate School of Public Health, USA

Purpose: Examine the role of trauma in major ''osteoporotic'' fracture (MOF) events in older men vs. older women.

Methods: We used data from 15698 adults aged $\geq$65 years (yrs) enrolled in the prospective community-based MrOS (5994 men) and SOF (9704 women) studies. In each study, participants were contacted every 4 months to ascertain incident fractures confirmed by radiographic reports. When a fracture was reported, research staff interviewed participants about circumstances of the event and coded the fracture according to degree of trauma. Degree of trauma was classified as LOW (fall from standing height or less; fall on stairs, steps or curb; minimal trauma other than fall (coughing, turning over); MODERATE (collisions with objects during normal activity without associated fall); or HIGH (fall more than standing height; severe trauma [motor vehicle accident, assault]). Fractures missing trauma status (n=274) or

coded as pathologic (peri-prosthetic or due to malignancy, n=17) were excluded. Fracture (hip, clinical vertebral, wrist, humerus, MOF [any of the preceding 4 types]) follow-up was from baseline until 10 yrs or until time of death or termination from study (mean follow-up 9.1 yrs in SOF and 8.7 yrs in MrOS).

Results: 307 of the 465 (66.0%) MOF events in men compared with 1408 of the 1880 (74.9%) MOF events in women were due to fall from standing height or less ($p<0.001$). 14.6% of the MOF events in men compared with 6.3% of the MOF events in women were classified as high trauma ($p<0.001$) (Figure); men vs. women more often experienced both fractures due to fall more than standing height and fractures due to severe trauma. High trauma fractures were more significantly common in men vs. women at the hip ($p=0.002$) and wrist ($p<0.001$), but not at the spine or humerus. After adjustment for baseline age, race, clinical center, health status, fall history, body mass index and femoral neck bone density, the odds ratio of a high trauma fracture among men vs. women was 3.12 (95% CI 1.70-5.71) among participants with MOF, 3.34 (95% CI 1.04-10.67) among participants with hip fracture, and 5.68 (2.03-15.85) among participants with wrist fracture.

Conclusion: Among community-dwelling older adults, major osteoporotic fracture events are more likely to be related to high trauma in men as compared with women. These findings are not explained by sex differences in traditional risk factors and may reflect a greater propensity among men to engage in risky behavior.

Identification of Osteoporosis Cases in Administrative Healthcare Databases: A Validation Study in the Province of Quebec,Canada. Sonia Jean*[1], Jacques P. Brown[2], Philippe Gamache[3], Suzanne Morin[4], Siobhan O'Donnell[5], William Leslie[6], Louis Bessette[7]. [1]Institut National De Santé Publique Du Québec, Canada, [2]CHU de Québec Research Centre, Canada, [3]INSPQ, Canada, [4]McGill University, Canada, [5]PHAC, Canada, [6]University of Manitoba, Canada, [7]CHU de Quebec Research Centre, Canada

Purpose: Administrative healthcare databases (AHDs) capture information during routine clinical care that can be used to track disease incidence, prevalence, outcomes, resources utilization and indicators of quality of care. This study assessed the validity of several case definitions to identify osteoporosis cases from AHDs, as compared with self-reported diagnosis, in a cohort of women who sustained fragility fractures as the gold standard.

Methods: Women (≥50y) without previous osteoporosis diagnosis or treatment who suffered a recent fragility fracture were recruited to the Recognizing Osteoporosis and its Consequences in Quebec (ROCQ) project. For this study, these women were used to compare several AHD case definitions for osteoporosis ascertainment. Participants were contacted at 6 and 18 months post fracture to complete questionnaires on personal and clinical characteristics related to osteoporosis (including diagnosis, treatment, co-morbidities, risk factors). BMD reports were also obtained. Each ROCQ participant's data were linked to population-based AHDs for the Province of Quebec, Canada. AHD case definitions for osteoporosis diagnosis were constructed using combinations of the number osteoporosis diagnosis codes (ICD-9 733.x and ICD-10 M80-81) from physician claims (P), hospitalizations (H), prescriptions for osteoporosis medications (Rx) and BMD tests during pre-specified time periods. The accuracy of the AHD case definitions were determined using ROCQ questionnaire data and BMD reports (gold standard). We calculated prevalence, sensitivity (Sn), specificity (Sp), positive predictive value (PPV), negative predictive value (NPV), area under the receiver operative curve (AUC), and the ratio of number of women who test positive to the number of women who have the condition (TAP).

Results: The cohort included 557 women (mean age: 61.7 years; ≥65 years: 31.4%). During the follow-up period (mean 20.7 months), 29.1% of the women (36% of women ≥65y) self-report an osteoporosis diagnosis on the ROCQ questionnaire. The most accurate case definition to identify women with diagnosed osteoporosis from AHDs was 1H or 1P or 1RX (Sn=0.70, Sp=0.83, PPV=0.63, NPV=0.87, AUC=0.77, TAP=1.11; Table1) In women ≥65 years, the performance of this case definition was even higher (Sn=0.89, Sp=0.81, PPV=0.73, NPV=0.93, AUC=0.84, TAP=1.22; Table 2).

Conclusions: We demonstrated a higgh level of accuracy for identifying patients with diagnosed osteoporosis using AHDs.

Serum 25-hydroxy vitamin D levels and fracture risk: The Dubbo Osteoporosis Epidemiology Study. Weiwen Chen*[1], Nguyen Nguyen[2], Tuan Nguyen[2], Jacqueline Center[2], John Eisman[2]. [1]St Vincent's Hospital (Sydney), Australia, [2]Garvan Institute of Medical Research, Australia

Background: Hypovitaminosis D is common in osteoporotic patients. Vitamin D deficiency leads to secondary hyperparathyroidism and possibly reduced postural stability with increased falls risk. However, the relationship between vitamin D and fracture risk is not well documented, especially in the ambulant healthy elderly population. Objectives: To examine the relationship between serum 25-hydroxyvitamin D levels and fracture risk Methods: Nested case-control study within the Dubbo Osteoporosis Epidemiology Study (DOES), a prospective cohort of men and women aged 60+ that commenced in 1989. Participants attended bi-annual follow-up. At each visit, a DXA bone density, anthropometric measures and lifestyle questionnaire, including dietary calcium intake and physical activity were completed. Participants with a minimal trauma fracture and a random sample of a non-fractured control were selected. Both groups had had serum taken and archived at -70℃. Samples from cases prior to fracture and comparable samples from controls had 25-OHD, PTH and creatinine measured. Differences in baseline measures between the fracture and non-

fracture cases were tested by paired t-test for normally distributed data and by the non-parametric Wilcoxon sign rank test for non-parametric data. Results: Fracture cases (n = 305) and non-fracture controls (n = 318) were included for analysis. The median length of follow-up was 4.52 years (IQ: 1.80 – 8.68). Of this healthy elderly cohort, < 5.3 % had 25-OH D levels of < 30 nmol/L (<12 ng/mL). 25-OH D levels were correlated with age (r=-0.16, P=<0.0001), FNBMD (r=0.14, P=0.0003), serum PTH levels (r=-0.26, P=0.0001) and quadriceps strength (r=0.22, P=<0.0001). However median vitamin D levels were 67 nmol/L in both cases (IQ: 49.3-83.5) and controls (IQ: 47.1-83.1). Moreover, 25-OH D levels were not associated with increased fracture (OR: 1.00, 95 CI: 0.86-1.17, P=0.968) or falls risk (OR: 1.22, 95% CI: 0.79-1.89, P=0.37) before or after adjustment for seasonal variation. Conclusion: In this sample of community dwelling elderly, serum 25-OH vitamin D levels were correlated with bone density and quadriceps strength. However, in these healthy elderly, 25-OH D levels were not associated with risk of fracture or of falls. This may be due to most participants being vitamin D sufficient.

Serum Periostin Improves Fracture Prediction in Older Men: the STRAMBO Study. Pawel Szulc*[1], Olivier Borel[2], Jean Charles Rousseau[2], Roland Chapurlat[3]. [1]INSERM UMR 1033, University of Lyon, Hopital E. Herriot, Pavillon F, France, [2]INSERM UMR 1033, University of Lyon, France, [3]E. Herriot Hospital, France

Identification of older men at high risk of fracture is a public health problem. Periostin is a protein synthesized by several tissues including bone. Its serum concentration may predict fractures in postmenopausal women *(Rousseau et al. J Clin Endocrinol Metab, 2014, online)*. Therefore, our aim was to assess the predictive value of serum periostin for fracture in older men. In a cohort of 716 men aged 60 to 87 years, 80 men sustained at least one fracture (including 68 fragility fractures) during a prospective follow-up (median 6 years). Serum periostin level was measured using a sandwich ELISA assay (USCN, Wuhan, China). At baseline, serum periostin did not correlate with bone mineral density (BMD) measured by dual energy X-ray absorptiometry (HOLOGIC Discovery A) or with serum and urinary levels of biochemical bone turnover markers. After adjustment for age, weight, femoral neck BMD as well as prior falls and fractures, the risk of fragility fracture increased with decreasing periostin level (HR=1.39 per SD decrease, 95%CI: 1.06-1.82, p<0.05). The fracture risk was higher in the lowest quartile of periostin level compared with three higher quartiles combined (HR=2.08, 95%CI: 1.26-3.43, p<0.005). In men who had periostin concentration in the lowest quartile and femoral neck BMD <0.776 g/cm^2 (median), the fracture risk was higher compared with men who did not have these characteristics (HR=3.97, 95%CI: 1.92-8.23, p<0.001). The results were similar in the analyses adjusted for BMD of other skeletal sites (e.g. adjusted for mid-radius BMD: HR=1.71, 95%CI: 1.06-2.77, p<0.05 for the first quartile vs three lower quartiles of periostin level). The results were also similar when all incident fractures were included in the analysis (HR=1.57, 95%CI: 1.01-2.45, p<0.05 for the first quartile vs three lower quartiles).

In conclusion, our data show that, in older men, lower serum periostin concentrations are associated with higher risk of fracture after adjustment for age, weight, BMD, history of falls and prior fracture.

Determinants of serum sclerostin in postmenopausal women. Pedro Rozas-Moreno*[1], Rebeca Reyes[2], Manuel Munoz-Torres[3], Antonia Garcia-Martin[4], Ines Luque-Fernandez[4], Verónica Avila-Rubio[4], Beatriz García-Fontana[4], Sonia Morales-Santana[4]. [1]Endocrinology Division. Hospital General de Ciudad Real. Ciudad Real, Spain., Spain, [2]Bone Metabolic Unit., Spain, [3]Hospital Universitario San Cecilio, Spain, [4]Bone Metabolic Unit, Spain

Background: Sclerostin is a 213 amino-acid glycoprotein that antagonize Wnt signaling. Some studies have demonstrated that higher concentrations of serum sclerostin are associated with increased fracture risk, particularly if coexisting with low bone mineral density. There is limited information about the determinants of sclerostin in postmenopausal women, and conflicting data have been reported.

Objectives: This study was performed to determine the predictive factors of serum sclerostin in postmenopausal women. We also analysed differences according to the presence of densitometric osteoporosis.

Patients and methods: We performed a cross-sectional study. We measured baseline serum sclerostin concentrations by ELISA (Biomedica) in 132 postmenopausal women without osteoporosis treatment. We analysed its relationship with age, weight, renal function, calciotropic hormones, bone mineral density (BMD), morphometric vertebral fractures, prevalent fragility fracture and the presence of type 2 diabetes mellitus (T2DM).

Results: Sclerostin levels were significantly higher in T2DM patients (43.13 $\pm$ 17,08 vs 36.7 $\pm$ 14.4 pmol/L, p=0.001) and non-osteoporotic women (41,24 $\pm$ 16,2 vs 31,71 $\pm$ 10,48 pmol/L p=0.000). In the total sample, the values of serum sclerostin were positively associated with BMD at all sites analysed (r=0.316, p=0.000; r=0.426, p=0.000; r=0.429,p=0.000, lumbar spine, femoral neck and total hip respectively). We found a negative correlation between circulating sclerostin and age (r=- 0.198, p=0.023). In stepwise multiple linear regression analysis, only the presence of densitometric osteoporosis was correlated with serum sclerostin concentrations (β=-0.374, p=0.002). There were no differences according to the presence of morphometric vertebral fractures or prevalent fragility fractures. In the subgroup of osteoporotic women, we did not find a significant relationship between serum levels of sclerostin and any of the parameters analysed.

Conclusions: In our study, the main determinant of serum sclerostin levels was the presence of densitometric osteoporosis.

Hypothyroidism, thyroxine replacement and major osteoporotic fractures – The OPENTHYRO register cohort. Bo Abrahamsen*[1], Henrik L Jørgensen[2], Anne Sofie Laulund[2], Mads Nybo[3], Douglas Bauer[4], Thomas H Brix[3], Laszlo Hegedüs[3]. [1]University of Southern Denmark, Denmark, [2]Bispebjerg Hospital, Denmark, [3]Odense University Hospital, Denmark, [4]University of California, San Francisco, USA

Introduction: The long term relationship between hypothyreosis and fracture risk is challenging to dissect due to the modifying influence of subsequent thyroxine replacement with the potential for excessive replacement doses. We studied changes in serum thyrotropin (TSH) levels over time and association with fracture risk in real world patients who presented with initially elevated TSH.

Population and methods: Register-based cohort study including all patients with a TSH measurement in the region of Funen 1996-2010. All TSH determinations were done in the same lab, which served all hospitals and GP practices in the region. The study population consisted of all adults with a first measurement of TSH > 4.0 mIU/l (N=8,414) or normal TSH (N=222138, comparator). We used a Cox PH analysis incorporating additional time dependent covariates to represent initiation of thyroxine replacement and cumulative number of periods with high vs low TSH after index date.

Results: While the risk of major osteoporotic fractures was significantly higher in patients with longer cumulative time with raised TSH (TSH> 4 mIU/l, table 1, "hypothyroid time"), cumulative time with low TSH (TSH<0.3 mIU/l, "hyperthyroid time") was a much stronger predictor of fracture risk. Hyperthyroid (OR 1.09, 95% CI 104-1.15, p=0.0012) but not hypothyroid time was significantly associated with the risk of hip fractures.

Conclusions: Among patients who present with an elevated TSH, the long term risk of hip and other osteoporotic fractures is strongly related to the cumulative duration of periods with low TSH- likely from excessive replacement- while the independent effects of elevated TSH do not appear to be clinically significant.

	Hip fracture (N_{event} = 5,994)	Major osteoporotic fracture (N_{event} = 15,984)
Per 6 mo of TSH > 4 mIU/l	0.99 (0.95-1.03) p=0.600	1.03 (1.01-1.06) p=0.005
Per 6 mo of TSH < 0.3 mIU/l	1.09 (1.04-1.15) p=0.0012	1.13 (1.08-1.15) p<0.0001
Thyroxine prescription	0.95 (0.77-1.17) p=0.620	0.89 (0.79-1.01) p=0.0787

Table 1. Cox analysis adjusted for age, sex, prior major osteoporotic fracture, comorbidity and use of Prednisolone or osteoporosis drugs.

Inflammatory Markers and Change in Bone Mineral Density among Older Men. Kamil Barbour*[1], Stephanie Harrison[2], Kristine Ensrud[3], Peggy Cawthon[4], Nancy Lane[5], Thuy-Tien Dam[6], Joseph Zmuda[7], Steven Cummings[2], Jane Cauley[7]. [1]CDC, USA, [2]San Francisco Coordinating Center, USA, [3]University of Minnesota & Minneapolis VA Health Care System, USA, [4]California Pacific Medical Center Research Institute, USA, [5]University of California, Davis Medical Center, USA, [6]Division of Geriatric Medicine & Aging, Columbia University, USA, [7]University of Pittsburgh Graduate School of Public Health, USA

Cytokines play a major role in bone remodeling with in vitro and rodent studies showing the involvement of inflammation in the pathogenesis of osteoporosis. Several longitudinal studies have found an association between high levels of inflammatory

makers and greater bone mineral density (BMD) loss in primarily older postmenopausal women. To test this hypothesis in older men, we followed 702 participants (mean age= 73.8 ± 5.9 years) from the Osteoporotic Fractures in Men Study (MrOS) for a median (range) follow-up period of 4.6 (3.7, 6.0) years. Inflammatory markers interleukin-6 (IL-6), tumor necrosis factor alpha (TNF-α), C-reactive protein (CRP) and soluble receptors (SR) for IL-6 (IL-6 SR) and TNF-α (TNF SR1 and TNF SR2) were measured at the baseline visit (2000-2002) using enzyme-linked (ELISA) with the exception of CRP which used an immunoturbidimetric assay. Total hip and femoral neck BMD were measured at baseline and visit 2 (2005-2006) using dual energy x-ray absorptiometry (DXA). Linear regression models were used to assess the association between these inflammatory markers and bone loss and included variables associated with inflammation at $p<0.1$. Multivariate models were adjusted for age, race, BMI, clinic site, smoking, physical activity, health status, diabetes, and congestive heart failure. The annualized rate of hip or femoral neck BMD loss did not vary by quartiles of individual inflammatory markers. In multivariable models, among men with 3-6, 2, and 0-1 inflammatory marker(s) in the highest quartile, the annualized rate of total hip BMD loss was 0.48%, 0.38%, and 0.36%, respectively, p-trend=0.16. The findings were similar for annualized rate of femoral neck BMD loss. While the average rate of bone loss appeared to higher among men with greater inflammatory marker burden, the test for trend did not reach significance. Future studies with larger sample size are needed to provide more definitive data on the association, and determine if this relationship truly varies by sex.

Table. Mean annualized rate of BMD change (95% CI) by number of inflammatory markers in the highest quartile.

Is the Swedish FRAX Model Appropriate for Immigrants to Sweden?. Helena Johansson*[1], Anders Odén[2], Mattias Lorentzon[3], Eugene McCloskey[4], Nicholas Harvey[5], John Kanis[6], Magnus Karlsson[7], Dan Mellstrom[8]. [1]Centre for Metabolic Bone Diseases, University of Sheffield Medical School, Sweden, [2]Sheffield University, United Kingdom, [3]Geriatric Medicine, Center for Bone Research at the Sahlgrenska Academy, Sweden, [4]University of Sheffield, United Kingdom, [5]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, [6]University of Sheffield, Belgium, [7]Skåne University Hospital Malmö, Lund University, Sweden, [8]Sahlgrenska University Hospital, Sweden

FRAX tools are country-specific since age-specific fracture and mortality rates vary between countries. This leads, in the case of immigrants, to the question of whether the model for the original or the new country is most appropriate. The aim of this study was, therefore, to compare the incidences of hip fractures in foreign-born and Swedish-born individuals living in Sweden.

We studied the incidence of hip fracture in all men and women aged 25 years or more in Sweden between 1987 and 2002. The population comprised 5 million Swedish-born and 770,000 foreign-born individuals. The effects of age, sex, and time from immigration, on hip fracture were examined by an extension of Poisson regression.

Incident hip fractures occurred in 249,850 Swedish-born and 13,612 foreign-born individuals. The hip fracture incidence rose with age for both groups and was higher for women than men (Hazard Ratio [HR] 1.6, 95% CI 1.6-1.6)) for Swedish-born and for foreign-born (HR 1.3, 95% CI 1.3-1.4). The hip fracture incidence for the Swedish-born cohort was approximately twice that of the foreign-born cohort. For example, at the age of 50 years the annual hip fracture incidence (per 100,000) was 39 (95% CI 38-39) for a Swedish-born woman and 19 (95% CI 18-21) for a foreign-born woman at 5 years after immigration. At the age of 90 years, the respective incidences were 5629 (95% CI 5523-5738) and 3611 (95% CI 3356-3886). The age-specific hip fracture incidence rose slowly with time from immigration for foreign-born men and women (0.6% per annum, 95% CI: 0.5-0.8%) but remained significantly lower than rates for Swedish-born individuals even after 40 years of residence.Our results indicate that hip fracture incidence in Sweden is substantially lower in immigrants than in the population born in Sweden. Although there is a small rise in incidence after immigration, the incidence remains markedly lower than that observed in Swedish-born individuals. Thus, the use of a FRAX model for Sweden will overestimate the risk of fracture for a foreign-born individual living in Sweden.

SU0326

Multimorbidity in Men with and without Osteoporosis:Results from a Large US Retrospective Cohort Study. Cynthia O'Malley*[1], Nguyet Tran[1], Carol Zapalowski[2], Nadia Daizadeh[1], Thomas Olenginski[3], Jane Cauley[4]. [1]Amgen Inc., USA, [2]Amgen, USA, [3]Geisinger Health System, USA, [4]University of Pittsburgh Graduate School of Public Health, USA

Introduction: As men age, the risk of osteoporosis (OP) and other morbidities increases. Multimorbidity is recognized as a critical element in treatment and management decisions for OP. As data on multimorbidity incidence in this population are few, this study was designed to inform the interpretation of adverse events in clinical trials of OP therapies.

Methods:Using 2004-2009 electronic health records data from an integrated healthcare system, we identified men aged 55–89 with and without OP. OP was defined by OP diagnosis, physician orders for anti-osteoporosis medicine or a fragility fracture. Men with OP were matched to controls on age and length of follow-up. For each condition, incidence rates (IR) were calculated by dividing the number of men with the condition by the total follow-up person-years (P-Y) at risk. Exact Poisson 95% confidence intervals (CI) were also generated.

Results: In this predominantly white population, 3,600 men with OP and their controls were identified. In these matched groups, the mean (standard deviation, SD) age was 70.9 (9.0) years with an average follow-up time of 2.2 years. Compared to the controls, more men with OP had at least 5 comorbidities (94% of men with OP vs. 71% of controls). Hospitalizations were identified in 49% of men with OP and 29% of controls. Overall, coronary artery disease and hypertension were lower in the OP group (Table 1). Hypertension had the largest IRs difference (IR [95% CI] = 45.9 per 1,000 P-Y [40.7–51.6] in the OP group vs.118.7 [108.5–129.7] in the control group). Cerebrovascular disease was slightly lower in the OP group (29.9 [26.0-34.2] vs. 35.9 [31.6- 40.6]; transient ischemic attacks were lower (9.6 [7.5-12.0] vs. 13.1 [10.7-15.9]) but stroke incidence was slightly higher in the OP group (17.5 [14.7-20.8] vs. 15.8 [13.1-18.9]). Men with OP had a higher incidence of deep vein thrombosis/pulmonary emboli (27.8 [24.2-31.9] vs. 19.1 [16.1-22.5]). IRs for depression/anxiety and migraine/headache were higher in the OP group. Diabetes IR was lower in the OP group. In the OP group, IRs for influenza and pneumonia were twice those in the control group (Table 2). Cystitis, sepsis and pancreatitis IRs were 50% higher in the OP group. Vision and musculoskeletal diagnoses IRs were higher in the OP group than the controls.

Conclusion: Multimorbidity burden in older men with OP is considerable. Effective management of OP requires a clear understanding of the medical complexity of these men.

Nationwide Osteoporosis Awareness and Screening Campaigns in Taiwan. Rong-Sen Yang[1], Ding-Cheng Chan*[2]. [1]National Taiwan University Hospital, Taiwan, [2]National Taiwan University Hospital, Taiwan

Objectives: To report the preparation and implementation of large scale nationwide osteoporosis awareness and screening campaigns in Taiwan.

Material and Methods: In 2013, the Wang Jhan-Yang Public Trust Fund (WJYPTF) donated grant to the Taiwanese Osteoporosis Association (TOA) for conducting series of osteoporosis awareness and screening campaigns for the entire country. A press conference was help before inauguration of the campaign to promote public awareness and to attract potential participants. The campaign was divided into four sub-studies with common core theme on osteoporosis/fracture risk screening, fall preventions, and nutrition assessments. Osteoporosis awareness was assessed in most sub-studies. Participants were screened with varies instruments including FRAX®, One-Minute Osteoporosis Risk Test (OMORT), etc. High risk individuals (definitions varied by studies) were referred to hospitals for further assessments and managements. Four sub-studies were analyzed separately because of heterogeneity of the data and participants.

Results: Overall, 74 courses were provided and 4,808 effective questionnaires were collected. Study one found that more than 70% of participants worried about their bone health but fewer than 50% received bone mineral density (BMD) test. Study two found that roughly 60% were considered high risks from FRAX® but only 1/5 of high risk group were referred for further assessments. Supplementation rate of Vitamin D_3 was about 20% and calcium was 35%. Osteoporosis knowledge and awareness significantly improved. Study 3 found that 1/5 of those screened with calcareous ultrasound had low BMD value. Among those referred to hospital with low BMD from ultrasound, 84% had low BMD from DXA. It also found that kyposcoliosis in patients was associated with 3.5 times the risks of having osteoporosis among participants. Study 4 found that 35-70% of participants were screened high risks with the OMORT in Southern Taiwan. More than 40% of men had smoking or drinking history and more than 40% of women had inadequate intake of calcium/dairy products. Participant satisfactions were high across studies.

Conclusions: This nationwide osteoporosis awareness and screening campaigns were flexible to fit local needs and highly appreciated by participants. However, wide variations existed among study protocols. Efforts should be made to collect common variables for comparisons across study sites.

***Disclosures: Ding-Cheng Chan**, None.*
This study received funding from: The authors thanked the WJYPTF for sponsoring the study. The sponsor reviewed and approved the study protocol but do not interfere with study conduction, data analysis or interpretation. The authors also thanked the TOA for coordinating the study.

Rapid resting heart rate is associated with low bone mineral density in Korean adults: the Dong-gu Study. Hee Nam Kim*[1], Sun-Seog Kweon[2], Jin-Su Choi[2], Jung-Ae Rhee[2], Min-Ho Shin[3]. [1]Center for Creative Biomedical Scientists, Chonnam National University, South Korea, [2]Department of Preventive Medicine, Chonnam National University Medical School, South Korea, [3]Chonnam National University Medical School, South Korea

A previous study reported that rapid resting heart rate (HR) was associated with an increased risk of osteoporotic fracture. However, there is no study on the association between HR and bone mineral density. We aimed to evaluate the association between resting HR and bone mineral density (BMD) in the general population. Our study included a total of 8835 Korean (3504 men and 5331 women) community-dwelling individuals aged 50 years and over enrolled between 2007 and 2010. Bone mineral density (BMD) was measured by dual-energy X-ray absorptiometry at lumbar spine and femoral neck skeletal sites. Resting HR was measured via a 12-lead electrocardiogram with participants in the supine position. Multiple linear regression analysis was used to evaluate the relationship between the quartiles of HR and BMD, adjusting for age, height, weight, smoking, alcohol consumption, physical activity, education, medication of hypertension, medication of diabetes, systolic blood pressure, fasting glucose, total cholesterol, parathyroid hormone, 25-hydroxyvitamin D, high-sensitivity C-reactive protein, and estimated glomerular filtration rate. In the fully adjusted model, femoral neck BMD decreased with increasing quartiles of HR (p for trend <0.001). Compared with subjects in the highest HR quartile, those in the lowest quartile had a significantly lower femoral neck BMD (0.832 ± 0.002 vs. 0.815 ± 0.002, $p<0.001$). In conclusion, we found that HR was inversely associated with femoral neck BMD but not lumbar spine BMD. Our results suggest that HR is a likely predictor of osteoporosis in middle- and old-aged Korean adults.

Table Association between resting heart rate and bone mineral density

Heart rate (/min)	Lumbar spine		Femoral neck	
	Model 1	Model 2	Model 1	Model 2
Q1 (≤57)	1.060±0.004	1.059±0.004	0.832±0.002	0.832±0.002
Q2 (58-63)	1.055±0.003	1.055±0.003	0.828±0.002	0.828±0.002
Q3 (64-69)	1.056±0.004	1.057±0.004	0.823±0.002	0.823±0.002
Q4 (≥70)	1.049±0.004	1.049±0.004	0.814±0.002	0.815±0.002
p for trend	0.050	0.062	<0.001	<0.001

All values are given as mean (standard error).
Model 1, adjusting for age, sex, weight and height
Model 2, adjusting for age, sex, weight, height, smoking, alcohol consumption, physical activity, medication of hypertension, medication of diabetes, systolic blood pressure, fasting glucose, total cholesterol, log-transformed parathyroid hormone, log-transformed 25-hydroxyvitamin D, log-transformed high-sensitivity C-reactive protein, and estimated glomerular filtration rate.

Serum 25-Hydroxivitamin D, Skin Phototype, Sun Exposure and the Metabolic Risk in a Large Sample of Subjects Living in the Tropics. Francisco Bandeira[1], Maria Azevedo[2], Aline Correia[3], Larissa Pimentel*[4], Sirley Vasconcelos[5]. [1]University of Pernambuco, Brazil, [2]endocrinology & diabetes, Brazil, [3]Endocrinology & diabetes unit of agamenon Magalhães Hospital, Brazil, [4], Brazil, [5]Hospital Agamenon Magalhães - Recife, Brazil

Background: Vitamin D deficiency is associated with extraskeletal disorders, including insulin resistance, metabolic syndrome, obesity and type 2 diabetes, but few studies have evaluated this association taking into account sun exposure and skin phototype.

Methods: Cross-sectional study involving 729 adults living in the tropics with the aim of evaluating serum 25OHD levels, skin phototype and the sun index and their association with the metabolic risk.

Results: Out of 729 subjects, 77.8% had hypertension and 74.5% had metabolic syndrome. Mean age: 65.13 ± 9.18 years; sun index: 5.71 ± 5.06; skin phototypes (Fitzpatrick's classification) III and IV in 60.6%, BMI: 27.60 ± 5.34; abdominal circumference: 97.29 ± 12.08cm. Mean serum 25OHD was 25.72 ± 10.91 ng/ml and the percentage of patients with 25OHD below 20ng/ml was 31.% and 25OHD below 30ng/ml was 73.1%. Although there were no significant differences between groups with vitamin D deficiency or sufficiency regarding age, BMI and waist circumference, in the group with 25OHD < 20 and sun index of 4.5 ± 4.08, higher levels of triglycerides and lower HDL-C levels were evidenced, compared to the group with 25OHD ⩾20 and sun index: 6.25 ± 5.36: triglycerides: 179.14 ± 103.53mg/dL vs 161.63 ± 90.23, p = 0.029 and HDL-C 43.48 ± 12.38mg/dL vs 45.94 ± 14.14mg/dl, p = 0.018.The group with 25OHD above P25th (18.7 ng/ml) had higher levels of triglycerides than the group with 25OHD < P75th: 176.63 ± 103.79 vs 157.47 ± 80.49,p=0.049.

Conclusion:We found a high prevalence of vitamin D deficiency, which is associated with higher levels of triglycerides and lower levels of serum HDL-C in

individuals with high rates of sun exposure, irrespective of age, BMI or waist circumference, suggesting a direct association between vitamin D deficiency and the mechanisms involved in the insulin resistance syndrome.

The 10-year probability of major osteoporotic fracture of FRAX is useful as a screening item for osteoporosis patients. A cross sectional study of Japanese women. Shinya Tanaka*[1], Sawako Moriwaki[2], Kiyoshi Tanaka[3], Yoshitaka Ikeda[4], Kazuhiro Uenishi[5], Shunpei Niida[2]. [1]Saitama Medical University, Japan, [2]Biobank, National Center for Geriatrics & Gerontology, Japan, [3]Kyoto Women's University, Japan, [4]Department of Biomolecular Sciences, Faculty of Medicine, Saga University, Japan, [5]Kagawa Nutrition University, Japan

Objective; Osteoporotic fractures give rise to deterioration of ADL and QOL. Although medication of osteoporosis is conclusively effective for preventing fracture, 70% of Japanese patients were left in no treatment. We performed cross-sectional study in aim to test the usefulness of FRAX to screen osteoporosis patients

Materials and Methods; Total 237 women, age from 43- to 75-y-o, living in a local governments in Aichi, Japan, were included in this study. They were performed anthropometry, analyzed bone mineral density from the 2nd to the 4th lumbar spine and left femoral neck, took X-ray of the thoracic and lumbar spine, and calculated the 10-year probability of fracture of FRAX. Osteoporosis was diagnosed in accordance with a 2012 revised version of primary osteoporosis of Japan. Multiple logistic regression analysis was performed using body height, body fat percentage, muscle volume, BMI and the 10-year probability of fracture as explanation factors to clarify predictive factors of osteoporosis. The ability in discriminate subjects with either osteoporosis or non-osteoporosis was made sure by making receiver operating characteristic (ROC) curve and calculation of sensitivity and specificity at adequate cutoff points.

Results: Seventy two in 237 (30.4%) women were diagnosed as osteoporosis. Only the 10-year probability of fracture was selected as predictive factor osteoporosis (odds ratio: 1.26; 95%CI: 1.16~1.37). The AUC of ROC was 0.777. If cutoff point was set at 7%, sensitivity and specificity were 74.3% and 65.7% respectively. When women aged over 70-y-o were excluded, 62 in 210 (29.5%) women were diagnosed as osteoporosis. The 10-year probability of fracture was selected as predictive factor osteoporosis (odds ratio: 1.34; 95%CI: 1.21~1.49). The AUC of ROC was 0.797. If cutoff point was set at 7%, sensitivity and specificity were 69.4% and 72.3% respectively

Conclusion; FRAX is useful for screening osteoporosis patients in group examinations.

Trabecular Bone Score as an Indicator for Skeletal Deterioration in Diabetes. Jung Hee Kim*[1], Hyung Jin Choi[2], Eu Jeong Ku[3], Kyoung Min Kim[4], Sang Wan Kim[5], Nam H. Cho[6], Chan Soo Shin[1]. [1]Seoul National University College of Medicine, South Korea, [2]Chungbuk National University Hospital, South Korea, [3]Seoul National University College of Medicine, South Korea, [4]Seoul National University Bundang Hospital, South Korea, [5]Seoul National University College of Medicine, Boramae Hospital, South Korea, [6]Ajou University School of Medicine, South Korea

Type 2 diabetic patients have paradoxically high bone mineral density (BMD) but increased fracture risk. Trabecular bone score (TBS) is a novel texture index that evaluates pixel gray-level variations in lumbar spine dual energy X-ray absorptiometry (DXA) images, and is related to bone microarchitecture independent of bone mineral density (BMD). We investigated the ability of lumbar spine TBS to predict skeletal deterioration in diabetic patients including men, and elucidated the underlying mechanism in a community-based Korean cohort.

We included 1,229 men and 1,529 postmenopausal women over 50 years old in the Ansung cohort. Cross-sectional data were collected from subjects participating in an ongoing prospective community-based cohort study from 2009 to 2010. Biochemical parameters, lumbar spine TBS and BMD from DXA image were measured.

The prevalence of diabetes was 325 (26.7%) in men and 370 (24.4%) in women. Lumbar spine TBS was lower in men with diabetes than in non-diabetic men (1.287 $\pm$ 0.005 vs. 1.316 $\pm$ 0.003, $p<0.001$), whereas lumbar spine BMD was higher in men with diabetes (1.135 $\pm$ 0.010 vs.1.088 $\pm$ 0.006 g/cm^2). Lumbar spine TBS was lower in women with diabetes than in non-diabetic women only in an unadjusted model (1.333 $\pm$ 0.004 vs. 1.353 $\pm$ 0.003). However, women <60 years (n=507) with diabetes had lower TBS than those without diabetes even after adjusted for covariates (p=0.032). Diabetes was not associated with BMD at femur sites in both genders. TBS was negatively correlated with HbA1c, fasting plasma glucose, fasting insulin, and homeostasis model assessment -insulin resistance (HOMA-IR), but not with HOMA-β cell function in both genders. Only serum triglycerides among lipid parameters were negatively associated with TBS in both genders in unadjusted and adjusted models. TBS was also inversely related with hs-CRP, an inflammatory marker, in both genders irrespective of age and BMI

The inverse association between lumbar spine TBS and insulin resistance may make it an indicator for determining skeletal deterioration in diabetic patients who have high BMD.

Unintentional Weight Loss and Fracture: The Global Longitudinal Study of Osteoporosis in Women. Juliet Compston*[1], Allison Wyman[2], Stephen Gehlbach[3], Nelson Watts[4], Ethel Siris[5], Coen Netelenbos[6], Adolfo Diez-Perez[7], Cyrus Cooper[8], Roland Chapurlat[9], Silvano Adami[10], Jonathan Adachi[11], Gordon FitzGerald[12]. [1]University of Cambridge School of Clinical Medicine, United Kingdom, [2]UMASS Medical School, USA, [3]University of Massachusetts, USA, [4]Mercy Health Osteoporosis & Bone Health Services, USA, [5]Columbia University College of Physicians & Surgeons, USA, [6]VU Medical Center, The Netherlands, [7]Autonomous University of Barcelona, Spain, [8]University of Southampton, United Kingdom, [9]E. Herriot Hospital, France, [10]University of Verona, Italy, [11]St. Joseph's Hospital, Canada, [12]UMASS Medical School, USA

Background: The adverse effects of weight loss on bone mineral density in postmenopausal women are well documented, and increased risk of distal forearm and hip fractures has been reported in studies with average follow-up periods of around 6 years after weight loss. The aim of this study was to investigate the effects of unintentional weight loss in postmenopausal women on the incidence of clinical fractures at multiple sites in the year following weight loss.

Methods: GLOW is an observational longitudinal study of non-institutionalized women aged ⩾55 years recruited from 723 primary physician practices in 10 countries. Self-administered questionnaires were mailed and data collected included demographics, medical history, fracture occurrence, medications and weight loss of 10 lb (4.5 kg) or more over the preceding year. Cox models treating weight loss as a time-varying covariate were used to predict fracture in the following survey year, adjusting for factors such as age, prior fracture, co-morbidities, and falls that we have previously shown to be associated with the specific fracture.[1]

Results: Unintentional weight loss of of ⩾10 lb during the previous 12 months was reported in Year 2 by 3405 (8.0%) of 42,756 and in Year 3 by 3322 (7.7%) of 43,004 women. After adjustment for clinically relevant variables, a significantly increased risk was seen for hip (HR 1.83, 95% CI 1.25–2.69, $p<0.01$) and spine fracture (HR 1.46, 95% CI 1.02–2.09, $p=0.04$) in the year following the unintentional weight loss.

Conclusions: Unintentional weight loss in postmenopausal women is associated with increased risk of hip and spine fracture within the year following weight loss. The rapid time course of this increase in risk has not previously been reported and emphasizes the need for prompt fracture risk assessment and appropriate management in women with unintentional bone loss.

SU0333

Use of the Safe Functional Motion-6 test to predict incident osteoporotic fractures at any site. Christopher Recknor*[1], Julie Recknor[2], Norma MacIntyre[3]. [1]United Osteoporosis Center, USA, [2]United Osteoporosis Centers, USA, [3]McMaster University, Canada

Purpose: In the osteoporosis (OP) population, we have shown that physical performance of daily activities, as assessed by the Safe Functional Motion test-6 tasks (SFM-6), predict incident morphometric vertebral fractures after adjusting for known risk factors. The total SFM-6 score is calculated as a percentage of the maximum points possible such that a score of 100 reflects consistent use of 'safe' movement patterns. The current study determines if 'safe' physical functioning, as measured by the SFM-6, is necessary to consider in addition to factors known to influence the risk of any osteoporotic fracture.

Methods: A prospective review of an OP clinic database was conducted to identify men and women with an initial SFM-6, history of prevalent osteoporotic fracture at any site, history of injurious falls, femoral neck bone mineral density (fnBMD), and 1- and 3-y follow up data (n=1490 and 884, respectively) for medication use and incident osteoporotic fracture. Multiple logistic regressions, adjusted for gender, age, prevalent fracture at any site, injurious fall(s), fnBMD at baseline, and bone sparing medication use, were used to determine whether SFM-6 score predicted incident osteoporotic fracture at follow-up visits.

Results: Table 1 summarizes the characteristics of the sample. Baseline SFM-6 score was a significant independent predictor of incident osteoporotic fracture at any site at 1-y follow-up (adjusted odds ratio (95%CI) = 0.80 (0.71-0.90) for each 10-pt increase in score; $p < 0.001$) and 3-y follow up (adjusted odds ratio (95%CI) = 0.77 (0.69-0.85) for each 10-pt increase in score; $p < 0.0001$). Baseline fnBMD and OP

medication use were also significant predictors at 1-y ($p = 0.01$ and $p < 0.05$, respectively) and 3-y ($p < 0.0001$ and $p = 0.0001$, respectively).

Conclusions: For every 10-pt increase in SFM-6 score (i.e., 'safer' movement patterns), the odds of a future osteoporotic fracture at any site decreases by 20% at 1-y and 23% at 3-y after adjusting for factors known to impact fracture risk. We conclude that, in the OP population, it is necessary to consider the quality of habitual functional movements when assessing the risk of incident fracture at any site.

	1-y Follow Up (n=1490)		3-y Follow Up (n=884)	
	Incident Fracture (n=87)	No Incident Fracture (n=1403)	Incident Fracture (n=186)	No Incident Fracture (n=698)
Female, n (%)	76 (87%)	1261 (90%)	165 (89%)	633 (91%)
Age, y*	70.4 ± 10.5	67.9 ± 10.5	71.0 ± 10.1	66.5 ± 10.0
No injurious falls, n (%)	73 (84%)	1274 (91%)	163 (88%)	644 (92%)
fnBMD, g/cm^2*	0.71 ± 0.09	0.75 ± 0.12	0.71 ± 0.11	0.76 ± 0.12
On bone meds, n (%)	65 (75%)	1111 (79%)	156 (84%)	625 (90%)
SFM-6 score*	67.6 ± 21.7	77.4 ± 17.1	60.7 ± 20.7	80.0 ± 15.2

BONE HEALTH COLLABORATIVE FRACTURE PREVENTION PLATFORM: *New tools that will enable the rapid implementation of a Fracture Liaison Service program focused on provider performance, quality improvement, care coordination and community*. Debbie Zeldow[1], David Lee*[2]. [1]National Bone Health Alliance, USA, [2]NBHA, USA

Due to the advent of healthcare reform, the healthcare system is shifting from one rooted in episodic care to one that focuses on better managing chronic disease conditions and improving the overall health status of the patient population with value and performance as the two key drivers for success.

The proven Fracture Liaison Service (FLS) model of care provides a unique opportunity to address the nearly 80% post-fracture care gap while helping providers, practices and organizations transition to the new pay-for-performance models and federal mandates that tie payment and reimbursement more closely to the health of their patients.

CECity, National Osteoporosis Foundation (NOF), and the National Bone Health Alliance (NBHA) are partnering with UPMC, MedStar Georgetown University and Creighton Alegent to launch a 15 month, Fracture Liaison Service (FLS) Demonstration Study through funding support by Merck & Co. to:

implement the proven FLS model of post-fracture care coordination in the open system

utilize CECity's cloud-based *MedConcert®* platform that will create a means for sites to automate, benchmark and improve their performance around selected osteoporosis/post-fracture quality measures and patient care

create a registry that can collect and report on each site's data

Through the MedConcert FLS platform, participating providers, practices and organizations will be able to utilize a secure social network to share best practices and connect in meaningful ways to address a variety of critical needs, including pay for performance, population health management, performance improvement, professional certification, patient experience and outcome surveys, care coordination, and much more.

The suite of MedConcert FLS platform tools built with input from the sites includes:

Patient registry

Patient task tracker

Quality measure performance dashboard (which allows for real-time tracking of performance by site or in comparison with other sites and national averages)

Quality improvement tools, resources and interventions to drive performance change

Coordination of care application that allows all members of the care team, regardless of institution, to coordinate patient care and follow-up

SU0335

Differences in Characteristics of Osteoporosis Patients Treated by Endocrine and Non-Endocrine Specialties. Leyda Callejas*[1], Philip Orlander[2], Kelly Wirfel[3], Nahid Rianon[4]. [1]University of Texas at Health Science Center, USA, [2]Department of Endocrinology Diabetes & Metabolism, University of Texas Health Science Center, USA, [3] Department of Endocrinology Diabetes & Metabolism, University of Texas Health Science Center, USA, [4]UTHealth The University of Texas Medical School at Houston, USA

Inadequate treatment of osteoporosis remains a challenge for physicians managing patients with this chronic disease. There was an increase in number of osteoporosis related office visits by older patients in the past decade, and similar percentages of these visits were made to the primary care physicians and other specialties. Many specialties are treating osteoporosis including OB/GYN, Internal Medicine and its subspecialties, and Orthopedics. A prior study at our institution noted that majority of osteoporosis patients were seen by endocrinologists. As a follow up, we investigated differences in characteristics of osteoporosis patients treated by endocrine and non-endocrine specialties.

A cross-sectional study collected information on demographics, co-morbidities, bone mineral densities in femur neck and spine regions and duration of osteoporosis treatment for 100 men and women 50 years or older who visited UT Health outpatient clinics (Internal Medicine, Endocrinology, Rheumatology, Geriatrics and Family Medicine) for osteoporosis care between January and December of 2012. Electronic chart review identified patients with a diagnosis of osteoporosis or related fractures using ICD 9 codes. A bivariate analysis described patient characteristics by specialty (endocrine vs. non-endocrine). A multivariate regression model determined patient characteristics associated with visit made to Endocrinologist.

Mean (SD) age for all patients was 70 (11) years with majority being women (89%), Caucasians (51%) and seen by endocrinologist (59%). Mean age of patients seen by endocrine was younger than those seen by other specialty (68 vs 73 years, $p < 0.05$). Younger age (beta coefficient, 95% confidence interval = 0.03, 0.01 to 0.05) and longer duration of osteoporosis treatment (-0.06, -0.10 to – 0.02) were significantly ($p<0.05$) associated with patients being seen by Endocrinologists.

Given their specific training in the field, endocrinologists may be more comfortable managing patients at risk of known side effects from long duration use of available medications for osteoporosis treatment. We also presume that a relative unfamiliarity in managing osteoporosis in younger age group by other specialties may be attributable to younger patients being seen by endocrine specialty. Our results need confirmation with a larger study. Physician characteristics from various specialties treating osteoporosis may also shed more light on our findings.

SU0336

Factors Associated with Non-Receipt of Osteoporosis Therapy Following an Osteoporotic Fracture. Delia Scholes*[1], Do Peterson[2], Akhila Balasubramanian[3], Cynthia O'Malley[4], Jane Grafton[2], Jackie Saint-Johnson[2], Denise Boudreau[2]. [1]Group Health CooperativeGroup Health Research Institute, USA, [2]Group Health Research Institute, USA, [3]Amgen Inc., USA, [4]Amgen, Inc., USA

Purpose: The two- to three-fold increased risk of future fracture after an initial osteoporotic fracture offers an important intervention opportunity. However, rates of post-fracture osteoporosis (OP) care are low. We evaluated factors associated with non-receipt of post-fracture OP pharmacotherapy in a population-based sample of female health plan enrollees.

Methods: The study population consisted of women aged >55 years who were diagnosed with an osteoporotic fracture between 2005 and 2012 and who were enrollees of Group Health Cooperative (GH), a Pacific Northwest health plan. Patient characteristics, diagnoses, medications, and healthcare utilization for the 12 months prior to the index fracture were accessed from GH administrative databases. Their associations with non-receipt of pharmacotherapy in the 6 months following the index fracture were assessed using Poisson regression to estimate age-adjusted relative risks (RR) and 95% confidence intervals (CI).

Results: Of 7,186 women diagnosed with osteoporotic fractures (mean age 79 years; 84% white), 20% received post-facture OP pharmacotherapy within 6 months. Non-receipt of pharmacotherapy increased over calendar time (RR=1.07, CI 1.04-1.10 for 2011-2012 vs 2005-2008)(Table). Women who had already received OP pharmacotherapy in the prior 12 months had significantly lower risk of non-receipt of post-fracture pharmacotherapy (RR=0.34, CI 0.32-0.38), as did those with more than one primary care visit (RR 0.93, CI 0.90-0.97 for 5-10 visits) and those with a pharmacy benefit (RR=0.92, CI 0.90-0.95) in the prior 12 months. Risks of non-receipt of pharmacotherapy also were lower with previous DXA testing, use of glucocorticoids or calcitonin, and with cancer, rheumatoid arthritis or OP diagnoses. Risks of non-receipt of care were higher for index fractures of the humerus and forearm relative to other sites, younger age, Black race, higher BMI, and prior diabetes or dementia diagnoses.

Conclusions: Women who received OP therapy or who had DXA in the 12 months prior to index fracture were far more likely to receive post-fracture therapy, as were other at-risk groups. However, the low proportion of women, overall, who received post-fracture pharmacotherapy points to further opportunities for future fracture prevention. Results also suggest that receipt of post-fracture therapy can be enhanced by continuity of primary care and by provision of a pharmacy benefit.

Table. Association of selected variables with non-receipt of osteoporosis pharmacotherapy within 6 months of osteoporotic fracture

Characteristic in the 12 Months prior to index fracture or at fracture index date		Relative Risk[1]	95% CI

Relationship of Spine Fracture Burden to Reduced Lung Volume in Postmenopausal Women With Osteoporosis. John Krege*[1], David Kendler[2], Kelly Krohn[3], Harry Genant[4], Pierre-Yves Berclaz[5], Corina Loghin[5]. [1]Eli Lilly & Company, USA, [2]Associate Professor University of British Columbia, Canada, [3]Lilly USA, LLC, USA, [4]UCSF/Synarc, USA, [5]Eli Lilly & Company, USA

Purpose: Pulmonary function may be compromised in patients with osteoporosis due to the presence of vertebral fractures. The aim of this study was to assess the relationship between burden of vertebral fractures and pulmonary function in elderly women with osteoporosis. Methods: This was a single-visit study measuring pulmonary function via spirometry in women (70 to 91 years of age) with osteoporosis and at least 1 moderate or severe vertebral fracture. Spinal deformity index (SDI) score was calculated as the sum of the semi-quantitative (SQ) scores of T4 to L4 from lateral spine radiographs (no fracture = 0, mild = 1, moderate = 2, severe = 3). Arm span-height was assessed as a measure of height loss, and current back pain was evaluated by a 100-point visual analog scale (VAS). Results: Forty-one women were enrolled in the study. The mean age was 78 years, arm span 161 cm, height 157 cm, weight 59 kg, and SDI 7 (range 2 to 22). SDI positively correlated with arm span-height (r=0.438, P=0.004). Height decreased and arm span-height increased each by about 0.5 cm per unit increase in SDI. SDI negatively correlated with forced inspiratory vital capacity (r=-0.41, P=0.008) and inspiratory time (r=-0.407, P=0.008). Forced inspiratory vital capacity and inspiratory time decreased by 1.6% and 2.4%, respectively, for each unit increase in SDI. SDI did not significantly correlate with forced inspiratory flow at 50% of forced inspiratory volume, forced inspiratory volume in 1 second, or peak inspiratory flow rate (all P-values >0.5). SDI also was not correlated with current back pain VAS score (P=0.403). Conclusion: Increased spine fracture burden was associated with decreased inspiratory lung volume, decreased duration of inspiration, and height loss. However, increased spine fracture burden was not associated with a change in inspiratory flow. These findings are consistent with increasing spine fracture burden reducing the lung volume. This study highlights the clinical relevance of vertebral fracture burden and quantifies its impact on lung volume.

Rural distribution and scope of a centralized, electronic consult program for patients with recent fracture. Richard Lee*[1], Megan Pearson[2], Kenneth Lyles[3], Patricia Jenkins[2], Cathleen Colon-Emeric[4]. [1]Duke University, USA, [2]Durham VAMC, USA, [3]Duke University Medical Center, USA, [4]Duke University Medical Center, USA

Background: While Fracture Liaison Services have been shown to significantly improve osteoporosis treatment, they require accurate and timely identification of recent fracture patients by the specialty team, which may be less feasible for people living in rural areas. We sought to determine whether a regional post-fracture E-consult program through a single, centralized Veterans Affairs Medical Center (VAMC) was adequately identifying rural and highly rural patients. Over 43 percent of the Veterans in this region live in rural or highly rural areas.

Objective: To evaluate the geographic distribution of the patients who received an E-consult and to assess if the E-consult program preferentially served urban patients.

Method: The E-consult program identified Veterans with potential osteoporotic fractures from inpatient and outpatient encounter data, based on ICD9 diagnosis codes (800-829) from the central data warehouse. The medical record of an eligible patient was reviewed by a bone health specialist, and an E-consult note was sent to the patient's primary care provider that specified recommendations for further management. Patients were identified as living in a rural or highly rural area if their ZIP code was not in a US Census Bureau-defined urban area, population density greater than 1000-persons per square mile.

Results: From Oct 2013 through March 2014, 176 E-consults were completed. Of those, 88 (50%) were for patients residing in a rural or highly rural area. Fifty-four (61%) of these resided outside of the central VAMC's catchment area. There was no statistical difference between the number of rural and highly rural E-consults completed and the number expected ($P = 0.17$).

Conclusion: A centralized, E-consult program can impartially provide specialty bone health services to patients residing in rural and highly rural areas.

Trends in Glucocorticoid-Induced Osteoporosis Management Among Seniors in Ontario, 1996-2012. Jordan Albaum*[1], Linda Levesque[2], Andrea Gershon[3], Guoyuan Liu[2], Yan Yun Liu[1], Suzanne Cadarette[4]. [1]University of Toronto, Canada, [2]Queen's University, Canada, [3]Sunnybrook Health Sciences Centre, Canada, [4]University of Toronto, Canada

Glucocorticoid (GC) therapy is the most common cause of secondary osteoporosis. Since 1996, North American osteoporosis practice guidelines recommend that all patients starting chronic oral GC therapy receive bone mineral density (BMD) testing and/or osteoporosis treatment. We sought to examine trends in GC-induced osteoporosis management over time. We identified all community-dwelling chronic oral GC users aged 66 years or older in Ontario using healthcare utilization data from 1996 to 2012. Chronic oral GC use was defined as ⩾ 2 oral GC prescriptions dispensed and ⩾ 450 mg prednisone equivalent over a 6-month (180-day) period. Osteoporosis management by BMD test (sensitivity=98%, 95%CI=95.9-99.1; specificity=93%, 95%CI=89.9-95.4) and/or osteoporosis treatment within 6 months of starting chronic oral GC therapy was examined by sex and year. Results were summarized using descriptive statistics. We identified 72,099 male (mean age=74.6, SD=6.3) and 95,975 female (mean age 75.1, SD=6.6) patients on chronic oral GC therapy. Over three quarters of patients (n=131,602) received ⩾ 675 mg, and two thirds (n=109,888) received ⩾ 900 mg within the 6-month window. Overall, 15% (7% BMD, 12% treatment) of men and 36% (13% BMD, 30% treatment) of women on chronic GC therapy received osteoporosis management. GC-induced osteoporosis management increased steadily from 2% (men) and 10% (women) in 1996, to a high of 23% (men) and 48% (women) in 2007, with a gradual decline to 17% (men) and 38% (women) in 2012. Rates of GC-induced osteoporosis management improved significantly over time in both sexes yet remain low, particularly among men. This represents a missed opportunity for fracture prevention among patients requiring prolonged GC therapy. Targeted interventions are needed to reduce the burden of fracture-related morbidity associated with GC-induced osteoporosis.

An Early Development Budget Impact Model for the Use of Melatonin in the Treatment and Prevention of Osteoporosis. Corry Bondi*[1], Rahul Khairnar[1], Khalid Kamal[1], Paula Witt-Enderby[2]. [1]Duquesne University Clinical, Social & Administrative Sciences, USA, [2]Duquesne University,School of Pharmacy, USA

The National Osteoporosis Foundation estimates approximately 9 million adults with and an additional 43 million adults at-risk for developing osteoporosis (OP). By 2030, 68 million adults (>50 years), will either have osteoporosis or be at-risk. The economic impact of OP is estimated to be $25.3 billion by 2025, which includes direct medical and non-medical expenses as well as indirect expenses like loss of work productivity. This OP burden underscores the importance of developing novel OP therapies, like melatonin, that have a high safety profile and that are well tolerated. Many studies demonstrate an association between melatonin and bone where a decline in circulating melatonin levels negatively impacts bone (e.g., shift work) while supplementation with melatonin improves bone marker turnover in perimenopausal women (Melatonin Osteoporosis Prevention Study, MOPS; NCT01152580). Given the chronic nature of osteoporosis coupled with high treatment costs, economic evaluation of melatonin over existing treatments could be very useful for those who manage and plan for health-care budgets. Budget impact models (BIM) provide necessary and sometimes unavailable evidence to understand both costs and outcomes of various treatment scenarios that may involve providing a new therapy. The goal was to determine the budgetary impact of addition of melatonin to treat and prevent OP in the US population from a payer perspective. A 1-year BIM with a hypothetical plan population of one million was utilized for the analysis for osteoporosis and osteopenia. Drug prices (WAC) for melatonin and comparators were taken from the Red Book; market share and prevalence data were taken from the literature. Univariate sensitivity analysis was integrated in the model and uncertainty in market share and drug prices was assessed. All costs were adjusted to 2013 US dollars. The model predicted 37,000 members with osteoporosis while 133,760 members with osteopenia. Market share for comparators in osteopenia were ibandronate (24.4%), alendronate (25.2%), zolendronate (16.2%), teriperatide (23.2%) and risedronate (10.96%) and for osteoporosis were ibandronate (51.3%) and teriperatide (48.7%). In osteopenia, the introduction of melatonin produced a per member per month (PMPM) change of -$2.92 suggesting major cost savings and in osteoporosis, a PMPM change of -$0.06 was estimated. As newer data on efficacy, costs and utilization on treatments gets available, the BIM can be updated to reflect the changes and estimate the economic impact of new treatments.

Reduction of fracture rate for treatment based on quality metrics in glucocorticoid-induced osteoporosis (GIO). Robert Overman*[1], Bradley Layton[2], Joel Farley[3], Alan Brookhart[3], Chad Deal[4], Margaret Gourlay[1]. [1]University of North Carolina, USA, [2]University of North Carolina, USA, [3]University of North Carolina, USA, [4]Cleveland Clinic Foundation, USA

Quality metrics have been proposed for glucocorticoid-induced osteoporosis (GIO) including receipt of anti-osteoporosis medications (AOM) following initiation of oral glucocorticoids (GC). However, fracture has not been a primary endpoint in any GIO trial. We created a cohort of new-users of GC based on first observable GC fill (index date) with a washout period (365 days) and having a prednisone equivalent daily dose of ⩾10mg and used chronically (⩾90 days). The cohort was comprised of 7,887 women from the Truven Health Analytics' MarketScan® Commercial and Medicare Supplemental databases (2000-2012) ⩾50 years of age at index date. Patients were continuously enrolled in their health plan and had no fracture, GC, or AOM (bisphosphonate, denosumab, teriparatide) fills during the washout period. Continuous health plan enrollment and a GC fill for ⩾90 days post-index date were also required. The quality measure (QM) period was 90 days post-index fill and receipt of QM was based on an AOM fill during this period or within 14 days before GC fill. Fractures included in the composite outcome were hip, humerus, pelvis, spine, and wrist. Covariates measured during washout: diseases and drugs associated with osteoporosis, Charlson comorbidity index, age, region, fracture, and healthcare utilization. Measured during both washout and QM period: DXA scan and diagnosis of osteoporosis. To reduce confounding, we created a propensity score of the likelihood of receipt of a QM using the measured covariates which was converted into stabilized IPTW (inverse probability of treatment weights), and the weights were applied to statistical outcome models. Cox proportional hazards models were used to estimate hazard ratios (HR) with 95% confidence intervals (95% CI) using the IPTW weights. Follow-up began at the end of the QM period (90 days post-index), and patients were followed for a maximum of 3 years until fracture, end of continuous enrollment, or AOM use after QM window. After weighting, mean age was 66.7 (95% CI 66.5, 67.0), 3.9% had osteoporosis, and 11.6% received AOM during the QM period. Mean days follow-up for QM was 639 days, and non-QM was 541 days. Fractures occurred in 3.2% of QM patients and 4.0% of non-QM patients. The weighted fracture HR was 0.67 (95% CI 0.46, 0.98). In women 50 and older, receipt of AOM within 90 days of chronic glucocorticoid initiation is associated with a 33% reduction in fracture risk by 3 years.

Table 1. Fracture Hazard Ratios (HR) for initiation of an anti-osteoporosis medication within 90 days of chronic high-dose oral glucocorticoids in women ≥50 years of age

Hazard Ratio (HR) Method	HR (95% Confidence Interval [CI])
Unadjusted	0.79 (95% CI 0.56, 1.11)
Adjusted using measured covariates	0.77 (95% CI 0.54, 1.12)
IPTW weighted	0.67 (95% CI 0.46, 0.98)

Adjusted HR and Weighted HR include diseases and drugs associated with osteoporosis, DXA scan use, Charlson comorbidity index, age, region, fracture, and healthcare utilization

The Effect of Dietary Calcium versus Supplemental Calcium on Vascular and Bone Markers in Healthy Postmenopausal Women: Results of A 12-Month Pilot Clinical Trial. Angel Ong*[1], Hope Weiler[2], Michelle Wall[3], Rouba Haddad[4], Emily Rose Hamilton-Leavitt[4], Stella Daskalopoulou[5], David Goltzman[6], Suzanne Morin[6]. [1]McGill University Health Centre Research Institute, Canada, [2]McGill University, USA, [3]McGill University Health Centre Research Institute, Canada, [4]School of Dietetics & Human Nutrition, McGill University, Canada, [5]McGill University, Canada, [6]McGill University, Canada

Purpose: Calcium supplements are reported to be associated with increased rates of cardiovascular events. Whether dietary calcium has similar effects to calcium from supplements on vascular and bone markers is unknown. This 12-month trial was piloted to determine the feasibility of an RCT and to estimate the effect of dietary calcium versus supplemental calcium on selected vascular and bone markers in postmenopausal women.

Methods: Healthy postmenopausal women ⩾ 55 years not taking calcium or vitamin D supplements were randomized to: a dietary intervention (DI) of 1200 mg calcium from food + 400 IU vitamin D supplement, or a supplemental intervention (SI) with 750 mg calcium from $CaCO_3$ supplements (and 450 mg calcium from food) + 800 IU vitamin D supplement daily. Correlations were assessed between baseline dietary intakes of calcium and vitamin D and arterial stiffness measured as carotid-femoral pulse wave velocity (cfPWV). Using repeated measures ANOVA, between-group differences in cfPWV (primary outcome), BP, anthropometric measures, vascular and bone biomarkers were examined at 0, 6, and 12 months. Dietary calcium and vitamin D intakes and compliance with supplements were determined every month.

Results: Thirteen participants were randomized (mean age 63 [SD 7] years; BMI 25 [SD 3] kg/m^2; waist circumference 81 [SD 8] cm; systolic BP 111 [SD 5] mmHg; diastolic BP 71 [SD 10] mmHg). At baseline, no associations were found between calcium and vitamin D intakes and cfPWV. Four participants were lost to follow-up early in the study. Results of the remaining 9 participants are presented. There were no significant between-group differences in cfPWV, BP, anthropometric measures, vascular or bone markers at any time points (final data in Table 1). Source of calcium and vitamin D did not significantly affect cfPWV nor 25(OH) vitamin D and PTH concentrations over the study period (Figure 1). Higher dietary calcium and vitamin D intakes were observed in the DI group as compared to the SI group throughout the trial and each group met their target intake. Overall compliance with supplements was 93%.

Conclusion: Although the sample size was small, we found no differential effect of dietary calcium intake as compared to supplemental calcium intake on vascular or bone markers. Subsequent to these findings and the high level of compliance of the participants with the interventions, a randomized control trial is currently ongoing (*ClinicalTrials.gov* ID: NCT01731340).

Table 1. Anthropometric measures, vascular and bone markers measured at 12-months in each intervention group

	Dietary intervention (n=4)	Supplemental intervention (n=5)	*P* Value
Energy intake (kcal)	1856 (1595-2319)	1862 (1537-3082)	0.605
BMI (kg/m^2)	24 (3)	26 (3)	0.357
Waist circumference (cm)	80 (9)	86 (11)	0.379

SU0343

Associations between serum parathyroid hormone concentrations, bone turnover markers and bone traits in Caucasian pre-menopausal females and males with fairly high dietary calcium intake. Suvi Itkonen*[1], Elisa Saarnio[2], Virpi Kemi[3], Heini Karp[3], Minna Pekkinen[4], Juha Risteli[5], Marja-Kaisa Koivula[6], Harri Sievanen[7], Christel Lamberg-Allardt[1]. [1]University of Helsinki, Finland, [2]University of Helsinki, Finland, [3]Calcium Research Unit, Department of Food & Environmental Sciences, University of Helsinki, Finland, [4]Folkhälsan Institute of Genetics, University of Helsinki, Finland, [5]University of Oulu, Finland, [6]Northern Finland Laboratory Centre Nordlab & Department of Clinical Chemistry, Institute of Diagnostics, University of Oulu, Finland, [7]The UKK Institute for Health Promotion Research, Finland

Dietary phosphorus (P) intake increases serum parathyroid hormone (S-PTH) concentrations acutely, thus, S-PTH can be considered as a surrogate marker of short-term dietary phosphorus intake. Earlier studies have shown that dietary P intake has negative effects on bone metabolism, and in some studies high P intake has also been associated with lower bone mineral density (BMD).

The aim of the study was to investigate the associations between S-PTH levels, certain bone turnover markers, and bone traits measured by peripheral quantitative tomography (pQCT) among 37-47-year old premenopausal females and males (n=550). Bone traits were measured in distal tibia and radius, as well in radial and tibial shaft. Serum PTH, intact pro-collagen type I amino-terminal propeptide (S-iPINP), and collagen type 1 cross-linked C-terminal telopeptide (S-CTX) were determined. Background and nutrient intake data were collected by a questionnaire.

The data was analyzed by regression models, and the final model included S-PTH, weight, height, calcium (Ca) intake, smoking, physical activity, and serum 25-hydroxy vitamin D concentrations (among females also contraceptive use). Among females, S-PTH was negatively associated with bone mineral content and cortical bone area in distal radius (p=0.015, p=0.012) and distal tibia (p=0.010, p=0.050). In the model including height, age, and weight, S-PTH was negatively associated with total area of distal tibia (p=0.042), but the significance disappeared when other confounding factors were introduced to the model. Further, S-PTH was associated with increased S-CTX concentrations (p=0.005), indicating increased bone resorption. No results were found between S-PTH and bone formation marker S-iPINP, or S-PTH and BMD (p for all >0.05). Among males, no associations between S-PTH and bone turnover markers or pQCT bone traits were found (p for all >0.05).

Notable is that Ca intake among our study subjects was fairly high (approximately 1200 mg/d among both sexes), which may hide the negative associations between P-related S-PTH and the measured bone traits. Among other factors, in this study height and weight were the most important determinants of bone traits. To conclude, these results indicate that high Ca intake may protect bone from the detrimental effects of high P intake and accelerated bone degradation indicated by increased S-PTH concentrations, but the results may be different in a population with lower Ca intake or post-menopausal females.

GPR40 limits bone loss induced by ovariectomy upon high fat diet. Claire Philippe*. INRA, France

In the current context of longer life expectancy, the prevalence of age-related diseases such as osteoporosis is increasingly important. The cost of treatment of these diseases is a major public health problem and the implementation of strategies tailored nutritional prevention appears to be an excellent alternative to conventional treatments. However, the study of biological activities of nutrients is too marginal for some tissues and certain types of molecules; this is particularly the case of bone and lipids, especially fatty acids. They are however capable of modulating the fate of bone either indirectly or directly by systemic mechanisms at the bone cell.

Descriptions of the direct effects of fatty acids at the cellular level by activating specific receptors are becoming increasingly common in the literature. Recently, the membrane receptor GPR40 (G Protein Coupled Receptor 40) was highlighted for its interaction with the free long-chain fatty acids as well as the existence of an osteoporotic phenotype in mice invalidated for GPR40.We formerly demonstrated that GPR40 prevents from osteoporosis establishment using synthetic agonist. Here, we questioned whether stimulation of GPR40 by fatty acids, the natural ligands for GPR40, may parallel with its described beneficial effects on bone. In this study we demonstrated for the first time that GPR40 limits bone loss induced by ovariectomy upon high fat diet. Taken together, our results demonstrate that GPR40 mediates beneficial effects of high fat diets mainly by targeting the bone cell coupling and subsequent osteoclastic bone resorption.

A New Paradigm for Vitamin D Supplementation: Treat to Target Using a Vitamin D Panel. Neil Binkley*[1], Ravinder Singh[2], Joan Lappe[3], Diane Krueger[1], Marc Drezner[4], Robert Blank[5]. [1]University of Wisconsin, Madison, USA, [2]Mayo Clinic, USA, [3]Creighton University Osteoporosis Research Center, USA, [4]University of Wisconsin, USA, [5]Medical College of Wisconsin, USA

Variability in 25(OH)D response to vitamin D supplementation is widely recognized. It is possible that this variability reflects, in part, differences in vitamin D absorption and/or degradation. However, all expert group recommendations, and most randomized prospective studies, endorse a single fixed dose for all individuals, an approach that does not assure attainment of any pre-defined, ''target'' 25(OH)D level. To improve the ability to individualize vitamin D supplementation, we measured serum 25(OH)D, cholecalciferol (D_3), and 24, $25(OH)_2D$ levels in women prior to and following vitamin D administration, to determine if baseline concentrations of these compounds explain the 25(OH)D increment following supplementation. In 91 postmenopausal women who received 2300 or 2500 IU of daily D_3 supplementation for 4-6 months, a ''vitamin D panel'' consisting of serum D_3, 25(OH)D and 24, $25(OH)_2D$ was measured in a single analytical run at baseline and study conclusion. At study entry, subjects had a 25(OH)D level that ranged from 10-30 ng/mL. Following supplementation, 25(OH)D levels ranged from 12-62 ng/mL. From these data, we developed a multiple linear regression model for post-treatment 25(OH)D with the equation: final 25(OH)D = 8.3 + (1.05* initial 25(OH)D) – (7.7* initial $24,25(OH)_2D$) + (0.53* final D_3) + (4.2* final $24,25(OH)_2D$). This model has an adjusted $R^2 = 0.55$, thus accounting for approximately half of the observed variance in the final 25(OH)D level. Neither dose nor duration of treatment was associated with the increment in 25(OH)D. Initial serum D_3 level could not be included in this model because its distribution did not satisfy the assumptions of normality and equal variance, even after transformation. The contributions of circulating D_3 and $24,25(OH)_2D$ to the regression model can be understood heuristically as representing the contributions of intestinal absorption and clearance, respectively. Incorporation of vitamin D panel data from larger studies of supplementation into the regression model may allow the development of approaches to determine the dose of vitamin D supplement, based on initial D_3, 25(OH)D and 24, $25(OH)_2D$ levels. This approach may allow efficient ''treat to 25(OH)D target'' strategies for use in both clinical practice and, importantly, in prospective randomized studies. Vitamin D dosing based on these data needs to be tested prospectively.

Association Between Serum Levels of Vitamin D and Osteocalcin In Older Patients with Osteoporosis. Matthew Hnatow*[1], Jonash Loh[2], Catherine Ambrose[3], Nahid Rianon[4]. [1]Univeristy of Texas Health Science Center at Houston - Medical School, USA, [2]UT Medical School - Houston, USA, [3]University of Texas Health Science Center at Houston, USA, [4]UTHealth The University of Texas Medical School at Houston, USA

There is a need for better understanding of bone turnover markers (BTM) and their relationship with factors affecting bone metabolism including vitamin D. Deficiency of vitamin D, an essential nutrient for bone health, is prevalent in older patients with osteoporosis and the relationship between vitamin D and BTM, e.g., osteocalcin (OC) remains inconclusive. We investigated associations between serum levels of OC and 25-hydroxy-vitamin D (25-HD) in older ambulatory women evaluated for osteoporosis.

Chart review identified 202 women (≥50 years) evaluated between August 2010 and May 2013 (81 excluded from analysis for not having 25-HD available). Clinical parameters obtained as part of our standard osteoporosis workup included age, ethnicity, height, weight, use of calcium and vitamin D supplements and use of bone promoting medications (bonemed), serum thyroid stimulating hormone (TSH), serum creatinine, femoral neck and spine (L1-L4) bone mineral density (BMD), and OC. Bivariate analysis described patient characteristics by low 25-HD (<30 ng/mL, N = 73) or normal 25-HD (≥30 ng/mL, N=48). A regression model adjusting for all the above variables determined associations between 25-HD and OC.

The mean (SD) age of the women was 79 (9) years. There were no significant differences between the two groups in age, height, weight, co-morbidities, femoral and spinal BMD, alcohol or tobacco use and bonemed. There was a significant difference in serum OC between the groups (p=0.039) with mean (SD) of 23.64 (10.12) ng/ml for the low and 17.58 (7.98) ng/ml for the normal serum 25-HD groups. Significant differences, seen in bivariate model, in serum 25-HD (<0.05) between patients from various racial/ethnic backgrounds and between patients using or not using calcium and vitamin D supplements did not remain significant in the regression model. An inverse relationship remained significant between serum OC and serum 25-HD in the regression model after adjusting for all variables mentioned above (beta coefficient -0.36, 95% confidence interval 0.72 to -0.01).

We report associations between higher OC (indicating high bone turnover) and lower serum 25-HD in our study patients. While high bone turnover may indicate high risk of fracture in older patients, lower serum 25-HD may also indicate sub-optimal bone health maintenance contributing to their higher risk of fracture. Future studies are needed to determine if vitamin D supplementation can significantly affect OC levels.

BMD changes in accordance with serum vitamin D changes in postmenopausal Korean women. Duck Joo Lee[1], Sanghyun Je*[2], Beomtek Kim[2]. [1]Ajou University School of Medicine, South Korea, [2]Ajou University Hospital, South Korea

Serum vitamin D has been considered to play one of the major roles in bone health. Postmenopausal women whose initial serum vitamin D level was measured and grouped to evaluated the how one year serum vitamin D change would influence their one year bone density in various sites.

Our hypothesis include that the increase in serum vitamin D regardless of their initial vitamin D level will increase bone mineral density in various sites. This could be evaluated in more than one thousand postmenopausal women who had been enrolled in annual health check up in one of the University Hospital Health Care Center in Seoul. These women provided full health information as well as annual physical check up and health behavior.

The four initial serum vitamin D quartile; low-10ng/%, 11-20ng, 21-30ng, 30ng-higer, consisted of 25% of total number of study subjects. Each quartile were subgrouped into 1, those whose serum vitamin D was increased from the initial serum level, 2, those whose serum vitamin D level was decreased from the initial serum level.

More than one thousand postmenopausal women who had both initial serum vitamin D, bone mineral density and their annual follow up. Our hypothesis is being tested and will be presented. This data will support the effect of serum vitamin D changes on postmenopausal women bone health with various physical and behavioral conditions considered.

Dairy products consumption and serum 25-hydroxyvitamin D level in Saudi children and adults. Nasser Al-Daghri*[1], Omar Al-Attas[2], Soundararajan Krishnaswamy[2], Hanan Alfawaz[2], Naji Aljohani[3], Shaun Sabico[2], Majed Alokail[2]. [1]King Saud University, Saudi Arabia, [2]King Saud University, Saudi Arabia, [3]King Saud University for Health Sciences, Saudi Arabia

Background

Vitamin D deficiency is common around the world and is implicated in calcium deficiency related conditions like secondary hyperparathyroidism and fracture risk and several chronic diseases, including type II diabetes, autoimmune conditions and cancer. We aimed to investigate the vitamin D status and its association with consumption frequencies of various dairy products in Saudi population.

Methods

Subjects of our study consisted of 820 children (327 boys; mean age 14.9 yrs and 493 girls; 14.8 yrs) and 565 adults (249 men, 27.9 yrs and 316 women 32.2 yrs). We estimated the consumption frequencies of various dairy food products (fresh milk, powdered milk, laban, yoghurt and cheese) using a qualitative food frequency questionnaire (FFQ) and also measured serum level of 25-hydroxyvitamin D (25(OH)D). Associations between variables of interest were assessed by Pearson correlation analysis.

Results

Approximately, 80% of the boys and 90% of the girls and 64% of men and 50% of women participants had deficient/insufficient levels of vitamin D. Modest associations were found between mean serum 25(OH)D concentration and consumption frequencies of fresh milk in children (r=0.11), more specifically in girls (r=0.12), and to the overall consumption of dairy products in women (r=0.12).

Conclusions

The results of this study indicate widespread vitamin D deficiency in children and adults of Saudi Arabia, and a lack of strong correlation between dairy product consumption frequency and serum level of vitamin D strongly implies a need for adequate fortification of milk and other dairy products with vitamin D.

Does Vitamin D Affect Femoral Cartilage Thickness? An Ultrasonographic Study. Aysen Akinci-tan*[1], Serdar Güven[2], Fevziye Unsal malas[3], Murat Kara[4], Lale Aktekin[3], Murat Ersoz[4], Levent Ozcakar[5]. [1]Hacettepe University, Turkey, [2]Hacettepe University School of Medicine, Turkey, [3]Ankara PMR Training & Research Hospital, Turkey, [4]Ankara PMR Training & Rehabilitation Center, Turkey, [5]Hacettepe University dept of PMR, Turkey

Aim: To investigate the association between vitamin D levels and distal femoral cartilage thickness in healthy subjects. Methods: Eighty patients who admitted to our outpatient clinic between May-July 2013 were classified into three subgroups according to their 25-OH vitamin D levels as <10 ng/ml, 10-20 ng/ml and ⩾ 20 ng/ml. Distal femoral cartilage thickness was measured from the mid-points of right medial condyle (RMC), right lateral condyle (RLC), right intercondylar area (RIA), left medial condyle (LMC), left lateral condyle (LLC) and left intercondylar area (LIA) by using musculoskeletal ultrasonography (US). Results: The group with severe vitamin D deficiency (<10 ng/mL) had thinner femoral cartilage thickness at LMC (p=0.005).

Positive correlations were determined only between vitamin D levels and US measurements for the group with a severe vitamin D deficiency (<10 ng/mL) at RLC (r=444, p=0.020), LMC (r=357, p=0.067) and LLC (r=568, p=0.002). Conclusion: Low levels of vitamin D (<10 ng/mL) seem to affect the femoral cartilage thickness negatively. Further studies are necessary to ascertain the clinical relevance of this change in cartilage thickness and whether vitamin D supplementation can reverse the cartilage thinning process or the allied clinical symptoms in case of knee osteoarthritis.

Optimal Dose of Vitamin D Replacement in Middle Eastern and North African Population: a Systematic Review and Meta-analysis. Marlene Chakhtoura*[1], Ghada El-Hajj Fuleihan[2], Asma Arabi[3], Sara El-Ghandour[4], Elie Akl[4], Khaled Shawwa[4]. [1]American University of Beirut, Lebanon, [2]American University of Beirut-Medical Center, Lebanon, [3]Calcium Metabolism & Osteoporosis Program, American University of Beirut, Lebanon, [4]American University of Beirut, Lebanon

Background: Hypovitaminosis D, defined as <20 ng/ml, is highly prevalent worldwide more so in the Middle East and North Africa (MENA) region (1,2). Relevant risk factors in adults, and similarly to other countries, include advancing age, female gender, multiparity, clothing style, season, socio-economic status and urban living (3). The latest Institute of Medicine (IOM) recommendations for dosing vitamin D targeted populations from North America, and may not necessarily apply to the MENA region.

Objectives:

A. Determine the mean 25-hydroxyvitamin D (25(OH)D) level reached with low (≤ 800IU), moderate (800-2000 IU) or high (>2000IU) daily dose of vitamin D in subjects in MENA countries, by age and reproductive status.

B. Estimate:

1) Mean serum 25(OH)D level reached by 97.5% of individuals in above treatment groups.

2) Proportion of subjects who reach a mean 25(OH)D ⩾20 ng/ml in above treatment groups.

C. Investigate the applicability of the IOM recommended daily allowance to subjects in MENA countries. Other outcomes investigated are fracture rates, mortality, hypercalcemia-hypercalciuria, bone mineral density, kidney stones and muscle strength.

Eligibility criteria: We included randomized clinical trials comparing different doses of oral vitamin D supplementation or placebo in MENA countries, of both genders and all age categories, including pregnant and lactating women.

Search method: A systematic search was conducted using Medline, PubMed, the Cochrane Library, EMBASE, Popline, Global Health Library, Index Medicus for WHO Eastern Mediterranean without any time or language restriction. Additional studies were identified on ClinicalTrial.gov and the WHO registry for clinical trials. Authors were contacted for unpublished data.

Selection and data abstraction process:References retrieved were reviewed in duplicate by 2 independent reviewers. We abstracted data, and assessed risk of bias using the Cochrane risk of bias tool in duplicate and independently. We used RevMan software for data entry and analysis.

Results:2542 articles were screened for title and abstract, 192 full texts were assessed for eligibility. We judged 20 studies as eligible: 10 in adults, 4 in children, 2 in neonates and infants, and 4 in pregnant women. The analysis is currently under progress to be completed by September 2014.

SU0351

Quantification of total 25-hydroxyvitamin D: Acomparison between the Elecsys® Vitamin D Total assay and LC-MS/MS. Christopher Washbourne*[1], Darrell Green[1], Emily Fisher[2], Isabelle Piec[3], Jonathan Tang[4], William Fraser[1]. [1]University of East Anglia, United Kingdom, [2]University of East Anglia, United Kingdom, [3]BioAnalytical Facility, University of East Anglia, United Kingdom, [4]University of East Anglia, Norwich, UK, United Kingdom

Background: Increasing demand for vitamin D testing has led to a plethora of semi- and fully-automated methodologies for quantification of serum 25-hydroxyvitamin D (25OHD) concentrations. The ability of an assay to measure 25OHD with precision and accuracy is essential in assessing vitamin D status of an individual. Liquid chromatography-mass spectrometry (LC-MS/MS) has been identified as the gold-standard method for determination of 25OHD due to its capacity to distinguish $25OHD_3$ and D_2. Immunoassays (IM) and competitive protein binding assays (CBP) remain popular due to a user-friendly format that can be easily automated. The CBP assay from Roche Diagnostics offers total 25OHD measurement in 27 minutes with high specificity to $25OHD_3$ and D_2.

Objectives: To evaluate the Roche Diagnostics Elecsys Vitamin D total and compare the results with a fully validated, NIST-aligned (LC-MS/MS) method.

Method: 293 routine patient samples with serum 25OHD that were determined by LC-MS/MS were selected in this comparison study. Of those samples, 153 contained both $25OHD_2$ and D_3 ranging between 2.6-128.7 and 5.7-166.9 nmol/L, respectively, and 140 exhibited $25OHD_3$ ranging between 7.6-234.8 nmol/L with undetectable $25OHD_2$. The samples were analysed on a COBAS 6000 using the Elecsys method according manufacturer instructions.

Results: Intra-assay imprecision of the Elecsys method was 3.5% (53.4±1.9 nmol/L) (CV% (±S.D)) and 2.4% (89.3±2.2 nmol/L). Interassay imprecision was 7.5% (51.2±3.8 nmol/L) and 5.1% (84.1±4.3 nmol/L). Bias plots comparing the mean concentration against the percentage difference between the Elecsys and LC-MS/MS methods showed an overall negative bias of 11.6% in total 25OHD concentrations. The sample group that consisted solely of $25OHD_3$ showed a negative bias of 2.2%, whereas the sample group that contained both $25OHD_3$ and D_2 were found to have a significantly higher negative bias of 20.2%.

Conclusions: We showed the Elecsys method is precise at the concentrations of 25OHD tested. However, when compared with a fully validated LC-MS/MS method, the Elecsys method was found to underestimate total 25OHD. This is exacerbated by the presence of $25OHD_2$ in the sample, suggesting there is a lower binding affinity for $25OHD_2$ in the Elecsys method resulting in lower recovery. Our findings were in accordance with current publications on comparison studies between other commercially available IM, CBP assays and LC-MS/MS.

Probitotic treatment prevents bone loss in type 1 diabetic mice. Laura McCabe[1], Sandi Raehtz*[2], Katherine Motyl[3], Jing Zhang[2], Robert Britton[2], Narayanan Parameswaran[2], Regina Irwin[2]. [1]Michigan State University, USA, [2]Michigan State University, USA, [3]Maine Medical Center Research Institute, USA

Type 1 diabetes (T1D) causes osteoporosis characterized by a predominant suppression of osteoblast number/activity and increased bone marrow adiposity. However, the fundamental mechansim and alternative treatments with fewer side-effects for T1D bone loss remain undetermined. Recent studies by our lab and others indicate that probiotics can be beneficial for bone. Here we demonstrate that T1D mice lose 35% femur trabecular bone volume. Surprisingly, treatment of T1D mice with L. reuteri, a probiotic with anti-inflammatory and bone health properties, completely prevented bone loss and marrow adiposity. The changes suggest a defect in Wnt10b levels which were reduced in T1D mice. This suppression was prevented with L. reuteri treatment. Taken together, probiotics may benefit T1D bone health.

Oxytocin is not a determinant of bone mineral density in men: analysis of the MINOS cohort. Veronique Breuil*[1], Eric Fontas[2], Roland Chapurlat[3], Patricia Panaia-Ferrari[2], Hedi Ben Yahia[4], Sylvie Faure[2], Yacine Allam[2], Liana Euller-Ziegler[2], Ez Zoubir Amri[4], Pawel Szulc[5]. [1]Chu De Nice, France, [2]Nice University Hospital, France, [3]E. Herriot Hospital, France, [4]CNRS, iBV UMR 7277, France, [5]INSERM UMR 1033, University of Lyon, Hopital E. Herriot, Pavillon F, France

Introduction: We previously showed that oxytocin (OT), a neurohypophysial hormone regulated by estrogen, leptin, testosterone and alcohol, is a determinant of bone mineral density (BMD) in post-menopausal women. The aim of our study was to assess the relationship between OT and bone status in men.

Subjects and methods: In 552 men aged 50 and older, included in the MINOS cohort, we measured OT serum levels (Phoenix Pharmaceuticals, Strasbourg, France) after a solid-phase extraction (Phoenix Pharmaceuticals, Strasbourg, France) and leptin (TECOmedical Group, Swizerland); estradiol and testosterone serum levels were already available. We examined the association between OT serum levels BMD (lumbar, femoral neck and hip, Hologic 1000W) and bone remodeling (PINP, BSAPand CTX).

Results: The median age of this population was 64.5 years (IQR 60 – 70); 6% were osteoporotic (OP), 49% osteopenic, 45% had normal BMD, 13% had at least 1 prevalent fragility fracture and 72% had an alcohol intake ⩾3 unit/day. In univariate analysis, OT serum level was not associated with BMD at any site or with any bone turnover marker. OT serum level was significantly but weakly associated with total estradiol (r=0.087; p=0.04), bioavailable estradiol (r=0.20; p<0.0001), free testosterone (r=0.17; p<0.0001) and leptin (r=0.15; p=0.0002); but not significantly related to age, alcohol intake or total testosterone. After adjustment for age, total and bioavailable estradiol, leptin, total and free testosterone, BMI or alcohol, the association was still not significant. When examining therelationship across quartiles of estradiol, bioavailable estradiol, free testosterone or leptin, we also found no significant association.

Conclusion: In men, OT serum levels are not associated with BMD and bone turnover. These results point out an additionaldifference in the pathophysiology of bone loss between men and women.

Pathologically Altered Osteocytes (Ocys) are Responsible for Osteoporosis. Yinshi Ren*[1], Baozhi Yuan[2], Ying Liu[3], Marc Drezner[2], Jian Feng[3]. [1]Baylor college of dentistry,Texas A&M Health Science Center, USA, [2]University of Wisconsin, USA, [3]Baylor college of dentistry,Texas A&M Health Science Center, USA

For a long time the osteocyte (Ocy) has been considered a mechanosensor, rather than a true bone builder, despite its ideal anatomic location to regulate bone mineralization. Using acid-etched and backscattered SEM, we found a close relationship between Ocy maturation and bone mineralization. The mature Ocy volume was 50% reduced, but its surface was >50% increased, due to increased dendrites, leading to replacement of the decreased cell volume by well-defined mineral, present in individual spheres and mineral sheets. Confocal microscopy of DAPI nuclear-stained bone, labeled with calcein and alizarin red, confirmed mineral deposition in the matrix surrounding Ocys, and at the mineralization front surrounding Ocy canaliculi, in both trabecular/cortical bone from rats, mice, rabbits, and dogs. In contrast, osteoblasts (Obs) were not located in areas of active mineralization, challenging the dogma that Obs regulate mineralization. We also identified two types of mineralization processes in dog cortical bone, synchronized mineralization on the non-osteon bone surface and highly dynamic mineralization in the osteon-rich interior bone. We confirmed these observations, using confocal double-labeled images to directly assess mineral deposition from Ocys, and backscattered SEM images to define mineral resorption. We found various degrees of mineral remodeling in different osteons of the cortical bone, in contrast to the non-osteon bone surface that displayed only one mineral deposition pattern. We also identified newly formed osteons and estimated their de nova formation rate as ~9.5%. These observations define a new role for Ocys in bone remodeling and suggest a possible role for alterations of Ocy structure and function in the genesis of osteoporosis. Several lines of evidence support this concept: 1) advanced osteoporosis in compact bone is due to an increase in the Haversian canal area (>2-fold), a change that correlates with significantly reduced Ocy numbers/osteon, altered Ocy shape, from spindle to round, and a reduced number, surface area, and volume of Ocy dendrites; and 2) a lack of cortical bone remodeling and abundant microcracks in aged cortical bone, which are directly linked to defective Ocys, not to abnormally functioning Obs or osteoclasts. Collectively, these data indicate that Ocys are the cells maintaining bone mineralization and remodeling, and poorly maintained bone remodeling, due to defective Ocys, plays a key causal role in osteoporosis.

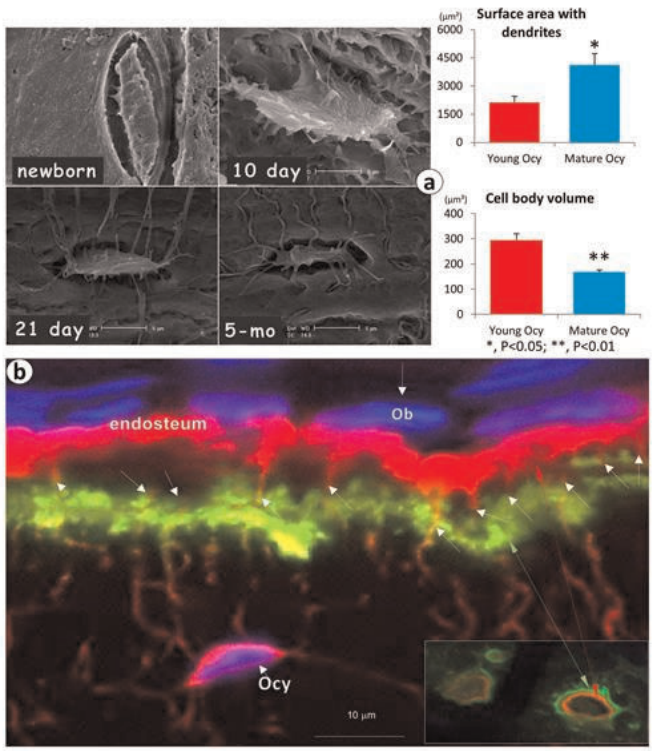

Figure 1. Bone mineralization is directly linked to osteocyte. (a). Acid-etched SEM images show mouse calvaria osteocyte maturation from newborn to 5 months of age. As it matured, the osteocyte volume was reduced by nearly 50%, but its surface area increased by >50%, due to an increased number of dendrites, which led to well-defined mineral filling the decreased cell volume. **(b).** Double labeling + Dapi staining revealed by confocal microscopy shows mineral deposition in the matrix surrounding the Ocys, and at the mineralization front surrounding the Ocy canaliculi.

ASBMR abstract figure 1

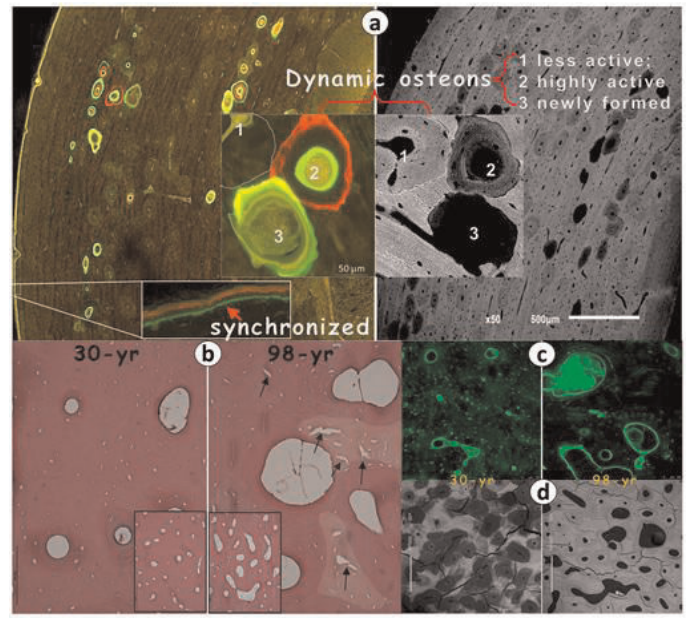

Figure 2. Double labeling revealed a dual mineralization pattern in osteon (dynamic, including active, inactive, and newly formed) and non-osteon area: (synchronized) within dog cortical bone **(a**, left**)**; which is confirmed by the backscatter SEM imaging technique on the same bone slide **(a,** right**)**; H&E stains showed increased micro-cracks in a 98-yr-old osteoporosis patient compared to a 30-yr-old male cortical bone **(b)**; The confocal FITC stained images revealed much enlarged Haversian canals with reduced Ocy number in each osteon in 98-yr-old bone **(c)**; and the backscatter SEM image revealed highly active remodeling in the same 30-yr-old male cortical bone, as reflected by a mixed pattern of light shade (less active) and dark (active, dominant) **(d,** left**)** in comparison with the 98-yr-old bone, in which most osteons were in light shade, indicating a lack of bone remodeling **(d,** right**).**

Effects of the Combination of Eldecalcitol, an Analog of Active Vitamin D_3, and Parathyroid Hormone in Ovariectomized Rat Bones. Tomomaya Yamamoto*[1], Tomoka Hasegawa[2], Sadaoki Sakai[3], Satoshi Takeda[4], Kimimitsu Oda[5], Minqi Li[6], Koichi Endo[7], Norio Amizuka[8]. [1]Hokkaido University, Japan, [2]Hokkaido University, Japan, [3]Chugai Pharmaceutical Co., Ltd., Japan, [4]Chugai Pharmaceutical Co., LTD, Japan, [5]Niigata University, Japan, [6]The School of Stomatology, Shandong University, Japan, [7]Chugai Pharmaceutical Co., Ltd., Japan, [8]Hokkaido University School of Dentistry, Japan

In works using rodent models, we have shown that intermittent hPTH (1-34) administration enhanced bone remodeling while promoting preosteoblastic proliferation (JBMR 2009). In addition, we have reported that eldecalcitol, an analog of active vitamin D_3, induced new bone formation via "minimodeling", a type of bone formation that is not coupled with osteoclastic bone resorption (Bone, 2011). Since both reagents appear to have anabolic effects in bone, we have histologically examined the biological effects of a combination of eldecalcitol and hPTH(1-34) on ovariectomized (OVX) rat bones.

Seventy-one 13-weeks old OVX Wistar rats received vehicle (OVX group), 10μg/kg of PTH (PTH group), 20 ng/kg of eldecalcitol (eldecalcitol group) or 10μg/kg of hPTH(1-34) and 20 ng/kg of eldecalcitol (combination group) for 4 or 8 weeks. Rats were then fixed with a paraformaldehyde solution, and their femora and tibiae were assessed in terms of histology, histochemical profile for alkaline phosphatase (ALP) and tartrate-resistant acid phosphatase (TRAP), and calcein labeling.

The eldecalcitol group revealed a rapid increase in metaphyseal trabecular number compared with the OVX group after 4 weeks. After 8 weeks, however, both PTH and combination groups had higher trabecular numbers than did the eldecalcitol and the OVX groups. PTH group showed a thick layer of ALP-positive preosteoblasts nearby several TRAP-reactive osteoclasts, suggesting accelerated bone remodeling. Unlike PTH, the eldecalcitol group showed increased bone volume while not developing a thick preosteoblastic layer. Eldecalcitol administration promoted a reduction in the number of TRAP-positive osteoclasts and stimulated minimodeling, defined as a focal budding of new bone deposited upon smooth arrest lines. Therefore, the mechanisms through which hPTH(1-34) and eldecalcitol promote bone anabolism seem to be different: PTH stimulates bone remodeling, while eldecalcitol both supports minimodeling and suppresses bone resorption by inhibiting osteoclast formation. The combination group displayed the highest increases in bone mass, but the osteoblast/preosteoblast numbers lied midway between those found in the PTH and in the eldecalcitol groups. Thus, it appears that the combination of hPTH(1-34) and

eldecalcitol augments the anabolic effects of both reagents on the osteoporotic rat model.

Experimental Hepatic Osteodystrophy: The Reciprocal Influence of Glucose Metabolism and Pamidronate Treatment on Bone Microstructure and Strength. Francisco Jose De Paula*[1], Fernando Cunha[2], Leandra Ramalho[2], Ariane Ariane[2], Antonio Shimano[2], Marcello Nogueira-Barbosa[2], Ingrid Dick-de-Paula[2], Vanda Jorgetti[3], Sandra Fukada[4], Adriano Spirlandeli[2]. [1]School of Medicine of Ribeirao Preto - USP, Brazil, [2]Ribeirao Preto Medical School, USP, Brazil, [3]University of São Paulo, Brazil, [4]School of Pharmaceutical Sciences of Ribeirao Preto, USP, Brazil

Introduction: The liver has a central role on energy metabolism, is the main source of endocrine IGF-1 and participates in vitamin D metabolism. Recent studies have shown a complex interplay between bone and energy metabolism. However, the reciprocal influence of glucose metabolism and bisphosphonate therapy in hepatic osteodystrophy has scarcely been studied. Objective: To evaluate bone microstructure and strength, glucose and insulin tolerance in mice with hepatic disease induced by carbon tetrachloride (CCl4) and treated with pamidronate (P). Methods: C57BL6 mice were divided in 4 groups (n=40). Controls [treated with vehicle (V) or V and P (V+P)] and mice subjected to CCl4+V or CCl4+P treatment. The CCl4 was injected for 8 weeks; at the end of the fourth week the animals received V or P (1.25 mg/kg). Histological analysis of liver was obtained in all animals. Biomechanical test was performed on tibia and femur. Quantitative μCT was performed in femur and L5. Bone histomorphometry was performed in tibia. GTT was done with a 1g of glucose/Kg (IP) and ITT with insulin dose of 1UI/Kg (IP). Results: Histological analysis showed that all mice subjected to CCl4 injections presented cirrhosis. The body weight was similar in all groups. While the weight of epididymal fat was lower in both groups with cirrhosis ($p<0.01$), the weight of brown fat and liver was lower in both control groups ($p<0.01$). The GTT was similar in all groups. However, the decrease in glucose levels, after insulin administration, was lower in mice with liver disease. The force at the time of fracture was higher in the two control groups (e.g., tibia: $V=15.2\pm1.2$; $V+P=17.2\pm1.0$; $CCl4+V=12.3\pm1.5$ N; $CCl4+P=13.5\pm3.2$ N, $p<0.001$). Data from μCT and histomorphometry showed reduced values of BV/TV and Tb.N, as well as increased values of Tb.S in CCl4+V group in comparison to control ($p<0.005$). However, pamidronate successfully reversed this bone profile in all bone sites (e.g., L5 (BV/TV): $V=6.17\pm0.64$; $V+P=7.96\pm0.56$; $CCl4=5.76\pm0.19$; CCl4+ HP= $6.99\pm0.80\%$, $p<0.01$), decreasing bone resorption parameters, namely Oc.S/BS and ES/BS. There was no association between energy metabolism with bone parameters.

Conclusion: Our data show that pamidronate efficiently reverses bone alterations in chronic liver disease. Cirrhosis is associated with insulin resistance, but there is no relationship between insulin resistance with bone microstructure and fragility in mice with liver disease.

SU0357

Integrative Analysis of GWASs, Human Protein Interaction and Gene Expression Identified Gene Modules Associated with BMDs. Hao He*[1], Lei Zhang[1], Jian Li[1], Yu-Ping Wang[1], Ji-Gang Zhang[1], Jie Shen[1], Yan-Fang Guo[1], Hong-Wen Deng[2]. [1]Center of Genomics & Bioinformatics, Tulane University, USA, [2]Tulane University, USA

To date, few systems genetics studies in bone field have been performed. We designed our study from a systems-level perspective by integrating GWASs, human protein-protein interaction (PPI) network and gene expression to identify gene modules contributing to osteoporosis risk. First we searched for modules significantly enriched with BMD-associated genes in human PPI network by using two large meta-analysis GWAS datasets through a dense module search algorithm. One was an imputation-based meta-analysis (referred to as Meta7), including seven individual GWAS samples. The other was the GWAS meta-analysis from Genetic Factors for Osteoporosis Consortium (GEFOS2). One was assigned as a discovery dataset and the other as an evaluation dataset, and *vice versa*. Through such a discovery-evaluation strategy, in total 42 modules and 129 modules were identified significantly in both Meta7 and GEFOS2 dataset, for femoral neck (FN) and spine (SPN) BMD respectively. 3340 modules were identified for Hip BMD only in Meta7, as Hip BMD weren't available in GEFOS2 for evaluation. Next, as candidate modules, they were assessed the biological relevance to BMD by gene set enrichment analysis (GSEA) in two independent microarray expression datasets (26 Chinese and 80 Caucasian subjects). Both expression profiles were generated from circulating monocytes isolated and purified in subjects with low versus high BMD. Interestingly, there were two final candidate modules significantly enriched in monocytes from low BMD group in both gene expression datasets (nominal p value < 0.05) (Table 1). Two modules had 16 nonredundant genes, including *ESR1*, *LRP5, TNFRSF11B*, *SMAD3*, *SFRP1*, *SFRP2*, *MDFI*, *LRP5*, *WNT1*, *WNT4* and *DKK1, etc*. These 16 genes were submitted for gene ontology (GO) term enrichment analysis in the WebGestalt website (http://bioinfo.vanderbilt.edu/webgestalt/) to compute the enrichment p value for each GO term. It revealed that both modules were enriched for genes involved in Wnt receptor signaling and osteoblast differentiation. The present study uncovered interactions among *DKK1*, *LRP5* and *SFRP* in both final candidate modules. These genes and their interactions had a great impact on Wnt signaling pathway, which may result in loss of bone mass. From a system-level analysis above, we highlighted two modules as well as genes in modules playing important roles in the regulation of bone mass, providing important clues for therapeutic approaches for osteoporosis.

Table 1. GSEA results of the two final candidate modules in gene expression datasets.

Trait	Module	Genes in the module	Gene expression sample	ES*	NES*	NOM p value*
SPN	Module 1	SMAD3, ESR1, DKK1, FN1, SFRP2, TNFRSF11B, SMAD9, LRP5, WNT1, SECISBP2, WNT4	Caucasian	-0.583	-1.500	0.049
			Chinese	-0.621	-1.722	0.024
Hip	Module 2	MDFI, ESR1, TAP1, DKK1, LRP5, ZNF408, SFRP1, EXOSC2, WNT1, WNT4	Caucasian	-0.685	-1.618	0.023
			Chinese	-0.657	-1.577	0.021

Refining Isolation Methods of Human Osteoblastic Cells from Small Needle Bone Biopsies Without In Vitro Culture: Exclusion of Quiescent Bone Lining Cells. Joshua Farr*[1], David Monroe[2], Sundeep Khosla[3]. [1]Mayo Clinic, USA, [2]Mayo Foundation, USA, [3]Mayo Clinic College of Medicine, USA

Historically, the inability to directly study mature human osteoblasts *in vivo*, or *ex vivo* following minimal manipulation, has represented a major technical problem. Indeed, most human studies to date have either used whole bone biopsies, containing a heterogeneous cell population, or cultured bone marrow stromal cells (MSCs). While potentially useful for some purposes, bone MSCs represent early progenitor cells and it is unclear how *in vitro* culture may alter their phenotype and/or mRNA expression profile. We have circumvented this problem by developing methods to rapidly isolate (without *in vitro* culture) highly enriched osteoblastic cells from small human needle bone biopsies (Osteo Int 2014;25:887-95). These isolation techniques can then be coupled to analytic tools to study genes and pathways unique to human osteoblastic cells *in vivo*. While these techniques should provide novel insights into the pathogenesis of osteoporosis and other skeletal disorders, a potential limitation of this isolation method is that quiescent bone lining cells may still be present within our osteoblast-enriched cell population, and therefore could act as a confounder. Thus, we utilized CD54 (ICAM-1), a unique cell surface marker expressed by bone lining cells, but not osteoblasts (JBMR 2002;17:77-90), to investigate whether bone lining cells exist in our human osteoblastic cell population. A small needle bone biopsy (1-2 mm by 1 cm) was obtained from the posterior iliac crest of a healthy 63 yr old male, and was subjected to sequential collagenase digests. We previously demonstrated that the 2nd fraction contains most of the osteoblasts; thus, we used magnetic-activated cell sorting of the 2nd fraction cells to rapidly isolate the alkaline phosphatase (AP)+ cells, which are capable of *in vitro* mineralization. The next level of purification involved selection for CD45/34/31- cells, a population completely devoid of hematopoietic/endothelial markers yet highly enriched for key osteoblast markers. Finally, we stained the AP+/CD45/34/31- cells with CD54 and used flow cytometry to establish that, relative to an isotype control, 11.5% of the human AP+/CD45/34/31- cells were ICAM-1+ (Figure). In conclusion, while relatively few ICAM-1+ cells were present in the AP+/CD45/34/31- cell population, CD54 should be included as an additional marker to ensure removal of any bone lining cells. Thus, AP+/CD45/34/31/54- cells represent a further enriched human osteoblastic cell population.

Serum Proteomic Profiles and Incident Vertebral Fracture in Older Men: The MrOS Study. Douglas Bauer*[1], Jian Shen[2], Jodi Lapidus[3], Peggy Cawthon[4], Andy Hoffman[5], Steven Cummings[6], Eric Orwoll[2]. [1]University of California, San Francisco, USA, [2]Oregon Health & Science University, USA, [3]OHSU, USA, [4]California Pacific Medical Center Research Institute, USA, [5]Stanford, USA, [6]San Francisco Coordinating Center, USA

The biologic pathways that mediate vertebral fracture (VF) in men are not well defined, and no established serum biomarkers are available. We utilized a novel approach to identify serum peptides and proteins associated with incident vertebral fracture in a cohort of older men.

A1923 men ⩾65 (mean age 73) were randomly selected from the Osteoporotic Fractures in Men Study (MrOS). Fasting baseline serum archived at -70C was analyzed using high throughput mass spectrometry. Incident VF (Genant grade ⩾1, n=86) were detected by review of paired lateral spine radiographs from baseline and after a mean follow-up of 4.5 years. After excluding men with a history of fracture after age 50 or taking osteoporosis treatments (23 men with incident VF and 390 men without), we used ANCOVA and linear regression models adjusted for age, BMI and clinical center to compare peptide abundance between men with and without new VF. We adjusted for multiple comparisons using the false discovery rate (FDR) calculated via the Storey method (q-value). Peptide abundance was considered significantly different when FDR≤0.1 and fold differential ⩾10%. A meta-analytic approach that combines p-values from peptides within the same protein was applied to generate an overall significance level and fold change for specific proteins. The abundance of selected peptides and risk of incident VF were further analyzed using adjusted logistic regression models.

Serum proteomic analysis identified 3099 unique peptides that mapped to 458 known proteins. None of the identified peptides or proteins met our predefined threshold for differential abundance but one peptide related to plasminogen, a coagulation protein that modulates expression of OPG in rodents, was less abundant among men with incident VF ($p=4.7*10^{-5}$, FDR q-value=0.13, fold differential= 1.29). Each SD decrease in the adjusted abundance of this peptide was associated with a 47% higher risk of new VF (OR=1.47, 95% CI: 1.20, 1.78). Two other peptides related to serum plasminogen were also less abundant among men with VF ($p<0.004$, FDR q-value=0.99, fold differential>1.15 for both), but meta-analysis of plasminogen peptide abundance did not differ among men with and without VF (p=0.04, FDR q-value=0.99, fold differential= 1.08).

Using novel, in depth proteomic methods in older men, we did not identify peptides or proteins significantly associated with incident vertebral fracture, but several peptides related to plasminogen appear promising and should be evaluated in larger studies.

Simvastatin action on bone repair after fracture in experimental surgical protocol. João Paulo Mardegan Issa*[1], Conrado Ingraci de Lucia[2], Fellipe Augusto Tocchini de Figueiredo[3], Junia Ramos[4], Daniela Mizusaki Iyomasa[3], Mamie Mizusaki Iyomasa[5], Ana Paula Macedo[4], Roberta Carminati Shimano[3]. [1]USP- University of São Paulo, Brazil, [2]Professor, Brazil, [3]University of São Paulo, Brazil, [4]Technician of University of São Paulo, Brazil, [5]Professor of University of São Paulo, Brazil

Statins are able to inhibit the osteoblast apoptosis, osteoclasts activities and this process might be good for osteoporotic bone tissue. The number of experimental studies which investigate the hypothesis that osteoporosis can difficult fractures repair are considerable. Ovariectomized animals models are the most commonly model used for bone metabolism evaluation in osteoporosis. This study evaluated the interaction between simvastatin and a metabolic disorder represented by ovariectomization on biochemical, immunohistochemical (BSP, OCN, VEGF, MMP-2 and MMP-9) and histological parameters for bone remodeling in female Wistar rats submitted to fracture on femur. Ninety female animals were divided into six experimental groups (n=15). SH, SH5mg, SH20mg, OVX, OVX5mg and OVX20mg, which SH means, sham operated simulating ovariectomy, and OVX was the ovariectomized rats, the 5mg/kg and 20mg/kg means the concentration of simvastatin. The drug was administrated on drinking water for 7, 14 and 21 days post-fracture, and both femurs were used for analyses. According to the histological data, statistical significance was found for time x medication ($P = 0.002$), surgery x medication ($P < 0.000$), and time x surgery x medication ($P = 0.001$). According to MMP-2 expression, experimental time was significant ($P<0.000$), but the surgery ($P = 0.427$) and medication ($P = 0.420$) were not significant. For MMP-9, experimental time ($P < 0.000$) and medication ($P = 0.042$) were significant, but not the surgery ($P = 0.662$). Immunostaining showed positive reaction as brownish color predominantly on the cytoplasm of some cells and extracellular matrix. In conclusion, the simvastatin executes a positive action for bone repair, especially on groups affected by osteometabolic disorder and those with 20 mg of this drug, and the process was strongly expressed on 14th day and after this period the bone maturation occurred, as evidenced by analyses on 28th day.

Effects of intermittent administration of teriparatide on bone mineral density and bone strength in autochthonous transgenic mice for diabetes mellitus (Akita mice). Kentaro Ohuchi*[1], Naohisa Miyakoshi[1], Yuji Kasukawa[1], Hayato Kinoshita[2], Yoichi Shimada[3]. [1]Akita University Graduate School of Medicine, Japan, [2]Akita University, Japan, [3]Akita University Graduate School of Medicine, Japan

Introduction: Diabetes mellitus (DM) causes secondary osteoporosis, which reduces bone mineral density (BMD) or bone strength, and increases the risk of fracture. Akita mice (AM) are a model of autochthonous transgenic mouse for DM, and are used to evaluate sugar metabolism. However, the variation of BMD and bone strength in AM remains unclear. The objectives of this study were to measure BMD and bone strength in AM and to evaluate the effects of intermittent administration of PTH on BMD and bone strength in AM.

Materials and Methods: Female AM and control mice (C57/BL/6NCrSlc: CM) at 14 weeks old were divided into four groups: 1) AM+PTH (n=8), AM treated with PTH; 2) AM+vehicle (n=8), AM treated with vehicle; 3) CM+PTH (n=8), CM treated with PTH; and 4) CM+vehicle (n=8), CM treated with vehicle. PTH (80 μg/kg) or vehicle alone (0.1% mouse albumin) was administered subcutaneously 3 times/week for 4 or 8 weeks. Blood sugar (BS) and BMD of the tibia were measured after 4 or 8 weeks treatment. Bone strength of the femoral shaft was evaluated using a 3-point bending test at 4 or 8 weeks.

Results: BS was significantly higher in the AM-group than in the CM-group with both PTH (4 weeks, p=0.001; 8 weeks, p=0.001) and vehicle (4 weeks, p=0.001; 8 weeks, p=0.001). BMD was significantly lower for AM+vehicle than for CM+vehicle at 8 weeks (p=0.003). Intermittent administration of PTH significantly increased BMD in both AM-groups (4 weeks, p=0.001; 8 weeks, p=0.001) and CM-groups (4 weeks, p=0.01; 8 weeks, p=0.005) compared with vehicle-treated groups. Bone strength tended to be lower for AM+vehicle than for CM+vehicle, but the difference was not significant. Maximum load (p=0.01), breaking power (p=0.01) and stiffness (p=0.04) were significantly higher in AM+PTH than in AM+vehicle at 8 weeks.

Conclusion: BMD was lower in the AM-group than in the CM-group. Intermittent administration of PTH also significantly increased BMD and bone strength in AM.

Osthole inhibits osteoclast formation and exerts an osteoprotective effect in mice model of 5/6 nephrectomy. Bing Shu*[1], Xiaofeng Li[2], Chunchun Xue[2], Yongjian Zhao[2], Weiwei Da[2], Sheng Lu[2], Dezhi Tang[3], Qi Shi[2], Yongjun Wang[4]. [1]Longhua Hospital, Peoples Republic of China, [2]Longhua Hospital, Spine Research Institute, Shanghai University of TCM, China, [3]Shanghai University of Traditional Chinese Medicine, Peoples Republic of China, [4]Othopedic Surgery, Peoples Republic of China

The objective of this study is to observe the function of osthole on osteoclast formation, and bone loss in mice model of 5/6 nephrectomy. 3-month old C57BL/6 were randomly divided into model group and osthole group, and were treat with placebo or osthole one week after 5/6 nephrectomy. Sham-operated group were set as control. Two month after treatment, L4 vertebre were harvested. BMD of cortical bone and cancellous bone were detected with micro-CT. Bone histomorphology was revealed by HE staining. Osteoclasts were shown with TRAP staining and quantified. c-fos, NFATc1, MMP9 and Cathepsin K expressions were detected with IHC staining. The L4 vertebre BMD of mice was significantly reduced after 5/6 nephrectomy($p<O.O5$)with reduced number and thickness of trabecula. Osteoclast number was significantly increased($p<O.O5$). c-fos, NFATc1, MMP9 and Cathepsin K expressions were increased.Compared with model group, mice in osthole group showed increased BMD of L4 vertebre($p<O.O5$), reduced osteoclast number($p<O.O5$)and c-fos, NFATc1, MMP9 and Cathepsin K expressions. The histomorphology of L4 vertebre was also improved. Osthole can inhibit osteoclast formation and partially reverse bone loss induced by 5/6 nephrectomy in mice.

An herbal formula prevents postmenopausal osteoporosis via DHEA suppressing osteoclastogenesis. Ling Wang*[1], Xuemin Qiu[2], Hans-Jürgen Gober[3], Dajin Li[2]. [1]Fudan University, Institute of Obstetrics & Gynecology, Obstetrics & Gynecology, Peoples Republic of China, [2]Laboratory for Reproductive Immunology, Hospital & Institute of Obstetrics & Gynecology, China, [3]Department of Cell Signaling, Graduate School of Medical & Dental Sciences, Tokyo Medical & Dental University, Japan

Bu-Shen-Ning-Xin Decoction (BSNXD), a traditional Chinese medicinal composition, has been used as a remedy for postmenopausal osteoporosis, but the efficient mechanisms on bone metabolism remain not fully understood. We sought to identify

whether BSNXD could regulate osteoclast differentiation. BSNXD administration ameliorated the osteoporotic phenotype of ovariectomized (OVX) mice, evidenced by an increase in bone mineral density (BMD), bone volume, and a decrease in osteoclast bone resorption; these effects could not be abolished by aromatase inhibitor letrozole. BSNXD-derived serum suppressed RANKL-activated osteoclastogenesis in a dose-dependent manner, and this suppressive effect could be reversed by estrogen receptor (ER)a antagonist Methyl-piperidino-pyrazole (MPP). The serum suppressed RANKL-induced NF-kappa B transcription, and inhibited accumulation of the nuclear factor of activated T-cells, cytoplasmic 1 (NFATc1) in osteoclast precursor cells; the inhibitory effect was abolished by MPP. Administration of BSNXD increased serum DHEA but not E2 concentration. DHEA treatment inhibited RANKL-induced osteoclastogenesis in BMMs via ERa-dependent pathway and ameliorated the bone phenotype of OVX mice. These results collectively suggest that administration with BSNXD increases serum DHEA that presents inhibitory effects on osteoclast differentiation by abrogation of RANKL-induced NFATc1 and NF-kappa B signaling pathway as downstream of ERa, which contributes to the inhibitory role in bone resorption.

Changes in Cortical and Trabecular vBMD After 5 Months of Ovarian Hormone Suppression in Premenopausal Women. Vanessa Sherk*[1], Karen Shea[2], Pamela Wolfe[2], Robert Schwartz[2], Wendy Kohrt[3]. [1]University of Colorado - Denver, USA, [2]University of Colorado Anschutz Medical Center, USA, [3]University of Colorado Denver, USA

Cortical and trabecular bone loss accelerates during menopause and with aging. Menopause is a process with large variability in its rate of progression and the effects of aging may confound the effects of the loss of ovarian function on BMD. GnRH agonist ($GnRH_{AG}$) therapy can be used as a model of menopause to isolate effects of ovarian function. The purpose of this pilot study was to determine the magnitude of the loss in volumetric BMD (vBMD) in response to the suppression of ovarian function and whether the loss is mitigated by exercise. Healthy premenopausal (20-40 y) women (n=27) with normal menstrual function started $GnRH_{AG}$ (leuprolide acetate 3.75 mg) therapy as monthly injections and were randomized to receive transdermal placebo $GnRH_{AG}$+PL or $GnRH_{AG}+E_2$ (0.075 mg/d) therapy for 5 months. Women in each treatment arm were also randomized to an exercise (EX) program or non-exercise control (CON). The exercise intervention was 4 days/week of progressive high-intensity resistance training with days split between upper and lower body exercises. Total (ToD), trabecular (TrD), and cortical (CoD) vBMD was measured at 4, 33, and 66% of the length of the tibia with pQCT. Differences in change from baseline to 5 months between groups were tested using an ANCOVA model conditioned on baseline. Planned contrasts were: $GnRH_{AG}$+PL vs. $GnRH_{AG}+E_2$, $GnRH_{AG}$+PL+CON vs. $GnRH_{AG}$+PL+EX, and $GnRH_{AG}$+PL+EX vs. $GnRH_{AG}+E_2$+CON. Decreases in vBMD in response to $GnRH_{AG}$ treatment were largest in trabecular regions (Table 1) and EX appeared to have a small benefit (TrD: $GnRH_{AG}$+PL+CON vs. $GnRH_{AG}$+PL+EX, p=0.02; $GnRH_{AG}$+PL+EX vs. $GnRH_{AG}+E_2$+CON, p=0.09). The benefit of EX was not detected in cortical regions (33% CoD: $GnRH_{AG}$+PL+EX vs. $GnRH_{AG}+E_2$+CON, p=0.06). Given the small sample sizes, results must be interpreted cautiously.

Table 1. Relative (%) changes in vBMD. Mean±SD

	$GnRH_{AG}$+PL+CON (n=7)	$GnRH_{AG}$+PL+EX (n=6)	$GnRH_{AG}+E_2$+CON (n=7)	$GnRH_{AG}+E_2$+EX (n=7)

Adefovir-induced nephrotoxicity with osteomalacia - cases series. Su Jin Lee*[1], Kwang Joon Kim[2], JO EUN Kim[3], Yumie Rhee[4], Sung-Kil Lim[3]. [1]Yonsei University Health System, South Korea, [2]Severance Hospital, South Korea, [3]Yonsei University College of Medicine, South Korea, [4]Department of Internal Medicine, College of Medicine, Yonsei University, South Korea

Background: Adefovir dipivoxyl (ADF) has been prescribed for patients with chronic hepatitis B (CHB) and increasingly used due to high prevalence of lamivudine resistance. Although adefovir-induced nephrotoxicity (AIN) has been reported in CHB, it is still uncertain the progress or prognosis of AIN. Hence, we report 4 cases of AIN and summarize the progress of AIN.

Method: Retrospective chart review was performed. The patients with abnormal liver function or have history of chronic kidney disease, cancer were excluded. From 2010 to 2013, four patients were diagnosed as AIN. Laboratory parameters including bone turnover markers, whole body bone scan (WBBS), bone mineral density (BMD) were measured at the time of diagnosis.

Result: Chief complaint of four patients was bone pain after taking ADF. All of the patients have taken lamivudine more than 3 years and after that taken ADF for more than 2 years. Laboratory parameters showed hypophosphatemia, hyperphosphateuria, decreased GFR and increased bone turn over markers. Two patients were osteoporotic and another two patients were diagnosed as osteopenia. Two patients had fractures. WBBS showed increased uptake at multiple sites. After diagnosed as AIN, all patients stopped taking ADF and entecavir (ECV) was prescribed. Phosphate supplement was recommended until serum phosphate level would be normalized (K-Phos® neutral 4g daily). After two months, the symptoms of all patients were subsided by changing medication and phosphate replacement.

Conclusion: Based on the results, risk factors for the development of AIN are previous lamivudine use, usage of adefovir more than 2 years. Changing ADF into ECV is effective to prevent progression of renal dysfunction. Phosphate replacement could be effective to control hypophosphatemia and bone pain. Patients undergoing long-term treatment with ADF should be monitored in order to detect renal dysfunction.

High circulating sclerostin levels and low bone formation in primary biliary cirrhosis. Ana Monegal[1], Silvia Ruiz-Gaspà[2], Laia Gifre[3], Albert Pares[4], Rosa Miquel[5], Pilar Peris[6], Marta Dubreuil[7], Ana Arias[8], Nuria Guanabens*[9]. [1]Hospital Clinic Barcelona, Spain, [2]Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd). Hospital Clínic Barcelona., Spain, [3]Hospital Clinic Barcelona, Spain, [4]Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd). Hospital Clínic Barcelona. 3Liver Unit. Hospital Clínic of Barcelona.University of Barcelona., Spain, [5]4Department of Pathology, Hospital Clínic of Barcelona, Spain, [6]Hospital Clínic of Barcelona, Spain, [7]Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBERehd). Hospital Clínic Barcelona, Spain, [8]Department of Rheumatology. Metabolic Bone Diseases Unit. Hospital Clínic of Barcelona, Spain, [9]Universitat De Barcelona, Spain

Background and aims: Low bone formation is the main pathogenic mechanism of osteoporosis in primary biliary cirrhosis (PBC). Sclerostin, an inhibitor of the Wnt pathway, is involved in the regulation of osteoblastogenesis and little is known about its role in the development of bone disease in PBC. Thus, we evaluated the circulating levels of sclerostin and its relationship to bone mass, the parameters of mineral metabolism and liver disease severity. Methods: Serum sclerostin levels were measured in 83 women with PBC (mean age: 60±12 years) treated with ursodeoxycolic acid and 101 control women of the same age. In patients with PBC, we assessed the degree of cholestasis, lumbar and femoral BMD (DXA), as well as parameters of mineral metabolism (Ca/P, PTH, 25OHD, PINP, bone ALP, sCTX, NTX and osteocalcin). In 20 PBC patients sclerostin levels were measured again after 5 years. Results: 77% of patients had low BMD (22% osteoporosis and 55% osteopenia). PBC patients showed higher sclerostin levels than controls (76.7±38.6 vs. 32.5±14.7 pmol/L, $p<0.001$). Sclerostin levels were higher in patients with less severe cholestasis. A direct correlation between sclerostin and lumbar (r=0.354, p=0.002) and femoral BMD (r=0.336, p=0.003), and age (r=0.256, p=0.002) was observed. In the 65 patients not receiving bisphosphonates at the time of the evaluation, there was an inverse correlation of sclerostin with bone formation markers, PINP (p=0.05) and osteocalcin (p=0.037) and bone resorption, NTX (p=0.01) and sCTX (p=0.03). Sclerostin significantly decreased in patients who were evaluated 5 years later (99.5±35.9 vs. 60.1±30.9 pmol/L, p=0.001). Conclusion: In primary biliary cirrhosis there is an increase in sclerostin, related to bone mass and liver disease severity. The inverse association with bone formation markers may indicate that sclerostin plays a role in the decreased bone formation in this liver disease.

Analysis of age among clinical risk factors in patients with glucocorticoid-induced osteoporosis (GIO). Ikuko Tanaka*[1], Mari Ushikubo[2], Harumi Kuda[3], Yuki Takane[3], Kumiko Akiya[3], Shigenori Tamaki[4], Hisaji Oshima[5]. [1]NAGOYA Rheumatology Clinic, Japan, [2]National Tokyo Medical Center, Japan, [3]National Tokyo Medical Center, Japan, [4]National Tokyo Medical Center, Japan, [5]Tokyo Medical Center, Japan

Background) Although management against GIO has been progressed, little data were available for younger patients with GIO.

Purpose) To clarify clinical relevant factors for management in younger patients with GIO.

Patients and Methods) Patients (n=137) with connective tissue diseases other than rheumatoid arthritis were recruited and observed for 2 years. The means of age, disease duration, total prednisolone (PSL) dosage, and daily PSL dosage during the study period were 61+/-15 (SD), 12+/-11 years, 34+/-34g, and 8+/-6mg/day, respectively. Prevalent vertebral fractures were seen in 44% of the patients. Agents used for prevention and treatment of GIO were Bis (54%), active vitamin D3 (7%), vitamin K2 (6%). Bone mineral densities (BMD) were measured with DXA.

Results) 1) The incident vertebral fracture determined with deteriorating grades by the SQ method was seen in 64 patients (47%). 2) In all subjects, logistic regression analysis showed the age (1.4(OR)/5yo), total PSL dosage (1.1/5g), daily PSL dosage (2.4/5mg), and BMD (1.3/5% decrease) as independent risk factors for the incident fracture, and treatments with Bis (0.02) and vitamin K2 (0.06) as preventing factors ($P<0.05$). 3) The older patients (age; ≥ 65) and the middle age patients (age; >40, <65) showed high incident fractures in 2 years (60% and 51%, respectively). Same risk factors for the incident fracture were found in these groups. 4) In younger patients (premenopausal women or age <50 for men), the incident fracture was observed in 17% of the patients, and was not found in patients treated with Bis. The dose of PSL was found a possible risk factor in this group.Conclusions) Because clinical importance of known risk factors in GIO might not be similar in younger patients as compared from those of older patients, careful individual management in younger patients should be considered

Effects of teriparatide (TPT) on bone mineral density and vertebral fractures in patients with severe glucocorticoid-induced osteoporosis (GIO) pretreated with bisphosphonates (BP). Mari Ushikubo*[1], Harumi Kuda[2], Yuki Takane[2], Kumiko Akiya[2], Shigenori Tamaki[3], Ikuko Tanaka[4], Hisaji Oshima[5]. [1]National Tokyo Medical Center, Japan, [2]National Tokyo Medical Center, Japan, [3]Nagoya Rheumatology Clinic, Japan, [4]NAGOYA Rheumatology Clinic, Japan, [5]Tokyo Medical Center, Japan

Background) Although BP and TPT are both recommended for prevention and treatment of GIO, it was not clear whether immediate switch from BP to TPT is effective or not.

Purpose) To clarify effects of immediate switch from BP to TPT on BMD and vertebral fractures in patients with severe GIO.

Patients and Methods) Patients (n=28, 89% women) with connective tissue diseases and severe GIO (low BMD or fragile fractures), who had been treated with alendronate or risedronate and switched to TPT, were recruited and observed for 2 years. The means of age, daily prednisolone (PSL) dosage during the study period were 71+/-11 (SD), 8.0+/-4.9 mg/day, respectively. Prevalent vertebral fractures were seen in 44% of the patients. Bone mineral densities (BMD) of the lumbar spine were measured with DXA. Prevalent vertebral fractures were found in 26 (93%) patients.

Results) 1) The BMD was increased from 77.9+/-11.3 (%YAM) to 80.7+/-11.5 and 79.7+/-11.4 after 1 and 2 years, respectively ($p<0.02$). 2) The levels of serum Ca and IP were not changed significantly. Serum NTX, TRACP-5b, PINP, BAP, ucOC were increased to 152 to 373% after 6 months to 1 year but tended to decrease in the 2nd year. 3) Incident vertebral fractures determined with deteriorating grades by the SQ method were seen in 29% of patients at the 1st year and 22% in the 2nd year (44% in 2 years).

Conclusions) PTP was effective to increase the lumbar spine BMD and to prevent vertebral fractures in severe GIO. Because significant percentages of ineffective cases were seen, a novel treatment strategy for a long time should be developed in GIO.

Rapid changes in bone metabolism and clinical benefits of alendronate in patients with systemic rheumatic diseases treated with high dose glucocorticoid: Early DIagnosis and Treatment of OsteopoRosis in Japan (EDITOR-J) Study. Yoshiya Tanaka*[1], Hiroko Mori[2], Takatoshi Aoki[3], Tatsuya Atsumi[4], Yutaka Kawahito[5], Hisanori Nakayama[6], Shigeto Tohma[7], Hitoshi Hasegawa[8], Kazuhide Tanimura[9], Nobuo Negoro[10], Yuji Yamanishi[11], Yukitaka Ueki[12], Atsushi Kawakami[13], Katsumi Eguchi[14], Kazuyoshi Saito[15], Yosuke Okada[16]. [1]University of Occupational & Environmental Health, Japan, Japan, [2]University of Occupational & Environmental Health, Japan, Japan, [3]Department of Radiology, University of Occupational & Environmental Health, Japan, Japan, [4]Hokkaido University School of Medicine, Japan, [5]Kyoto Prefectural University of Medicine, Department of Inflammation & Immunology, Japan, [6]Samihara National Hospital, Department of Rheumatology, Japan, [7]Sagamihara National Hospital, National Hospital Organization, Department of Rheumatology, Clinical Research Center for Allergy & Rheumatology, Japan, [8]Ehime University Graduate School of Medicine, Department of Rheumatology, Japan, [9]Hokkaido Medical Center for Rheumatic Diseases, Japan, [10]Clinical Immunology & Rheumatology, Osaka City University, Japan, [11]Department of Rheumatology, Hiroshima Rheumatology Clinic, Japan, [12]Sasebo Chuo Hospital, Rheumatic & Collagen Disease Center, Japan, [13]Nagasaki University Graduate School of Biomedical Sciences, Department of Immunology & Rheumatology, Japan, [14]Sasebo Municipal Hospital, Department of Internal Medicine, Japan, [15]The First Department of Internal medicine, University of Occupational & Environmental Health, Japan, Japan, [16]University of Occupational & Environmental Health, Japan

Although glucocorticoids are widely used for the treatment of rheumatic diseases, osteoporosis is the most common and serious side effect in glucocorticoid therapy and bone fracture occurs in 30% to 50% of patients on long-term glucocorticoid therapy. However, there is not enough evidence for the prevention of osteoporosis induced by high-dose glucocorticoid therapy. We conducted a prospective multicenter study to assess early changes in the dynamics of bone metabolism in patients with systemic connective tissue diseases following commencement of high-dose glucocorticoid and the benefits of early treatment with bisphosphonate and a vitamin D analog. The subjects of this randomized controlled trial were 106 female, including 37 SLE, 42 vasculitis syndrome and 27 DM/PM, treated for the first time with PSL ?20 mg/day. One week after initiation of glucocorticoid therapy, patients were randomly assigned to treatment with alfacalcidol, a vitamin D analog, at 1 μg/day, alendronate, a bisphosphonate, 35 mg/week, and alfacalcidol plus alendronate. The primary endpoints were changes in lumbar spine bone density at 6 months of treatment and the frequency of bone fracture at 12 months. The study included 58 premenopausal and 48 postmenopausal women, with a mean age of 47.8 years; the initial dose of PSL was 45.5 mg/day, bone mineral density (BMD) for L2-4 was 0.976 g/cm^2, BMD for femoral neck 0.737 kg/m^2. Significant and rapid increases in bone resorption markers (serum CTx, serum NTx and urinary NTx) were observed after 1 week of glucocorticoid therapy. There were no significant differences in baseline characteristics among the treatment groups. After the intervention, bone resorption makers were significantly lower at 24 weeks in the alendronate group and the combination group, compared to the alfacalcidol group. Although the BMD for lumbar spine and femoral neck was markedly lower at 24 weeks after the treatment of alfacalcidol, alendronate and the combination significantly prevented the decrease in BMD. At 12 months after the glucocorticoid therapy, vertebral and non-vertebral bone fractures were observed in 6 (21.4%) patients of the alfacalcidol group, in 2 (6%) of the alendronate group, and in none (0%) of the combination group. Among the various factors at baseline, multivariate analysis identified treatment type as the single significant determinant of the rate of change in lumbar BMD as well as bone fractures. Taken together, we first observed that rapid and marked enhancement of bone resorption was induced within 1 week of the start of glucocorticoid therapy in patients with systemic connective tissue diseases. The combination of alfacalcidol and alendronate administered after the first week of glucocorticoid therapy increased bone density and reduced the incidence of bone fracture for 12 months.

Abaloparatide (BA058), a Human PTHrP Analog: Correlation of In vivo Bone Mass Gains and Improved Bone Strength in an Osteopenic Rat Model. Aurore Varela*[1], Elisabeth Lesage[2], Susan Y. Smith[1], Gary Hattersley[3]. [1]Charles River Laboratories, Canada, [2]Charles River, Canada, [3]Radius, USA

Abaloparatide (ABL) is a PTHrP(1-34) analog being developed for the treatment of osteoporosis. Long-term effects of ABL on bone mass and bone strength were studied in ovariectomized (OVX) skeletally mature rats. Four groups were OVX and one group underwent Sham surgery. After a 3-month bone depletion period, animals received daily subcutaneous injections of either vehicle (Sham and OVX controls) or ABL at 1, 5 or 25 μg/kg for 12 months. DXA and pQCT were performed at the end of the bone depletion period (EBD) and after 12 months of treatment. Lumbar vertebrae and femurs were retained for biomechanical tests. In order to assess the relationship between bone mass change with bone strength, correlation analyses within all OVX groups were performed between % change from the EBD and strength data (L1-L4 DXA vs. L4-L5 compression, proximal femur DXA vs. femoral neck shear, mid-femur DXA vs. femur 3-pt bending and tibia diaphysis cortical pQCT data vs. femur 3-pt bending). Marked gains in bone mass after 12 months of ABL treatment resulted in positive effects on bone strength at all sites. At the lumbar spine, these changes in strength parameters correlated strongly with in vivo gains in BMC/BMD (yield load vs. DXA BMC, r=0.89, yield stress vs. DXA BMD, r=0.90). At the femur diaphysis, strength parameters correlated strongly with in vivo gains in BMC/BMD (peak load vs. DXA BMC, r=0.78, ultimate stress vs. DXA BMD, r=0.76). A positive association was also obtained at another cortical site: the tibia pQCT diaphysis vs. femur diaphysis 3-point bending (peak load vs. pQCT cortical BMC, r=0.84, ultimate stress vs. pQCT cortical BMD, r=0.59). At the femoral neck, gains in bone strength were slightly less marked vs. the in vivo gains in bone mass, resulting in positive but more modest correlations (peak load vs. DXA BMC, r=0.45, ultimate stress vs. pQCT cortical BMD, r=0.54). Individual correlation plots showed a clear dose-response with increased values in both densitometry and strength data as dose increased. Correlations were positive for both primary strength parameters (influenced by geometry) and also for material bone properties, showing positive effects of ABL not only on bone mass but also on bone quality. In summary, ABL resulted in dose-related in vivo bone mass gains and improved bone strength, with strong positive correlations at clinically relevant sites, illustrating the potential clinical impact to mitigate fracture risk.

Abaloparatide (BA058), a Human PTHrP Analog: Correlation of In Vivo Bone Mass Gains and Improved Bone Strength in the Osteopenic Cynomolgus Monkey. Nancy Doyle*[1], Aurore Varela[1], Susan Y. Smith[1], Gary Hattersley[2]. [1]Charles River Laboratories, Canada, [2]Radius, USA

Abaloparatide (ABL) is an analog of hPTHrP (1-34) undergoing clinical development for the treatment of osteoporosis. Long-term effects of ABL on bone mass and bone strength were evaluated in aged osteopenic, ovariectomized (OVX) monkeys. Four groups were ovariectomized (OVX) and one group underwent Sham surgery. Treatment commenced after a 9-month bone depletion period. Animals received daily subcutaneous injection of either vehicle (Sham and OVX controls), or ABL at 0.2, 1 or 5 μg/kg for 16 months. DXA and pQCT scanning were performed at the end of the bone depletion period (EBD) and after 16 months of treatment. Lumbar vertebrae and femurs were retained for biomechanical testing (compression and femoral neck shear). In order to assess the impact of bone mass gains on bone strength, correlation analyses were performed between % change in bone mass from the EBD and strength data for all OVX animals for L1-L4 DXA vs. L5+L6 vertebral core compression, L1-L4 DXA vs. L3+L4 vertebral body compression, and for all OVX groups for proximal femur DXA vs. femoral neck shear. Marked gains in bone mass after 16 months of ABL treatment at the lumbar spine and femoral neck resulted in positive effects on bone strength at these sites. At the femoral neck, these changes in strength parameters correlated strongly with gains in BMC (peak load vs. femoral neck DXA BMC, r=0.89, stiffness vs. femoral neck DXA BMC, r=0.71). For the vertebral cores, strength parameters correlated positively with gains in BMC/BMD (yield load vs. DXA BMC, r=0.50, apparent strength vs. DXA BMD, r=0.53). For the vertebral bodies, gains in bone strength were slightly less marked vs. the gains in bone mass, resulting in positive but more modest correlations (yield load vs. DXA BMC, r=0.38, apparent strength vs. DXA BMD, r=0.50). Correlation analyses generally showed increased values in both densitometry and strength data as dose increased, with strength values at ⩾1 μg/kg being generally comparable to sham controls. Correlations at the spine were greater for strength parameters adjusted for bone geometry. The overall correlation analysis not only showed positive effects of ABL on bone mass but also on bone quality. In summary, ABL resulted in dose-related bone mass gains and improved bone strength, with positive correlations at the spine and femoral neck, two clinically relevant sites, illustrating the potential clinical impact to mitigate fracture risk.

Activation of the cAMP/PKA Pathway is Dominant During Vasodilation of the Femoral Principal Nutrient Artery to PTH 1-84 and PTHrP, While Activation of PKC and cAMP/PKA are Equally Important for Vasodilation to PTH 1-34. Jahyun Kim*[1], Brianna Hood[2], Ashley Bice[3], Rhonda Prisby[1]. [1]University of Delaware, USA, [2]University of Delaware, USA, [3]University of Delaware, USA

BACKGROUND: Nitric oxide (NO) blockade with the endothelial nitric oxide synthase (eNOS) inhibitor L-NAME reduced vasodilation of the femoral principal nutrient artery (PNA) by 81%, 92% and 54% in response to PTH 1-84, PTH 1-34 and PTHrP, respectively (Benson et al., 2012). Further, endothelial cell removal eliminated vasodilation to PTHrP (Prisby & Bice, 2013) and PTH 1-84 (Benson & Prisby, 2013) and dramatically impaired vasodilation to PTH 1-34 (Prisby & Bice, 2013). In human umbilical vein endothelial cells, PTH 1-34 stimulated eNOS via the protein kinase C (PKC) and A (PKA) pathways (Rashid et al., 2007). Thus, we sought to determine the pathways of eNOS activation in response to PTH 1-84, PTH 1-34 and PTHrP in intact bone blood vessels. *METHODS:* Right femoral PNAs were dissected from male Wistar rats (4-6 mon) and cannulated to assess vasodilation to PTH 1-84 (10^{-13} – 10^{-8} M; n=9), PTH 1-34 (10^{-13} – 10^{-8} M; n=9) and PTHrP (10^{-13} – 10^{-8} M; n=8) in the presence of 1) PSS buffer, 2) PSS buffer with the PKC inhibitor, Calphostin, 3) PSS buffer with the cAMP antagonist, Rp-cAMP and 4) PSS buffer with the PTH1 receptor blocker, [Nle ^{8,18,} Tyr^{34}]-PTH(7-34) amide. *RESULTS:* Blockade of PKC, cAMP/PKA and PTHR1 reduced ($p<0.05$) vasodilation by 65%, 86% and 104%, respectively, to PTH 1-84. PTH1 receptor and cAMP/PKA blockade reduced ($p<0.05$) vasodilation to PTHrP by 88% and 80%, respectively, and tended (p=0.08) to reduce vasodilation to PTH 1-34 by 42% and 67%, respectively. *CONCLUSION:* The PKC and PKA pathways are equally important for vasodilation to PTH 1-34. Activation of cAMP/PKA is the dominant vasodilator pathway in response to PTH 1-84 and PTHrP. Finally, vasodilation of the femoral PNA to PTH 1-84, PTH 1-34 and PTHrP occurs via the PTH1 receptor.

Characteristics of premenopausal women with idiopathic osteoporosis who experience significant bone loss after teriparatide cessation. Adi Cohen*[1], Mafo Kamanda-Kosseh[2], Robert Recker[3], Joan Lappe[4], David Dempster[5], Hua Zhou[6], Serge Cremers[2], Mariana Bucovsky[2], Julie Stubby[7], Elizabeth Shane[8]. [1]Columbia University Medical Center, USA, [2]Columbia University, USA, [3]Creighton University, USA, [4]Creighton University Osteoporosis Research Center, USA, [5]Columbia University, USA, [6]Helen Hayes Hospital, USA, [7]Creighton University, USA, [8]Columbia University College of Physicians & Surgeons, USA

We conducted an open-label pilot study of teriparatide (TPTD; 20 mcg daily for 2 years) in 21 premenopausal women with idiopathic osteoporosis (IOP), and reported substantial BMD increases at the lumbar spine (LS; mean ± SD: 10.8 ± 8.3%), total hip (TH; 6.2 ± 5.6%) and femoral neck (FN; 7.6 ± 3.4%). Although postmenopausal women treated with TPTD lose bone mass after therapy is stopped, BMD remains stable after TPTD cessation in postmenopausal women taking estrogen. We hypothesized that our subjects, who by definition had sufficient endogenous estrogen production to menstruate regularly, would maintain the BMD gains associated with TPTD therapy. Of 21 women who completed the pilot study, 4 declined further participation and 2 were perimenopausal and began antiresorptive therapy. BMD was remeasured 2.0 ± 0.6 years after TPTD cessation in the remaining 15 women. LS BMD declined by 4.8 ± 4.3% (p=0.0007) overall and by 3.9 ± 3.9% (p=0.004) after excluding 2 women who became menopausal during follow-up. On average, BMD was stable at the FN (-1.5 ± 4.2), total hip (-1.1 ± 3.7%) and 1/3 radius (+0.2 ± 2.5%). Those who sustained significant LS bone loss, defined as >3% (-7.3 ± 2.9%; n=10), did not differ from those with stable LS BMD (0.1 ± 1.1%; n=5) with regard to baseline BMI, BMD at any site or duration of follow-up (2.1 ± 0.5 vs 1.7 ± 0.8 yrs; p=0.2). Those with LS bone loss tended to be older at baseline (41 ± 3 vs 34 ± 7; p=0.1) and TPTD completion (44 ± 3 vs 36 ± 7; p=0.07), and were significantly older at re-evaluation (46 ± 3 vs 38 ± 7; p=0.046). Those who lost bone mass had larger increases in LS BMD during TPTD treatment (12.7 ± 6.4% vs 5.8 ± 4.2%; p=0.047) and had higher cancellous bone remodeling (mineralized perimeter) on transiliac biopsy at baseline (4.4 ± 2.9 vs 1.7 ± 1.3%; p=0.07) and completion of TPTD treatment (3.4 ± 2.2 vs 0.9 ± 0.8%; p=0.049). However, serum bone turnover markers (BTMs) did not differ at baseline, TPTD completion or follow-up. In summary, 2 years after completing a course of TPTD, the majority of premenopausal women with IOP sustain partial loss of lumbar spine BMD, while gains at the hip are maintained. Those with significant bone loss were usually older, had a more robust response to TPTD and had higher bone turnover on transiliac biopsy, though not by serum BTMs. These findings lead us to conclude that premenopausal women with IOP, particularly those over 40 may require antiresorptive treatment to prevent bone loss after TPTD.

Effect of Teriparatide on Trabecular Bone Microarchitecture Assessed by the Trabecular Bone Score (TBS) in Patients with Osteoporosis. Oksana Davydov*[1], Didier Hans[2], Richard Bockman[3]. [1]New York Presbyterian Hospital/ Weill-Cornell Medical Center, USA, [2]Lausanne University Hospital, Switzerland, [3]Hospital for Special Surgery, Weill Cornell Medical College, USA

Bone mineral density (BMD) is the main measure of bone strength that is used clinically to diagnose osteoporosis. However, it does not always accurately predict fracture risk. Evaluating the trabecular bone microarchitecture increases the accuracy and sensitivity of bone quality examinations. TBS, a texture measurement of 2D projections of existing lumbar spine dual-energy X-ray absorptiometry (DXA) images, is a surrogate measure of trabecular microarchitecture. It has been shown to predict fracture risk independent of BMD. The goal of this study was to analyze the effects of teriparatide (TPTD) treatment on BMD and TBS in a population of patients with osteoporosis.

Bone densities were collected retrospectively for 30 patients treated for osteoporosis with TPTD at the Hospital for Special Surgery. Patients were treated for an average of 24 months. All participants were given calcium and vitamin D supplementation to meet their daily calcium requirements and to maintain 25-hydroxy-vitamin D (25-OH Vit D) levels within normal range. Each patient underwent a baseline and a follow up DXA at the end of the treatment period. BMD at the lumbar spine was assessed by DXA using GE-Lunar Prodigy in 11 participants and Hologic Discovery in 19 patients. The standardized BMD (sBMD) for lumbar spine was calculated using the formula proposed by Hui, et. al. in JBMR (1997) to cross-calibrate the BMD for differences in DXA machines. Twenty-five participants had BMD measured by DXA in the femoral neck (17 Hologic and 8 GE-Lunar). The femoral neck BMD was standardized using the formula in Fan, et. al. in Osteoporosis Int (2010). TBS was determined by TBS INsight software version 2.1.

Twenty-six out of 30 participants were women (Results, Table 1). Percent change in TBS and sBMD did not significantly change if men were excluded from the analysis. The changes in TBS and sBMD did not correlate. Nineteen out of the 30 patients were previously treated with bisphosphonates for an average of 6 years. Baseline and post-TPTD TBS and sBMD values were not affected by prior bisphosphonate (Bisph) exposure, Table 2.

In conclusion: Teriparatide treatment resulted in independent increases in lumbar spine sBMD and TBS, with a greater effect seen on the lumbar spine bone mineral density. Prior exposure to bisphosphonates did not affect the improvement in trabecular bone microarchitecture as measured by the TBS.

	Baseline (mean ± SD)	Post TPTD (mean ± SD)	p-value	Percent Change from Baseline (%)

Effects of Sclerostin antibody on osteoblast and osteocyte viability/autophagy in mouse model of glucocorticoid-induced bone loss. Weiwei Dai[1], Yu-An Lay[2], Li Jiang[3], Xiaodong Li[4], Hua Zhu (David) Ke[5], Nancy Lane[6], Wei Yao*[6]. [1]Longhua Hospital Shanghai University of Traditional Chinese Medicine, USA, [2]UC Davis Medical center, USA, [3]UC Davis Medical Center, USA, [4]Amgen, Inc., USA, [5]Amgen Inc., USA, [6]University of California, Davis Medical Center, USA

Objective. Sclerostin is a negative regulator of bone formation. A monoclonal antibody to sclerostin (Scl-Ab) is a new anabolic agent that builds bone by stimulating bone formation and decreasing bone resorption. We have previously demonstrated that glucocorticoids (GCs) over -stimulate sclerostin expression in bone and, accordingly, inhibits bone formation. Furthermore, high dose or prolong GC treatments inhibit osteoblast and osteocyte cell viabilities through autophagy, an intracellular degradative mechanism that removes dysfunctional organelles and/or oxidized proteins to maintain cell viability. To understand the effects of Scl-Ab on autophagy in response to GC excess *in vivo*, we have generated transgenic mice systemically expressing dsRed fused to LC3, a protein marker for autophagosomes. We then studied the effects of GCs and Scl-Ab on autophagic osteoblasts and osteocytes, bone structure, and strength in these mice.

Methods. Two-month-old male dsRed-LC3 reporter mice received placebo (PL) or prednisolone (2.8mg/kg/d) implantation and then were treated immediately with Scl-Ab (25mg/kg, 2x/wk) for three weeks. Bone volume (BV/TV) and bone formation were measured at the distal femur (DF), lumbar vertebral body (LVB), and mid-femoral shaft (FS) by μCT and bone histomorphometry (n=8-10/group). LC3+ osteoblast surface/bone surface (Ob.S/BS) was determined at LVB and LC3+ osteocyte density was determined at the femoral shaft (FS) in all the study animals. Autophagic RNA and protein levels were determined by RT-PCR and western blotting (WB) on the FS (n=3).

Results. - GC significantly lowered osteoblast surface and inhibited bone formation at both LVB and FS as compared to PL. These changes were associated with reduced bone volume and strength. Scl-Ab completely prevented the decrease in bone formation and the vertebral and femoral strength due to GC excess. GC excess reduced the gene expression in the autophagy pathway by 3-5-fold at the FS and Scl-Ab maintained autophagic gene expression at the PL level. Autophagy of the osteoblast surface (Auto.Ob) was observed at bone surface and frequently co-localized with double-labeled surface. The Auto.Ob was reduced at the trabecular bone surface by nearly 70% in GC group as compared the PL group and was not significantly affected in Scl-Ab group. The autophagic osteocyte density was 39% lower in GC group than in the PL group, whereas it was not significantly affected in Scl-Ab group. Western blot analyses performed at the FS demonstrated that GC reduced the expression of ATG-7, ATG-16L and LC3-II, by more than 50%, indicating reduced formation of autophagosome. Scl-Ab preserved expressions of ATG- 7 and ATG -16L and LC3-II at the PL levels.

Conclusion. GC reduced bone formation, bone mass and osteoblast and osteocyte autophagy. Scl-Ab prevented the detrimental effects of GC on bone formation, bone mass and osteoblast and osteocyte autophagy.

Factors related to the response rate of bone mineral density (BMD) to osteoanabolic therapy (teriparatide/PTH) in patients with severe osteoporosis. Laia Gifre*[1], Ana Monegal[2], Xavier Filella[3], Africa Muxi[4], Nuria Guanabens[5], Pilar Peris[6]. [1]Hospital Clinic Barcelona, Spain, [2]Hospital Clinic Barcelona, Spain, [3]Department of Biochemistry & Molecular Genetics, Hospital Clinic., Spain, [4]Nuclear Medicine Department. Hospital Clinic, Spain, [5]Universitat De Barcelona, Spain, [6]Hospital Clínic of Barcelona, Spain

Background: Factors related to the magnitude of BMD response to osteoanabolic treatment (teriparatide/PTH) remain unclear.

Aim: To evaluate the long-term BMD response rate to osteoanabolic treatment in patients with severe osteoporosis and the factors related to ''inadequate'' response (IR) to therapy.

Methods: 49 patients (46F:3M) with a mean age of 69.5±11.1 years treated with teriparatide (41) or PTH1-84 (8) during 18 or 24months were included (84% had vertebral fractures [mean 5±4], 71% non-vertebral fractures, 86% had been previously treated with bisphosphonates [mean duration 5.7±4.5 years, time range of discontinuation 0-29 months] and 22% were receiving glucocorticoid treatment). Bone turnover markers (BTM)(formation: P1NP, bone ALP; resorption: sCTx, NTx) and 25OH vitamin D (25OHD) levels were assessed before and at 3, 6, 12 and 18/24 months of treatment. Lumbar and femoral BMD and spinal X-ray were assessed at baseline, and at 12 and 18/24 months. Previous and incidental fractures, previous antiosteoporotic treatment, risk factors and cause of osteoporosis were recorded in all patients. IR was defined by a lumbar BMD increase <3% at 18/24 months. BTM were also evaluated in fold-number over/under normal values and as a normalized bone formation/resorption index.

Results: 29% of patients showed IR to therapy. No significant differences were observed in age, length of previous bisphosphonate use or discontinuation, baseline BMD and BTM or bone formation/resorption index, and 25OHD levels between patients with or without IR. As expected, IR patients presented worse BMD evolution in lumbar spine and femur at 18/24 months (Lumbar BMD: -3.4% vs. 12.8%, p <0.001; femur total -0.6% vs. 4.5%, p=0.012). Nevertheless, no significant differences were observed in the magnitude of changes in BTM (formation and resorption markers) throughout the study or in the evolution of their corrected values (by normal range) or the normalized bone formation/resorption index. 25OHD serum levels were similar in both groups of patients throughout the study as was the incidence of new fractures.

Conclusions: In patients with severe osteoporosis previously treated with other antiosteoporotic therapies no factors to predict the efficacy of osteoanabolic agents were identified.

FRAX and the effect of teriparatide on vertebral and non-vertebral fracture. John Kanis[1], Anders Oden[2], Helena Johansson[3], Russel Burge[4], Bruce Mitlak[4], Eugene McCloskey*[5]. [1]University of Sheffield, Belgium, [2]University of Sheffield, United Kingdom, [3]Centre for Metabolic Bone Diseases, University of Sheffield Medical School, Sweden, [4]Eli Lilly & Company, USA, [5]University of Sheffield, United Kingdom

Daily administration of 20 μg or 40 μg teriparatide has been shown to significantly decrease the risk of vertebral and non-vertebral fracture compared with placebo. The aim of the present study was to evaluate fracture risk assessed at baseline using the FRAX® tool and to determine the efficacy of teriparatide as a function of baseline fracture risk. Because there was no difference in fracture efficacy of 20 and 40 μg teriparatide daily, the two active groups were merged. Baseline clinical risk factors (age, BMI, prior fracture, glucocorticoid use, rheumatoid arthritis, smoking and maternal history of hip fracture) were entered into country-specific FRAX models to compute the 10-year probability of major osteoporotic fractures with or without input of femoral neck BMD. The interaction between probability of a major fracture and treatment efficacy was examined by Poisson regression.The 10-year probability of major osteoporotic fractures (with BMD) ranged from 2.2-67.2%. Treatment with teriparatide was associated with a 37% decrease in all non-vertebral fractures compared to placebo treatment (95% CI = 10-56 %). In patients in whom fractures were characterised as low energy, the decrease in fracture risk was more marked (RRR=56%; 95% CI = 24-75 %). The risk of vertebral fractures decreased significantly by 66% (50-77 %). There was no significant effect on hip fracture. Hazard ratios for the effect of teriparatide on the fracture outcome did not change significantly with increasing fracture probability (p>0.30). Similar findings were noted for the interaction when BMD was excluded from the FRAX model. Comparable findings were also noted for the interaction between probability of a hip fracture and treatment efficacy. We conclude that teriparatide significantly decreases the risk of non-vertebral and morphometric fractures in women by a similar extent, irrespective of baseline fracture probability.

Indirubin-3′-oxime, an activator of Wnt/β-catenin pathway, induces osteogenic lineage commitment of ST2 cells and reverses bone loss in high-fat diet-induced obese mice. Jeong-Ha Hwang*[1], Zahoor Muhammad[2], Kang-Yell Choi[2], Pu-Hyeon Cha[2]. [1]Translational Research Center for Protein Function Control, Yonsei University, South Korea, [2]Translational Research Center for Protein Function Control, Yonsei University, South Korea

Obesity is a global issue of the modern world, and its negative impact on bones in obese male patients has been recently reported. The Wnt/β-catenin pathway has an established role in the regulation of body fat content and bone density. We investigated the effects of indirubin-3′-oxime (I3O), the GSK3β inhibitor that activates Wnt/β-catenin signaling, on trabecular bone in high-fat diet (HFD)-induced obese male mice. I3O reverses the downregulating effect of fatty acid (FA) on Wnt/β-catenin signaling and enhances the osteogenic commitment of the bone marrow-derived stromal cell line ST2. FA induces the adipogenic differentiation of bone marrow stromal cells in vitro. In a male mouse model of HFD-induced obesity, trabecular bone loss was observed in the femora, with a gross increase in abdominal fat; however, the HFD effects were rescued with the activation of Wnt/β-catenin signaling by I3O treatment. I3O administration also reversed the increase in the number of HFD-induced adipocytes in the femur bone marrow in trabecular bone. Taken together, our results indicate that I3O could be a potential therapeutic agent for obese male patients through downregulation of abdominal fat and net increment in trabecular bone density.

Noninvasive Quantification of Focal Osteogenesis Induced by Mechanical Loading. Brandon Ausk*[1], Philippe Huber[2], Ted Gross[1], Sundar Srinivasan[1]. [1]University of Washington, USA, [2]University of Washington, USA

Exercise holds potential to focally enhance bone mass at skeletal sites most at risk for fracture. However, current imaging techniques do not permit the noninvasive assessment of exercise induced focal alterations in bone mass. We have previously developed an image registration technique capable of quantifying focal resorption in a model of profound osteoclastogenesis. Here, we sought to extend this technique to noninvasively quantify focal alterations in osteoblast activity induced by mechanical loading of bone. Five female C57 mice (22 mo) underwent cyclic cantilever bending of the right tibia (50 cycles, 1700 με) on M, W, F for 9 wks. A primary μCT scan of the right tibia midshaft (4.45 mm starting 1.78 mm distal to tib-fib junction) was obtained on d 0, with secondary scans obtain on d 21, d 42 and post-sacrifice (d 63). To enable histomorphometric validation of the image registration technique, all mice received calcein (day 10 and 19) and alizarin (day 52 and 61) injections. Based upon previous data, the distal 2.0 mm of the scanned tibia that displays minimal periosteal adaptation was defined as the invariant registration volume (IRV) critical for registration of scans obtained over time. We assessed bone adaptation throughout the scan volume by registering the primary and secondary scans of the tibia segments. As an initial proof of concept, μCT based focal bone alterations were then compared at 3 wks to dynamic histomorphometry parameters at the mid-shaft cross-section (2.0 mm proximal to tib-fib) around 16 circumferential sectors. In this time period, the registration accuracy of the primary and secondary IRVs was consistent with our previous data (1.9 ± 0.3% misalignment). Focal periosteal bone formation rates, as quantified by μCT, was highly correlated with that determined via dynamic histomorphometry (r=0.76, p<0.001; Fig 1). In addition to quantifying osteoblast activity, the image registration technique enabled the tracking of focal osteoclastic bone resorption as well (Fig 1). These results demonstrate that when temporally invariant bone volumes can be identified, image registration enables the accurate quantification of focal bone alterations arising over time from the accumulated activity of bone cells. As this goal can be achieved regardless of whether the intervention is anabolic or catabolic, these data underscore its potential use in clinical trials where it is not possible to quantify bone cell responses via histomorphometry.

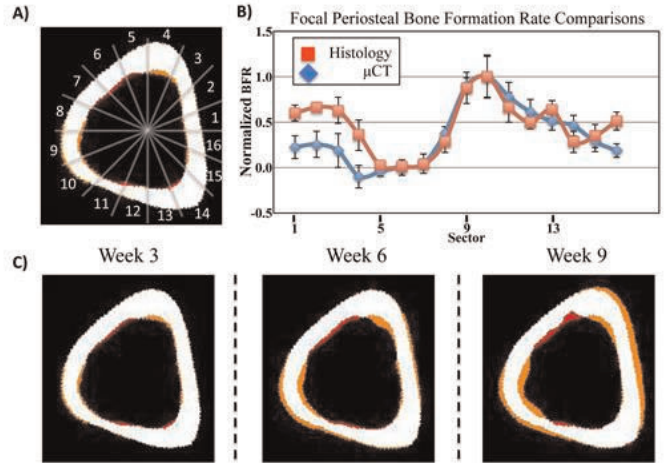

Fig 1: Within the first three weeks, focal periosteal bone formation quantified through µCT image registration (A) was highly correlated to that determined through traditional dynamic histomorphometry (mean ± s.e., B) and allowed for temporal quantification of bone formation (orange, C) and bone resorption (red, C) on all bone surface throughout the 9 wk study.

PTH-CBD, a Long-Acting Parathyroid Hormone Analog, restores normal bone formation after cyclophosphamide therapy in mice. Ranjitha Katikaneni[1], Robyn Goforth[2], Andrew Seymour[3], Robert Gensure[4], Tulasi Ponnapakkam*[5]. [1]Childrens Hospital at Montefiore/Albert Einstein College of Medicine, USA, [2]BiologicsMD, Inc, USA, [3]Department of Pathology, Montefiore Medical Center, USA, [4]Children's Hospital at Montefiore, Albert Einstein College of Medicine, USA, [5]Childrens Hospital at Montefiore, New York/Albert Einstein College of Medicine, USA

PTH-CBD is a hybrid protein of PTH(1-33) and a bacterial collagen binding domain designed to accumulate in collagen rich areas such as bone. We have previously shown that PTH-CBD can improve bone mineral density (BMD) in chemotherapy osteoporosis. We now investigate the time course of this response, examining effects on bone formation and bone removal evident in serology and histological analysis, paired with measurements of BMD, in a mouse model with chemotherapy-induced impairments in bone formation. 8 week old C57BL/6 mice were treated with cyclophosphamide (50 mg/kg/wk IP x 3 weeks), cyclophosphamide plus PTH-CBD (320 mcg/kg SQ x1), or vehicle alone. BMD was measured every 2 weeks. Animals were sacrificed at baseline, 1 month, 2 months, or 3 months to provide blood and tissue samples throughout the expected time of the treatment response. BMD measurements confirm that cyclophosphamide treatment prevented the normal increases in BMD expected in young mice (BMD at 6 weeks: 68.2+/-1.2 chemo vs. 74.4+/-1.1 mg/cm2 no chemo, $p<0.05$), presumably because of impairments in bone formation. PTH-CBD therapy restored the normal pattern of increases in BMD in cyclophosphamide-treated mice (BMD at 6 weeks: 72.9+/-1.2 PTH-CBD + Chemo vs. 68.2+/-1.2 mg/cm2 chemo, $p<0.05$), such that there was no difference between animals which did not receive chemotherapy. Serum samples will be processed for alkaline phosphatase, osteoproteregin, TRAP to assess effects of cyclophosphamide and PTH-CBD on bone turnover. Calcium will also be measured to assess for potential side effects. Histological samples will be processed for histomorphometry and TRAP staining. Together, these data will provide confirmation of the effects of cyclophosphamide on bone formation and bone removal, and will define which of these processes is most important in mediating the restoration of normal BMD seen with PTH-CBD treatment.

Safety of daily subcutaneous administration of teriparatide with regard to calcium metabolism in patients with serum procollagen type 1 N-terminal propeptide elevation above the upper limit of normal range. Takanori Yamamoto*[1], Mika Tsujimoto[2], Hideaki Sowa[3]. [1]Eli Lilly, Japan, [2]Asia Pacific Statistical Science, Eli Lilly Japan K.K., Japan, [3]Lilly Research Laboratories Japan, Eli Lilly Japan K.K., Japan

Purpose: Daily administration of teriparatide enhances bone formation-precedent and -dominant bone metabolism. Procollagen type 1 N-terminal propeptide (P1NP), which is produced in the course of bone metabolism, is a useful marker of therapeutic efficacy. On the other hand, elevation of P1NP over the upper limit of normal range may indicate adverse effects such as calcium metabolism disorders. Thus, we evaluated the relationship between serum P1NP elevation and patient safety using data from a phase 3 study in Japanese patients with osteoporosis. Methods: A randomized clinical trial of teriparatide 20 µg/day was previously conducted in Japanese patients with osteoporosis at high risk of fracture (Full Analysis Set, n = 203; ClinicalTrials.gov identifier: NCT00433160). This study consisted of a 12-month placebo-controlled double-blinded period and a 12-month treatment period in which all patients received open-label teriparatide. Vitamin D and calcium were also administered throughout the study period. Serum P1NP and serum calcium levels were measured at baseline, and 1, 3, 6, 12 and 24 months after starting treatment (24 hours after dosing). Adverse events related to calcium metabolism disorders, metastatic bone neoplasms, and other metabolic bone disorders were analyzed using MedDRA ver.12.0. Results: Median value of serum P1NP increased in the teriparatide group from 52.5 µg/L at baseline to 95.5 µg/L at 1 month after starting treatment and remained high until 24 months. In either treatment group, there was no significant difference in albumin-corrected serum calcium between patients who had a P1NP level >200 µg/L at least once during the study period or those who had P1NP levels ≤200 µg/L over the entire study period. One patient in teriparatide group and 1 patient in placebo-teriparatide group had hypercalcemia during the teriparatide treatment period, but recovered without changing teriparatide dosage or requiring additional medication. Other adverse events possibly related to calcium metabolism disorders included periarthritis calcarea (1 patient in teriparatide group) and chondrocalcinosis pyrophosphate (2 patients in teriparatide group), but none of these were accompanied by significant increases in serum P1NP or serum calcium. Conclusion: Serum P1NP elevation after daily subcutaneous teriparatide treatment indicates efficacy for osteoporosis, however, its relationship with safety concerns related to bone metabolism disorders was not determined.

Thapsigargin increases bone volume in mice in vivo by inhibiting Notch signaling in mesenchymal progenitors and promoting osteoblast differentiation. Hengwei Zhang*[1], Xing Li[2], Brendan Boyce[3], Lianping Xing[4]. [1]Univeristy of Rochester, USA, [2]University of Rochester, USA, [3]University of Rochester Medical Center, USA, [4]University of Rochester, USA

Notch plays critical roles in osteoblasts (OBs) and osteoclasts (OCs) to maintain bone homeostasis under physiological conditions. TNF transgenic (TNF-Tg) mice (a model of rheumatoid arthritis and inflammatory osteoporosis) have sustained Notch activation in their mesenchymal stem cells (MSCs) associated with decreased bone formation. Treatment of these mice with DAPT, a Notch inhibitor, resulted in increased OB differentiation and bone volume, indicating a beneficial effect of Notch inhibition on inflammation-associated bone loss. Thapsigargin (THAP), a long-known regulator of OB and OC function in vitro via effects on intracellular Ca^{++} and ER stress and which is in phase I clinical trials for treatment of solid cancers, was shown recently through complementary genomic screening to also be a Notch inhibitor (Cancer Cell, 2013), but no studies to date have examined its effects on bone volume in vivo. We treated TNF-Tg mice and WT littermates long-term with THAP (0.4mg/kg/injection ip/day for 2 months) and found using in vivo microCT that it slightly increased BV/TV in lumbar vertebrae at 1 month and this increase was significant at 2 months in both TNF-Tg and WT mice: 32±6 vs 27±5% in WT; 24±3 vs 18±2% in TNF-Tg ($p<0.05$ vs. vehicle-treated mice). Histomorphometric analyses showed increased BV/TV (15±4 vs 9±2% in WT; 13±3 vs 5±2% in TNF-Tg, $p<0.05$) and OB numbers (50±9 vs 41±7/mm bone surface in WT; 38±5 vs 22±3/mm in TNF-Tg, $p<0.05$) in tibial sections from THAP-treated mice. Unlike DAPT, which increases OC numbers, THAP significantly decreased OC numbers (1±0.8 vs 2.8±0.7/mm in WT; 1.4±0.7 vs 5.7±1.2/mm in TNF-Tg, $p<0.05$). THAP decreased mRNA levels of the Notch target gene, Hes1, in CD45-MSC-enriched cells from THAP-treated WT (by 90±5%) and TNF-Tg (by 95±8%) mice and increased the formation of CFU-ALP+ colonies (57±5 vs 24±4/dish in PBS-treated WT; 22±2 vs 11±3 in PBS-treated TNF-Tg mice) and nodule formation (68±4 vs 47±6/well in PBS-treated WT; 41±4 vs 8±2 in PBS-treated TNF-Tg) from bone marrow stromal cells from the mice. Long-term Thapsigargin treatment did not affect body weight or survival. Thus, THAP increases bone volume and inhibits Notch signaling in both TNF-Tg and WT mice. THAP has several advantages over DAPT: it more efficiently suppresses Notch signaling, increases bone volume in both TNF-Tg and WT mice, and decreases OC formation. Thus, THAP is a potential new anabolic agent to increase bone mass by inhibiting Notch signaling.

The LRP5 Variants rs312024 and rs312009 are not Associated with Teriparatide Efficacy in the Treatment of Osteoporosis. Hou-Feng Zheng*[1], Lauren Morkry[2], Lee O'Brien[3], Bente Langdahl[4], Brent Richards[1]. [1]McGill University, Canada, [2]McGill University, Canada, [3]Eli Lilly & Company, USA, [4]Aarhus University Hospital, Dnk

Results from a teriparatide pharmacogenetics study [ASBMR Abstract, Presentation Number 1172, 2012], indicated that genetic variants in LRP5 may be associated with a change in femoral neck (FN) bone mineral density (BMD) following 12 months of teriparatide treatment. The rationale for this study was to replicate these results in a second cohort of teriparatide treated patients. DNA samples from two well-characterized cohorts of osteoporosis patients receiving teriparatide for at least 6 months (Canadian cohort, n = 44 and Danish cohort, n= 121), were genotyped by Taqman for 2 SNPs in LRP5 (rs312009 and rs312024). Changes in BMD from baseline to the BMD measurement collected closest to 12 months was assessed using linear regression where the model included covariate adjustments for baseline BMD, BMI, age, gender and years since menopause. Each SNP was tested under a dominant mode of inheritance in the combined Canadian/Danish cohorts (since the primary analysis was for the combined analysis population) and in each individual cohort. The baseline demographics between the Canadian and Danish cohorts were similar; however, an increase in FN BMD was only observed in the Canadian cohort ($P = 0.59$ vs <0.0001 for Danish and Canadian cohorts, respectively). The rs312009 variant was not associated with changes in FN BMD in the overall analysis population or the individual cohorts. The rs312024 variant was not associated with changes in FN BMD in the overall analysis population or the Danish cohort; however an associated with teriparatide induced changes in BMD was observed in the Canadian cohort ($p = 0.02$). However, the effect in the Canadian cohort was in the opposite direction than the discovery cohort, where the GG genotype group had a larger BMD increase in the discovery cohort, and the AA/AG genotype group had a larger BMD increase in the Canadian cohort. The conflicting results may be due to limited power in the current study as the Canadian cohort analysis only included 28 subjects with genotype and relevant clinical information. Analyses in larger cohorts will be necessary to discern the conflicting results. In the current study, we find no evidence that the LRP5 variants rs312009 and rs312024 are associated with teriparatide treatment in the overall analysis population.

Treatment of Severe Osteoporosis in Youngs with Teriparatide And Denosumab. Jose Manuel Quesada Gomez*[1], Concepción Muñoz[2], Maria Angeles Galvez[2], Adolfo Diez-Perez[3]. [1]Quesper R&D, Spain, [2]SAS, Spain, [3]Autonomous University of Barcelona, Spain

Osteoporosis treatment with bone-active drugs is a challenge in young and premenopausal patients with severe osteoporosis. The conventional therapeutic strategy is to stimulate bone formation (anabolic treatment) or inhibit bone turnover (anti-catabolic treatment). The combined treatment of the monoclonal anti RANKL denosumab (Dab) every six months with teriparatide (TPT) every day would maintain the anabolic effects of TPT, inhibiting its catabolic activity.

We have carried out a proof-of-concept study in young patients with severe osteoporosis treated with TPT and Dab to assess bone mineral density (BMD) and bone turnover markers (BTM).

We studied twelve patients (38 ± 15 yr.) with low BMD (lumbar spine (LS) of 0.77 ± 0.1 g/cm^2; total femur (TF) 0.77 ± 0.12 g/cm^2 and increased bone turnover markers and/or spine fracture at baseline. Treated for one to two years with TDP (s.c.) 20 mg/day and denosumab (s.c.) 60 mg/six months.BMD significantly increased at 12 months compared with baseline: CL (0.87 ± 0.9 cm^2, $P < 0.0001$) and TF (0.8 ± 0.13 g/cm^2, $P < 0.0001$) with a gain of 16% after the first year, even reaching a normalized BMD in patients after two years. This treatment was associated with suppression of BTM.

Thus,the combined treatment of teriparatide and denosumab provides a significant and fast gain in BMD. This combinationconstitutes an interesting therapeutical approach for young patients with osteoporosis (low BMD) or high risk of osteoporotic fracture.Acknowledgements: Grant of Intensification of Research in Andalusia and Institute of Health Carlos III (Ministry of Science and Innovation) PI08/1692 project. Bisphosphonate drug holiday: results from the ESTRATOS survey. Enrique Casado*[1], Jorge Malouf[2], Esteban Salas[3], Manuel Caamaño[4], Santos Castañeda[5], Juan Sánchez-Bursón[6], Gabriel Herrero-Beaumont[7]. [1]University Hospital Parc Taulí, Spain, [2]Hospital de la Santa Creu i Sant Pau, Spain, [3]Hospital Universitario de San Juan de Alicante, Spain, [4]Hospital Clínico Universitario Santiago de Compostela, Spain, [5]Hospital Universitario de la Princesa, Spain, [6]Hospital Universitario Nuestra Señora de Valme, Spain, [7]Fundación Jiménez Díaz, Spain

Introduction: Long-term treatment with bisphosphonates (BP) has been associated with some complications. Therefore, although scientific evidence is scarce, some experts recommend a temporary discontinuation of these drugs in patients with osteoporosis who are receiving them for several years.

Purpose : To evaluate the opinion of bone specialists regarding the concept ''BP drug holiday'' and to ascertain their routine clinical practice.

Methods: The ESTRATOS (from Spanish: Treatment Strategy in Osteoporosis) is a 19-item survey regarding the concept ''BP drug holiday'' and decision-making criteria in clinical practice, addressing members of the Spanish Bone Mineral Metabolism and

Research Society (SEIOMM). SPSS v.13.00 software (Chicago, IL) was used for data analysis. Categorical variables were expressed as absolute and relative frequencies; and continuous variables as mean and standard deviation or, as median and range.

Results: We collected 146 completed surveys from bone specialists (62% Rheumatologists, and the remaining 58% from Internal Medicine, General Practitioners, Orthopaedic Surgeons and others). About 88% of the participants had good knowledge of the concept ''BP drug holiday'', and only 3% stated this should never or exceptionally be considered. More than half (57%) of the participants usually take a time off BP after several years of treatment because of the sustained efficacy of BP after withdrawal, while 40% of them due to the risk of long-term complications, especially atypical femoral fractures. DXA and spine X-ray are the most used tools to make a decision of BP discontinuation, and 1 out of 3 participants believe both are necessary. According to 55% of the participants, BP drug holiday should be considered after 5 to 10 years of treatment, although 35% thought it should be considered after 3-5 years. 99% of the participants have already recommended drug holiday to some of their patients, and 90% consider that it should last 2 or more years, regardless of the type of BP. The main indicators for reintroducing treatment are the occurrence of a new fragility fracture or a significant decrease in BMD.

Conclusions: According to our survey bone specialists withdraw temporarily the treatment with BP (drug holiday) in their osteoporotic patients after 3 to 10 years of treatment. Nevertheless, for them it is important to monitor BMD and the incidence of new fragility fractures during the untreated period.

Bisphosphonate ISS Flight Experiment. Adrian LeBlanc*[1], Toshio Matsumoto[2], Jeffrey Jones[3], Jay Shapiro[4], Thomas Lang[5], Linda Shackelford[6], Scott Smith[7], Harlan Evans[8], Elisabeth Spector[8], Robert Ploutz-Snyder[9], Jean Sibonga[7], Joyce Keyak[10], Toshitaka Nakamura[11], Kenjiro Kohri[12], Hiroshi Ohshima[13], Gilbert Moralez[14]. [1]Baylor College of Medicine, USA, [2]University of Tokushima Graduate School of Medical Sciences, Japan, [3]Baylor College of Medicine, USA, [4]Kennedy Krieger Institute, Johns Hopkins, USA, [5]University of California, San Francisco, USA, [6]NASA JSC, USA, [7]NASA, USA, [8]Wyle, USA, [9]USRA, USA, [10]Department of Radiological Sciences, University of California, Irvine, USA, [11]National Center for Global Health & Medicine, Japan, [12]Nagoya City University, Japan, [13]JAXASpace Biomedical Research Office, Japan, [14]UNTHSC, USA

Elevated bone resorption is a hallmark of human spaceflight and bed rest (common zero G analog). In a collaborative effort between the NASA and JAXA space agencies, we tested whether an antiresorptive drug in combination with in-flight exercise would ameliorate bone loss and hypercalciuria during long-duration spaceflight. Measurements of bone loss included DXA, QCT, pQCT, urine and blood biomarkers. We have completed analysis of R+1year data from 7 crewmembers treated with alendronate during flight, as well as immediate post flight (R+<2wks) data from 5 of 10 controls without treatment. Both the treated and current control group used the Advanced Resistive Exercise Device (ARED) during their missions.

We previously reported the pre/post flight results of crew taking alendronate during flight (Osteoporosis Int. 24:2105–2114, 2013). The purpose of this report is to present the 12-month follow-up data in the treated astronauts and to compare these results with preliminary data from untreated crewmembers exercising with ARED (ARED control) or without ARED (Pre-ARED control, previously published). Results: the table presents DXA and QCT BMD expressed as % change from preflight in the control astronauts (18 Pre-ARED and the current 5 ARED-one year data not yet available) and the 7 treated subjects. As shown previously the combination of exercise plus antiresorptive is effective in preventing bone loss during flight. Bone

measures for treated subjects, 1 year after return from space remain at or near baseline values. Except for one region, the treated group maintained or gained bone one year after flight. Biomarker data are not currently available for either control group and therefore not presented. However data from other studies with or without ARED show elevated bone resorption and urinary Ca excretion while bisphosphonate treated subjects show decreases during flight. Comparing the two control groups suggests significant but incomplete improvement in maintaining BMD using the newer exercise protocols compared to earlier resistive exercise protocols. Quantitative characterization of this improvement requires additional measurements in the ARED control group which we are currently collecting. In conclusion, these results indicate that an antiresorptive may be an effective adjunct to exercise during long-duration spaceflight.

Bone Benefit of Fish Oil Supplementation Depends on Its EPA and DHA Content. Md Rahman*[1], Xiao Yang[2], Mohiuddin Rasel[3]. [1]University of Texas Health Science Center, USA, [2]University of Texas at San Antonio, USA, [3]UT Health Science Center at San Antonio, USA

The goal of this study is to determine the effective minimal dose of eicosapenaenoic acid (EPA) and docosahexaenoic acid (DHA) in fish oil (FO) supplementation to maintain better bone health during aging. FO is one of the most popular dietary supplements used by American people for various health benefits. We earlier showed that 9% regular fish oil (RFO) with low content of EPA and DHA could maintain better bone mineral density (BMD) during aging. However, this amount of FO is not feasible for human consumption. To determine if low dose RFO can maintain the bone health during aging, 6 month old C57BL/6 female mice were fed either with 4% RFO or 4% corn oil (representative of American diets which have high content of linoleic acids) fed for 6 months and 14 months. All mice were DXA scanned at 6 month of age as a baseline value. Mice were again DXA scanned after 6 and 14 months of feeding. BMD was analyzed using PIXIMUS software. We did not see any significant improvement of BMD in different bone regions of 4% RFO fed mice as compared to CO fed mice in both age groups. Mice were sacrificed at 12 and 20 month of age and performed the digital x-ray of bones for histomorphometric analysis. No significant difference was found between the groups. We hypothesized that low content of EPA and DHA in 4% RFO may not be sufficient to maintain bone mineral density during aging. Recently, concentrated FO (CFO) with high content of EPA and DHA are available. We further examined if 4% CFO can maintain BMD during aging. Twelve month old female C57BL/6 mice were divided into 4 groups and supplemented for 12 months with 1) 4% CO, (2) 4% RFO, (3) 4% CFO and (4) 1% CFO. Mice were DXA scanned once at 12 month and again at 24 month of age. Interestingly, 4% CFO could maintain higher BMD in lumber, proximal tibial metaphysis, tibial diaphysis, distal femoral metaphysis and femoral diaphysis regions as compared to 4% CO and 4% RFO. This bone beneficial effect of 4% CFO was even more effective than seen in our earlier 9% RFO fed aging mice. Better BMD in 4% CFO was also correlated with reduced pro-inflammatory and enhanced anti-inflammatory cytokine levels in bone marrow cells treated with LPS. Bone marrow cells from 4% CFO mice also exhibited lower levels of NF-κB and MAPK signaling activation. 4% CFO, in fact supplies more amount of EPA and DHA than 9% RFO. These data indicate that bone benefit of FO may depend on how much EPA and DHA consumed through the supplementation.

SU0388

Comparative Characteristics of Subtrochanteric Fracture cases fulfilling and not fulfilling the ASBMR Task Force Criteria. Angela Juby*[1], Sean Crowther[2], Marilyn Cree[2]. [1]University of Alberta, Canada, [2]University of Alberta, Canada

Purpose

Atypical femoral fractures (AFF) are rare, but still have significant impact on quality of life. Association with antiresorptive therapy and duration of treatment is not absolute. Identification of potential subjects at increased risk for these fractures is important. Recent publications suggests that AFF subjects are younger, more likely to be Asian, have fewer co-morbidities, have a diagnosis of osteoporosis, have exposure to bisphosphonates (BP) for >6 years, and are less likely to be men. This study was done to see if the suggested risk criteria from other studies and population groups, are similar in a Canadian population of AFF patients.

Methods

An eleven year review of data from two referral hospitals in Alberta, Canada for subtrochanteric fracture, identified 79 cases. 70 cases were available for radiographic review for assessment of the 2013 ASBMR Task force criteria. The Charlson/Deyo comorbidity index was calculated from the chart review, all cases over 18 years were included (men and women).

Results

There were 41 cases fulfilling the ASBMR criteria, including one male. They were significantly younger (69.9 vs 80.9 years) than the 29 non criteria fracture patients. Also, 27% had prodromal pain compared to 0% in the non ASBMR criteria fracture group. The percentage of Asian patients was low (5%) and not different between the groups. There were similar rates of osteoporosis diagnosis and Charlson co-morbididty, but there were significantly more cases of COPD in the non criteria group (12 vs 4). There were no differences in documented numbers exposed to corticosteroids, or BP, although the AFF group had significantly more cases with BP exposure >10 years, but not with exposure > 6 years. Significance was calculated at 0.05 level.

Conclusion

Our study corroborates some of the data in the literature about potential risk factors for AFF. However, it does not suggest Asian ethnicity, or BP exposure <10 years to be risk factors, but the numbers of non Caucasians was very low in both groups. COPD was suggested as a risk factor for the non AFF group, although there was no clear link with oral glucocorticoid use. Research in this area needs to continue to identify those at risk of AFF with antiresorptive therapy.

Comparative Effects of Raloxifene and Bisphosphonate on Bone Marrow Density and Osteoporotic Fracture Outcomes in Rheumatoid Arthritis Patients. Kowoon Joo*[1], Won Park[1], Seong-Ryul Kwon[2], Mie-Jin Lim[2], Kyong-Hee Jung[2]. [1]Inha University Hospital, South Korea, [2]Inha University Hospital, South Korea

Purpose: Rheumatoid arthritis (RA) accelerates bone loss, increasing the risk of osteoporosis and osteoporotic fractures. We evaluated the effect of raloxifene and bisphosphonate on bone marrow density (BMD) and osteoporotic fractures in RA patients.

Method: We retrospectively examined data of 112 seropositive RA patients who were diagnosed with osteoporosis and started on either raloxifene or bisphosphonate from January 2006 to December 2010 with no prior history of either medication. Patients with baseline BMD and at least one follow up BMD were included. The patients were examined for maximum of 3 years. Bisphosphonates consisted of risendronate, alendronate or oral ibandronate. Vertebral fractures were defined using Genant's semiquantitative classification.

Results: Forty-four patients were in the raloxifene group and 68 patients were in the bisphosphonate group. The patients in the raloxifene group were older and lighter in weight compared to the bisphosphonate group (Table 1). The patients in the bisphosphonate group consumed higher doses of calcium and vitamin D through medication compared to the raloxifene group. There was no significant difference in duration of RA, the daily dosage of prednisolone and medication possession ratio between the 2 groups. Thirty-six patients in the raloxifene group and 67 patients in the bisphosphonate group had follow up BMD at 1 year of treatment. Nineteen patients in the raloxifene group and 40 patients in the bisphosphonate group had follow up BMD at 2 years of treatment. There was no significant difference in the mean change of lumbar, total hip and femoral neck BMD from baseline and the number of vertebral fractures between the 2 groups at 1 year and at 2 years of treatment. Eighteen patients in the raloxifene group and 29 patients in the bisphosphonate group had follow up BMD at 3 years of treatment. There was no significant difference in the mean change of lumbar and femoral neck BMD from baseline and the number of vertebral and non-vertebral fractures between the 2 groups at 3 years of treatment. However the mean change of total hip BMD was higher in the bisphosphonate group compared to the raloxifene group (Table 2).

Conclusion: There was no significant difference in BMD changes and osteoporotic fractures in RA patients treated with raloxifene and bisphosphonate.

Comparison of Bone Turnover in Patients with Prodromal Bone Deterioration (Pbd) and Atypical Femoral Fracture (AFF). Shijing Qiu*[1], George Divine[2], Mahalakshmi Honasoge[1], Saroj Palnitkar[2], Sudhaker Rao[1]. [1]Henry Ford Hospital, USA, [2]Henry Ford Hospital, USA

Background: It is now well established that AFF is one of the most serious complications after long-term bisphosphonate (BP) treatment, which may be linked to severely suppressed bone turnover (SSBT). A lateral femoral cortical crack, which we refer to as PBD, usually precedes AFF. PBD is characterized by a focal bump on the lateral cortex of the femur in which a horizontal fracture line is often present. However, it is unclear if there are differences in bone turnover between patients with PBD and AFF.

Methods and Results: We examined trans-iliac bone biopsies obtained from 12 white women with long-term (>5 years) BP treatment with either PBD (n = 6) or AFF (n = 6). In order to better define the change in bone turnover in PBD and AFF patients, iliac bone biopsies from 48 age-matched healthy white women were used as controls. Histomorphometric measurements were conducted on cancellous bone. AFF patients were significantly younger than PBD patients (57.8 ± 11.2 *vs* 71.5 ± 6.0 years; $p<0.05$). There were no significant differences in the variables examined between PBD and AFF patients, although the bone turnover values in AFF patients were lower than in PBD patients (Table 1). More importantly, compared to the healthy women, the bone turnover-related variables were all significantly decreased in both PBD and AFF patients ($p< 0.05$-0.001; see-Table 1).Conclusions: Both PBD and AFF are associated with SSBT without a significant difference in bone turnover between them. This implies that SSBT appears much earlier than the occurrence of PBD, which in turn precedes AFF. The occurrence of AFF in younger women is likely to be due to the greater amount of physical activity and exercise that would accelerate the damage of bone, resulting in PBD and thus predisposing to AFF. To the best of our knowledge this is the first report on comparative bone turnover status in PBD and AFF. We propose the following sequence for the pathogenesis of AFF: SSBT-PBD-AFF.

Table 1. Comparison of histomorphometric values for iliac cancellous bone between patients with PBD and AFF as well as between PBD/AFF patients and normal postmenopausal women

Effect of Denosumab Three Years Therapy in Women with Osteoporosis and Contraindications to Oral Bisphosphonates on Bone Mineral Density. Andrzej Sawicki*[1], Radoslaw Janiak[2], Ireneusz Nawrot[3], Piotr Sawicki[4]. [1]Synexus Poland, Poland, [2]Medical Centre Synexus, Poland, [3]Medical University of Warsaw, Poland, [4]Medical Centre Synexus, Poland

Objectives: Denosumab is a fully human monoclonal antibody that inhibits bone resorption by neutralizing RANKL, a key mediator of osteoclast formation, function, and survival. In clinical trials denosumab treatment was well-tolerated and increased BMD. The aim was to evaluate whether osteoporotic women with contraindication to oral bisphosphonates treatment (e.g. GERD) or intolerance or resistance, have similar positive effect on bone mass after denosumab have positive effect on bone mass after denosumab as in FREEDOM study patients , in open study in out-patients clinic. We report observational BMD results from the 3 years of treatment. Materials/Method: The study was performed in 138 women with osteoporosis aged 29 to 93 with contraindication to oral bisphosphonates treatment or intolerance or resistance. Bone Mineral Densitometry (BMD) was assessed in AP Spine, Femur Neck and Femur Total regions by Hologic 4500 W before and after 6, 12, 18, 24 and 36 months denosumab treatment and calcium 400-800 mg and vitamin D 800- 1000 i.u. daily. Results: Table 1. Percentage change in BMD from baseline and after 6, 12, 18 , 24. 36 months of denosumab treatment in 138 women with osteoporosis and contraindications to oral bisphosphonates. Note: number of patients in 6, 12, 18, 24, 36 months groups is not the same. Conclusions: These data demonstrated that denosumab treatment for up to 3 years in patients with contraindication to oral bisphosphonates treatment or intolerance or resistance was associated with continued gains in Spine BMD in patients and have good effect in beginning of treatment at 6 months. Denosumab treatment has positive effect on femur BMD up to 3 years of treatment. Denosumab have similar positive effect on bone mass as in FREEDOM study patients.

SU0392

Effects of denosumab on microarchitecture and bone mineral density in a Swiss outpatient women population. Berengere Aubry-rozier*[1], Delphine Stoll[2], Olivier Lamy[3], Didier Hans[1]. [1]Lausanne University Hospital, Switzerland, [2]Centre a bone diseases, Che, [3]University Hospital, Switzerland

Introduction

Bone mineral density (BMD) is a standard for osteoporosis diagnosis and fracture risk prediction. The trabecular bone score (TBS) is a new parameter obtained after a

re-analysis of a DXA exam. TBS is a texture measurement that correlates with parameters of bone microarchitecture. Spine TBS and BMD predict osteoporotic fracture independently and their combination is superior to either measurement alone. TBS and BMD seem to react differently to different treatments for osteoporosis. The subcutaneous administration of denosumab reduces bone turnover and increases bone mineral density and is associated with a reduction of vertebral, nonvertebral and hip fracture. The aim of our study was to evaluate the effect of two years treatment of six-monthly subcutaneous denosumab on TBS and BMD parameters in our post-menopausal women outpatient population.

Method

We selected all consecutive women treated for 2 years with denosumab (60 mg subcutaneously every 6 months) for osteoporosis between October 2010 and December 2013. Patients who had not at least one DXA scan before and one after 2 years of treatment were excluded.

Results

Thirty eight women were included. Mean age was 65 yo (57-80) before treatment with denosumab. Mean body mass index was 24.7 kg/m2 (17.9-36.2) before treatment. It did not significantly change after 2 years. 70% had a prevalent major osteoporotic fracture and 35% already received a previous specific treatment against osteoporosis. After 2 years, TBS increased significantly from 1.283 to 1.307 (+1.8%; $p<0.05$). Spine BMD increased significantly from 0.799 to 0.861 g/cm2 (+7.7%; $p<0.05$) and neck BMD from 0.609 to 0.631 g/cm2 (+3.6%,$p<0.05$).

Conclusion

In our clinical routine population, we found that two years of six-monthly injections of denosumab increased significantly spine BMD, neck BMD and spine TBS.

SU0393

Effects of local administration of zoledronate for the local osteoporotic lesion of ovariectomized rats. Yohei Matsuo*[1], Masafumi Kashii[2], Tsuyoshi Sugiura[3], Masayuki Furuya[4], Tokimitsu Morimoto[5], Takahiro Makino[4], Takaaki Noguchi[4], Kosuke Ebina[6], Takashi Kaito[4], Motoki Iwasaki[4], Hideki Yoshikawa[7]. [1], Japan, [2]Osaka University Graduate School of Medicine, Japan, [3]Faculty of Medicine, Graduate School of Medicine, Osaka University, Japan, [4]Department of Orthopaedic Surgery, Osaka University Graduate School of Medicine, Japan, [5]Department of Orthopaedic Surgery, Osaka University Graduate School of Medicine, Japan, [6]Osaka University, Graduate School of Medicine, Japan, [7]Osaka University Graduate School of Medicine, Japan

Management of local osteoporotic or osteolytic lesions is a clinical challenging problem, and intravenous administration of bisphosphonates has a limited effect for local pathological lesions. We hypothesized that local administration of high-dose zoledronate (ZOL) for local osteoporotic or osteolytic lesions enables to improve local bone structure with little systemic adverse effects. To examine the efficacy and safety of local administration of ZOL on local osteoporotic lesion of ovariectomized rats.6 weeks later after ovariectomy, 30 six-months-old female SD rats were divided into the 3 groups (group L, S, and C). In the group L, 50μl ZOL at a dose of 67μg/kg were locally injected into the bone marrow between the 2 drilled holes and 50μl saline was systemically administrated by subcutaneous injection. In the group S, 50μl saline was locally injected, and 50μl ZOL at a dose of 67μg/kg was systemically administrated. In the group C, 50μl saline was locally and systemically administrated, respectively. 2 local osteoporotic lesions (Area 1: cancellous bone area of right proximal tibia between the two holes where ZOL or saline were injected, Area 2: left side mirror area) were analysed using in vivo micro-CT at 2, 4, 6, and 8 weeks after administration. Histological evaluations of proximal tibiae (Area 1 & 2) were evaluated using HE and TRAP staining. In the group C, vBMD of the Area1 and 2 continuously decreased until week 8 (Area 1: -9%, Area 2: -10%) and local osteoporotic lesion developed. In the group L, vBMD of Area 1 where ZOL was locally administrated increased continuously until week 8 (+40%), but vBMD increased and stayed constant in the group S (+16%). In the group L, vBMD of the Area 2 continuously decreased until week 8 (-9%), but vBMD maintained at the pre-treated level in the group S. TRAP positive osteoclast surface at Area 1 was significantly reduced in the group L compared with the other 2 groups. However, serum TRACP-5b level continuously decreased in the group L, and there were no significant differences in serum TRACP5b level between the group L and S. ZOL is the most potent bisphosphonate that strongly inhibits osteoclast function with high binding affinities for bone. Taking advantage of these characteristics, we showed that local administration of high-dose ZOL for local osteoporotic lesion have more beneficial effects on local bone structure than the systemic administration, and have a little influence on other bone tissue.

Long-term Oral Bisphosphonate Use for Osteoporosis Among Older Women – US and Canadian Perspective. Nicole Wright*[1], Suzanne Cadarette[2], Wilson Smith[3], Andrea Burden[2], Amy Warriner[1], P. Jeffrey Foster[3], Huifeng Yun[1], Mary Melton[3], Jeffrey Curtis[1], Kenneth Saag[1]. [1]University of Alabama at Birmingham, USA, [2]University of Toronto, Canada, [3]University of Alabama at Birmingham, USA

Purpose: Bisphosphonates (BPs) have been widely used for the treatment and prevention of osteoporosis for two decades. Although new parenteral preparations have been introduced, oral BPs still represent the vast majority of osteoporosis treatments. Little is known about the characteristics of or regional differences in long-term oral BP users.

Methods: We evaluated the long-term use of oral BPs in the national US Medicare and Ontario (ON) Canada data systems. The US Medicare cohort consisted of women aged ⩾65 years with an osteoporosis or fracture diagnosis code, or BP prescription fill. The ON data consisted of women aged ⩾66 years who were new users of oral BPs. We identified women with three years of continuous medical and pharmacy coverage. Long-term BP users were those with exposure to an oral BP (alendronate, risedronate, ibandronate, and etidronate) in each of the three most recent years of available data (2009-2011). We evaluated demographic and BP utilization data including, BP exclusivity (no exposure to another BP agent in three year period) and compliance to therapy using proportion of days covered (PDC) *(*days of drug supplied in 3 years/ 3*365.25) . Users with a PDC of ⩾*70%* were considered compliant.

Results: We identified 888,704 US and 99,530 ON women meeting the inclusion criteria with at least one oral BP prescription in the most recent data. We then identified 698,012 US and 54,656 ON long-term oral BPs users (Table). Alendronate was primarily used by Medicare patients (78.0%), whereas risedronate was the primary oral BP in ON (56%). Based on the available data, the mean duration of us among the long-term BP users was five years in both US (SD: 1.1) and ON (SD: 2.2). In the US, risedronate users were more likely to be exclusive users (83%) compared to alendronate users; whereas in ON, a higher proportion of alendronate users were considered exclusive users than risedronate users. All ibandronate users were exclusive users in US data. Compliance was higher in ON (80% alendronate, 78% risedronate) than in US (63% alendronate, 63% risedronate).

Conclusion: Although alternative preparations of BPs and new non-BP drugs have emerged in the market, the prevalence of oral BP use is high. In the data evaluated, the prevalence of long-term use (⩾3years), was also high in both countries. However, compliance differed by country. Evaluations in more recent data would determine if and how drug holidays have altered these characteristics.

Table. Characteristics of Long-term Oral Bisphosphonate Users

	US, 2009-2011 (n=698,012)	ON, 2009-2011 (n=54,656)
Age, mean (SD)	79.3 (7.4)	74.0 (6.4)
Mean BP duration[a], yrs (SD)	5.0 (1.1)	4.9 (2.2)
Most recent BP, (n,%)		
Alendronate	544,656 (78.0)	24,056 (44.0)
Risedronate	96,795 (13.9)	30,600 (56.0)
Ibandronate	56,561 (8.1)	-
Exclusive BP users[b], (n,%)		
Alendronate	419,496 (77.2)	22,596 (93.9)
Risedronate	80,314 (83.0)	26,981 (88.2)
Ibandronate	56,561 (100.0)	-
Compliant BP users[c], (n,%)		
Alendronate	262,125 (62.5)	18,173 (80.4)
Risedronate	50,880 (63.4)	20,981 (77.8)
Ibandronate	33,981 (60.1)	-

[a]Mean duration based on first BP dispensed in each data system. US = 2006-2011; ON: 2002-2011
[b]Exclusive users are those who only filled a prescription for each oral BP among most recent BP users
[c]Compliance estimated at proportion of days covered (PDC) of ≥70% among exclusive BP users

SU0395

The Positive Effects of Bisphosphonate on the Biomechanics of Human Bone Are Not Seen with Long-Term Treatment. Jonathan Ward[1], Constance Wood[2], Keith Rouch[3], David Pienkowski[4], Hartmut Malluche*[5]. [1]University of Kentucky, Department of Biomedical Engineering, USA, [2]University of Kentucky, Department of Statistics, USA, [3]University of Kentucky, Department of Mechanical Engineering, USA, [4]University of Kentucky, USA, [5]University of Kentucky Medical Center, USA

Oral bisphosphonates (BPs) are an established treatment modality for osteoporosis. Although the short-term beneficial effects of BPs on bone mass are known, concerns exist that long-term BP use may predispose to atypical fractures. To address this concern, this study quantified the load-bearing competence of human bone versus the duration of BP treatment.

Fifty-three anterior iliac crest bone biopsies from Caucasian women with osteoporosis (diagnosed by DXA t-scores) were obtained from the Kentucky Bone Registry; 45 from women treated with oral BPs for 1 to 16 years and 8 from women before the start of treatment. Bone samples were scanned using micro-computed

tomography (Scanco μCT 40). A 3D image of trabecular bone from each sample was derived from this micro-CT and subjected to uniaxial compression simulation using finite element analysis (ANSYS 14.0). The apparent elastic modulus (Eapp, reflective of sample rigidity) and failure stress (Pfail, reflective of fracture propensity) of each sample were calculated. A general linear model was then used to fit response curves relating the square root transformed biomechanical response variables to patient characteristics and BP treatment duration at time of biopsy.

The fitted models showed that patient age, BP treatment duration, and BP treatment duration-squared adequately described and were significant predictors of the response variables Eapp and Pfail. Specifically, the prediction equation for the square root of Pfail was: 0.265 - 0.032 age + 0.239 duration - 0.017 duration^2. All p-values for these coefficients were <0.0047. This response curve increased, reached a maximum at 7.06 $\pm$ 0.65 years of BP treatment, and then declined. The prediction equation for Eapp also initially increased with BP treatment duration, reached a maximum at 7.16 $\pm$ 0.67 years, and then declined.

This study provides relevant and much needed information on the relationship between human bone mechanics and BP treatment duration spanning the period of 1 to 16 years. Based on these fitted models showing the relationship between BP treatment duration and bone biomechanics, an initial increase is observed followed by a decline after an estimated 7 years (95% C.I. 5.76 – 8.35 years) of treatment. Mechanistic insights regarding these long-term BP treatment-related changes await prospective studies and complementary evaluation of bone material properties.

SU0396

Treatment of Nonunion of Long Bones in Bisphosphonate users vs Non Bisphosphonate users with Concentrated Autogenous Iliac Crest Bone Marrow Aspirate (BMAC) and Demineralized bone matrix(DBM) and/or Bone Morphogenic Protein. Pingal Desai*[1], Lester Zambrana[2], Saad Hasan[2], Joseph Nguyen[3], Libi Galmer[3], Joseph Lane[1]. [1]Hospital for special surgery, USA, [2]Weil Corneil medical college, USA, [3]Hospital for special surgery, USA

Bisphosphonates are the antiresorptive drugs used to treat osteoporosis and various metabolic bone conditions. They reduce bone resoprtion and so are useful in the treatment of osteoporosis. A long term use of the drug causes alterations to normal pattern of collagen cross-linking in bone, increased mineralization, reduced heterogeneity of mineralization, reduced vascularity and eventually reduced bone turnover. A reduction in bone turnover causes ineffective curing of cracks in the bone. This results in delayed fracture healing in patients with bisphosphonate use.

While the current gold standard of treatment of nonunion is open autologous bone grafting, studies have shown that concentrated percutaneous autologous bone marrow grafting (BMAC) with osteoinductors is an effective treatment for nonunions.

Methods

We hypothesized that BMAC with osteoinductors would be equally effective in treatment of nonunions in patients with bisphosphonate users as compared to nonusers.

We used BMAC with demineralized bone matrix (DBM) and/or recombinant human bone morphogenic protein-2 (BMP) in 82 consecutive patients for delayed union or nonunion fractures between 2006 and 2012 by one surgeon at two institutions. Patients were at least on bisphosphonate therapy for a year prior to the fracture to qualify to be in bisphosphonate user group. Patients were age and sex matched between two groups and followed until radiographic union was achieved, nonunion or another procedure was performed. Differences in clinical characteristics and healing of nonunion between bisphosphonate users and nonusers were evaluated using independent sample t-tests and chi-square tests.

Results

Forty nine patients met the inclusion criteria.There was no significant difference in clinical characteristics between bisphosphonate users and nonusers ($p> 0.05$). The rate of healing bisphosphonate users was 75% and nonusers was 82.7% ($p =0.5$). The time to union in bisphosphonate user was 6.1 months and in nonuser was 4.0 months ($p=0.03$).

Conclusion

This study shows that use of BMAC with osteoinductors is minimally invasive, cost-effective and useful in healing of nonunion in both bisphosphonate users and nonusers. However, time to union of long bone in bisphosphonate user is long as compared to nonusers.

Level of Evidence: Level II, prospective comparative study

Why don't we treat her right? Documentation from physicians when not prescribing medications for women with osteopenia, osteoporosis, or osteoporosis-suspicious fractures. Meg Durbin*[1], Miriam Rotman[2], Bradley Stolshek[3], Harold Luft[4]. [1]Palo Alto Medical FoundationSutter Health, USA, [2]Palo Alto Medical Foundation, USA, [3]Amgen, USA, [4]Palo Alto Medical Foundation Research Institute, USA

Background: National Osteoporosis Foundation (NOF) guidelines recommend screening and treating women for low bone mineral density and high fracture (fx) risk to prevent such fx. Despite proven efficacy, prescription medications (Rx) are inconsistently prescribed. Few studies explore why physicians do not prescribe guideline-consistent treatment (tx).

Objective: To describe physicians' documented reasons for tx not consistent with NOF guidelines for women age ⩾ 50 years with osteopenia, osteoporosis, or osteoporosis-suspicious fx.

Methods: Data were obtained from 2009-10 electronic health records (EHR) in a large multispecialty practice. We identified 9047 patients (pts) with osteopenia, 3112 with osteoporosis, and 2748 with fx. "Rx" included prescriptions from the EHR medication list. "No Rx" reflects no Rx or Rx stopped between 2 mo before and 1 mo after DXA or fx. Pts without Rx included 61% of the 4718 pts with osteopenia and high or no FRAX (2878), 29% of pts with osteoporosis (891), and 59% of pts with fx (1635). We randomly selected and reviewed charts and categorized reasons discernible for tx not consistent with NOF guidelines among 412 pts: 47 pts with severe osteopenia (-2.5 <T score <-2.0) + high FRAX, 218 with osteoporosis; and 147 with fx.

Results: In pts with severe osteopenia + high FRAX (Fig. 1), reasons documented included: prior bisphosphonates > 5 yrs, 14%, pt declined Rx, 9%, MDs noted risk but did not prescribe Rx, 23%; and MD did not document risk or follow up, 53%. In pts with osteoporosis (Fig. 2), pt declined Rx, 15%; prior bisphosphonates > 5 yrs, 17%; MDs noted risk but did not prescribe Rx, 45%; and MDs did not document risk or follow up, 18%. In all 218 pts reviewed with fx (Fig. 3), reasons included: pt frailty, 14% (26% in hip fx); pt declined Rx 5% (10% in upper extremity fx), prior bisphosphonates > 5 yrs, 4% (10% in rib fx); MD noted risk but did not Rx, 49% (60% in rib fx), and MD did not document risk or follow up, 27% (35% in spine fx).

Conclusion: The proportion of different reasons documented for tx that is not guideline-consistent differed across groups. In pts with osteopenia or osteoporosis without fx, MDs most commonly did not document risk or follow up. In pts with fx, MDs most commonly noted risk but did not prescribe Rx. Frailty was more often noted as a reason for no Rx in pts with fx vs. those without fx. Opportunity exists to improve how MDs identify, document and treat patients at high risk for fx.

Factors associated with Hardware Failure, Non-union and other Complications of Atypical Femoral Fractures. R Bleakney*[1], Linda Probyn[2], Leon Lenchik[3], Jonathan Adachi[4], Aliya Khan[5], Earl Bogoch[6], Catherine Lang[7], Robert Josse[8], Angela M. Cheung[9]. [1]Mount Sinai Hospital, Canada, [2]University of Toronto, Sunnybrook Health Sciences Centre, Dept Medical Imaging, Canada, [3]Wake Forest University, USA, [4]St. Joseph's Hospital, Canada, [5]McMaster University, Canada, [6]St. Michael's Hospital, Canada, [7]University of Toronto, Canada, [8]St. Michael's Hospital, University of Toronto, Canada, [9]University Health Network-University of Toronto, Canada

Purpose: Long-term bisphosphonate use has been associated with Atypical Femoral Fractures (AFFs). The purpose of this study is to evaluate the association of fracture morphology and hardware type with hardware failure in patients with AFFs.

Materials and Methods: Imaging studies of 100 patients from the Ontario AFF cohort with 131 AFFs (4 men, 96 women, mean age 68.1 years) with hardware instrumentation from July 2004 to February 2014 were reviewed. Type of instrumentation, fracture morphology (overall fracture morphology (OFM), lateral cortical fracture angle (LCFA), lateral cortical thickness, femoral angle), and fracture location were compared in the hardware complication group and control group using the Wilcoxon rank sum test or Fisher's exact test.

Results: 131 AFFs had instrumentation (98 for complete and 33 for incomplete fractures). Instrumentation included intramedullary (IM) nailing (117), dynamic hip screw (7), lateral plate (2), short gamma nail (3), total hip arthroplasty (1), compression plate (1). Hardware complications occurred in 15.3% (21/131) and were more common in complete (18/21) than incomplete (3/21) fractures. Complications included screw fractures in 19%(4/21), plate fractures in 14.3%(3/21), loosening of hardware in 28.6%(6/21), nonunion in 9.5%(2/21), and combination of complications in 28.6%(6/21). Hardware failure was significantly less common after IM nailing (12.8%) compared to other hardware (35.7%) (p=0.04). Comparing failure to non-failure group, the mean OFM 31.9 degrees (vs 36.3), LCFA 7.0 degrees (vs 11.3), lateral cortical thickness 12.1 mm (vs 12.1), medial cortical thickness 8.9 mm (vs 7.8), femoral angle 133 degrees (vs 133). Comparing failure to the non-failure group, the location of fracture was 14.9 cm (vs 16.8) from the greater trochanter. Of all measured parameters, only LCFA was significantly associated with hardware failure (p= 0.03).

Conclusion: In patients with AFFs, hardware complications are not uncommon. Hardware failure is more common in AFFs with smaller LCFA and when fixation other than IM nailing is used.

Concentration of Urinary C-terminal Telopeptide of Type I Collagen Predicts Bone Mineral Density in Modeling and Simulation Analysis: MOVER Study with Monthly Intravenous Administration of Ibandronate. Kiyohiko Nakai*[1], Satofumi Iida[2], Masato Tobinai[2], Junko Hashimoto[3], Takehiko Kawanishi[2], Yoshiaki Matsumoto[4]. [1], Japan, [2]Chugai Pharmaceutical CO., LTD., Japan, [3]Chugai Pharmaceutical Corporation Limited, Japan, [4]Nihon University, Japan

Purpose: Modeling & simulation (M&S) based on population pharmacokinetics/pharmacodynamics contributes to the efficient development of new drugs; by predicting efficacy, it allows the optimization of clinical trial design, including dose/dosage, observation period, and patient population. Previously conducted M&S has shown links between ibandronate (IBN) dosage, urinary C-terminal telopeptide of type I collagen (uCTx), and lumbar bone mineral density (BMD). In this study, the potential of uCTx as an early response marker was explored by using M&S based on data from the MOVER study.

Methods: Modeling was performed based on the uCTx and BMD values obtained in the MOVER study, where IBN (0.5?or 1 mg) was intravenously administered monthly for 3 years to 758 Japanese osteoporosis patients. The model used nonlinear mixed effects modeling software (NONMEM version 7.2) with a first-order conditional estimation method to link the dosage of IBN, uCTx, and BMD. In addition to modeling using the full data set, modeling was also performed using subsets of the uCTx data up to 3, 6, 12, or 24 months after the first administration of IBN. The BMD values for 3 years were simulated based on the model parameters estimated from each cut-off set of data. These simulated BMD values were compared with the observed ones.

Results: Goodness-of-fit and visual predictive check plots showed that the predictions were in good agreement with the observations. When the absolute BMD values for 3 years simulated from uCTx data until 3, 6, 12, or 24?months were compared with corresponding observed values, median absolute simulation error (representing precision of simulation) was approximately 3% and median simulation error (representing bias of simulation) was approximately 1%. On the other hand, with respect to change in BMD from baseline, the simulated and observed values were not as comparable due to high variability.

Conclusions: This model was successfully applied to the results of the MOVER study. Moreover, the absolute BMD values for 3 years simulated by the model based on uCTx levels until 3 months well reflected the observed results. This suggests that uCTx would be useful as a quantitative early response marker with which to predict the efficacy of long-term IBN treatment. An ultimate objective of osteoporosis treatment is to reduce the risk of fractures. We are currently working on expanding the model to incorporate fracture risk by a time-to-event model.

The Effect of Food on Odanacatib Pharmacokinetics. Stefan Zajic*[1], Aubrey Stoch[2], David Hreniuk[3], Filipos Kesisoglou[4], Fang Liu[5], Deborah Panebianco[5], Stefaan Rossenu[6], Julie Stone[5], Rose Witter[5], Sachiko Yama[7], Randall Stoltz[8]. [1]Merck Research Laboratories, USA, [2]Merck & Co., Inc., USA, [3]Akros Pharma, USA, [4]Merck Research Labs, USA, [5]Merck Research Labs, USA, [6]Merck Research Labs, Netherlands, [7]Merck Research Labs, Japan, [8]Covance, Inc., USA

Odanacatib (ODN) is a selective inhibitor of human cathepsin K being developed for the treatment of osteoporosis in men and women. ODN is an oral, once-weekly drug being studied at the anticipated marketed dose of 50 mg in pivotal trials. The effect of dosing with food on ODN pharmacokinetics (PK) was evaluated in four Phase (Ph) I studies. In addition to study-specific PK analyses, food effect was assessed via absorption modeling based on data from an absolute bioavailability study and via pooled population PK (pop-PK) analysis of data from Ph I, II and III studies. Dosing in Ph II and III clinical trials was done without respect to food.

ODN exposure was increased when dosed with food compared to fasted, with increasing meal fat content corresponding to greater increases in exposure. The effect of food on AUC0-∞ was generally less than that on Cmax. When administered with a high-fat meal, ODN AUC0-∞ was increased by 63% at 50 mg and Cmax by 76 to 136% at 25 to 200 mg compared to fasted. Administration of 25 mg with a Japanese meal of moderate fat content resulted in an increase in AUC0-∞ of 34% and in Cmax of 70% compared to fasted. For doses of 50 to 100 mg with a low-fat meal, AUC0-∞ was increased by 15 to 39% and Cmax by 16 to 20% compared to fasted.

The bioavailability of 50 mg ODN was 30% in the fasted state, and was increased to 36% and 49% when dosed with low-fat and high-fat meals, respectively. An absorption modeling analysis showed that dosing ODN with food appeared to affect primarily the extent of bioavailability, with minor effects on the rate of absorption (ka). These findings are consistent with the hypothesis that ODN absorption, and thus bioavailability, is limited by solubility, and that administration with meals containing dietary lipids increases the solubility of ODN, due to its lipophilicity (logP 3.12). In addition, a pop-PK analysis based on data from Ph I, II, and III studies indicated that meal state was not a meaningful covariate for ODN exposure, suggesting that in patients, dosing ODN with or without food would not be an effective way to control food-related variability in exposure.

Taken together, Ph I, II, and III data support that meal state is not a meaningful determinant of ODN exposure. In light of the available safety and BMD efficacy data obtained in Phase II and III studies in which odanacatib was dosed without respect to food, it is appropriate to recommend that odanacatib may be dosed with or without a meal.

The Effect of Raloxifene on Sclerostin, Bone Turnover and Bone Balance in Postmenopausal Women with Osteopenia. Fatma Gossiel*[1], Kim Naylor[1], Richard Jacques[2], Nicola Peel[3], Richard Eastell[4]. [1]The University of Sheffield, United Kingdom, [2]University of Sheffield, United Kingdom, [3]Sheffield Teaching Hospitals, United Kingdom, [4]University of Sheffield, United Kingdom

Sclerostin is a regulator of bone formation produced by the osteocytes. In postmenopausal women estrogen therapy reduces sclerostin production. Raloxifene is a selective estrogen receptor modulator (SERM) which acts as an agonist on bone, reduces bone turnover and may restore the imbalance between resorption and formation in postmenopausal women with osteopenia. These effects may be mediated by levels of circulating sclerostin. The aims were to investigate the effects of raloxifene on i) sclerostin in postmenopausal women with osteopenia and ii) bone turnover and bone balance compared to healthy premenopausal women.We studied postmenopausal women with osteopenia (mean age 62 years) from a parallel open trial, n=21 receiving 60mg/day of raloxifene (Evista Eli Lilly & Co) and n=23 untreated. Lumbar spine BMD T-score was between -1 and -2.5. Fasting serum was collected at baseline

and up to 48 weeks. Sclerostin was measured by ELISA (TECO Medical Group). The data were $\log_{10}$ transformed and the change from baseline was back transformed and expressed as a percentage change. Fasting serum was also collected from healthy premenopausal women (n=205) (mean age 38 years). We measured PINP and CTX by automated assay (iSYS IDS) and calculated the multiple of the median (MoM) for bone formation (PINP) and bone resorption (CTX) at baseline. The rate of bone turnover was calculated as the square root of the sums of the squared MoMs. Bone balance was calculated from the ratio of the formation MoMs to the resorption MoM. The data were log transformed. After 2 weeks of treatment the mean levels of sclerostin were different between the treated and non-treated groups ($p<0.001$). Sclerostin continued to decrease significantly by 10 to 15% throughout the treatment period, ($p<0.001$), figure. Osteopenic women had higher rates of bone turnover and a more negative balance than premenopausal women (Mahalanobis distance 1.29, $p<0.001$). After 48 weeks of treatment there was no difference in balance and turnover as compared to premenopausal women (Mahalanobis distance 0.15, p=0.802). Raloxifene decreases bone turnover and restores bone balance to levels shown by healthy premenopausal women. These effects may be mediated by sclerostin.

The effects of combination therapy of Raloxifene with Eldecalcitol in postmenopausal osteoporosisswitch from Alfacalcidol to Eldecalcitol. Kozaburo Inoue*[1], Shoichi Ichimura[2], Masaichi Hasegawa[1], Tomoo Inoue[3]. [1]Kyorin Univercity school of Medicine Department of Orthopedic Surgery, Japan, [2]Kyorin University School of MedicineDepartment of Orthopedic Surgery, Japan, [3]Yamanasi Hospital Orpthopedic Surgery, Japan

Objective : The aim of this study was to compare bone mineral density(BMD) and biochemical markers of bone turnover in patients receiving lomg-term raloxifene(RLX) therapy with alfacalcidol(ALF) who continued with ALF or were switched to combination therapy with eldecalcitol(ELD).

Patients and study design : We conducted a randomized, open-labeled, multicenter study with 132 postmenopausal osteoporosis women. A total of 119 women who were diagnosed with postmenopausal osteoporosis and treated with RLX(60mg/d) and ALF(0.5-1?/d) for a mean period of months were randomized into the two groups, continuation of RLX with ALF (n=58, Group RA) or switching combination therapy with RLX and ELD (0.75?/d; n=61, Group RE). Patients continued their assigned treatment in a 12-months study phase.

Outcome measures : BMD (lumbar spine and total hip) was measured at baseline and after the 6 and 12 months. Biochemical parameters (serum Tartrate Resistant Acid Phosphatase-5b; TRACP-5b, Bone specific Alkaline Phosphatase; BAP, calcium; Ca, and urinary Ca excretion) were assessed at baseline and after the 3, 6 and 12 months.

Results : The switching to RLX with ELD therapy, compared with continuation of RLX with ALF, prevented lumbar spine BMD loss (percent cange from baseline at 12 months: +2.16% vs -0.61% ; $p<0.001$). Continuation of combination therapy with RLX and ALF resulted in a decrease in lumbar spine BMD at 12 months, but increased total hip BMD. The percent changes of total hip BMD at 12 months in the both group caused a similar increase (+1.26% and +1.00%; not significant). At 3 months after switching, the percent changes of TRACP-5b and BAP from baseline in the RE group was significantly lower than the RA group (TRACP-5b: -20.2% vs +3.4% ; $p<0.001$). The significant differences of these bone markers among the two groups were also observed at 6 and 12 months. Throughout the sturdy period, in the RA group, the mean value of change in TRACP-5b and BAP remained unchanged. Bone turnover markers in all patients of the both group were not less than the normal premenopausal reference values. The values of the corrected serum Ca and urinary Ca excretion in all patients remained unchanged during the sturdy period, and no significant change was observed among the two groups.

Conclusions: Combination therapy with RLX and ELD switched from RLX and ALF demonstrated beneficial effects on BMD and bone turnover after long-term RLX therapy with ALF.

SU0405

Age and gender differences in the treatment of different osteoporotic fractures. Hans-Christof Schober*[1], Reimer Andresen[2], Kathrin Baessgen[3], Thomas Mittlmeier[4]. [1]Klinikum Südstadt RostockKlinik Für Innere Medizin I, Germany, [2]Westküstenklinikum, Germany, [3]Klinikum Suedstadt Rostock, Germany, [4]University of Rostock, Dept Traumatology, Germany

Introduction: Osteoporotic fractures represent a major health problem. Treatment of femur-,humerus-,distal radius and vertebral fractures comprises a large economic burden. In order to prevent complications immediate and appropriate treatment is necessary. The aim of the study presented was to identify medical and surgical treatment procedures concerning the above mentioned 4 fracture types in women and men in different age groups.

Methods: Between October 2008 and October 2009 we prospectively collected all patients sutaining a fracture of the proximal femur, the proximal humerus, the distal radius and clinically vertebral fractures presenting to all health care institutions in the city of Rostock (200 413 inhabitants, located at the baltic sea). For every patient the type of fracture was ensured by X-Ray. All of the health care reports were reviewed. The different treatment methods were determined.

Results: We detected 242 fractures of the proximal femur (f.162, m.80), 190 of the proximal humerus (f.127, m.63), 395 of the distal radius (f.293,m.102) and 152 clinically vertebral fractures (f.109, m.43).

Treatment options were conservative or surgical procedures. The following options were used:

proximal femur fractures: surgery: female 97 %, male: 100 %
proximal humerus fractures: surgery: female 57%, male 52%
distal radius fractures: surgery: female 24%, male 31 %
vertebral fractures: kyphoplasty: female 33%, male 23 %.

Differences in the duration of hospitalization concerning age groups and gender were observed:

Distal radius fractures: age 75 -89 y. female $7,8 \pm 1,7$ days, male $12,2 \pm 3,2$ days ($p< 0,05$).

Vertebral fractures: age 70 -74 y: $4,2 \pm 0,7$ days vs 85-89y:$9,4 \pm 2,3$ days ($p<0,05$)

Kyphoplasty: $5,9 \pm 0,6$ days vs conservative: $7,2 \pm 0,9$ days (ns)

Conclusion:Despite the different behaviour of women and men especially in different age groups no real differences concerning the treatment aspects could be observed. The longer duration of hospitalization in older age groups should lead to methods with the potential of a faster recovery.

Bone Mineral Density and Vitamin D Status in Antiretroviral-naïve HIV-infected Thais: A Preliminary Result from a Five-Year Prospective Cohort Study. Lalita Wattanachanya*[1], Jureeporn Jantrapakde[2], Anchalee Avihingsanon[3], Reshmie Ramautarsing[3], Nipat Teeratakulpisarn[2], Tanate Jadwattanakul[4], Nittaya Phanuphak[2], Praphan Phanuphak[3]. [1]Kingchulalongkorn memorial hospital, Thailand, [2]Thai Red Cross AIDS Research Centre, Thailand, [3]The HIV Netherlands Australia Thailand Research Collaboration (HIV-NAT), Thai Red Cross AIDS Research Centre, Thailand, [4]Queen Savang Vadhana Memorial Hospital, Thailand

Background: Low bone mineral density (BMD) has been commonly documented in HIV-infected patients from many Western countries, however, there are scant published studies regarding bone mass in Asian populations, especially in females.

Methods: We have conducted a five-year prospective cohort study to determine the prevalence of low BMD, rates of BMD decline and possible risk factors for bone loss in HIV-infected Thais of both sexes. Here, we report cross-sectional analyses of the baseline visit of the study. BMD was performed by dual-energy x-ray absorptiometry scan (Hologic®). CD4+ T-cell count, blood HIV RNA, bone turnover markers, serum 25OHD, parathyroid hormone, calcium, phosphate and sex hormones were measured.

Results: A total of 453 Thai participants were recruited from HIV-NAT and the Thai Red Cross Anonymous Clinic in Bangkok and the Queen Savang Vadhana Memorial Hospital in Chonburi: 117 HIV-infected men, 111 HIV-uninfected men, 103 HIV-infected women and 122 HIV-uninfected women. All HIV-infected individuals were antiretroviral therapy (ART) naïve. Mean age was comparable for all groups (39 ± 6 vs.40 ± 6 years in HIV-infected and uninfected men and 39 ± 4 vs. 41 ± 5 years in HIV-infected and uninfected women). For HIV-infected men, average duration since HIV diagnosis was 2.57 ± 1.3 years, mean CD4+ T-cell count was 339 ± 203 cells/mm^3 and mean HIV RNA was 4.49 ± 0.9 copies/ml. HIV-infected men have lower body mass index (BMI; 22 ± 3 vs.24 ± 3 kg/m^2) but similar lumbar spine Z score [median (IQR) -0.1 (-0.7, 0.5) vs. -0.2 (-0.7, 0.3)] and total hip Z score [0.1 (-0.7, 0.8) vs. 0 (-0.5, 0.5)], compared to controls. Serum 25OHD among men was not significantly different (32.6 ± 13 vs.27.7 ± 11 ng/ml). For HIV-infected women, average duration since HIV diagnosis was 2.58 ± 1.1 years, mean CD4+ T-cell count was 357 ± 188 cells/mm^3 and mean HIV RNA was 4.32 ± 0.9 copies/ml. There was no significant difference in BMD between HIV-infected women and controls with Z score (median, IQR) of -0.1(-0.7, 0.6) vs. 0.1 (-0.6, 0.7) at lumbar spine and 0.4(-0.4, 1.2) vs. 0.6 (0, 1.1) at total hip. No significant difference was observed in 25OHD level

between HIV-infected women and controls (22.7 ± 7 vs.26.4 ± 9 ng/ml). There was no history of previous fracture in any participants.

Conclusion: Low BMD is not detected in middle-aged, ART naïve HIV-infected Thais of both sexes. Vitamin D deficiency was not more prevalent in these patients.

Key words: Bone mineral density, Vitamin D, HIV, Asia

Adequate Glucose Control Attenuates the Effects of Longstanding Type 2 Diabetes on Bone. Tomaz Kocjan*[1], Ana Tomc[2], Jan Zmuc[2], Mojca Jensterle[2], Andrej Janez[2], Ajda Bicek[2], Janez Prezelj[3]. [1]University Medical Centre Ljubljana, Slovenia, [2]University Medical Centre Ljubljana, Slovenia, [3]University Medical Centre Ljubljana, Slovenia

Objective: Longer disease duration and poor glycemic control are among main determinants of the increased fracture risk in patients with type 2 diabetes (T2D). Our aim was to examine the impact of adequately controlled longstanding T2D on established and potential new surrogate predictors of fracture risk.

Methods: This was a cross-sectional study. We compared 25 postmenopausal women with longstanding T2D (average time since diagnosis 10.14 years) on oral antihyperglycemic agents without microvascular complications (mean ± SD, aged 63.4 ± 5.4 years, with BMI 28.6 ± 2.8 kg/m^2) and 25 controls with normal glucose homeostasis matched for age, time since menopause and BMI. Their fasting venous blood samples were taken for the determination of HbA1c, procollagen type 1 N-terminal propeptide (P1NP), C-terminal cross-linked telopeptide of type-I collagen (CTX), osteocalcin, undercarboxylated osteocalcin and osteopontin. Bone mineral density (BMD) at lumbar spine, total hip, femoral neck and distal radius was measured by DXA and trabecular bone microarchitecture was assessed by trabecular bone score (TBS) in both groups.

Results: Glycemia was well controlled in 48.3% of T2D patients (HbA1c ≤ 7.0%) and the average serum HbA1c value of the group was still acceptable at 7.42%. TBS was lower in the T2D patients, however the difference reached only borderline statistical significance (mean ± SD; 1.264 ± 0.107 vs. 1.318 ± 0.104; p=0.074). There were no statistically significant differences in BMD values at all sites between the two groups. The same was true for all measured bone markers with the probable exception of CTX and P1NP where a tendency for lower values in T2D patients was indicated (mean ± SD; 3,707 ± 1,800 pmol/L vs. 4,500 ± 1,599 pmol/L; p=0.072 and 43.9 ± 20.4 μg/L vs. 46.5 ± 13.8 μg/L; p=0.079, respectively).

Conclusions: Our results suggest that adequate glucose control indicated by absence of microvascular complications and satisfactory HbA1c values attenuates the effects of longstanding T2D on bone. However, some negative consequences of the disease reflected in lower TBS and lower bone formation seem imminent.

SU0408

Defects in cortical microarchitecture among postmenopausal African-American women with DM2. Elaine Yu*[1], Melissa Putman[2], Nicolas Derrico[3], Gabriela Abrishamanian-Garcia[3], Joel Finkelstein[1], Mary Bouxsein[4]. [1]Massachusetts General Hospital, USA, [2]Massachusetts General HospitalChildren's Hospital Boston, USA, [3]MGH, USA, [4]Beth Israel Deaconess Medical Center, Harvard Medical School, USA

PURPOSE: Fracture risk is increased in patients with type 2 diabetes mellitus (DM2) despite normal bone mineral density (BMD). In populations comprised predominantly of Caucasians, cortical porosity is higher in diabetics than in non-diabetics. DM2 is more common in African-Americans than in Caucasians. We tested whether postmenopausal African-American women with DM2 have cortical bone deficits as compared to non-diabetic African-American women.

Methods: We measured BMD at the spine, hip, and total body by DXA, and volumetric bone density and microarchitecture at the distal radius and tibia by HR-pQCT in 22 type 2 diabetic and 78 non-diabetic postmenopausal African-American women participating in the Study of Women Across the Nation (SWAN). Microfinite element analysis was performed to estimate bone strength. We measured fasting glucose and insulin and calculated HOMA-IR.

Results: There were no significant differences in age (60 ± 3 yr vs. 59 ± 3 yr, p=NS) or weight (87 ± 20 kg vs. 84 ± 19 kg, p=NS) between the diabetic and non-diabetic groups. DXA BMD was similar in the diabetics and non-diabetics at all bone sites. At the radius, cortical porosity and cortical pore volume were greater ($P<0.04$ for both) and cortical BMD and tissue mineral density were lower ($p<0.05$ for both) in diabetics than in non-diabetics (Table). There were no differences in radius total BMD or trabecular BMD between groups. Measures of cortical bone strength were significantly lower in the diabetic women though overall failure load was similar (Table). There were no significant associations between cortical parameters and either the duration of DM2 or with HOMA-IR. In the full cohort, fasting glucose levels were associated with worse cortical porosity (r=0.25, p=0.02) and lower cortical BMD (r=-0.35, $p<0.01$). In particular, cortical porosity and cortical pore volume were higher among those who had fasting glucose >100 mg/dL ($p<0.05$ for both). There were no differences in tibial bone density or microarchitecture between diabetic and non-diabetic women. These findings remained similar after adjustment for use of diabetes or osteoporosis medications.

CONCLUSIONS: DM2 and higher fasting glucose are associated with unfavorable changes in cortical bone at the non-weight-bearing radius in postmenopausal African-American women. These structural deficits may contribute to the increased fracture risk among women with DM2. Further our results suggest that hyperglycemia may be involved in mechanisms of skeletal fragility associated with DM2.

Sex-specific differences in the relationship between glycemic status and hip geometry: The Baltimore Longitudinal Study of Aging. Kendall Moseley*[1], Chee Chia[2], Eleanor Simonsick[2], Josephine Egan[2], Deborah Sellmeyer[3]. [1]Division of Endocrinology, Johns Hopkins Bayview Medical Center, USA, [2]NIA, USA, [3]The Johns Hopkins Bayview Medical Center, USA

Despite normal to high bone mineral density (BMD) compared to age and weight-matched controls, older men and women with type 2 diabetes mellitus (T2DM) are at increased risk for fracture. The discordance between bone quantity and skeletal fragility has prompted investigation into measures of bone quality in T2DM. The aim of this study was to determine differences in bone quantity, as measured by dual energy X-ray absorptiometry (DXA) and parameters of bone quality, as measured by Hip Structure Analysis (HSA), among older men and women with normal glucose tolerance (NGT), impaired glucose tolerance (IGT) and T2DM. The HSA method utilizes data derived from DXA scans to estimate hip geometry and strength parameters. Older (age > 55 years) men (n=472) and women (n=473) participating in the Baltimore Longitudinal Study of Aging (BLSA) were classified as NGT, IGT or T2DM based on 2-hour oral glucose tolerance testing. Individuals on diabetes medications were categorized as having T2DM and did not undergo oral glucose tolerance testing. Bone quantity was measured using BMD of the spine and hip. Bone quality was measured using DXA and standardized HSA equations. Specifically, bone quality parameters of hip geometry and strength included section modulus (Z), cross sectional area (CSA), and buckling ratio (BR). Men had higher bone quantity (BMD) and quality (hip geometry) than women on all measures. Men and women with T2DM (n=128) had higher BMD of the spine and total hip than those with NGT (n=512, p=0.01). In multivariate models controlling for demographic, anthropometric, biochemical and medication variables, T2DM remained positively associated with BMD of the total hip (R^2 = 0.012; p=0.01). In analyses stratified by sex, both IGT and T2DM were negatively associated with CSA (both $p<0.01$), Z (both $p<0.01$) and hip BR (both $p<0.05$) in women only. There was no observed association between glycemic status and hip geometry parameters in men. In summary, among women over age 55 years, T2DM was positively associated with BMD; however, both IGT and T2DM were inversely associated with the hip geometry and strength parameters CSA and Z although also associated with lower BR. These results indicate a sex-specific association between impairment in hip geometry and the evolution of T2DM. Additionally, the findings in women with IGT suggest that impairments in bone quality may begin early in the development of glycemic derangement.

Musculoskeletal Effects of Two Functional Electrical Stimulation Cycling Paradigms for People with Spinal Cord Injury. Therese Johnston*[1], Mary Schmidt-Read[2], Ralph Marino[3], Christina Oleson[4], Benjamin Leiby[3], Christopher Modlesky[5]. [1]Thomas Jefferson University, USA, [2]Magee Rehabilitation Hospital, USA, [3]Thomas Jefferson University, USA, [4]Thomas Jefferson University, USA, [5]University of Delaware, USA

Purpose: People with spinal cord injury (SCI) rapidly lose bone mass following injury. Rate of loss slows within 2 years but bone loss continues, increasing fracture risk especially in the distal femur and proximal tibia. To attempt to increase load on the lower extremities, the objective of this study was to compare the musculoskeletal effects of a novel low cadence cycling paradigm (LOW-CAD) with functional electrical stimulation (FES) to a high cadence paradigm (HIGH-CAD) for people

SCI. It was hypothesized that LOW-CAD would show greater changes in bone and muscle as greater resistance and thus greater loading could be obtained. Methods: Fourteen men and 3 women ages 22-67 years with C4-T6 motor complete chronic SCI participated. Nine subjects were randomized to LOW-CAD and eight to HIGH-CAD. Subjects cycled with FES 1 hour, 3 times/week for 6 months. LOW-CAD cycled at 20 rpm and HIGH-CAD at 50 rpm. Resistance increased automatically if cadence was maintained. Pre and post training, bone changes were measured via dual-energy x-ray absorptiometry to assess areal bone mineral density (distal femur/proximal tibia), magnetic resonance imaging (MRI) to assess microarchitecture (mid/distal femur), and biochemical bone markers to assess bone formation and resorption. Thigh muscle volume was measured via MRI. Results: LOW-CAD obtained maximal resistance of 2.9 $\pm$ 2.8 Nm and HIGH-CAD of 0.8 $\pm$ 0.2 Nm. Over time, LOW-CAD showed greater decreases ($p<0.05$) in bone-specific-alkaline-phosphatase (BALP) compared to HIGH-CAD (LOW-CAD: 12.9 $\pm$ 3.6 to 10.6 $\pm$ 3.4 µg/L; HIGH-CAD: 13.4 $\pm$ 4.9 to 14.7 $\pm$ 6.1 µg/L) indicating less bone formation. However, N-telopeptide decreased within LOW-CAD ($p<0.05$, 53.4 $\pm$ 25.3 to 34.1 $\pm$ 15.5 mg/dL), suggesting less bone turnover. BALP to N-telopeptide ratio (formation/resorption) increased non-significantly from 0.29 $\pm$ 0.14 to 0.36 $\pm$ 0.16 for LOW-CAD and 0.35 $\pm$ 0.21 to 0.39 $\pm$ 0.21 for HIGH-CAD, indicating less bone turnover for LOW-CAD. Both groups increased muscle volume (LOW-CAD: 1193 $\pm$ 603.7 to1361.1 $\pm$ 546.4 cm3; HIGH-CAD: 1215.6 $\pm$ 331.8 to 1335.1 $\pm$ 342.6 cm3). LOW-CAD showed a non-significant increase (1.08 $\pm$ 0.23 to 1.13 $\pm$ 0.22) in trabecular bone number (measured at 12 images proximal to condyles) while HIGH-CAD showed a non-significant decrease (1.17 $\pm$ 0.33 to 1.14 $\pm$ 0.27). Conclusion: This preliminary study suggests that LOW-CAD may stimulate greater musculoskeletal changes. Research is needed with a larger sample size.

Combined Effects of Spaceflight and Age in Astronauts as Assessed by Areal Bone Mineral Density [BMD] and Trabecular Bone Score [TBS]. Jean Sibonga*[1], Elisabeth Spector[2], Robert Ploutz-Snyder[3], Harlan Evans[2], Lisa King[2], Nelson Watts[4], Didier Hans[5], Scott Smith[2]. [1]NASA Johnson Space Center, USA, [2]Wyle, USA, [3]USRA, USA, [4]Mercy Health Osteoporosis & Bone Health Services, USA, [5]Lausanne University Hospital, Switzerland

Spaceflight is a potential risk factor for secondary osteoporosis in astronauts. Although lumbar spine (LS) BMD declines rapidly, more than expected for age, there have been no fragility fractures in astronauts that can clearly be attributed to spaceflight. Recently, astronauts have been returning from 6-month spaceflights with absolute BMD still above young adult mean BMD. In spite of these BMD measurements, we project that the rapid loss in bone mass over long-duration spaceflight affects the bone microarchitecture of the LS which might predispose astronauts to premature vertebral fractures. Thus, we evaluated TBS, a novel texture index correlated with vertebral bone microarchitecture, as a means of monitoring changes to bone microarchitecture in astronauts as they age. We previously reported that TBS detects an effect of spaceflight (~6-month duration), independent of BMD, in 51 astronauts (47+/-4 y) (Smith et al, J Clin Densitometry 2014). Hence, TBS was evaluated in serial DXA scans (Hologic Discovery W) conducted triennially in all active and retired astronauts and more frequently (before spaceflight, after spaceflight and until recovery) in the subset of astronauts flying 4-6-month missions. We used non-linear models to describe trends in observations (BMD or TBS) plotted as a function of astronaut age. We fitted 1175 observations of 311 astronauts, pre-flight and then post-flight starting 3 years after landing or after astronaut's BMD for LS was restored to within 2% of preflight BMD. Observations were then grouped and defined as follows: 1) LD: after exposure to at least one long-duration spaceflight $>$ 100 days and 2) SD: before LD and after exposure to at least one short-duration spaceflight $<$ 30 days. Data from males and females were analyzed separately. Models of SD observations revealed that TBS and BMD had similar curvilinear declines with age for both male and female astronauts. However, models of LD observations showed TBS declining with age while BMD appeared stable or trending upward. For females (n=8) LD observations were too few to discern a trend. Notably, models describing trends in TBS appeared to be more sensitive to the effects of age than the models for BMD. We conclude that TBS may provide an additional index for the lumbar spine to monitor the combined changes due to spaceflight and due to aging. This increased knowledge may enhance the ability to identify an intervention trigger for premature vertebral fractures in astronauts.

Cortical and trabecular bone microarchitecture after severe burn injury. Christian Muschitz*[1], Gabriela Katharina Muschitz[2], Roland Kocijan[3], Gerald Ihra[4], Heinrich Resch[5], Lukas A. Fischer[6], Thomas Rath[2]. [1]St. Vincent's Hospital, Austria, [2]Division of Plastic & Reconstructive Surgery Department of Surgery, Medical University Vienna, Austria, [3]St. Vincent Hospital Vienna, Austria, [4]Department of Anesthesia & Intensive Care, Medical University Vienna, Austria, [5]Medical University Vienna, Austria, [6]CIR Lab, Department of Radiology, Medical University of Vienna, Austria

Purpose:

Extensive thermal injury causes immediate and severe katabolic metabolism, increased inflammatory cytokines and glucocorticoids, alterations in calcium levels as well as an early detoriation of bone matrix. The objective of this study was to evaluate prolonged alterations in bone microarchitecture and bone metabolism.

Methods:

Male Caucasian patients, who had sustained at least a burn injury stage IIb – III°, were included in this single center case-control study. The minimum timeframe from trauma to evaluation was 24 months. Exclusion criteria were a high-voltage injury, any prior or ongoing antiresorptive or anabolic therapy, any calcium and vitamin D supplementation, any endocrine disease affecting bone metabolism or permanent immobilization. All patients had a HR-pQCT examination of the radius and tibia and an evaluation of fasting serum markers of bone formation (P1NP) and resorption (CTX) as well as 25-OH vitamin D and iPTH levels.

Results:

20 male patients (mean age: 38.0 $\pm$ 10.6 years, mean burn total body surface area: 43.9 $\pm$ 12.3 %) were and compared to 30 age-matched healthy male controls (HC). The mean time after trauma was 27.5 $\pm$ 2.9 months, the mean time of immobilization directly after trauma was 35.9 $\pm$ 11.6 days. At both, the radius and the tibia, CtBMD ($p<0.05$) and CtTMD ($p<0.005$) was significantly lower, CtPo was significantly higher ($p<0.001$) when compared to HC. No differences were observed in CtTh at the radius, but CtTh was decreased by trend at the tibia ($p=0.078$). At the radius and tibia EndoCtPm ($p<0.05$) and TbAr ($p<0.01$) were increased. Serum markers were comparable, but vitamin D was decreased (19.3 $\pm$ 6.4 vs 34.5 $\pm$8.4 ng/ml, $p<0.001$). Five patients had fragility fractures after trauma (radius: 2, humerus: 2, rib 1).

Conclusions:

In this study young male patients who had sustained a severe trauma more than two years prior to all examinations show altered cortical and trabecular bone microstructure. These differences are likely due to the impaired and highly increased bone metabolism in the early stage after trauma. Bone turnover markers do not reflect these alterations and are of less validity. Decreased cortical structures, increased cortical porosity, trabecular area and endocortical perimeter enhance the vulnerability of these patients for fragility fractures.

Hepatitis C Infection is Associated with Lower Bone Mineral Density. Naim Maalouf*[1], Xilong Li[2], Beverley Huet[2], James Cutrell[3], Roger Bedimo[3]. [1]University of Texas Southwestern Medical Center, Dallas, USA, [2]University of Texas Southwestern Medical Center, USA, [3]VA North Texas Health Care System, USA

Background: Hepatitis C virus (HCV) infection, either as mono-infection or as co-infection in HIV-positive individuals, has been associated with an increased risk of fracture in several studies. However, the mechanisms underlying the skeletal effects of HCV are not clearly understood, and the impact of HCV infection on bone mineral density (BMD) has not been well-studied.

Objectives: To compare BMD in HCV-infected (HCV+) vs. non-infected (HCV-) controls, and evaluate the impact of liver disease activity and systemic inflammation on BMD among HCV+.

Methods: Using the National Health and Nutrition Examination Survey (NHANES) 2007-2010 surveys, we identified 205 HCV+ individuals (defined by presence of HCV antibody and confirmed by detectable HCV RNA viral load in blood) who had BMD measurement. For each HCV+ participant, two control (HCV-) subjects matched for gender, race, age ($\pm$5 years) and body mass index (BMI, $\pm$5 Kg/m^2) and available BMD measurement were randomly selected. Liver disease activity was assessed by serum alanine aminotransferase (ALT). Systemic inflammation was assessed by serum C-reactive protein (CRP).

Results: By design, HCV+ and HCV- participants were well-matched with respect to gender, race, age, and BMI (Table). Prevalence of family history of osteoporosis was 7% in both groups. HCV+ were significantly more likely to be current smokers, to consume ⩾ 3 alcoholic drinks daily, to be past drug users, and to have higher serum ALT (61±42 vs. 26±24 IU/L, p<0.001). After adjusting for age, gender, race and BMI, HCV+ had significantly lower BMD at the lumbar spine, femoral neck and total hip (p<0.05, Table). A significant gender x HCV status interaction was detected for BMD. In subgroup analysis, HCV+ men and postmenopausal women had significantly lower BMD at all sites after adjusting for age, race, BMI, tobacco and alcohol use (p<0.05), whereas BMD was similar in HCV+ and HCV- premenopausal women. Among HCV+, there was no significant correlation between BMD and serum ALT or serum CRP.

Conclusions: HCV infection is associated with low BMD independent of age, race, BMI, tobacco and alcohol use in men and postmenopausal women. Severity of systemic inflammation and of liver disease activity (as assessed by serum CRP and ALT respectively) do not explain BMD lowering in HCV+. Additional mechanisms by which HCV impacts bone health and the role of HCV therapy on BMD and fracture risk remain to be determined.

	HCV+ (N=205)	HCV- (N=410)
Age, years	50.4 ± 10.4	50.3 ± 11.4

Risk Factors for Fractures in Women with Breast Cancer, the WHI Bone Density Study. Beatrice Edwards*[1], Zhao Chen[2], Wenjun Li[3], Carolyn Crandall[4], Marilyn Kwan[5], Meryl Leboff[6], Jane Cauley[7]. [1]MD Anderson Cancer Center, USA, [2]University of Arizona College of Public Health, USA, [3]University of California, San Francisco, USA, [4]University of California, Los Angeles, USA, [5]Kaiser Permanente, USA, [6]Brigham & Women's HospitalProfessor of Medicine, Harvard Medical School, USA, [7]University of Pittsburgh Graduate School of Public Health, USA

Background: Fractures are common in women with breast cancer (BC)

Objective: To assess risk factors for fractures in women with prevalent BC

Methods: prospetcive cohort study, WHI Bone Density Study

Results: Within the 11,006 participants, 211 women with prevalent BC were identified at enrollment. During follow up, women with BC sustained 33 fractures (16%). Fractures sites included wrist (11/33), other sites (11/33), hip fractures (6/33) and clinical vertebral fractures (5/33). Women with BC who fractureed were older (67± 6 yr. v. 64 ± 7 yr., p=0.03), had lower BMI (26± 4 v. 28 ± 7, p=0.03), were white (90% v. 63%, p=0.003), and had a history of prior fracture (33% v. 8 %, p=0.001). Few participants were receiving gonadotropin releasing hormones agonists or aromatse inhibitors. Fractures were observed approximatley 4 years after study enrollment (1 - 5 yr). In multivariate logistic regression, being white (O.R.= 5.15, 95% C.I. 1.45, 18.25, p=0.01), and having a prior fracture (O.R. = 3.8, 95% C.I. 1.46, 9.83, p= 0.006) were significant risk factors for fracture, while there was a trend for a higher bMD (O.R. 0.669, 95% C.I. 0.43, 1.04, p=0.07) to be protective in women with BC. Bone density was lower in women with fractures (hip T-score -1.61 ± 0.9 v. -1.03 ± 1.1, p=0.004) than in women with BC without fractures.

Conclusion: Fractures are common in women with BC who have low bone mass. Traditional risk factors such s white ethnicity and a prior fracture are present in women with BC. HIgher BMD was protective in women with BC.

SU0415

serum sclerostin change after exercise in breast cancer patients. Seong-Bin Hong*[1], Soo Hyun Kim[2], Joo Young Han[3], So Hun Kim[4], Moonsuk Nam[4], Yong Seong Kim[4]. [1]INHA University, South Korea, [2]Department of Nursing, Inha University, South Korea, [3]Inha University hospital, South Korea, [4]Inha University School of Medicine, South Korea

Sclerostin, an endogenous regulator of the Wnt pathway and bone formation has been investigate the role in cancer induced bone loss. Its levels increase with age and regulated by PTH. However, there are no data regarding the relationship between sclerostin and bone mineral density in the breast cancer and effect of exercise on the sclerostin level.

Objective: To assess relationships between serum sclerostin level and BMD, and serum sclerostin change after 6 month exercise program in breast cancer patients.

Methods: Serum sclerostin, Ntx and 25(OH) vitamin D were measured in breast cancer patients who hadn't done active exercise. Subjects were divided into exercise and normal activity group. Vitamin D 800 IU and calcium 1000 mg were supplied in both groups. BMD was measured by DXA at baseline and 6 month. Serum sclerostin and bone turnover marker repeated at 6 month.

Results: 46 patients were enrolled. Mean age was 55 7 ± 7 years, Serum sclerostin was measured twice in 24 patients. Serum sclerostin 17.22 ± 9.81 pg/mL, Circulating sclerostin was positively associated with bone mineral density in the spine (r=0.286, P<0.05). However its change was not different in two groups. Sclerostin and 25(OH)D3 level increased in both groups (p<0.05).

Conclusions: In this cross-sectional study, circulating sclerostin was positively associated with BMD in the spine. Although exercise did not effect change of sclerostin, sclerostin may play a role in skeletal mineral metabolism in breast cancer patient.

The Effect of Kidney Function on the Performance of FRAX: A Population-based report from CaMos. Kyla Naylor*[1], William Leslie[2], Amit Garg[3], Guangyong Zou[3], Lisa-Ann Fraser[1], Suzanne Morin[4], Jonathan Adachi[5], Brian Lentle[6], David Goltzman[4], Stuart Jackson[7], Sophie Jamal[8]. [1]Western University, Canada, [2]University of Manitoba, Canada, [3]Western University, Canada, [4]McGill University, Canada, [5]St. Joseph's Hospital, Canada, [6]University of British Columbia, Canada, [7]University of Alberta, Canada, [8]The University of Toronto, Canada

Background: Individuals with chronic kidney disease (CKD) are at an increased risk for fracture. The World Health Organization's Fracture Risk Assessment Tool (FRAX) is widely used in clinical practice to predict the 10-year probability of fracture in the general population. It is not known if FRAX accurately predicts fracture in CKD.

Methods: We examined the discrimination and calibration of FRAX (Canadian tool) using data from the Canadian Multicentre Osteoporosis Study. We included men and women 40 years of age or older who had an estimated glomerular filtration rate (eGFR) value at year 10 of the study. We stratified the cohort by kidney function at baseline (eGFR <60 mL/min/1.73 m^2 *vs.* ⩾60 mL/min/1.73 m^2) and followed subjects for a mean of 4.7 years for an incident major osteoporotic fracture (clinical spine, hip, forearm/wrist, or humerus).

Results: Our analyses included 320 individuals with an eGFR <60 mL/min/1.73 m^2 and 1787 individuals with an eGFR ⩾60 mL/min/1.73 m^2; mean age was 67±10 years and 70.5% were women. There were 20 (6.6%, 95% confidence interval [CI], 4.3 to 10.1%) major osteoporotic fractures over 4.7 years of follow-up in individuals with an eGFR <60 mL/min/1.73 m^2 which was similar to the FRAX predicted fracture risk (5.8% with bone mineral density [BMD]; 7.4% without BMD). FRAX major osteoporotic fracture prediction was slightly lower in individuals with an eGFR <60 mL/min/1.73 m^2 compared to individuals with an eGFR ⩾60 mL/min/1.73 m^2. For example, in individuals with an eGFR <60 mL/min/1.73 m^2 the area under the curve (AUC) value for FRAX with BMD was 0.67 (95% CI, 0.54 to 0.80) compared to those with an eGFR ⩾60 mL/min/1.73 m^2 (AUC: 0.75, 95% CI, 0.69 to 0.81); however, this did not reach statistical significance (p-value=0.257). In individuals with an eGFR <60 mL/min/1.73 m^2 the AUC value for FRAX without BMD was 0.65 (95% CI, 0.51 to 0.78) and in individuals with an eGFR ⩾60 mL/min/1.73 m^2 the AUC was 0.73 (95% CI, 0.67 to 0.80).

Conclusions: In individuals with an eGFR <60 mL/min/1.73 m^2 FRAX demonstrated major osteoporotic fracture predictive discrimination which was slightly lower than individuals with an eGFR ⩾60 mL/min/1.73 m^2. Observed and FRAX predicted fracture rates were similar in individuals with an eGFR <60 mL/min/1.73 m^2. If confirmed by larger studies, FRAX may become a helpful tool for clinicians to use to assess fracture risk in individuals with reduced kidney function.

Assessment of mineral bone diseases in adult post-pancreas transplantation recipients in Japan. Megumi Shibata*[1], Atsushi Suzuki[2], Izumi Hiratsuka[3], Mizuho Kondo-Ando[3], Hiroyuki Hirai[4], Sahoko Sekiguchi-Ueda[2], Takeshi Takayanagi[5], Masaki Makino[6], Hitomi Sasaki[7], Mamoru Kusaka[7], Taihei Itoh[8], Takashi Kenmochi[8], Kiyotaka Hoshinaga[7], Mitsuyasu Itoh[9]. [1]Fujita Health University Division of Endocrinology, Japan, [2]Fujita Health University, Division of Endocrinology, Japan, [3]Division of Endcrinology & Metabolism,Department of Internal Medicine, Fujita Health University School of Medicine,Toyoake, Japan, [4]Fujita Health University Division of Endocrinology, Japan, Japan, [5]Division of Endocrinology & Metabolism, Department of Internal Medicine, Fujita Health University School of Medicine, Toyoake, Japan, [6]Division of Endcrinology & Metabolism, Department of Internal Medicine, Fujita Health University School of Medicine, Toyoake, Japan, [7]Department of Urology, Fujita Health University School of Medicine, Toyoake, Japan, [8]Department of Organ Transplant Surgery, Fujita Health University School of Medicine, Toyoake, Japan, [9]Division of Endocrinology & Metabolism, Department of Internal Medicine, Fujita Health University School of Medicine, Toyoake, Japan

Background: Type 1 diabetes (T1DM) is known to be a risk factor for osteoporotic fracture. Pancreas transplantation is nowadays one of good therapeutic option for unstable T1DM patients, especially when they have end-stage renal diseases (ESRD). Recovery of insulin secretion from transplanted pancreas must give beneficial effect on bone metabolism, but pre-existing chronic kidney disease-mineral and bone disease (CKD-MBD) and other clinical risk factors such as hyperparathyroidism and glucocorticoid therapy would make osteoporosis as a serious problem in post-transplant patients. The aim of this study is to estimate the MBD in post-pancreas transplant recipients. Subjects and Methods: Post-pancreas transplant recipients of Fujita Health University Hospital were recruited (n=14, M/F=4/10, age, 45.9 $\pm$ 7.2 years old, 10 SPK and 2 PTA). Mean age of onset of T1DM was 13.2 $\pm$ 6.5 years old. Simultaneous pancreas-kidney transplantation (SPK) was performed in 11 cases, pancreas-after-kidney transplant (*PAK*) was in 2 cases, and 1 other case had pancreas transplant alone (PTA). Measurement of bone mineral density at lumbar spine and hip were performed during their stay in the hospital for the transplantation. When we examined bone turn over markers, all the patients took continuous glucocoritioid therapy. The data were shown as median with interquartile range. Results: Pre-existing vertebral fracture on x-ray was found in 3 cases. Median hip BMD was 0.59 [0.52 - 0.68] g/cm^2 (Z-score:-1.40[-1.80 - -0.60]), while median lumbar BMD was 0.92 [0.76 -0.99] g/cm^2 (Z-score: -0.50[-1.48 – 0.23]). Serum intact PTH level and TRACP-5b were high (intact PTH, 103.7 [63.6-191.9] pg/mL; TRACP-5b, 508 [343-640] mU/dL). On the other hand, serum osteocalcin level was low (6.1 [3.1-8.0] ng/mL). Serum BAP was 14.0 [9.0-26.2] mg/L. Serum iPTH level was negatively correlated with hip BMD but was not associated with lumbar BMD. These results suggest that post-pancreas transplantation recipients seem to have relatively high risk of osteoporosis, especially when they have secondary hyperparathyroidism after transplantation.

Utility of trabecular bone score in kidney transplantation recipients. Sahoko Sekiguchi-Ueda*[1], Atsushi Suzuki[1], Hitomi Sasaki[2], Midori Hasegawa[3], Hiroyuki Hirai[4], Megumi Shibata[5], Tamotsu Sugita[6], Masashi Sugimoto[7], Yutaka Kinomura[7], Hiroshi Toyama[7], Yukio Yuzawa[8], Kiyotaka Hoshinaga[2], Mitsuyasu Itoh[9]. [1]Fujita Health University, Division of Endocrinology, Japan, [2]Department of Urology Fujita Health University, Japan, [3]Devision of Nephrology, Department of Internal Medicine Fujita Health University, Japan, [4]Fujita Health University Division of Endocrinology, Japan, Japan, [5]Fujita Health University Division of Endocrinology, Japan, [6]Department Radiology Fujita Health University, Japan, [7]Department of Radiology Fujita Health University, Japan, [8]Department of Nephrology Fujita Health University, Japan, [9]Division of Endocrinology & Metabolism, Japan

Background: Despite Kidney transplantation (KTx) could restore many disorders in end-stage renal diseases (ESRD) patients, pre-existing chronic kidney disease-mineral and bone disease (CKD-MBD) and other clinical risk factors such as hyperparathyroidism and glucocorticoid therapy would make osteoporosis as a serious problem in post-KTx patients. The bone density (BMD) measurement by DXA is a ''golden standard'' technique of bone quantity evaluation, but it's not useful for evaluating about bone microstructure and bone quality. Trabecular bone score (TBS) is new type of analysis to evaluate bone microstructure by using lumbar spine front view taken by DXA. The aim of this study is to explore the utility of TBS in post-KTx patients.

Subjects and Methods: Post-KTx recipients in outpatient clinic of Fujita Health University Hospital were recruited (n=32, M/F=20/12, age 51 $\pm$ 1.8 years old, mean duration from KTx, 136 $\pm$ 16 months). Prednisolone or methylprednisolone were prescribed to all patients, and 20 patients (20/32) took oral bisphosphonate.

Result : Mean BMD of lumber spine evaluated by DXA was 0.84$\pm$0.03 g/cm^2, Mean TBS score was 1.29 $\pm$ 0.01. Seven patients were categorized in the range of osteoporosis by lumbar BMD, while 3 patients were by TBS. Only one patient was diagnosed as osteoporosis by both methods. There was significant association between lumbar BMD and TBS in female post-KTx patients ($p<0.01$), but not in male population. Femoral neck BMD was also measured in 25 cases (mean TBS was 1.29 $\pm$ 0.07). Mean femoral neck BMD evaluated by DXA was 0.65$\pm$0.02 g/cm^2 (mean T-score was -1.55$\pm$0.2 SD, and mean Z-score was -0.88 $\pm$ 0.2 SD). TBS was not correlated with hip BMD, its T-score or Z-score regardless of gender. Discussion: TBS is considered to assess bone microstructure independently from BMD. The present study showed that lumbar BMD was correlated with TBS in only female population of post-KTx patients. As MBD in post-KTx patients was modulated by CKD-MBD, medication and treatment for co-existing diseases, more precise assessment of bone and further prospective study should be needed for the prevention of osteoporotic fracture. In post-KTx patients.

SDF-1β / BMP-2 Co-Therapy Augments BMSC-Mediated Healing of Critical-Size Mouse Calvarial Defects. Samuel Herberg*[1], Alexandra Aguilar[2], Sudharsan Periyasamy-Thandavan[3], R. Nicole Howie[4], Mohammed Elsalanty[5], Xing-Ming Shi[5], Mark Hamrick[6], Carlos Isales[5], William Hill[7], James Cray[8]. [1]Case Western Reserve University, USA, [2]UCC School of MedicineGeorgia Regents University, USA, [3]Georgia Regents University & Charlie Norwood VAMC, USA, [4]Georgia Regents University, USA, [5]Georgia Regents University, USA, [6]Georgia Health Sciences University, USA, [7]Georgia Regents University & Charlie Norwood VAMC, USA, [8]Medical University of South Carolina, USA

Purpose: Bone has the potential for spontaneous healing. However, this regenerative process often fails in patients with underlying impairments requiring clinical intervention. Numerous experimental and clinical studies have revealed that bone marrow-derived mesenchymal stem/stromal cells (BMSCs) hold great potential for regenerative therapies. Increasing evidence suggests that stromal cell-derived factor-1 (SDF-1) is involved in bone formation. We have shown that SDF-1β, the second most abundant splice variant, enhances osteogenesis by regulating bone morphogenetic protein-2 (BMP-2) signaling *in vitro* and *in vivo*. Here we investigated healing of critical-size mouse calvarial defects following transplantation of GFP-positive Tet-Off BMSCs that overexpress SDF-1β, either alone or co-delivered with BMP-2, on acellular DermaMatrix (ADM). We tested the hypothesis that SDF-1β/BMP-2 co-therapy augments BMSC-mediated bone formation.

Materials: Critical-size (5-mm) calvarial defects were created in 2-month-old male C57BL/6J mice. 70 animals randomized in 7 groups (n=10) received Tet-Off-EV (empty vector) or Tet-Off-SDF-1β BMSCs alone or co-delivered with 542.5 ng BMP-2 soak-loaded onto ADM. Controls included sham, vehicle, and BMP-2. Animals were euthanized 4-weeks post-surgery. Surgical sites were explanted and subjected to radiographic, μCT, and histomorphometric analyses.

Results: Radiographic and μCT analyses (e.g. BV/TV) revealed significant BMP-2-induced bone formation relative to vehicle controls ($p<0.01$) and BMSCs ($p<0.05$). Both Tet-Off-EV and Tet-Off-SDF-1β BMSCs showed limited healing, comparable to vehicle controls. Co-delivery of BMP-2 promoted the BMSC-mediated regenerative effects, which were significantly enhanced with SDF-1β overexpression ($p<0.05$). However, BMSCs+BMP-2 produced less bone than BMP-2 alone. Quantitative histomorphometry (e.g. B.Ar/T.Ar) confirmed the microstructural bone evaluation. Immunohistochemistry for GFP showed significantly greater signal intensity in ADM soak-loaded with BMSCs+BMP-2 compared to BMSCs alone. *In vitro* cell culture studies suggested that the decrease in BMP-2 osteoinduction with co-delivery of BMSCs is due to both cell adsorption and uptake, reducing the bioavailable BMP-2 dose on the ADM carrier.

Conclusion: Our data suggest that SDF-1β/BMP-2 co-delivery provides significant synergistic effects supporting BMSC-mediated bone healing and appears a suitable strategy for optimization of clinical bone augmentation.

Acute inflammatory response in macrophages induced by titanium particles released from ultrasonic scaling of surface-treated dental implants. Michal Eger*[1], Nir Sterer[2], Tamar Liron[1], David Kohavi[2], Yankel Gabet[3]. [1]Department of Anatomy & Anthropology, Sackler Faculty of Medicine, Tel Aviv University, Israel, [2]Department of Prosthodontics, Goldschleger School of Dental Medicine, Sackler Faculty of Medicine, Tel Aviv University, Israel, [3]Department of Anatomy & AnthropologySackler Faculty of Medicine, Israel

Titanium and its alloys are widely used as dental implants due to their biocompatibility, mechanical strength, high corrosion resistance and above all osseointegration (direct bone-titanium bonding). To date, virtually all available implants undergo surface roughening in order to accelerate osseointegration and shorten healing time before loading. Peri-implantitis is a major clinical concern and main cause of long term implant failure. Triggered by specific oral bacteria, it consists of an inflammatory process that leads to bone resorption around dental implants. Once the process starts it can hardly be controlled and often results in implant loss. Treatment includes mechanical cleaning of the surrounding oral flora by ultrasonic scaling. We hypothesize that the scaling process releases titanium particles into the implant micro environment and that these particles aggravate or even trigger the inflammatory response. To test this hypothesis, we performed ultrasonic scaling (NanoSight®) of titanium discs that had a sand-blasted/acid etched (SLA) surface. The released particles were then added to bone marrow-derived mouse macrophages (BMDM) cultures. Bacterial lipopolysaccharides (LPS) were added to parallel cultures as positive control and in addition to titanium particles to assess additive/synergistic effects. RT-qPCR indicated that titanium particles stimulated gene expression of pro-inflammatory cytokines (TNFα, IL1β, IL6) to a greater extent than LPS. We then compared the profile and quantity of titanium particles obtained from 3 different surface types, namely machined, SLA and sand-blasted (SB). Using SEM, we found implant surfaces differed in the micro-roughness and quantity of titanium particles released during scaling but not their average size. BMDM were then cultured with the particles released from each surface type. Particles originating from SB implants yielded the most severe inflammatory response, while particles from machined implants induced the mildest inflammasome. This was mainly due to differences in the number of released particles. These data suggest that scaling of titanium implants, intended at preventing peri-implantitis, may actually aggravate the catabolic inflammatory response by causing an accumulation of titanium particles in the peri-implant environment. This adverse reaction is likely to be even more severe around roughened titanium implants.

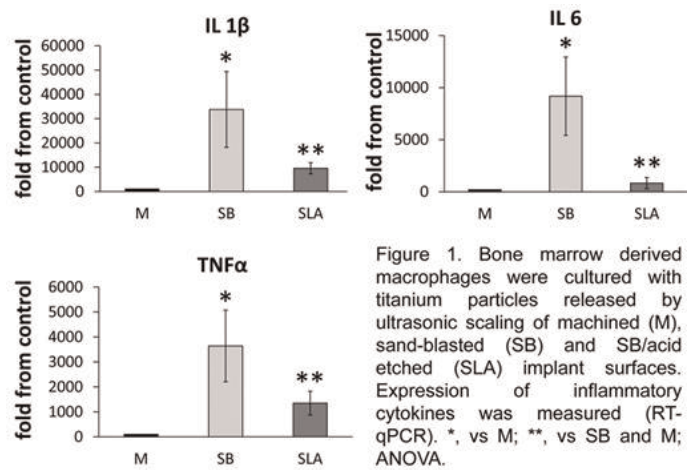

Figure 1. Bone marrow derived macrophages were cultured with titanium particles released by ultrasonic scaling of machined (M), sand-blasted (SB) and SB/acid etched (SLA) implant surfaces. Expression of inflammatory cytokines was measured (RT-qPCR). *, vs M; **, vs SB and M; ANOVA.

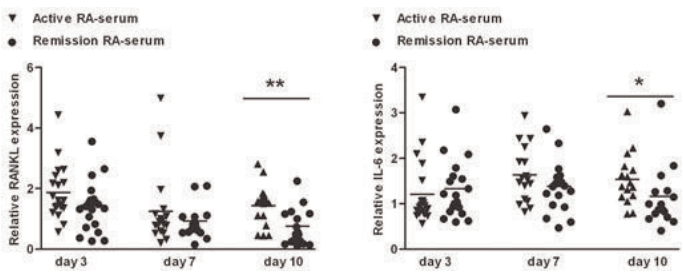
Inflammatory Factors in the Circulation of Patients with Active Rheumatoid Arthritis Stimulate Osteoclastogenesis via Endogenous Cytokine Production by Osteoblasts. Janak L Pathak[1], Nathalie Bravenboer[2], Patrick Verschueren[3], Willem F Lems[4], Frank P Luyten[5], Jenneke Klein-Nulend*[6], Astrid D Bakker[7]. [1]ACTA-University of Amsterdam & VU University Amsterdam, Dept Oral Cell Biology, MOVE Research Institute Amsterdam, Netherlands, [2]VU University Medical Center, The Netherlands, [3]Skeletal Biology & Engineering Research Center, KU Leuven, Belgium, [4]Department of Rheumatology, VU University Medical Center, MOVE Research Institute Amsterdam, Netherlands, [5]Skeletal Biology & Engineering Research Center, KU Leuven, Belgium, [6]ACTA-VU University AmsterdamDept Oral Cell Biology (Rm # 11N-63), The Netherlands, [7]Department of Oral Cell Biology, Academic Centre for Dentistry Amsterdam (ACTA), University of Amsterdam & VU University Amsterdam, MOVE Research Institute Amsterdam, Netherlands

Introduction: Generalized bone loss, as occurs in patients with rheumatoid arthritis (RA), is related to elevated levels of circulating cytokines. Individual cytokines have deleterious effects on proliferation and differentiation of osteoblast cell lines, but little is known about the effect of the interaction between inflammatory factors in the circulation of patients with active RA on human osteoblast function, including their communication towards other bone cells. The purpose of this study was to investigate whether serum from patients with active RA enhances cytokine production by osteoblasts, thereby effectively altering osteoblast-stimulated osteoclastogenesis.

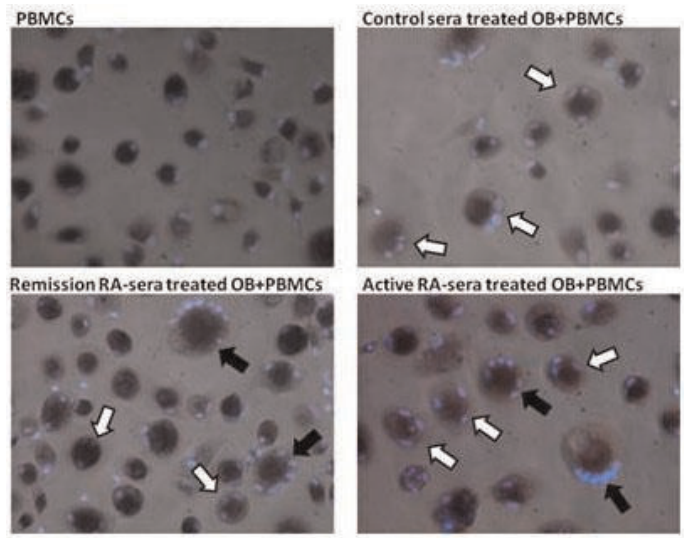
Methods: Serum was obtained from 20 patients with active RA (active RA-sera) and from the same patients in clinical remission (remission RA-sera). Primary human osteoblasts (OB) were cultured with 10% active or remission RA-sera. Osteoblast proliferation, differentiation as well as cytokine gene expression was analyzed. To determine osteoclastogenesis, RA-sera-pretreated primary human osteoblast cultures were established in direct contact with human peripheral blood mononuclear cells (PBMCs) in the presence or absence of osteoprotegerin or IL-6 inhibitor.

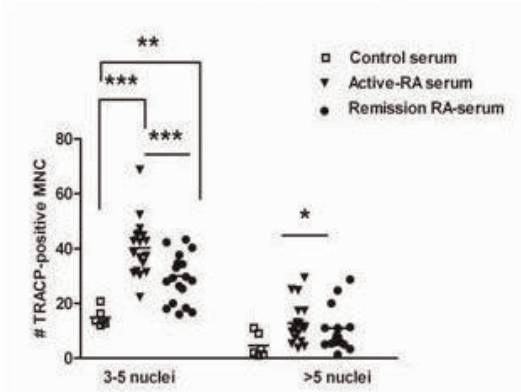
Results: Compared to remission RA-sera, active RA-sera inhibited osteoblast proliferation and differentiation *in vitro* as demonstrated by a reduced DNA content and decreased gene expression of KI-67, collagen type 1, osteopontin, and osteocalcin. Active RA-sera inhibited osteoprotegerin expression and enhanced RANKL and IL-6 expression (Fig. 1), but did not alter IL-8 expression in osteoblasts. IL-1β, IL-17 and TNF-α expression were undetectable. In co-culture, active RA-sera treatment of osteoblasts stimulated (Fig. 2), while addition of osteoprotegerin or IL-6 inhibitory antibodies significantly reduced the number of osteoclasts (Fig. 3).

Conclusion: Active RA-sera contain circulating factors, likely cytokines and chemokines that might contribute to bone loss by directly inhibiting osteoblast proliferation and differentiation. Especially these factors modulate endogenous cytokine (i.e. RANKL and IL-6) production by osteoblasts, thereby affecting osteoclastogenesis.

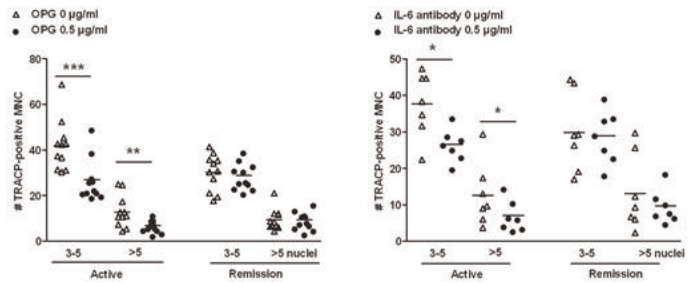


Active RA-sera enhanced RANKL and IL-6 gene expression in osteoblasts





Active RA-sera-pretreated osteoblasts enhanced osteoclastogenesis



OPG and IL-6 antibody reduced osteoclastogenesis enhanced by active RA-sera-pretreated osteoblasts

Prevention of hyper-active PTH signaling and function by VPS35. Lei Xiong[1], Wen-Fang Xia[2], Fu-Lei Tang[1], Shan Xiong[1], Wen-Cheng Xiong*[3]. [1]Georgia Health Sciences University, Charlie Norwood VA Medical Center, USA, [2]Georgia Health Sciences University, Charlie Norwood VA Medical Center, Union Hospital, Tongji Medical College, Huazhong University of Science & Technology, USA, [3]Georgia Regents University, USA

PTH plays a critical role in bone remodeling. Although the signaling and function of PTH have been investigated extensively, much less is known about negative regulatory mechanisms of its signaling. We demonstrate here that PTH1R trafficking, signaling, and function are negatively regulated by VPS35, a major component of retromer essential for selective endosome-to-Golgi retrieval of membrane proteins. VPS35 loss-of-function altered PTH-induced PTH1R distribution, enhanced PTH signaling, and suppressed it's catabolic response. Although hemizygous deletion of Vps35 gene in mouse at young adult age decreased bone formation, such an osteoporotic deficit was ameliorated by intermittent injections of PTH. These results

indicate that VPS35 critically deregulates PTH1R signaling, thus restraining increased anabolic response and promoting adequate bone remodeling.

PTHrP Induces Lactation in the Absence of Pregnancy and Affects Breast Cancer Initiation and Progression Differentially in Two Murine Models. Farzin Takyar*[1], Kata Boras-Granic[2], Pamela Dann[3], Christina Marmol[3], Alexzandrea Buscarello[3], John Wysolmerski[4]. [1]Yale University, School of Medicine, USA, [2]Yale School of Medicine, USA, [3]Yale University, School of Medicine, USA, [4]Yale University School of Medicine, USA

PTHrP affects mammary development and breast cancer. PTHrP is expressed in basal myoepithelial cells until late pregnancy,when it also becomes expressed in alveolar epithelial cells.During lactation, PTHrP is secreted into milk and into the circulation, where it regulates systemic calcium and bone metabolism. When PTHrP is secreted by breast cancers, it stimulates bone resorption, promoting the growth of skeletal metastases and/or the development of hypercalcemia. Less is known about the contribution of PTHrP to the development and/or progression of primary breast cancers. However, recent GWAS reports have identified the PTHrP gene as a breast cancer susceptibility locus. In order to test the effects of PTHrP overexpression on the development of mammary tumors in mice, we developed a tetracyline-regulated, MMTV-*driven transgenic model of PTHrP overexpression targeted to mammary epithelial cells (*MMTV-rtTA;tetO-hPTHrP*). Surprisingly, we found that PTHrP overexpression in luminal epithelial cells causes alveolar hyperplasia, secretory differentiation and milk production in virgin mice. This phenotype was associated with an increase in the number of both luminal progenitor cells and basal stem cells upon FACS analysis of mammary stem/progenitor cell populations. Overexpression of PTHrP for 7 days in virgin mice was associated with activation of Stat5, but not Jak2 in mammary epithelial cells. Initial studies demonstrate activation of Focal Adhesion Kinase (FAK), but not integrin-linked kinase (ILK).Mammary secretory differentiation requires cooperation between prolactin and integrin signaling and these data suggest that PTHrP may act to enhance matrix-related signaling in these cells.Overexpression of PTHrP in* MMTV-PyMT *mice, a transgenic model of breast cancer,dramatically accelerated the formation of mammary tumors reducing both the latency of tumor formation and survival of the mice dramatically. All* MMTV-rtTA;tetO-hPTHrP;MMTV-PyMT *mice developed palpable tumors in all mammary glands within 3 weeks of age, became hypercalcemic and died before 4.5 weeks of age. However, PTHrP overexpression in* MMTV-Neu *mice, another model of breast cancer, had no effect on tumor latency or survival, suggesting that PTHrP influences only certain pathways of transformation. Ongoing profiling of gene expression in these two tumor models will hopefully define the molecular pathways through which PTHrP acts to accelerate breast cancer formation.*

PTHrP-Induced BMP Signaling Contributes to Specification of The Mammary Mesenchyme. Minoti Hiremath[1], Pamela Dann[2], Wei Shi[3], John Wysolmerski*[4]. [1]Boise State University, USA, [2]Yale University, USA, [3]Children's Hospital Los Angeles, USA, [4]Yale University School of Medicine, USA

PTHrP regulates mammary cell fate by specifying the mammary mesenchyme during embryonic mammary development. Loss of PTHrP ($PTHrP^{-/-}$) or its receptor ($PTH1R^{-/-}$) causes epithelial cells within the mammary bud to revert to an epidermal fate and disrupts mammary bud outgrowth. In contrast, overexpression of PTHrP in the epidermis (K14-PTHrP) induces inappropriate differentiation of the ventral epidermis into nipple-like skin. In previous studies, PTHrP-mediated upregulation of BMPR1a was implicated in mammary bud outgrowth. Therefore, we hypothesized that PTHrP might regulate levels of BMP signaling in the mammary mesenchyme. We first examined BMP-signaling in the embryonic mammary mesenchyme expression using a transgenic Bre-*lacZ* reporter mouse. X-gal staining of whole embryos detected Bre-*lacZ* expression in the mammary mesenchyme as early as day 12 and up to day 18 of embryogenesis. To determine whether PTHrP regulates BMP signaling, we examined expression of the BMP reporter in $PTHrP^{-/-}$ mice. Our studies show that loss of PTHrP abolishes reporter expression of BRE-*lacZ* in mammary mesenchyme, demonstrating that PTHrP regulates BMP signaling. To determine the contribution of BMP signaling in mammary mesenchyme specification, we conditionally deleted BMPR1a using the Dermo1 promoter to drive Cre recombinase expression in the mammary mesenchyme of $BMPR1a^{lox/lox}$ mice. We confirmed that BMPR1a deletion almost completely abolishes Bre-*LacZ* expression in the mammary mesenchyme of the second and third pairs of mammary buds. Furthermore, deletion of BMPR1a in the mammary mesenchyme caused a delay in bud outgrowth and reduced mesenchymal proliferation, resulting in fewer layers of cells in the condensed mammary mesenchyme. Deletion of BMPR1a in the mesenchyme reduces the expression of mammary mesenchyme markers such as Lef1, estrogen receptor, b-catenin and androgen receptor but not to the same degree as does loss of PTHrP. Despite this, the androgen-mediated apoptosis of the male mammary buds is severely retarded, demonstrating loss of mammary mesenchyme function. Taken together, our studies suggest that BMP signaling via BMPR1a is required for functional differentiation of the mammary mesenchyme and for mammary bud outgrowth. Our studies suggest that BMP signaling acts downstream of PTHrP to specify the mammary mesenchyme.

Regulation of bone metabolism by Semaphorin 3A derived from osteoblast lineage cells. Mikihito Hayashi*[1], Tomoki Nakashima[2], Hiroshi Takayanagi[3]. [1]Tokyo Medical & Dental University, Japan, [2]Tokyo Medical & Dental University, Japan, [3]The University of Tokyo, Japan

Cells in bone, including osteoblasts, osteoclasts and osteocytes, mutually influence each other to achieve bone homeostasis. We previously demonstrated that Sema3A plays an important role in the regulation of bone homeostasis (Hayashi *et al*., Nature, 2012). However, a recent publication showed that osteoblast–specific Sema3A–deficient mice had normal bone mass, even though the expression of Sema3A in bone was substantially decreased (Fukuda *et al*., Nature, 2013). They concluded that neuron–derived Sema3A regulates bone remodeling indirectly through the modulation of sensory nerve development, but not directly through the action on osteoblasts. However, they could not explain why does osteoblast lineage cell–derived Sema3A have no effect on bone homeostasis and innervation into bone although *Sema3a* is highly expressed in osteoblast lineage cells.

To examine the role of osteoblast lineage cell–derived Sema3A, we crossed *Sema3a* floxed mice with *Osx–Cre*$^{+}$ and *Dmp1–Cre*$^{+}$ mice. In contrast to the results obtained by Fukuda *et al*., the deletion of *Sema3a* in *Osx*–expressing cells recapitulates the low bone mass phenotype of long bone as observed in *Sema3a*$^{-/-}$ mice, due to an increase in bone resorption accompanied by decreased bone formation. Interestingly, these mice have normal bone phenotype in vertebrae. In addition, *Sema3a* deletion in osteoblasts from newborn or adult mice, by means of *Osx-Cre*-tTA, led to low bone mass phenotype, indicating that Sema3A expression in osteoblasts is important for the regulation of bone homeostasis.

In contrast, *Dmp1–Cre*$^{+}$ *Sema3a*$^{flox/\Delta}$ mice had normal bone mass at 10 weeks of age. However, the bone volume of these mice decreased with age and aged *Dmp1–Cre*$^{+}$ *Sema3a*$^{flox/\Delta}$ mice developed an extremely low bone mass phenotype. These observations suggest that Sema3A expression in osteoblast lineage cells (especially osteocytes) is essential for the maintenance of bone homeostasis.

Quality of life assessment of adults patients with X-Linked Hypophosphoremia. Hélène Che[1], Adrien Etcheto[2], Anya Rothenbuhler[3], Peter Kamenicky[3], Agnès Linglart[3], Christian Roux[4], Karine Briot*[5]. [1]Paris Descartes University, Cochin Hospital, France, [2]Paris Descartes Uniiversity, Cochin Hospital, France, [3]Hôpital Bicêtre, France, [4]Hospital Cochin, France, [5]Paris Descartes University, Cochin hospital, Rheumatology Hospital, France

X-Linked Hypophosphatemia (XLH) is the most common form of heritable rickets. Although disease severity is variable, adults with XLH may suffer from skeletal symptoms leading to function disability. There are no data on the consequences of these symptoms on quality of life (QoL) of adults with XLH. The objective was to evaluate the QoL and the variables associated with low QoL in adult patients with XLH

We conducted a cross sectional study in adult patients with XLH, who consulted in rheumatology, for skeletal symptoms, between 2013 and 2014. We assessed the intensity of pain (VAS Visual Analogic Scale) and QoL using 3 Patient Reported Outcomes: HAQ (Health Assessment Questionnaire, high if >0.5), RAPID3 (Routine Assessment of Patient Index Data 3, high if >6) and 36-item short-form health (SF36) survey. We also collected demographic and disease characteristics, radiographic features and data on treatments of XLH. We described the QoL of XLH patients and analysed the variables associated with low QoL.

Thirty two patients with XLH (27 women; mean age of 42.8 yrs) with PHEX mutations were included. 15 (48.4%), 16 (51.6%), 12 (40%) received respectively phosphate supplements, vitamin D analogues, and 25 OH-vitamin D supplements, at the time of assessment. X-rays showed osteoarthritis (knee, hip or spine) (n=27, 90%), enthesopathies (n=19, 61.3%) and sequelae of insufficiency fractures (n=4, 14.8%). Skeletal pain was reported by 64.3% of patients with a mean VAS of 4.6 (+/-2.6). Age is significantly associated with low QoL ($p \leq 0.05$), indicated by high scores of HAQ (mean value 0.71 ± 0.6, HAQ>0.5 in n=19), RAPID3 (mean value 11.32 ± 6.4, RAPID3>6 in n=23), and physical domains of SF36 (physical functioning (mean value 58.4 ± 23.6) and physical role (mean value 37.5 ± 39.1)). Osteoarthritis was associated with low QoL indicated by high HAQ ($p \leq 0.05$). Radiographic enthesopathies were significantly higher in patients with high RAPID3 and low bodily pain scale of SF36 (mean value 55 ± 24) ($p \leq 0.05$). Phosphate supplements, vitamin D analogues and physiotherapy treatments were associated with high general health (mean value 40.23 ± 17.1) and social functioning (mean value 70.31 ± 21.7) scales of SF36 ($p \leq 0.05$).

This study showed that QoL of adults with XLH is altered; age and radiographical involvement (osteoarthritis and enthesopathies) are significantly associated with low QoL; adults treated for XLH reported better general health and social functioning scores.

Bone Material Properties in Osteogenesis Imperfecta: a Matter of Quantity Over Quality. Carolyne Albert*[1], John Jameson[2], Peter Smith[3], Gerald Harris[4]. [1]Marquette University, USA, [2]Lawrence Berkeley National Lab, USA, [3]Shriners Hospitals for Children, USA, [4]Marquette University, USA

Osteogenesis Imperfecta (OI) is a collagen-related genetic disorder resulting in a high susceptibility to bone fracture. The mechanisms behind bone fragility in OI are not yet well understood. In addition to a characteristic low bone mass, i.e., structural deficiency, studies in mice suggest that the material properties of bone tissue may also be compromised in OI [1, 2]. However, little is known about bone material properties in humans with this disorder. The objectives of this study were investigate relationships between bone material properties, bone volume fraction, volumetric tissue mineral density (vTMD), and donor age in children with OI.

Ten small diaphyseal specimens from long bones of eight children with mild to severe OI (ages 3-16) were obtained during routine osteotomy procedures. Longitudinal beams were machined from these specimens, and elastic modulus and yield strength were measured in bending. Bone volume fraction (1 – intracortical vascular porosity), representing the quantity of bone material per unit volume, and vTMD, representing the density of the bone material, were determined by synchrotron micro-computed tomography.

Average elastic modulus and flexural strength were 4.8 GPa (SD 2.0 GPa) and 91 (39 MPa), respectively. Bone volume fraction was 0.80 (0.12), and vTMD 1.58 g/cm^3 (0.12 g/cm^3). Each property was associated significantly with volume fraction, but not with vTMD or donor age (Table 1, Figure 1).

Reduced modulus and flexural strength were observed compared to typical values for children and adolescents [3]. Volume fraction and vTMD were also lower than in normal pediatric bone [4]. Unlike in normal bone tissue [3], bone properties in children and adolescents with OI did not appear related to age. Results of this preliminary study indicate that bone material properties at the mesoscale in OI may be associated more with bone quantity (volume fraction) than with the quality (density) of the bone material itself. These results offer valuable insight toward a better understanding of bone fragility in OI.

Demographics, bone mass density, lifetime fractures and bisphosphonate use in an adult Osteogenesis Imperfecta cohort: a cross-sectional explorative study. Anton Franken*[1], Luuk Scheres[2], Guus Janus[3], Fleur van Dijk[4]. [1]Isala clinics, The Netherlands, [2]Isala clinics, Netherlands, [3]Isala, Netherlands, [4]VU medical center, Netherlands

We present data from one of the largest adult Osteogenesis Imperfecta (OI) patient cohorts ever reported. A database was created which stores data on all adult OI patients which have visited our expert center for OI adult patients. Over 200 adult patients have visited our outpatient-clinic already. This is the first report on data retrieved from this database. We present extensive demographical features of this cohort and results on bone mass density (BMD) measured at different sites of the body. We collected data from 149 (106 type I, 20 type III and 23 type IV) adult OI patients.

There was a discrepancy between BMD measured at lumbar spine and hip region by means of dual-energy X-ray absorptiometry (DXA). In all three types the lumbar spine measurement yielded lower BMD levels than the measurement of the hip region

For type I and IV patients the total amount of fractures did not seem to increase in adulthood. In type III the total mean fractures almost double from early adulthood to the age of 65. For type I patients there was no difference in fracture total per decade of life, independently of bisphosphonates (BP) use. Half of all type I and IV patients had never used BP's in their lifeThese findings suggest that the effectiveness of BP's solely in terms of fracture reduction in type I adult patients is questionable. OI in adults is not just a form of osteoporosis where loss of bone mass and structure predominate. OI is characterized by increased bone fragility due to defective matrix quality caused by defective collagen

HSP47 and FKBP65 cooperate in the synthesis of type I procollagen. Ivan Duran*[1], Lisette Nevarez[2], Anna Sarukhanov[3], Sulin Wu[3], Katrina Lee[4], Maryann Weis[5], David Eyre[5], Deborah Krakow[6], Daniel H. Cohn[2]. [1]University of California Los Angeles, USA, [2]Department of Molecular, Cell, & Developmental Biology. UCLA, USA, [3]Orthopaedic Surgery, USA, [4]Department of Molecular, Cell, & Developmental Biology, USA, [5]Department of Orthopaedics & Sports Medicine, University of Washington, USA, [6]Orthopaedic Surgery, UCLA, USA

Osteogenesis Imperfecta (OI) is a genetic disorder that results in low bone mineral density and brittle bones. Most cases result from dominant mutations in the type I procollagen genes, but about 10% of cases result from primarily recessively inherited mutations. The latter cases include mutations in the genes *SERPINH1* and *FKBP10* which encode the type I procollagen chaperones HSP47 and FKBP65, respectively, and which produce a mild to moderately severe form of OI, similar to OI type IV. Little is known about the biochemical consequences of the mutations and how they produce OI. We identify a new OI mutation in *SERPINH1* that results in destabilization and mislocalization of HSP47, and that secondarily has similar effects on FKBP65. We found evidence that HSP47 and FKBP65 act cooperatively during posttranslational maturation of type I procollagen. Furthermore, mutations in either *SERPINH1* or *FKBP10* alter type I procollagen trafficking through the ER and Golgi, triggering an Unfolded Protein Response and ER-associated degradation of mislocalized molecules. These findings suggest that a chaperone complex including HSP47 and FKBP65 act downstream from the CRTAP complex during the maturation of fibrillar collagens.

Improved Bone Density in a patient with Osteogenesis Imperfecta using Denosumab. Jessica Abramowitz*[1], Stuart Weinerman[2]. [1]Hofstra North Shore LIJ, USA, [2]Division of Endocrinology, USA

Introduction: Osteogenesis imperfecta is a rare inherited disease caused by a defect in collagen formation. Bone histology reveals increased bone remodeling in types I, III and IV. The syndrome is characterized clinically by low bone density and fractures. Treatment goals are to: reduce fracture rates, skeletal deformities and maximize mobility while reducing pain. The mainstay of treatment has been bisphosphonates. Denosumab binds RANKL and inhibits osteoclast formation and thereby decreases bone resorption, increases bone density and thus reduces fractures. It is known to be effective in the treatment of postmenopausal osteoporosis and bone metastases of cancer but its use in treatment of adults with osteogenesis imperfect has not been reported.

Case presentation: A 38 yo male with type IV osteogenesis imperfecta presented for evaluation in our department for management of osteoporsis. He had been diagnosed with osteoprosis 3 years prior and had been on Alendronate since the time of diagnosis. He had a history of multiple fractures which subsided after starting bisphosphonate treatment. After 10 years of treatment with Alendronate treatment was held for 1 year. Bone density prior to drug holiday showed a T score of -3.5 in the lumbar spine, -2.7 in the femoral neck, -1.8 in the total hip and 1.2 in the radius. Following 1 year off treatment for osteoporosis the patient was started on Denosumab 60mg every 6 months. After 3 doses bone density was stable or improved, with a T score of -3.2 (+4.8%) in the lumbar spine, -2.6 (+2.3%) in the femoral neck, -1.9 (-1.7%) in the total hip and 2.4 in the radius. Bone specific alkaline phsophatase was 10 mcg/L and calcium 9.8 mg/dL. After 6 doses of Denosumab lumbar spine bone density T score was -2.8 (+5.2%), femoral neck was -2.5 (+1.5%), and -1.9 (-0.5%) in the total hip, and 2.9 (+2.7%) in the radius. In addition to improvement in bone density the patient reported decreased bone pain during treatment with Denosumab.

Conclusions: Denosumab is a potential agent for use in osteogenesis imperfecta. We report a case of decrease in fractures and increase in bone density in a patient with type IV osteogenesis imperfecta.

Intravenous bisphosphonate therapy prevent the development and progression of spinal deformity associated with osteogenesis imperfecta. Masafumi Kashii*[1], Sadaaki Kanayama[2], Taichi Kitaoka[3], Takahiro Makino[4], Takashi Kaito[2], Kosuke Ebina[5], Tsuneo Shigi[6], Takuo Kubota[7], Noriyuki Namba[3], Motoki Iwasaki[4], Takehisa Yamamoto[8], Keiichi Ozono[9], Hideki Yoshikawa[10]. [1]Osaka University Graduate School of Medicine, Japan, [2]Osaka University, Graduate School od Medicine, Japan, [3]Osaka University Graduate School of Medicine, Japan, [4]Osaka University Graduate School of Medicine, Japan, [5]Osaka University, Graduate School of Medicine, Japan, [6]Minoh City Hospital, Japan, [7]Osaka University Graduate School of Medicine & Dentistry, Japan, [8]Minoh City Hospital, Japan, [9]Osaka University Graduate School of Medicine, Japan, [10]Osaka University Graduate School of Medicine, Japan

Osteogenesis imperfecta (OI) is characterized by fragile bone and hypermobility of the spinal ligaments, and is often associated with spinal deformities. Bisphosphonate (BP) is used to prevent fragility fractures and subsequent bony deformities of the limbs, but there are no studies to examine the effect of BP on spinal deformities associated with OI. The purpose of this study is to analyze the development and progression of spinal deformities in OI patients treated by intravenous BP therapy.

Ninety-one OI patients were enrolled in this study and 40 patients who were treated by intravenous pamidronate alone (mean age: 9.8 years, range 2-20) were studied to clarify the prevalence of scoliotic deformities and to determine risk factors for scoliotic deformities. Scoliotic angle (L1-4 Cobb angle) was measured using the DXA scout view, and scoliotic deformities were defined by the presence of a curvature 10 or larger. We examined the relationship between scoliotic deformities and age, BMI, OI type, physical activities and lumber L2-4 BMD (Z-score).

Cyclic intravenous pamidronate was administrated for an average of 3.8 years. The mean lumber Z-score was -2.4 (-7.7 to 2.2). The prevalence of scoliotic deformities was 23%, and vertebral deformities were found only in 5 patients (5 vertebras). OI patients with scoliotic deformities had a higher BMI ($p<0.01$) and a higher proportion of OI type3 by Sillence classification ($p=0.01$). Lower lumber Z-score tended to be related to a larger scoliotic curve, but there were no statistical significances in OI patients with scoliotic deformities. In 16 OI type3 patients without scoliotic deformities, time of initiation of BP therapy is significantly younger (average age 2 years). The retrospective longitudinal study of 6 OI patients with scoliotic deformities revealed that coronal vertebral deformity caused by fragile vertebral fracture lead to the development and progression of scoliotic deformities.

The prevalence of scoliotic deformity and coronal vertebral deformity were extremely lower compared with previous reports (50-100%). This study firstly shows that BP administration effectively prevents coronal vertebral deformity due to bone fragility and subsequently decreases the development and progression of scoliosis in OI patients. BP administration from early childhood prevents the development and progression of scoliosis in OI type3.

SU0432

Physical Activity and Muscle Function in Children with Osteogenesis Imperfecta Type I. Louis-Nicolas Veilleux*[1], Annie Pouliot-Laforte[2], Martin Lemay[2], Frank Rauch[3]. [1]McGill University/Shriners Hospital for Children, Canada, [2]Université du Québec à Montréal; Marie Enfant Rehabilitation Center, Canada, [3]Shriners Hospital for Children, Montreal, Canada

Context: Osteogenesis imperfecta (OI) type I is a heritable bone fragility disorder that is caused by mutations affecting collagen type I. In addition to bone fragility, recent evidences showed that patients with OI type I frequently have muscle weakness. The cause of this weakness remains unclear at present. One hypothesis is that patients with OI type I are hypoactive due to fractures or fear of fracture. Objective: To evaluate the relationship between physical activity and muscle function in patients with OI type I and in healthy age and gender-matched controls. Patients and other participants: Fourteen children with OI type I (mean age [SD]: 12.72 [4.57] years, 9 females) and 14 age- and gender-matched controls (mean age [SD]: 12.75 [4.62] years) took part in this study. All participants were between 6 and 21 years of age. Main Outcome Measures Muscle force and muscle power were determined through mechanography. Physical activity (sedentary, light and moderate to vigorous) was measured with an accelerometer whereas energy expenditure was estimated with the 'Bouchard' questionnaire on physical activity. Results: Compared to age- and gender-matched controls, patients with OI type I had lower muscle force ($p<0.001$) and power ($p<0.04$) than controls. However, in contrast with our expectations OI type I patients were as active as their age- and gender-matched controls with a daily average of 36 minutes and 39 minutes of moderate to vigorous physical activity for the OI group and the control group respectively ($p>0.31$). Regression analysis showed that within all three type of physical activity only the time spend in the light physical activity was found to be a negative predictor of the power tests but not of the force tests. Conclusion: This is the first study evaluating physical activity in children and adolescent with OI type I. The difference in muscle function and the similarities in the volume of physical activity between the two groups suggest that hypoactive lifestyle is not the primary cause of muscle weakness in the study participants.

A Case of Tumor-Induced Osteomalacia and Hyperparathyroidism: Primary vs.Tertiary?. Racha Dermesropian*, Pamela Taxel. university of connecticut health center, USA

We present a 10-year postoperative follow up of a patient with oncogenic osteomalacia.

The patient is a 60-year-old male who initially presented at age 47 years with a 6 months history of severe joint pain and a new onset gait instability resulting in recurrent falls.

He was found to have multiple bilateral fractures of his ribs, heels, and metatarsals as well as a right femoral neck fracture. Biochemical testing showed low levels of serum phosphate, increased serum alkaline phosphatase, reduced renal tubular reabsorption of phosphorus and inappropriately normal levels of 1,25-dihydroxyvitamin D. Octreotide scan showed increased uptake in the right shoulder. An MRI showed a 1.8 cm suspicious lesion in the greater tuberosity of the right humerus . Over the next 2-3 years, the patient underwent surgical resection x two with incomplete excision, as well as radiation therapy and eventual complete right shoulder replacement. Medical therapy during that time included oral phosphorous and calcitriol. Ultimately, normalization of serum phosphate and resolution of symptoms occurred.

The patient was lost to follow-up for 7 years until he presented recently with recurrent generalized body aches. His biochemical profile showed elevated FGF23 with normal serum phosphorus, elevated serum calcium and PTH levels. His differential diagnosis included primary vs. tertiary hyperparathyroidism due to long-term therapy with phosphorus and vitamin D. Investigation of his hyperparathyroidism is ongoing.

Tumor induced osteomalacia is a rare paraneoplastic syndrome caused by unregulated secretion of FGF23. It can be associated with tertiary hyperparathyroidism due to prolonged treatment with phosphorous that is unopposed by calcitriol. This outcome was not anticipated in this patient who had appropriate medical therapy for 2-3 years. Thus we suspect that his hyperparathyroidism is likely a primary event.

Assessment of Adverse Effects Associated with Zoledronic Acid Use in Children and Young Adults with Metabolic and Genetic Bone Disease. Sobenna George*[1], David Weber[2], Heather Bodenstab[3], Kelly Hummel[3], Paige Kaplan[3], Jaya Ganesh[3], Michael Levine[1]. [1]Children's Hospital of Philadelphia, USA, [2]Golisano Chilldren's HospitalThe University of Rochester, USA, [3]The Children's Hospital of Philadelphia, USA

PURPOSE: The intravenous bisphosphonate zoledronic acid (ZA) is increasingly used to treat children with a variety of bone disorders due to its greater potency, shorter infusion time, and longer dosing interval than pamidronate. However, data related to the safety and efficacy of ZA in this population are limited. The goal of this study was to describe the prevalence of adverse events (AE) and identify risk factors for AEs in children treated with ZA at The Children's Hospital of Philadelphia.

METHODS: We systematically evaluated medical charts of all children treated with ZA for bone disorders between July 2010 and January 2014. Charts were reviewed for diagnoses, dose of ZA and adjunct medication, type of AEs, and potential risk factors for AEs. Chi-square tests and multivariate regression were used to analyze data.

RESULTS: We examined charts for 83 children (55% male; mean age 11.6 ± 5.6 yrs) who had a total of 210 ZA infusions. 27% had osteogenesis imperfecta (OI), accounting for 42% of the infusions. Remaining patients had osteoporosis (34%), chronic recurrent multifocal osteomyelitis (16%), avascular necrosis (7%) and other genetic or metabolic bone diseases (16%). Median ZA dose was 0.025 mg/kg (IQR:0.025-0.075). AEs occurred after 29% of all infusions and were more common after a first than a subsequent infusion (50% vs 17%; $p<0.0001$). In previously bisphosphonate naive patients, the most common AEs after the first ZA infusion were acute phase reaction (43%),hypophosphatemia (41%), and hypocalcemia (32%). Risk of AEs with initial infusion was similar between patients with and without OI (58% vs 62%, p=0.8). However, the risk of AEs with subsequent infusions was less in patients with OI than non-OI (7% vs 25%, $p = 0.002$). AEs were not associated with ZA dose, baseline blood chemistries (including serum 25(OH)D and calcium), parathyroid hormone or calcium/vitamin D supplementation

CONCLUSIONS: Our study found that children with OI and non-OI have similar risks of AEs after the initial infusion, but non-OI have significantly greater risk of experiencing AEs after subsequent infusions, for reasons that are not obvious. Prospective longer term studies to evaluate the underlying risk factors that are associated with AEs in youths receiving ZA are necessary.

Paternal Uniparental Isodisomy Involving Chromosome 20q (patUPD20q) as a Cause of Japanese Patients Affected by Sporadic Pseudohypoparathyroidism Type Ib. Rieko Takatani*[1], Masanori Minagawa[2], Kaori Kinoshita[3], Tomozumi Takatani[3], Angelo Molinaro[4], Harald Jueppner[5]. [1]Massachusetts General Hospital & Harvard Medical School, USA, [2]Chiba Children's Hospital, Japan, [3]Chiba University, Japan, [4]Massachusetts General Hospital & Harvard Medical School, USA, [5]Massachusetts General Hospital, USA

Context: Pseudohypoparathyroidism type Ib (PHP-Ib) is caused by proximal tubular resistance to parathyroid hormone that occurs in most cases in the absence of Albright's Hereditary Osteodystrophy (AHO). Patients affected by PHP-Ib have epigenetic changes that involve one or multiple differentially methylated regions (DMRs) in *GNAS*, the gene encoding Gsα and several splice variants thereof. Maternally inherited microdeletions within *STX16*, the gene encoding syntaxin 16, or within *GNAS* cause familial forms of PHP-Ib. Most sporadic cases of PHP-Ib show broad *GNAS* methylation abnormalities, but the underlying molecular mechanism remains unknown. Paternal uniparental isodisomy involving chromosome 20q (patUPD20q), which includes the *GNAS* locus, can be a rare cause of sporadic PHP-Ib.

Objective: To determine whether patUPD20q can be a cause of Japanese patients affected by sporadic PHP-Ib.

Methods: We investigated 23 Japanese sporadic PHP-Ib cases, who had presented with PTH-resistant hypocalcemia and hyperphosphatemia, some of whom had mild AHO. The *GNAS* methylation status was evaluated by Southern blot analysis after digestion of DNA with methylation-sensitive endonucleases, Methylation-Specific PCR (MS-PCR), and Methylation-Specific Multiplex Ligation-dependent Probe Amplification (MS-MLPA) followed by analysis of single nucleotide polymorphism and microsatellite markers across the entire chromosome 20.

Result: All investigated sporadic PHP-Ib patients showed broad *GNAS* methylation changes. Several patients were homozygous for SNPs within the NESP55 region and a pentanucleotide repeat in exon A/B, and two of these individuals revealed homozygosity for numerous microsatellite markers on chromosome 20q raising the possibility of patUPD20q; this was confirmed for one PHP-Ib patient through the analysis of parental DNA.

Conclusion: Our findings suggest that patUPD20q may be a more frequent cause of sporadic PHP-Ib than initially thought.

The Type 2 Diabetes associated rs7903146 T allele within *TCF7L2* is significantly under-represented in Hereditary Multiple Exostoses: insights into pathogenesis. Federica Sgariglia*[1], Elena Pedrini[2], Jonathan Bradfield[3], Tricia Bhatti[3], Pio D'Adamo[4], John Dormans[3], Aruni Gunawardena[3], Hakon Hakonarson[3], Jacqueline Hecht[5], Luca Sangiorgi[2], Maurizio Pacifici[6], Motomi Enomoto-Iwamoto[6], Struan Grant[7]. [1]Children's Hospital of Philadelphia, USA, [2]Rizzoli Orthopaedic Institute, Italy, [3]Children's Hospital of Philadelphia, USA, [4]Institute for Maternal & Child Health, IRCCS "Burlo Garofolo", Italy, [5]UTHealth School of Dentistry, USA, [6]Children's Hospital of Philadelphia, USA, [7]Children's Hospital of Philadelphia / University of Pennsylvania, USA

TCF7L2 and *EXT2* are among the earliest associated loci reported in genome wide appraisals of type 2 diabetes (T2D). Intriguingly, *EXT2* is one of two genes, the other being *EXT1*, to carry heterozygous loss-of-function mutations that account for the vast majority (~80-90%) of the primary genetic component of Hereditary Multiple Exostoses (HME), an autosomal-dominant disorder characterized by benign cartilage tumors (exostoses), causing skeletal deformations, growth retardation and chronic pain. Despite the wide clinical heterogeneity presented by patients, no clear genotype-phenotype correlation has been described so far suggesting that modifier genes contributing to severity still need to be found. Our previous work has implicated Wnt signaling in HME etiology, pointing to an imbalance of b-catenin signaling being involved in the pathogenesis of osteochondroma formation. Activation of Wnt signaling results in b-catenin nuclear translocation, where it forms a transcriptional complex with members of TCF family, including TCF7L2; indeed TCF7L2 is highly expressed in both human and mouse cartilage. Thus, we investigated if the key T allele of SNP rs7903146 within *TCF7L2*, strongly over-represented among T2D cases, was also associated with HME. We leveraged genotype data available from ongoing GWAS efforts from orthopaedic centers in the US, Canada and Italy. Collectively 213 cases and 1,890 controls were analyzed and, surprisingly, the T allele was significantly under-represented in the HME patient group [P=0.009; OR=0.737 (95% C.I. 0.587 - 0.926)] and the direction of effect was consistent within each individual cohort. Immunohistochemical analyses revealed that TCF7L2 is differentially expressed and distributed in the human growth plate and is exclusively observed in resting and hypertrophic chondrocyte zones. Furthermore, TCF7L2 expression exhibited substantial variability in human exostosis surgical specimens in terms of staining intensity and distribution. These observations resonate with our previous reports that b-catenin levels are lower in human exostoses specimens and that deficiency in murine cartilage leads to formation of osteochondroma-like masses, supporting the notion of

a role of the Wnt/b-catenin pathway in HME pathogenesis. In summary, the data in this study indicate that there is a putative genetic connection between *TCF7L2* and *EXT* in the context of HME, as well as T2D, orchestrated by the modulation of shared pathways, in particular with respect to b-catenin.

SU0437

To determine the prevalence of osteonecrosis of the jaw in patients who take bisphosphonate for osteoporosis treatment. Tak Kee Dicky Choy*. The Chinese University of Hong Kong, Hong Kong

Dicky Choy[1], Timothy Kwok[1], Jason Leung[1], Anthony Kwok[2], [1]Jockey Club Centre for Osteoporosis Care and Control, School of Public Health, Chinese University of Hong Kong, Hong Kong; [2]Department of Orthopaedics and Traumatology, Chinese University of Hong Kong, Hong Kong

Osteonecrosis of the Jaw (ONJ) is a serious condition which is difficult to treat. Bisphosphonate-Related Osteonecrosis of the Jaw (BRONJ) is a well known complication in patients receiving high dose intravenous bisphosphonate for the treatment of metastatic bone disease. In recent years, there have been reported cases of BRONJ in post-menopausal women receiving oral bisphosphonate for the treatment of osteoporosis as well.

Determine the prevalence of osteonecrosis of the jaw in patients on chronic bisphosphonate for osteoporosis treatment.

Patients with history of 3 years or more of oral bisphosphonate treatment for osteoporosis will be invited to the telephone interview using a dental screening questionnaire. The questionnaire was designed by a dental surgeon experienced in managing BRONJ. For those who report any suspicious symptoms of BRONJ, we tried to find out the dental records for BRONJ confirmation. If those records were not available or the records did not contain clear information about the diagnosis, the subjects were invited to have a dental examination for the confirmation of ONJ.

One thousand two hundred and eighty four eligible subjects completed the screening questionnaire by telephone, the response rate being 62.8%. There were four clinically confirmed cases of BRONJ. The prevalence of BRONJ in our study was 0.3% with a frequency of 73.53 per 100,000 person-years of oral bisphosphonate treatment. Three of the patients had tooth extraction and none of them had regular dental visits.

In conclusion, the prevalence of BRONJ in our study was relatively high. Most of them were related to tooth extraction.

Table 1. Baseline clinical characteristics of the study respondent (n=1,284)

Table 2. Characteristics of the 4 cases of BRONJ

Characteristic	Respondents
Mean age ± SD (yr)	74.6 ± 7.9
Women	1224 (95%)
Mean BP duration ± SD (yr)	4.2 ± 1.2
BP type	
Alendronate	758
Risedronate	566
Ibandronate (oral)	57
Regular dental check	295 (23%)

Abbreviation: BP, bisphosphonate

Body Composition Analysis in Brazilian Men: Normative Data. Marcela Ushida[1], Vera Szejnfeld*[2], Marcelo Pinheiro[3]. [1]Universidade Federal de São Paulo, Brazil, [2]UNIFESF/EPM, Brazil, [3]Sao Paulo Federal University/ Unifesp/ Escola Paulista De Medicina, Brazil

Background: Dual-energy x-ray absorptiometry (DXA) is the gold-standard method to evaluate bone mineral density (BMD) and to estimate risk of osteoporotic fracture. Recently, it has also used to measure body composition (BC), including fat and lean mass. Considering ethnic and anthropometric differences among populations, it is interesting to have specific normative data for each population.

Objective: To assess BC's normative data in Brazilian healthy men.

Patients and Methods: A total of 284 Brazilian healthy men aged 20 years or over were enrolled in this study. Details about concomitant diseases, alcohol intake, smoking and physical activity were evaluated in all subjects. Black and Asian individuals were excluded as well as those with any condition that could interfere on bone, fat or lean mass, including drugs. All of them performed BC measurements by DXA (DPX MD+, version 8.5; GE-Lunar). $P<0.005$ was considered as significant.

Results: Mean age, BMI, weight and height were 40.0 ± 15.1 years, 26.1 ± 3.4 kg/ m^2, 77.6 ± 11.2 kg, 172 ± 7cm, respectively. Almost 80% was White and almost 50% was considered as physically active and only 10% was current smokers. Mean appendicular lean mass (ALM) was 8.48 ± 0.87 kg/ m^2. Regarding fat mass, more than 60% was overweight by BMI. Total body fat and fat mass index (FMI) were 27% and 6.93 ± 2.82kg/ m^2, respectively. There was negative and significant association between ALM ($p=0.005$) and FMI ($p=0.004$) with age. Besides, there was positive association among ALM, FMI and BF with physical activity evaluated by Baecke's Sport Index ($p<0.005$).

Conclusion: This is the first study to determine the BC's normative data in Brazilian healthy male. Reduction of ALM and higher fat mass were associated with increasing age.

SU0439

Bone, muscle, fat triad in women: Determining the threshold at which body fat becomes harmful for bone. Pei-Yang Liu[1], Jasminka Z. Ilich*[2]. [1]University of Akron, USA, [2]Florida State University, USA

Objective: To investigate the relationships among lean mass (LM), fat mass (FM), and bone mineral density (BMD) in women stratified by body mass index (BMI – normal-weight, overweight, obese) and to determine threshold at which body fat becomes harmful for bone. Methods: BMD, LM, and FM were measured by iDXA. ANOVA with Bonferroni corrections was used to test BMI group differences. Regression models were used to examine independent contributions of LM and FM on BMD of various skeletal sites (controlling for age and height). In overweight/obese women PROC LOESS plots (adjusted for age) were used to determine the inflection points at which either LM or FM relationship with BMD changes direction. Results: Spine and femoral neck BMD were not different among three BMI groups while total body, femur and radius BMD were statistically different (the highest in the obese group). Linear regression revealed that LM had significant positive association with BMD of various skeletal sites in all groups. FM showed a negative association with BMD of femoral neck and femur in normal-weight and overwight women and spine in overweight women but a positive association with radius in obese women. Inflection points showed that body fat between 33-38% assumed negative relationship with BMD for most skeletal sites. Conclusions: While LM has strong positive relationship with BMD, FM above 33% in overweight/obese women is negatively related to BMD of most skeletal sites. Therefore, overweight/obesity after certin amount of FM, may not be a protective factor against osteoporosis in females. For clinical practice, it is important to maintain LM and keep FM accrual below ~30% body fat to maintain good skeletal health in women.

Development of a QCT- and MRI-compatible Muscle Phantom. Andy Kin On Wong*[1], Zamir Merali[2], Jonathan Adachi[3]. [1]McMaster UniversityUniversity Health Network, Canada, [2]University of Toronto, Canada, [3]St. Joseph's Hospital, Canada

Objectives: To determine the optimal concentrations of $CuCl_2$, EDTA and agar to yield physiologically similar values to muscle density on peripheral quantitative computed tomography (pQCT) and muscle T2 relaxation time on 1.0T peripheral magnetic resonance imaging.

Methods: Evaporated milk (50 mL) was heated to 50°C. Agar was dissolved in 0.08% v/v 50 mL ethanol heated to 90°C and pH adjusted to 9.0. This solution was cooled to 50°C, mixed with the evaporated milk and reheated to 80°C before rapidly dissolving EDTA, $CuCl_2$ (Table I) and 80 µL of ProClin 150 with continued mixing. The completed solution was cooled to room temperature until hardened. Phantoms were prepared with varying concentrations of EDTA and $CuCl_2$, sequentially altered to achieve different T2 relaxation times and linear attenuation values.

T2 relaxation times were quantified using a 4 mm single-slice fast spin echo sequence repeated for 6 serial echo times at 937 µm resolution. MRMap software compiled T2 relaxation maps using the Levenberg-Marquardt equation. A pQCT scanner measured density of phantoms. Five 2.3 ± 0.5 mm thick slices were acquired at 15 mm/s scan speed and 500 µm resolution. A linear regression model was fitted to data for QCT-density regressed on [$CuCl_2$]. Logarithmic functions were fitted to T2 relaxation time regressed on each of [$CuCl_2$] and [EDTA].

Results: Density (D) was linearly dependent on [$CuCl_2$] (D = 0.27[$CuCl_2$] + 63.92, R^2 = 0.84, p = 0.01) and invariant to [EDTA]. T2 relaxation time was related negatively to [$CuCl_2$] (T2 = -10.13ln[$CuCl_2$] +66.70, R^2 =0.91, p<0.01) and positively to [EDTA] (T2 = 5.72 ln[EDTA]+54.47, R^2=0.86, p<0.01). For an average muscle T2 relaxation time of 45 ms as determined from in vivo fast spin echo scanning of the calf muscles, an [EDTA] of 0.79 mM was required if [$CuCl_2$] was fixed at 22.52 mM, yielding a mean density of 70 mg/cm^3. Two other scenarios are illustrated in Table I.Conclusions: This phantom optimization protocol provides a means for altering a soft-tissue mimic phantom to be suited for calibrating MRI and QCT signals within the range of a muscle. The proposed composition adjustment equations (Figure 1) apply only for density values as low as 64 mg/cm^3 as this lower limit results when [$CuCl_2$] approaches 0.00 mM and T2 relaxation time approaches the upper limit of muscle values (79.9 ms in the gluteus maximus). Any lower density must be calibrated by altering the agar composition, thus affecting gelatination power.

Table I. Example of muscle phantom values representing different muscle quality

Phantom Properties	Fatty Muscle	Average Muscle	Lean Muscle
[$CuCl_2$]	4.00 mM	22.52 mM	41.04 mM
[EDTA]	0.73 mM	0.03 mM	0.01 mM
T2 relaxation time	52.65 ms	35.15 ms	29.07 ms
Density	65 mg/cm^3	70.00 mg/cm^3	75.00 mg/cm^3

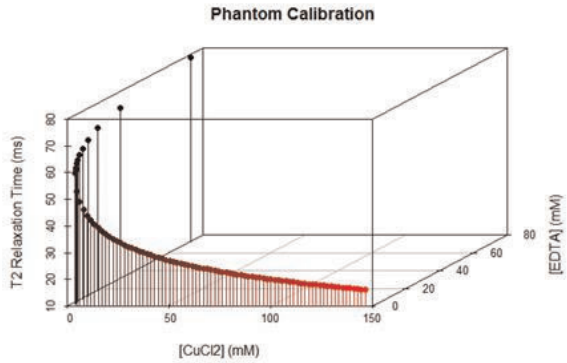

Figure 1. Combined logarithmic relation among [EDTA], [$CuCl_2$] concentrations and T2 relaxation time. Density was not included in this three-dimensional plot since it depends mostly on [$CuCl_2$] only.

Table I. Figure 1.

Dietary protein patterns are not associated with lean mass or strength among adults from the Framingham 3rd Generation Study. Kelsey Mangano*[1], Shivani Sahni[2], Robert McLean[3], Alyssa Dufour[4], Douglas Kiel[4], Katherine Tucker[5], Marian Hannan[6]. [1]Institute for Aging ResearchHebrew SeniorLifeHarvard Medical School, USA, [2]Hebrew SeniorLife, Institute for Aging Research & Harvard Medical School, USA, [3]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, [4]Hebrew SeniorLife, USA, [5]University of Massachusetts Lowell, USA, [6]HSL Institute for Aging Research & Harvard Medical School, USA

Background: Total protein intake has been shown to benefit lean mass and muscle strength among adults, yet little is known about the influence of protein food source on muscle. It is essential to examine food sources of protein due to their different nutritional profiles and synergy with other nutrients consumed in the diet, which may affect muscle health differentially. Purpose: To examine the cross-sectional association of dietary protein patterns with quadriceps strength and appendicular lean mass (aLM) among adults. Methods: Quadriceps strength (n=2,846) and aLM (n=2,926) were measured in Framingham 3rd Generation Study participants (2008-2011). Isometric quadriceps strength (kg) of the right leg was measured using the Lafayette Manual Muscle Test System. aLM was calculated as the sum of leg and arm lean mass (kg) from whole body dual energy x-ray absorptiometry scans, and normalized for body size by dividing height (m^2). Dietary intakes were estimated using the Willett food frequency questionnaire (2002-2005). Cluster analysis (fastclus procedure, k-means method) classified participants into clusters, determined by major source of dietary protein. Linear regression was used to compare crude and multivariable-adjusted least-squares mean aLM and quadriceps strength across dietary protein clusters. Results: Average age was 41 ± 9y (range: 19-72y); 46% were men; mean total protein intake was 93 ± 32g/d; mean aLM, 22 ± 6kg and mean quadriceps strength, 28 ± 9kg. Five dietary protein clusters were identified (Table). Crude models showed significantly greater aLM in the red/processed meat cluster compared to the fish/plant/whole grains and low-fat milk clusters. The fish/plant/whole grains cluster had the lowest aLM. Similar results were observed with aLM/m^2. However, following multivariable adjustment, no significant differences were observed. No statistically significant differences in mean quadriceps strength were observed in crude or adjusted models. Results were similar when men and women were analyzed separately. Conclusions: In this cohort of men and women across a wide age range, dietary protein patterns were not associated with measures of lean mass or strength following adjustment for other factors associated with muscle health. These results suggest the benefit of dietary protein to muscle health occurs apart from protein food source in the context of the whole diet.

Least squares means ± SD[1] for appendicular lean mass (aLM) and quadriceps strength by dietary protein pattern

Variable	n	Cluster 1 Fish, plant & whole grains	Cluster 2 Processed foods	Cluster 3 Low fat milk	Cluster 4 Red meat & processed meat	Cluster 5 Chicken

Do Strong Women Have Strong Bones?. Julie Pasco*[1], Sharon Brennan[1], Kara Holloway[2], David Moloney[2], Mark Kotowicz[3]. [1]Deakin University, Australia, [2]Deakin University, Australia, [3]Deakin University School of Medicine, Australia

Purpose: Resistance training and high impact exercises are promoted for building and maintaining a healthy skeleton. However, the linkages between muscle and bone are not yet fully understood. We aimed to investigate the relationship between hip flexor strength and areal bone mineral density (BMD) in women.

Methods: This cross-sectional study utilises data from 865 women (age 26-97 years) assessed for the 6-year follow-up phase of the Geelong Osteoporosis Study. Isometric hip flexor strength was measured three times on each leg, using a hand-held dynamometer (Nicholas Manual Muscle Tester). The maximal measure was used for analyses. BMD was measured at multiple skeletal sites using dual energy x-ray absorptiometry (DXA; Lunar DPX-L). Appendicular lean mass and body fat mass were determined from whole body DXA scans. Height and weight were measured. Relationships were analysed using linear regression techniques, with muscle strength as the independent variable and BMD as the dependent variable of interest.

Results: Muscle strength was negatively correlated with age and positively with appendicular lean mass (r=-0.49 and r=0.40; both p<0.001). Age-adjusted hip flexor strength was positively associated with BMD at all sites; for each standard deviation (SD) increase in muscle strength, the increase in BMD (SD) was 12.3% at the PA-spine (p=0.013), 10.4% at the total hip (p=0.009), 16.2% for the whole body (p<0.001), 14.3% at the ultra-distal forearm (p=0.003) and 21.5% at the mid forearm (p<0.001). The associations were independent of height and remained significant after adjustment for appendicular lean mass and body fat mass only at the mid-forearm.

Conclusion: The positive association between muscle strength and BMD was explained by differences in body composition at all sites except the mid-forearm. The findings suggest that the muscle-bone interaction might reflect muscle quantity rather than muscle strength.

How Does the Frailty Status of a Population-based Cohort Change? Results from the Longitudinal Canadian Multicentre Osteoporosis Study (CaMos). Courtney Kennedy*[1], George Ioannidis[2], Jonathan Adachi[3], Lehana Thabane[4], Kenneth Rockwood[5], Susan Kirkland[5], Andy Kin On Wong[6], Laura Pickard[1], Alexandra Papaioannou[7]. [1]McMaster University, Canada, [2]McMaster University, Canada, [3]St. Joseph's Hospital, Canada, [4]McMaster University, Canada, [5]Dalhousie University, Canada, [6]McMaster UniversityUniversity Health Network, Canada, [7]Hamilton Health Sciences, Canada

Purpose: A Frailty Index is a continuous measure which considers the degree of frailty as proportional to the number of accumulated "health deficits" (symptoms, signs, diseases, and disabilities). The CaMos Frailty Index (CFI) was developed using a cumulative deficits framework and consisted of 30 items including co-morbidities, cognition, energy, functional and mobility measures. We examined frailty status of all CaMos participants at baseline and after 10-years of follow-up. Methods: CaMos began in 1995 and is a prospective cohort study of randomly selected Canadian men and women aged 25 years and older. Total CFI scores were derived by summing the deficit score on individual variables (0=absent, 1=maximal expression of deficit) and dividing by the total number of variables (n=30), yielding a continuous score between 0 (least frail) and 1 (most frail). We examined the prevalence of frailty among those in the cohort at baseline and at 10-years, with a CFI score $\geqslant$0.25 considered as frail. We also examined the change in frailty scores over ten years for individuals who completed the 10-year follow-up; a change of 0.03 in CFI was considered clinically significant. Results: The CaMos baseline cohort was 9423 non-institutionalized individuals aged 25 years and older, including 6539 women (70.7%). The mean baseline CFI was 0.13 [standard deviation (SD)=0.11] in the entire cohort and 0.11 (SD=0.09) in participants completing the 10-year follow-up (n=5566). Of 1386 individuals (mean age=71.2 years, SD=11.2) classified as frail at baseline, 66.7% died/dropped out, 14.7% were also frail at year 10, and 18.6% were non-frail by year 10. Of 8037 individuals (mean age=61.1 years, SD=13.2) not frail at baseline, 36.5% died/dropped out, 4.5% were frail at year 10, and 59% were also non-frail at year 10. In the cohort reaching 10-years (n=5566), the mean change in frailty scores ranged from -0.37 to +0.46 (mean =0.004, SD=0.08). Overall, 32% increased their frailty status (i.e., >0.03 CFI increase), 30% decreased frailty status (i.e., >0.03 CFI decrease) and 38% did not change. Conclusion: As we would expect, the frailest participants died/dropped-out during the study period. The dynamic nature of frailty is indicated, with similar proportions of individuals who increased and decreased their frailty status over 10-years.

Identification of a Particular Clinical, Functional and Biochemical Profile in Sarco-Osteoporotic Older Persons. Ruth Huo*[1], Pushpa Suriyaarachchi[2], Piumali Gunawardene[2], Oddom Demontiero[3], Gustavo Duque[4]. [1]University of New South Wales, Australia, [2]Ageing Bone Research Program, The University of Sydney, Australia, [3]The University of Sydney Nepean Clinical School, Australia, [4]Ageing Bone Research Program, University of Sydney, Australia

In older persons, the combination of sarcopenia and osteopenia/osteoporosis has been proposed as a subset of frailer individuals at higher risk of falls and fractures. However, the particular clinical, functional and biochemical characteristics of the sarco-osteoporotic patients remain unknown. In this study, we aimed to identify a standard definition of sarco-osteoporosis (SOP) and to determine the clinical, functional and biochemical features that are unique to SOP within a population of older persons. 680 subjects (mean age=79, 65% female) were assessed between 2009-2012 at the Falls & Fractures Clinic, Nepean Hospital (Penrith, Australia). Assessment included physical examination, bone densitometry and body composition by DXA, posturography, grip strength, gait assessment (GaitRITE), and blood tests for nutrition and secondary causes of SOP. Patients were divided in 4 groups: 1) osteopenia/osteoporosis (BMD<-1.0 SD); 2) sarcopenia (following the European Consensus criteria); 3) SOP and; 4) normal. Difference between groups was assessed with one-way ANOVA and chi square analysis. Multivariable linear regression evaluated the association between the groups and measures of physical function. Multivariable logistic regression evaluated risk factors for being in the SOP group. Sarcopenia was present in 47.4% of those with osteopenia (167/352) and 62.7% in those with osteoporosis (91/145). Mean age of the SOP was 80.4$\pm$7 years. Univariate analyses showed that SOP are older, mostly female (OR 6.0, CI95% 3.67 – 9.87, p<0.001), at high risk for depression and malnutrition, BMI <25, and showed higher prevalence of peptic disease, inflammatory arthritis, history of maternal hip fracture, previous atraumatic fracture, and impaired mobility. Levels of parathyroid hormone were higher in SOP subjects (p<0.01). In summary, we have identified a set of clinical, functional and biochemical characteristics that are highly prevalent in SOP. This study could be used to inform the design future trials and to develop interventions for this particular syndrome.

Longitudinal Decline of Quality of Life is Determined by Loss of Muscle Mass and Reduced Physical Functioning in Older Adults. Andrea Trombetti*[1], Kieran Reid[2], Mélany Hars[1], François Herrmann[1], Roger Fielding[3]. [1]Division of Bone Diseases, Geneva University Hospitals & Faculty of Medicine, Switzerland, [2]Jean Mayer USDA HNRCA At Tufts University, USA, [3]Jean Mayer USDA HNRCA At Tufts University, USA

Purpose: The age-related loss of skeletal muscle mass and function are critical determinants of independent physical functioning in later life. Longitudinal studies examining how decrements in these parameters impact quality of life in older adults are lacking.

Methods: Twenty-six healthy older subjects (age (mean $\pm$ SD), 74.1 $\pm$ 3.7; Short Physical Performance Battery (SPPB) score, 11.0 $\pm$ 0.9) and twenty-two older mobility-limited subjects (age, 77.2 $\pm$ 4.4; SPPB score, 7.9 $\pm$ 1.3) underwent evaluations of mid-thigh by computed tomography to estimate total muscle cross-sectional area (CSA), leg extensor muscle power, and 400m walk performance at baseline and after 3 years of follow-up. Quality of life was assessed at both timepoints using the Physical Component Score (PCS) of the Short-Form 36 questionnaire.

Results: At 3-year follow-up, muscle CSA decreased by 3% ($p < 0.01$), muscle power decreased by 9.4% ($p < 0.001$), while time to complete 400m increased by 22 $\pm$ 46 seconds ($p < 0.001$). Using linear mixed-effects regression models to adjust for study group (healthy/mobility-limited), gender, duration of follow-up and depressive symptoms, the decline of muscle mass ($\beta = 0.10$; $p < 0.05$) and decreased 400m walk time ($\beta = -0.04$; $p < 0.003$) were independent determinants of PCS at follow-up.

Conclusions: In older adults with and without mobility-limitations, declining muscle mass and physical function are independent factors that compromise quality of life over a 3 year follow-up period. Future studies should evaluate how intervention strategies designed to maintain muscle mass or restore physical functioning impact quality of life in older adults.

MMP-2 Mediated Degradation of Titin in Muscle Atrophy Study. Shu Sun*[1], Anders Nedergaard[2], Morten Karsdal[1], Kim Henriksen[1], Gabriele Armbrecht[3], Daniel L. Belavý[4], Dieter Felsenberg[5]. [1]Nordic Bioscience A/S, Denmark, [2]Nordic Bioscience Biomarkers & Research, Denmark, [3]Centre of Muscle & Bone Research, Charite-CBF, Germany, [4]Center for Muscle & Bone Research, Charite Campus Benjamin Franklin, Free University & Humboldt-University Berlin, Germany, [5]Charité - Campus Benjamin Franklin, Germany

Background: Muscle loss is a problem which is getting increased clinical awareness, as loss of muscle mass and function are important predictors of mortality, morbidity and quality of life. In muscle loss syndromes, there is a pronounced lack of biochemical biomarkers that can predict or monitor pathological progress. In order to identify novel biomarkers of muscle loss, we set out to test if a cleavage fragment of the muscle protein titin identified in urine could be used as such a marker and we raised an antibody and constructed an ELISA assay for serum detection of said fragment.

Methods: A competitive ELISA assay measuring the titin fragment was developed. For biological validation of the assay, it was measured in rat tissue extractions and in vitro rat muscle enzymatic cleavage model, in order to characterize how the fragment is produced in vivo. Then the titin degradation marker was validated in a human 56-day bed rest study.

Results: The ELISA measuring titin fragment was technically robust and the fragment was shown to be produced by MMP-2 cleavage. This titin-MMP2 degradation fragment had higher expression in rat EDL muscle extraction compared to extractions from soleus and cardiac muscle. In a human bed rest study, the titin-MMP2 fragment was initially decreased about 10% after 1 day of bed rest, and then gradually increased until day 47, up to an average of 17% increase. On the last day of bed rest, the concentration did not significant differ to day 47.

Conclusions: We developed an ELISA measuring titin-MMP2 degradation fragment in human serum. We proposed that the titin-MMP2 marker during bed rest process may potentially reflect compensatory mechanisms to the catabolic immobilization stimulus. The gradually increased titin-MMP2 may reflect aspects of the catabolic processes in human long-term bed rest-induced muscle loss.

Nutritional and Laboratory Associations with Skeletal Muscle Mass in Postmenopausal Women. Karen Hansen*[1], Sheeva Marvdashti[2], Christina Lemon[2], Kaitlin Chambers[2], R. Erin Johnson[2], Bjoern Buehring[3]. [1]University of Wisconsin, USA, [2]University of Wisconsin School of Medicine & Public Health, USA, [3]University of Wisconsin, Madison, USA

Sarcopenia, an age-associated decline in skeletal muscle mass and function, associates with falls, fractures, hospitalization and death. We evaluated relationships between height-corrected appendicular lean mass (ALM/Ht^2), physical function, nutritional habits and laboratory studies in ambulatory postmenopausal women.

Subjects were 231 postmenopausal women age 61 ± 6 years old randomized into a double-blind, placebo-controlled trial evaluating changes in calcium absorption, bone mineral density and physical function with treatment of vitamin D insufficiency. Subjects' baseline data were analyzed. ALM/Ht^2 was determined by whole body DXA (GE Lunar), using appendicular lean mass and height measured without shoes using a wall-mounted stadiometer. Nutritional habits were determined by 4–day diet diaries, and physical function was assessed by Timed Up and Go (TUG) and 5 Sit to Stand (STS) tests. Subjects completed questionnaires (Physical Activity Scale for the Elderly, PASE and Health Assessment Questionnaire, HAQ) assessing daily activities. Spearman correlation coefficients and linear models were used to evaluate associations between ALM/Ht^2 and subject characteristics.

Subjects' mean ± SD ALM/Ht^2 was 7.29 ± 1.15 kg/m^2; 55% had sarcopenia (ALM/Ht^2 ≤7.23 kg/m^2). Body weight was strongly associated with ALM/Ht^2 (ρ=0.821, p<0.001) and accounted for 73% of its variance (R^2). Additionally, ALM/Ht^2 was associated with the TUG, STS and Health Assessment Questionnaire scores, consumption of alcohol and sodium, use of supplemental calcium, iron and potassium, and serum parathyroid hormone and estradiol levels (Table). In linear models controlling for weight and age, ALM/Ht2 was positively associated with the TUG and PASE scores, dietary magnesium and use of magnesium and potassium supplements. Addition of the STS test, serum calcium and albumin improved the model and together, these 10 variables explained 79% of the variance in ALM/Ht^2.

Body weight is the largest factor associated with ALM/Ht^2. Like other researchers, we found that alcohol, parathyroid hormone levels and estradiol were associated with muscle mass in univariate analyses. Both univariate and multivariate analyses identified potassium and magnesium intake as statistically significant. Future studies are needed to clarify the role of magnesium and potassium intake in skeletal muscle mass.

Prevalence of 'Dysmobility Syndrome' in Community Dwelling Older Adults: Findings from the UK and US. Bjoern Buehring*[1], Mark Edwards[2], Rebecca Moon[3], MA Clynes[4], Celia Gregson[5], Ellen Fidler[6], Nicholas Harvey[7], Elaine Dennison[8], Neil Binkley[1], Cyrus Cooper[9]. [1]University of Wisconsin, Madison, USA, [2]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, [3]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, [4]MRC Lifecourse Epidemiology Unit, University of Southampton, UK, United Kingdom, [5]University of Bristol, United Kingdom, [6]University of Wisconsin, USA, [7]MRC Lifecourse Epidemiology Unit, University of Southampton, United Kingdom, [8]MRC Lifecourse Epidemiology Unit, United Kingdom, [9]University of Southampton, United Kingdom

Sarcopenia and osteoporosis become common with advancing age, often coexist, and increase risk for adverse outcomes such as falls and fracture. We recently proposed a score-based system to diagnose ''dysmobility syndrome'' in an attempt to combine adverse musculoskeletal phenotypes to identify older individuals at risk for falls and fractures. This report compares the prevalence of dysmobility, and sarcopenia using conventional definitions, in two cohorts of community dwelling older adults; a group from the Hertfordshire Cohort Study in the UK and a convenience sample from the US.

In both cohorts, body composition was measured by DXA, gait speed and grip strength were assessed in routine manner. Participants completed a questionnaire detailing self-reported falls and fracture history. Dysmobility syndrome was arbitrarily defined as 3 or more of low appendicular lean mass/height ratio, low grip strength, low gait speed, low leg lean/fat mass ratio, osteoporosis, and fall in the last year. Sarcopenia prevalence was determined using the European Working Group on Sarcopenia in Older People (EWG) and International Working Group on Sarcopenia (IWG) definitions. The UK cohort included 156 men and 142 women of mean (SD) age 76.1 (2.6) years and BMI of 27.4 (4.1) kg/m^2; the US cohort included 48 men and 49 women with mean (SD) age 80.7 (5.9) and BMI 25.6 (4.1). Sarcopenia prevalence (EWG/IWG) was 7%/8% in the UK and 20%/10% in the US group. Dysmobility prevalence was 25% in the UK and 41% in the US cohort. Dysmobility syndrome was more common (p<0.05) in women than men in both cohorts (33.1% vs. 17.3% in the UK and 59.2% vs. 22.9% in the US). The higher dysmobility syndrome prevalence in women was associated with a higher frequency of abnormal parameters in several of the chosen factors. In the UK cohort, those with dysmobility reported a higher number (p <0.01) of falls than counterparts without dysmobility, but no increased fracture rate was observed in the dysmobility group (p=0.96). No significant differences in falls and fracture prevalence were found in the US cohort (all p>0.1).

In conclusion, dysmobility syndrome is common among older community dwelling adults in the UK and US, with higher rates observed in the US cohort. Prevalence was higher in women than men. Further work is needed to optimally define how muscle mass/function, in combination with body composition assessment, can be used to identify older adults at risk for falls and fractures.

SU0449

Use of the Safe Functional Motion-6 test to classify individuals at risk for functional decline following a distal radius fracture. Norma MacIntyre*[1], Joy MacDermid[2], Julie Richardson[2], Ruby Grewal[3], Christopher Recknor[4]. [1]McMaster University, Canada, [2]McMaster University, Canada, [3]St Joseph's Health Care, Canada, [4]United Osteoporosis Center, USA

Purpose: A distal radius fracture (DRF) may mark the onset of osteoporosis (OP) and/or functional decline. This study determines the effects of age and physical functioning on functional recovery in individuals followed for 1 year after DRF.

Methods: Adults with recent DRF completed the 6-task Safe Functional Motion test (SFM-6) at follow-up clinic visits. The SFM-6 quantifies observed physical performance during activities typical of daily living with a score calculated as a percentage of the maximum points possible where higher scores reflect better movement patterns. Prevalence of OP at the time of the DRF was defned as DXA-based total hip t-score <-2.5, where available, and use of bone sparing medications. Since assessments were done at varying time intervals, hierarchical linear modeling was used to determine if the pattern of functional recovery, as measured by the SFM-6, was predicted by age (<60 vs ⩾60yr) and initial SFM-6 score (⩾80 vs <80 points).

Results: Seventy-nine DRF patients (mean(SD) age=61.3(6.8)yr; 8 men), completed the SFM-6 on at least 2 occasions. Musculoskeletal conditions were the most prevalent comorbidities (osteoarthritis: n=32 and back pain: n=20). Few had prevalent OP (t-score < -2.5: n=3; on bone sparing medications: n= 8). Figure 1 illustrates individual SFM-6 scores over 1 year for the cohort according to age and physical functioning at baseline. Age and baseline SFM-6 score were significant predictors of functional recovery (^{2}=41.74, p<0.001). The ⩾ 60yr group scored 3 points lower than the <60yr group at baseline (p = 0.038); age was not a significant predictor of the linear or nonlinear slopes modelling functional recovery. Those with SFM-6 scores <80 points at baseline had a steeper linear slope than those with scores ⩾80 points at baseline (β coefficient=11.3, p<0.001). The rate of change in SFM-6 scores was attenuated in those ⩾60yr with low physical functioning at baseline but this difference was not statistically significant.Conclusions: Whereas age was a

predictor of physical functioning, only baseline physical functioning predicted patterns of functional recovery in our sample. The SFM-6 may be useful for classifying those at risk for functional decline following DRF. Few participants had an elevated risk for OP fracture and long-term follow-up is required to determine if SFM-6 scores predict future fracture in the DRF population.

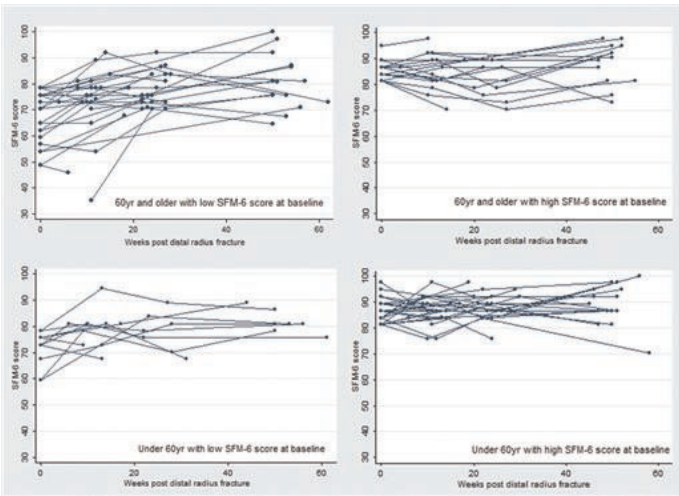

Figure 1. SFM-6 scores for participants followed over 1 year post distal radius fracture.

Compartment Specific Changes in Bone Mass with Advanced Age in a Mouse Model with Enhanced Sympathetic Tone and Impaired Brown Adipose Tissue Function. Phuong Le*[1], Katherine Motyl[1], Kathleen Bishop[1], David Maridas[1], Daniel Brooks[2], Mary Bouxsein[3], Clifford Rosen[4]. [1]Maine Medical Center Research Institute, USA, [2]Beth Israel Deaconess Medical Center, USA, [3]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [4]Maine Medical Center, USA

'Browning' of white adipose tissue (WAT) is a critical goal for novel weight loss drugs; however, these agents may have deleterious effects on the skeleton. The *Misty* mice (*m/m*) have a spontaneous mutation leading to a loss of function in the *Dock7* gene which acts downstream of the EGFR to activate Rac1 and Cdc42. *Misty* at 16wk have low trabecular bone mass, loss of brown adipose tissue (BAT) function, increased sympathetic tone (SNS), and marked browning of WAT depots. As predicted, *m/m* are resistant to high fat diet-induced obesity. In this study, we hypothesized *m/m* would have accelerated age-related bone loss in conjunction with progressive browning of peripheral WAT depots. Female *m/m* and their littermate controls (WT) were aged to 78wk on a regular chow. Body composition and areal bone mineral density (aBMD) were measured by DXA; femur trabecular and cortical microarchitecture were measured by μCT. Total aBMD and trabecular BV/TV were significantly reduced in *m/m* and remained at low levels beyond 1 year ($p<0.001$, age x genotype interaction). With regard to cortical bone, *m/m* have greater total area (TtAr) younger ages, but smaller TtAr at 78 wk, suggesting impaired age-related periosteal apposition. Cortical thickness and cortical bone area fraction (CtAr/TtAr) are consistently lower in *m/m* than WT, though with increasing age, WT CtAr/TtAr declines at a faster rate. This suggests *m/m* are less susceptible to age-related endosteal resorption, which could explain in part, their lower rate of periosteal expansion. Body weight increased with age in both strains, but *m/m* were slightly thinner than WT. From 52 to 78wk, *m/m* did not increase body weight but the WT did. Inguinal fat depots in *m/m* had smaller adipocytes and more UCP-1 staining at 52 and 78wk *vs.* WT mice. In both genotypes, BAT weight increased with age. *Misty* BAT had larger lipid droplets than WT, with less UCP-1 staining at 78wk. Thus, progressive browning of WAT continues unabated in *m/m*. Age-related changes in trabecular bone are likely related to the high SNS drive from impaired BAT function, while cortical bone loss may be associated with the absence of weight gain in the older *m/m* mice. The absence of periosteal compensation with age in *m/m* may also be due to a cell autonomous effect of the *Dock7* mutation. In conclusion, although SNS activation may protect against diet-induced obesity, the long term effects on body composition and bone mass are profound.

Cortical porosity increases with age in murine long bones and is associated with elevated RANKL and reduced OPG expression in osteocytes. Charles O'Brien*[1], Jinhu Xiong[1], Marilina Piemontese[2], Stuart Berryhill[3], Priscilla Baltz[3], Robert Weinstein[1], Maria Jose Almeida[1], Stavros Manolagas[1], Robert Jilka[1]. [1]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [2]University of Arkansas for Medical Sciences, USA, [3]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA

Increased cortical porosity is now recognized as an important contributor to skeletal fragility in elderly humans. However, the cellular and molecular mechanisms responsible for the increase in cortical porosity associated with advanced age are

unclear. Here we have investigated changes in structure and gene expression in cortical bone of aged mice. Cortical bone architecture was investigated in the femur, tibia, and humerus of C57BL/6 female mice at 6, 18, and 24 months of age using micro-CT. Cortical thickness of the femur was reduced at the two older ages compared with 6-month-old mice and this was associated with increases in both the inner and outer diameters of the cortical bone. Porosity, as observed in full-length scans of the femoral cortical bone, also increased with age and was especially prominent at both the distal and proximal metaphyses. Moreover, porosity in the region of the third trochanter increased. In the tibia, porosity increased throughout the proximal region. The humerus of aged mice exhibited the same pattern of porosity, along with a striking increase in the porosity of the deltoid tuberosity. These changes in bone structure were associated with increased levels of the osteoclast-specific mRNAs cathepsin K, calcitonin receptor, and TRAPase in cortical bone, consistent with increased remodeling. Notably, RANKL mRNA was increased and OPG mRNA was decreased in osteocyte-enriched cortical bone of aged mice compared with 6-month-old mice. Soluble RANKL protein was also elevated in bone marrow supernatants of aged mice as measured by both ELISA and Luminex bead assays. The highly localized porosity that develops in the murine appendicular skeleton with advancing age appears to occur at sites of high bone strain, i.e. the metaphyses and trochanteric sites of muscle attachment. In view of the evidence that osteocytes are an important source of RANKL, these results suggest that altered osteocyte function or viability with age leads to changes in the RANKL/OPG axis that promote intra-cortical bone resorption, predominantly at sites of higher loading. Moreover, since bone remodeling is reduced in the cancellous bone of aged mice, these findings suggest there are important mechanistic differences underlying the age-associated changes in bone remodeling in cortical versus cancellous bone.

Galectin-3: A novel regulator of bone mass. Kevin Maupin*[1], John Wang[2], Bart Williams[3]. [1]Van Andel Institute Graduate School, USA, [2]Michigan State University, USA, [3]Van Andel Research Institute, USA

The decline of hormone production during aging leads to a gradual loss of bone mass. Over time, these bones can become porous and brittle, leading to osteoporosis. Half of all women over the age of 60 will suffer an osteoporotic fracture and of those women who fracture, nearly 40% will die within 5-years due to complications. While hormone replacement therapy is effective at reducing bone loss and preventing fractures, it also carries the risk of breast cancer, endometrial hyperplasia, and liver disease. The identification of novel non-hormonal regulators of bone mass will lead to improved treatment strategies to prevent/reverse osteoporosis. We have identified one potential target: Galectin-3 (Gal3).

Gal3 is a beta-galactoside binding protein expressed by all bone lineage cells and has been implicated as a negative regulator of both osteoblast and osteoclast differentiation. In order to understand the role of Gal3 in bone during aging, we analyzed femurs and L3 vertebrae from mice carrying a null mutation of the Gal3 gene (*Lgals3*) on a C57BL/6 background and their wildtype littermates at pre-skeletal maturity (12 wks), post-skeletal maturity (24 wks), and advanced age (36 wks). Using micro computed tomography (μCT) we found that the vertebra of female *Lgals3*-null mice have 10% higher trabecular bone mineral density (tBMD) and a 35% greater bone volume fraction (BV/TV) at both the 24- and 36-wk time points. The femurs of *Lgals3*-null females showed no difference until 36 wks when their femurs failed to show the normal age-related loss of trabecular bone. This preservation of bone resulted in 45% higher tBMD and 239% greater BV/TV compared to *Lgals3*-wildtype females. Interestingly there was no significant difference in trabecular bone parameters at any measured time point when *Lgals3* was deleted in males. Our findings indicate that Gal3 is a negative regulator of trabecular bone formation and/or a positive regulator of trabecular bone resorption in females. Additionally, genetic loss of *Lgals3* was well tolerated in mice, and therefore, pharmacological targeting of Gal3 may be an efficacious option for treating/preventing osteoporosis.

SU0453

Mitochondria-targeted expression of catalase does not prevent the low bone mass caused by suppression of autophagy in osteoblasts and osteocytes. Marilina Piemontese*[1], Jinhu Xiong[2], Priscilla Baltz[3], Rajamani Selvam[3], Li Han[2], Stuart Berryhill[3], Stavros Manolagas[2], Charles O'Brien[2]. [1]University of Arkansas for Medical Sciences, USA, [2]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [3]University of Arkansas for Medical Sciences, USA

Autophagy maintains cell function and homeostasis by recycling damaged intracellular components. Previous studies have shown that deletion of Atg7, a gene required for the formation of autophagosomes, with an osteoblast-specific Cre recombinase (Osx1-Cre) causes low bone mass and spontaneous fractures. Suppression of autophagy in other cells types often results in reduced recycling of mitochondria leading to accumulation of damaged mitochondria and oxidative stress. Consistent with this, we observed elevated levels of reactive oxygen species (ROS) in the bone marrow of Osx1-Cre;Atg7f/f (Atg7ΔOb) mice. To determine whether the increase in oxidative stress contributes to the low bone mass caused by Atg7 deletion, Atg7ΔOb mice were crossed with mice harboring a conditionally-activated transgene expressing mitochondria-targeted catalase (mCAT), an antioxidant enzyme. Thus, in the offspring of this cross the Osx1-Cre transgene simultaneously deletes Atg7 and activates the catalase transgene in the same cell populations (osteoblasts and osteocytes). Serial BMD analysis up to 24 weeks of age confirmed low bone mass in the femur and spine of Atg7ΔOb mice compared to both Atg7f/f and Osx1-Cre control littermates. Expression of mCAT in Atg7ΔOb mice did not alter the low bone mass caused by suppression of autophagy. Catalase activity, measured in stromal cells cultured in osteogenic medium, was greatly elevated in mCAT;Atg7ΔOb mice compared to control littermates, confirming activation of the transgene. ROS levels measured in the bone marrow and phosphorylation of p66shc protein, an oxidative stress mediator, were increased in Atg7ΔOb mice and did not change with expression of catalase. Thus, mitochondrial expression of catalase in osteoblasts and osteocytes did not prevent the increase in oxidative stress in the bone marrow caused by suppression of autophagy. Analysis of femoral and vertebral architecture confirmed the low trabecular bone volume in Atg7ΔOb mice as well as the reduction in strength, and expression of mCAT did not prevent any of these changes. Consistent with this, the rate of spontaneous fractures occurring in tibias of conditional knockout mice was similar in conditional knockout mice expressing catalase. Together these results suggest that autophagy exerts its positive effects on the skeleton by mechanisms other than suppression of H202 levels in the mitochondria of osteoblasts and osteocytes

Osteoblast depletion increases osteoblast activity and reduces bone toughness in mice. Adeline Ng*[1], Gurpreet Baht[2], Marc Grynpas[3], Benjamin Alman[2]. [1]University of Toronto Samuel Lunenfeld Research Institute, Canada, [2]Program in Developmental & Stem Cell Biology, Hospital for Sick Children, Canada, [3]Lunenfeld-Tanenbaum Research Institute of Mount Sinai Hospital, Canada

Background: Literature has suggested factors that sustain stem cell levels in the bone marrow decline with age and this deficit may be related to age-associated bone loss. Using the Col2.3Δtk (DTK) transgenic mouse, we investigated the consequences of repeated ablation of differentiated osteoblasts on osteogenic progenitor cells in the bone marrow. The DTK transgenic mouse takes advantage of the HSV-tk (herpes simplex virus thymidine kinase)/GCV (ganciclovir) system to conditionally ablate differentiated osteoblasts.

Methods: In an osteoblast-depletion experiment, 4-month old DTK mice were repeatedly treated with ganciclovir (GCV) to conditionally ablate differentiated osteoblasts, while controls were treated with saline. All animals were sacrificed at 8 months; bone marrow stromal cells (BMSCs) were harvested for cell culture and whole bones were excised for bone quality assessment. Colony forming unit (CFU) assays were conducted to investigate BMSC osteogenic potential. RNA was extracted from cell culture and whole bones (tibias) to assess the expression of genes defining BMSC lineage. *Ex vivo* bone quality assessments included bone histomorphometry, TRAP-staining, microcomputed tomography, and biomechanical testing.

Results: Osteoblast depletion using GCV decreased CFU-F (fibroblast), CFU-ALP (alkaline phosphatase) and CFU-VK (von Kossa) counts in cell culture. *Ex vivo*, there was no difference in bone mineral density (vertebrae and femurs) between treatment groups despite differences in BMSC osteogenic capacity *in vitro*. Histology showed a decrease in bone volume and bone connectivity with repeated osteoblast depletion; this was accompanied by an increase in osteoid volume and surface, mineralizing surface, and bone formation rate. Although osteoblast depletion did not decrease the number of active osteoblasts between treatment groups, it decreased the number of TRAP-positive osteolcasts. Repeated osteoblast depletion decreased the energy to failure in vertebral compression and 3-point bending tests.

Discussion: This study aims to connect *in vitro* cell culture data with *in vivo* skeletal phenotypes. Results suggest that the number of healthy bone marrow stromal cells (BMSCs) and the osteogenic potential of those healthy BMSCs decline with repeated osteoblast ablation. Activity of the remaining osteoblasts increases to compensate for this loss in osteogenic potential, but mechanical properties remain compromised with repeated osteoblast ablation.

PTH/PTHrP Receptor (PPR) Signaling in Osteocytes Delays Osteocyte Senescence and Protects from Age-related Osteopenia. Vaibhav Saini*[1], Keertik Fulzele[2], Xiaolong Liu[3], Christopher G Dedic[3], Vladimir Zoubine[3], Jordan Spatz[4], Hiroaki Saito[5], Katharina Jahn[5], Saman F Khaled[3], Kathryn D Held[3], Eric Hesse[6], Paola Divieti Pajevic[7]. [1]MGH, Harvard Medical School, USA, [2]Massachusetts General Hospital; Harvard Medical School, USA, [3]MGH, USA, [4]Harvard-MIT Division of Health Sciences & Technology (HST), USA, [5]University Medical Center Hamburg-Eppendorf, Germany, [6]University Medical Center Hamburg-Eppendorf, Deu, [7]Massachusetts General Hospital & Harvard Medical School, USA

We have previously shown that PPR signaling in osteocytes is essential for bone remodeling and generating anabolic and catabolic skeletal responses to parathyroid hormone (PTH) administration. Herein, to understand age-induced osteoporosis, we investigated the effect of ablated PPR signaling in osteocytes on aged skeleton. Towards our goal, we used mice lacking PPR in osteocytes (OcyPPRKO), generated, as in the previous study, by mating 10kb-DMP1-Cre mice with PPR floxed mice. Littermates lacking Cre-expression were used as control. To investigate the role of PPR signaling in aging, we analyzed adult (4 months (mo)) and aged (12mo) OcyPPRKO and control. Histological analysis of long bones showed increased trabecular bone at 4mo which was dramatically decreased by 12mo in OcyPPRKO. High resolution μCT of L5 vertebrae and distal femurs showed increased trabecular bone at 4mo ($p<0.05$, N=6-12) which was decreased by 12mo ($p<0.05$, N=7-12) in OcyPPRKO than control. Histomorphometric analysis showed reduced osteoclast number and bone resorption in OcyPPRKO at 4mo ($p<0.05$, N=6-10) which were increased by 12mo ($p<0.05$, N=8-10). Osteoblasts and bone formation, on the other hand, were unchanged, as was SOST mRNA level in osteocyte-enriched calvariae from OcyPPRKO and control. Immunohistochemistry on tibiae showed reduced RANKL expression in osteocytes at 4mo ($p<0.05$) in OcyPPRKO, possibly accounting for decreased osteoclasts at 4mo; however RANKL expression was unchanged at 12mo between OcyPPRKO and control. TNFα mRNA level in osteocyte-enriched calvariae was similar between OcyPPRKO and control at 4mo; however it was increased by 62% ($p<0.05$) at 12mo in OcyPPRKO, possibly accounting for increased osteoclasts at 12mo. To investigate PPR signaling in osteocytes, we knocked-down PPR expression by lentiviral-delivered shRNA in Ocy454, a murine osteocyte cell line established in our laboratory. As compared with Ocy454-shGFP (control), Ocy454-shPPR cells showed reduced proliferation by time-lapse microscopy upon sequential passaging, intense senescence-associated ß-galactosidase staining at 11 and 21 days, and increased p53 mRNA level (270%, $p<0.05$) at 11 days *in vitro.* Furthermore, there was a 650% increase ($p<0.05$) in TNFα mRNA level in Ocy454-shPPR at 11 days. Our results demonstrate that PPR signaling in osteocytes delays senescence by decreasing p53 expression and protects from age-related osteopenia by decreasing TNFα expression and preventing osteoclast activation.

TNFα modulates cholesterol transport protein synthesis and efflux in osteocytes. Kent Wehmeier*[1], Salma Makhoul-Ahwach[2], Melanie Thomas[3], William Kurban[3], Harshit Shah[3], Aiham Chamseddin[4], Michael Haas[5], Arshag Mooradian[6], Luisa M. Onstead-Haas[6]. [1]University of Florida, College of Medicine, Jacksonville, USA, [2]Division of Endocrinology, Diabetes & Metabolism. University of Florida, College of Medicine Jacksonville, USA, [3]Division of Endocrinology, Diabetes & Metabolism, University of Florida, College of Medicine Jacksonville, USA, [4]Division of Endocrinology, Diabetes & MetabolismUniversity of Florida, College of Medicine Jacksonville, USA, [5]Division of Endocrinology, Department of Medicine, University of Florida, College of Medicine Jacksonville, USA, [6]Department of Medicine, University of Florida, College of Medicine Jacksonville, USA

Hip fracture and myocardial infarction cause significant morbidity and mortality. In vivo studies raising serum cholesterol levels as well as pro-inflammatory cytokines such as TNFα manifest bone loss and atherosclerotic vascular disease, suggesting that abnormalities of cholesterol transport may contribute to osteoporosis. We used the mouse osteocyte cell line (MLO-Y4) to investigate the effects of TNFα on the expression of cholesterol acceptor proteins such as apolipoprotein A-I and apolipoprotein E, as well as on ATP-binding cassette-1 (ABCA1) and scavenger receptor class B type 1 (SRB1). MLO-Y4 cells do not express apolipoprotein A-I or apolipoprotein E; however they do express the cholesterol transporters ABCA1 and SRB1. Treatment of MLO-Y4 cells with TNFα had no effect on osteocalcin levels; however TNFα reduced ABCA1 protein levels and cholesterol efflux to apolipoprotein A-I. Interestingly, TNFα treatment increased ABCA1 mRNA levels 1.8-fold and increased liver-x-receptor-alpha (LXRα) protein expression but had no effect on retinoid-x-receptor-alpha (RXRα) and retinoic acid receptor alpha (RARα) protein levels. TNFα treatment suppressed SRB1 mRNA levels (18%) but there was no change in SRB1 protein expression. TNFα induced p38 mitogen-activated protein (MAP) kinase activity, but had little effect on c-jun N-terminal kinase 1 and extracellular regulated kinase 1/2. Pharmacological inhibition of p38 MAP kinase restored ABCA1 protein levels. These results demonstrate that pro-inflammatory cytokines regulate cholesterol transport in osteocytes. Understanding cholesterol movement within bone cells may suggest novel therapeutic approaches to osteoporosis.

Factors Associated with Kyphosis and Kyphosis Progression in Older Men: the MrOS Study. Deborah Kado*[1], Mei-Hua Huang[2], Peggy Cawthon[3], Howard Fink[4], John Schousboe[5], Elizabeth Barrett-Connor[1]. [1]University of California, San Diego, USA, [2]UCLA, USA, [3]California Pacific Medical Center Research Institute, USA, [4]GRECC, Minneapolis VA Medical Center, USA, [5]Park Nicollet ClinicUniversity of Minnesota, USA

Hyperkyphosis, or increased thoracic curvature, is common in older men and women. While it is thought that vertebral fractures are the major cause of increased kyphosis, only about a third of those with the worst degrees of kyphosis have underlying vertebral fractures. In older men, hyperkyphosis is associated with increased risk of worse physical function, injurious falls, and earlier mortality. Thus, it would be useful to better understand the determinants of kyphosis progression in older men. Therefore, we studied 1051 men from the MrOS Study aged 64 – 92 (mean age 72.7) who had repeated standardized measures of Cobb angle kyphosis calculated from lateral spine x-rays taken at baseline and an average of 4.6 years later (SD = 0.4). Using multivariable linear regression, we analyzed the association between known and hypothesized risk factors of kyphosis and kyphosis progression. Specifically, we examined the association of age, family history of stooped posture, prevalent radiographic thoracic and lumbar vertebral fractures (RVF), incident RVF (longitudinal analyses only), degenerative disc disease (DDD), hip bone mineral density (BMD), bone density loss, BMI, weight, weight loss, co-morbidities such as diabetes, and health behaviors. Men had an average baseline kyphosis of 38.8° (SD = 11.2); over 4.6 years, they progressed an average of 1.4° (SD = 4.6). In cross-sectional analyses, older age (p = 0.002), DDD (p = <0.0001), lower hip BMD (p = 0.007) and lower body weight (p = 0.015) were associated with increased kyphosis, but prevalent vertebral fracture was not. In multivariable longitudinal analyses, incident vertebral fracture, lower hip BMD and DDD were the factors that significantly associated with increasing kyphosis (Table).

Other factors not included in the Table such as diabetes, smoking, alcohol use, and self-reported physical activity did not affect kyphosis progression. In contrast to the associations in older women, prevalent vertebral fracture was not associated with kyphosis while DDD was a significant predictor of both baseline kyphosis and kyphosis progression, possibly reflecting sex differences in the causes of worsening age-related posture. Common to both sexes, however, was the importance of BMD and incident vertebral fractures, suggesting that identifying and treating osteoporosis in both older men and women may help prevent or delay age-related kyphosis progression.

Table. Multivariable-Adjusted Beta Coefficients for Association Between Selected Characteristics and Kyphosis Progression over 4.6 years

Variable	Parameter Estimate	95% CI	P-value
Baseline kyphosis (per degree)	-0.046	(-0.07, -0.02)	0.0003
Prevalent RVF	0.69	(-0.71, 2.09)	0.33
Incident RVF	1.60	(0.0003, 3.16)	0.05
Hip BMD (per SD)	-0.55	(-0.82, -0.27)	0.0001
Degenerative Disc Disease (DDD)	0.60	(0.031, 1.17)	0.04
Above model also adjusted for age, clinic, weight change, and family history of stooped posture.

Self-reported Estrogen Use, Kyphosis and Kyphosis Progression in Older Women: the Study of Osteoporotic Fractures. Deborah Kado[1], Gina Woods*[2], Mei-Hua Huang[3], Corinne McDaniels-Davidson[4], Peggy Cawthon[5], Howard Fink[6]. [1]University of California, San Diego, USA, [2]UCSD, USA, [3]UCLA, USA, [4]SDSU/UCSD Joint Doctoral Program in Public Health (Epidemiology), USA, [5]California Pacific Medical Center Research Institute, USA, [6]GRECC, Minneapolis VA Medical Center, USA

Hyperkyphosis (HK), or increased thoracic spine curvature, tends to progress with age and is associated with poor physical and pulmonary function and earlier mortality. Although closely associated with osteoporosis, only 1/3 of older persons with the worst degrees of kyphosis have underlying vertebral fractures (VF) and the underlying biological correlates of kyphosis progression are not known. Rodent

models of kyphosis suggest that there is a link between sex steroid hormones and HK and we have recently reported that older men with lower serum estradiol have worse kyphosis. Therefore, to test the hypothesis that estrogen may play a role in kyphosis and kyphosis progression in older women, we studied 983 women from the Study of Osteoporotic Fractures aged >65 (mean age 69.4, SD = 4.0) who provided detailed information on estrogen use and who had their Cobb angle of kyphosis measured from baseline and follow-up lateral spine x-rays done an average of 3.7 and 15 years later. Using linear mixed effects regression, we examined the correlation between self-reported estrogen use (categorized as current, past or never), adjusting for factors thought to influence kyphosis alone or both estrogen use and kyphosis. Women had an average kyphosis of 44.9˚ (SD = 11.8) that progressed an average of 7˚ over 15 years. At baseline, 154 (16%) women reported current, 324 (33%) reported past, and 505 (51%) women reported never use of estrogen replacement. While we found no cross-sectional association between self-reported estrogen use and HK, there was a strong association between baseline reported estrogen use and kyphosis progression over the next 15 years. In age and clinic adjusted models, baseline reported current estrogen use was associated with 2.5˚ less (p = 0.0007) and past use with 1.6˚ less kyphosis progression (p = 0.005) than those who reported never using estrogen. In fully adjusted multivariable models that included BMD, degenerative disc disease, prevalent & incident VF's, weight, weight change, smoking, alcohol and self-reported physical activity, women who reported current or past estrogen use at baseline experienced 1.8˚(95% CI: 0.47, 3.2, p = 0.0081) or 1.3˚(95% CI: 0.28, 2.35, p = 0.014) less kyphosis progression, respectively, compared with those who reported never using estrogen. Confirming results from the animal literature and recent findings in older men, we conclude that estrogen may play an important role in the development of age-related HK.

Statement of Changes in Muscle Mass during Life by DXA. Silvana Di Gregorio[1], Jorge Malouf[2], Luis Del Rio*[3], Beatriz Oliveri[4]. [1]Ph, Spain, [2]Hospital de la Santa Creu i Sant Pau, Spain, [3]Cetir Centre Medical, Spain, [4]Mautalen, Salud e Investigación, Argentina

Aging is a physiological process that involves a progressive, generalized impairment of the functions of various systems. Muscle mass decreases especially in the lower extremities, leading to impairment in gait speed, stability and an increased fall risk. Thus, the clinical relevance of sarcopenia is widely recognized, but currently there is no universally accepted definition of this disorder. Muscle mass assessment, as the main item of the diagnostic definition of sarcopenia, needs to be feasible for both research and clinical practice, and accurate in older people. The study of Whole body composition by DXA allows the quantification of lean mass and the calculation of the appendicular fat-free mass of the upper and lower limbs. These measures divided by square body height gives us the patient's muscle mass index. Sarcopenia is diagnosed if it is >2 standard deviations (SD) below the sex-specific average in healthy young adults. There is a demographic in body composition variation due to physical and diet habits.

Objective: To evaluate the lean mass by DXA in healthy young adults, to obtain the normal values in our population, and ??to estimate the degree of lean mass lost in the elderly population to be able to identify those at risk.

Population and Methods: This is a retrospective cross sectional study. Subjects of both sexes stratified by decades of age were scanned with Hologic (965 subjects); iDXA (930subjects) and Prodigy (1110) scanners. The population was stratified by sex and decade of age , 20^{th}-40^{th} were used as reference category . Total Lean Mass (TLM); Legs Lean Mass (LLM); Appendicular Lean Skeletal Mass and its respective index related to (height –m-)2 , Appendicular Lean Skeletal Mass Index (ALSMI)and Lean mass index- LMI were calculated. T test was applied to establish statistical significance of media differences between the results obtained and those of the reference decade, $p<0.00$ was assumed as statistically significant.

Results : An increment of BMI in both genders was seen. A significant decrease in Lean mass absolute values (total, legs and extremities) along life was observed. Moreover, indices had a varied behavior (only men 80 and older had both indices lower than young men ($p<0.000$) regardless of the scanner used. This finding could be explained by the 10 cm height increase in Spanish population in the last century. Consequently the older subjects are compared to normal subjects, which are 10 cm higher that they were at similar age. This could explain that absolute values discriminate better the aging change.

How Muscle Force Shapes a Growing Mandible. Donna Jones*. Cincinnati Children's Hospital, USA

Alteration in muscle force brought about by a change in food texture produces shape differences in the mandible. The biochemical and cellular mechanisms by which this occurs, however, is not well understood. This research aims to empirically determine the specific anatomic locations affected by differential muscle milieus through three dimensional multivariate shape analyses to elucidate which cell populations are responsible for producing altered shape (pre-osteoblasts, osteoblasts, and/or osteocytes).

Prx1-CreER-GFP mice were grown with two different diet consistencies. Animals were weaned at 3 weeks of age to a hard (standard chow) or soft (DietGel7A) diet. Four males from each diet were sampled weekly from 4 to 12 weeks of age. After sacrifice, μCT scans and 3D reconstructions were produced and 12 landmarks were localized to capture mandibular shape differences among the two treatments. A generalized Procrustes superimposition was performed, and the full set of residuals that were regressed on age, within treatment groups. Principal components analysis was used to visualize the major dimensions of variation. Growth trajectories (i.e., the direction through shape space with age) for each treatment were calculated. To determine whether the trajectories between the treatments altered direction by more than expected by chance, the angle between them was calculated. By resampling and recalculating trajectories, 95% confidence intervals of variance in the data were established, indicating a statistically significant difference among treatments. Thin plate spline analyses were then employed to elucidate the anatomical pattern of shape change correlated with increasing age.

The diets produced differently shaped mandibles, with shape differences localized in the angle, position of the condyle, and length of the diastema. The three dimensional analyses also captured shape differences in the breadth of the mandible and integration with the skull base, missed in previous analyses. The shape trajectories differed significantly, with the greatest disparity generated before 6 weeks of age.

Histological analyses of the identified areas were used to identify differences in osteoblastogenesis (Prx1 expression), osteogenesis (increased mineralization; Von Kossa), and/or osteoclastic activity (TRAP). These results provide data essential to discovering the etiology of a variety of orofacial myofunctional disorders, including idiosyncratic mandibular hypoplasia.

Intermittent Parathyroid Hormone Treatment Enhances Both Trabecular and Cortical Bone Modeling in Growing Rats. Allison Altman*[1], Wei-Ju Tseng[2], Abhishek Chandra[1], Ling Qin[1], Xiaowei Liu[1]. [1]University of Pennsylvania, USA, [2]University of Pennsylvania, USA

Intermittent parathyroid hormone (PTH), a potent bone anabolic agent, is a treatment candidate for stunted skeletal growth and adolescent idiopathic osteoporosis. However, the mechanism of PTH's anabolic effect on the growing skeleton is unclear. The objective of this study was to delineate the effect of PTH on bone modeling in young rats. We hypothesized that PTH would enhance bone modeling in the growing skeleton in both the trabecular (Tb) and cortical (Ct) compartments.

14 1-month-old rats were treated with either saline (Veh, n=6) or PTH (n=8, 80 μg/kg) daily for 12 days. A 3 mm region of the proximal tibia, distal to growth, plate was scanned by *in vivo* μCT (Scanco, 10.5 μm) every 4 days. By overlaying 2 sequential scans based on their unaltered Tb pattern (Fig 1), we visualized periosteal bone resorption and endosteal bone accrual due to rapid bone modeling. Linear growth rate was measured to be 0.25 mm/day. Therefore, the region imaged at day 12 represented newly generated bone tissue from the growth plate that did not exist on day 0.

Compared to day 0, PTH-treated primary spongiosa had 2.1, 1.1, and 1.4-fold increase in bone volume fraction (BV/TV), Tb number (Tb.N), and Tb thickness (Tb.Th), respectively, after 12 days. Similar increases were also found in the secondary spongiosa. In contrast, no change was found in the Veh-treated group after 12 days . Histology revealed a 22% wider growth plate height in the PTH group compared to Veh due to a 30% thicker hypertrophic zone. While the number of chondrocyte columns and bone spicules was similar between groups, bone spicules had greater mineral deposition in the PTH group, resulting in 44% thicker Tb.Th and 114% higher BV/TV in the primary spongiosa than the Veh group.

The Ct bone at the proximal tibia also thickened more in the PTH group (23%) than the Veh group (14%). This was primarily driven by endosteal bone formation and coalescence of trabecular bone into the cortex (Fig 1C). As a result, the cortex after PTH treatment was 31% less porous, and had a 22% greater polar moment of inertia compared to the Veh group.

These data demonstrate that, in addition to its well defined effect on bone remodeling, PTH also enhanced bone modeling on the growing skeleton. The modeling effect is apparent by the enhanced endochondral ossification, resulting in improved Tb quality in the primary spongiosa, and more effective Tb coalescence at the endosteal surface, resulting in improved Ct bone structure.

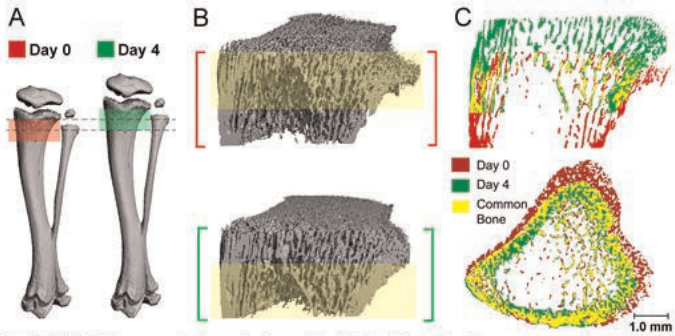

Fig 1. (A&B) The same trabecular bone (highlighted in yellow) moves away from the growth plate due to longitudinal growth from day 0 (red) to 4 (green). (C) Overlaid 2D view of registered bone structure at days 0 (red) and 4 (green), where bone present in both images is shown in yellow (common bone), top-sagittal, bottom-coronal.

C57Bl/6J mice have a lower bone mass than C3H/HeJ mice but are less sensitive to the skeletal effect of intrauterine stress by teratogens. Maria Raygorodskaya*[1], Arkady Torchinsky[2], Yankel Gabet[3], Eugene Kobyliansky[2], David Karasik[4]. [1]Faculty of Medicine, Bar Ilan University, Israel, [2]Department of Anatomy & AnthropologySackler Faculty of Medicine, Israel, [3]Department of Anatomy & AnthropologySackler Faculty of Medicine, Israel, [4]Hebrew SeniorLife; Bar Ilan University, USA

Establishment of normal structure and functioning of bones begins early in life. Several studies demonstrated that exposure of mouse embryo to different environmental factors, including teratogens at a sub-threshold dose, can detrimentally affect bone microarchitecture later in life. The purpose of our study was to investigate to what extent the genetic differences between mouse strains determine the skeletal sensitivity to 5-deoxy-2'-cytidine (5-AZA). 5-AZA is a teratogen capable of inducing phocomelia (absence of long bones of limbs).

We used mice of 2 inbred strains, C3H/HeJ (C3H, high bone mass) and C57Bl/6J (C57, low bone mass), males and females. Animals from these 4 groups (strain/sex) were 6-month old offspring of mice injected with 5-AZA at a sub-threshold dose (or saline for untreated controls) on day 10 of pregnancy. Sample size was 5 for each condition, except for treated C3H females group (n=4) totaling 39 mice. We collected the left femur from each mouse and compared treated and untreated mice within each of the strain/sex groups using micro-CT (Scanco Medical).

Analysis of bone mineral density within both strains did not reveal significant difference between treated and untreated mice, although vBMD was slightly lower in treated C3H (both males and females) compared to their respective controls. Treated C3H males demonstrated reduced cortical thickness ($p<0.01$), reduced trabecular number and increased trabecular spacing ($p<0.05$). On the other hand, treated C57 mice, both males and females, demonstrated no difference in trabecular number and spacing and a significant increase of trabecular thickness compared to the untreated groups ($p<0.05$).

Ultimately, this study demonstrates for the first time that the exposure to a sub-threshold teratogenic dose of 5-AZA during embryonic life causes femoral bone loss in the offspring of a mouse strain with high bone mass (C3H), but not in a low bone mass strain (C57). Furthermore, in mice with inherently weaker bones such an exposure seems to trigger some compensatory mechanisms, that is reflected in thickening of bone trabeculae.

Ephrin Reverse Signaling Mediates Palatal Fusion and Epithelial-to-Mesenchymal Transition Independently of Tgfß3. Maria Serrano*[1], Jingpeng Liu[2], Kathy Svoboda[1], Ali Nawshad[2], M. Douglas Benson[3]. [1]Baylor College of Dentistry, USA, [2]University of Nebraska Medical Center College of Dentistry, USA, [3]TA&M HSC Baylor College of Dentistry, USA

The mammalian secondary palate forms from shelves of epithelia-covered mesenchyme that meet at midline and fuse. Failure of the midline epithelial seam (MES) to degrade blocks fusion and causes cleft palate. It was previously thought that transforming growth factor ß3 (Tgfß3) is required to initiate fusion. Members of the Eph tyrosine kinase receptor family and their membrane-bound ligands, the ephrins, are expressed on the MES. The purpose of this study was to discover if Eph/ephrin signaling is required for mammalian palatal fusion. We discovered that activation of ephrin reverse signaling (where the ephrin acts as a receptor and transduces signals from its cytodomain) was sufficient to cause fusion in cultured mouse palates and epithelial-to-mesenchymal transition (EMT) in palatal epithelial cells, even in the absence of Tgfß3 signaling. We cultured mouse palates in the presence of either a blocking antibody against Tgfß3 or an inhibitor of the TgfßrI serine/threonine receptor kinase. Fusion was abolished by both treatments, but was significantly rescued by the addition of EphB2/Fc recombinant protein to activate ephrin reverse signaling. Treatment with Tgfß3, however, was not able to rescue fusion when ephirn signaling was blocked. Cultured palate epithelial cells traded their expression of epithelial cell markers for that of mesenchymal cells after treatment with EphB2/Fc and became motile. They concurrently increased their expression of the EMT-associated transcription factors Snail, Sip1, and Twist1. These data confirm that ephrins direct palatal fusion in mammals and activate a gene expression program not previously associated with reverse signaling.

HDAC inhibitor MS-275 could attenuate phenotypes of cleidocranial dysplasia syndrome in $Runx2^{+/-}$ mice through the activation of Runx2 activity. Han-sol Bae*[1], Won-Joon Yoon[2], Young-Dan Cho[3], Rabia Islam[4], Hea-rim Shin[1], Bong-Soo Kim[2], Kyung-Mi Woo[2], Jeong-Hwa Baek[5], Hyun-Mo Ryoo[6]. [1]Seoul National University, South Korea, [2]Seoul National University School of Dentistry, South Korea, [3]Seoul National University, South Korea, [4]School of Dentistry, Seoul National University, South Korea, [5]Seoul National University, School of Dentistry, South Korea, [6]Seoul National University School of Dentistry, South Korea

Runx2 is essential for osteogenesis and bone growth. Cleidocranial dysplasia (CCD) is an autosomal-dominant skeletal disorder caused by haploinsufficiency of Runx2. Aplastic or hypoplastic clavicles and delayed suture closure are major symptoms of CCD. Previous reports indicated that CCD phenotypes developed when Runx2 mRNA level is less than 70% that of WT littermates. We previously identified that HDAC inhibitors (HDACi) stimulated RUNX2 protein stability and its transcriptional activity. Specific aim of this study was to examine whether genetic Runx2 haploinsufficiency could be overcome by an HDACi. $Runx2^{+/+}$ and $Runx2^{+/-}$ mice were mated and pregnant mice were injected once with MS-275 or vehicle at 14.5 d.p.c. The MS-275 neither caused pregnant mice to die or show toxic behaviors nor did it affect littermate numbers. MS-275 remarkably improved most of the skeletal deformities associated with $Runx2^{+/-}$; cranial bone development and clavicle maturation, spinal bone maturations, mandible growth and ribcage development. The recovered CCD phenotypes were maintained at postnatal stage. In the in vitro study, MS-275 has positive effects on osteoblasts differentiation. MS-275 stimulated bone marker gene expression in primary calvaria cell culture. Primary calvarial osteoblast from $Runx2^{+/-}$ mice showed a significantly lower Runx2 protein level than that from WT mice. Treatment of MS-275 increased Runx2 protein level in both genotype cells. In addition, Runx2 protein level of MS-275-treated $Runx2^{+/-}$ mice was increased quite significantly compared to that of untreated WT mice. Lastly, Runx2 transacting activity was also increased by the MS-275 treatment both in $Runx2^{+/+}$ and $Runx2^{+/-}$ calvarial osteoblasts. Taken together, these results indicated that MS-275 could be applied for the intervention of CCD phenotype development. Moreover, the mechanism of action we identified in this study strongly suggests that HDACi could also be applied for bone regeneration.

Involvement of PiT-1 (Slc20a1) function during endochondral ossification. Manisha Yadav*[1], Pia Kuss[2], Campbell Sheen[2], Laurent Beck[3], Colin Farquharson[4], Jose Luis Millan[1]. [1]Sanford-Burnham Medical Research Institute, USA, [2]Sanford Burnham Medical Research Institute, USA, [3]Inserm U791, France, [4]Roslin Institute, University of Edinburgh, United Kingdom

Mineralization of cartilage and bone occurs by a series of physicochemical and biochemical processes that together facilitate the deposition of hydroxyapatite in specific areas of the extracellular matrix (ECM). We have shown that tissue-nonspecific alkaline phosphatase (TNAP) plays a crucial role in restricting the concentration of extracellular inorganic pyrophosphate (PPi), a mineralization inhibitor, to maintain a Pi/PPi ratio permissive for normal bone mineralization. We have also shown that together with TNAP, PHOSPHO1 is required for proper bone mineralization. Using genetically modified mice we have found that 1) the lack of TNAP (Alpl-/- mice) leads to reduced MV calcification but mice are born with a normally mineralized skeleton and only develop hypophosphatasia at postnatal day 6. 2) The lack of PHOSPHO1 (Phospho1-/- mice) also leads to reduced MV calcification and hyperosteoidosis and the born pups show fractures in their curved long bones and in the rib cage as early as post-natal day 1. Scoliosis is a prominent feature from postnatal day 10 onwards. 3) The [Alpl-/-; Phospho1-/-] double knockout mice are embryonic lethal and the E16.5 embryos, show complete absence of skeletal mineralization and MVs devoid of mineral.

We hypothesized that HA crystals appear inside the MVs favored by Pi accumulation resulting from a dual mechanism, i.e. PHOSPHO1-mediated intra-

vesicular production and transporter-mediated influx of Pi produced extra-vesicularly primarily by TNAP's ATPase activity. To test this hypothesis, we generated mice with a conditional ablation of PiT-1, the major Pi-transporter in chondrocytes, in the Phospho1-/- background, [Phospho1-/-; PiT-1flox/flox; Col2a1-Cre]. While mice with a conditional deletion of PiT-1 in chondrocytes, [PiT-1flox/flox; Col2a1-Cre], did not show any phenotypic abnormalities at 1 month of age, severe skeletal deformities were observed in the [Phospho1-/-; PiT-1flox/flox; Col2a1-Cre] double knockout mice, which were more pronounced than those in the Phospho1-/- mice. Histological analysis showed growth plate abnormalities with a shorter hypertrophic chondrocyte zone in the double knockout samples and extensive unmineralized osteoid was observed both in the vertebrae, tibial and femoral sections. These data support the involvement of PiT-1 in the initiation of endochondral ossification.

Supported by grant AR053102 from the National Institutes of Health, USA.

Mechanism of Longitudinal Overgrowth of Femur of Developing Rat Following Circumferential Periosteal Division. Shinjiro Takata*. Tokushima National Hospital,National Hospital Organization, Japan

We showed the mechanisms of longitudinal overgrowth of femur of developing rat aged 8 weeks following circumferential periosteal division (CPD). The previous study have shown that CPD of rat tibia produces an increase in its growth rate and in the activity of both the proliferative and hypertrophic zones (Taylor FJ et al. J Anat 151:221-231,1987).

Eigthteen male Wistar rats aged 8 weeks were used for this study. Periosteum of diaphysis of the right femur was divided circumferentially (CPD group), and the left femur was control (Control group). Rats were sacrificed 4 weeks after CPD. The longitudinal length of femur (n=6) and rate of longitudinal growth and bone turnover by bone histmorphometry were compared between CPD group and Control group 4 weeks after CPD (n=6). Histological and immunohistological analyses in distal growth plate of femur were performed with hematoxylin and eosin (HE), alcian blue (AB), tartrate-resistant acid phosphatase (TRAP), collagen X, indian hedgehog (IHH) , parathyroid hormone-related protein (PTH-rP), runt-related transcription factor 2 (Runx2) staining.

Longitudinal length of rat femur of CPD group and Control group were 39.4 ± 1.2 mm and 38.5 ± 0.8mm, respectively ($p=0.0086$), showing that CPD for 4 weeks produced an approximately 2.5% increase of rat femur compared with Control group.

Bone histomorphometry shows that the rate of longitudinal growth of femur of CPD group and Control group 4 weeks after CPD was 92.3 ± 5.3 and 54.4 ± 4.6 μm/day, respectively ($p<0.0001$). Mineral apposition rate of femora of CPD group and Control group 4 weeks after CPD was 3.90 ± 0.38 and 3.07 ± 0.25 μm/day, respectively ($p=0.0004$). Osteoclast surface/bone surface of CPD group and Control group 4 weeks after CPD was 13.1 ± 1.0 and 9.1 ± 1.8%, respectively ($p<0.0001$).

HE and AB staining analysis in distal growth plate of rat femur showed an increased number of hypertrophic chondrocytes and width of hypertrophic zone of the distal growth plate of rat femur of CPD group compared with Control group. Immunohistogical expression of Runx2 and IHH of CPD group in the growth plate was higher than that of Control group.

The major finding of this study was that CPD of diaphysis of rat femur stimulates endochondral ossification to produce longitudinal overgrowth. The results suggest that periosteum of tubular bone plays an critical role in endochondral ossification of growth plate.

Osterix-Cre Transgene Causes Craniofacial Bone Development Defect. Li Wang*[1], Fei Liu[2]. [1]School of dentistry, University of Michigan, USA, [2]University of Michigan School of Dentistry, USA

The Cre/loxP system has been widely used to generate bone-targeted gene knockout mice. One of the most widely used Cre mouse lines that targets osteoblasts is Osx-GFP::Cre (Osx-Cre) mouse line, which contains a tTA and a tetracycline responsive element-controlled GFP/Cre fusion protein under the control of osterix (Sp7) promoter. Recently, defective intramembranous bone development phenotype was reported in several conditional knockout mouse models with Osx-Cre. However, it is unknown to what extent that Osx-Cre transgene itself may contribute to these defects. In this study, we investigated the effect of Osx-Cre on early postnatal bone development (from birth to day 21). Osx-Cre mice exhibited reduced body weight at all time-points except at birth. Osx-Cre mice and control mice at different ages (at birth, p7, p14 and p21) were analyzed by whole skeletal staining. Despite normal development pattern in the axial and appendicular bones, Osx-Cre mice showed severe hypomineralization in parietal, frontal, and nasal bones and the integrity of cranial sutures were also compromised compared to control mice at birth. Among the craniofacial bones, the nasal bone had the severest defect shown by 30.5% (N=10, SD=6.21%) decrease of the mineralized area at birth. The defects became less severe when mice grew older. At postnatal day 21, the major defects disappeared while sporadic hypomineralization spots were still present. Interestingly, Doxycycline treatment could completely eliminate the craniofacial defects at birth, indicating that the Cre expression may be responsible for the phenotype. To determine the potential effect of Osx-Cre transgene on osteoblast differentiation, we isolated primary calvaria osteoblasts from Osx-Cre and control neonatal mice and found that Osx-Cre transgene did not affect osteoblast differentiation and mineralization *in* vitro (by Day 7 ALP staining and Day 21 AR staining). In conclusion, Osx-Cre transgene can cause craniofacial bone defect at early development stages and this defect is gradually resolved at later stages. In addition, Osx-Cre does not affect in vitro osteoblast differentiation. This study reinforces the necessity of including Cre transgenic littermate controls for in vivo phenotyping and validates the use of primary calvarial osteoblasts isolated from CKO mice with Osx-Cre for in vitro differentiation study.

Quantitative Micro-CT Analysis of Bone in Zebrafish: Accessing an Untapped Resource. Julia Charles*[1], Katrin Henke[2], Kelly Tsang[3], Ruby Russell[4], Matthew P. Harris[2], Jeffrey Duryea[5], Antonios Aliprantis[6]. [1]Brigham & Women's Hospital & Harvard School of Medicine, USA, [2]Department of Genetics Harvard Medical School, Department of Orthopedics, Boston Children's Hospital, USA, [3]Department of Medicine, Brigham & Women's Hospital & Harvard Medical School, USA, [4]. Department of Radiology, Brigham & Women's Hospital, USA, [5]Department of Radiology, Brigham & Women's Hospital, USA, [6]Brigham & Women's Hospital, USA

Zebrafish are a commonly used research model to investigate the genetic and developmental causes of disease. Similar to higher vertebrates, bone formation and remodeling in zebrafish rely on the coordinated activity of osteoclasts, osteoblasts and osteocytes. Given this, many of the key genes regulating bone differentiation are likely conserved. Several zebrafish mutants correlating to human bone disorders (e.g. osteogenesis imperfect, Raine syndrome) recently identified in forward genetic screens supports this concept. However, the use of zebrafish (and other small laboratory fish models) to investigate skeletogenesis and skeletal dysplasias has been limited by the lack of systematic analytical techniques to assess bone quality and shape. We performed mutagenesis screens in the zebrafish and have identified a large number of mutants having specific defects in skeletal differentiation and patterning. In order to characterize these mutants, we set out to develop a standardized micro-computed tomography (μCT) analysis method to quantify bone parameters at two anatomic sites: the parasphenoid bone of the skull base and the last precaudal and first 2 caudal vertebral bodies. Ontological series of male and female siblings at 3, 5 and 10 months of age (n=5) were imaged by μCT at 6 micron resolution (Scanco μCT35). Scanco software was utilized to measure parasphenoid length, volume, and mg HA/mm^3. Vertebrae were analyzed using custom software to determine length, bone volume, and radius of vertebral opening. No sex difference was apparent, thus males and females were combined for analysis. We show that these measures are robust, as within group variance is low and show consistent isometry during development allowing for within and between strain comparisons (Fig.1). As a proof of the utility of this application, analysis of the hypermineralization mutant *Khronos* identified significant differences in bone density and size, demonstrating the utility of our standardized analysis methods for quantification of skeletal phenotypes in zebrafish. These techniques can be expanded to include quantitative analysis of vertebral morphology and regional variation in mineralization, as well as to characterize more subtle skeletal phenotypes that qualitative assessment by Alizarin red staining cannot provide. These analyses lay the foundation to tap into the power of zebrafish to better understand the genetic and cellular mechanisms regulating skeletal biology in vertebrates.

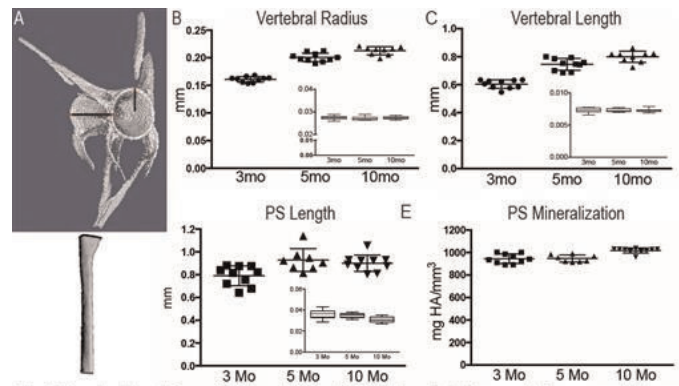

Fig. Standardized Quantitation Method for Zebrafish Bone. A. Representative images of vertebrae (top) and parasphenoid (PS) showing measurement parameters (black lines). **B-C.** Quantitative analysis of first caudal vertebrae demonstrates age related increase in (B) radius and (C) length but stable ratio of radius/length:standard length (insets) consistent with isotropic growth; 1 way ANOVA $p<0.0001$ for radius and length. **D-E.** Analysis of parasphenoid similarly demonstrates age dependent increases in (D) length and (E) mineralization as determined by mg HA/mm^3 of bone volume; 1 way ANOVA $p<0.005$ for each.

Stat3 signaling modulates the osteochondro transcription factor Sox9 in vivo to influence endochondral ossification and is important in the pathology of campomelic dysplasia. Michael Hall*[1], Alan Perantoni[2]. [1]National Cancer Institute, USA, [2]National Cancer Institute, USA

Campomelic dysplasia (CD) is an often-fatal human congenital abnormality characterized by a hallmark bowing of the long bones and features such as short stature, cleft palate, and laryngotracheomalacia. The pathology of CD is frequently underpinned by mutations in and around the coding region of the Sry-box gene Sox9, a master regulator of multipotent osteochondro progenitor cells. Beyond this, little is known about the normal regulation of Sox9 or, in cases where Sox9 mutations have not been detected, if CD is also caused by alterations in the control of Sox9 expression. To elucidate novel regulators of Sox9, we analyzed its proximal promoter region and discovered several potential Stat DNA response elements (DRE). Stat3 has been implicated in stem cell maintenance, and disruption of Stat3 signaling through deletion of leukemia inhibitory factor (LIF) receptor causes a defect in bone mineralization, suggesting the possible involvement of Sox9. Indeed, we found that a Sox9 promoter-driven reporter is activated in cells by oncostatin M in a Stat3-dependent fashion. Further, reporter activation is mediated by the Stat DREs, and Stat3 physically binds the promoter of Sox9. In the developing mouse, Stat3 is expressed in somites and early limb buds, mesodermal compartments where Sox9 mediates endochondral ossification of vertebrae and limbs, respectively. We engineered mesodermal Stat3 loss of function mutant mice, which, as neonates, yielded a phenotype consistent with CD, i.e., limb bowing, labored breathing, and mortality. The histology of Stat3 mutants was also consistent with Sox9 heterozygous mutants, including shortening of the long bones, and expansion of the hypertrophic chondrocyte zone, suggesting modulation of Sox9 function. Furthermore, Sox9 levels were decreased in Stat3 mutant mice, as was the direct target Col2a1, a marker for a functional decrease in Sox9 in vivo. Other skeletal features such as reduced trabecular mineralization, regional restriction and death of osteoblasts, and elevated osteoclast activity were also observed, indicating a critical role for Stat3 in skeletogenesis. We posit that Stat3 instructs bone development by fine-tuning Sox9 expression in mesenchymal stem cells to drive the differentiation of osteochondro progenitors. These findings demonstrate for the first time a role for Stat signaling in regulating SRY-box factors in vivo and provide a potential alternative mechanism for CD where Sox9 mutations are not detected.

Targeted Deletion of Atg5 or Atg7 in Chondrocytes Impairs Cell Viability and Bone Growth. Karuna Vuppalapati*[1], Thibault Bouderlique[2], Vitaliy Kaminskyy[3], Phillip Newton[2], Lars Sävendahl[4], Boris Zhivotovsky[3], Andrei Chagin[5]. [1]Department of Physiology & Pharmacology, Karolinksa Institutet, Sweden, [2]Department of Physiology & Pharmacology, Karolinska Institutet, Sweden, [3]Institute of Environmental Medicine, Karolinska Institutet, Sweden, [4]Department of Women's & Children's Health, Karolinska Institutet, Sweden, [5]Karolinska Institutet, Swe

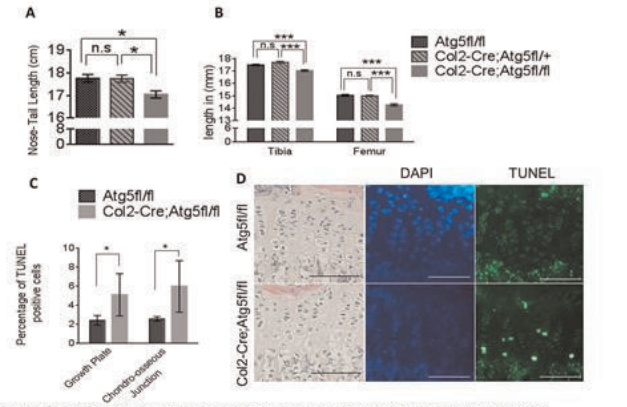
Background: Longitudinal bone growth takes place in the epiphyseal growth plate, a cartilage structure located in the ends of long bones. The growth plate consists of chondrocytes traversing from undifferentiated (resting zone) to terminally differentiated (hypertrophic zone) stage. Chondrocytes in the middle of the growth plate are hypoxic and nutritionally depleted due to the avascular nature of the growth plate. Autophagy is activated during nutritionally depleted or hypoxic conditions in order to facilitate cell survival Autophagy is an intracellular catabolic process of lysosome dependent recycling of protein complexes and intracellular organelles.

Objective and hypotheses: We hypothesized that chondrocytes may utilize autophagy for their survival.

Methods: To explore the role of autophagy in chondrocyte survival and longitudinal bone growth we generated mice with cartilage-specific ablation of either Atg5 (Atg5 cKO) or Atg7 (Atg7 cKO) by crossing Atg5 or Atg7 floxed mice with cartilage-specific collagen type 2 promoter driven Cre. To delineate the underlying mechanisms we employed *ex vivo* cultures of human growth plate tissue, mouse metatarsal bones and the RCJ3.IC5.18 rat chondrogenic cell line and exposed them to autophagy inhibitors Bafilomycin-A1 (Baf) or 3-Methyladenine (3MA).

Results: Both Atg5 cKO and Atg7 cKO mice showed growth retardation associated with enhanced chondrocyte cell death and decreased cell proliferation. Furthermore, pharmacological inhibition of autophagy by Baf or 3MA promoted cell death in cultured slices of human growth plate tissue. Baf or 3MA impaired metatarsal bone growth associated with activation of caspase-3 and caspase-9 as well as massive cell death. Similarly, treatment of RCJ3.IC5.18 chondrogenic cells with Baf also showed massive cell death as well as caspase-3 and caspase-9 processing. This effect was associated with cytochrome C release.

Conclusion: Altogether our data suggest that autophagy is important for chondrocyte survival and inhibition of this process leads to stunted growth and caspase dependent death of chondrocytes.



Ablation of Atg5 in the growth plate impaired skeletal growth and elevated chondrocyte cell death.

The Transcriptional Regulator Jab1 Is Essential for Osteoblast Differentiation *In Vivo*. Lindsay Bashur[1], Zhijun Chen[2], Shunichi Murakami[1], Guang Zhou*[1]. [1]Case Western Reserve University, USA, [2]Case Western Reserve University, USA

The transcriptional regulator Jab1 controls cell proliferation, apoptosis, and differentiation in diverse developmental processes. Still very limited, however, is our understanding of Jab1's physiological role in skeletal development. Osteoblast differentiation is a finely-tuned process governed by a spatiotemporal-specific transcriptional circuit. Interestingly, *Jab1* knock-down in primary osteoblasts resulted in impaired osteoblast differentiation. To elucidate Jab1's function at successive steps of osteogenesis *in vivo*, we mated $Jab1^{flox/flox}$ mice with various *Cre* drivers to ablate *Jab1* expression at different stages of osteoblast differentiation. To determine the role of Jab1 during early limb development, we generated $Jab1^{flox/flox}$; *Prx1-Cre* conditional knockout (*Prx1-Cre/cKO*) mutant mice in which *Jab1* was deleted in the osteochondral progenitor cells of the limb buds. At E18.5, *Prx1-Cre/cKO* mutants exhibited significantly shorter limbs with: very few hypertrophic chondrocytes, much smaller primary ossification centers with reduced von Kossa staining, and significantly decreased expression of *Runx2* and *Col1a1*. Thus, Jab1 is required for early osteoblast differentiation of osteochondral progenitor cells. To determine a more specific role of Jab1 in osteoblasts, we generated $Jab1^{flox/flox}$; *Osx-Cre* conditional knockout (*Osx-Cre/cKO*) mutant mice in which *Jab1* was deleted in the osteoblast precursor cells. *Osx-Cre/cKO* mutants appeared grossly normal in size at birth. However, histological study revealed greatly reduced trabecular thickness and fewer trabecular areas in newborn *Osx-Cre/cKO* mutant long bones. Furthermore, *Osx-Cre/cKO* mutant long bones grew less after birth and all the mutants died before weaning age. Thus, Jab1 is likely to be required for the proliferation and function of osteoblast precursor cells. Finally, to specifically target differentiating osteoblasts, we generated $Jab1^{flox/flox}$; *Col1a1-Cre* conditional knockout (*Col1a1-Cre/cKO*) mutant mice, using a *2.3 Col1a1-Cre* driver. *Col1a1-Cre/cKO* mice were viable, fertile, and showed no gross phenotype until 12-month age, indicating that Jab1 plays a less prominent role at later stage of osteoblast differentiation. In summary, our study revealed the crucial and stage-specific role of Jab1 in osteoblast differentiation. We are further characterizing these novel *Jab1* mutant models to elucidate the underlying mechanism of Jab1's function during osteogenesis.

Biological and clinical benefits of a systematic protocol of bone evaluation and treatment in kidney transplantation. Rose-Marie Javier*[1], Clotilde Kiener[2], Peggy Perrin[2], Sophie Caillard[2], Bruno Moulin[2]. [1]Department of Rheumatology, University Hospital, France, [2]Nephrology-Transplantation Department , University Hospital Strasbourg, France

Introduction: Over the last years, clinical practice for Chronic Kidney Disease-Mineral and Bone Disorders has changed. The impact of a systematic bone evaluation before transplantation and 25OHD normalization, cinacalcet if needed and prophylactic bisphosphonates treatment in renal transplant recipients with T-score lower –2.5 has not been evaluated yet, in particular on the incidence of fractures.

PATIENTS AND METHODS: We have analyzed the mineral and bone disorders during the first posttransplant year in 141 patients who underwent kidney transplantation between 2009 and 2011 in our center compared to 152 other patients transplanted five years earlier (2004-2006). Biochemical parameters were prospectively determined before transplant, at M3 and M12 and in our routine pretransplant evaluation, bone mineral density was systematically measured (Hologic Delphi densitometer) at lumbar spine and hip. Since February 2006, a systematic scheme of 25OHD normalization is applied. In the presence of a T-score<–2.5 and/or osteoporotic fractures before transplant, our local practices recommended a preventive treatment with pamidronate (two 30 mg intravenous infusions 15 and 45 days after transplantation) in the absence of adynamic bone and severe kidney dysfunction. All the collected clinical fractures are documented after a clinical rheumatologic assessment (RMJ).

Results: At time of transplantation, hyperparathyroidism rate and vitamin D insufficiency have decreased in the more recent cohort (PTH>585ng/L in 13.2% versus 28%; p=0.002 and 25OHD 28.1 versus 14.3 ng/mL; p<0.001). In the first posttransplant year, 25OHD is twice higher and near to 30 µg/L with a better control of HPT at M3 and M12. At one year, the incidence of fractures is three-fold lower (3.1% versus 9.1%, p=0.0036) and patients with pretransplant OP were more treated by BP. Nevertheless, fracture risk seems to be higher in subjects with pretransplant osteopenia in the recent cohort.

Conclusion: The evolution of our clinical practice have led to reduction in fracture risk, persistent hyperparathyroidism and vitamin D insufficiency in the first posttransplant year. However, we have to reconsider the management of renal transplant recipients with osteopenia.

Bone Adiposity and Magnetic Resonance Spectroscopy in Kidney Disease. Ranjani Moorthi*[1], Chen Lin[2], Kristen Ponsler-Sipes[2], Sharon Moe[1]. [1]Indiana University School of Medicine, USA, [2]Indiana University School of Medicine, USA

Chronic Kidney Disease (CKD) is an important public health problem affecting more than 26 million Americans. Fractures are 2-4.4 times more prevalent in CKD compared to the general population. Histologically, bone remodeling is abnormal in CKD with extremes such as adynamic bone disease and osteitis fibrosa cystica. However, changes within the bone marrow are not well characterized in CKD. We propose that there is excessive fat deposition in the marrow of patients with CKD and that this can be demonstrated by magnetic resonance spectroscopy (MRS). Our project aims were to 1) determine reproducibility of bone marrow fat assessment in CKD patients by MRS 2) determine differences in bone marrow fat% at various skeletal sites in CKD and 3) in a pilot study, compare marrow fat% in CKD patients compared to matched controls with normal kidney function.

Methods: This is a case-control study of 5 subjects with CKD and 5 age, sex and race matched controls. MRS of the iliac crest, the tibia and L2-4 vertebrae were performed. Each subject underwent 2 scans per site with repositioning between measurements. The coefficient of repeatability for marrow fat% at each site was calculated. Graphs were plotted to compare fat content at different skeletal sites. T-tests were used to compare marrow fat% between CKD subjects and controls at each location.

Results: The mean age of CKD subjects in the study was 64.3+6.3 years and mean eGFR was 25.6+7.8 ml/min. In CKD subjects, 58% of marrow was composed of fat in the L2-3 area, as compared to most of the tibia(86%). The coefficient of repeatability was low at all sites in CKD, ranging from 2.4-13% (see Table). There was no significant difference between CKD subjects and controls in bone marrow fat% at any of the sites studied.

Conclusion: Bone marrow fat assessment can be performed at the iliac crest (the site of traditional histomorphometry) in patients with CKD by MRS and it is highly reproducible at all skeletal sites. In CKD, patterns of marrow fat deposition are different at the tibia, vertebrae and iliac crest. MRS is suitable to study changes in marrow fat over time at various skeletal sites in CKD patients. Preferential differentiation of adipocytes in bone marrow from mesenchymal stems cells may lead to alterations in bone remodeling in patients with CKD as well as in normal aging. This needs to be explored in future studies that relate bone quality and marrow fat assessment in CKD compared to healthy controls..

Skeletal Site	CKD		Controls	
	Mean±SD (%)#	COR (%)*	Mean±SD (%)#	COR (%)*
L2	58.1±11.2	13.0	47.5±9.9	4.9
L3	58.6±10.7	6.1	51.4±8.9	6.6
L4	60.9±11.4	3.5	51.8±9.9	6.6
Iliac crest	59.4±15.5	5.5	52.4±8.8	7.1
Tibia	86.4±1.35	2.4	84.8±2.6	3.9

*Coefficient of Repeatability (COR) is the value under which the difference between any two repeat measurements on the same patient acquired under identical conditions should fall with 95% probability
#Paired t-test for marrow fat% between CKD and controls at all sites were not significant at a level of 0.05

Marrow fat% at Different Sites in CKD and Controls by MRS and Coefficients of Repeatability

Determination of FGF23/FGFR3 Interfacing Domains; Insights into Developing Novel Therapeutics. Abdulhafez Selim*[1], Mohamed Hafez[2], Mourad Ali[3], Osama Yasin[3], Tarek El-Ghandour[3]. [1]Center for Chronic Disorders of Aging, PCOM, USA, [2]Inspire, Egypt, [3]Ain Shams University, Egypt

Fibroblast growth factor 23 (FGF23) is a phosphaturic factor that suppresses both sodium-dependent phosphate transport and production of 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] in the proximal tubule. *In vitro studies indicated that FGF23 can activate FGFR1, 3, and 4. Liu et al demonstrated that neither* FGFR3 nor FGFR4 is the principal mediator of FGF23 effects in the proximal tubule, and co-localization of FGFR1 and Klotho suggests that the distal tubule may be an effector site of FGF23 through the FGFR1.

Gutierrez et al, demonstrated that in chronic kidney disease (CKD), circulating FGF-23 levels gradually increase with declining renal function such that by the time patients reach end-stage renal disease, FGF23 levels can be up to 1000-fold above the normal range. Wahl et al demonstrated that it is also possible that markedly increased FGF23 levels in CKD could contribute directly to tissue injury in the heart and vessels. Moreover, it has been hypothesized by Razzaque et al, that FGF-23 at very high serum concentrations (as observed in CKD patients) may exert certain nonspecific and presumably adverse effects through low-affinity, Klotho-independent binding to FGF-R, for example, on endothelial cells. Therefore, it is of great importance to characterize FGF23 interactions with other receptors including FGFR3 and FGFR4.

Since no previous studies characterized the FGF23/FGFR3 or FGF23/FGFR1 complexes, we decided to address this task. Three dimensional models for the complexes were constructed and validated. This was followed by protein-protein interface analytical studies. The FGF23/FGFR3 complex interface data showed that four regions of FGF23 (A, B, C and D) were involved in the interface. In contrast to that, the FGF23/FGFR1 interface data revealed that three regions only (A, B and C) were involved in the interaction. Data suggested that region D and its complementary sequences are attractive candidates for drug development.These findings could pave the way for designing novel specific inhibitors including peptides, mono-clonal antibodies, or small molecules. Those inhibitors could be used to prevent andlor reduce FGF23-related complications in CKD patients.

Low Bone Mineral Density and Fractures in Stages 3-5 CKD: An Updated Systematic Review and Meta-Analysis. Roxana Bucur*[1], Dilshaan Panjwani[2], Lucy Turner[3], Tamara Rader[4], Sarah West[5], Sophie Jamal[6]. [1], Canada, [2]Women's College Research Institute, Women's College Hospital, The University of Toronto, Canada, [3]Ottawa Hospital Research Institute, Canada, [4]Cochrane Musculoskeletal Group, Centre for Global Health, University of Ottawa, Canada, [5]University of Toronto, Canada, [6]The University of Toronto, Canada

Chronic kidney disease (CKD) is associated with an increased risk of fracture. The utility of dual energy x-ray absorptiometry (DXA) to assess fracture risk in CKD is unknown.

We performed an updated meta-analysis and systematic review of published studies (from 1946 to April 12, 2013) that reported on the association between DXA and fracture (morphometric spine or clinical non-spine) in predialysis and dialysis CKD. We identified 2894 potential publications, retrieved 292 for detailed review and included 13 in our analysis. There were a total of 1785 subjects; 989 men. All but one study was cross-sectional and 3 reported on the ability of DXA to discriminate fracture status in predialysis CKD. Results were pooled using a random effects model and statistical heterogeneity was assessed using the I2 statistic.

BMD was statistically significantly lower at the femoral neck, lumbar spine, the 1/3 and ultradistal radius in subjects with fractures compared to those without, regardless of dialysis status. For example, compared to those without fractures, femoral neck BMD was 0.06 g/cm2 lower in dialysis subjects with fractures and 0.102 g/cm2 lower in predialysis subjects with fractures. Lumbar spine BMD was 0.05 g/cm2 lower in dialysis subjects and 0.108 g/cm2 lower in predialysis subjects with fractures compared to those without. In predialysis subjects, BMD at the total hip was lower in those with fractures but there was no difference in BMD at the total hip by fracture status in those on dialysis. BMD at the mid radius was lower in dialysis subjects with fractures compared to those without fractures and was not reported in predialysis subjects. We performed further subgroup analyses comparing pooled effects across studies that adjusted for age and weight. Data allowed for BMD at the femoral neck, total hip and lumbar spine to be compared. We found no difference in the overall effect for any these sites, regardless of dialysis status. Our meta-analysis was limited to studies with small numbers of subjects and even smaller numbers of fractures. All of the studies were observational and only one was prospective. There was statistical heterogeneity at the lumbar spine, 1/3 and ultradistal radius.

Our findings suggest that BMD can discriminate fracture status in predialysis and dialysis CKD. Larger, prospective studies are needed.

Vitamin D2 vs.Vitamin D3 in Stage 5 Chronic Kidney Disease Patients on Dialysis. Valentina D. Tarasova*[1], Laura Armas[2], Robert Dunlay[3]. [1]Creighton University, USA, [2]Creighton University, USA, [3]Creighton University, USA

Background: Studies in healthy people have shown differences in 25(OH)D response to large doses of ergocalciferol (D2) or cholecalciferol (D3), but there were no studies estimating such response in patients with Stage 5 CKD on hemodialysis.

Methods: This was a randomized, single blind, placebo controlled study of a single oral dose of 47,095 IU D2 or 43,730 IU D3. 26 subjects (17 males, 9 females), with average age 53 years, from two hemodialysis centers in Omaha, Nebraska completed the study. 25(OH)D levels were measured at days 0, 2, 4, 7, 14, 21, 28, 42, 56, 70, 84, 96 and 112, prior to a hemodialysis session. 25(OH)D was measured by the DiaSorin Liaison method (DiaSorin, Inc., Stillwater, MN). The 25(OH)D levels were adjusted for the difference between doses in the 2 intervention groups and for seasonal change seen in the placebo group. Area under the serum curves (AUC) of 25(OH)D increments at 56, 84 and 112 days were calculated by the trapezoidal method individually for each subject. The study was approved by the IRB at Creighton University and registered on clinicaltrials.gov in August 2012 (NCT01675557).

Results: The median (IQR) for all participants baseline 25(OH)D level was 18.1 (13.6-29.4) ng/ml. The placebo group's 25(OH)D level decreased 3.4 (6.0-0.7) ng/ml over the course of the study. The median (IQR) maximum 25(OH)D AUC was 919 (676-1204) ng·day/ml in the D3 group at day 112 and 621(332-797) ng·day/ml in the D2 group. There was wide interindividual variation and because of the small sample size, $AUC_{56,}$ $AUC_{84\ and}$ AUC_{112} between the 2 types of vitamin D did not reach statistical significance (P=0.07, 0.07 and 0.08, respectively (Mann Whitney U).

Conclusion: Ergocalciferol (D2) and cholecalciferol (D3) likely produce different 25(OH)D pharmacokinetic profiles, but a larger sample size is needed to show an effect.

Low Circulating 25 Hydroxyvitamin D in Obesity is not Associated with Lower 24-hour Urine Calcium, Higher Bone Turnover or Lower Bone Mineral Density. Jennifer Walsh*[1], Amy Evans[2], Kim Naylor[3], Fatma Gossiel[4], Simon Bowles[4], Richard Jacques[4], Richard Eastell[2]. [1]University of Sheffield, United Kingdom, [2]University of Sheffield, United Kingdom, [3]The University of Sheffield, United Kingdom, [4]University of Sheffield, United Kingdom

The aims of this study were to determine if lower 25OHD in obesity is associated with higher PTH, lower calcium absorption (assessed by 24-hour urine calcium), higher bone turnover or lower bone density.

We conducted a cross-sectional study of 216 healthy Caucasian adults (ages 25 to 40 and 55 to 75) from Sheffield and South Yorkshire, UK. Participants were recruited in three body weight categories: normal weight (BMI 18.5 to 24.9 kg/m^2), overweight (BMI 25 to 29.9 kg/m^2), or obese (BMI >30 kg/m^2). Vitamin D measurements were made in autumn or spring by immunoassay and results were adjusted for date of sample collection, age group and gender.

25OHD was lower in overweight and obese people. PTH and 24 hour urine calcium:creatinine did not differ by BMI group. CTX and osteocalcin were lower in obese people, but PINP and bone ALP did not differ by BMI group.

BMD by DXA at the whole body, lumbar spine and hip were higher in obese people (all ANCOVA $p<0.001$). In regression models of DXA BMD, including age, gender and BMI, 25OHD was not a significant predictor of BMD. Total, cortical and trabecular BMD by HR-pQCT at the distal radius and tibia and were higher in obese people (all ANCOVA $p<0.001$).

We conclude that the lower circulating 25OHD in obesity is not associated with higher PTH, lower intestinal calcium absorption, higher bone turnover or lower BMD. Therefore, it is not clear whether there would be skeletal benefits from treating obese people to the same serum vitamin D targets as normal weight people.

MO0007

Conditional ablation of *Alpl* in osteoblasts and mesenchymal cells leads to murine models of adult hypophosphatasia. Pia Kuss*[1], Manisha C. Yadav[2], Sonoko Narisawa[1], Jose Luis Millan[3]. [1]Sanford Burnham Medical Research Institute, USA, [2]Sanford Burnham Medical Research Institute, USA, [3]Sanford-Burnham Medical Research Institute, USA

Hypophosphatasia (HPP) is a rare inherited disease that features rickets or osteomalacia due to loss-of-function mutation in the gene for tissue-nonspecific alkaline phosphatase (TNAP). The clinical severity in HPP patients varies widely, from severe life-threatening perinatal and infantile forms to the milder childhood, adult and odonto-HPP. The phenotypes range from complete absence of bone mineralization and stillbirth to spontaneous fractures and loss of teeth in adult life. Adult HPP usually manifests during middle age, with a history of rickets and/or early loss of teeth. Recurrent metatarsal stress fractures and arthritis are common. TNAP knockout mice (*Alpl*$^{-/-}$) phenocopy infantile HPP, and their rickets/osteomalacia is caused by extracellular accumulation of PP_i, a substrate of TNAP and a potent calcification inhibitor. Epileptic seizures, caused by pyridoxal deficiency, lead to early lethality in that model. To phenocopy the milder forms of HPP, we analyzed mice with tissue-specific ablation of TNAP function in both chondrocytes and osteoblasts in the appendicular skeleton (*Alpl*$^{flox/flox}$*; Prx1-Cre*), and in osteoblasts only (*Alpl*$^{flox/flox}$*; Col1a1-Cre*). Both mouse strains are viable, fertile and display normal growth curves, while displaying drastically reduced levels of plasma alkaline phosphatase activity, without manifesting seizures. Histomorphometry revealed the presence of osteomalacia in both conditional knockout strains. These new mouse models will enable us to investigate aspects of HPP pathophysiology not manifested by the *Alpl*$^{-/-}$ model due to their short life span, such as chondrocalcinosis, and to evaluate the potential use of enzyme replacement with mineral-targeting TNAP for the improvement of adult HPP disease.

MO0008

Direct and indirect effect of cytokines on osteoclast differentiation. Enver Aydilek[1], Martina Blaschke[1], Regine Koepp[1], Ute Hempel[2], Sabine Blaschke[3], Heide Siggelkow*[4]. [1]Clinic of Gastroenterology, Germany, [2]Institute of Physiological Chemistry, Greenland, [3]Clinic for Nephrology & Rheumatology, Germany, [4]University Medicine of Goettingen, Dep. of Gastroenterology & Endocrinology, Germany

The pathogenesis of osteoporosis in Crohn's disease is still controversial, yet disease activity is thought to be one of the main contributing factors, especially the cytokines interleukin-6 (IL-6), interleukin-1 (IL-1) and tumor necrosis factor alpha

(TNF-α) seemed to be involved. We now investigated the effect of a cytokine combination in a concentration as measured in patients with active CD on osteoclasts. In parallel, conditioned medium from identically incubated SCP-1 cells were applied.

Immortalized osteoblastic cells (SCP-1 cells) were incubated with a cytokine combination for 48 hours at day 14 of culture at 7 days after confluence. The concentration of cytokines was 0.01 ng/ml IL-6, 0.001 ng/ml IL-1 beta and 0.005 ng/ml TNF-α in 0.1% bovine serum albumin (BSA). After 48 hours medium was collected for osteoclast experiments and cells were prepared for mRNA analysis. For osteoclast culture monocytes obtained from healthy individuals were isolated by MACS cell separation method (CD14) and differentiation to mature osteoclasts was achieved by the addition of RANKL (100 ng/ml) and M-CSF (25 ng/ml) in 6 well plates for 14-17 days. Osteoclasts expressed the characteristic protein profile and resorbed osteoblast-derived matrix in a bone resorption assay. On day 6, 9 and 13 cells were treated with either (a) control medium, (b) the cytokine combination (IL-1, IL-6, TNF-α) or (c) with the supernatants obtained from SCP-1 cells. After 17 days mRNA from osteoclasts was isolated. In three independent experiments marker expression was determined by real-time PCR and beta-actin was used as housekeeping gene.

The cytokine combination decreased cathepsin K significantly by about 25%. No significant effect on osteoclast activity as measured by vitronectin, RANK or TRAP mRNA expression was shown. In contrast, the supernatant of SCP-1 decreased cathepsin K significantly and also affected TRAP. In SCP-1 cells RANKL/OPG was increased to 1.57 fold by the combination of cytokines.

We can show a direct effect of the cytokine combination on mRNA expression of cathepsin K as osteoclast specific marker. The conditioned medium revealed additional effects on osteoclast differentiation possibly by an increased RANKL/OPG ratio as shown by mRNA levels in SCP-1 cells. These results suggest, that bone resorption in CD is mediated by a direct effect of the involved cytokines on the osteoclast but primarily by osteoblast-osteoclast interaction.

***SQSTM1* Mutations Lead to Enhanced Immunoglobulin Production in Paget's Disease of Bone.** Daniela Merlotti*[1], Luigi Gennari[1], Fernando Gianfrancesco[2], Niccolò Pengo[3], Domenico Rendina[4], Riccardo Muscariello[4], Laura Oliva[5], Teresa Esposito[6], Stefano Rotatori[7], Maria Beatrice Franci[7], Barbara Lucani[7], Maria Stella Campagna[7], Ranuccio Nuti[1], Simone Cenci[8]. [1]University of Siena, Italy, [2]National Research Council of Italy, Italy, [3]MRC LMCB; University College London, United Kingdom, [4]Department of Clinical & Experimental Medicine, Federico II University, Italy, [5]Division of Genetics & Cell Biology; San Raffaele Scientific Institute & University Vita-Salute San Raffaele, Italy, [6]Institute of Genetics & Biophysics, National Research Council of Italy, Italy, [7]Department of Medicine, Surgery & Neurosciences, University of Siena, Italy, [8]Fondazione Centro San Raffaele, Italy

Mutations in *SQSTM1* gene encoding p62 have been associated with Paget's disease of bone (PDB) in up to 50% and 15% of familial and sporadic cases, respectively. Among other functions, p62 is the prototypical cargo receptor for autophagy, a lysosomal recycling process recently implicated in plasma cell ontogenesis and immunoglobulin (Ig) production. Apart from one report of elevated Ig levels in a subset of PDB patients, whether antibody immunity is altered in PDB has not been explored. To address this issue, we assessed serum Ig levels in a cohort of 154 patients with active PDB in relation to *SQSTM1* mutation status. Compared with age-matched controls (n=60), PDB cases showed higher IgG ($p<0.05$) and gamma globulin levels by protein electrophoresis ($p<0.05$). This effect was mainly driven by patients with *SQSTM1* mutations (n=27) and became non-significant when patients without *SQSTM1* mutation were considered. A similar but not significant trend was observed in IgM levels in *SQSTM1* mutated patients versus controls (p=0.09). Moreover, among *SQSTM1* mutation carriers, patients with truncating mutations (Y383X and E396X) were associated with the highest serum IgG levels. Since treatment with nitrogen containing bisphosphonates may exert adjuvant, immune-modulating effects, Ig levels were monitored in 10 and 15 patients with and without *SQSTM1* mutations, respectively, before and after 1, 3, 6, and 12 months from intravenous treatment with zoledronic acid. In both treatment groups, IgG and IgM levels increased between 1 and 3 months from treatment and then decreased towards pretreatment levels. At each time-point, IgG levels were higher in *SQSTM1* mutation carriers than in patients without mutation. To conclusively assess whether *SQSTM1* mutations affect plasma cell activity in a cell-autonomous fashion, we lentivirally engineered the IgM-producing B18 plasmocytoma and the IgG-producing OKT3 hybridoma cell lines to stably express wild type and mutant (E396X) p62. Standard 4 hr Ig secretion assays demonstrated increased rates of Ig secretion in cell lines expressing mutant p62, as compared to controls engineered to express wild type p62. In conclusion, our clinical and experimental data indicate that PDB-associated *SQSTM1* mutations affect plasma cell activity and humoral immunity. The possible implications of these findings in the pathogenesis of the disorder and the occurrence of comorbidities in mutated PDB patients warrant further investigation.

MO0010

Functional study of *OPTN* variants associated with Paget's disease of bone. Iris A. L. Silva*[1], Natércia Conceição[2], Laetitia Michou[3], M. Leonor Cancela[4]. [1]University of Algarve - PhD program in Biomedical Sciences; Dept of Biomedical Sciences & Medicine, Portugal, [2]University of Algarve - Centre of Marine Sciences (CCMAR), Portugal, [3]Université Laval, Canada, [4]University Algarve - CCMAR, Portugal

Paget's disease of bone (PDB) is the second most frequent metabolic bone disease after osteoporosis. Genetic factors play an important role in PDB, but to date the only PDB causal gene identified was the Sequestosome 1 gene. A significant association was identified between PDB and Optineurin (OPTN) gene in 10p13 (PDB6 locus). Several groups replicated the strong association of rs1561570 with PDB, but no functional studies on OPTN and PDB were reported to date. We proposed here to assess the functional contribution of rs1561570, as well as other variants to PDB pathogenesis. First, we screened OPTN gene to search for additional relevant variants associated with PDB. We found that rs2234968, a SNP in an OPTN coding exon, was associated with PDB but functional data did not reveal any functional effect. Using a combination of in silico and expression analysis, we concluded that there were two SNPs in linkage disequilibrium with rs2234968 - rs10906303 and rs79529484 - that changed the OPTN splicing pattern, altering the reading frame and creating a premature STOP codon. In addition, we predicted that rs1561570 C allele - the most frequent in controls - was methylated. Using bisulfite sequencing and qPCR techniques, we showed that the C allele was indeed methylated in all samples and it was also responsible for lower levels of OPTN transcription when compared to the T allele. Since methylation is known to be related to transcription inhibition, the methylated rs1561570 C allele in healthy controls was probably inhibiting OPTN expression, which was confirmed by our qPCR results. Since OPTN has a NEMO functional domain and NEMO proteins are responsible for the degradation of NFKB inhibitor along with IKK, controls will have an increase in the levels of the inhibitor and thus a decrease in NFKB. In contrast in patients where the T allele is no longer methylated, this would lead to higher levels of OPTN expression, higher levels of NFKB inhibitor degradation and also higher levels of NFKB translocation to the nucleus, which will increase the expression of genes related to osteoclastogenesis and thus may contribute to the PDB phenotype. In conclusion, our work clarifies the effect of rs1561570 in PDB and also describes other functional SNPs in OPTN gene potentially important for PDB pathophysiology.

Changes in Trabecular Bone Score up to Two Years After Parathyroidectomy in Primary Hyperparathyroidism. Alice Abraham*[1], Chiyuan Zhang[2], Barbara Silva[3], Fan Wen-Wei[4], Didier Hans[5], Natalie Cusano[6], John Bilezikian[7]. [1]Endocrinology fellow, USA, [2]Columbia University, USA, [3]Federal University of Minas Gerais, Brazil, Brazil, [4]Columbia University College of Physicians & Surgeons, USA, [5]Lausanne University Hospital, Switzerland, [6]Columbia University College of Physicians & Surgeons, USA, [7]Columbia University College of Physicians & Surgeons, USA

Following parathyroidectomy (PTX), BMD improves in patients with primary hyperparathyroidism (PHPT), but little is known about changes in microarchitectural texture by trabecular bone score (TBS). We have recently shown that TBS is associated with HRpQCT measures of bone microstructure in PHPT. Moreover, TBS predicts fracture risk, independent of BMD.

In this study, we investigated site, time and sex-specific changes in BMD and TBS up to 24 months after PTX. We studied 31 subjects with PHPT after PTX, of whom 21 were followed for 6 months, 16 were followed for 12 months, 14 were followed for 18 months and 9 were followed for 24 months after surgery. Site-matched spine TBS was extracted from the DXA image (Hologic) using TBS iNsight software. Linear mixed model was performed to assess the % change in BMD and TBS relative to the baseline over 24 months.

The mean age was 61 ± 13 yrs. Our cohort included 20 women and 11 men. At baseline, the mean TBS was low at 1.309 ± 0.129 (normal ≥1.35). TBS was lower in men than in women (1.242 ± 0.144 vs 1.346 ± 0.106; $p<0.001$). Overall, there was an increase in BMD at the lumbar spine at 6 months ($+2.1\pm5.1\%$, p=0.001), which was sustained at 12 months ($+4.3\pm7.5\%$; p=0.000), 18 months ($+4.5\pm8.8\%$; p=0.000) and 24 months ($3.0\pm10.3\%$; p=0.009). There were similar significant increases at 6, 12, 18 and 24 months at the femoral neck and total hip. We found sex-specific changes at the lumbar spine and total hip. In men, there were significant increases in BMD at all time points at the lumbar spine and hip. In contrast, women had a significant increase in BMD at the lumbar spine alone at 12 months. At the hip, women significantly gained BMD at 6 and 12 months. Overall, there were no significant changes in BMD at the radius and 33% radius. Among all subjects, there was a trend toward significant increase in TBS at 12 months ($+2.2\pm11.9\%$; p=0.088).

While TBS markedly improved at 6 ($+6.1\pm8.0\%$; p=0.003) and 12 ($+6.0\pm11.7\%$; p=0.013) months post PTX in men, it did not change in women ($-1.2\pm7.6\%$; p=0.323

at 6 months; -0.4±8.1%; p=0.750 at 12 months). There were no significant changes in TBS at 18 or 24 months.

TBS increases after PTX in men up to 12 months, while it does not change in women. The results confirm the previous findings by HRpQCT of similar or better trabecular microstructure after PTX, and also reveal differences between men and women. We demonstrate that TBS has potential clinical utility in evaluation of patients following PTX.

MO0013

No Seasonal Variation in 25-Hydroxyvitamin D in Mild Primary Hyperparathyroidism. Elaine Cong*[1], Marcella Walker[2], Anna Kepley[2], Chiyuan Zhang[2], Donald McMahon[3], Shonni Silverberg[2]. [1]Columbia Presbyterian Medical Center, USA, [2]Columbia University, USA, [3]Columbia University College of Physicians & Surgeons, USA

Population-based studies have demonstrated seasonal variability in 25-hydroxyvitamin D (25OHD) levels with a nadir in the winter and a peak in the summer which inversely correlate with serum parathyroid hormone (PTH), markers of bone turnover and areal bone mineral density (aBMD). In 1999, we reported similar seasonal variability in 25OHD and PTH levels in mild primary hyperparathyroidism (PHPT) at our latitude (New York City: 40.67°N, 73.9°W). Given the increased awareness of vitamin D deficiency and widespread use of supplements, we sought to determine if seasonal variability in 25OHD is still present in PHPT patients.

In a cross-sectional study of 100 PHPT patients (79% female, 87% white, 84% non-Hispanic, 1 black, age [mean±SD] 62±12 years, calcium 10.7±0.6 mg/dl, PTH 83±41 pg/ml), mean 25OHD was 29±10 ng/ml, and vitamin D insufficiency and deficiency were common (54%<30 ng/ml; 20%≤20 ng/ml). No differences in the levels of 25OHD, PTH or 1,25(OH)2D, or in the prevalence of vitamin D deficiency or insufficiency were seen by season of enrollment as defined by the almanac (see Table). To compare 25OHD in winter vs summer seasons, we combined winter/spring vs summer/fall to reflect the time-lag of 25OHD production in response to sunlight exposure and found no differences. Patients enrolled in different seasons did not differ in age, gender, race, ethnicity or BMI. In addition, no seasonal differences were observed in serum calcium, CTX, aBMD (spine, hip, radius) or cortical and trabecular indices by high resolution peripheral QCT (radius, tibia). No seasonal variations were observed in any parameter when subgroups were analyzed by gender or race. Omitting the single African-American participant did not affect the results.

Vitamin D intake was high. Supplementation was common (64%; mean 1414±1489 IU/d [range:71-7143 IU]). The average combined dietary and supplemental intake was 2045±1680 IU daily (range:181-8000 IU). Patients not on supplements had an average dietary vitamin D intake of 401±42 IU daily (range:1-2000 IU). No difference was seen in the use or quantity of vitamin D supplementation, dietary intake or both by season.

In conclusion, in a cohort with mild PHPT, we no longer see evidence for seasonal variability in 25OHD levels or markers of PHPT disease activity. This change is likely due to high vitamin D supplement intake, which can mask the effect of season on serum 25OHD levels.

Measurement (mean±SD)	Spring (N=26)	Summer (N=20)	Fall (N=24)	Winter (N=32)	P-value
25OHD≤20 (N/%)	4 (15%)	4 (20%)	3 (13%)	9 (28%)	0.40
25OHD>30 (N/%)	12 (46%)	9 (45%)	13 (54%)	20 (63%)	0.49
25OHD ng/ml	31±11	31±12	29±6	26±11	0.20
PTH pg/ml	88±48	65±30	89±42	84±38	0.27
1,25(OH)2D pg/ml	70±24	60±27	83±36	62±23	0.21

Plasma PTH levels measured with the 3rd generation 1-84 PTH assay in patients with different stages of chronic kidney disease. Giuseppe Viccica[1], Simona Borsari[1], Elena Pardi[1], Filomena Cetani[2], Roberta Centoni[3], Sonia Albertini[3], Silvia Chiavistelli[4], Giordano Fumagalli[1], Adamasco Cupisti[1], Claudio Marcocci*[5]. [1]Department of Clinical & Experimental Medicine, University of Pisa, Italy, [2]University Hospital of Pisa, Italy, [3]University Hospital of Pisa, Italy, [4]Azienda Ospedaliera Pisana, Italy, [5]University of Pisa, Italy

Patients with chronic kidney disease (CKD) have decreased renal function and increased plasma PTH levels. Previous guidelines based on the Allegro intact PTH assay recommended that patients with different disease stages should be managed in order to maintain plasma PTH within a given range, which was fixed between 150 and 300 pg/ml in CKD stage 5 patients. Several methods of intact PTH assay are available and a wide inter-method variability in the PTH results has been shown and opposite therapeutic attitudes may be reached in a single patient depending on the PTH assay used. A new 3rd generation PTH assay, which measures only the full length molecule, is currently available. Aim of the present study was to define PTH ranges using this assay in patients with different stages of CKD.

A series of 141 patients (65 females and 76 males, age 21-89 yr) with CKD stage 3-5 followed in a tertiary care center were enrolled in the study. Patients were classified according to the estimated GFR (eGFR, stage 3: n=46; stage 4: n= 42; stage 5: n=53). Plasma PTH was measured using the 3rd generation LIAISON® 1-84 PTH assay (Diasorin; normal range 5-40 pg/ml). Serum bone specific alkaline phosphatase (BASP, LIAISON®BAP OSTASE®, normal range 16-26 ng/ml), serum C-terminal telopeptide (S-CTx; Serum CrossLaps® ELISA, Nordic Bioscience Diagnostics A/S; normal range 0.07-1.43 ng/ml) and 25OH vitamin D (25OHD; LIAISON®25 OH Vitamin D TOTAL Assay, Diasorin, normal range 4-64 ng/ml) were also measured. Finally, in a subgroup of patients (n=80) plasma intact PTH was measured using the 2nd generation LIAISON® N-tact™PTH (Diasorin, normal range 15-75 pg/ml).

Plasma 1-84 PTH was increased in the majority (72%) of our patients and there was a significant negative correlation with the eGFR (r=-0.46, P<0.001). Conversely, a significantly positive correlation was found between plasma 1-84 PTH and BSAP (r= 0.23, P=0.008) and S-CTx (r=0.31, P=0.001), and a no correlation with serum 25OHD and age.

A significantly high positive correlation was found between plasma 3nd generation 1-84 PTH and intact 2nd generation PTH concentrations (r=0.94, P<0.0001).

The table summarizes our data in whole group of patients grouped according to the different CKD classes. Results are expressed as mean±SD. [table1] The 1-84 PTH assay values nicely segregate patients with different stages of CKD and could provide a reference point for managements of CKD patients across the various stages of CKD.

CKD class	Age (yr)	eGFR (ml/min/1.73 m²)	1-84 PTH (pg/ml)	BSAP (ng/ml)	S-CTx (ng/ml)	25OHD (ng/ml)
3 (n=46)	61±14	42±9 [a,b]	46±26 [a,b]	17±9 [b]	0.76±0.50 [a,b]	17±9
4 (n=52)	66±13	21±4 [a,c]	89±58 [a,c]	20±12	2.00±1.93 [a]	16±7
5 (n=43)	64±14	8±3 [b,c]	134±103 [b,c]	23±10 [b]	2.56±2.18 [b]	15±10

Predictors of Depression Response in Primary Hyperparathyroidism. Ann Kearns*[1], Rachel Espiritu[2], Kristin Vickers Douglas[3], Clive Grant[3], Euijung Ryu[3], Robert Wermers[1]. [1]Mayo Clinic, USA, [2]Summa Physicians, Inc., USA, [3]Mayo Clinic, USA

Neuropsychiatric symptoms including depression are common in patients with primary hyperparathyroidism (PHPT). However, the clinical characteristics that predict improvement are not defined by existing studies.

To understand the improvement in depression symptoms, we examined the relationship between clinical and biochemical parameters and the depression response.

We previously conducted a prospective case-control study of PHPT patients with parathyroidectomy (n=88) and observation (n=81). Depression scores were assessed using a validated depression questionnaire (PHQ-9) longitudinally for 12 months. Patients were classified as depression response if their PHQ-9 scores at 12 months were less than 10. Biochemical parameters (PTH, calcium, and vitamin D) and clinical characteristics (age, sex, depression history and baseline PHQ-9 and its symptom category) were considered as potential factors associated with the depression response. Logistic regression models were used and odds ratios (ORs) and their 95% confidence intervals (CIs) were presented.

Overall, 88% of PHPT patients had PHQ-9 scores less than 10 at 12 months (i.e., depression response). These patients were slightly younger (median age 65.9 vs 68.4 yrs) and more males (18% vs 17%) compared to the patients with depression non-response. Adjusting for age and sex, parathyroidectomy was positively associated with the depression response (OR 2.52, 95% CI 0.92 – 7.61). Biochemical parameters at baseline were not associated with depression response, except for marginal impact of vitamin D values (OR 1.96, 95% CI 0.91 – 1.00). Baseline depression severity was strongly associated with the risk of depression non-response (OR 14.3, 95% CI 4.0 – 50.0). Two baseline symptom categories (cognitive or somatic) showed comparable association with the risk of depression non-response (OR 1.52, 95% CI 1.27 – 1.85).

These results show that baseline PHQ-9 scores strongly predict improvement in depression scores whereas baseline biochemical parameters do not. Our results may not be applicable to severe primary hyperparathyroidism or normocalcemic hyperparathyroidism, which are not represented in this group. This information may be useful to clinicians who are counseling patients with primary hyperparathyroidism about the benefits of parathyroidectomy.

Primary Hyperparathyroidism Not Confounded by Coexisting Vitamin D Deficiency. Anna Kepley*[1], Marcella Walker[1], Elaine Cong[2], Chiyuan Zhang[1], James Lee[3], Shonni Silverberg[1]. [1]Columbia University, USA, [2]Columbia Presbyterian Medical Center, USA, [3]Columbia University, USA

Vitamin D (D) deficiency and insufficiency are common in PHPT and thought to be associated with more severe disease. Because these two common conditions often coexist, our understanding of PHPT is confounded by the effect of D-deficiency. We describe the clinical, biochemical and skeletal phenotype of a PHPT cohort not confounded by D status (25OHD≥30ng/ml; mean 38±6 [range: 30-54 ng/ml]). Notably, 80% were on D supplements (dose: 2043±1741 IU/d). Patients (n=46; age±SD 67±9 yrs) were mostly female (87%), white (92%), and non-Hispanic (82%). Most were asymptomatic, but 15% had a history of nephrolithiasis. None had *osteitis fibrosa cystica*, but 20% had a history of fragility fracture at the spine (n=4), ankle (n=2), forearm (n=2) and metatarsal (n=1).

PHPT was biochemically mild: PTH 73±38 pg/ml, serum calcium 10.7±0.6 mg/dl, phosphate 3.2±0.4 mg/dl, urinary calcium 219±133 mg/d and $1,25(OH)_2D$ 63±19 pg/ml. Markers of bone formation and resorption were normal (BSAP 37.4±15 [nl: 14.2-42.7 U/L]; CTX 0.604 ± 0.374 [nl: 0.142-1.351 ng/ml]). Mean DXA T-scores were in the osteopenic range, but osteoporosis was common (n=19; 41%). T-Scores at the 1/3 radius (RAD:-1.4±1.7) were not lower than those at the lumbar spine (LS:-1.1±1.6), femoral neck (FN:-1.6±1.0) or total hip (TH:-1.3±0.9). High resolution peripheral QCT T-scores were in the osteopenic range at the radius: cortical density (Dcort) -2.2±2.3, cortical thickness (Ct.Th) -1.1±1.4, trabecular density (Dtrab) -1.2±1.2, trabecular thickness (Tb.Th) -1.9±0.8; while tibial cortical density was severely affected: Dcort T-score -4.6±2.7, Ct.Th -1.9±1.2, Dtrab -0.7±1.0, and Tb.Th –1.4±0.8.

Most (76%; n=35) met 3rd International Workshop on Asymptomatic PHPT surgical criteria: 10 (22%) had serum calcium >1.0 mg/dl above normal; 7 (15%) had stones; 10 (22%) had an estimated glomerular filtration rate <60 ml/min; 9 (20%) had fragility fractures; 19 (41%) had osteoporosis by T-score (LS n=11, 24%; TH n=4; 9%; FN n=7,15%; RAD n=9, 20%); and 1 (2%) was <50 yrs.

In summary, this D-replete PHPT cohort was nearly all Caucasian, female and taking high doses of vitamin D. Although their PHPT was biochemically mild, they had a typical prevalence of kidney stones, a high prevalence of fragility fractures and osteoporosis by DXA, and most met surgical criteria. Their fracture history and BMD do not suggest a disorder affecting only cortical bone. We find no evidence that D-replete PHPT patients have unusually mild disease.

MO0017

PTH(1-84) Is Associated with Improved Quality of Life in Hypoparathyroidism Through 5 Years of Therapy. Natalie Cusano*[1], Mishaela Rubin[2], Donald McMahon[1], Dinaz Irani[3], Laura Beth Anderson[2], Elizabeth Levy[4], John Bilezikian[1]. [1]Columbia University College of Physicians & Surgeons, USA, [2]Columbia University, USA, [3]Columbia University Medical Center, USA, [4]Columbia University College of Physicians & Surgeons, USA

Hypoparathyroidism is a rare disease characterized by low serum calcium and PTH concentrations. Our group and others have shown that hypoparathyroid patients have compromised quality of life (QOL) compared to normal subjects. We have shown that QOL improves after 1 year of PTH(1-84) treatment in hypoparathyroidism. We now report our data through 5 years of therapy.

Sixty-nine hypoparathyroid subjects [age 46 ± 13 years (X ± SD); 55 women; etiology: 42 surgical, 26 idiopathic, 1 DiGeorge; duration 12 ± 11 years; serum calcium 8.7 ± 0.9 mg/dL; PTH 2.4 ± 5 pg/mL] were treated with PTH(1-84) for up to 5 years. Subjects completed the RAND SF-36 survey, a validated measure of health-related QOL covering 8 domains of physical and mental health. We analyzed data from baseline and months 2, 6, 12 (n=58), 18, 24 (n=42), 30, 36 (n=33), 42, 48 (n=26), 54 and 60 (n=25) of treatment. Some subjects dropped out before reaching the 5-year mark (n=27), while others have not yet reached 5 years of therapy (n=17). At baseline, hypoparathyroid subjects were below the normative reference range in all domains ($p<0.001$). With PTH therapy, intention-to-treat analysis showed significant improvement in the overall score at 2 months (386 ± 206 to 468 ± 245; $p<0.0001$) that persisted through 5 years (482 ± 391; $p<0.0001$). The mental component summary (MCS) score improved significantly at 2 months and remained significantly improved through 5 years (199 ± 121 to 246 ± 245; p=0.001), as did each of the 4 mental health domains [vitality (VT), social functioning (SF), role emotional (RE), mental health (MH)]. The physical component summary score improved significantly at 2 months and remained significantly improved through 5 years (187 ± 110 to 237 ± 210; $p<0.0001$), as did 3 of the physical health domains [physical functioning (PF), role physical (RF), general health (GH)]. Using T-scores, 7 of 8 domains improved early with sustained effects through 5 years: VT, -1.4 to -0.9 (p=0.001); SF, -1.1 to -0.7 (p=0.003); RE, -0.9 to -0.4 (p=0.011); MH, -0.9 to -0.4 (p=0.001); PF, -0.9 to -0.3 ($p<0.0001$); RF, -1.2 to -0.5 (p=0.002); GH, -1.3 to -0.9 (p=0.001).

These results document that PTH(1-84) therapy is not only associated with improvement in biochemical and skeletal indices (previously well-documented), but also in mental and physical health, among the major complaints of subjects with hypoparathyroidism.

Vitamin D Status in Hyperthyroidism. Ana Paula Barbosa*[1], Mário Rui Mascarenhas[2], Manuel Bicho[3]. [1]Endocrinology, Santa Maria Hospital & Faculty of Medicine, Portugal, [2]Lisbon's Faculty of Medicine, Santa Maria University Hospital, CHLN,EPE, Portugal, [3]Environmental Health Institute of Lisbons Faculty of Medicine, Portugal

Hyperthyroidism is a known risk factor for reduced bone mineral density (BMD), osteoporosis and fragility fractures because of the increased bone resorption induced by the thyroid hormones. Also, the coexistence of nutrient malabsorption and urinary calcium loss can contribute to vitamin D abnormalities and consequently to BMD changes and influences in the risk of falls.

PURPOSE

To evaluate the relationships between the vitamin D status and BMD, in patients with hyperthyroidism.

MATERIAL AND METHODS

A group of 44 patients with hyperthyroidism (21 men and 23 premenopausal women) were evaluated. Fasting venous sampling was done to measure the free thyroid hormones, TSH, iPTH, calcium, phosphorus, pituitary hormones and 25(OH)vitamin D.

The BMD (g/cm^2) at the lumbar spine (L_1-L_4), at the proximal femur, at the distal radius and at the whole body and the total body soft tissues composition (lean and fat masses, Kg) were evaluated by dual X-ray absorciometry (Hologic QDR Discovery W densitometer).

No patient was previously treated for hyperthyroidism and/or osteoporosis.

According to the endocrine society and IOM criteria, the vitamin D levels (ng/mL), were divided in deficient (<20), insufficient (21-29) and normal (>30).

Descriptive and regression tests were used and statistical significance was considered for $P<0.05$.

RESULTS

In the men group the vitamin D deficiency was detected in 42.8%, insufficiency in 33.4% and normal in 23.8%, but in the women group the deficiency was 34.8%, the insufficiency was 39.1% and normal levels in 26.1%.

CONCLUSIONS

The results of this study suggest the presence of inadequate levels of vitamin D in almost 75% of the patients with hyperthyroidism, which, associated to an increased bone turnover, can contribute to bone mass loss and the possible increase of osteoporotic fractures risk.

MO0019

Are left and right the same? Contralateral microstructural differences between HR-pQCT images at the radius and tibia. Bin Zhou*[1], Eric Yu[1], Ji Wang[1], Zhengdong Zhang[2], Fernando Rosete[3], Kyle Nishiyama[1], Elizabeth Shane[4], X Guo[1]. [1]Columbia University, USA, [2]Columbia university, USA, [3]Columbia University Medical Center, USA, [4]Columbia University College of Physicians & Surgeons, USA

HR-pQCT has become a popular clinical research tool to distinguish fragility fractures and assess efficacy of pharmacological interventions for osteoporosis. In general, the non-dominant radius (usually the left) along with the ipsilateral tibia is chosen for imaging. Under certain circumstances, such as prior fracture, the contralateral limbs are scanned instead. However, the variance in microstructural and mechanical properties between contralateral limbs is unknown. In this study, we investigated differences in these properties between left and right radii and tibiae.

Twenty-seven sets of paired cadaveric human left and right distal radii and tibiae were scanned by HR-pQCT and μCT. Regions corresponding to the standard HR-pQCT scan were identified in μCT images using 3D image registration. Volumetric bone mineral densities and trabecular microstructure were examined, and the trabecular compartments were subjected to individual trabecula segmentation (ITS) analysis to evaluate plate- and rod-related microstructural parameters. Whole bone stiffness was determined by image μFE analysis.

By gold standard μCT, right radius had higher BV/TV and stiffness. However, at the tibia, both parameters were similar (Table 1). By ITS-based microstructural analysis, the right radius had higher plate and rod BV/TV, while plate BV/TV was similar between left and right tibiae. By HR-pQCT, the right radius had higher total area and lower average BMD. At the tibia, only average BMD was modestly but significant different between sides (Table 2). The majority of microstructural parameters from standard and ITS analysis were significantly different at both sites. Strong correlations between microstructural parameters and stiffness were found between sides; however, the correlations were relatively lower in the radius compared to the tibia.

These data suggest the selection of the contralateral radius can introduce significant variance to *in vivo* HR-pQCT analysis. For tibia, though some microstructural parameters differed, important indicators like μCT-based BV/TV and stiffness are similar. Compared with radius, the higher correlation in tibia likely originates from routine loads that are evenly distributed on the lower limbs but may be more asymmetric in the upper limbs. In conclusion, careful consideration of the selection of the dominant or non-dominant limb for scanning is important for HR-pQCT studies. The consistency between HR-pQCT and μCT needs to be further examined.

Table 1. μCT (37μm)-based morphological, ITS analysis, μFE and the correlations between left and right radius and tibia. Bone Density, Geometry, and Strength Changes after Lower Limb Amputation. Debra Bemben*[1], Vanessa Sherk[2], Michael Bemben[1], William Ertl[3]. [1]University of Oklahoma, USA, [2]University of Colorado - Denver, USA, [3]University of Oklahoma Health Sciences Center, USA

We have previously documented in cross-sectional and longitudinal studies that there are large losses in areal BMD (aBMD) for the hip sites after lower limb amputation. There is a lack of information about the changes that occur to bone quantity and quality at the end of the amputated bone, which is important for prosthesis fit and long term ambulation. The purpose of this study was to assess changes in at the end of the amputated bone using pQCT that occur in the early stages post-amputation of a lower limb. Nine participants (1 premenopausal female, 8 males), ages 23 to 53 years were enrolled immediately prior to their amputation surgery. They all were traumatic unilateral amputees (1 above-knee, 7 below-knee) who had undergone the Ertl procedure. pQCT was used to assess volumetric BMD (vBMD), bone content (BMC), bone area, bone strength (SSI, Imax, Imin), and muscle cross-sectional area (MCSA) at 5% of the residual limb length proximal to the top of the bone-bridge and at the same distance on the contralateral limb. Changes in cortical bone porosity were estimated by determining the proportion of the bone area that was contained within different vBMD cutoffs (>650, >480 mg/cm^3). Bone measurements were obtained at 3 time points: after amputation prior to prosthesis fitting (pre-ambulatory baseline); at 6 months walking with prosthesis; and at 12 months walking with prosthesis. There were no significant changes for bone or muscle variables in the intact bone. The amputated bone had significant decreases ($p<0.01$) in BMC (-28%) and vBMD (-24%) from pre-ambulatory to 6 and 12 month time points, but there were no differences between the 6 and 12 month time points (Table 1). SSI, Imin and MCSA showed the same pattern of results, but Imax decreased only at the 6 month time point. On the amputated bone, there was a decrease ($p<0.05$) in the proportion of bone area that was > 650 mg/cm^3 (56.2% to 41.5% of total area) or > 480 mg/cm^3 (63.4% to 51.3%), suggesting that the cortical bone became more porous after amputation. In conclusion, rapid and substantial losses in bone content and bone strength occur early after amputation and are not regained by 12 months of becoming ambulatory. It is unclear whether bone loss from amputation can be recovered; early post-amputation appears to be the most critical window for potential efforts to prevent bone loss.

Table 1. Changes (Mean ± SE) in the Amputated Bone (n=9)

Variable	Pre-Ambulatory	6 Months with Prosthesis	12 months with Prosthesis
BMC (mg/mm)	430.63 ± 19.66	329.37 ± 24.49**	310.45 ± 27.44**
vBMD (mg/mm^3)	683.63 ± 37.03	550.96 ± 49.01**	530.50 ± 55.80**
SSI (mm^3)	2521.30 ± 148.08	1871.42 ± 209.66*	1793.53 ± 224.37*
Imax (mm^4)	28433.24 ± 3021.45	19193.67 ± 2283.35*	19813.31 ± 3008.43

Comparison of short term *in vivo* precision of cortical bone micro-architecture between two HR-pQCT assessment methods at the distal radius and tibia in postmenopausal women and young adults. Chantal Kawalilak*[1], James Johnston[1], David Cooper[1], W.P. Olszynski[2], Saija Kontulainen[1]. [1]University of Saskatchewan, Canada, [2]Midtown Professional Center (#103), Canada

Introduction. Precise measurement of cortical bone micro-architecture is fundamental when monitoring cortical bone changes and treatment effects. At present, it is unknown how endocortical boundary contour definition influences precision of cortical bone micro-architecture using HR-pQCT. Our purpose was to assess whether HR-pQCT precision of cortical bone micro-architecture in postmenopausal women and young adults differed when using the automatic and modified endocortical contouring methods.

Methods. We scanned the distal radius and tibia at two time points in 30 young adults (mean age 27, SD ± 9 years) and 34 postmenopausal women (74 ± 7 years) using HR-pQCT (XtremeCT). Standard protocols were used to define the periosteal surface. Dual-threshold technique was used to define endocortical surface. Cortical bone outcomes of repeated scans were determined using a) automatically generated contour line, and b) manual correction of the endocortical contour line. Precision error (CV%$_{RMS}$), Least Significant Change, and 95% Limits of Agreement were calculated for the following cortical bone outcomes: perimeter, endocortical perimeter, porosity, porosity volume, pore diameter, pore diameter distribution, total volume, bone volume, density, and thickness. We used Wilcoxon sign rank tests to compare precision error between the two contour protocols for non-parametric variables. Paired samples *t*-tests were used to compare parametric variables. Bonferroni adjustments for multiple comparisons were used for all analyses. Significance was accepted at $P<0.005$.

Results. No significant differences were found between the two methods apart from the endocortical perimeter measure in the distal tibia of postmenopausal women (Automatic CV%$_{RMS}$: 0.6, Modified CV%$_{RMS}$: 3.2; $P<0.0001$).

Discussion. The automatic endocortical contouring method appeared to provide as precise cortical bone outcomes as manually modified endocortical contours in both postmenopausal women and young adults. Based on these results, automatic contouring of the endocortical surface can be recommended to save time and costs in cortical bone image analysis from HR-pQCT scans.

Composite but Not Individual Tissue-Level Bone Traits Differ Significantly Between Femurs that are Stronger vs. Weaker for Body Size. Daniel Nicolella*[1], Arthur Nicholls[2], Don Moravits[2], Jennifer Harris[3], Shayna Levine[3], Travis Eliason[2], Jeffry Nyman[4], Todd Bredbenner[1], Lorena Havill[5]. [1]Southwest Research Institute, USA, [2]Southwest Research Institute, USA, [3]Texas Biomedical Research Institute, USA, [4]Vanderbilt University Medical Center, USA, [5]Texas Biomedical Research Institute, USA

The structural integrity of bone is an integrative function of a multitude of complex and interrelated traits of the bone matrix, microstructure, macroscopic bone morphology, and bone density. Co-adaptation of these traits provides for redundant combinations of traits through which the skeleton is able to provide nominally equivalent functionality under "normal" loading conditions; however, particular

combinations of traits sufficient for everyday loading could be suboptimal when subjected to atypical, traumatic loads such as those encountered in a fall. We measured the following compositional and biomechanical traits in cortical bone from 45 pedigreed baboons: porosity, apparent density, ash and water content, collagen crosslinks (pyridinoline, deoxypyridinoline, pentosidine, and total collagen content), elastic modulus, yield and peak strain, yield and ultimate stress, toughness, and post yield toughness. We also measured robustness, polar moment of inertia, anterior-posterior (AP) and medial-lateral (ML) section modulus, and AP and ML slenderness ratios. We used principal components analysis to identify independent composite traits (combinations of the compositional, biomechanical, and morphological traits) that describe variability within the group. The strength of the proximal femur was measured in 3-point bending in a loading direction orthogonal to the predominant daily functional load direction then normalized by body mass. Femurs were ranked from high to low based on strength/mass ratio. The highest ranking half and the lowest ranking half were compared as the "stronger" vs. the "weaker" group and tested for significant differences in individual and PCA-derived composite traits. None of the individual tissue-level traits differed significantly between groups ($p>0.05$) while all morphology traits did differ significantly ($p=0.002$-0.016). However, the composite traits of bone tissue-level properties (porosity, ash and water content, collagen crosslinks, modulus, tissue yield properties) together with morphology differed significantly between groups ($p=0.001$-0.023). Our results support that bone traits co-adapt to functional loading in a complex multivariate manner at multiple hierarchical length scales, and indicate that multivariate discriminators (composite traits) that encompass variation at all of these levels are most appropriate for rapidly advancing our understanding of bone fragility and identifying novel targets for therapeutic intervention.

MO0023

Effects of strontium ranelate on the intrinsic quality of human bone tissue. Sebastien Rizzo*[1], Delphine Farlay[2], Audrey Doublier[1], Georges Boivin[3]. [1]INSERM, UMR 1033, Université de Lyon, France, [2]INSERM, UMR1033; Université De Lyon, France, [3]INSERM, UMR1033 ; Universite De Lyon, France

To assess precisely the effects of strontium ranelate (SrRan) on bone tissue, intrinsic quality (mineralization, microhardness, mineral and organic characteristics) was analyzed in women with postmenopausal osteoporosis before and after prolonged treatment with SrRan. This treatment reduces the risk of fracture (1,2) via a mechanism of action partially elucidated. Thirty eight iliac bone biopsies were taken from women with postmenopausal osteoporosis before (N=10) or after 3-8 yrs of SrRan (N=28), then were embedded in methyl methacrylate (3). Degree of bone mineralization, heterogeneity index of mineralization and microhardness were measured by quantitative microradiography and microhardness (4). Mineral and organic characteristics were assessed by Fourier transform infrared microspectroscopy (5,6). Degree of mineralization was not significantly modified by SrRan [before, cortical bone (cort): 1.05 ± 0.07 g/cm^3, cancellous bone (canc): 1.09 ± 0.09 g/cm^3; after 3 yrs, cort: 1.16 ± 0.09 g/cm^3, canc: 1.18 ± 0.08 g/cm^3; after 8 yrs, cort: 1.21 ± 0.07 g/cm^3, canc: 1.22 ± 0.03 g/cm^3]. Bone microhardness was also unchanged after SrRan (before, cort: 52.05 ± 2.73 kg/mm^2, canc: 52.93 ± 2.01 kg/mm^2; after 3 yrs, cort: 50.81 ± 3.50 kg/mm^2, canc: 52.96 ± 3.23 kg/mm^2; after 8 yrs, cort: 58.15 ± 1.80 kg/mm^2, canc: 56.76 ± 2.76 kg/mm^2). Mineral and organic characteristics of newly formed bone (mineralization index, mineral maturity, crystallinity index, carbonation and collagen maturity) were not significantly modified whatever duration of SrRan. Thus, in cortical and cancellous bone, intrinsic quality was not modified by a treatment, even prolonged, with SrRan. Present data are in agreement with those related on apatite crystals [crystallinity (size and/or perfection), lattice parameters (a) and (c), inter-reticular distances 002 (d_{002}) and 310 (d_{310})] showing that these variables were not modified either by duration (3 yrs vs before) or type (SrRan vs placebo) of treatment (7). In conclusion, intrinsic quality of bone tissue was maintained at a physiologically normal level after different durations of treatment with SrRan at therapeutic dose.

High Resolution 3D-Printing of Trabecular Bone based on microCT data. Volker Kuhn*[1], Nikola Ivanovic[2], Wolfgang Recheis[3]. [1]Medical University Innsbruck, Austria, [2]Medical University Innsbruck, Austria, [3]Medical University Innsbruck, Austria

Introduction:

Modern high-end 3D-printers enable resolutions up to 16µm. Purpose of the presented study was firstly, to investigate the quality and difference of microCT-based 3D-printed trabecular bone structures, and secondly, the biomechanical properties of such 3D-printed trabecular bone samples.

Material and Methods:

MicroCT scans of human trabecular samples with different bone quality were performed with a vivaCT40 (Scanco/CH) and analyzed according the standard settings. Based on these data typical STL-files were created for 3D-printing purpose for the use with a high-end 3D-printer. The washing-out procedure of the necessary supporting material was optimized with appropriate chemical solutions. In the next step original bone structures were compared with the 3D-printed copies from microCT based data by image registration.

Results:

The selected procedure enables high conformity between original and high resolution 3D-printed trabecular bone structures. The conformity is affected by image and printing resolution, thresholding and filtering parameters.

Conclusion:

After further optimization of the selected 3D-printing materials it is possible to achive appropriate E-modulus values of different trabecular bone qualities. Such artificial created bone samples may be helpful for future standardized biomechanical testing of newly developed osteosynthesis screws and implants for osteoporotic fractures.

Menopause is Not Followed by Increased Mineral Loss but Increase in Bone Size. Magnus Karlsson*[1], Henrik Ahlborg[2], Ola Svejme[3], Jan-Åke Nilsson[4], Bjorn Rosengren[1]. [1]Skåne University Hospital Malmö, Lund University, Sweden, [2]Malmo University Hospital, Sweden, [3]Lunds Universitet, Sweden, [4]Department of Orthopedics & Clinical Sciences, Lund University, SUS, Sweden

Purpose: Bone mineral density (BMD) is the clinical used estimate of bone mass, incorporated in the World Health Organization definition of osteoporosis. However, BMD (sometimes called areal BMD) depends not only on the amount of mineral but also bone size. The increased postmenopausal decline in BMD could thus hypothetically be the result of increased bone mineral loss, increased bone size, or both, to our knowledge never being evaluated.

Methods: We measured the amount of bone mineral, bone mineral content (BMC; mg), BMD (mg/cm^2) and bone width (mm) by single-photon absorptiometry at the cortical site of the forearm in a prospective observational study that included a population-based sample of 105 Caucasian women without medication or disease interfering with bone metabolism. We conducted 12 measurements during a 28-year period from mean 5 years (range 2 to 9) before to mean 24 years (range 18–28) after menopause. Menopause was defined according to World Health Organization criteria, i.e. permanent cessation of menstruation due to the loss of ovarian follicular activity. The onset of menopause was therefore determined retrospectively when 12 months of spontaneous amenorrhea was reported in conjunction with elevated serum levels of follicle-stimulating hormone.We calculated individual slopes for changes in the periods before, 0 to <8, 8 to <16 and 16 to 28 years after menopause. Data are presented as means with 95% confidence intervals.

Results: The were in all four periods a significant annual BMC loss of respectively 1.4% (–0.1, –2.6), –1.1% (–0.9, –1.4), –1.2% (–0.9, –1.6) and –1.1% (–0.8, –1.4). That is, that were no different loss in BMC in the four periods. In contrast, the was an annual increase in bone width only in the immediate postmenopausal period; the increase in bone width was in the four periods 0.4% (–1.2, 1.9), 0.7% (0.5, 0.9), 0.1% (–0.2, 0.4) and 0.1% (–0.2, 0.4), respectively. The increase in bone width was also significantly higher in the first than in the second ($p=0.003$) and the third ($p=0.01$) postmenopausal period.

Conclusion: Menopause is followed by an increase in bone with but no increased mineral loss.

Micro-Architectural Parameters other than BV/TV and Fabric Bring No Further Contribution to Stiffness of Human Trabecular bone. Sarah Khadri[1], Ghislain Maquer[1], Jasmin Wandel[2], Philippe Zysset*[3]. [1]University of Bern, Switzerland, [2]Bern University of Applied Sciences, Switzerland, [3]University of Bern, Switzerland

Degradation of trabecular bone architecture belongs to most definitions of osteoporosis, but its actual contribution to bone fragility remains unclear. Although several studies reported statistically significant effects for the influence of morphological parameters on trabecular bone stiffness and/or strength, no systematic analysis was performed to compare the relative importance of these parameters on multi-axial stiffness at relevant fracture sites.

Seven hundred and one trabecular bone cubes of 5.3 mm edge length from 44-82 years old male and female proximal femora, vertebral bodies and distal radii were scanned with 18 microns resolution. Classical morphometric indices such as bone volume fraction (BV/TV), mean intercept length based fabric tensor, degree of anisotropy (DA), bone surface (BS), connectivity density (Conn.D), structure model index (SMI), trabecular number (Tb.N), thickness (Tb.Th), spacing (Tb.Sp) and their

standard deviations (Tb.Th.SD, Tb.Sp.SD) were calculated. The homogenized stiffness tensors of all cubes were computed by linear micro finite element analysis using kinematic uniform boundary conditions. Relationships of the morphological parameters with the orthotropic elastic constants were investigated by linear models after log transform. Their relative contribution to the orthotropic model was established via ANOVA.

For the pooled data, all morphological parameters exhibit significant and sometimes high correlation with BV/TV, except DA derived from the fabric tensor ($r=0.032$ $p>0.05$). In single regressions, BV/TV achieves higher coefficients of determination with the elastic constants than any other parameter. In multiple regressions, parameters other than BV/TV and fabric are often significant, but contribute less to the total sum of squares of the bone elastic properties than the residuals (Table 1).Thirty years after introduction of bone histomorphometry, these results from a large sample database suggest that architectural parameters other than BV/TV and fabric do not further contribute to the prediction of trabecular stiffness at 3 major fracture sites. This implies that in terms of stiffness, there is no identifiable degradation in architectural quality beyond bone loss. In other words, trabecular bone remodelling maintains an optimally stiff structure for a given bone mass. Further studies are needed to test if this finding holds for yield strength and for bone altered by specific metabolic diseases.

	Femur	Radius	Vertebra	All
n	264	81	356	701
BV/TV	91.4	73.1	86.7	88.7

MO0027

Modulation of material property and composition parameters that contribute to impaired bone quality in Osteogenesis Imperfecta by anti-TGFβ treatment. Xiaohong Bi*[1], Hao Ding[2], Ingo Grafe[3], Stefanie Alexander[4], Elda Munivez[4], Ming-Ming Jiang[4], Brian Dawson[4], Annie Abraham[5], Brendan Lee[6], Catherine Ambrose[7]. [1]University of Texas Health Science Center at Houst, USA, [2]Department of Nanomedicine & Biomedical Engineering, University of Texas Health Science Center, USA, [3]Department of Molecular & Human Genetics, Baylor College of Medicine, USA, [4]Department of Molecular & Human Genetics, Baylor College of Medicine, USA, [5]Department of Orthopaedic Surgery, University of Texas Health Science Center, USA, [6]Baylor College of Medicine, USA, [7]University of Texas Health Science Center at Houston, USA

Osteogenesis Imperfecta (OI) is characterized by low bone mass, deformities and fractures. In mouse models of OI some studies have demonstrated significant changes in bone mechanical properties and molecular composition compared with wildtype (WT) controls. Anti-TGFβ treatment using the neutralizing antibody 1D11 (Genzyme) improved the bone phenotype in OI mice with improved mechanical properties in a previous report. This study seeks to identify the material factors substantially contributing to the impaired bone quality in OI, and to characterize the response of such factors to anti-TGFβ treatment. For this, we utilized mice harboring a G610C mutation in the *Col1a2* gene that model a dominantly inherited form of OI. Femurs from 16 week old female mice (8 week old mice treated for 8 weeks: control WT, control OI and 1D11 treated OI) were analyzed with biomechanical testing and Raman spectroscopy.

When compared to WT, the control OI bones were significantly less stiff, withstood less energy and underwent less displacement after yield before failure. The parameters associated with bone plasticity (post-yield (PY) energy, displacement, toughness and strain) were also significantly reduced, consistent with increased brittleness. Collagen mineralization was significantly increased in OI bones and demonstrated a positive correlation with ultimate strength and elastic modulus and a negative correlation with PY energy and toughness. Decreased collagen density, carbonation, and mineral crystallinity were observed in OI compared to WT femurs. Collagen density was significantly correlated with bone plasticity. Carbonation and mineral crystallinity also correlated positively with PY energy and toughness.

With 1D11 treatment, the OI bones demonstrated a slightly higher ultimate strength and an increased elastic modulus, as well as a more normal carbonation, collagen density and mineral crystallinity. In the OI control and treated animals, enhanced mineral crystallinity and carbonation significantly correlated with bone plasticity, indicating an inverse relationship with brittleness. Increased collagen mineralization correlated to bone stiffness and the improved elastic modulus.

In summary, we find that collagen density, carbonate substitution and mineral crystallinity likely play critical roles in the inferior bone quality in OI. Anti-TGFβ treatment improved those parameters and could potentially be useful for reducing the fracture risk in OI patients.

Patients with stress fractures exhibit impaired bone material properties by microindentation. Daysi Duarte Sosa*[1], Erik Fink Eriksen[2]. [1]Ph.D., Norway, [2]Oslo University Hospital, Norway

Bone material properties are one of the key determinants of bone quality. Stress fractures are considered to result from microdamage accumulation secondary to repetitive strains exerting negative effects on bone material properties. We therefore wanted to test, whether subjects with stress fractures show impaired bone material properties. Bone material properties were assessed by microindentation, which measures the indentation distance increase (IDI) into the thick cortex of the tibia. We used a new instrument (Osteoprobe®, Active Life Scientific, Santa Barbara, CA) to measure IDI in 16 subjects with stress fractures (age range, 18-74 yrs, males 3, females 13) and 41controls (age range 23-76 yrs, males 3, females 38). The IDI measured was standardized against a calibration phantom of methyl methacrylate, and results expressed in BMS (Bone Material Strength) units as percentage of this reference value.

Average BMS values were lower in stress fracture patients than controls (68.9 ± 9.9 % vs 76.7 ± 7.3% p= 0.01)(Figure). Total hip BMD was increased in controls 1.206 ± 0.160g/cm2 vs subjects with stress fracture $1.042 \pm 0,166$g/cm2 p= 0,005). Patients with stress fracture exhibited increased serum PINP ($61 \pm (30)$) vs. controls, ($43 \pm (17)$; p=0,04), but revealed similar vitamin D levels (61 ± 19 vs 64 ± 31; p=0,72). No correlations between BMS and BMD at the hip, bone turnover, S-calcium and vitamin D were demonstrable.

Subjects with stress fracture show impaired bone material properties and reduced Bone Mineral Density. This combination may contribute to the increased fracture propensity in these patients.

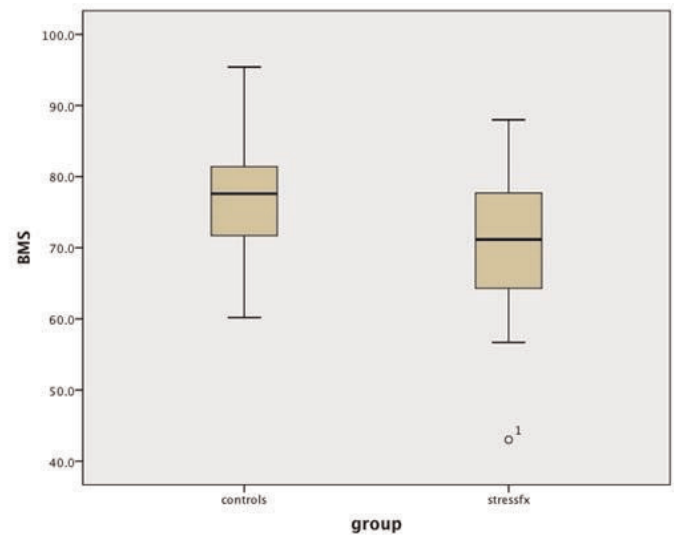

Figure BMS: Stress fx vs controls

MO0029

Proximal Femoral Strengths in Men and Women Age 27 to 90+: A Subject-Specific Finite Element Modeling Study. Joyce Keyak*[1], Tadashi Kaneko[2], Sundeep Khosla[3], Shreyasee Amin[4]. [1]Department of Radiological Sciences, University of California, Irvine, USA, [2]University of California, USA, [3]Mayo Clinic College of Medicine, USA, [4]Mayo Clinic, USA

Subject-specific finite element (FE) modeling is a robust tool for evaluating proximal femoral strength and hip fracture risk. However, interpreting FE strength values can be difficult, requiring a reference database containing FE-computed strengths for subjects with and without hip fractures. Unfortunately, most FE studies have focused on older subjects, making FE assessment of fracture risk in younger subjects, e.g. astronauts, problematic. Thus, the purpose of this study was to create a reference database containing FE-computed proximal femoral strengths of adult men and women of all ages.

QCT scans of the hips of 216 women and 181 men [mean age (range): 61 (27 to over 90) years, and 60 (28 to over 90) years, respectively] were obtained, with no exclusions, from a previous study of an age-stratified, random sample of Rochester, MN residents, the majority of whom were white (≥96%). The QCT scans (Light Speed QX-I; GE Medical Systems, Wakesha, WI, USA; 120kVp; 80mA; 3-mm-thick slices) were obtained using a K_2HPO_4 calibration phantom (Model 3, Mindways Software, Inc., San Francisco, CA, USA).

For each subject, FE models of the left proximal femur were generated using heterogeneous nonlinear material properties computed from QCT density (Keyak, Bone, 2013). Displacement was applied incrementally to the femoral head, and proximal femoral strength (the maximum femoral head reaction force) was computed for single-limb stance loading and for a posterolateral fall onto the greater trochanter.

Multiple linear regression was performed to relate strength in each loading condition to age (years) and sex (women=0, men=1).

Proximal femoral strengths (N) were associated with age ($p<0.001$) and sex ($p<0.001$) [Stance=19,973−137.5(Age)+3278(Sex), $R^2=0.39$; Fall=4763−18.2(Age)+685(Sex), $R^2=0.37$], indicating that, on average, stance and fall strengths, respectively, are 3278N and 685N greater in men than in women and demonstrate age-related decreases of 138N/year and 18N/year, with no age-sex interaction ($p>0.4$). From these rates, reductions in stance and fall strengths associated with fracture (Keyak, Bone, 2013) are respectively equivalent to 17 and 27 years of aging in men, and 7 and 11 years of aging in women. For comparison, mean reductions in stance (1648N) and fall (459N) strengths from long-duration spaceflight astronauts (age 40 to 55) (LeBlanc, Osteoporos Int, 2013) are equivalent to strength reductions normally associated with 12 and 25 years of aging, respectively.

Structural and Mechanical Properties of Trabecular Bone in the Distal Extremities Studied by Micro-MRI in Postmenopausal Women. Mahdieh Bashoor-Zadeh*[1], Mona Al Mukaddam[2], Wenli Sun[2], Eual Phillips[2], Chamith Rajapakse[3], Felix Werner Wehrli[4]. [1]University of Pennsylvania, USA, [2]University of Pennsylvania, USA, [3]University of Pennsylvania School of Medicine, USA, [4]University of Pennsylvania Medical Center, USA

Trabecular bone integrity is known to decline rapidly following menopause, resulting in compromised mechanical competence. There is evidence these effects are systemic but less is known whether bone loaded during daily living (tibia) is affected differently than unloaded bone (radius). This cross-sectional study examined μMR-derived trabecular structural parameters in the tibia and radius and determined the ability of these parameters to predict axial stiffness (AS). In addition, associations were examined between μMR-derived parameters at the two peripheral sites and DXA BMD in the central skeleton.

75 postmenopausal women, ages 55-78 years, were evaluated by μMRI of the left distal tibia and radius and DXA BMD at the spine and hip. High-resolution μMR images (137x137x410 μm^3 voxel size, 32 slices) were acquired at 3T field strength using a 3D spin-echo sequence with a 4-element receive coil (tibia) and elliptical birdcage transmit-receive coil (wrist) at the distal metaphysis. Structural parameters (bone volume fraction (BV/TV), surface-to-curve ratio (S/C), trabecular thickness (Tb.Th) and number (Tb. N)) were measured. Finite-element analysis (FEA) was performed to compute trabecular AS by converting each voxel into hexahedral finite elements. AS was computed as the ratio of the stress on the proximal face to the applied axial strain.

MicroMR-derived structural parameters correlated with AS; the strongest explanatory variable was BV/TV at both distal sites (tibia $R^2=0.89$; radius $R^2=0.55$, $p<0.0005$); the association was stronger at the load-bearing site (tibia) than radius (Table1). Mean AS ($\pm$SD) of the tibia (917 $\pm$ 99 MPa) was much greater than that of the radius (358 $\pm$ 95 MPa, $p<0.0005$). AS of the tibia weakly correlated with DXA BMD at spine and hip ($R^2=0.07$ and 0.09, respectively, $p<0.05$), however those involving the radius did not.

BV/TV map of trabecular region of the tibia and radius, from two subjects (A, 59-YO, B,79-YO) highlight the loss of trabecular connectivity with age (Fig.1). The degree of structural integrity is reflected by the structural and mechanical parameters that are higher in subject A. In contrast, DXA BMD at the lumbar spine was greater in subject B (Table2), likely the result of aortic calcification or osteophytes.

In conclusion, μMRI-derived BV/TV is a strong predictor of mechanical competence (AS) of trabecular bone. Inclusion of other structural parameters into the model did not significantly improve that association.

Table1.Correlation (R^2, n=75) between μMR-derived structural parameters and AS at tibia and radius (* indicates p<0.0005).

	Axial Stiffness	
Structural Parameters	Tibia	Radius
BV/TV	0.89*	0.55*
S/C	0.66*	0.16*
Tb. Th.	0.47*	---
Tb. N	0.86*	0.65*
BV/TV & S/C	0.89*	0.58*
BV/TV & Tb.Th.	0.91*	0.67*
BV/TV & Tb.N	0.91*	0.66*

Table2. μMR-derived structural and mechanical parameters at distal tibia and radius of subject A (59-YO) and subject B (79-YO)

	Subject A		Subject B	
Parameters	Tibia	Radius	Tibia	Radius

The Effect of Diabetes on Bone Strength and Collagen Cross-linking. Stephen Warner*[1], Heather Hunt[2], Jonathan Jo[3], Kate Meyers[3], Edward DiCarlo[3], Joseph Lane[1], Eve Donnelly[4]. [1]Hospital for Special Surgery, USA, [2]Cornell University, USA, [3]Hospital for Special Surgery, USA, [4]Cornell University, USA

Patients with diabetes have an increased fracture risk compared to non-diabetics even after accounting for changes in bone mineral density (BMD), suggesting that diabetes affects not only the quantity of bone but also the quality. Studies using diabetic animal models demonstrate that diabetic animal bone is weaker than non-diabetic bone, and this may correlate with changes in collagen advanced glycation end products (AGEs). However, an extension into humans is lacking. Because of the high and increasing prevalence of diabetes, in addition to the morbidity that results from fractures, insight into how diabetes affects bone quality in humans has significant clinical implications. Our objective was to examine whether diabetes is associated with changes in bone mechanical properties and collagen AGEs.

Cancellous bone cores were removed from femoral neck specimens of patients undergoing total hip arthroplasties for osteoarthritis. All patients included in the study had a glycated hemoglobin (HbA1c) measurement within one month of surgery. Specimens were allocated to the control group (HbA1c < 6.0) or the pre-diabetic and diabetic group (HbA1c > 6.0). Each core was imaged using micro-computed tomography to assess bone microarchitecture and density. Unconfined compression testing was performed to obtain load-displacement data. Subsequently, specimens were assayed for AGEs and total collagen content.

Based on power analyses from animal studies, a total of 18 specimens underwent complete testing, including 9 control and 9 pre-diabetic and diabetic age- and gender-matched specimens. The average HbA1c was 5.52 in the control patients and 6.86 in the pre-diabetic and diabetic group ($p < 0.001$). Average elastic modulus was decreased by 20% in the diabetic patients compared to controls (214.6 MPa versus 267.3 MPa) and average AGE content was 23% increased in the diabetic samples compared to controls (1193 versus 972). However, these differences were not statistically significant. Bivariate regression analyses did not demonstrate a significant association between HbA1c and core mechanical properties.

In our cohort of patients, HbA1c did not significantly correlate with changes in bone mechanical properties or with local AGE content in the femoral neck. Additional studies will be useful to determine if differences exist with a larger subset of patients or in different anatomic areas. Alternatively, other clinical measures of diabetes other than HbA1c may be more representative of altered bone metabolism.

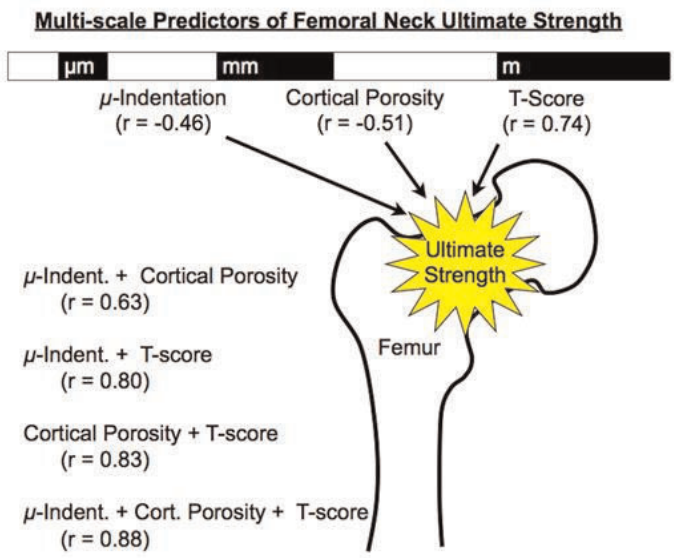
The Femoral Neck Strength of Post-menopausal Women is Predicted by Factors at Multiple Length Scales. Adam Abraham*[1], Simon Tang[2], Avinesh Agarwalla[3]. [1]Washington University at St.Louis, USA, [2]Washington University in St Louis, USA, [3]Washington University in St.Louis, USA

As a hierarchical structure, bones' overall ability to resist fracture is determined by factors at multiple length scales. Although bone mineral density is routinely used to assess fracture risk, recent clinical evidence show that patients with altered bone material properties and structure, such as those with diabetes mellitus, have an elevated risk of fracture independently of BMD. It is thus critical to assess fracture risk at multiple scales. We sought to understand the relative contributions of material level properties (reference point micro-indentation, RPI), tissue structure (cortical porosity), and bone mass (DeXA T-score) on the femoral neck strength of postmenopausal women. Using these relationships we aim to improve to predictive fidelity of femoral neck strength by incorporating these clinically measurable factors at multiple scales. 48 whole lower limbs from fresh postmenopausal female cadavers (57-97y) were used for this study. T-score was acquired using a clinical DeXA system (Hologic). RPI (BioDent Hfc) was performed *in situ* at the tibia mid-diaphysis for each leg through the skin (15 sites/limb), and the parameter indentation distance increase (IDI) was averaged for each leg. Micro-CT (Scanco Medical Ag, 30μm^3 voxel size) was used to determine the cortical porosity at the anterior tibial mid-diaphysis. Femoral neck strength was assessed by compressively loading at the femoral head to failure at adduction 12° using a material test stand (Instron). Linear correlations were examined between the predictors T-score, cortical porosity, and IDI and response variables ultimate strength and work-to-failure. T-score ranged from -4.6 to +0.5. T-score, cortical porosity, and IDI were significantly linearly correlated with ultimate strength (r=0.74; r=-0.51; r=-0.46, respectively) and work-to-fracture (r=0.51; r=-0.45; r=-0.44, respectively). Multivariate regression analysis incorporating each permutation for predictors of strength improved the correlation (IDI+Porosity, r=0.63; IDI+T-score, r=0.80; IDI+Porosity, r=0.83; IDI+Porosity+T-score, r=0.88). Although the T-score is the strongest single predictor of strength, our findings reveal that factors at other scales are also significant predictors. Moreover, the prediction of an individual's bone strength is improved by incorporating multiple personalized quantitative factors, demonstrating the diagnostic potential of such a multi-scale approach.



Multi-scale predictors of femoral neck ultimate strength

MO0033

Validation of a digitized device of microradiography for the characterization of bone mineralization. Florian Montagner*[1], Valérie Kaftandjian[2], Delphine Farlay[3], Daniel Brau[4], Georges Boivin[5], Helene Follet[5]. [1]INSERM UMR 1033, Université de Lyon, France, [2]Laboratoire Vibrations Acoustique, INSA de Lyon, France, [3]INSERM, UMR1033; Université De Lyon, France, [4]Photonic Science, France, [5]INSERM, UMR1033 ; Universite De Lyon, France

The quantitative microradiography is an imaging technique for the study of variables characterizing the quality of bone mineralization. Until now, photographic films were used for their high power of resolution. New digital detectors, now allow to obtain an image quality close to that of films. Our aim is to validate the replacement of films by a digital detector for bone mineralization analysis. A prototype has been developed in collaboration with Photonic Science. The X-ray source is a copper anode associated with a nickel filter (similar to the photographic system). The parameters chosen to evaluate the quality of the image are: the contrast-to-noise ratio (CNR) and spatial resolution. CNR evaluates the quality of the information provided by the gray levels contained in the image. CNR was calculated between two aluminum steps whose attenuations are close to those obtained with a 100 µm-thick section of bone. With a power of 2 W, the best CNR (i.e., 6) was obtained at 50 kV, 40 µA and with an averaging of 6 images. The spatial resolution concerns the ability to separate details in an image. It is generally measured by curves representing the contrast obtained for a periodic object whose spatial frequency is expressed in pair of lines per millimeter (lp/mm). The modulation transfer function (MTF) when the profile of the object is sinusoidal and the contrast transfer function (CTF) when the profile is rectangular, were used. The MTF is defined by the modulus of the Fourier transform of the impulse response of the system and obtained by deriving a straight edge profile. MTF and CTF have been obtained by imaging respectively a straight object and a calibration pattern engraved lp/mm. Both curves showed that with the digital system, a magnification factor of 4 is necessary to have an equivalent resolution of the photographic system. It represents a resolution of 100 lp/mm. Photographic and digital systems had a similar image quality. The digital system has advantages: easy to use and absence of supplies, reduced acquisition time and digital data storage. The reproducibility was also improved by removing the photographic processing. Digitized microradiography has been validated to measure the different variables characterizing bone mineralization. These variables are validated by comparing the measurements with both systems for the same group of samples and calculating the level of uncertainty associated with the measurements.

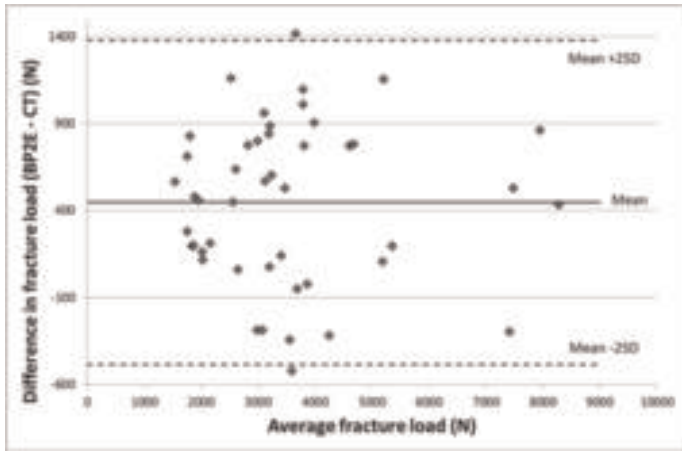
MO0034

Vertebral Fracture Load Predicted with Finite Element Model from Bi-planar X-rays Absorptiometry for Osteoporosis Assessment. Julie Choisne*[1], Christophe Travert[1], Jean-Marc Valiadis[2], Anabela Darbon[3], Philippe Rouch[2], Wafa Skalli[1]. [1]Arts et Metiers ParisTech, France, [2]Arts et Metiers ParisTech, LBM, France, [3]EOS imaging, France

Finite element models (FEM) derived from QCT-scans were developed to evaluate vertebral strength, and fracture load. However, the high dose, time and cost of CT-scanner are limitations for routine osteoporotic diagnosis. A new approach considers using bi-planar dual energy (BP2E) X-rays absorptiometry to build vertebral FEM using synchronized lateral and frontal radiographs. A previous pilot study showed the feasibility of estimation of the 3D bone mineral density (BMD) distribution within vertebrae using a BP2E model from EOS radiographs. The purpose of this study was to confirm the predictability of the vertebral fracture load calculated from a BP2E-based FEM compared to a QCT-scan based FEM which is considered as a gold standard.

Eighteen vertebrae were used for the pilot study and were QCT scanned with a mindway calibration phantom. In addition, 28 vertebrae were scanned with the European Spine Phantom (ESP). All the forty six lumbar vertebrae (8 women and 5 men, donor age 83 $\pm$9 years) were imaged in BP2E using the EOS imaging dual energy prototype device along with the ESP phantom for bone mineral density calibration. In the QCT-based FEM, the geometry was obtained by segmentation of the QCT-scan slices, and material properties were assigned to each element of the mesh according to the BMD value measured in the corresponding voxels of the calibrated QCT-scans. In the BP2E based FEM, the geometry was reconstructed in 3D using bi-planar EOS images acquired simultaneously in the frontal and sagittal planes. First a generic BMD distribution is applied to this geometry from an independent vertebral model database, and then each element's BMD values are adjusted to fit the BMD value measured in the lateral dual energy image. Vertebral fracture load prediction from the BP2E based FEM and the CT scan based FEM were compared.

The average vertebral fracture load was 3321N $\pm$1657 and 4030N $\pm$1728 for the QCT scan based FEM and BP2E based FEM respectively with a root mean square error of 641N. The coefficient of determination was 0.92 with a standard error of the estimate of 461N in fracture load prediction from the BP2E model.With a Pearson's correlation of 0.96, the bi-planar dual energy X-rays absorptiometry model appears to be a good alternative to QCT FEM. With its fast acquisition and analysis time, this low-dose technique could be used in routine clinic for osteoporotic fracture risk assessment after *in vitro* and *in vivo* validation.



Bland Altman plot of the differences in vertebral fracture load prediction between the 2 models

Differences in Bone Microarchitecture and the Degree of Bone Loss during Hindlimb Unloading between C57BL/6J and C57BL/6N Mice. Jeyantt Srinivas Sankaran*[1], Alyssa Tuthill[2], Leah Rae Donahue[3], Stefan Judex[1]. [1]Stony Brook University, USA, [2]Stony Brook University, USA, [3]Jackson Laboratory, USA

Differences in the amount of bone loss induced by unloading can be large between inbred strains of mice. While environmental factors may account for some differences, genetic variability is a principal determinant of bone's sensitivity to unloading. C57BL/6 knockout (KO) mice are often used to investigate gene-effects on the musculoskeletal response to hindlimb unloading (HLU). C57BL/6J (B6J) and C57BL/6N (B6N) are the two main sub-strains used to generate genetic KO. These sub-strains exhibit slight variations in their genome including 34 single nucleotide polymorphisms (SNP) and 2 insertion-deletion (INDELS) in coding regions and 15 gene linked chromosomal structural variations (SV). We recently identified one SNP and one SV as potential modulators of bone's sensitivity to unloading in a genetic linkage study. We therefore hypothesized that B6J and B6N will respond differently to HLU. 9wk old female B6J and B6N mice (n=34) were assigned to baseline control, age matched control and hindlimb unloaded (HLU) groups. Mice were HLU for 2wk and variables indicative of bone quantity and architecture were analyzed by μCT in the distal metaphysis and midshaft of the femur. In the metaphysis, at baseline, B6N mice had 21% lower bone volume (BV), bone volume fraction and 6% lower trabecular number and thickness when compared to B6J mice (all $P<0.05$) while total volume (TV) and connectivity density were similar between strains. The cortical compartment of the metaphysis was similar between the two strains at baseline. In the midshaft, however, cortical bone morphology was different in B6N including a 9%, 10% and 14%, lower cortical thickness, cortical area, and porosity when compared to B6J (all $P<0.01$) while marrow area and the total area remained similar. Upon HLU, tissue losses were similar between B6J and B6N in the trabecular metaphysis and cortical bone in the midshaft. However, cortical bone in the metaphysis of HLU B6N was more susceptible with 18%, 9% and 3% lower BV, TV and marrow volume when compared to its respective controls. In contrast, B6J mice displayed only 15%, 6.5% and 1% reductions in these indices (Gene*HLU, all $P<0.05$). These data show complex differences in trabecular architecture and its response to unloading between B6N and B6J mice. Together, they highlight the importance of even very subtle genomic differences between inbred sub-strains and emphasize that the genetic background of C57BL/6 knockout mice needs to be selected carefully.

MO0036

Zolendronic Acid Administered Before Disuse Conserves Cancellous Bone Microarchitecture by Suppressing Turnover. Corinne Metzger*[1], Michael Junior[1], Ramon Boudreaux[1], Jacqueline Perticone[1], Harry Hogan[2], Susan Bloomfield[3]. [1]Texas A&M University, USA, [2]Texas A&M University, USA, [3]Texas A&M University, USA

Periods of disuse such as bed-rest, injury, or long-duration spaceflight induce rapid bone loss, especially in cancellous compartments. Through independent mechanisms, bisphosphonates and exercise can mitigate bone loss due to disuse. However, our group's previous data demonstrated that a bisphosphonate blunted the anabolic effect of exercise on bone during rodent hindlimb unloading (HU). The goal of this study was to quantify the effects of simulated exercise [impact loading (IL)] and a single administration of Zoledronic acid (ZA) immediately prior to a period of disuse. We hypothesized this novel sequential pre-treatment would better protect against disuse-induced cancellous bone loss than either treatment alone. Male Sprague Dawley rats (6 mo.) were block assigned by weight to cage control (CC), hindlimb unloading without any pre-treatment (HU), 5 weeks of IL prior to HU (IL+HU), ZA administration prior to HU (ZA+HU), and IL plus ZA prior to HU (IL+ZA+HU). IL consisted of 25 high-impact, free fall drops from 60 cm per session 3x/week. A single dose of ZA (60 μg/kg) was given immediately following IL and just prior to 28 days of HU. Standard histomorphometry at the proximal tibia metaphysis revealed that ZA treated HU groups had greater cancellous bone mass (BV/TV %), higher trabecular number, and lower trabecular separation than both non-ZA treated HU groups ($p<0.05$). Osteoclast surface increased 2-fold in HU compared to CC, but was 4-fold lower with ZA treated groups vs. HU ($p<0.001$); IL alone mildly reduced osteoclast surface compared to HU (47% lower, $p<0.05$). IL mitigated the HU-induced increase in serum TRAcP 5b, but ZA treatment exhibited the lowest TRAcP 5b values of all groups – 5-fold lower than HU alone ($p<0.05$). Serum TRAcP 5b and osteoclast surface were positively correlated ($R^2 = 0.58$). Bone formation rate was 2-fold lower in HU vs. CC and ZA treated groups were significantly lower compared to HU and IL+HU. In conclusion, we found pre-treatment with IL improved measures of osteoclast activity compared to HU, but did not maintain optimal microarchitecture. ZA prior to a period of disuse successfully preserved cancellous micro-architecture while suppressing overall bone turnover. There was no synergistic effect of IL and ZA pre-treatments. ZA appears to be a potent inhibitor of disuse-induced bone loss and may be a valuable pre-treatment in clinical populations to mitigate the detrimental impact of prolonged periods of bed rest.

MO0037

A comprehensive study of long-term skeletal changes after spinal cord injury in adult rats. Tiao Lin*[1], Wei Tong[2], Abhishek Chandra[1], Shao-Yun Hsu[3], Haoruo Jia[4], Wei-Ju Tseng[1], Ji Zhu[5], Xiaowei Liu[1], Dongming Sun[3], Wise Young[3], Ling Qin[1]. [1]University of Pennsylvania, USA, [2]Perelman school of medicine, USA, [3]Rutgers, The State University of New Jersey, USA, [4]University of Pennsylvania, USA, [5]University of Pennsylvania, School of Medicine, USA

Rapid bone loss in low extremities after spinal cord injury (SCI) represents one of the most severe forms of osteoporosis. Almost all previous rodent studies have examined bone damage at the acute SCI stage in adolescent rodents. To mimic the clinical scenario that SCI patients are normally adults and to search for possible remedy, we performed a comprehensive analysis of long-term structural and mechanical changes in axial and appendicular bones in skeletally mature rats with or without olfactory ensheathing glia (OEG) transplantation, a treatment accelerating axonal regeneration in the central nerve system. Four-month old Fischer 344 male rats received a spinal cord contusion injury at T13 were divided into two groups (n=5/group) injected with either vehicle or OEG cells (400,000/rat). Four months later, femurs, tibiae, humeri, L4 and T8 vertebrae, were collected from these SCI rats and age-matched uninjured controls (n=6) for microCT, micro-finite element, and histomorphology analyses. We found extreme losses of bone mass (65%) and mechanical competence (90%), accompanied by reductions in trabecular number (36%) and thickness (26%) and an increase in structure model index (SMI, 3.9-fold), in the metaphysis of sublesional bones, particularly distal femur and proximal tibia, in SCI rats compared to controls. Interestingly, the subchondral trabecular bone had a much milder bone loss (20%) and structural deterioration, implying that the mechanism for SCI-induced trabecular bone loss is site-specific even within the same bone. In contrast, SCI mildly affected supralesional humeri with only a trend of trabecular bone loss. In regards to axial bones, significant decreases in bone mass and strength were observed in both superlesional T8 and sublesional L4 vertebrates with more severer bone damage in L4. Histomorphometry revealed that SCI resulted in a 71% decrease in osteoblast number and a 3.7-fold increase in osteoclast number, which were consistent with changes in serum bone markers. OEG treatment did not significantly improve bone structure and mechanical property after SCI. In conclusion, our data revealed site-specific effects of SCI on bone and demonstrated sustained inhibition of bone formation and elevation of bone resorption at the chronic stage of SCI. Hence, bone anabolic agents that greatly stimulate new bone formation should be suitable treatments for long-term SCI-induced osteoporosis.

MO0038

Age-related calcification may increase the stiffness of costal cartilage. Dennis Anderson*[1], Daniel Brooks[2], Alexander Bruno[3], Mary Bouxsein[4]. [1]Beth Israel Deaconess Medical Center, USA, [2]Beth Israel Deaconess Medical Center, USA, [3]Harvard-MIT, USA, [4]Beth Israel Deaconess Medical Center, Harvard Medical School, USA

The mechanical properties of costal cartilage, which connects the bony ribs to the sternum, have not been well studied. Age-related changes may alter mechanical properties. In particular, calcification within the cartilage is known to increase with age. We hypothesized that larger amounts of calcification would increase the measured bending modulus of costal cartilage. We tested 12 fresh frozen human cadaveric costal cartilage from 5 donors (2 men, 3 women, age range 47 – 93 years).

Cartilages were from left ribs 3 – 6, and were potted at each end in polymethylmethacrylate cement, and mechanically tested in a four-point bending configuration with the posterior side up. Images were taken during testing and analyzed to determine the curvature of the specimen. Specimens also underwent pQCT scans to determine cross-sectional geometry and quantify the amount of calcification in each specimen. Bending modulus for each specimen was calculated, and correlated with amount of calcification. Mean bending modulus was 121 ± 111 MPa, and mean amount of calcification was 15.0 ± 13.9%. Modulus was positively correlated with amount of calcification ($r = 0.61$, $p = 0.035$). This indicates that cartilage stiffness is affected by calcification in the cartilage, a known age-related change, which may result in altered thoracic biomechanics.

Alterations in vertebral endplate microarchitecture and adjacent disc health in the UCD-T2DM rat model of type 2 diabetes. Aaron Fields*[1], Britta Berg-Johansen[2], Lionel Metz[2], James Graham[3], Kimber Stanhope[3], Peter Havel[3], Jeffrey Lotz[2]. [1]University of California, San Francisco, USA, [2]University of California, San Francisco, USA, [3]University of California, Davis, USA

Type 2 diabetes adversely affects many tissues, and the greater incidence of intervertebral disc pathologies among diabetics suggests that the disc is affected too. Although diabetes-related complications in the disc may relate to the increased accumulation of advanced glycation end products (AGEs) with hyperglycemia, hyperinsulinemia could also be important. For example, increased insulin levels during the pre-diabetic state can have an anabolic effect on bone metabolism. Any increases in bone formation in the vertebral endplate, i.e. sclerosis, could negatively impact disc health since the disc is avascular and thus, sclerosis could hinder nutrient transport to the disc. The purpose of this study was to test the hypothesis that T2DM compromises disc health, and that these changes associate with diminished endplate microarchitecture and with increased AGE accumulation. Caudal motion segments were harvested from 6-month-old lean Sprague Dawley rats, non-diabetic obese Sprague Dawley rats, and diabetic obese UCD-T2DM rats (diabetic for 69 ± 7 days; $n = 6$ rats/group). At sacrifice, the obese diabetic and non-diabetic rats had significantly higher insulin levels than age-matched controls (Table). Diabetic rats also had substantially higher glucose and HbA1c concentrations. Diabetes but not obesity caused dramatic changes in disc composition that were consistent with the early stages of degeneration. Diabetes reduced disc nucleus glycosaminoglycan (GAG) content by 51% ($p < 0.005$) and water content by 12% ($p < 0.005$); these degenerative changes correlated with a 21% increase in endplate thickness and 41% decrease in endplate porosity (Figure 1). GAG content decreased with increasing endplate thickness ($r = -0.56$, $p = 0.02$) and with decreasing endplate porosity ($r = 0.47$, $p = 0.05$). Also, diabetes but not obesity significantly increased AGE concentrations in the disc. In the annulus, AGE concentration was elevated by 50% ($p < 0.001$); in the nucleus, by 140% ($p < 0.0001$). As expected, increased AGE concentrations were independently correlated with lower GAG contents ($r = -0.72$, $p = 0.002$). These findings indicate that in addition to increased AGE levels in the disc, adjacent endplate sclerosis could also be an important factor for explaining the higher incidence of disc pathology in type 2 diabetes.

Table 1: Body weight, glucose, insulin, and HbA1c data (mean ± SEM) for 6-month-old lean Sprague Dawley (SD), obese SD, and UCD-T2DM rats.

	Lean SD ($n = 5$ rats)	Obese SD ($n = 6$ rats)	UCD-T2DM ($n = 6$ rats)
Diabetes duration (days)	NA	NA	69 ± 7
Body weight (g)	426.0 ± 12.1	693.7 ± 29.0[a]	563.5 ± 18.9[c,d]
Non-fasting glucose (mg/dl)	112.2 ± 3.4	112.2 ± 4.7	546.2 ± 18.5[a,b]
Fasting glucose (mg/dl)	91.8 ± 3.2	98.7 ± 2.8	246.4 ± 52.6[c,d]
Fasting insulin (ng/ml)	0.6 ± 0.07	1.4 ± 0.2[c]	1.4 ± 0.3[c]
HbA1c (%)	4.5 ± 0.09	4.3 ± 0.06	11.8 ± 1.28[a,b]

ANOVA w/ Tukey-Kramer test; [a] $p < 0.0001$ vs. lean SD; [b] $p < 0.0001$ vs. obese SD; [c] $p < 0.05$ vs. lean SD; [d] $p < 0.05$ vs. obese SD

Differential effects of strontium ranelate on bone microarchitecture in vivo and osteogenic differentiation in vitro - role of vitamin D. Claudia Sedlinsky*[1], Juan Manuel Fernandez[2], María Silvina Molinuevo[2], León Schurman[2], Ana María Cortizo[2], Anthony Desmond McCarthy[2]. [1]Universidad Nacional de La Plata, La PlataHospital Cesar Milstein, Buenos Aires, Argentina, [2]LIOMM, Universidad Nacional de La Plata, Argentina

Advanced glycation end products (AGEs) are increased in diabetes, and this has been associated with bone fragility and vascular calcifications. Strontium ranelate (SrRan) has been approved in several countries as a therapeutical option for osteoporosis treatment. We evaluated the effects of SrRan on bone microarchitecture in diabetic rats, and of SrRan and/or 25-OH-vitamin D (VD) on the osteogenic potential of vascular smooth muscle cells (VSMC). Diabetic Sprague Dawley rats were either untreated (D) or treated with 625 mg/kg/day SrRan (DR). Untreated non-diabetic rats (C) were also evaluated. Femora were dissected for histologic examination. VSMC were isolated from the aorta of C rats, and incubated with 100 µg/ml of either bovine serum albumin (BSA) or AGEs-BSA, in the presence or absence of 100 µM SrRan and/or 70 ng/ml VD. Cell proliferation (MTT bioassay) and cell migration (wound assay) were assessed. VSMC were also cultured in an osteogenic medium, after which collagen production, mineral nodules, Runx-2 and alpha-actin were determined. Results: bone histology was altered in D group (trabecular area: 71% vs. C, $p<0.01$; osteocytes: 69% vs. C, $p<0.01$; marrow adiposity: 1339% vs. C, $p<0.001$); SrRan significantly prevented Diabetes-induced trabecular area loss ($p<0.01$) and bone marrow adiposity ($p<0.05$). SrRan increased VSMC proliferation and migration (125% and 150% vs. BSA respectively, $p<0.01$), as did incubation with AGEs (130% and 150% vs. BSA respectively, $p<0.01$). Co-incubation with SrRan and AGEs showed an additive effect on proliferation: 160% vs. BSA and migration: 200% vs. BSA, $p<0.01$). After osteogenic induction of VSMC, the presence of SrRan and/or AGEs increased collagen and mineral vs. BSA in an additive manner ($p<0.01$). SrRan and AGEs also increased the Runx2/alpha-actin ratio (180% and 250% vs. BSA, respectively, $p<0.01$). Co-incubation with physiological levels of VD abolished all the effects of SrRan and/or AGEs on VSMC *in vitro*. In conclusion, our *in vivo* results show that SrRan treatment may prevent diabetic bone disease by improving trabecular microarchitecture and decreasing bone marrow adiposity. Our *in vitro* results show that SrRan may promote VSMC proliferation, migration and osteoblastic trans-differentiation, particularly in the context of diabetic AGEs accumulation. Nevertheless, these effects can be prevented by physiological levels of VD. Our *in vitro* results remain to be confirmed in a diabetic animal model.

Effects of Single vs. Hypofractionated Focused Radiation Therapy on Vertebral Structure and Biomechanical Integrity. Christina Holmes*[1], Ioan Lina[2], Jason A Liauw[2], Sheng-fu Larry Lo[2], Annie Mao[2], Matthew Naumann[2], Debebe Theodros[2], Varun Puvanesarajah[2], Benjamin Elder[2], Timothy F Witham[2]. [1]Johns Hopkins School of Medicine, USA, [2]Johns Hopkins School of Medicine, USA

Stereotactic radiosurgery has shown great promise in the treatment of metastatic lesions within the spine. However, recent clinical studies have indicated that the procedure may increase the risk of developing vertebral compression fractions, particularly in osteoporotic patients [1, 2]. There is thus a critical need for research examining the effects of focused radiation on bone quality and mechanical properties. We have developed a rabbit model which enables the analysis of the effects of focused radiation on vertebral osteonecrosis, structure and biomechanical integrity. Using this model we are testing the hypothesis that fractionation of radiation dosing can reduce radiation osteonecrosis and preserve structural and biomechanical integrity of the spine.

The L5 vertebral body of New Zealand White (NZW) rabbits was treated, under computerized tomography (CT) guidance, with either a single 24 Gy dose of radiation or three fractionated doses over three days of 8 Gy radiation via the small animal radiation research platform (SARRP) [3]. Effects of radiation treatment on L2, L4, L5 and L6 vertebral osteonecrosis, structure and biomechanical integrity were evaluated 6 months post-irradiation via high-resolution CT-imaging, histology, and non-destructive biomechanical compression testing and compared to non-irradiated controls. Vertebral bone volume over total volume (BV/TV), trabecular thickness (Tb.Th.) and trabecular spacing (TB.Sp) were evaluated from CT images via the BoneJ plugin (4) of ImageJ software (NIH, Bethesda, MD).

Preliminary data suggests that the L5 vertebra from rabbits that underwent single-dose irradiation exhibits osteopenia, as indicated by decreased BV/TV and Tb.Th and increased Tb.Sp, compared to both non-irradiated controls and rabbits who received hypofractionated radiation. Whether these changes in bone morphology translate into reduced mechanical integrity is currently under analysis. Future work will utilize this rabbit focused irradiation model to evaluate the efficacy of various therapies, such as teriparatide (PTH (1-34)), in the prevention of radiation induced osteonecrosis.

New Approach to Analysis of Bone Loss Patterns in Longitudinal Studies. Tomas Cervinka*[1], Harri Sievanen[2], Jörn Rittweger[3], Jari Hyttinen[4]. [1]Tampere University of Technology, Finland, [2]The UKK Institute for Health Promotion Research, Finland, [3]Institute of Aerospace Medicine, German Aerospace Center, Germany, [4]Department of Electronics & Communications Engineering, Tampere University of Technology, Finland

The aim of this study was to perform a robust and threshold-free analysis of pQCT-measured traits in the same bone cross-sectional areas. The analysis employed recently developed segmentation algorithm, called OBS, and a fast rigid image registration on longitudinal pQCT data. More specifically, we addressed whether our analysis approach would reveal changes that remained masked in conventional analysis.

In this study, we reanalysed pQCT image data from control group of the 56-day 1st Berlin Bed Rest study (N = 10) that was carried out in Berlin/Germany in 2003 and 2004. The analysed images were obtained from the left leg at the 4% distal site of the tibia. The pixel size of the pQCT images was 0.5 x 0.5 mm and the slice thickness was 2.5 mm. For each participant, the raw data from the first baseline pQCT image was used for the determination of an individual reference template for the cortical cross-sectional area (CoA). The reference template was made with use of OBS method that accurately detected CoA and an additional enlargement of detected CoA to compensate possible small alignment differences between the baseline and follow-up images. In order to determine changes in cortical and trabecular bone mass within the same cross-sectional area through the study, the reference template was applied to all follow-up images of the given participant. As descriptive statistics, the means and standard error of the mean (SEM) of relative changes of bone mineral content (BMC) in the cortical and trabecular area are given.

The novel analysis approach revealed that cortical and trabecular bone loss might have different time responses to the immobilization (Figure 1). While bone loss in the trabecular compartment linearly increases, the cortical loss seems to be more sudden. In addition, in contrast with previously published results, this approach suggests that magnitude of bone loss in both cortical and trabecular compartments is similar at the end of immobilization. However, at the onset of a recovery period, the cortical loss continues with the same rate and exceeds the trabecular loss by ~2%.In conclusion, in this study we demonstrated that OBS method in conjunction with image registration procedure is a promising approach for analysis of longitudinal bone studies and newly opened question whether bone loss induced by immobilization is more pronounced in the cortical or trabecular compartment.

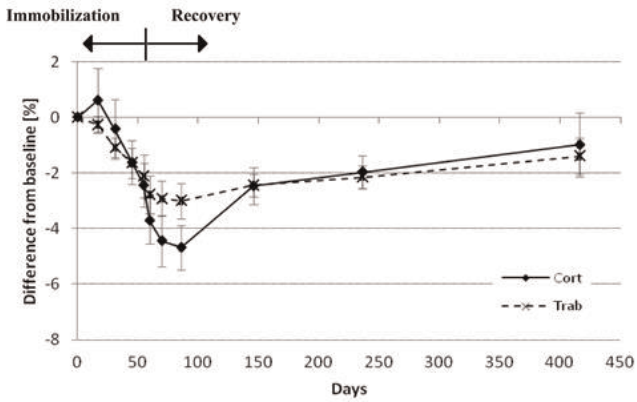

Figure 1: Assessment of the distribution of relative bone losses in the cortical and trabecular compartments of distal tibia. Values are given as the differences from baseline and SEM

The Effect of a High Resolution Flat Panel Detector on a Single X-Ray Absorptiometry (SEXA) system versus the Lower Resolution Detector on a Dual X-ray Absorptiometry (DEXA) system in-vitro in the Calculation of Mouse Bone Mineral Density (BMD). Chester Lowe*[1], Li Sun[2], Jianhua Li[3]. [1]KUB Technologies, Inc, USA, [2]Mount Sinai School of Medicine, USA, [3]Tount Sinai School of Medicine, USA

OBJECTIVE: To evaluate the effect of a high resolution detector on the efficacy and accuracy of mouse bone mineral density (BMD) measurements utilizing a single-energy absorptiometry (SEXA) system versus a lower resolution detector Dual X-ray Absorptiometry (DEXA) system in vivo.

Methods: (1) The coefficients of variation (CV) for BMD measurements at various skeletal regions were repeatedly determined by DEXA and SEXA in a preliminary study of mice and were analyzed on both a DEXA machine and a SEXA machine equipped with high resolution flat panel detector. (2) Identical Regions of Interest, Lumbar Region L3-L5, Lumbar Region >L6, both sides of femurs and tibias, were visualized and the BMD calculated on both the SEXA and DEXA machines. And (3) resultant calculations were compared.

Results: (1) The CVs of the preliminary BMD measurements in different regions of mice weighing between 17.4 grams to 38.5 grams by SEXA calculations versus the DEXA calculations were as follows, 99.88% for lumbar vertebra (L3-L5), 100.13% for lumbar vertebra >L6, 99.91% for left femur, 99.08% for right femur, 99.40% for left tibia, and 99.42% right tibia, respectively. (2) The mean BMD values of the 25 mice were (51.1 +/- 8.2 SEXA; 50.7 +/- 7.0 DEXA) mg/cm2 in lumbar vertebra L3-L5, (51.0 +/- 13 SEXA; 50.2 +/- 11.2 DEXA) mg/cm2 in lumbar vertebra >L6 , (66.8 +/- 12.5 SEXA; 63.5 +/- 16.9 DEXA) mg/cm2 in left femur and (57.3 +/- 14.8 SEXA; 57.1+/- 14.5 DEXA;) mg/cm2 in right femur, (41.9 +/- 8.4 SEXA; 42.7 +/- 10.4 DEXA) mg/cm2 in left tibia and (37.2+/- 8.5 SEXA; 39.8+/- 8.2 DEXA;) mg/cm2 in right tibia, respectively., (3) The BMD values calculated and recorded were consistent

between the SEXA and DEXA unit on the ROIs selected with variations between the 2 techniques being accounted for by the higher resolution and the 16-bit output of the SEXA detector versus the lower resolution and 8-bit output of the DEXA unit.

DISCUSSION: Measurement of MOUSE BMD in vitro by a system utilizing a higher resolution detector and SEXA is a useful method, it can produce repeatable results, and it can reflect the changes in mouse bone masses with good precision and as accurately as can the tried and true low resolution detector system utilizing DEXA.

SIGNIFICANCE: The Kubtec DIGICOM BMD calculates BMD utilizing a high resolution flat panel detector and Single X-ray Absorptiometry (SEXA), where only a short single exposure of the subject, thereby reducing radiation exposure, and from the resultant image the X-ray absorption in the bone is used for determining the BMD of the bone.

ACKNOWLEDGEMENTS: I would like to acknowledge the help of Li Sun, M.D. Ph.D. and Jianhua Li – Mt Sinai Medical Center Division of Endocrinology, Diabetes & Bone Disease Department of Medicine with the collection of my data.

The Role of Osteocalcin Carboxylation on Bone Fragility. Timothy Cleland*[1], Caren Gundberg[2], Deepak Vashishth[1]. [1]Rensselaer Polytechnic Institute, USA, [2]Yale University School of Medicine, USA

Recently, osteocalcin (OC) has been shown to play an integral role in the mechanical properties of bone based on differences in toughness between wild type and osteocalcin knockout mice models. However, the full knockout of this protein does not provide evidence for the effect of OC carboxylation level on bone mechanical properties. This may be especially important in humans where the levels of carboxylation in bone have been shown to be variable likely due to long-term variations in vitamin K nutrition (Cairnes and Price, 1994 JBMR). The variation in carboxylation may provide lesser affinity of OC for the mineral and thereby lead to a change in the organic-inorganic interface and the resulting mechanical properties of bone.

Tibiae from six donors (48M, 68M, 82M, 44F, 62F, 81F) were used to extract bone osteocalcin and measure bone toughness. Extracted osteocalcin was further digested using trypsin to analyze the variation in carboxylation by mass spectrometry. Carboxylation shows a +44 Da mass shift between the undercarboxylated and carboxylated peptides, allowing for direct quantification of carboxylation level (Fig. 1).

Using newly developed sample preparation and mass spectrometry methodology, we have evaluated the levels of OC carboxylation from donor bone of varying age and sex. Through this study, we found that bone fragility increases (toughness values decrease from 0.6 to 0.1) with age and this fragility increase is accompanied by variation in carboxylation level. For example, we found that the first carboxyglutamic acid (Gla) residue is only 23% carboxylated in the 48M (Fig. 1).

Biomechanical Analyses of Bone Tissue Damage from Fatigue Loading *In Vivo*. Mohammed Akhter*[1], Diane Cullen[2], John Danforth[3], Gwendolin Alvarez[2], Bryan Hackfort[2], Robert Recker[2]. [1]Creighton University Osteoporosis Research Center, USA, [2]Creighton University, USA, [3]Creighton University, USA

It is hypothesized that fatigue loading-related micro damage is responsible for bone tissue inflammation response and subsequent targeted remodeling. Rat ulna model was used to induce micro damage using a fatigue loading technique in vivo. We present biomechanical analyses of fatigue loading to reduce ulnar strength/stiffness by 40%. Six-month-old, retired breeder (Sprague Dawley, n=12) female rats were used. Right ulna of each rat was fatigue loaded in vivo in compression at 4 Hz until the ulnar stiffness declined by 40%, which is an indication of structural damage. During this in vivo loading the lateral ulnar surface was in tension, the medial surface in compression. After the completion of fatigue loading, rats were euthanized. Both left (contra lateral control) and right (loaded) mid-shaft ulnae were scanned at 6 micron resolution using microCT (Scanco) to investigate presence of damage in the loaded ulnae. This is an ongoing work and will be pursued at even submicron level with the new MicroXCT-200. The data suggest that at 15N and 20N compression loads, the induced average surface strain in the mid-shaft (medial side) region was 3000 and 4000 microstrain (um) respectively. Most of the ulnae reached 40% stiffness decline by an average of 20,000 fatigue cycles. Initial ulnar stiffness (@1000 cycles) at the start of the actual fatigue loading and final stiffness (@ 22,600 cycles) for one rat is shown in Figure 1. Mid-shaft ulna (right loaded) shows an ~18 micron deep microcrack along the lateral region of the cross section (Figure 2). These biomechanical data are important to understand the bone response with respect to signaling molecules in blood and bone tissue resulting from fatigue damage in vivo. These data will be helpful in understanding the mechanism of fatigue-related damage that results in significant strength/stiffness decline. This work will help characterize the relationship between the magnitude of microdamage and stiffness decline in bone tissue. The current work in this animal model is highly applicable to humans in understanding targeted bone remodeling resulting from excessive skeletal loading/exercise.

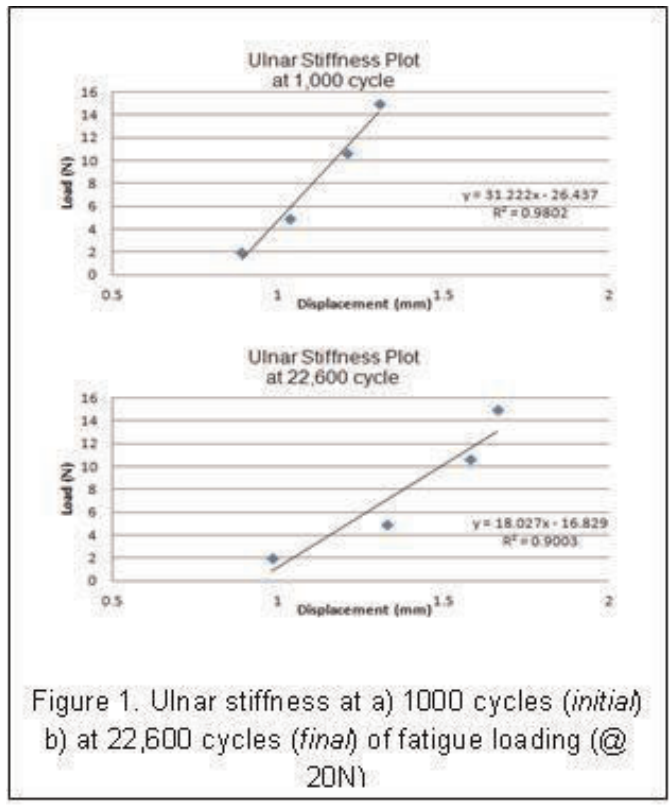

Figure 1. Ulnar stiffness at a) 1000 cycles (*initial*) b) at 22,600 cycles (*final*) of fatigue loading (@ 20N)

Figure-1

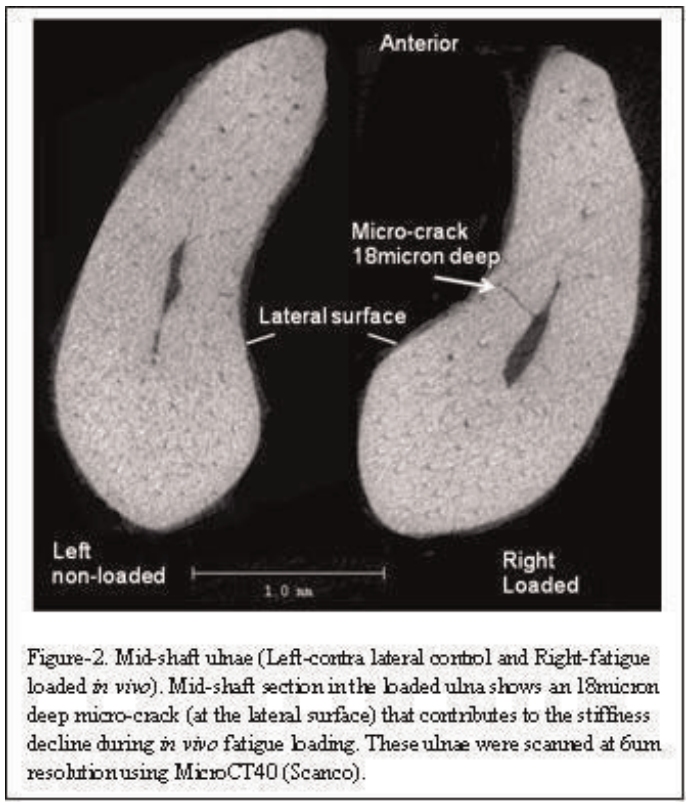

Figure-2. Mid-shaft ulnae (Left-contra lateral control and Right-fatigue loaded *in vivo*). Mid-shaft section in the loaded ulna shows an 18micron deep micro-crack (at the lateral surface) that contributes to the stiffness decline during *in vivo* fatigue loading. These ulnae were scanned at 6um resolution using MicroCT40 (Scanco).

MO0046

Cyclooxygenase Response to Multiple Mechanical Loads. Bryan Hackfort*[1], Mohammed Akhter[2], Diane Cullen[1]. [1]Creighton University, USA, [2]Creighton University Osteoporosis Research Center, USA

Cox-2 inhibitors are used for daily treatment of arthritis and chronic pain. Cox-2 inhibition blocks the bone formation response to a single mechanical load, but not to multiple loads. We hypothesized that Cox-1 is up-regulated in response to mechanical loading under chronic Cox-2 inhibition. Immunohistochemistry (IHC) was used to visualize Cox expression after loading. The right tibia of C57Bl6 mice (N = 7/grp) were loaded in compression (360 cycles, 2 Hz, 1450 ??) either 1 time and collected 1, 6, or 12 hrs post loading or loaded 1, 2, or 3 times and collected 24 hours post load. Bones were fixed in 4% paraformaldehyde, decalcified, and paraffin embedded. Sections were cut 3 mm proximal to the tibia-fibula junction and stained for Cox-1 or Cox-2. Sections were quantified for percent positive periosteal and endocortical perimeter and positive osteocyte density. We used qPCR to investigate the PTGS (Cox) gene response to load with vehicle and Cox-2 inhibition over time. Tibias were loaded in compression (100 cycles, 2 Hz, 1450 ??) 3 d/wk and groups (N = 10) were collected after 1, 5, and 10 loads. Cox-2 inhibitor (NS-398) or control (DMSO) was given daily (3 hrs prior to load). Tibias from two mice were pooled, dissected of all soft tissue, RNA was extracted and cDNA was obtained for qPCR of PTGS1 (Cox-1), PTGS2 (Cox-2) and GAPDH (control). Loading did not increase Cox-1 or Cox-2 positive osteocytes. Cox-1 and Cox-2 periosteal expression were similar (2%) but Cox-2 endocortical expression was two-fold greater than Cox-1 (8.8 vs 4.1%). Cox-1 positive periosteal and endocortical surface increased with time and load, the greatest expression occurred after day 3 ($P < 0.05$). Cox-2 positive periosteal label was increased at 12 and 48 hours ($P < 0.03$) after the first load. Neither PTGS1 nor PTGS2 mRNA differed with number of days loaded. PTGS1 increased 1.5 fold in vehicle versus no increase with NS398. PTGS2 increased 2.0 fold ($P < 0.03$) after loading in NS398 and DMSO groups. In conclusion, periosteal cells increased Cox-1 expression after 3 loads while endocortical cells increased both Cox-1 and Cox-2. Loading did not increase Cox-1 or Cox-2 osteocyte staining with up to 3 days of loading. PTGS1 mRNA was up-regulated after loading in cortical bone of only the vehicle group. PTGS2 increased similarly in both groups in response to loading. Given these results, we reject our hypothesis since Cox 1 did not increase with Cox-2 inhibition.

MO0047

Mechanical Loading as an Anabolic Stimulus After Exposure to Ionizing Radiation. Yasaman Shirazi-Fard*[1], Joshua Alwood[1], Alesha Castillo[2], Ruth Globus[1]. [1]NASA Ames Research Center, USA, [2]VA Palo Alto Health Care System, USA

Long-term spaceflight leads to extensive changes in the musculoskeletal system attributable, in large part, to unloading during microgravity exposure. Additionally, irradiation at doses similar to those of solar particle events or a round-trip sojourn to Mars (1-2 Gy) may cause significant depletion of stem/progenitor cell pools throughout the body as well as skeletal tissue degradation. Previously, we demonstrated that irradiation leads to rapid bone loss as a function of cumulative dose. Exposure to 50 or 200 cGy of high Z, high energy (LET) 56Fe (600-100MeV, 50-100cGy/min) can cause significant bone loss 30 days after irradiation and progressive bone loss continues even after 180 days. Ex vivo culture to assess growth and terminal differentiation of osteoblast lineage cells shows that 56Fe exposure impairs osteoblastogenesis and causes persistent defects in progenitor and stem cells. We hypothesized that heavy ion radiation damages skeletal tissue despite a prolonged recovery period and depletes the ability of osteoblasts to respond to anabolic stimuli. Male, 16-week old, C57BL6/J mice were exposed to 0 (sham) or 200 cGy 56Fe total body irradiation at NASA Space Radiation Laboratory/Brookhaven National Lab. We used the axial loading model for anabolic stimulation of the tibia 5 months post-irradiation, where %Bone Volume (BV/TV) was 20% lower in irradiated compared to sham animals. A rest-inserted (10s) prescription was used to load the right tibia (9N in compression, 60cycles/day, 3days/wk, for 4 wks). The left tibia was used as the contralateral control. At the end of the loading period, the cancellous bone microarchitecture was quantified and a 2-factor ANOVA was performed. The data show a main effect of mechanical loading for BV/TV, Trabecular Thickness (Tb.Th), and Trabecular Number (Tb.N.). Microarchitectural parameters for the loaded tibia were normalized to the contralateral control tibia for each animal. The axial loading paradigm increased BV/TV by 41% and 25%, Tb.Th by 17% and 23%, and Tb.N. by 20% and 2% in sham and irradiation groups, respectively. More detailed histomorphometric analyses are in progress to yield further insight. Based on these preliminary results, high LET radiation did not impair ability of the bone to respond to a mechanical anabolic stimulus. Anabolic mechanical stimulation of the skeleton has the potential to mitigate persistent, adverse effects of radiation and improve bone microarchitecture.

MO0048

Tamoxifen does not affect the anabolic response to tibial compression in male mice 3 weeks after initial injection. Heather Zannit*[1], Michael Brodt[2], Matthew Silva[3]. [1]Washington University St. Louis, USA, [2]Washington University in St Louis, USA, [3]Washington University in St. Louis School of Medicine, USA

As the use of reporter mice driven by tamoxifen (TMX) inducible Cre-mediated recombination increases, it is important to evaluate the effects of TMX on the murine skeleton. Our goals were to (1) evaluate how tamoxifen affects bone formation in Osx-Cre-ERT2;mTmG mice, (2) determine if there is a sex-dependent effect, (3) evaluate the effect of recovery time, and (4) determine if TMX persists in the bone.

In each experiment, TMX or vehicle was administered i.p. for 5 consecutive days (3mg/40g BW/day), a protocol shown to turn reporter. In an initial study, the right tibia of 5 month old male and female mice were scanned by in vivo micro-computed tomography (μCT), administered TMX or vehicle, and 26 days later re-scanned and euthanized. We found no interaction of TMX on temporal changes in cortical and trabecular bone morphology (BV, TV, BV/TV, and BMD). In addition, dynamic histomorphometry at the mid-diaphysis revealed no significant effect of TMX on Ps.MS/BS, Ps.MAR, Ps.BFR, Ec.MAR, and Ec.BFR.

Next, to determine if TMX affects loading-induced bone formation, 5 month old male and female mice were administered TMX or vehicle, allowed a 1 or 3 week recovery, and then the right tibia was subjected to axial tibial compression for 1 week (1200 cycles/day; -2200 με peak strain). After a 1 week recovery, both male and female relative Ec.MS/BS were less in the TMX treated group than the in the vehicle treated group (Fig. 1). However, in males after a 3 week recovery period, there was no TMX effect on cortical bone formation indices. In both male TMX and vehicle treated groups with a 3 week recovery, tibial loading increased Ps.MS/BS, Ps.MAR, Ps.BFR, Ec.BFR ($p<0.05$), Ec.MAR, and Ec.MS/BS ($p<0.08$) in the right tibias compared to contralateral controls (Fig. 2).

Finally, to determine the persistence of TMX in the bone, a set of mice were administered TMX, euthanized corresponding to the start of tibial loading, and tibias prepared for mass spectrometry. After a 1 week recovery, the presence of TMX was found in all bones (n=4 of 4), but after 3 weeks, half of the bones had none (n=2 of 4) and half had only trace amounts of TMX (n=2 of 4).

In conclusion, TMX administered in a manner sufficient to turn on reporter expression, did not affect bone structure. Nor did it affect loading induced bone formation of males after a 3 week recovery. This corresponds with a decrease in the presence of TMX in bones after a 3 week recovery as assessed by mass spectrometry.

Human Tibia Bone Strength is Unaffected Following Long-Term Spinal Cord Injury or Bed Rest. Alex Ireland[1], Ricardo Capozza[2], Gustavo Cointry[3], Jose Ferretti*[4], Jorn Rittweger[5]. [1]Manchester Metropolitan University, United Kingdom, [2]Center of P-Ca Metabolism Studies (CEMFoC); National University of Rosario, Argentina, [3]Center of P-Ca Metabolism Studies (CEMFoC); National University of Rosario, Argentina, [4]National University of Rosario, Argentina, [5]Division of Space Physiology, Institute of Aerospace Medicine, German Aerospace Center, Germany

The tibia bears over 80% of compressive loading in the shank in humans (Wang et al, Clin Orthop Rel Res, 1996). Given this high level of habitual loading, it is unsurprisingly highly responsive to disuse. Long-term spinal cord injury is associated with a 60% reduction in tibial bone mass (Eser et al, Bone, 2004), and 90 days' bed rest results in up to 4.4% loss of bone mass dependent on site (Rittweger et al, Bone, 2005). Conversely the fibula contributes to only -6 to +19% of shank compressive force transmission, with greater contributions observed during pronounced foot eversion and plantar flexion (Goh et al, Clin Orthop Rel Res, 1992) and as absolute load increases. However, the influence of disuse on the human fibula has not previously been explored. To investigate fibular response to disuse, re-analysis of two previous pQCT datasets were completed. First, serial scans at 5% increments from 5% to 95% distal-proximal tibia length in 9 long-term spinal cord injury (SCI) patients aged 39.2±6.2y taken 9-32 years post-injury, and in 9 age, height and mass-matched controls were compared. Also, scans taken in 25 young male volunteers aged 33.7±3.7y prior to and 14 days after 90 days of 6° head-down tilt bed rest were examined. No significant differences or group-site interactions in total & cortical BMC, and bone area, cortical vBMD, periosteal and endocortical circumferences and cortical thickness of the fibula were found between SCI patients and controls ($P > 0.16$ for all parameters). In contrast, tibial BMC was 22-51% lower in SCI patients with group-site interactions revealing more pronounced differences in distal and proximal sites as opposed to shaft measures (both $P < 0.001$). There was no effect of bed rest on tibial bone mass, with only fibular trabecular BMD differing significantly (-1.4%, $P = 0.04$) from baseline measures. Tibial analysis revealed significant 0.9%-4.4% lower tibia bone mass following bed rest (all $P < 0.01$). Results suggest that the fibula is affected little by disuse, with diaphyseal sites in particular displaying no effects of reduced physical activity in either SCI or bed rest data. This may be a result of the fibula's comparatively small contribution to load-bearing in the shank. Exercise models involving high compressive shank loads and pronounced eversion and /or plantarflexion may be effective in elucidating substantial exercise response in the fibula.

Evaluation of Bone Density and Muscle Function in Mitochondrial Respiratory Chain Disorders. Anna Middleton*[1], Craig Munns[1], John Christodoulou[2], Hiran Selvadurai[2]. [1]The Children's Hospital at Westmead, Australia, [2]The Children's Hospital at Westmead, Australia

Purpose: Mitochondrial respiratory chain disorders (MRCD) are common inborn errors of metabolism where mitochondria exhibit impaired ability to generate energy. Reduced mobility and physical activity cause a decline in muscle mass and strength over time with resultant disuse osteoporosis. Alterations in bone, biomechanics and physical activity have not been investigated in this population.

Methods: Participants (n=19, 5-65 years) were recruited from one adult and one paediatric tertiary referral hospital. Participants performed a 6 minute walk test (6MWT) and parameters of muscle function (power, force and coordination) using the single two leg jump (S2LJ), multiple one leg jump (M1LJ) and chair rise test (CRT) on the Leonardo Jumping Platform. Bone mineral density (BMD) and bone mineral content (BMC) were assessed using duel energy x-ray absorptiometry (DEXA) of the total body and lumbar spine and peripheral quantitative computed tomography (pQCT) of the tibia at 4% and 66% of the tibial length. One-sample t-tests were used to explore difference from zero in parameters of bone density, biomechanics and physical activity in the MRCD population. Correlations between these parameters were assessed using Pearson Correlations (significance $p<0.05$).

Results: Parameters of muscle mass and function and bone mass and density are significantly altered in MRCD (Table 1). Performance in the S2LJ correlated strongly with BMD measured by DEXA ($r=0.8$, $p<0.00$), BMC ($r=0.7$, $p<0.00$) and muscle CSA ($r=0.5$, $p<0.04$) at the 66% pQCT site and vBMD ($r=0.6$, $p<0.02$) at the 4% site. Cortical vBMD at the 66% site correlated most strongly with M1LJ force ($r=0.7$, $p<0.01$). Distance achieved during the 6MWT showed moderate to strong correlations with parameters of muscle function, especially the time taken to complete the CRT ($r=-0.8$, $p<0.00$).

Conclusions: Muscle and bone parameters are altered in children and adults with MRCD. There is an obvious correlation between physical activity, biomechanics and bone despite the underlying impairments in muscle function. Therapies supporting normal skeletal loading and physical activity may be beneficial in this population.

MO0052

Increasing Bone and Reducing Fat with Modified Capoeira in the Primary School Setting: The CAPO Kids Trial. Rossana Nogueira*[1], Benjamin Weeks[2], Belinda Beck[3]. [1]Griffith University - Gold Coast CampusSchool of Allied Health Sciences, Australia, [2]Griffith University, Australia, [3]Griffith University, Australia

Introduction: The increasing incidence of both chronic bone and obesity-related disease places a heavy burden on health economies. Both conditions may arise in childhood. While exercise in youth is beneficial for both bone and metabolism, the nature of exercise recommendations for each traditionally differs.

Aim: Our goal was to determine the effect of a brief, novel, enjoyable, school-based exercise regimen targeting both bone and fat in primary school children.

Methods: A controlled exercise intervention trial was conducted over a full school year (9 months). The intervention comprised 10 minutes of thrice-weekly capoeira and jumping activities. Anthropometrics, waist circumference (WC), calcaneal broadband ultrasound attenuation (BUA) and stiffness index (SI) (Lunar Achilles, GE), maximum vertical jump (VJ), cardiovascular endurance (predicted VO2 max), resting heart rate (HR), blood pressure (BP) and maturity (YAPHV) were recorded at baseline and 9 months. A subset of whole body (WB), lumbar spine (LS) and femoral neck (FN) BMD, lean and fat mass (DXA, XR800, Norland), and indices of tibial and radial morphology and density (pQCT, XT3000, Stratec) was also collected. Changes in outcome variables were compared between groups using two-way ANOVA,

controlling for YAPHV and initial values. Stepwise linear regression were performed to determine the relationships between bone parameters.

Results: 296 children, including 130 control (CON) (10.7 ± 0.6yo; YAPHV -1.9 ± 0.9y) and 166 treatment (EX) (10.5 ± 0.5yo, YAPHV -2.1 ± 0.9y) participated. EX improved WC (EX: 1.95 ± 2.82 cm; CON: 4.09 ± 4.05 cm; p = 0.001), HR (EX: -4.11 ± 3.35 BPM; CON: 0.22 ± 3.8 BPM; p = 0.001), VJ (EX: 3.47 ± 4.01; CON: -0.59 ± 5.16; p = 0.001), predicted VO2 max (EX: 2.68 ± 3.96; CON: -0.20 ± 3.38 ml/kg/min; p = 0.001), SI (EX: 6.25 ± 10.04%; CON: 4.09 ± 6.99%; p = 0.05) and BUA (EX: 3.99 ± 9.06 dB/MHz; CON: 1.33 ± 8.3 dB/MHz; p = 0.01) compared to control. Sex-specific effects largely mirrored those findings. Baseline BUA and maturity predicted 32.2% of the variance in BUA change (p = 0.001) for boys; while BMI and baseline BUA accounted for 16.4% of the variance in BUA change (p = 0.006) for girls.

Conclusion: School-based capoeira with jumping improved markers of metabolic and musculoskeletal health in primary school children. The exercise program was safe, enjoyable and easily incorporated into the school schedule.

MO0053

Individually Tailored Rehabilitation Regimen Did Not Prevent Tibial Bone Weakening Following Hip Fracture in Elderly Patients. Leg Bone Structural Analysis of a 12-Month Randomized Controlled Intervention. Ari Heinonen*[1], Tuuli Suominen[2], Tapio Senne[3], Johanna Edgren[3], Anu Salpakoski[3], Maija Pesola[4], Maria Arkela[5], Markku Kauppinen[3], Mauri Kallinen[6], Sarianna Sipilä[3]. [1]Department of Health Sciences, University of Jyväskylä, Finland, [2]Gerontology Research Center, Department of Health Sciences, University of Jyväskylä, Finland, [3]Gerontology Research Center Department of Health Sciences, University of Jyväskylä, Finland, [4]Department of Ortopedic, Central Finland Central Hospital, Finland, [5]Department of Physical & Rehabilitation Medicine, Central Finland Central Hospital, Finland, [6]Department of Medical Rehabilitation, Oulu University Hospital, Finland

The purpose of this study was to examine the effects of a home-based rehabilitation program on leg bone traits in elderly hip fracture patients. Population-based clinical sample of men and women operated for hip fracture (n=81, mean age 80 years, 78% women) were randomly assigned into a control (Standard Care, n=41) and an intervention (n=40) groups on average 70 (SD 28) days after discharged to home. The year-long intervention included an evaluation and modification of environmental hazards, guidance for safe walking, non-pharmacological pain management, progressive home exercise program, physical activity counseling and Standard Care. Distal tibia compressive strength (BSId, mm^3), total density (ToD, mg/cm^3) and total area (ToA, mm^2), as well as tibial mid-shaft bending strength (SSI, g^2/dm^4), CoA (mm^2) and total density (ToD, mg/cm^3) were measured from fractured and non-fractured side with pQCT. Assessments were performed at baseline and in 3, 6 and 12 months. Effect of the intervention was analyzed by GEE and longitudinal repeated measures mixture path model.

Intervention had no effect (group x time) on tibial mid-shaft and distal tibia bone traits, neither in the fractured leg nor in the non-fractured leg.

Fractured side tibial mid-shaft SSI (time effect, p=0.001) ToD ($p<0.020$) and CoA (p=0.035) decreased significantly in both group from -1.2% to-1.9% in the intervention group and from -0.4% to -0.9% in the control group. Fractured side distal tibia ToD (time effect, p=0.004) decreased significantly in both group, -1.7% in the intervention group and -0.7% in the control group. In the non-fractured tibial mid shaft, ToD (time effect, p=0.004) and SSI (p=0.001) decreased significantly in both group, from -0.5% to –1.0% in the intervention and from -1.0% to -1.1% in the control group.

At baseline there were no side-to-side differences in tibial mid-shaft bone traits in the whole group. However, at baseline in distal tibia, there were significant side-to-side difference in BSId (p=0.005) and in ToA (p=0.006). In mid tibia, significant side-to-side difference developed in CoA, SSI and ToD. In distal tibia, the significant side-to-side difference continued in BSId and developed in ToD.

Leg bone traits weakened after hip fracture in both fractured and non-fractured side in trabecular and cortical bone. The year-long progressive and individually tailored rehabilitation program or standard care was not able to prevent leg bone weakening after hip fracture.

MO0054

Overhand Throwing Athletes as a Model for Exploring the Skeletal Benefits of Exercise during Growth. Alyssa Weatherholt*[1], Robyn Fuchs[1], Stuart Warden[2]. [1]Indiana University, USA, [2]Indiana University School of Health & Rehabilitation Sciences, USA

Exercise influences bone properties in pre-pubertal children, but few studies demonstrate the rate of response. Most longitudinal studies either follow subjects for 12 months or require participants to perform some form of forced exercise (i.e. jumping exercises) to show an exercise effect. This longitudinal pilot study investigated the skeletal influence of voluntary exercise in the form of overhand throwing in male pre-pubertal baseball players (n=13; age=10.4±0.7 yrs, Tanner stage= 1.6±0.5) followed over one competitive season (6 months). Throwing athletes are a useful model as they unilaterally expose their throwing arm to elevated loads enabling the contralateral, nonthrowing arm to serve as an internal control site for growth. pQCT of the distal humerus diaphysis (75% of humerus length) was performed to assess: cortical volumetric bone mineral density (Ct.vBMD), cortical bone mineral content (Ct.BMC), total area (Tt.Ar), cortical area (Ct.Ar), medullary area (Me.Ar) and polar moment of inertia (IP). One sample t-tests were used to assess baseline percent differences between the throwing and nonthrowing arms, whereas paired t-tests were used to compare throwing-to-nonthrowing arm percent differences over time (baseline vs. 6 months). At baseline, the throwing arm had 20.2% (95%CI, 13.7 to 26.7%) greater Ct.BMC ($p<0.001$) than the nonthrowing arm. The extra mass was distributed on the periosteal and endosteal surfaces, as indicated by 7.2% (95%CI, 4.5 to 9.9%; $p<0.001$) greater Tt.Ar and 14.5% (95%CI, 7.3 to 21.7%; p=0.001) smaller Me.Ar within the throwing arm. There was no throwing-to-nonthrowing arm difference in Ct.vBMD (-0.6%; 95%CI, -1.3 to 0.2%; p=0.13). The mass and structural changes resulted in the throwing arm having 18.2% (95%CI, 11.9 to 24.5%; $p<0.001$) greater IP at baseline. Over the course of 6 months, the throwing arm gained 4.2% (95%CI, 0.1 to 8.5%) and 5.2% (95%CI, 0.2 to 10.3%) more Ct.BMC and Ct.Ar than the nonthrowing arm, respectively (all $p<0.05$). Gains in Tt.Ar (3.8%; 95%CI, -1.0 to 8.6%) and IP (10.0%; 95%CI, -2.5 to 22.5%) were not significant (all p=0.11). These data indicate that pre-pubertal throwing athletes have side-to-side differences in humeral cortical bone properties, with throwing-related changes in some bone properties being detectable with as little as 6 months follow-up. This suggests throwing athletes may be a useful within-subject controlled model for exploring the skeletal effects of exercise during growth.

MO0055

Physical performance, handgrip strength, functional limitations and 10-year mortality in a representative sample of the elderly Dutch population, a LASA-study. Joseph Biedermann[1], Natasja Van Schoor[2], Mirjam Oosterwerff[1], Nathalie Bravenboer[3], Mireille Van Poppel[2], Dorly Deeg[2], Elisabeth Eekhoff*[4]. [1]Department of Internal Medicine, Section Endocrinology, VU University Medical Center, Netherlands, [2]EMGO Institute for Health & Care Research, VU University Medical Center, Netherlands, [3]VU University Medical Center, The Netherlands, [4]VU University Medical Center, Amsterdam, The Netherlands, The Netherlands

Background: Prior studies have shown a relationship between decreased physical functioning and various negative health outcomes in the elderly, including all-cause mortality.

The comparative predictive ability of often used measurements of physical functioning, including physical performance (tests), grip strength and functional limitations, for all-cause and cause-specific, cardiovascular related disease (CVD) and non-CVD related, mortality in older men and women is unknown.

Objective: To assess the predictive values of both objective (physical performance, handgrip strength) and self-reported (functional limitations) measures of physical functioning on 10-year mortality risk (all-cause, CVD and non-CVD) in a representative sample of older persons.

Design: Data from the second cycle of the Longitudinal Aging Study Amsterdam, an ongoing cohort study in a population based sample of the elderly Dutch population were used. A total of 1,242 subjects between the age of 65 and 88 years were included in this study.

Methods and measurements: Physical performance was defined as the sum of the scores on chair stand, tandem stand and walk tests. Handgrip strength was measured using a size-adjusted hand-held dynamometer (HHD). Functional limitations were assessed by asking about difficulty doing six activities.

Cox regression analysis and Cox proportional hazard models were used to determine the predictive value of the three measures of physical functioning on (cause-specific) mortality risk during 10 years follow-up.

Results: 585 deadly events, of which 203 CVD related and 382 non-CVD related, occurred over an average of 8.4 (SD ±3.3) years of follow-up. In men, after adjustments for confounders, all measurements (HR 1.35-1.56 $P<0.005$) were predictors but only of all-cause mortality. In women, only physical performance (HR 2.25 P=0.001) and handgrip strength (HR 1.75 P=0.007) predicted all-cause mortality, while for CVD-related mortality physical performance (HR 2.72 P=0.012) and functional limitations (HR 2.40 P=0.012) were the significant predictors.

Conclusion: In men, all measurements of physical functioning predict only all-cause mortality. In contrast, in older women physical performance are proved the best predictor of all-cause mortality and the only measure related to all and CVD-related causes of mortality.

MO0056

Bone remodeling compartment canopies in pediatric renal osteodystrophy. Renata Pereira*[1], Thomas Andersen[2], Peter Friedman[3], Isidro Salusky[4], Katherine Wesseling-Perry[5]. [1]UCLA, USA, [2]Vejle Hospital - Lillebaelt Hospital, IRS, University of Southern Denmark, Denmark, [3]University of Pittsburgh School of Medicine, USA, [4]University of California, Los Angeles School of Medicine, USA, [5]UCLA Medical Center, USA

Absence of BRC canopies—a layer of flat cells which are lifted from the bone surface to form an enclosed compartment over the remodeling surface, separating osteoclasts and osteoblasts from the bone marrow—is associated with impairments in bone formation despite increased bone resorption (i.e. osteolysis) in patients with normal kidney function. Their role in bone remodeling in chronic kidney disease (CKD) remains undefined. To characterize the role of these structures in ROD, BRC canopies were assessed in 106 bone biopsies of pediatric patients with CKD stages 2-5. BRC canopy histology was quantified by a trained observer (RCP) on a subjective scale of 0 to 4 (0: no surfaces with canopy lift; 0.5: 1-2 surfaces; 1: 3-4 surfaces; 2: 5-6 surfaces; 3: 7-9 surfaces; 4: > 10 surfaces). The presence of PTHR1 immunoreactivity in undecalcified bone was assessed simultaneously by immunohistochemistry using polyclonal rabbit anti-human PTHR1 and quantified on the same subjective scale. Biochemical values were obtained at bone biopsy (Table 1). PTHR1 immunoreactivity was observed in canopies as well as in bone lining cells, but not in osteoblasts, osteoclasts, or osteocytes. Circulating PTH values were lower and fewer canopies were seen in pre-dialysis CKD than in dialysis patients. Circulating PTH levels correlated with canopies (r=0.54, p<0.01). The osteoid surface to eroded surface (OS/ES) ratio was higher in patients with BRC canopies than in those without, suggesting a role for BRC canopies in coupling of bone formation and resorption. In summary, disruption of BRC canopies appears to coincide with disrupted coordination of bone formation and resorption in CKD. BRC canopies, may play a role in PTH mediated bone formation and resorption in CKD. The role of BRC canopies in the pathogenesis of ROD, including in the development of skeletal PTH resistance, warrants further investigation.

Parameter	CKD stages 2-4 (n=18)	Dialysis (n=88)

Adult Bone Density Loci and Sex Specific Bone Mass in Childhood. Jonathan Mitchell*[1], Alessandra Chesi[2], Okan Elci[2], Shana McCormack[2], Heidi Kalkwarf[3], Joan Lappe[4], Vicente Gilsanz[5], Sharon Oberfield[6], John Shepherd[7], Andrea Kelly[8], Babette Zemel[9], Struan Grant[10]. [1]University of Pennsylvania, USA, [2]Children's Hospital of Philadelphia, USA, [3]Cincinnati Children's Hospital Medical Center, USA, [4]Creighton University Osteoporosis Research Center, USA, [5]Children's Hospital Los Angeles, USA, [6]Columbia University Medical Center, USA, [7]University of California, San Francisco, USA, [8]Children's Hospital of Philadelphia / University of Pennsylvania, USA, [9]Children's Hospital of Philadelphia, USA, [10]Children's Hospital of Philadelphia / University of Pennsylvania, USA

Osteoporosis is a heritable condition that is particularly prevalent among postmenopausal women. Adult bone mineral density (BMD) and osteoporotic susceptibility loci have been identified; however, it is not known if these loci affect bone mass in childhood or if they affect bone mass equally in boys and girls. We therefore tested if adult BMD susceptibility loci played a role in the pediatric setting and if they interacted with sex.

Our sample comprised of 694 subjects (331 boys and 363 girls) of European ancestry, aged 5-20y at baseline who enrolled in the Bone Mineral Density in Childhood Study. Participants completed annual dual energy X-ray absorptiometry scans (up to 7y) and we calculated BMD or bone mineral content (BMC) z-scores (adjusted for age, sex and height) for the total hip (hip-BMD), femoral neck (FN-BMD), distal $^1/_3$ radius (radius-BMD), spine (spine-BMD), and whole body less head (WB-BMC). We used mixed-effects linear regression models accounting for correlations arising from the repeated measures and siblings and tested for sex interactions with each of the 77 single nucleotide polymorphisms (SNPs) after adjusting for age, Tanner stage, BMI, dietary calcium and self-reported physical activity.

Nineteen sex-SNP interactions were observed at one or more skeletal sites, with *P*-values $<1.3\times10^{-4}$. SNPs in/near *MBL2* (radius-BMD, $P=6.46\times10^{-11}$ and spine-BMD, $P=1.03\times10^{-4}$), *CPED1* (radius-BMD, $P=1.76\times10^{-8}$), *C12orf53* (spine-BMD, $P=5.46\times10^{-7}$ and FN-BMD, $P=3.61\times10^{-6}$), *AXIN1* (spine-BMD, $P=7.31\times10^{-7}$) and *LEKR1* (WB-BMC, $P=6.46\times10^{-6}$ and spine-BMD, $P=6.56\times10^{-5}$) were more strongly associated with bone mass in girls. SNPs in/near *WNT16* (radius-BMD, $P=1.22\times10^{-6}$ and WB-BMC, $P=3.12\times10^{-6}$), *SOX9* (WB-BMC, $P=5.16\times10^{-5}$) and *XKR9* (radius-BMD, $P=6.29\times10^{-5}$) were more strongly associated with bone mass in boys. For example, per rs13245690 risk allele (*CPED1*) mean radius-BMD z-score was lower in girls by 0.38 (girls: b=-0.38, $P=7.04\times10^{-10}$; boys: b=-0.05, $P=0.51$). Whereas, per rs3779381 risk allele (*WNT16*) mean radius-BMD z-score was higher in boys by 0.30 (girls: b=0.03, $P=0.12$, boys: b=0.30, $P=4.55\times10^{-13}$).

This is the first study to show that specific adult BMD susceptibility loci associate with pediatric bone mass in a sex specific manner, suggesting that different biological pathways contribute to bone mass in boys and girls. The reason for the dichotomous findings will need further investigation.

MO0059

Effect of Dietary Calcium on Phosphorus Balance and Net Absorption in Healthy Adolescent Girls. Colby Vorland*[1], Berdine Martin[2], Connie Weaver[2], Munro Peacock[3], Kathleen Hill Gallant[2]. [1], USA, [2]Purdue University, USA, [3]Indiana University Medical Center, USA

Phosphorus is an essential nutrient which plays a critical role in energy metabolism as ATP and as a major structural component of bone. Phosphorus deficiencies are extremely rare as it is widespread in the food supply. Conversely, there is increasing concern over potential harms of dietary phosphorus excess. Inorganic forms of phosphorus are commonly used as food additives, which contributes to an increased intake in the U.S. Emerging evidence shows that elevated serum phosphorus and high dietary phosphorus intake may increase the risk of cardiovascular disease and mortality in patients with chronic kidney disease as well as the general population. However, few phosphorus balance studies have been conducted, and are needed to examine factors that influence whole body phosphorus metabolism.

The purpose of this study was to determine the effect of dietary calcium on phosphorus balance and net phosphorus absorption in healthy adolescent girls, utilizing a unique resource of banked urine, fecal, and diet samples from a controlled calcium balance study previously conducted at Purdue University. Eleven healthy girls ages 11-14y participated in a randomized crossover study conducted in 2007 which consisted of two 3-week periods of a controlled diet with low (817 ± 62 mg/d) or high (1418 ± 35 mg/d) calcium, separated by a 1-week washout period. Phosphorus intake was the same on the low and high calcium diets (1531 ± 29 and 1534 ± 30 mg/d, respectively, p = 0.83). Results show urinary phosphorus excretion was lower on the high calcium diet (649 ± 41 vs 535 ± 42 mg/d, p = 0.01). However, fecal phosphorus (553 ± 60 vs 678 ± 63 vs mg/d, p = 0.14), net phosphorus absorption (980 ± 56 vs 859 ± 58 mg/d, p = 0.14), and overall phosphorus balance (339 ± 72 vs 329 ± 74 mg/d, p = 0.90) were not significantly different between low and high calcium intake. This agrees with our previously published study of phosphorus balance in adult moderate-stage chronic kidney disease patients, where increased calcium intake modestly reduced urinary phosphorus, but did not affect overall phosphorus balance or absorption. Combined, these balance studies suggest that increasing dietary calcium is not an effective strategy for reducing phosphorus absorption or retention.

MO0060

Preeclampsia and gestational hypertension are associated with adolescent offspring bone mineral density in a UK population based cohort. Kim Hannam*[1], Jon Tobias[2], Debbie Lawlor[2]. [1]University of Bristol, United Kingdom, [2]University of Bristol, United Kingdom

Introduction: Intra uterine insufficiency has been postulated to have long term effects on health, including risk of osteoporosis, via fetal programming. Since preeclampsia (PE) and to a lesser extent gestational hypertension (GH) are associated with impaired placental dysfunction we postulated that these represent hitherto unrecognised risk factors for reduced bone mineral density (BMD) of the off spring. *Objective:* To investigate if exposure to PE or GH in utero influences BMD of

the offspring as measured in late adolescence. *Methods:* Mother-offspring pairs from the UK population based cohort study ALSPAC were investigated (N=3224 with relevant data). PE and GH were determined by abstracting every antenatal blood pressure (BP) and proteinuria record and applying the International association of hypertension in pregnancy guidelines to the measurements; PE was defined as systolic BP >139mmHg or diastolic BP >89mmHg on at least two occasions after 20wks gestation with proteinuria and GH as the same elevated BP without proteinuria. Multivariable linear regression was used to examine associations between PE/GH and BMD as measured by whole body and hip DXA at age 17. Fully adjusted analyses included gender, age at scan, maternal age, parity, maternal smoking (self-reported in 3rd trimester), maternal socioeconomic status (based on highest parental occupation) and maternal pre-pregnancy body mass index. *Results:* Of the 3224 mother-offspring pairs 2% (n=64) of the mothers fulfilled criteria for PE and 14% (n=433) for GH. In unadjusted analyses, GH was positively associated with BMD of the total hip, spine sub-region and total body; these associations remained after adjustment at the spine (mean SD difference= 0.12, 95% CI= 0.02-0.22 p=0.02) and total hip (mean SD difference= 0.10, 95% CI= 0.01-0.20 p=0.04). In contrast, in unadjusted analyses, there was evidence of a negative association between PE and total hip BMD (mean SD difference= -0.23, 95% CI= -0.48-0.02 p=0.07), which was strengthened after confounder adjustment (mean SD difference= -0.35, 95%CI=-0.58 - -0.11 p=0.003). There was no evidence of association between PE and BMD at other sites. *Conclusion:* Whereas PE appears to represent a risk factor for low BMD of the off-spring, if anything GH may be protective, possibly reflecting distinct effects of these two hypertensive disorders of pregnancy on placental function and/or intra uterine insufficiency.

MO0061

Osteocyte Dysfunction After Burns: Possible Role of Bisphosphonates. Gordon Klein*[1], David Herndon[2], Phuong Le[3], Debra Benjamin[2], Clark Andersen[2], Clifford Rosen[4]. [1]University of Texas Medical Branch, USA, [2]University of Texas Medical Branch & Shriners Burns Hospital, USA, [3]Maine Medical Center Research Institute, USA, [4]Maine Medical Center, USA

We previously reported that burned children receiving pamidronate in a randomized controlled trial (RCT) had sparing of both resorptive bone loss (Bone 2007; 41: 297) and muscle protein breakdown (J Bone Miner Res pub online 18 Dec 2013). Based on the hypothesis that bisphosphonates prevent osteocyte apoptosis, possibly permitting release of paracrine factors that prevent muscle catabolism, we measured serum concentrations of sclerostin (SOST) and fibroblast growth factor (FGF)23 in 18 children originally enrolled in the RCT using blood obtained 6-60d post-burn. FGF23, which can cause left ventricular hypertrophy, was undetectable in both groups starting at day 6 post-burn. SOST concentrations in serum were normal in both groups. However, SOST vs time post-burn was significantly different between controls (n=9) and the pamidronate group (n=9), p=0.016 by ANCOVA. The control group had a slope of -2.5 while the pamidronate group had a slope of +3.5. Normal range of the assay is 67-300 pg/ml. The explanation for the undetectable levels of FGF23 is uncertain but would appear to precede osteoblast apoptosis, which occurs at approximately 14d post-burn (Osteoporos Int 2004; 15: 468). All subjects were hypoparathyroid, not improved with bisphosphonates (Osteoporos Int 2005; 16: 631). Since serum SOST varies inversely with serum PTH concentrations, the low PTH could be driving the normal levels of SOST. The negative slope of the SOST concentrations in the controls and the positive slope of SOST concentrations in the pamidronate group are consistent with the hypothesis that pamidronate preserves osteocytes following burn injury. However, FGF23 is not the osteocytic paracrine factor that preserves muscle protein from breakdown post-burn.

MO0062

Bisphosphonate Treatment and Dental Development in Children with Osteogenesis Imperfecta. Ilkka Vuorimies*[1], Heidi Arponen[2], Helena Valta[1], Outi Tiesalo[2], Marja Ekholm[2], Outi Makitie[3], Janna Waltimo-Sirén[2]. [1]Hospital for Children & Adolescents, University of Helsinki, Helsinki Finland, Finland, [2]Institute of Dentistry, University of Helsinki, Helsinki, FINLAND, Finland, [3]Children's Hospital, Helsinki University Central Hospital, Finland

Osteogenesis imperfecta (OI) is an inherited disorder characterized by bone fragility. Bisphosphonates (BPs) have become an established therapy for paediatric OI patients. As tooth eruption requires resorption of alveolar bone and roots of the deciduous teeth, it has been hypothesized that antiresorptive BPs might delay tooth eruption. This phenomenon has been established in rats, but in OI patients evidence for such an effect is lacking. The purpose of the present study was to assess whether BP treatment affects eruption of permanent teeth in children with OI.

We analyzed dental panoramic tomograms for 22 OI patients (age 3-16 yrs, mean 10.4 yrs) treated with BPs (pamidronate, zoledronic acid or risedronate) for a minimum period of a year. We performed dental age assessment using the method introduced by Demirjian et al., evaluated the number of erupted left mandibular permanent teeth and assessed the resorption rate of the persistent deciduous teeth using a method described by Haavikko with some modification. Radiographs of 50 age-matched OI patients naïve to BPs were used as controls. In addition, we used published and own normative data for healthy Finnish children.

In OI patients without BPs the dental age and the number of left mandibular permanent teeth were significantly advanced (mean difference 0.55 years, P<0.001 and 0.29 teeth, P=0.048, respectively) but were similar to healthy children in the BP-treated group. No statistically significant difference was found between the OI groups. Furthermore, no difference was found between the OI groups in resorption rate.

In conclusion, OI children treated with BPs were similar to healthy control children in terms of rate of dental development. OI patients who have not received BPs have somewhat advanced dental development, and BPs seem to slow it down to a rate comparable to normal.

MO0063

Vibration Induced Cytoskeletal F-Actin Alignment and Molecular Gene Expression Patterns of Human Bone Marrow Mesenchymal Stem Cells are Influenced by Vibration Direction. Suphannee Pongkitwitoon*[1], Gunes Uzer[2], Janet Rubin[3], Stefan Judex[4]. [1]Stony Brook University, USA, [2]University of North Carolina, USA, [3]University of North Carolina, Chapel Hill, School of Medicine, USA, [4]Stony Brook University, USA

Human bone marrow derived mesenchymal stem cells (hBMSCs) are sensitive to mechanical stimulation in vitro and in vivo but the transduction pathway by which hBMSCs can respond to vibrations at very low intensities is unclear. We recently showed in vitro that vibration enhanced hBMSC proliferation, and osteogenic differentiation is similar between vibrations applied in the horizontal and vertical direction. Here, we investigated the molecular and cytoskeletal response between the two directions. hBMSCs were subjected to two bouts of vibrations in horizontal or vertical direction using vibration frequency/acceleration combinations of 100Hz-0.15g and 30Hz-1g and compared to non-vibrated controls. Gene expression analysis was performed with 96-gene PCR arrays while two-photon laser confocal microscopy visualized cytoskeletal elements. Gene expression of many skeletal transcription factors, growth factors and matrix molecules was up-regulated in vibration groups compared to non-vibrated controls. Adiponectin and PPARg were down regulated in most vibration groups compared to non-vibration. Osteoblast markers (e.g. ALP, BMP2, COL1 and RUNX2) were up-regulated up to 6-fold with vibrations. Genes for cytoskeletal fibers (e.g. talin, tubulin up-regulated 2-4 fold) and nuclear fibers (e.g., NESPRIN-1,2 and SUN1,2 up-regulated 2-4 fold) were also up-regulated. Cluster analysis grouping up- or down-regulated gene transcripts showed that horizontal vibrations tended to up-regulate osteoblast differentiation markers more effectively than vertical vibrations. For instance, up-regulation of alkaline phosphate, collagen-I, RUNX2 was up to 2x greater in horizontally vibrated (100Hz-0.15g) hBMSCs than in vertically vibrated (100Hz-0.15g) hBMSCs. Further, two-photon microscopy revealed that cytoskeletal F-actin became more aligned in one direction with horizontal vibrations (100Hz-0.15g) than with vertical vibrations (100Hz-0.15g) or in non-vibrated control hBMSCs. Reflecting this cytoskeletal reorientation, lamins, nesprins and sun proteins were up-regulated primarily with horizontal vibrations. β-catenin and wnts were up-regulated with both horizontal and vertical vibrations. Across the two loading directions, the 100Hz-0.15g vibration signal generally elicited a greater molecular response than the 30Hz-1g signal. The data show the rapid molecular response of hBMSC to vibrations and suggest that the direction in which the vibration is applied may play a role in 2D culture.

MO0064

Increased type II diabetes indices and compromised bone marrow niche caused by obesity is salvaged by inclusion of refractory periods in low intensity mechanical vibrations in adult C57BL/6 mice. Vihitaben Patel*[1], Meilin Chan[2], Clinton Rubin[3]. [1]Stony Brook University, USA, [2]Stony Brook University, USA, [3]State University of New York at Stony Brook, USA

Obesity-induced type II diabetes (T2D) has been shown to degrade bone health. In addition, current drug treatments for T2D may also inadvertently deteriorate bone quality. This study aims to investigate whether various loading regimes for mechanical stimulation, as an element of exercise, can serve as a non-pharmacologic treatment to cure T2D and improve bone health simultaneously. Thirty-four, 17 weeks old, male C57BL/6 mice were separated in four groups, regular diet (RD, n=8), high fat diet (HF, n=8), high fat diet with 30 minutes of mechanical stimulation (HFv, n=9), high fat diet with two 15 minute bouts of mechanical stimulation with 5 hour refractory period (RHFv, n=9). The mechanical stimulation was delivered via low intensity vibration (LIV) protocol (90Hz frequency and 0.2g peak acceleration) for 5 days/week. While the RD mice were fed regular diet (10kcal% fat), the HF, HFv and RHFv mice were fed high fat diet (45kcal% fat) for 2 weeks to induce obese phenotype. Continuing on the same diets, the HFv and RHFv mice were subjected to their respective LIV treatment, whereas RD and HF mice were sham handled for 6 weeks. At the end of the experiment, HF had increased glucose intolerance (+15%, p=0.005), a typical characteristic of T2D, paralleled with crippled bone marrow mesenchymal stem cell (MSC, Sca1+ CD90.2+ Ckit+ CD44+ CD105+) population (-56%, p=0.002), B cell (B220+) population (-50%, p=0.0001) and T cell (CD4+) population (-52%, p<0.0001) suggesting compromised bone marrow niche. While 30 minutes of mechanical stimulation without a refractory period was capable of only salvaging B cell population (+56%, p=0.037), inclusion of 5-hour refractory period between two bouts of 15 minutes mechanical stimulation resulted in parallel normalization of both T2D and bone marrow niche. Compared to HF, RHFv

resulted in decreased glucose intolerance (-7.8%, p=0.055) and increased bone marrow MSC population (+90%, p=0.046), B cell population (+59%, p=0.026) and T cell population (+43%, p=0.05). In summary, this study suggests the potential benefit of refractory period incorporation in the mechanical stimulation loading regime to simultaneously improve T2D and bone marrow niche by affecting bone marrow MSC, B cell and T cell population in adult mice.

MO0065

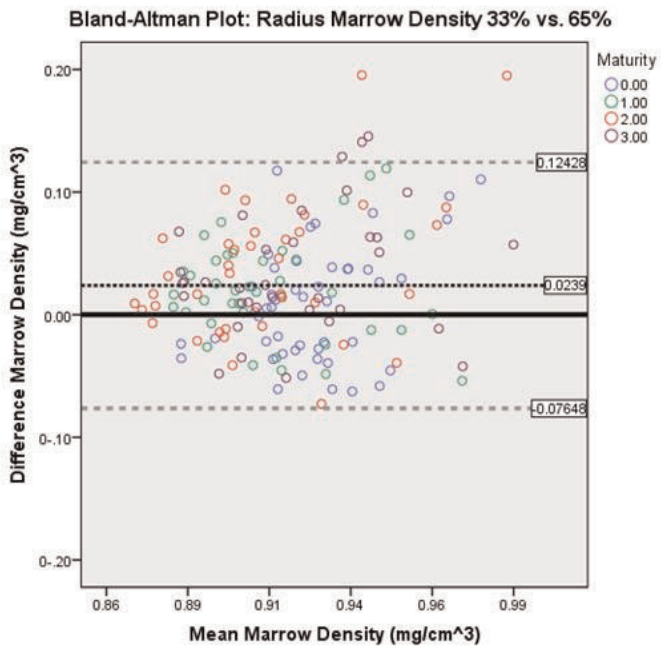
Regional Variability in Radius Marrow Density- A pQCT Study in Females Aged 8 to 58. Jodi Dowthwaite*[1], Tomas Cervinka[2], Charity Ntansah[3], Paula F. Rosenbaum[4], Harri Sievanen[5], Tamara Scerpella[6]. [1]SUNY Upstate Medical University;Syracuse University, USA, [2]Tampere Institute of Technology, Finland, [3]Syracuse University, USA, [4]SUNY Upstate Medical University, USA, [5]The UKK Institute for Health Promotion Research, Finland, [6]University of Wisconsin, USA

Purpose : Bone marrow density may indicate the proportion of osteogenic versus adipogenic progenitor cells, with higher marrow density indicating greater osteogenic propensity. However, the homogeneity of marrow density assessments within a single bone is unknown. The current analysis examined relationships between 33% and 65% radius marrow and cortical properties across a broad subject age and maturity range (pre-puberty through post-menopause).

Methods: We evaluated pQCT scan results for 33% and 65% radius sites from 160 females. Marrow and cortical properties were evaluated using threshold definitions of 550 mg/cm^3 for bone and 80 mg/cm^3 for marrow. Coefficients of variation were calculated from duplicate, repositioned pQCT scan results for 31 adult women. Kolmogorov-Smirnov tests indicated non-normal data distributions. Spearman correlations quantified associations among variables. Wilcoxon signed-rank tests assessed site-to-site differences for marrow (M) and cortical (C) tissue densities (vBMD). Bland-Altman plots evaluated agreement between 33% and 65% marrow vBMD, labeling data points by subject age group (8-13yrs, 13.1-18yrs, 18.1-30yrs, 30yrs+).

Results: Subject ages ranged from 8.1 to 57.8yrs (mean 22.3, sd 13.2). No relationship was detected between sites for marrow density (rho= 0.00, p=0.99; Figure 1; 33% site MvBMD greater, Wilcoxon p<0.001). In contrast, site-to-site correlations for cortical density (CvBMD), thickness (CTh) and cross-sectional area (CCSA) were strong (rho: CvBMD= +0.85, CTh= +0.75, CCSA= +0.90; p<0.001), despite inequality (33% greater, Wilcoxon p<0.001). Coefficients of variation for pQCT outcomes were <2% for all but MvBMD (33%= 2.5%, 65%= 5.6%).

Conclusions: No associations were detected between marrow densities at 33% and 65% radius sites, whereas site-to-site cortical properties were strongly positively correlated. Thus, marrow density results are not interchangeable. As 65% medullary cavity area is larger than 33% medullary area, the 65% site may be preferable for marrow density assessment in small subjects. However, cortical thickness is lower at 65% than 33% radius, making 33% radius preferable for cortical density assessment in small subjects. To maximize data quality for assessment of radius marrow and cortical properties, scans should be performed at both sites (33% cortex, 65% marrow). The significance of site-to-site marrow density variation within bone has yet to be determined.



Bland-Altman Plot: 33% vs 65% Radius Marrow Density

MO0066

Macrophagic cells are abundant along the bone marrow envelope in human and mice cancellous bone. Thomas Andersen*[1], Maja Hinge[2], Jean-Marie Delaisse[3]. [1]Vejle Hospital - Lillebaelt Hospital, IRS, University of Southern Denmark, Denmark, [2]Department of Clinical Cell Biology (KCB), Vejle Hospital – Lillebaelt Hospital, IRS, University of Southern Denmark, Denmark, Denmark, [3]Vejle Hospital, IRS, University of Southern Denmark, Denmark

Recent studies identified several bone physiology-relevant features at the marrow-bone interface. (i) Very thin elongated mesenchymal cells surround the bone marrow, forming a bone marrow envelope (BME), which get the appearance of a canopy above the remodeling sites. (ii) Marrow cell activities in an area within 50 µm of the BME/canopy correlate with bone surface events. Recently, the canopies were proposed to consist of a mixture of osteoblastic and macrophagic cells, and the latter were also ascribed a role in bone formation.

Here we clarified the position of the macrophagic cells both in relation with the canopy/BME and bone surface events. Immunolocalizations were performed in cancellous iliac crest biopsies of 9 human controls and in vertebrae, tibiae and femur of 4 aged mice. Macrophagic and osteoblastic markers were respectively, CD68/CD163 and CD56/Runx2 for the humans, and F4/80 and CD56/β-catenin for the mice.

In humans, we consistently observed that none of the BME/canopy cells were immunoreactive for the macrophagic markers (<1%), while basically all the BME/canopy cells were immunoreactive for the osteoblastic markers (>98%). This confirms that the BME contains only osteoblastic cells and no macrophagic cells. The same conclusion was drawn for the cells on the bone surface, except for the osteoclasts, which were positive for CD68. Interestingly however, 57% of the BME/canopy was found in contact with CD68$^+$ cells at its marrow side, but only 5% of it was found in contact with CD163$^+$ cells. This suggests that CD68$^+$CD163$^-$ macrophagic cells are abundant in the bone marrow right next to the BME/canopy. Furthermore, 37% of the bone marrow cells within 50 µm of the BME/canopy were immunoreactive for CD68 and/or CD163. Of note, the CD68 $^+$ macrophagic cells in the bone marrow appeared most abundant above osteoid surfaces, less abundant above eroded surfaces, and least abundant above quiescent surfaces.

In mice, the BME/canopy is more difficult to detect. When detectable, the BME/canopy cells were only immunoreactivity for the osteoblastic markers CD56 and β-catenin, and not stained with the macrophagic marker F4/80. As in humans F4/80$^+$ macrophagic cells were found lining the marrow side of the BME/canopy and were abundant in neighboring bone marrow.

In conclusion, macrophagic cells are abundant right next to the osteoblastic BME/canopy both in human and mouse cancellous bone - a position compatible with a role at the marrow-bone interface.

MO0067

The Other Side of Osteoimmunology: Osteoclasts as Myeloid Derived Immune Regulator. Ichiro Nishimura*[1], Keiichi Kanayama[2], Han-Ching Tseng[2], Shuting Sun[3], Charles McKenna[3], Sil Park[4], Anahid Jewett[2]. [1]University of California, Los Angeles, USA, [2]UCLA School of Dentistry, USA, [3]USC Department of Chemistry, USA, [4]UCLA, School of Dentistry, USA

The interaction between immune cells and bone has suggested important regulatory processes for physiological bone remodeling and pathological bone diseases. Osteoimmunology has identified the role of immune cells for osteoclast development. Osteoclasts are originated from myeloid-derived immune cells that regulate lymphocytic inflammatory activities. In this study, we have tested the hypothesis that fully differentiated osteoclasts may still retain the myeloid immune cell characteristics. Human peripheral blood mononuclear cells from volunteer subjects were used to purify CD14+ monocytes. Monocytes were then differentiated to different lineages by medium containing M-CSF/RANKL (osteoclasts), GM-CSF/IL-4 (dendritic cells), LPS/IFN-gamma (M1 macrophages) or M-CSF (M2 macrophages). The condition medium of each group was subjected to multiplex cytokine profiling. Osteoclasts were found to secrete cytokines and chemokines that showed a similar profile as that of monocytes and M2 macrophages but not of dendritic cells and M1 macrophages. By determining cell surface markers using FACS analysis, osteoclasts were found to express CD14[dim]CD11b+. The cytokine profile and cell surface markers indicated that osteoclasts resembled the characteristics of myeloid-derived suppressor cells (MDSC). Thus, osteoclasts' conditional medium was further subjected to ELISA, which revealed the secretion of anti-inflammatory IL-10. After the exposure to Zoledronate or Alendronate, the secretion of IL-10 was significantly decreased. By contrast, these nitrogen-containing bisphosphonates dose dependently increased the osteoclastic secretion of pro-inflammatory cytokines, IL-6 and TNFa. The cytokine modulations were not induced by Etidronate. In a mouse model for osteonecrosis of the jaw (ONJ) using Zoledronate, some oral osteoclasts were detached from the jawbone and positively stained by anti-IL-6 antibody. The detached osteoclasts were shown to contain fluorescent-labeled Zoledronate and surrounded by inflammatory infiltrates in the oral mucosa. This study demonstrated that osteoclasts retained an MDSC-like characteristic with a potential to mediate immune suppressive effect, but nitrogen-containing bisphosphonates changed it to

pro-inflammatory characteristics. These findings suggest a potential role of osteoclasts in supporting bone marrow tumors by MDSC-like mechanism and also a role as pro-inflammatory regulator in bisphosphonate-related ONJ.

Diet-induced obesity promotes a myeloma-like disorder *in vivo*. Seint Lwin*[1], Sam Olechnowicz[2], Jessica Fowler[3], Claire Edwards[1]. [1]University of Oxford, United Kingdom, [2]University of Oxford, GBR, [3]University of California, Los Angeles, USA

The relationship between obesity and bone biology is complex, with evidence to support an association between obesity and risk of multiple myeloma (MM). The mechanisms that mediate this association remain unknown. In the present study, we have combined the well-characterized 5TGM1 murine model of MM with diet-induced obesity (DIO) and a genetic model of obesity to determine the effect of increased adiposity on MM development *in vivo*. In the 5TGM1 MM model, MM only develops if 5TGM1MM cells are inoculated into C57Bl/KaLwRij (KaLwRij) mice and not in closely related C57Bl6 mice. Non-permissive C57Bl6 or permissive KaLwRij mice were fed a high fat diet (42% kcal from fat) or control diet (10% kcal from fat) for 5 weeks, when a significant increase in body fat was detected. Mice were then inoculated with 5TGM1MM cells. C57Bl6 mice on a high-fat diet developed features of MM, including a 3.7-fold increase in serum paraprotein ($p<0.001$), GFP-positive cells in bone marrow (5.75%, $p<0.001$) and a 10% decrease in trabecular bone volume. Removal of the high fat diet upon detection of MM reduced tumour burden ($p<0.05$). Inoculation of MM-permissive KaLwRij mice resulted in MM, but no significant difference in serum paraprotein, tumour burden within bone marrow or trabecular bone volume was detected in mice on a high fat diet as compared to control, despite a significant increase in body fat at time of tumour inoculation. This suggests that the obese host microenvironment created by DIO is not directly promoting tumour growth or survival, but may instead be creating and maintaining a permissive environment. In support of this, analysis of MM-permissive KaLwRij mice revealed a 29% increase in body weight ($p<0.05$), an 82% increase in body fat ($p<0.05$), and a 58% decrease in trabecular bone volume ($p<0.01$) as compared to age-and sex-matched C57Bl6 mice. To investigate whether general adiposity in the absence of a high-fat diet would provide a supportive niche, mice deficient in leptin (ob/ob) were inoculated with 5TGM1MM cells. Surprisingly, no evidence of tumour burden or bone loss was detected, suggesting that distinct differences in the obese microenvironments created by DIO and leptin deficiency. Our studies demonstrate that DIO creates a permissive environment for the development of a MM-like disorder. Furthermore, the reduction in tumour burden following removal of the high fat diet suggests the potential for dietary intervention strategies.

Expression and role of sonic hedgehog in oral squamous cell carcinoma induced jaw bone destruction. Tsuyoshi Shimo*[1], Naito Kurio[2], Masahiro Iwamoto[3], Tatsuo Okui[4], Hiromasa Kuroda[5], Kenichi Matsumoto[5], Soichiro Ibaragi[5], Norie Yoshioka[5], Yuichirou Takebe[5], Hitoshi Nagatsuka[5], Akira Sasaki[6]. [1]Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sci, Japan, [2]Japan, Japan, [3]Children's Hospital of Philadelphia, USA, [4]Okayama University, Japan, [5]Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sciences, Japan, [6]Okayama University, Japan

Introduction: Sonic hedgehog (Shh) and its signaling have been identified in several human cancers, and increased levels of its expression appear to correlate with disease progression and metastasis. However, the role of Shh in bone destruction associated with oral squamous cell carcinomas is still unclear. In this study we have analyzed the expression and how hedgehog signaling is involved in the gingival carcinoma induced jaw bone destruction.

Methods: From surgically resected lower gingival squamous cell carcinoma mandible samples, decalcified, immunohistochemical staining was performed. To evaluate the effects of SHH on osteoclastogenesis and activity in vitro, osteoclast formation assay and pit formation assays were performed by using RAW264.7 cells and CD11b+ cells from mouse bone marrow cells. The expression of SHH related signals were confirmed by Western blot analysis.

Results: We found that SHH was highly expressed in stromal cells and osteoblsts near the tumor cell that had invaded bone matrix. On the other hand, hedgehog signal Gli-2 was highly expressed in the preosteoclasts and mature osteoclasts. SHH stimulated osteoclast formation and pit formation in the presence of receptor activator for nuclear factor-κB ligand (RANKL). SHH upregulated phosphorylation of ERK1/2 and p38 MAPK, NFATc1, tartrate-resistant acid phosphatase (TRAP), and cathepsin K expression in RAW264.7 cells.

DISCUSSION: Our results suggest that tumor derived growth factors stimulated the SHH in the stromal cells and osteoblasts near the bone invaded tumor cells, and regulated osteoclast formation and bone resorption in the tumor bone microenvironment.

MO0070

Increased Expression of TAF12 in the Bone Microenvironment in Multiple Myeloma Enhances Tumor Cell Growth and Osteoclast Formation. Yukiko Kitagawa[1], Jumpei Teramachi[2], Jolene Windle[3], John Chirgwin[1], G. David Roodman[1], Noriyoshi Kurihara*[1]. [1]Indiana University, USA, [2]The University of Tokushima, Japan, [3]Virginia Commonwealth University, USA

Vitamin D has been implicated in the progression of many cancers; however, its role in multiple myeloma (MM) is unclear. Vitamin D insufficiency or deficiency has been reported in the majority of MM patients, but it is unknown how Vitamin D levels affect disease activity. We reported that TAF12 expression, a VDR coactivator, was induced in bone marrow stromal cells (BMSC) by pagetic osteoclasts (OCL) that have increased NFκB signaling. Further, the increased TAF12 expression in BMSC enhanced their production of RANKL in response to low concentrations of 1,25-D_3 (10^{-10}M). MM cells also have increased NFκB signaling analogous to pagetic OCL. Therefore, we determined if TAF12 was also increased in BMSC of MM patients (MM-BMSC) and enhanced RANKL production or VCAM1 expression in BMSC treated with 1,25-D_3. We found that MM-BMSC expressed increased TAF12 levels compared to normal BMSC. TAF12 expression in MM-BMSC was increased by TNFα and IL-6, and TAF12 enhanced RANKL and VCAM1 expression by MM-BMSC in response to 10^{-10}M 1,25-D_3. Further, 1,25-D_3 enhanced adhesive interactions between MM cells and BMSC to increase the growth of human myeloma cells. To confirm that TAF12 increased MM cell growth by BMSC in response to 1,25-D_3, we generated TAF12 heterozygous knock-out ($TAF12^{+/-}$) mice, because $TAF12^{-/-}$ mice die during gestation. BMSC from $TAF12^{+/-}$ mice expressed 50% lower TAF12 levels compared to WT, and had decreased RANKL and VCAM1 production, and CYP24A1 accumulation in response to 1,25-D_3. VDR content in BMSC from $TAF12^{+/-}$ mice treated with 1,25-D_3 (10^{-10} to 10^{-8}M) was also decreased compared to WT cells. Co-culture of JJN3 human MM cells with $TAF12^{+/-}$ BMSC treated with 1,25-D_3 resulted in decreased MM cell growth as compared to co-cultures with WT BMSC. WT mouse OCL precursors co-cultured with $TAF12^{+/-}$ BMSC formed fewer OCL with 1,25-D_3 treatment compared to normal BMSC and the increased OCL formation was blocked by OPG. These results show that increased expression of TAF12 in the MM microenvironment upregulates VDR transcription in response to low levels of 1,25-D_3 to enhance MM cell growth and osteoclast formation. Since we have shown that primary myeloma cells from patients also express increased TAF12 levels, these results suggest that TAF12 may be a novel target for treating MM bone disease.

MO0071

Acid sensing and survival signaling in myeloma cells in acidic bone lesions: formation of acid-induced vicious cycle. Ryota Amachi*[1], Masahiro Hiasa[2], Jumpei Teramachi[3], Keiichiro Watanabe[4], Takeshi Harada[5], Shiro Fujii[5], Shingen Nakamura[5], Hirokazu Miki[5], Asuka Oda[5], Eiji Tanaka[6], Itsuro Endo[7], Toshio Matsumoto[7], Masahiro Abe[1]. [1]University of Tokushima, Japan, [2]Indiana University School of Medicine, USA, [3]The University of Tokushima, Japan, [4]Tokushima University Hospital, Japan, [5]Dept. of Medicine & Bioregulatory Sciences, Tokushima Univ., Japan, [6]Dept. of Orthodontics & Dentofacial Orthopedics, Tokushima Univ., Japan, [7]University of Tokushima Graduate School of Medical Sciences, Japan

In osteolytic lesions in myeloma (MM), MM cells and osteoclasts (OCs) interact with each other to enhance their growth and activity. The interaction creates an acidic milieu by protons produced by OCs and lactate by MM cells, which further confers drug resistance in MM cells. We found that such mutual interaction enhanced the expression of Pim-2 in MM cells as a prosurvival mediator. However, precise mechanisms of acid sensing in MM cells and its role in tumor survival are largely unknown. In the present study, we therefore explored the relationship between acid sensing and survival signaling in MM cells in acidic conditions. MM cell lines as well as primary MM cells variably expressed extracelluar pH sensors, TDAG8, OGR1, and TRPV1, at pH7.4; the expression of these pH sensors was up-regulated at mRNA levels in MM cells cultured at pH6.8 or cocultured with acid-producing OCs. The pH sensor levels were further up-regulated in the MM cells cocultured with OCs in acidic conditions. The acidic conditions also induced Pim-2 expression and phosphorylated Akt in MM cells. The addition of the PI3K inhibitor LY294002 abolished the up-regulation of these pH sensors along with the suppression of Akt phosphorylation at pH6.8. The Pim inhibitor SMI16a also reduced the expression of these pH sensors in MM cells at pH6.8. Acid-induced activation of the PI3K-Akt pathway enhanced the nuclear localization of the transcription factor Sp1 in MM cells. Among the pH sensors up-regulated in MM cells in acidic conditions, treatment with terameprocol, a competitive inhibitor of Sp1 binding, selectively abolished the expression of TRPV1, a sensor for lower ranges of pH to sense pH as low as pH4.0. LY294002 and SMI16a in combination cooperatively induced MM cell death more markedly in acidic conditions than at pH7.4. These results suggest that MM cells respond to acid and activate the PI3K-Akt and Pim-2-mediated survival pathways, which in turn up-regulates their expression of pH sensors, thereby forming a positive feedback loop between the edition of pH sensors and activation of the survival pathways in MM cells under acidic conditions. Besides skewed cellular microenvironment surrounding MM

cells, protons and/or lactate may act as niche factors for MM cells to elicit their drug resistance while adapting to acidic environment. Combinatory treatment with PI3K and Pim inhibitors may be a good therapeutic option against MM cells in acidic bone lesions in MM.

C-11-Acetate Metabolic PET Imaging uncovers a Role for Acetate Metabolism in Multiple Myeloma. Francesca Fontana*[1], Michelle Hurchla[2], Kooresh Shoghi[3], Walter Akers[3], Simone Cenci[4], Michael Tomasson[5], Andre D'Avignon[6], Monica Shokeen[7], Roberto Civitelli[8], Katherine Weilbaecher[8]. [1]Bone & Mineral Diseases, USA, [2]Washington University in St. Louis, USA, [3]Washington University School of Medicine Department of Radiology, USA, [4]Fondazione Centro San Raffaele, Italy, [5]Division of Oncology - Washington University School of Medicine, USA, [6]Department of Chemistry - Washington University in St Louis, USA, [7]Washington University School of Medicine - Department of Radiology, USA, [8]Washington University in St. Louis School of Medicine, USA

Multiple Myeloma (MM), a bone marrow (BM) plasma cell malignancy, is characterized by high levels of monoclonal immunoglobulins (Ig), bone osteolytic lesions and systemic symptoms. 18FDG-Positron Emission Tomography (PET) is the current gold standard for metabolic imaging of MM, yet it can fail to detect nearly 40% of lesions, particularly in intramedullary disease. We hypothesized that membrane biosynthesis and lipid metabolism may represent novel targets for developing better diagnostic tools and new therapeutic modalities, as these are key biologic processes for MM cells, which produce large amounts of Ig and undergo fast cell replication. We applied dynamic PET imaging using 11C-acetate to preclinical models of MM. 18F-Sodium fluoride scans were performed for co-registration with the skeleton. High 11C-acetate uptake was demonstrable in subcutaneous grafts of 5TGM1-GFP tumor cells in immunodeficient mice, and areas of uptake matched the optical imaging signal for the same tumors. Upon intravenous injection, 5TGM1 cells engraft to the bones of syngeneic KaLwRij mice; in this orthotopic model we found a significant increase of 11-C-acetate SUV (standardized uptake value) in tumor-bearing vs. control bones ($p<0.05$). The presence of tumor cells at sites of increased 11C-acetate uptake was then demonstrated by in vivo and ex-vivo optical imaging, flow cytometery, histology, and immunohistochemistry for IgG. To directly address acetate utilization by tumor cells, we analyzed by 1H/13C-NMR in the supernatant of MM cells incubated with13C-acetate, and found a consistent uptake depending on incubation time and cell density. As Fatty Acid Synthase (FASN) is a key enzyme in acetate metabolism, we further hypothesized that targeting FASN may result in anti-myeloma effects, and potentiate the effects of proteasome inhibitors. Indeed, the FASN-inhibitor orlistat was toxic for a panel of myeloma cell lines ($p<0.01$). Importantly, at comparable doses, bone marrow mesenchymal stem cells were affected by orlistat with respect to adipogenic differentiation, but did not undergo apoptosis. Additionally, FASN synergized in MM cells with proteasome inhibitors and with tunicamycin, an endoplasmic reticulum stressor. Thus, we identified acetate metabolism as crucial to MM biology. This holds potential for a new, clinically robust diagnostic tool for tumor identification by PET imaging, and represents a promising new therapeutic target for this bone invading tumor.

MO0073

Comparing the Incidence of Bone Tumors in Rats Chronically Exposed to Abaloparatide (BA058) or PTH(1-34). Jacquelin Jolette*[1], Aurore Varela[2], Bassem Attalla[3], Susan Y. Smith[2], Gary Hattersley[4]. [1]Charles River Laboratories, Preclinical Services Montreal, Canada, [2]Charles River Laboratories, Canada, [3]Charles River, Canada, [4]Radius, USA

Prolonged treatment with rhPTH(1-34) or rhPTH(1-84) in rats results in development of bone tumors. However to date, this rodent response has not translated into evidence of an increased osteosarcoma risk in patients treated with these drugs or in diseases associated with chronic PTH elevation. This study was conducted to evaluate the potential for abaloparatide (ABL) to induce bone tumors in rats exposed for up to 2 years. Six-week old F344 rats (60/sex/dose) were subcutaneously injected with 0, 10, 25, or 50μg/kg ABL or 30μg/kg PTH(1-34) daily. PTH(1-34) served as positive control. Whole body radiographs were taken from all rats to facilitate tumor detection at necropsy. Systemic hyperostosis, increased bone radiopacity and BMD (Table) were observed in rats treated with ABL at ⩾10μg/kg or PTH(1-34), consistent with expected pharmacodynamics. A comparable continuum of proliferative changes in bones, mostly osteosarcoma, were observed in both ABL and PTH(1-34) treated rats. Comparison of these findings for ABL and PTH(1-34), at similar exposure multiples to the human therapeutic dose (25μg/kg ABL and 30μg/kg PTH), showed marked similarities in osteosarcoma-associated mortality, tumor incidence (Table), age at first occurrence and metastatic potential. Females were less sensitive than males to bone tumor development with both compounds. In conclusion, close to whole life treatment with ABL in rats resulted in the dose and time dependent formation of osteosarcomas, with a comparable response to PTH(1-34) at similar exposure. These results suggest no increased risk of bone tumors would be expected in patients treated with ABL compared to PTH(1-34).

Histomorphometric Assessment of Breast Cancer Bone Metastases with the 2mm Jamshidi Trephine Reveals Intense Woven Bone Formation and Resistance to Bisphosphonates. Richard Kremer*[1], Iryna Kuchuk[2], Monzur Murshed[3], Nathaniel Bouganim[2], Natasha Kekre[2], Susan Robertson[2], Lisa Vandermeer[2], Jin Li[4], Christina Addison[2], Roanna Segal[2], Mark Clemons[2]. [1]McGill University, Royal Victoria Hospital, Canada, [2]Ottawa Hospital Research Institute, Canada, [3]McGill University, Canada, [4]McGill University, Canada

Despite widespread use of bisphosphonates in breast cancer patients with metastatic spread to the skeleton, relatively little is known about their effects on tumor growth within bone and on the surrounding bone microarchitecture. A major limitation to better understand these histomorphometric changes is the invasiveness of the traditional 7mm trephine to obtain routine transiliac bone biopsies. In this study we examined these histomorphometric changes using a 2 mm ''Jamshidi'' bone biopsy trephine in a series of breast cancer patients with and without metastatic spread to the skeleton. Patients were divided into 4 groups based on histological evidence of tumor invasion in the skeleton and on IV administration of pamidronate(PM): group 1(n=1) no evidence of bone invasion and no treatment with PM, group 2(n=1) evidence of bone invasion and not treatment with PM, group 3(n=3) no evidence of bone invasion and treatment with PM, group 4(n=6) evidence of bone invasion and treatment with PM. Three dimensional micro-computed tomography revealed significant architectural disruption in bone samples with evidence of tumor invasion with variable indices of bone volume(BV/TV) ranging from low to high. Biopsies were embedded in methylmethacrylate and sections were stained with haematoxylin and eosin, Von Kossa, tartrate-resistant acid phosphatase (TRAP) for osteoclasts and toluidine blue or alkaline phosphatase for osteoblasts. Histomorphometric analysis of group 1 showed number of osteoclasts (Oc) and osteoblasts (Ob) consistent with post-menopausal bone turnover (mean NOc/T.Ar=2.2, mean NOb/T.Ar=138). Group 2 was characterized with very high Oc number (mean NOc/T.Ar =30) and normal Ob number (mean NOb/T.Ar=111). Group 3 was characterized by an almost absence of Oc (mean NOc/T.Ar=0) with apparently normal Ob number (mean NOb/T.Ar=101). Group 4 had very high Oc number (mean NOc/T.Ar =14) with normal Ob number (NOb/T.Ar=102). Furthermore, in group 4 tumor invasion was accompanied by disruption of the trabecular bone structure immediately juxtaposed to tumor cells as well as large areas of unmineralized woven bone characteristic of osteoblastic bone metastases. In conclusion our data support the mixed osteolytic/osteoblastic nature of metastatic skeletal lesions in breast cancer and their apparent resistance to bisphosphonate therapy. Our minimally invasive approach should prove useful in monitoring the efficacy of bone targeting agents in patients with skeletal metastases.

Human CD138+ myeloma cells suppress osteoblastogenesis when co-cultured with human mesenchymal stem cells. Wei Zhang[1], Moustapha Kassem[2], Matthew Drake*[3]. [1]Mayo Clinic, USA, [2]Odense University Hospital, Denmark, [3]College of Medicine, Mayo Clinic, USA

Multiple myeloma (MM) is a malignancy of terminally differentiated plasma cells. MM cells undergo clonal expansion in the bone marrow cavity in close proximity to mesenchymal stem cells (MSCs), a dynamic population of self-renewing multi-potent progenitor cells capable of differentiation along the osteoblast (OB) lineage. Osteolytic lesions affect nearly all patients with MM, and result from localized bone resorption unmatched by bone formation. As such, MM cell suppression of MSC to OB differentiation is critical for the development of MM bone disease.

We developed an *in vitro* system in which the immortalized human MSC line hMSC-TERT was cultured in a transwell system with human MM cells. hMSC-TERT cells co-cultured with hMSC-TERT cells served as a negative control. We employed whole transcriptome sequencing (RNA-seq) to identify differentially expressed genes (defined as $p < 0.05$ and a false discovery rate < 0.10) between hMSCs co-cultured with or without human MM cells.

Co-culture significantly reduced hMSC matrix mineralization and the expression of known OB differentiation marker genes including alkaline phosphatase, col1α1, osteoprotegerin, and osteonectin. RNA-seq identified 97 specific pathways uniquely regulated in the MSCs during MM cell co-culture, including signaling pathways involving interleukin (IL)-1, IL-6, tumor necrosis factor-alpha, NFκB, ephrin B, BMP, RANK, and apoptosis. Further cluster analyses of pre-specified gene sets identified statistically significant suppression of pathways involved in OB differentiation, Wnt/Wnt-related signaling, and proliferation, with up-regulation of pathways involving NFκB and inflammation. Collectively, these data demonstrate the validity of this model for assessing the effects of monoclonal plasma cell-secreted factors on hMSC function. In summary, MM cells significantly inhibited the OB lineage differentiation of hMSCs via regulation of both known and novel pathways in a co-culture model used to simulate human MM cell/hMSC interactions. These results are consistent with the OB suppression that occurs *in vivo* in humans with osteolytic myeloma. Whether similar gene expression changes also occur when hMSCs are co-cultured with CD138+ monoclonal plasma cells from patients with the myeloma precursor condition monoclonal gammopathy of undetermined significance (MGUS) are unknown, but if found may provide insight into the bone loss and increased fractures known to occur in this common condition.

Interactions Between Multiple Myeloma Cells and Osteocytes Alter Osteocytic Gene Expression: Evidence for Osteocyte-Driven Dysregulation of Bone Remodeling in Multiple Myeloma. Jesus Delgado-Calle*[1], Lilian Plotkin[1], Teresita Bellido[1], G. David Roodman[2]. [1]Indiana University School of Medicine, USA, [2]Indiana University, USA

Multiple myeloma (MM)-induced bone disease is characterized by exacerbated bone resorption with osteolytic lesions that do not heal due to a concomitant reduction in bone formation. Osteocytes are major producers of the pro- and anti-osteoclastogenic cytokines RANKL and OPG and also secrete sclerostin, a potent inhibitor of bone formation. In MM, monoclonal plasma cells grow into bone allowing the exchange of soluble factors as well as direct cell-to-cell contact between MM cells and osteocytes. We investigated whether direct contact or soluble factors produced by MM cells alter osteocytic gene expression. Human JJN3 MM cells were cultured in direct cell-to-cell contact with murine osteocytic MLO-A5 cells, or cells were cultured separated by a membrane that only allows the passage of soluble factors. Direct cell-to-cell contact with JJN3 MM cells up-regulated Sost mRNA expression in MLO-A5 osteocytic cells by 3-fold as early as 4h and remained elevated up to 24h. Simultaneous with Sost upregulation, OPG mRNA was decreased by 30-50%. The expression of other Wnt target genes including Axin2 and Smad6 was also decreased. In contrast, Sost/Wnt target gene expression was not altered when MM and MLO-A5 cells were not in direct cell-to-cell contact; however, RANKL gene expression was upregulated suggesting that molecules secreted by MM cells stimulate RANKL. Treatment with TNFa, known to be secreted by MM cells, increased RANKL expression in osteocytic cells after 4 and 24h. However, addition of TGFβ or IL-6, other potential RANKL regulators secreted by MM cells, did not affect RANKL mRNA expression. Further, OPG protein was reduced by 25 and 50% at 4 and 24h respectively, and soluble RANKL was increased by 3-fold at 24h compared to media of MLO-A5 cells cultured alone. These findings demonstrate that direct interactions between osteocytes and MM cells, upregulate the expression of the bone formation inhibitor Sost in osteocytes, which in turn decreases Wnt signaling and reduces osteocytic OPG expression. In addition, soluble factors secreted by MM cells increase osteocytic RANKL expression. Our results suggest that direct contact with MM cells or MM-derived soluble factors alter osteocytic gene expression, which drives the dysregulated bone remodeling in MM.

Cross-talk between Runx2 regulatory network and IGF-1R pathway: A novel regulatory mechanism of bone metastasis. Jitesh Pratap[1], Manish Tandon*[2], Zujian Chen[2], Amarjit Virdi[1]. [1]Rush University Medical Center, USA, [2]Rush University Medical Center, USA

Bone is one of the most common target sites of distant metastasis of epithelial cancers, resulting in cancer-related deaths and skeletal complications. The paracrine signaling between tumor cells and the bone microenvironment leads to a selective growth advantage for the cancer cells. The bone-derived insulin-like growth factor-1 (IGF-1) binds to insulin-like growth factor receptor (IGF-1R) to initiate intracellular signaling. The downstream signaling events in response to IGF-1 stimulation include activation of phosphatidyl inositol 3' kinase and mitogen activated protein kinases that regulate survival and proliferation of cancer cells. However, the inhibition of these signaling pathways has shown modest benefit in recent clinical trials necessitating the need to understand the regulatory mechanisms of the IGF-1R pathway and to block bone metastasis. The Runt-related transcription factor, Runx2, is required for bone development but is also aberrantly expressed at higher levels in invasive mammary epithelial cells and promotes invasive properties. Recently, we have shown that Runx2 promotes survival of invasive breast cancer cells by increasing phosphorylation of serine/threonine kinase Akt (pAkt-Serine 473) via mammalian target of rapamycin complex-2. To determine the implications of Runx2-mediated pAkt regulation in bone metastasis of breast cancers, we isolated Runx2 knockdown or control MDA-MB-231 cells from bones 7-8 weeks post intracardiac injections in SCID mice. The expression profiling of IGF-1R/Akt signaling pathway showed increased IGF-1Rβ, pIGF1R-β and pAkt levels in bone-seeking Runx2 knockdown cells compared to controls and that could be inhibited with IGF-1Rβ inhibitor OSI-906 (Linsitinib). However, despite inhibition of IGF-1R and Akt activity with OSI-906, no apparent phenotypic alterations were observed. Interestingly, in contrast to IGF-1Rβ and pAkt, the Erk 1/2 levels were reduced in bone-seeking Runx2 knockdown cells compared to parental MDA-MB-231 cells. The treatment with Erk 1/2 inhibitor reduced clonogenic potential of these cells. Taken together, our studies indicate a temporal requirement of Runx2-mediated regulation of IGF-1R/Akt/Erk signaling during bone metastasis of breast cancer and suggest that the inhibition of Runx2 could enhance sensitivity of cancer cells towards Erk inhibitors targeting bone metastasis with high IGF-1R.

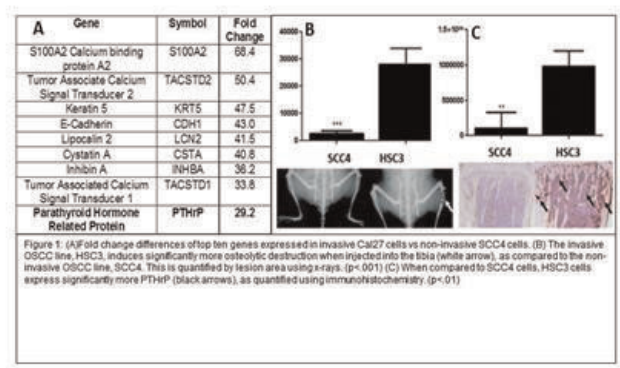
Hedgehog and mechanical signaling regulate PTHrP expression and bony invasion of oral squamous cell carcinomas. Shellese Cannonier*[1], Cara Gonzales[2], Jonathan Page[3], Scott Guelcher[4], Julie Sterling[5]. [1], USA, [2]UT Health Science Center, USA, [3]Department of Cehmical & Biomolecular Engineering, Vanderbilt University, USA, [4]Vanderbilt University, USA, [5]Department of Veterans Affairs (TVHS)/Vanderbilt University Medical Center, USA

Oral Squamous Cell Carcinoma (OSCC) frequently invades the mandible, which dramatically reduces survival rates while increasing associated morbidity. Despite decades of research, the molecular mechanisms of OSCC mandibular invasion are not well understood. PTHrP is expressed in OSCC biopsies with mandibular invasion and PTHrP knock-down in a murine OSCC line prevented invasion. Clinical data shows that the Hedgehog (Hh) signaling pathway regulator, Gli2, correlates with invasion and poor overall survival, and we have shown that in tumors that metastasize to bone, Gli2 activates PTHrP expression. Based on this data and our preliminary microarray data showing that PTHrP is over-expressed 29-fold by invasive OSCC cells (Fig 1), we hypothesized that Gli2 controls PTHrP expression in bony invasive OSCC. Therefore, we examined a panel of 10 OSCC cell lines, and found that 8 lines expressed both Gli2 and PTHrP. To determine if this increased expression correlated with bony invasion, we injected SCC4 cells, a non-invasive OSCC line with low PTHrP expression, or HSC3 cells, an invasive OSCC line with high PTHrP expression similar to that of Cal27, into the tibia of mice. HSC3 cells induced a 12-fold increase in osteolytic lesion area by X-ray and 8-fold more PTHrP by IHC than SCC4 cells (Fig 1). To explore the regulation of Gli2 and PTHrP expression, we examined pathways known to regulate both in other tumors, including rigidity, TGF-β, Hh, and Wnt signaling. Firstly, using 2D polyurethane films of varying rigidities, we found that PTHrP expression was increased 13-fold in cells grown on films approximating the rigidity of the mandible compared to soft tissue rigidities (Fig 2). To determine the upstream modulators of Gli2 and PTHrP, we used agonists and antagonists against known regulators of Gli2. Using promoter assays and qPCR, we found that while the activation of Hh, Wnt, and TGFβ signaling pathways all modulate PTHrP expression, only Hh signaling is required, as cyclopamine treatment (Hh inhibitor) completely blocked PTHrP stimulation by other pathways. To determine if this effect was specific to Gli2, we examined the efficacy of Gli inhibitors, Gant58 and HPI-1, both of which reduced PTHrP expression by 5 to 6 fold. Together, our data demonstrate that PTHrP expression in bony-invasive OSCC is regulated by Gli2, and Hh inhibition reduces PTHrP expression, suggesting Gli2 as a potential therapeutic target for inhibiting bony invasion of OSCC.



A Gene	Symbol	Fold Change
S100A2 Calcium binding protein A2	S100A2	68.4
Tumor Associate Calcium Signal Transducer 2	TACSTD2	50.4
Keratin 5	KRT5	47.5
E-Cadherin	CDH1	43.0
Lipocalin 2	LCN2	41.5
Cystatin A	CSTA	40.8
Inhibin A	INHBA	36.2
Tumor Associated Calcium Signal Transducer 1	TACSTD1	33.8
Parathyroid Hormone Related Protein	PTHrP	29.2

Figure 1: (A)Fold change differences of top ten genes expressed in invasive Cal27 cells vs non-invasive SCC4 cells. (B) The invasive OSCC line, HSC3, induces significantly more osteolytic destruction when injected into the tibia (white arrow), as compared to the non-invasive OSCC line, SCC4. This is quantified by lesion area using x-rays. (p< 001) (C) When compared to SCC4 cells, HSC3 cells express significantly more PTHrP (black arrows), as quantified using immunohistochemistry. (p<.01)

1

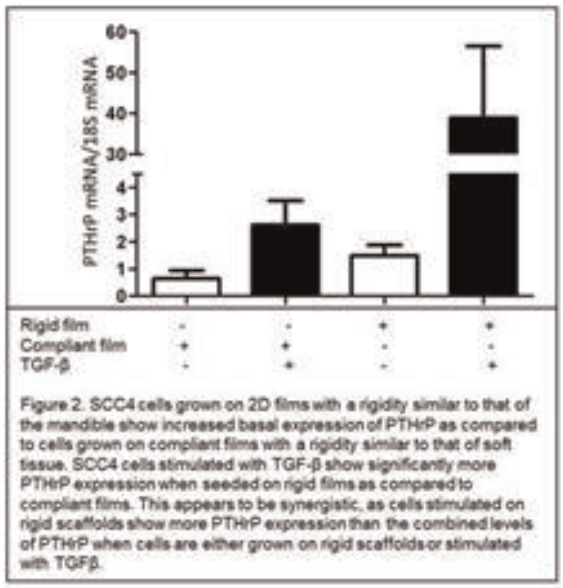


Figure 2. SCC4 cells grown on 2D films with a rigidity similar to that of the mandible show increased basal expression of PTHrP as compared to cells grown on compliant films with a rigidity similar to that of soft tissue. SCC4 cells stimulated with TGF-β show significantly more PTHrP expression when seeded on rigid films as compared to compliant films. This appears to be synergistic, as cells stimulated on rigid scaffolds show more PTHrP expression than the combined levels of PTHrP when cells are either grown on rigid scaffolds or stimulated with TGFβ.

Inhibition of Autophagy Increases Cytotoxic Effects in Chondrosarcoma Cells. Stephan Reumann[1], Kristen Shogren[1], Michael Yaszemski[2], Avudaiappan Maran*[2]. [1]Mayo Clinic College of Medicine, USA, [2]Mayo Clinic College of Medicine, USA

Chondrosarcoma is a cancer of cartilage cells and is the second most common type of bone tumor in the United States. Unlike other musculoskeletal tumors, chondrosarcomas are resistant to conventional chemotherapy and radiotherapy. Autophagy is a homeostatic mechanism through which cellular proteins and organelles are subjected to lysosomal degradation and recycling and could play a dual role in cancer by facilitating either cell death or cell survival. Although autophagy has been shown to contribute to chemoresistance in several cancers, its involvement in chondrosarcoma has not yet been investigated. To determine whether autophagy plays a role in chondrosarcoma, we have studied the individual effects of 2-methoxyestradiol (2-ME) and cis-platin, two compounds that have been shown to induce cell death. Transmission electron microscopy imaging indicates that 2-ME treatment resulted in the accumulation of autophagosomes in human chondrosarcoma cells. Both 2-ME and cis-platin induced the conversion of microtubule-associated protein LC3-I to LC3-II, a protein marker that is correlated with the formation of autophagosomes. In addition, our results show that treatment with Bafilomycin and 3-methyl adenine, the inhibitors of autophagy, further increased the cell death in 2-ME and cis-platin-treated chondrosarcoma cells. Together, this study demonstrates that 2-ME and cis-platin induce autophagy in chondrosarcoma cells which might contribute to the chemoresistance. Thus, our studies show that the targeted treatment and the efficacy of chemotherapeutic drugs in chondrosarcoma could be further improved by modulating autophagy.

Interleukin-6 receptor inhibitor suppresses bone metastases in a breast cancer cell line. Hiroki Wakabayashi*[1], Takahiko Hamaguchi[2], Takahiro Iino[2], Akihiko Matsumine[2], Akihiro Sudo[2]. [1]Mie University Graduate School of Medicine, Japan, [2]Mie University, Japan

Background. Interleukin-6 (IL-6) is a multipoietic cytokine produced by many cell types. IL-6 acts on a wide range of tissues and cell lines and induces cell growth and differentiation, production and expression of other cytokines, and acute phase protein synthesis. IL-6 is a potent inflammatory cytokine that appears to play a key role in cancer growth and metastasis. In the present study, the effects of IL-6 receptor (IL-6R) inhibitor on breast cancer aggressiveness and bone metastases were investigated.

Methods. MDA-MB-231 (MDA-231) cells were injected into the left heart ventricle of mice, and then anti-human IL-6R monoclonal antibody or saline was administered intraperitoneally for 28 days. After 28 days, incidence of bone metastases was evaluated in the hindlimbs by radiography and histology. MDA-231 cells were treated in presence or absence of IL-6R inhibitor and were examined with respect to cell survival. The appearance of signal transducer and activator of transcription 3 (Stat3) and vascular endothelial growth factor (VEGF) was analyzed by SDS-PAGE and immunoblotting.

Results. In X-ray, osteolytic bone metastases appeared around the knee joints in the mice without tocilizumab treatment. 93.8% (15/16) of untreated mice developed metastases per mouse. In contrast, 60% (9/15) of treated mice developed metastases per mouse. In histomorphometric analysis, the area of metastases per hind limb bone was 22.7% $\pm$ 6.1% and 8.3% $\pm$ 4.5% in untreated and treated mice, respectively. Radiological and histomorphometric analysis showed that the area of metastatic bone tumor was decreased significantly in treated mice. The mechanism of bone metastasis inhibition involved inhibited cell proliferation and decreased expressions of phospho-Stat3 and VEGF in MDA-231 cells.

Conclusions. IL-6R inhibitor reduced bone metastases in an animal model injected with MDA-231 cells. These results suggest a novel role for IL-6 signal inhibition in the reduction bone metastases in this breast cancer model. The results of the present study suggest that inhibition of IL-6 signal may become a preventive therapeutic option for breast cancer.

Osteopenia and Osteolysis Resulting from Multiple Myeloma Partially Suppressed through Low Intensity Mechanical Signals. Gabriel Pagnotti*[1], Benjamin Adler[1], M. Ete Chan[1], Mallory Korman[2], Kenneth R Shroyer[2], Clinton Rubin[3]. [1]Stony Brook University, USA, [2]Stony Brook Medicine Department of Pathology, USA, [3]State University of New York at Stony Brook, USA

Multiple myeloma promotes osteopenia and osteolysis while causing marked destruction of healthy marrow, elevating fracture risk while simultaneously compromising the capacity for bone repair. In this study, we evaluated the capacity of low intensity vibration (LIV) as a means to harness bone's sensitivity to mechanical signals and protect skeletal quantity and quality put at risk as a consequence of multiple myeloma. Twenty-five 7w old immunocompromised mice (*NSG*, The Jackson Laboratory) were tail-injected with 2 x 10^6 U266β1 (ATCC) human myeloma cells, while 8 controls (AC) were saline-injected. Of the 25 myeloma injected animals, 13 were subject to 15 minutes per day of low intensity vibration (V; 0.3g @ 90Hz), while 12 received sham handling (M). At 9w post-injection, histological assessment of the femoral and tibial bone marrow revealed extensive plasma cell infiltration throughout the medullary cavity in both M and V as compared to AC, resulting in displacement of healthy marrow constituents, phenotypically consistent with gross anemia and leukopenia. As reviewed by a pathologist, evaluation of the marrow space estimates a 75% infiltration of the disease in M, with a 61% invasion in V. FACS analysis of marrow isolated from the femur showed a +180% ($p<0.002$) greater number of early-stage hematopoietic stem cells (KLS) in M versus AC, while a -6% decrease was observed in V as compared to M. Micro-CT of the distal femora demonstrated a -73% ($p<0.04$) lower trabecular bone volume fraction (BV/TV) in M as compared to AC. In contrast, the mechanically stimulated V group had a +36% greater BV/TV ($p<0.05$) as compared to M. Cortical BV/TV of the femoral diaphysis was -16% ($p<0.03$) lower in M as compared to AC, while V was +6% greater than M (nsd). Cross-cortical perforation of the metaphysis observed in many M mice was not evident in V or AC. This murine model of multiple myeloma demonstrates the rapid invasion of the tumor through the marrow, and the resulting erosion of both bone quality and quantity. These preliminary experiments suggest that the introduction of mechanical signals – perhaps as a surrogate to exercise – helps slow the progress of the disease by potentially protecting the bone marrow microenvironment.

Connexin 43 Regulates Chondrocyte Differentiation. Yue Zhang[1], Alayna Loiselle[2], Yanghue Xing[3], Jun You[4], Henry Donahue*[4]. [1]Pennsylvania State University College of Medicine, USA, [2]University of Rochester, USA, [3]Pennsylvania State University College of Medicine, USA, [4]The Pennsylvania State University College of Medicine, USA

Osteoarthritis (OA) is the most common joint disorder. Recent studies suggest connexin 43 (Cx43) and gap junctions (GJs) are increased in human OA cells. GJs are membrane-spanning channels which facilitate intercellular communication. It has been reported that Cx43 and GJ regulate differentiation of musculoskeletal cells including osteocytes, osteoblasts and osteoclasts, however, it is unknown whether Cx43 regulates chondrocyte differentiation, a key step in initiating OA. In this study, we used mouse primary chondrocytes and a chondrocytic cell line, ATDC5, as models to study the function of Cx43 during chondrocyte differentiation. We examined the hypothesis that Cx43 regulates chondrocyte differentiation.

Our qPCR data showed that Cx43 mRNA levels in ATDC5 cells significantly increased during 3 weeks culture in differentiation media. Interestingly, over expression of Cx43 in ATDC5 cells prevented chondrocyte differentiation, as demonstrated by inhibition of Alcian blue staining and prevention of increases in Col2, Aggrecan, and Sox9 mRNA levels. Col10 mRNA levels also did not increase, suggesting inhibition of chondrocyte hypertrophy. To verify these results, we transiently ablated Cx43 from mouse primary chondrocytes ($Cx43^{-}$) using a Cre-loxp system. Despite low primary cell transient transfection efficiency, our data showed that Cre transfection inhibited Cx43 mRNA levels about 44%. After culturing in differentiation media, $Cx43^{-}$ cells showed moderate non-significant increases in Col10, Col2, AGN and Sox9 mRNA levels relative to control cells, suggesting an increase in chondrocyte differentiation and hypetrophy.

By using gain and loss of function approaches, we examined the function of Cx43 during chondrocyte differentiation. Our results clearly demonstrated that Cx43 is closely related to chondrocyte differentiation, a step initiating OA. We showed that Cx43 mRNA levels increased during chondrocyte differentiation and overexpression of Cx43 prevents chondrocyte differentiation and hypertrophy. These results suggest that normal (non OA) chondrocyte Cx43 levels increase as the cells differentiate and eventually this moderates, in a negative feedback manner, chondrocyte differentiation and development of hypertrophic chondrocytes. The increased levels of Cx43 in OA chondrocytes previously reported suggest that OA chondrocytes are resistant to the moderating effect of Cx43 and Cx43 levels increase further to overcome this resistance.

Pulsed Electromagnetic Field (PEMF) Treatment Reduces Expression of Genes Associated with Disc Degeneration in Human Intervertebral Disc Cells. Stephanie Miller*[1], Rachel Bradshaw[2], Dezba Couglin[3], Jeffrey Lotz[2]. [1]University of California, San Francisco, USA, [2]UCSF, USA, [3]UCSF, USA

Imbalances in inflammation, innervation, and extracellular matrix maintenance are potential unifying clinical features of intervertebral disc (IVD) degeneration and low back pain (LBP). Pulsed electromagnetic field (PEMF) therapies have been applied to stimulate bone health and healing as well as to reduce the symptoms of arthritis, but the effects of PEMF on IVD biology is unknown.

Human IVD tissues were collected from patients being surgically treated for discogenic pain or spinal instability. The IVD tissues of annulus fibrosus (AF) and nucleus pulposus (NP) were separated by blunt dissection, incubated, and cultured separately until use at passage 4. Each cell type was separately encapsulated in 1.2% alginate beads, and the cells were acclimated for 24 hours before treatment. Cells were treated with IL-1α (10 ng/mL) to stimulate an inflammatory environment associated with chronic LBP. Cells were also exposed to an FDA-approved PEMF waveform (Orthofix, Inc., Lewisville, TX) for four hours daily. At each terminal incubation point (1, 4, 7 days), RNA was isolated from cells from each treatment group to assess IL-1α- and PEMF-induced changes in gene expression. NuGEN Pico V2 was used for amplification, fragmentation and biotin-labeling of cDNA, and the labeled cDNA was hybridized to Human GeneChip Gene 2.0 ST microarrays. Linear models were fitted for each gene using the Bioconductor Limma package in R, and moderated t-statistics, fold-change and the associated p-values were calculated for each gene.

PEMF treatment lessened the IL-1-induced upregulation of particular genes known to play a role in IVD degeneration and LBP. Consistent with our previous results, PEMF tended to reduce IL-1α-associated expression of IL-6 (25%, p=0.069) in NP cells and MMP13 (26%, p=0.10) in AF cells. Additionally, PEMF treatment significantly diminished IL-1α-induced expression of IL-17A (33%, p=0.011) and MMP2 (24%, p=0.0059) in NP cells. In AF cells, PEMF treatment significantly decreased IL-1α-linked NFκB (11%, p=0.042) expression. These results demonstrate that disc cells are responsive to PEMF, and motivate future studies to determine whether PEMF may be helpful for patients with IVD degeneration and LBP.

The dynamics of mineralized cartilage formation. David Rowe[1], Nathaniel Dyment*[2], Yusuke Hagiwara[1], Andrew Breidenbach[3], David Butler[3], Thomas Thomopoulos[4], Andrea Schwartz[4], Lindsey Aschbacher-Smith[5], Han Liu[5], Rulang Jiang[5]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut Health Center, USA, [3]University of Cincinnati School of Engineering, USA, [4]Washington University, Department of Orthopedics, USA, [5]Cincinnati Children's Hospital Research Foundation, USA

The boundary that separates subchondral bone from the mineralized portion of articular cartilage (AC) and the fibrocartilage (FC) that attaches tendon/ligaments to bone (enthesis) juxtaposes two tissues with distinctly different cell environments and mechanical functions. Both undergo a mineralization process that is driven by different cells and molecular processes. Using non-decalcified cryohistology, appositional mineral deposition is found in rapidly growing mice in both types of mineralizing cartilage (MC). The mineralization lines of bone and MC are formed in opposite directions indicating that a mineralized interface is being created. Collagen fibers run vertically through the MC where they juxtapose with horizontally oriented

subchondral bone. Bone formation is characterized by Col3.6GFP+ osteoblasts overlying a mineralization label in close association with TRAP+ osteoclastic activity. In contrast, ColX-RFPchry+, alkaline phosphatase (AP+), and occasionally TRAP+ chondrocytes are located at the tidemark and extend into the MC zone. Using a Gli1-CreERT2/Ai14 lineage tracing strategy, cells in the unmineralized zone can be chased into the mineralized zone indicating that the mineralization front extends into the tendon/ligament/cartilage as cell differentiation progresses away from the MC (fig 1). This concept is strengthened by the observation that Scx-Cre:Smof/- mice have severely underdeveloped entheses, suggesting that hedgehog signaling is crucial for MC formation (fig 2). After skeletal maturity, minimal mineralization activity is observed, but in the case of the enthesis (not AC), it can reactivate when abrupt mechanical forces are experienced. Using an ACL transection model, the enthesis initiates appositional mineral growth with the ColX-RFP/AP+ cells extending ahead of the tidemark. Chondrocytes in the unmineralized cartilage just above the tidemark become TRAP+ showing a punctate morphology that is distinctly different from osteoclasts (fig 3). These changes are prominent in the uninjured MCL and can be observed within two weeks after surgical intervention. Osteophytes subsequently develop reflecting the loss in the barrier between the two tissues. Understanding the molecular and cellular environment of the FC that produces the barrier and the limitations it has in maintaining this boundary when a new mechanical load is experienced may be an avenue of research for understanding the pathogenesis of degenerative arthritis.

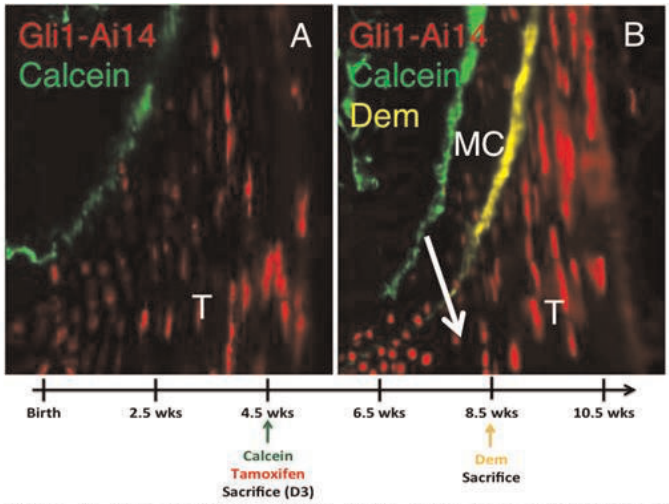

Figure 1. Lineage trace of Gli1-Ai14+ cells from unmineralized fibrocartilage (A) in the patellar tendon enthesis to mineralized fibrocartilage (B). Tamoxifen and calcein were delivered at 4 weeks of age followed by demeclocycline (Dem) at 8 weeks of age. Mice were analyzed at 3 days (A) and 28 days (B) following tamoxifen injection. Tendon (T), Mineralized Fibrocartilage (MC).

The Effects of Reduced Gravity On Subchondral Bone And Articular Cartilage: Are They Good Neighbors?. Liliana Mellor*[1], Elizabeth Loboa[2], Julia Oxford[3], Travis Baker[4], Minoti Hiremath[5]. [1]North Carolina State University, USA, [2]North Carolina State University, USA, [3]Boise State University, USA, [4]Boise State University, USA, [5]Boise State University, USA

Astronauts are exposed to prolonged periods of microgravity during spaceflight. Lack of gravity is known to negatively affect the musculoskeletal system, mainly bone and skeletal muscle, which are constantly exposed to mechanical loading on Earth. However, another important component of the musculoskeletal system, the synovial joint, has not been fully investigated in space-like conditions. Unlike bone and muscle, the articular cartilage of the synovial joint has limited regenerative capacity. Cartilage degradation leads to a severe disease known as osteoarthritis (OA). OA is the leading cause of disability in the US, and one of the few chronic diseases of aging without a cure. Little is known about the effects of microgravity on the synovial joint and changes in cartilage homeostasis. The goal of this project is to elucidate the molecular changes triggered by microgravity that cause degradation of articular cartilage and subchondral bone, and to investigate the interactions between these adjacent tissues. Changes in subchondral bone density are commonly associated with the onset of cartilage degradation in OA. Aberrant cross-talk between signaling pathways in the two tissues may precipitate pathological conditions. This is the first study to address interactions between these two tissues in reduced gravity conditions.

The Wnt pathway plays a crucial role in bone and cartilage mechanotransduction. It has been shown that inhibitors of the Wnt pathway are up-regulated in bone during unloading conditions, contributing to a decrease in bone formation that leads to bone density loss. We used primary chondrocytes and Rat Chondrosarcoma cells (RCS) cultured under reduced gravity conditions using a Rotating Wall Vessel bioreactor to determine changes in chondrocyte gene expression and Wnt signaling in response to simulated microgravity. Our data shows that similar to bone, Wnt inhibitors are also up-regulated in chondrocytes in response to reduced gravity; however, this may be a chondro-protective mechanism to prevent further cartilage degradation. We have found that Wnt activation and inhibition appear to have opposite effects on adjacent subchondral bone and articular cartilage; therapeutic targeting against Wnt inhibitors to prevent bone loss needs to be further investigated.

MO0088

An *in Vitro* Chondrogenic Differentiation Model Using KS483 Mouse Mesenchymal Progenitor Cell Line. Katja Fagerlund*[1], Natalia Habilainen-Kirillov[2], Clemens Lowik[3], Alan Chan[4], Jussi Halleen[5]. [1]Pharmatest Services Ltd, Finland, [2]Pharmatest Services Ltd, Finland, [3]Department of Radiology, Leiden University Medical Center, Netherlands, [4]Percuros BV, Netherlands, [5]Pharmatest Services Ltd, Fin

KS483 cells are multipotent mouse mesenchymal progenitor cells that are able to differentiate into chondrocytes, adipocytes and osteoblasts and are a well-characterized model for the study of osteoblast differentiation and bone formation. We have studied the use of KS483 cell line in an *in vitro* model of chondrogenic differentiation. The cells were cultured in three-dimensional (3D) pellet culture system in serum-free differentiation medium in the presence and absence of BMP-6 for 17-28 days. The pellets were cultured in 96-well plates and the medium was changed in 2-3 day intervals. The pellets were embedded in paraffin, sectioned and stained for

Safranin O and Alcain blue for assessment of sulfated glycosaminoglycan (sGAG) content, and processed for immunohistochemistry to visualize type II collagen. For biochemical analysis, the pellets were digested with proteinase K and assayed for sGAG at days 17, 24 and 28. Type II collagen carboxyterminal propeptide (CP-II) was determined in the culture medium collected at day 17. Based on histological analysis, BMP-6 showed concentration-dependent stimulatory effects on chondrogenic differentiation, increased sGAG content of the pellets, and increased CP-II released into the culture medium. These results suggest that the KS483 cell line can be used for setting up an *in vitro* model for studying chondrogenic differentiation and for identifying novel compounds with anabolic effects on chondrogenesis. As these cells can rapidly proliferate, they provide an unlimited source of easily expanded progenitor cells for conducting large number of replicates and studies.

MO0089

Antiangiogenic Drug, TNP-470, Inhibited Early Chondrocyte Condensation During Ectopic Bone Formation. Beth Bragdon*[1], Stephanie Lam[2], Sherif Aly[3], Elise Morgan[4], Louis Gerstenfeld[5]. [1]Boston University School of Medicine Department of Orthopaedics, USA, [2]Department of Orthopaedic Surgery, Boston University School of Medicine, USA, [3]Department of Orthopaedic Surgery, Boston University School of Medicine, USA, [4]Boston University, USA, [5]Boston University School of Medicine, USA

Introduction: Angiogenesis is required for endochondral ossification where vessels invade hypertrophic cartilage and facilitates the replacement of cartilage with mineralized bone tissue during embryological skeletal development. Blocking angiogenesis impedes fracture repair and BMP2-induced ectopic bone formation. Although angiogenesis and bone formation is a coupled process, little is known about the angiogenic role during endochondral ossification in ectopic bone formation.

Methods: Human Demineralized Bone Matrix(DBM) was obtained with an MTA from Medtronics Inc. Fifty milligrams were implanted at the periosteum of the femur of male B6,129S7-Rag1$^{tm1/MOM}$/J. Antiangiogenic drug, TNP-470 (EMD Millipore), was subcutaneously injected (25mg/kg) daily starting the day of surgery. Ectopic bone formation was followed for 16 days. Micro-CT quantified new bone. RNA was isolated from the implant at post-operative day 2, 8 and 16. RT-qPCR was used to quantify mRNA expression for stem cell recruitment (*Sox2*, *Nanog*), chondrocyte commitment and condensation (*Sox9*, *Sox5*, and *NCam1*), chondrocyte (*Aggrecan* and *Collagen10a*), osteoblast (*Osterix* and *Osteocalcin*), and vascular (*VEGFA*, and *Pecam1*) development.

Results: Ectopic bone was induced by the DBM implant by days 8 and 16. TNP-470 significantly decreased bone volume at both time points (Fig1A). Molecular assessment showed stem cell marker expression was present at day 2 for control and TNP-470. This was followed by peak expression of chondrocyte differentiation at day 8 and osteoblasts at day 16 for control implants. While TNP-470 treated implants showed expression for chondrocyte commitment marker, *Sox9*, there was a significant decrease in gene expression for early chondrocyte condensation, *N-Cam1*, and progression of chondrocyte differentiation (Fig1B). Endothelial maker, *Pecam1*, was significantly decreased whereas *VEGFA* expression was increased at day 2 and 4 with TNP-470.

Discussion: Consistent with prior findings inhibition of angiogenesis with TNP-470 decreased ectopic bone. While inhibition of angiogenesis had no effect on stem cell recruitment to the implant site and commitment to the chondrogenic lineage, subsequent chondrogenesis failed to progress. Most striking, however, is that chondrogenic progression was halted prior to chondrocyte condensation, noticeably earlier than the expected hypertrophic chondrocytes. These results suggest an earlier role for angiogenesis for postnatal endochondral ossification.

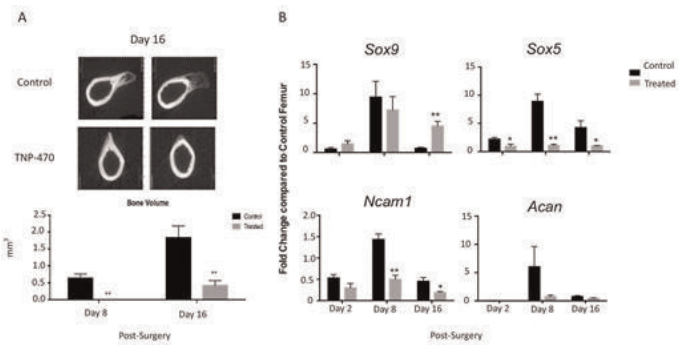

Figure1 A. Micro-CT individual bone slices show cross-sectional view of bone in white and surrounding implant in textured grey. Bone volume at day 8 and 16 for control and TNP-470-treated samples. * = p<0.05, ** = p<0.005. **B.** qRT-PCR analysis of cartilage genes. n= 3-7.

Environmental Stress Promotes Chondrogenic Commitment of Skeletal Progenitor Cells by Activating Autophagy. Nick Van Gastel*[1], Sophie Torrekens[2], Patrizia Agostinis[3], Geert Carmeliet[4]. [1]Laboratory of Clinical & Experimental Endocrinology, KU Leuven, Belgium, Belgium, [2]Laboratory of Clinical & Experimental Endocrinology, KU Leuven, Belgium, Belgium, [3]Laboratory of Cell Death Research & Therapy, KU Leuven, Belgium, Belgium, [4]Katholieke Universiteit Leuven, Belgium

Skeletal progenitor cells present in the periosteum are crucial for successful bone fracture healing, making them an attractive cell source for bone regeneration strategies. Insight in the signaling pathways regulating the activation and differentiation of these cells remains however limited. In the current study, we determined how environmental stress controls the fate of periosteal progenitor cells.

Periosteal progenitor cells were isolated from adult mice and exposed to low nutrient availability (reduced serum, glucose, glutamine and oxygen or low serum alone), which induced activation of autophagy, as determined by measuring LC3 conversion and degradation and p62 protein levels. No changes in AMPK signaling were noted, indicating that the cells were able to maintain their energy balance. Inhibition of autophagy by chloroquine showed that the increased autophagic flux allowed periosteal cells to survive the stressful conditions. Surprisingly, we found that nutrient reduction also alters the fate of periosteal cells and upregulates chondrogenic markers, an effect that was blocked by pharmacological inhibition of autophagy. We observed a similar chondrogenic switch *in vivo* using a new mouse model for compromised bone healing, in which we physically prevented early blood vessel ingrowth from the muscle to the expanding periosteal region, confirming that nutrient availability controls the fate of periosteal cells. Further dissection of the autophagic process using a range of pharmacological compounds indicated that not macroautophagy but rather chaperone-mediated autophagy, a highly selective form of autophagy, is responsible for the chondrogenic switch of periosteal cells upon nutrient deprivation.

Taken together, our data show that the change in the autophagic flux induced by environmental stress not only acts as a survival mechanism, but is also actively involved in determining the fate of periosteal cells, an exciting finding with important implications for skeletal biology and regenerative medicine.

MO0091

Enhanced ST2 Expression in Late Stages of Chondrocyte Differentiation in Growth Plate is Regulated by Transcriptional Activity of Runx2. Ehsan Bonyadi Rad*[1], Karin Pichler[2], Giuseppe Musumeci[3], Egon Marth[4], Annelie Weinberg[2]. [1]Medical University Graz, Austria, [2]Medical University Graz, Austria, [3]University of Catania, Italy, [4]Medical University of Graz, Austria

The primary response gene ST2 which is also known as IL1RL1 or T1 is expressed in various cell types including preosteoblasts. It is suggested that ST2 plays a role in early differentiation stages in osteogenic cells and ST2 receptor regulates osteogenic potential in mouse osteosarcoma cells. Evidently, there are no studies about importance of ST2 in cartilaginous tissue therefore we aimed to investigate expression, regulation and possible biological role of this gene, in murine growth plate chondrocytes. Reverse transcription PCR (RT-PCR) confirmed mRNA expression of ST2 receptor (ST2L) and secreted ST2 (sST2) in murine chondrogenic cell line ATDC5. Immunohistochemistry (IHC) of murine tibiae of euthanized three week old mice showed increased ST2 expression at pre-hypertrophic to strong persistent expression at hypertrophic chondrocyte in the growth plate. Interestingly, consistent with significant ST2 upregulation at pre- and hypertrophic growth plate chondrocyte, mRNA expression of ST2L and sST2 were increased to several folds in ATDC5 cells after differentiation. In these cells, markers of chondrocyte hypertrophy, e.g. ColX and MMP-13 were also significantly increased. Previous studies reported that Runx2 a master transcription factor for osteoblast differentiation controls hypertrophic chondrocyte differentiation. Moreover, Runx2 upregulation in differentiated ATDC5 cells were documented before. In an evaluation for possible effect of Runx2 on ST2 expression, quantitative RT-PCR of ATDC5 cells stably transfected with Runx2 cDNA showed significant upregulation of both ST2L and sST2 mRNA expressions. Accordingly, selective knockdown of Runx2 by siRNA led to substantial downregulation of both variants in ATDC5 cells. Expression of ST2 splice variants are regulated by alternative promoters (distal and proximal) which is cell dependent. Whereas our results demonstrated that both ST2L and sST2 are transcribed from proximal promoter, low mRNA expressions produced from distal promoter were observed in Runx2 overexpressing cells. Using genomic analysis we identified putative Runx2 binding sites on both distal and proximal promoters and electrophoretic mobility shift assay demonstrated binding of Runx2 to both promoters. Overall, our data so far suggest that Runx2 is involved in transcriptional activation of ST2 in pre- and hypertrophic chondrocytes and further investigations might lead to better understanding of ST2 function in the growth plate.

MO0092

Expression and function of CCAAT/enhancer-binding protein family in chondrocytes. Tomotake Okuma*[1], Makoto Hirata[2], Sakae Tanaka[3], Hiroshi Kawaguchi[4], Taku Saito[5]. [1]University of Tokyo, Japan, [2]University of Tokyo, Japan, [3]The University of Tokyo, Japan, [4]JCHO Tokyo Shinjuku Medical Center, Japan, [5]University of Tokyo, Graduate School of Medicine, Japan

CCAAT/enhancer-binding protein (C/EBP) is a member of the leucine zipper family of transcription factors. Among six isoforms of C/EBP family members, C/EBPα, C/EBPβ, C/EBPδ and C/EBPε have a transactivation domain (TAD) and exert redundant functions in many physiological processes such as cell differentiation, cell proliferation, cell cycle regulation, inflammation and immunity. We previously reported that C/EBPβ is abundantly expressed in chondrocytes and regulates skeletal growth and osteoarthritis through the induction of cell cycle-related genes and metalloproteinases. Since the roles of C/EBPα, C/EBPδ and C/EBPε remain unclear, we examined expressions and functions of these C/EBPs in chondrocytes. Among the four C/EBPs with TAD, expression of C/EBPβ and C/EBPδ in mouse primary costal chondrocytes was abundant compared to C/EBPα, while C/EBPε was hardly expressed at the mRNA level. Immunofluorescence showed that C/EBPβ and C/EBPδ proteins were predominantly localized in the prehypertrophic and hypertrophic zones of mouse embryonic limb cartilage, while C/EBPα protein was localized in the proliferative zone. Retroviral overexpression of each of the three C/EBPs in ATDC5 cells suppressed expressions of early differentiation markers including *Col2a1* and *Sox9*, enhanced those of late differentiation markers including *Mmp13* and *Vegfa*, and decelerated cell proliferation, indicating their redundant functions in chondrocytes. To investigate loss-of-function of the three C/EBPs, we used A-C/EBP which exerts a dominant-negative effect against all C/EBPs. Lentiviral overexpression of A-C/EBP into ATDC5 cells increased expressions of *Col2a1* and *Sox9*, decreased those of *Mmp13* and *Vegfa*, and accelerated cell proliferation, confirming that these three C/EBPs suppress the early stage of chondrocyte differentiation and proliferation while enhancing the late stage. Finally, microarray and gene ontology analyses identified many genes regulated by the A-C/EBP overexpression: 19, 17, 35 and 13 genes were upregulated while 26, 41, 97 and 62 genes were downregulated in the skeletal development-related, cell cycle-related, apoptosis-related, and inflammation-related gene groups, respectively. In conclusion, C/EBPβ, C/EBPδ and C/EBPα regulate proliferation and differentiation of chondrocytes and may possibly be involved with apoptosis and inflammation. C/EBPs may play a variety of roles in the homeostasis of joint cartilage under physiological and pathological conditions.

LSD1-Mediated Demethylation of Histone H3 Lysine 9 Contributes to Interleukin 1-Induced Microsomal Prostaglandin E Synthase-1 Expression. Fatima Ezzahra El Mansouri*[1], Sarah Nebbaki[1], Hassan Afif[2], Johanne Martel-Pelletier[2], Jean-Pierre Pelletier[2], Mohamed Benderdour[3], Hassan Fahmi[2]. [1]Research Center-CHUM, Canada, [2]Osteoarthritis Research Unit, CR-CHUM, Canada, [3]Hopital Sacre-Coeur, Canada

Objective: Microsomal prostaglandin E synthase-1 (mPGES-1) catalyzes the terminal step in the biosynthesis of PGE_2, a critical mediator in the pathophysiology of osteoarthritis (OA). Histone methylation plays an important role in epigenetic gene regulation. In this study, we investigated the roles of histone H3 (H3K9) methylation in interleukin-1β (IL-1)-induced mPGES-1 expression in human chondrocytes.

Methods: Chondrocytes were stimulated with IL-1 and the expression of mPGES-1 mRNA was evaluated using real-time reverse transcriptase-polymerase chain reaction (RT-PCR). H3K9 methylation and the recruitment of the histone demethylase LSD1 to the mPGES-1 promoter were evaluated using chromatin immunoprecipitation (ChIP) assays. The role of LSD1 was further evaluated using the pharmacological inhibitors, tranylcypromine and pargyline, and siRNA-mediated gene silencing. The LSD1 level in cartilage was determined using RT-PCR and immunohistochemistry.

Results: The induction of mPGES-1 expression by IL-1 correlated with decreased levels of mono- and dimethylated H3K9 at the mPGES-1 promoter. These changes were concomitant with the recruitment of the histone demethylase LSD1. Treatment with tranylcypromine and pargyline, potent inhibitors of LSD1, prevented IL-1-induced H3K9 demethylation at the mPGES-1 promoter and mPGES-1 expression. Consistently, LSD1 gene silencing with siRNA prevented IL-1-induced H3K9 demethylation and mPGES-1 expression, suggesting that LSD1 mediates IL-1-induced mPGES-1 expression via H3K9 demethylation. Finally, we showed that the level of LSD1 was elevated in OA compared to normal cartilage.

Conclusion: These results indicate that H3K9 demethylation by LSD1 contributes to IL-1-induced mPGES-1 expression and suggest that this pathway could be a potential target for pharmacological intervention in the treatment of OA and possibly other arthritic conditions.

MO0094

PTHrP Uses HDAC4 and 5 to Suppress Mef2 Action and Inhibit Chondrocyte Hypertrophy. Shigeki Nishimori*[1], Forest Lai[2], Marc Wein[1], Elena Kozhemyakina[3], Andrew Lassar[3], Eric Olson[4], Henry Kronenberg[1]. [1]Massachusetts General Hospital, USA, [2]Massachusetts General Hospital, USA, [3]Harvard Medical School, USA, [4]UT Southwestern Medical Center at Dallas, USA

PTHrP (Parathyroid Hormone-related Peptide) is a powerful inhibitor of chondrocyte hypertrophy. In the chondrocyte-specific PTHrP transgenic mouse (Weir, PNAS 1996), the long bones are composed of only round proliferating chondrocytes without hypertrophic chondrocytes until 7 days after birth. In contrast, the PTHrP KO mouse (Karaplis, Genes Dev 1994) dies just after birth due to respiratory failure caused by abnormal chondrocyte hypertrophy and ossification in the rib cartilage.

Olson's group reported that the transcription factor, Mef2c, drives the hypertrophic program and that Histone Deacetylase 4 (HDAC4), a class IIa HDAC, suppresses this activity (Vega, Cell 2004, Arnold, Dev Cell 2007). Using cultured cells, Lassar's group proposed that PTHrP suppresses hypertrophy by increasing HDAC4 suppression of Mef2c action through a kinase/phosphatase cascade (Kozhemyakina, MCB 2009). Here, we test the validity of these hypotheses *in vivo*.

The HDAC4 KO mouse shows a lethal chondrocyte phenotype similar to that of the PTHrP KO mouse. However, to explain the longer life span (around 10 days) and the delayed onset of the phenotype in the HDAC4 KO mouse, we found that another Class II HDAC member, HDAC5 also mediates the action of PTHrP. The double HDAC4, 5 KO mouse dies at birth with the same phenotype as the PTHrP KO mouse. Even though the HDAC5 KO mouse has normal chondrocyte differentiation, removal of only one allele of the HDAC5 gene in the context of the HDAC4 KO mouse dramatically changes Collagen II and Collagen X mRNA expression in the rib cartilage (Figure).

To exclude the possibility of systemic effects by HDAC4 expressed in other tissues, we compared the phenotypes of the universal HDAC4 KO and the chondrocyte-specific (Collagen II-Cre) conditional HDAC4 KO mouse. We confirmed similar phenotypes in the tibial growth plates, suggesting that the growth plate phenotype in the universal KO mouse is a consequence of deletion of HDAC4 in chondrocytes.

Rib chondocytes never normally differentiate into hypertrophic chondrocytes, but these chondrocytes have a potential to become hypertrophic chondrocytes, as we can see in Figure. Thus, chondrocyte differentiation is regulated by the balance between the activator (Mef2) and the suppressors (PTHrP/HDAC4/HDAC5) in each cartilage.

MO0095

Deletion of Connexin 43 in osteocytes blunts the response to intermittent PTH administration in the bone matrix. Rafael Pacheco Da Costa[1], Iraj Hassan[2], Eduardo Katchburian[3], Hannah Davis[4], Lilian Plotkin[5], Rejane Reginato*[6]. [1]Indiana University/Universidade Federal de Sao Paulo - Brazil, Brazil, [2]Indiana University School of Medicine, USA, [3]Federal University of São Paulo, Brazil, [4]Indiana University School of Medicine, USA, [5]Indiana University School of Medicine, USA, [6]UNIFESP - Federal University of São Paulo, Brazil

Connexin (Cx) 43 form gap junction channels and hemichannels, which mediate intercellular communication in osteoblasts, osteocytes and osteoclasts. Earlier studies showed that mice lacking Cx43 have impaired bone mineralization and a defective anabolic response to intermittent PTH administration (iPTH). However, the role of osteocytes on the response of Cx43 deficient mice to iPTH is unknown. To address

this question, we generated mice lacking Cx43 in osteocytes ($Cx43^{fl/fl}$;DMP1-8kb-Cre). Longitudinal DXA analysis in males from 1 to 4 months of age (N=6-11) did not show differences in BMD between $Cx43^{fl/fl}$;DMP1-8kb-Cre and $Cx43^{fl/fl}$ littermate controls expressing Cx43 in osteocytes. Similarly, the expression of genes associated with bone matrix glycosaminoglycans (has1-3, chsy1, chpf and chsy3), proteoglycans (luminican, decorin and biglycan), collagens (col1a1, col3a1, lox and loxl1-loxl4) and mineralization (osteocalcin, alp and runx2) was not changed by deleting Cx43 from osteocytes in vertebral bone (L6), measured by qPCR. Daily iPTH injections (100ng/g for 14d) increased vertebral, femoral and total BMD by DXA and BV/TV in the lumbar vertebra (L4) by μCT in mice from either genotype in a similar fashion, indicating that Cx43 in osteocytes is not required for increased bone mass induced by iPTH. We next examined the expression of matrix-associated proteins by qPCR and we found that, whereas iPTH induced an increase in the expression of bone sialoprotein in vertebral bones obtained from mice of either genotype; Runx2 and osteocalcin were only increased in $Cx43^{fl/fl}$ mice. Collagen analysis in bone sections stained by picrosirius red under polarized light microscopy did not show changes in the pattern of birefringence in femoral bone sections from vehicle-treated $Cx43^{fl/fl}$;DMP1-8kb-Cre compared to $Cx43^{fl/fl}$ mice. On the other hand, iPTH administration increased the predominance of greenish birefringence, suggesting an intense collagen remodeling in $Cx43^{fl/fl}$, but not in $Cx43^{fl/fl}$;DMP1-8kb-Cre mice. In summary, deletion of Cx43 from osteocytes renders the bone less susceptible to the effects of iPTH administration on the bone matrix. These findings suggest that the inability of PTH to modify the bone matrix in the absence of osteocytic Cx43 expression might contributes to the defective anabolic response to the hormone in mice lacking Cx43.

Healing of the bone and tendon interface: an in vivo study using a lactoferrin seeded biomaterial scaffold. David Musson*[1], Matthew Street[2], Michael Dray[3], Ashvin Thambayah[2], Karen Callon[2], Donna Tuari[2], Brendan Coleman[4], Jillian Cornish[5]. [1]University of Auckland, New Zealand, New Zealand, [2]University of Auckland, New Zealand, [3]Waikato District Health Board, New Zealand, [4]Counties Manukau District Health Board, New Zealand, [5]University of Auckland, New Zealand

Healing of hard-soft tissue interfaces are a significant clinical problem. Up to 40% of people over 60yrs of age experience rotator cuff tears, which predominantly occur at the bone-tendon interface. Due to the complex nature of the osteotendinous junction surgical repair is challenging and re-tear rates are about 70%. A potential approach for the improvement of surgical outcomes is the insertion of scaffold materials and growth factors that accelerate the healing. Decellularized extracellular matrix (ECM) scaffolds are known to improve soft tissue regeneration and our preliminary studies demonstrated that a novel ovine forestomach ECM scaffold is cytocompatable and has low immunogenicity. In addition, our group established that lactoferrin (LF) is a potent bone anabolic factor. The aim of this study was to assess the potential use of the decellularized forestomach ECM scaffold, in combination with LF, for augmenting bone and tendon repair.

Complete unilateral supraspinatus tears were surgically created in 46 Sprague-Dawley rats. The tendons were surgically repaired via a single row technique and the rats were randomised into 3 groups. Group 1 (control), received surgical repair only; group 2 received an augmented repair using the ECM scaffold; and group 3 received the ECM scaffold with LF. The repairs were assessed 6 and 12 weeks postoperatively. Primary endpoints were biomechanical testing and blinded histological scoring of bone-tendon interdigitation, collagen fibre density and alignment, inflammatory response and vascularity of the tendon.

At 6 weeks the ECM scaffolds had completely degraded in all animals. Group 3 scored highest in the overall histological evaluation of healing. Both groups 2 and 3 scored significantly higher than group 1, with improved collagen fibre orientation and bone and tendon interdigitation at 6 and 12 weeks. Both stiffness and modulus were increased in group 2, compared to groups 1 and 3 at both time points, although this did not reach significance (11.8N/mm stiffness in group 2 vs. 9.1N/mm in and 9.5N/mm in groups 1 and 3, respectively, at 12 weeks).

This study demonstrated that combining the positive effects of LF and a decllularized ovine forestomach ECM scaffold augments rotator cuff tendon repair in a rat model, and thus has the potential to improve clinical outcomes. Therefore further continuing research is required to identify the ideal augment for delivering LF and improving bone and tendon healing.

MO0097

The Leader Tripeptide of Mature DMP1 Guides the Transportation of Secretory DMP1 from Endoplasmic Reticulum to Golgi Apparatus. Suzhen Wang[1], Tian Meng[1], Chunlin Qin[2], Yongbo Lu*[3]. [1]Texas A&M University Baylor College of Dentistry, USA, [2]Texas A & M University Baylor College of Dentistry, USA, [3]Texas A&M University Baylor College of Dentistry, USA

Dentin matrix protein 1 (DMP1) is highly expressed in tooth and bone. The secretory DMP1 is processed into a 37 kDa amino-terminal fragment and a 57 kDa carboxyl-terminal fragment. Previous in vivo studies have demonstrated that the 57 kDa fragment is the biological functional form of DMP1 that rescues the *Dmp1*-null mouse skeletal and serum biochemical abnormalities, but the function of the 37 kDa fragment remains unknown. The purpose of this study was to examine the function of the 37 kDa amino-terminal region in the secretion of DMP1. Polymerase chain reaction (PCR) and site-directed mutagenesis were employed to generate various DMP1-expressing constructs. These DNA constructs were then transfected into a preosteoblast cell line, MC3T3-E1 cells, and immunofluorescent staining was performed to determine the expression and subcellular localization of various DMP1 proteins. Immunofluorescent staining showed that the full-length DMP1 proteins and 37 kDa amino-terminal fragments were predominantly localized in the Golgi apparatus, whereas the 57 kDa carboxyl-terminal fragments were largely accumulated in the endoplasmic reticulum (ER). However, when the leader tripeptide, leucine-proline-aspartic acid (LPD), of the mature DMP1 was fused to the 57 kDa carboxyl-terminal fragment, the resulting fusion proteins were mainly located in the Golgi apparatus, suggesting that the leader tripeptide was sufficient to guide the transportation of the 57 kDa carboxyl-terminal fragment from the ER to the Golgi apparatus. Furthermore, when the proline (P) residue in the leader tripeptide was substituted with a leucine (L) residue, the mutated full-length DMP1 proteins were primarily found in the ER. These data indicate that the 37 kDa amino-terminal region, particularly the leader tripeptide LPD, plays an essential role in directing the transportation of the secretory DMP1 from the ER to the Golgi apparatus.

MO0098

Tartrate-Resistant Acid Phosphatase – a Potential Regulator of Bone Mineralization Controlled by Osteopontin. Cecilia Halling Linder*[1], Michael Krumpel[2], Barbro Ek-Rylander[2], Göran Andersson[2], Per Magnusson[1]. [1]Department of Clinical Chemistry, Linköping University, Sweden, [2]Division of Pathology, Department of Laboratory Medicine, Karolinska Institute, Sweden

Osteopontin (OPN) is a phosphoprotein secreted by osteoblasts and osteocytes that can act as an inhibitor of hydroxyapatite (HA) crystal formation and growth when extensively phosphorylated. Consequently, dephosphorylation of OPN is an important trigger of mineralization. Bone alkaline phosphatase (ALP) is an important promoter of mineralization by degradation of the mineralization inhibitor inorganic pyrophosphate (PPi) and by acting as an OPN phosphatase. Tartrate-resistant acid phosphatase (TRAP), secreted from osteoclasts and osteoblasts, has also been shown to exert phosphatase activity towards OPN; however, its potential capacity as a regulator of mineralization has not been addressed. Moreover, a model to explain the differential roles of the two phosphatases, their possible functional interplay or how they might substitute for each other as regulators of mineralization is missing. Our aim was to investigate ALP and TRAP regarding their substrate specificity and their impact on mineralization *in vitro* by dephosphorylation of OPN.

Phosphatase activity for bone ALP extracted from human SaOS-2 osteosarcoma cells and TRAP extracted from rat bone was assessed by the Malachite green-based phosphate assay. Kinetic properties were evaluated using the physiological substrates for ALP, PPi and pyridoxal 5'-phosphate (PLP), as well as fully phosphorylated OPN purified from bovine milk. SaOS-2 cells were cultured for 10 days in the presence of β-glycerophosphate to initiate mineralization. After treating the cells with fully phosphorylated OPN and OPN dephosphorylated by ALP or TRAP, the degree of mineralization was quantified using the OsteoImage fluorescent dye, which specifically binds to HA nodules.

TRAP showed higher phosphatase activity towards phosphorylated OPN and PPi than ALP, whereas the activity for TRAP towards PLP was significantly lower in comparison with ALP. Phosphorylated OPN was able to inhibit mineralization in cell culture, whereas OPN dephosphorylated by either ALP or TRAP showed a decreased inhibitory capacity on the formation of mineralized HA nodules.

In conclusion, TRAP has similar, if not superior kinetic properties towards OPN and PPi compared with ALP, but PLP seems to be a better substrate for ALP compared with TRAP. Similarly to ALP, TRAP can modify the mineralization inhibitory property of OPN in an *in vitro* system. Further studies are warranted to explore the possible physiological relevance of TRAP in bone mineralization.

Age-Related Soft Tissue Body Composition Changes in CD-1 Mice. Nancy Doyle*[1], Luc Chouinard[2], Ousmane-Noel Diallo[3], Angela Keightley[3], Lewis Gruber[4], Susan Y. Smith[1]. [1]Charles River Laboratories, Canada, [2]Charles River Laboratories, PCS Montreal, Canada, [3]Charles River Laboratories, Canada, [4]SIWA Regenerative Medicine Corporation, USA

Aging is a complex process associated with metabolic changes that ultimately contribute to terminal metabolic dysfunction and or disease. Some studies have characterized the clinical and metabolic aspects of aging in animal models. Understanding the age-related soft tissue composition in a rodent model is valuable to characterize the senescence process and evaluate novel therapeutic intervention. The objectives of this study were to compare soft tissue body composition and evaluate expression of p16Ink4a mRNA, a marker of senescence, in adipose tissue in

young and old CD-1 Mice. Old mice were approximately 92 weeks (~21 months) old while young mice were 10 weeks old at the initiation of the study. Young mice were observed for 3 weeks and old mice were observed for 3 months and euthanized at the end of the observation period. Body composition (lean/fat mass) was measured at baseline, Week 3 and 12 by dual energy X-ray absorptiometry (DXA), and body weights were evaluated weekly during the in life phase. Gastrocnemius muscle weights were recorded at necropsy, adipocyte and muscle fiber size were measured with histomorphometry, and quantitative determination of p16Ink4a mRNA was performed in inguinal adipose tissue using real-time reverse transcription quantitative PCR (RT-QPCR). Compared to young mice, old mice showed statistically significant age-related effects, higher body weights (45g vs 30g at Week 3), lower whole body lean mass (relative to body weight) (55 vs 73% at Week 3) corroborating the lower gastrocnemius muscle weights (relative to body weight) (0.77 vs 1.1%), smaller muscle fiber size (Fiber area – 1139 vs 1317 μm^2), higher fat mass (relative to body weight) (32 vs 16 % at Week 3) and larger adipocyte size (Cytoplasm Area – 1952 vs 828 μm^2). p16Ink4a mRNA expression was significantly increased in inguinal adipose tissue of old mice (approximately 2.6-fold) compared to young mice. Based on these results, the old CD-1 mice can be considered a good model for the evaluation of new therapeutics targeting age-related muscle or fat metabolic changes.

Enhanced Mitochondrial Oxygen Consumption by Noncanonical Wnt5a is Reversed in Aortic Myofibroblasts From LRP6-Null Mice. John Stabley*[1], Abraham Berhmann[2], Karen Krchma[2], Su-Li Cheng[2], Bindu Ramachandran[2], Megan Mead[2], Bart Williams[3], Dwight Towler[1]. [1]Sanford-Burnham Medical Research Institute, USA, [2]Sanford-Burnham Medical Research Institute at Lake Nona, USA, [3]Van Andel Research Institute, USA

Msx-Wnt signaling regulates osteogenic differentiation during bone formation and the pathological mineralization of arterial calcification. Multiple Wnt ligands are upregulated in the aorta of mice lacking the LDL receptor (LDLR) when fed an arteriosclerotic high fat diet, entrained to TNF. The complex I inhibitor rotenone reduces TNF-dependent induction of mitochondrial reactive oxygen species and downstream osteogenic Msx2-Wnt programs in aortic myofibroblasts. To investigate the effects of canonical and noncanonical Wnt signaling on mitochondrial function in aortic myofibroblasts, the present study measured oxygen consumption rate (OCR) in myofibroblasts isolated from LRP6(fl/fl);$LDLR^{-/-}$ mice with (LRP6-CKO) and without (CON) an active Cre recombinase directed by the SM22 promoter. Primary myofibroblasts from 6-8 wk old mice with and without LRP6 were treated for 6 hr with Wnt3a (15 ng/mL), Wnt5a (15 ng/mL), or vehicle (Veh) prior to measurement of OCR (XF96, Seahorse Bioscience). The canonical ligand Wnt3a had no effect on basal OCR in CON (Veh: 86±3, Wnt3a: 79±3 pmol/min) or LRP6-CKO (Veh: 69±2, Wnt3a: 78±4 pmol/min) cells. However, while the noncanonical ligand Wnt5a produced an increase in basal OCR of CON cells (Veh: 86±3, Wnt5a: 126±6 pmol/min; $p<0.0001$), it reduced basal OCR in LRP6-CKO cells (Veh: 69±2, Wnt5a: 43±2 pmol/min; $p<0.0001$). When ATP synthase was arrested by acute treatment with oligomycin (1 μM), OCR remained unchanged in myofibroblasts treated with Wnt3a from CON (Veh: 47±3, Wnt3a: 43±3 pmol/min) and from LRP6-CKO (Veh: 37±2, Wnt3a: 38±2 pmol/min) cells. However, similar to the basal condition, Wnt5a increased OCR in CON cells (Veh: 47±3, Wnt5a: 62±6 pmol/min; $p<0.001$) and decreased OCR in LRP6-CKO cells (Veh: 37±2, Wnt5a: 24±2 pmol/min; $p<0.01$). Disruption of the proton motive force with carbonyl cyanide-p-trifluoromethoxyphenylhydrazone (FCCP, 1 μM) did not alter OCR in response to Wnt3a in CON (Veh: 347±39, Wnt3a: 300±29 pmol/min) or LRP6-CKO (Veh: 253±4, Wnt3a: 274±2 pmol/min) cells. Similar again to the basal condition, Wnt5a increased OCR in CON cells (Veh: 347±39, Wnt5a: 475±57 pmol/min; $p<0.001$) and decreased OCR in LRP6-CKO cells (Veh: 253±4, Wnt5a: 119±6 pmol/min; $p<0.001$) following acute FCCP treatment. Thus, noncanonical Wnt signaling activates mitochondrial respiration in vascular myofibroblasts, modulated by LRP6 expression.

The Effect of PTH Treatment on Bone Tissue Mechanics, Mineral Density and Non-enzymatic Glycation in Rats with Type 2 Diabetes Mellitus. Graeme Campbell*[1], Christine Hamann[2], Ann-Kirstin Picke[2], Martina Rauner[3], Sanjay Tiwari[4], Gerd Huber[5], Jaime Peña[6], Timo Damm[6], Reinhard Barkmann[7], Michael Morlock[5], Lorenz Hofbauer[8], Claus-C Glueer[9]. [1]University Hospital Schleswig-Holstein, Kiel Campus, Germany, [2]Dresden Technical University Medical Center, Germany, [3]Medical Faculty of the TU Dresden, Germany, [4]University Hospital Schleswig-Holstein, Campus Kiel, Germany, [5]Technical University of Hamburg, Germany, [6]University Hospital Schleswig-Holstein, Kiel Campus, Germany, [7]Universitaetskinikum Kiel, Germany, [8]Dresden University Medical Center, Germany, [9]Christian Albrechts Universitaet zu Kiel, Germany

Diabetes mellitus results in increased skeletal fragility through reduced bone mineral density and altered collagen structure. How these changes affect bone mechanics at the tissue level remains largely unclear. Anti-osteoporosis medications improve bone mass, but it is not known whether these treatments can fully restore tissue strength in diabetic bone. The objective of this study was to determine the effect of type 2 diabetes mellitus and bone-anabolic treatment on bone mechanics, tissue mineral density (TMD) and non-enzymatic glycation (NEG) in Zucker Diabetic Fatty (ZDF) rats. We hypothesized that diabetic rats have inferior tissue mechanics, which cannot be fully restored with anabolic treatment due to diabetes-induced changes in the organic phase of the bone.

Eleven-week old ZDF diabetic and non-diabetic rats were given 75 μg/kg PTH(1-84) or vehicle five days per week for 12 weeks (4 groups, N=7 per group). L4 vertebrae were excised, micro-CT scanned, and tested to failure in compression. The TMD was calculated as the mineral content within the bone tissue volume in the micro-CT scans. From the mechanical tests, stress-strain curves were produced, and tissue mechanical properties including elastic modulus (intrinsic stiffness), yield and failure strain, and toughness were determined. To determine NEG content, the samples were demineralized, papain-digested and analysed for fluorescence at 370nm excitation and 440nm emission wavelength standardized against a quinine sulphate solution. The NEG content was normalized to the amount of collagen determined from hydroxyproline content after hydrolysis.

Diabetic rats showed significantly reduced failure strain (–22%) and toughness (–42%), but not yield strain, elastic modulus or NEG compared to controls. In the healthy animals, PTH treatment increased the failure strain, (+24%) and reduced NEG content (-81%) compared to the untreated controls. In the PTH-treated diabetic animals, no significant changes in mechanical or NEG properties compared to untreated diabetic animals were observed. TMD was reduced with PTH treatment in both healthy (-7%) and diabetic (-6%) animals. This study shows that diabetes weakens the post-yield biomechanics of ZDF rat bone, and that there is a differential effect of PTH treatment on healthy and diabetic animals. The lack of improved mechanics after PTH treatment in diabetic animals may be due to an inability to reduce non-enzymatic glycation, as was observed in healthy bone.

Induction of Heterotopic Ossification is Severely Curtailed in Mice lacking Apolipoprotein E. Eric Beal*[1], Elizabeth Salisbury[1], Zbigniew Gugala[2], Elizabeth Olmsted-Davis[1], Alan Davis[1]. [1]Baylor College of Medicine, USA, [2]University of Texas Medical Branch, USA

Evaluation by plain X-ray or microCT shows that heterotopic ossification is severely curtailed in mice lacking apolipoprotein E. Additionally, we find that injection of BMP2-producing cells into the quadriceps of wild type C57BL/6 mice induces the appearance of a ''new'' population of CD31-containing endothelial cells, separable from the CD31-positive cells present in untreated wild type mice by fluorescent-activated cell sorting. This population increases 6-fold 2 days after BMP2 induction and 8-fold 4 days after BMP2 induction in wild type mice. In the ApoE (-/-) mouse this population increases similarly at two and four days after BMP2 induction. However, unlike the wild type mouse, this population of CD31-positive cells (e.g. analogous to those present in untreated wild type controls) decreases 2 to 3-fold 4 days after BMP2 induction of ApoE (-/-) mice. We interpret this to mean that the ApoE (-/-) mouse is perhaps incapable of supplying the new vasculature necessary to transport these cells to areas where new cartilage and bone would form.

Both wild type and ApoE (-/-) mice were also evaluated for hypoxic regions in tissue around the site of injection of BMP2-producing cells using Hypoxyprobe®. At both 2 and 4 days after BMP2 induction areas of hypoxia were both more extensive and more intense in the ApoE (-/-) mice. Surprisingly, vessels were also found that were profoundly hypoxia in the ApoE (-/-) mice, but not in their wild type counterparts. This result also points to dysfunctional endothelial cells in the ApoE (-/-) mice in that these endothelial cells seem unable to maintain a normoxic environment in the vessel. Whether this deficiency is due to the endothelial cells themselves or to deficiencies in other cells interacting with the endothelial cells, such as astrocyte-like cells produced after BMP2 induction, is currently unknown.

MO0103

Influence of obesity on the prevalence of osteoporosis and low-impact fractures in Brazilian women. Marcelo Pinheiro[1], Bruna Castro*[2], Edgard Reis Neto[2], Jacob Szejnfeld[2], Vera Szejnfeld[3]. [1]Sao Paulo Federal University/ Unifesp/ Escola Paulista De Medicina, Brazil, [2]Federal University of Sao Paulo (Unifesp/ EPM), Brazil, [3]UNIFESF/EPM, Brazil

Background: Several studies have emphasized the protective role of body weight on the risk of osteoporosis (OP) and low-impact fractures (Fx). However, more recently, higher rate of fragility fractures has been shown in overweight and obese individuals, especially of the lower limbs.Aim: To determine the prevalence of Fx and OP in women, according to the stratification by body mass index (BMI). Furthermore, we investigated the relationship between obesity, OP and Fx, as well as the performance of the SAPORI (Sao Paulo Osteoporosis Risk Index) tool in each BMI category, according to the World Health Organization (WHO) classification. Patients and Methods: A total of 6.182 women over 40 years old, regardless menopausal status, from Brazilian primary care centers were enrolled in this research. All of them answered detailed questionnaires about clinical risk factors for OP and Fx, as well as they underwent spine and femur bone mass measurements by DXA (DPX NT, GE-Lunar).

Results: The prevalence of osteoporosis in overweight and obese women was 33.6% and 20.8%, respectively. The increase of BMI played a protective role for osteoporosis (OR=0.88, 95%CI 0.87-0.89, $p<0.001$), according DXA. On the other hand, the prevalence of low-impact Fx was quite similar among the categories of BMI (13.7% for underweight, 12.3% for healthy weight, 11.8% for overweight and 12.7% for obese women; p=0.81). Wrist fractures were the most prevalent (24.9%), followed by metatarsal (24.5%), humerus (11%) and ankle (11.1%). After excluding women with low weight, it was observed the obese women had lower risk of hip fracture than non-obese women (OR=0.44, 95%CI 0.2-0.97, p=0.03). Regarding SAPORI tool's performance, there was impairment of sensitivity to identify women with low bone mineral density (BMD), according to increase of BMI (from 67% to 41% for femur and from 93.8% to 51.7% for spine BMD; $p<0.001$). Conclusion: Our data showed that anthropometric measures had a significant impact on BMD measurements in women, but not on the prevalence of low-impact fractures. These findings suggest that other factors, regardless BMD, may be involved with higher risk of fractures in overweight and obese individuals. Moreover, our results point out the need of identifying new cut points to improve the clinical performance of SAPORI tool.

MO0104

Mechanisms of reduced bone mineral density are diet- and strain-dependent. Casey Doucette*[1], Clifford Rosen[2]. [1]Maine Medical Center Research Institute, USA, [2]Maine Medical Center, USA

The relationship between energy status and bone mineral density (BMD) is well-studied, but not well understood. Mechanical loading during obesity is thought to have a positive effect on bone density, but the effects of endocrine factors released by adipocytes are unclear. On the other hand, anorexia nervosa causes a dramatic reduction in BMD and visceral adipose tissue with a paradoxical increase in marrow adipose tissue (MAT) volume. Here, we have tested the effects of calorie insufficiency and calorie excess to compare their profiles in two strains of mice, C57BL/6J (B6) and C3H/HeJ (C3H), which are innately different in their bone properties; C3H mice have significantly higher BMD and MAT volume. Male mice from both strains were given a 30% calorie restricted diet (30%CR), 60% high fat diet (HFD), or control diet from 3-15 weeks of age. Calorie-restricted mice from both strains had significant loss of femoral trabecular and cortical bone as compared to control (n=10, $p<0.01$). Interestingly, we also found compartment-specific loss of BMD in HFD-fed mice, with C3H mice displaying a loss of BMD in the cortical region of the femur (n=10, $p<0.04$), while B6 mice on a HFD had a reduction in trabecular parameters as compared to control (n=10, $p<0.03$). Serum analysis showed increased insulin levels and a decrease in osteoprotegerin (OPG) in HFD-fed B6 mice ($p<0.03$), supporting a mechanism for decreased cancellous bone mass through insulin-mediated inhibition of OPG expression and subsequent increase in RANKL-mediated bone resorption. We also noted an increase in serum levels of osteocalcin (OC) and insulin in B6 mice on a 30%CR diet as compared to controls ($p<0.01$), which may be indicative of OC release from the bone matrix during resorption and subsequent stimulation of insulin secretion by β-cells. Changes in OC serum levels were not seen in C3H mice on a 30%CR diet and may indicate that, during adolescence in this strain, 30%CR may result in a lowered rate of bone formation rather than increased resorption as compared to controls, resulting in lower bone mass. Our results demonstrate that HFD has strain-dependent and compartment-specific effects on BMD, which may be mediated by insulin-dependent inhibition of OPG expression. We also conclude that differential mechanisms of reduced BMD in response to 30%CR between the two strains are likely due to underlying genetic differences and may have implications for a genetically heterogeneous human population.

MO0105

Nerve Growth Factor and Brain-derived Neurotrophic Factor are differently expressed in energy stores, bone and reproductive organs. Claudia Camerino*[1], Maria Cannone[2], Elena Conte[2], Domenico Tricarico[2]. [1]School of Medicine, University of Bari, Italy & University of Cincinnati, USA, [2]Dept. of Pharmacy-Drug Sciences, University of Bari, Italy

That gonadal failure favors the appearance of osteoporosis while obesity seems to protect from osteoporosis shows that bone mass, energy metabolism, and reproduction are linked. On this regard, recent data indicate that the bone derived hormone Osteocalcin favors insulin sensitivity and male fertility by promoting testosterone production in Leydig cells. It has also been reported that the neurotrophin Nerve Growth Factor (NGF) is the ovulation inducing factor in the seminal plasma that following an endocrine route, crosses the Blood Brain Barrier of the female and elicit the surge of LH. This sparked our interest since NGF is also involved in energy regulation, upregulating the adipocyte-derived hormone leptin and increases bone turnover. To further investigate the role of NGF in these tissues we analyzed by RT-PCR the mRNA levels of NGF and its receptor p75NTR and NTRK1 in white and brown fat, bone and reproductive organs of 3 months old mice of both genders with brain as positive control. We compared these data with the expression of the Brain-derived Neurotrophic Factor (BDNF) and its receptor TRKb. Interestingly our preliminary data show that NGF as well as p75NTR mRNA are expressed in brown fat at levels greater than the positive control. NGF is expressed also in white fat and bone at levels comparable in both genders. BDNF and TRKB expression in bone is higher than in the brain, but lower in white and brown fat, conversely TRKB is down-regulated in bone and up-regulated in adipose tissue. Furthermore, NGF as well as p75NTR is highly expressed in ovaries and uterus. Differently NGF is down-regulated in testes while p75NTR is expressed at levels higher than the brain. NTRK1 is down-regulated in all tissues. Neither BDNF or TRKB are expressed in the ovaries, uterus or testis excluding a role in this organ. In sum, our work shows that NGF is expressed in brown fat, white fat and bone and with an opposite trend comparing to BDNF. NGF is also expressed in reproductive organs in a gender specific fashion. The pattern of expression of NGF and receptors in the fat stores is consistent with our hypothesis, of NGF as a regulator of energy metabolism, and the inverse correlation of NGF and BDNF in these tissues, confirms a previous study that shows NGF and BDNF exerting opposite effect on leptin with BDNF playing a relevant role in bone. Further studies will clarify the role of NGF in energy and bone metabolism and its correlation with the reproductive function.

MO0106

Oleic acid protects hMSC from healthy donors and osteonecrotic patients against lipotoxicity by inducing intracellular lipid droplet formation and preventing ERK activation. Céline Gillet*[1], Delphine Spruyt[1], Jessica Berlier[2], Sabrina Rigutto[1], Antoine Dalla Valle[1], Caroline Louis[3], Cathy Debier[3], Nathalie Gaspard[1], Willy J Malaisse[1], Valerie Gangji[4], Joanne Rasschaert[5]. [1]Université libre de Bruxelles, Belgium, [2]Université Libre de Bruxelles, Belgium, [3]Université catholique de Louvain, Belgium, [4]Hôpital Erasme, Université Libre de Bruxelles, Belgium, [5]Laboratory of Bone & Metabolic Biochemistry, Belgium

Osteoporosis and osteonecrosis are characterized by adipocyte accumulation in bone marrow. Adipocytes are not inert cells; they release cytokines, adipokines and free fatty acids (FFAs) that modify the bone marrow niche and may alter the biology of adjacent cells. Although it is known that FFAs affect the viability and function of various cell types, only a few studies examined their effect on human mesenchymal stem cells (hMSC) and osteoblasts (Ob). In a previous work, we showed that palmitic acid (PAL), a saturated FFA, exerted a cytotoxic action on hMSC and Ob via activation of NF-κB and initiation of endoplasmic reticulum stress. We demonstrated that oleic acid (OL), a monounsaturated FFA, fully neutralized lipotoxicity in both cell types.

In the present study,hMSC were obtained from bone marrow of healthy donors or patients with non-traumatic osteonecrosis of the femoral head (ON-MSC). Cells were cultured in standard medium or in osteogenic conditions. Viability was evaluated by nuclear staining and detection of caspases 3/7 activation. ERK phosphorylation was quantified by Western blot. Triglyceride (TG) content was measured by gaz chromatography and cellular neutral lipids were stained by Oil Red. Gene expression was analyzed by qPCR. IL-6 secretion was quantified by ELISA.

We showed that OL rescued hMSC and Ob from PAL-induced toxicity by inducing a preferential channeling of PAL into the TG cellular pool via restoration of DGAT-2 (diacyl-glycerol acyl-transferase) expression which controls the last step of TG synthesis. OL thus promoted the formation of lipid droplets (LD) which are now considered as highly dynamic organelles. In parallel, we observed that PAL decreased Runx2 expression, a key osteogenic factor, whilst it upregulated PPARγ, a regulator of adipogenesis. OL abolished PAL-induced gene modifications. PAL also stimulated ERK and secretion of IL-6, a cytokine favoring osteoclast activity. The presence of OL restored ERK activity and IL-6 level to basal values. Lastly, we demonstrated that ON-MSC displayed a higher sensitivity to lipotoxicity than healthy hMSC. This was correlated to a 2-fold higher basal phosphorylation level of ERK in ON-MSC.

In conclusion, we demonstrated that in hMSC and Ob OL prevents lipotoxicity via increasing LD formation and blocking ERK-activation. OL also abolished

PAL-induced cytokine expression and adipogenesis. Of interest, the susceptibility to lipotoxicity is enhanced in hMSC of osteonecrotic patients.

MO0107

Stem Cell Transplantation in Type 1 Diabetes Mellitus: Influence on Bone Marrow Fat (BMF) and Bone Mineral Density (BMD). Adriana Carvalho*[1], Bianca Massaro[2], Marcello Nogueira-Barbosa[2], Carlos Salmon[2], Belinda Simões[2], Maria Carolina Rodrigues[2], Clifford Rosen[3], Francisco Jose De Paula[4]. [1], Brazil, [2]University of São Paulo, Brazil, [3]Maine Medical Center, USA, [4]School of Medicine of Ribeirao Preto - USP, Brazil

Introduction: Type 1 diabetes mellitus (T1D) is classically one of the secondary causes of osteoporosis. Enhanced osteoclastogenesis from myeloid progenitors cells and suppressed bone formation contribute to low bone mass. Recently, hematopoietic stem cell transplantation (HSCT) was reported as an alternative treatment for T1D. However, there is no study regarding the impact of this treatment on bone mass or turnover. Our aim was to investigate BMD and bone marrow fat (BMF) in conventionally treated T1D as well as in patients subjected to HSCT. Material and Methods: The study comprised three groups: T1D (10M/6F; 31±12 years; 73±11 Kg; 1.71±0.08m, 24.9±3.5 Kg/m^2, 16±11 years of diagnosis), T1HSCT (7M/5F; 26±6 years; 64±10 Kg; 1.69±0.09m, 22.3±2.1 Kg/m^2, 4.4±3.4 years of diagnosis) and Control group (11M/10F, 29±6 years; 67±15Kg; 1.70±0.07m, 23.0±3.8 Kg/m^2). Blood samples were collected for measurement of glucose, HbA_1C, IGF-1. BMD was assessed in the lumbar spine, proximal femur and total body by DXA. ^{1}H magnetic resonance spectroscopy (1,5T) was used to evaluate BMF in the lumbar spine (L3). Results: T1D and T1HSCT showed higher HbA_1C and serum levels of glucose than C group. T1HSCT group had better glycemic control than T1D group (T1=8.9±1.4 vs T1HSCT=6.7±0.8 vs C=5.2±0.3 %; $p<0.0001$). BMD was similar in all sites for the three groups (e.g., L1-L4: T1=0.982±0.124 vs T1HSCT=0.986±0.117 vs C=0.999±0.137 g/cm^2). There was no difference in total body fat (T1=20±7 vs T1HSCT=17±6 vs C=19±6 Kg) and android fat mass (T1=1.5±0.8 Kg vs T1HSCT=1.2±0.4 Kg vs C= 1.4±0.6 Kg) between groups. T1HSCT exhibited a trend to have higher BMF than the other groups (T1=23±7 vs T1HSCT=30±7 vs C=23±9 %; p=0.07). Also, there was no association between lumbar BMD with android fat and HbA_1C, neither in T1D nor in the T1HSCT group. Lumbar BMD correlated negatively with total fat in T1D (r= -0.52; p=0.04). Additionally, BMF had no relationship with lumbar BMD, android and total body fat in both diabetic groups. Conclusion: The present results suggest that well controlled T1D have normal BMD, independent of metabolic control and previous HSCT. There was no relationship of body composition and glycemic control to BMF. Despite the lower dose of insulin therapy, T1HSCT group has better metabolic control than T1. T1HSCT had slightly higher BMF but lower body fat. Our results support the need for further studies to uncover the mechanism for the relationship between T1D and osteoporosis.

MO0108

A General Theory of Metabolism Demonstrating an Organizing Principle for Calciotropic Signals. Robert Fredericks*. Endocrine Associates, USA

Metabolism modeled as heterostatic organization of heat provides insight for the role of calciotropic signals in the maintenance of health. Hierarchical structure increases complexity, but conserves the heterostatic principle where positive feed forward and negative feedback create multiple basins of attraction functioning as authorities governing system behavior, contrasting with the single authority of homeostasis. Validation rests on coherently organizing available data and demonstrating utility in finding solutions for problems. Application of genome wide sequencing (GWS) to healthcare personalization is facilitated with metabolic modeling at the case level.

Utilizing a field study directed toward clarification of metabolism as influenced by calciotropic signals, GWS has been engaged to explore causality of phenotypes and discover appropriate utilization of interventions, including repurposing of existing modalities. Outcomes are assessed at the case level in accordance with the dictates of the Helsinki Accords.

A case of normocortisolemic Cushing's syndrome demonstrated mutations in creb binding protein and its closely related signal EP300. An additional mutation in ISX that modifies vitamin A signaling appears to have rescued the patient from the expected myodystrophic phenotype. Initial interventions unmasked a predisposition to febrile seizures associated with mutations causal of Dravet's syndrome also present in the patient. These interactions can be explained in the context of the metabolic models engaging the heterostatic organization of heat as an organizing principle.

It is proposed that hydroxylations of vitamin D evolutionarily originated from non-enzymatic interactions with metabolism. Interactions of the metabolites with receptors for vitamin D create a complex sensing device for the interface between physiology and metabolism that accounts for the findings in this and many other informative cases.

Investigating informative cases with GWS and a metabolic evaluation in the context of structural equation models clarifies the clinically expressed variance in phenotypes and demonstrates the effectiveness of this strategy for the understanding of functionalities of calciotropic hormones in the organization of heat. Appropriate personalization of healthcare delivery based on available technology becomes apparent when findings in osteo-immunology and osteo-endocrinology are incorporated into the models.

Insulin Resistance and Bone Strength in Children. Joseph Kindler*[1], Norman Pollock[2], Emma Laing[1], Kathleen Hill Gallant[3], Stuart Warden[4], Berdine Martin[3], Connie Weaver[3], Munro Peacock[5], Richard Lewis[1]. [1]The University of Georgia, USA, [2]Georgia Regents University, USA, [3]Purdue University, USA, [4]Indiana University School of Health & Rehabilitation Sciences, USA, [5]Indiana University Medical Center, USA

Given that type 2-diabetes (T2D) is a potential risk factor for fracture, combined with recent evidence indicating that 1 in 4 adolescents will most likely develop impaired glucose tolerance, it is important to understand the effects of insulin resistance (a key pathology in T2D) on bone strength in children during the early stages of puberty. This ancillary study investigated the relationships between insulin resistance and cortical bone strength at the radius and tibia in 314 early pubertal children aged 9 to 13 years (50% male, 49% black) participating in a multi-site clinical trial. Serum glucose and insulin were measured and used to calculate homeostasis model assessment of insulin resistance (HOMA-IR). Peripheral QCT (Stratec XCT-2000) scans of the radius and tibia were obtained at the 66% site from the distal metaphyses. Bone strength was estimated by calculating the polar strength-strain index (SSIp) from volumetric BMD and bone geometry. Comparability of bone data at different study sites was accomplished using a cortical bone phantom. Total body fat mass (FM) and fat-free soft tissue (FFST) mass were measured by DXA and data from different study sites were cross-calibrated for the specific DXA instrument used. Multiple linear regression analyses, adjusting for race, sex, pubertal maturation stage, FM, and FFST, revealed that HOMA-IR was negatively correlated with SSIp at the radius (β = -0.12) and tibia (β = -0.10) (both $P < 0.01$). These findings in children suggest a negative influence of insulin resistance on bone strength in the growing skeleton. Future studies should examine the influence of chronic insulin resistance on cortical and trabecular bone development.

Protection from Fracture Risk in Long Term Type 1 Diabetes: 50- Year Medalist Study. Hillary Keenan*[1], Stephanie Hastings[2], George King[3]. [1]Joslin Diabetes CenterHarvard Medical School, USA, [2]Joslin Diabetes Center, USA, [3]Joslin Diabetes Center, USA

Studies of individuals with type 1 diabetes (T1D) have demonstrated a 12-fold increased risk of fragility fractures over their age-matched peers. As hospitalization for fracture is highly associated with decreased quality of life, morbidity and mortality, this is an important, yet little studied diabetic complication particularly amongst those with extreme duration T1D. The 50-Year Medalist Study has extensively characterized over 800 individuals with a mean age of 69 years and duration of 55 years of T1D. The purpose of the Medalist Study is to determine how individuals with long term T1D have resisted complications. Early examination of self-reported rates of hip, vertebral, and wrist fractures show extraordinarily low rates (0.33%, 0%, and 1.7%, respectively) in stark contrast to the expected 12-fold increased prevalence compared to non-diabetic individuals. To further examine these findings, 63 participants received DXA scans, 32 females, 31 males with a mean ±SD HbA1c of 7.2±0.8% and 7.1±1.3%, age 62.7±7.3 years and 66.1±7.2 years, and duration of 52.7±2.9 years and 55.1±4.8 years, respectively. BMI for this age group was low with 25.6±5.2 kg/m^2 for females and 26.2±7.5 kg/m^2 for males. T-scores, indicative of risk for fracture, for females at the hip was -0.63 ±0.82 and lumbar spine (LS) 0.1±1.2. For males the hip T-score was -0.56±0.88 and at the LS was -0.1±1.8. Total vitamin D, D2, D3 and calcium did not correlate with T scores among females or males, except for D3 among male and the LS T-score (R=0.5, p=0.03). There was no association of T scores with HbA1c, BMI, age or duration in either gender, $p>0.05$. As BMIs were low in males and females, the lower than expected risk T scores are likely not due to increased weight bearing as seen in T2D patients. These pilot data suggest protection from fracture, and low risk in this group with long term T1DM suggestive of a protective factor preventing bone health deterioration.

Reduced Biomechanical Loading may Contribute to the Bone Phenotype of FGF21 Overexpressing Mice. Yanfei Ma*[1], Armando R. Irizarry[2], Tamer Coskun[2], Qianqiang Zeng[2], Mattew Hamang[2], Venkatesh Krishnan[1], Henry Bryant[1], Vincent L Reynolds[2], Malgorzata Gonciarz[2], Libbey O'Farrell[2], Alexei Kharitonenkov[2], Ruth E Gimeno[2], Andrew Charles Adams[2]. [1]Eli Lilly & Company, USA, [2]Eli Lilly & Company, USA

FGF21 is known for its beneficial effects on glucose and lipid metabolism. However, a recent report showed that FGF21 transgenic (Tg) mice have lower bone mass compared to wild-type mice (WT). The goal of our studies was to characterize the bone phenotype of our independently generated FGF21Tg mice. Tg mice had substantially lower body weight compared to WT (-32% at 3 month and -43% at 6 month age), primarily due to reduced fat mass. In vivo μCT scanning of Tg mice at 3 and 6 months of age revealed significantly lower bone mineral content (BMC) in lumbar vertebrae (LV, -26%, -17%), proximal tibial metaphysis (PTM, -30%, -20%), tibial shaft (TX, -20%, -23%), and bone mineral density (BMD) in LV (-9, -5%). Because bone growth readily adapts to mechanical loading, we normalized bone values to body weight. When data were normalized, Tg mice at 3 and 6-months of age had significantly higher LV-BMC (16% to 45%), PTM-BMC (37% to 41%) and TX-BMC (19% to 34%) than WT. The bone formation biomarkers PINP (26%, 48%) and intact OCN (106%, 176%), were higher in Tg mice at 3 and 4 month age, and no different from WT at 6 months of age. The bone resorption biomarker CTX-1 was -13% lower in Tg mice at 3 months of age and no different at 4-6 months age. Ex vivo studies at 6-months of age showed a similar pattern of bone changes as observed in vivo, where absolute values of BMC and bone strength were lower but body weight normalized values were higher in Tg mice. Bone histomorphometry showed that mineralizing surface, osteoblast surface and bone formation rate (BFR/BS) were higher in LV of Tg mice. While endocortical mineral appositional rate was -30% lower in Tg mice, no other differences were observed in bone formation indices of cortical bone. In a separate study, hFGF21 infusion for 14 days resulted in body weight loss in both 8 month old diet induced obese (DIO, -23%) and chow fed control (-21%) mice. A significant reduction -10% in BMD was seen in the distal femur of hFGF21 treated chow fed mice but not in DIO mice. Bone histomorphometric analyses revealed the only significant change was a reduced periosteal BFR/BS in both cohorts of hFGF21 treated mice. Finally, in a separate mouse food restriction study aimed to address directly the role of reduced body weight on bone, bone mass declined in parallel with reduced body weight. Our data suggest that lower mechanical loading plays a contributory role in the bone phenotype of FGF21 overexpressing mice.

MO0112

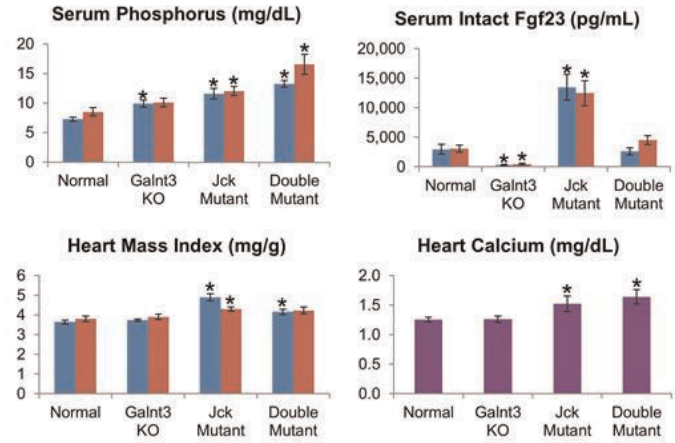
A Murine Model of CKD Has Increased Heart Mass, Even in the Absence of Elevated Fgf23. Shoji Ichikawa*[1], Tyler Unsicker[2], Amie Gray[2], Sharon Moe[1]. [1]Indiana University School of Medicine, USA, [2]Indiana University School of Medicine, USA

Background: In early stages of chronic kidney disease (CKD), a phosphaturic hormone, fibroblast growth factor 23 (FGF23), begins to rise in order to maximize renal phosphorus excretion. As the kidney function declines, phosphorus excretion becomes insufficient despite continuously increasing FGF23, and hyperphosphatemia ensues. Due to the concomitant rise in both Fgf23 and phosphorus, it is difficult to distinguish relative contributions between elevated FGF23 and hyperphosphatemia to cardiovascular and skeletal abnormalities associated with CKD.

Materials and Methods: To determine independent effects of phosphorus and Fgf23, we created high and low Fgf23 states in the *jck* mutant mouse, a naturally progressive CKD model. By crossing *jck* mice with *Galnt3* knockout mice, we could induce low Fgf23 levels despite CKD and hyperphosphatemia. We then compared serum biochemistries, heart mass index, heart calcium and phosphorus, and bone volume and mineralization.

Results: Compared to normal mice, serum phosphorus was higher in all three mutant mice. As expected with CKD, the *jck* mice had a 4 fold increase in Fgf23 levels. *Galnt3* knockout mice had 87% reduction in intact Fgf23, whereas the *jck*/*Galnt3* double mutants had normal Fgf23 levels. *Jck* mutant mice had cardiac hypertrophy with significantly higher heart mass index (25% increment compared to normal animals). Double mutant mice also had on average 13% higher heart mass than the *jck* mice despite normal Fgf23. In addition, both CKD mice – *jck* and double mutant mice – had 21 and 31% increases in heart calcium, respectively, suggesting the presence of cardiovascular calcification. Micro CT analysis of the femurs showed that trabecular thickness was also significantly lower in female double mutant mice. Compared to *jck* mutant mice, double mutants had decreased bone volume and trabecular thickness.

Conclusion: The *jck* mice with CKD had increased heart mass index and elevated Fgf23. The double mutants also had increased heart mass despite normal Fgf23 levels. Thus, even in setting of normal Fgf23, the CKD mice have increased heart mass, perhaps due to elevated phosphorus, deposition of calcium or other kidney disease-related factors. The severe bone defects in the double mutants also suggest that non-Fgf23 factors in the setting of CKD may have an adverse effect on bone.



Blue, males; red, females; purple, males and females combined. Number of animals = 5-14 per group. *Significant difference to same-sex normal littermates (unpaired t-test p-value < 0.05).

Biochemical and cardiovascular measures of jck/Galnt3 double mutants and littermate controls

A Quantitative Trait Loci Analysis for BMD using the Diversity Outbred Mouse Population. Hayley Britz*[1], Denise Liberton[2], Fernando de Villena[3], Benedikt Hallgrimsson[1]. [1]University of Calgary, Canada, [2]University of Calgary, Canada, [3]University of North Carolina, USA

Osteoporosis is a heritable bone disease characterized by a decreased bone mineral density (BMD) and a deterioration in bone microarchitecture. The genetic determinants of osteoporosis remain largely unknown and without these we cannot begin to develop more effective treatments or a cure for this disease. Multiple studies using quantitative trait loci (QTL) analysis to map the chromosomal location of genes affecting BMD have been conducted; however, the mouse crosses utilized often result in large haplotype blocks, meaning that many of the biologically significant QTLs for BMD have occurred within large regions and thus may not have been fully described.

To partially overcome this limitation, I will be using 500 mice from the Diversity Outbred (DO) mouse population for the QTL analysis. The DO mice are derived from the eight founder strains of the Collaborative Cross (CC) instead of two strains like the recombinant inbred mice most commonly used for this type of analysis. The breeding scheme employed for developing the DO leads to increased recombination, resulting in a level of genetic diversity that better mirrors what is seen in human populations and leads to a higher, sub-Mb mapping resolution for detecting QTL. The aim of this study was to investigate whether the increased variation in the DO mice will allow for the detection of new QTLs in narrower intervals and better localize the regions of QTLs that have been previously observed.

In the DO mice, we found a broad range of BMD values, with a 95% confidence interval of 653 +/- 10.3 mg HA/cm^3, which is larger compared to what was seen in the CC parental mice (520 +/- 12.3 mg HA/cm^3). Using SNPs from the MegaMUGA genotyping array (~75K SNPs), we performed a QTL analysis for BMD using the DOQTL package in R. First, a Hidden Markov Model was used to reconstruct haplotype blocks from the eight founder populations. BMD measures were then regressed on the allelic dosage for each of the founder alleles. Additionally, given the complex pedigree of the DO mice, we accounted for the effects of relatedness via a kinship matrix calculated directly from the genotypes to better improve mapping power. Our results indicate several regions of interest associated with BMD after controlling for the effects of multiple testing. This suggests that the DO continues to be a useful resource for mapping the genetics of complex traits, including those related to bone diseases such as osteoporosis.

Altered osteoclast homeostasis responsible for bone changes in progressive myoclonus epilepsy EPM1. Otto Manninen*[1], Elina Harittu[2], Tiina Laitala[2], Riku Kiviranta[3], Anna-Elina Lehesjoki[4], Outi Kopra[4]. [1]Folkhalsan Institute of Genetics, Finland, [2]University of Turku, Finland, [3]Medical Biochemistry & Genetics & Turku PET Centre, University of Turku, Finland, [4]Folkhalsan Research Center, Finland

Unverricht-Lundborg type progressive myoclonus epilepsy (EPM1, OMIM 254800) is an autosomal recessive disorder, characterized by myoclonus and epileptic seizures. EPM1 is caused by mutations in the gene encoding cystatin B (CSTB).

Cystatin B is an inhibitor of one of the key enzymes in bone resorbtion, cathepsin K, and has been shown to modulate bone resorbtion *in vitro.* In line with these findings patients with EPM1 exhibit various skeletal abnormalities including changes in skull bones and appendicular skeleton. The purpose of this study was to elucidate the molecular mechanismsby which lack of cystatin B alter bone metabolism.

In the study, we utilized male cystatin B deficient ($Cstb^{-/-}$) mice (129-$^{Cstbtm1Rml/J}$; stock 003486; Jackson Laboratories) between 1 of 6 months of age and wild-type animals of the same background served as controls. Microtomography of perfusion fixed hindlegs revealed thicker trabeculae in $Cstb^{-/-}$ mice when compared to controls, indicating that the bone changes in EPM1 patients do not result of anti-epileptic drugs, as suggested previously, but in fact are connected to the lack of cystatin B. Subsequently, histology from hindlegs and calvarie was performed, revealing changes in trabecular bone morphology, thinner growthplates and lower osteoclast number in $Cstb^{-/-}$ animals. Furthermore, immunohistochemistry showed more TRACP 5b and Cathepsin K staining in osteoclasts of $Cstb^{-/-}$bone, indicating higher resorbtion activity by $Cstb^{-/-}$ osteoclasts. As expected, culturing bonemarrow derived osteoclasts did not reveal cross changes in $Cstb^{-/-}$ osteoclast morphology, when compared to controls. We did, however, detect elevated Cathepsin K expression in $Cstb^{-/-}$ cells, and counting of osteoclasts showed significantly reduced number of mature $Cstb^{-/-}$ osteoclasts. These findings indicate that lack of cystatin B affects the bone morphology through changes in osteoclast homeostasis and resorbtion activity, and the results warrant further studies on the role of cystatin B in bone and osteoclasts.

An *Fkbp10* mouse model recapitulates joint contractures found in Bruck syndrome. Caressa Lietman*[1], Keren Machol[2], Elda Munivez[2], Brian Dawson[2], Terry Bertin[2], Yuqing Chen[2], Deborah Krakow[3], Brendan Lee[1]. [1]Baylor College of Medicine, USA, [2]Baylor College of Medicine, USA, [3]UCLA, USA

Osteogenesis Imperfecta (OI) is the most commonly inherited form of brittle bone disease and displays a spectrum of severity from mild phenotypes to severe early lethality. Mutations in FK506 Binding Protein 10 (*FKBP10*) that encode the FKBP65 protein result in recessive OI as well as Bruck Syndrome, characterized with congenital joint contractures in addition to the low bone mass phenotype. FKBP65 is thought to act as a collagen chaperone and possesses PPIase activity for proper trimer formation. Currently, we do not understand the consequences of *FKBP10* loss and its role in collagen and ECM formation. Therefore our goal is to elucidate the role of *FKBP10* in the skeleton and how null mutations lead to progressively deforming OI and Bruck syndrome. We generated a mouse model using the EUCOMM allele to further elucidate the function of *Fkbp10* in connective tissues. We have utilized the LacZ knockin allele to assess expression during development as well as the knockout allele to discern the phenotypic outcomes of FKBP65 loss in the mouse. Furthermore, mouse embryonic fibroblasts (MEFs) have been used for comparison to human cells and for collagen studies and analysis. We found that *Fkbp10* is expressed at low levels at E13.5 particularly in skeletal tissues and increasing through E17.5 with expression in not only skeletal tissues, but also other mesothelial lined tissues, and vessels. Postnatally, expression is limited to developing bone, tendons and ligaments, suggesting a more restricted role at this timepoint. Null mice display neonatal lethality with viable embryos isolated up to E18.5 but not after birth, growth delay and generalized tissue fragility. $Fkbp10^{-/-}$ mouse embryonic fibroblasts show retention of procollagen in the cell layer, similar to what is seen in patient fibroblasts. These data suggest a requirement for *Fkbp10* function during embryonic connective tissue development in mice but restricted expression postnatally in bone, ligaments, and tendons correlating with the bone fragility and contracture phenotype in humans. Furthermore, we generated conditional knockout mice with scleraxis Cre in order to further investigate the tendon/ligament requirement for *Fkbp10*. We show that these mice recapitulate human features of Bruck syndrome and characterize this phenotype. Together, we suggest that this is a model mimicking joint contractures in humans due to alterations in tendons and ligaments.

Calcium Absorption Efficiency Protects Bone from Dietary Ca Restriction During Growth: Evidence for Common Genetic Control. Perla Reyes*, Rebecca Replogle, James Fleet. Purdue University, USA

Habitual low dietary Ca intake during growth limits peak bone mass but physiological adaptation can limit the adverse effects of dietary Ca restriction on bone. We previously reported that bone parameters and their adaptation to dietary Ca restriction are significantly variable across a genetically diverse panel of 11 inbred mouse lines. We conducted a forward genetic study in 51 BXD recombinant inbred mouse lines fed with either 0.5% (normal) or 0.25% (low) Ca diets from 4-12 wks of age (n=8/line/diet) to identify the genetic loci controlling bone/mineral metabolism and their response to low Ca intake. Ca absorption (CaAbs) was measured by an oral gavage test (^{45}Ca, 0.1 mM/L Ca, 10 min absorption) while femur BMD and BMC were measured by DEXA. After correcting phenotypes for confounding effects of body size, Analysis of Variance was used to detect significant line/diet main effects, line-by-diet interactions, and to provide heritability estimates. Genetic mapping was conducted for each corrected phenotype using composite interval mapping (CIM) for each diet and for an additional parameter reflecting adaptation to Ca restriction. Phenotypes on the 0.5% Ca diet (basal), on the 0.25% Ca diet, and after adaptation to low Ca had moderate heritability estimates (h^2) of 32%-51%. Interestingly, the adaptive responses of BMD or BMC to Ca restriction were significantly correlated to CaAbs on low (r=0.52 and r=0.33 respectively) and normal Ca diets (r=0.36 and r=0.33 respectively). This indicates that in a genetically diverse population, the ability to protect bone under dietary Ca stress depends on high CaAbs efficiency. Genetic mapping identified multiple significant quantitative trait loci (QTL) for each diet and adaptation phenotype. Several QTL were linked to both bone and CaAbs phenotypes. For example, significant peaks affecting basal BMC (39 cM, 45.8 cM) and BMC adaptation (49.2 cM) on chromosome (Chr) 4 overlap with a significant QTL for basal CaAbs (49.4 cM). This suggests a cluster of genes may exist on Chr 4 to regulate multiple interdependent bone metabolism-related phenotypes. Similarly, a significant peak for basal BMC on Chr 1 (88.3 cM) and a putative peak for basal BMC on Chr 10 (66 cM) were also close to loci controlling basal CaAbs (Chr 1, 90.6 cM; Chr 10, 64.6 cM), suggesting novel relationships between bone and Ca metabolism during growth. Our data reveal novel gene-by-diet interactions that may ultimately have relevance to human bone health.

Dysregulated TGF-β signaling alters bone microarchitecture in a mouse model of Loeys-Dietz Syndrome. Ashvin Dewan*[1], Ryan Tomlinson[2], Brian Goh[3], Stuart Mitchell[1], Rachel Yung[1], Sarvesh Kumar[4], Eric Tan[1], Harry Dietz[1], Thomas Clemens[2], Paul Sponseller[1]. [1]Johns Hopkins University, USA, [2]Johns Hopkins University, USA, [3]Johns Hopkins University School of Medicine, USA, [4]Johns Hopkins University, Baltimore MD, USA

Loeys-Dietz Syndrome (LDS) is a complex connective tissue disorder characterized by vascular, craniofacial, and musculoskeletal abnormalities that is most commonly caused by heterozygous mutations in the genes encoding the transforming growth factor β (TGF-β) receptor type I or II subunits (TGFBR1 or TGFBR2, respectively). Patients with LDS commonly show osteoporosis with a predisposition for pathologic fracture. In this study, we characterized the skeletal phenotype of mice harboring a very severe LDS mutation, $Tgfbr2^{G357W/+}$. Morphometric analysis by micro-computed tomography (CT) revealed reduced tissue area, bone area, and cortical thickness along with increased eccentricity in the cortical bone of LDS mice, but no detectable alterations in the trabecular compartment. Mechanical testing using three point bending showed that LDS femora had reduced strength and fracture resistance, a common characteristic of bone in patients with LDS. Histomorphometric analysis showed that LDS mice had a decreased mineral apposition rate but normal numbers of osteoblasts and osteoclasts. Primary osteoblasts cultured from LDS mice had impaired TGFβ1 induced Smad2 phosphorylation, an effector of signal transduction, compared to controls, confirming that G357W is a loss-of-function mutation in osteoblasts. Surprisingly, however, LDS osteoblasts demonstrated more mineralization and had increased expression of osteoblast differentiation markers compared to controls. These changes were associated with increased expression of TGFβ1 ligand. Finally, immunohistochemistry revealed increased pSmad2 in cortical osteocytes from LDS mice. Our findings in this mouse model mimic the principal structural features of bone observed in humans with LDS and consequently provide a useful model with which to further investigate the role of dysregulated TGF-β signaling in this bone disorder.

Mice with Sclerostin Gene Deficiency are Resistant to Bone Loss after Acute Spinal Cord Injury. Weiping Qin*[1], Xiaodong Li[2], Jay Cao[3], Lauren Collier[4], Yuanzhen Peng[5], Jerry Feng[6], Jiliang Li[7], Yiwen Qin[4], Tom Brown[8], Hua Zhu (David) Ke[9], William A. Bauman[4], Christopher Cardozo[1]. [1]James J. Peters Va Medical Center, USA, [2]Amgen, Inc., USA, [3]USDA ARS, USA, [4]James J. Peters VA Medical Center, USA, [5]The Mount Sinai School of Medicine, USA, [6]Baylor College of Dentistry, TX A&M, USA, [7]Indiana University Purdue University Indianapolis, USA, [8]Amgen Inc., USA, [9]Amgen Inc., USA

The bone loss secondary to spinal cord injury (SCI) has several unique pathological features that are different from other forms of osteoporosis. These features include the permanent immobilization, neurological dysfunction, systemic hormonal alternations and associated metabolic disorders. It remains unclear how these complex pathophysiological changes are linked to molecular alterations that influence bone formation and bone resorption. Sclerostin is considered as a key negative regulator of bone formation and bone mass. Thus, we hypothesized that sclerostin could function as a major mediator of bone loss following acute SCI. To test this hypothesis, 10 week-old sclerostin knockout (SOST ko) and wild type (WT) mice underwent complete spinal cord transection at T10 or sham operation and were followed for 8 weeks. As expected, significant loss of bone mineral density was observed at the distal femur and proximal tibia in WT-SCI mice. However, no such loss was observed in SOST ko-SCI mice compared with the SOST ko-sham animals. Trabecular bone volume of the distal femur by μCT was markedly decreased by 40%

in WT-SCI mice compared with WT-sham mice. In striking contrast, there was no significant reduction of bone volume in SOST ko-SCI mice compared with SOST ko-sham mice, whose trabecular bone volume was 4-fold higher than that in WT-sham mice. The trabecular bone thickness, number and connectivity density were not significantly altered in SOST ko-SCI animals, relative to the SOST ko-sham animals. Histomorphometry of trabecular bone in SOST ko-sham mice revealed a significant increase in bone formation rate (BFR) and significant decrease in osteoclast surface. Notably there was no reduction of BFR in SOST ko-SCI mice when compared to SOST ko-sham mice. Finally, the differentiation potential of bone marrow stem cells was studied and revealed no difference in the number of TRAP+ multinucleated cells or osteoblast number between SOST ko animals with or without SCI. In summary, our findings demonstrated that SOST ko mice were protected from the dramatic bone loss associated with SCI. The evidence indicates that sclerostin is an important mediator of the marked sublesional bone loss after acute SCI, and that pharmacological inhibition of sclerostin may represent a promising novel approach to this challenging problem.

Oxidative DNA damage as the cause for osteoporosis in gerodermia osteodysplastica, a premature aging disorder. Hardy WL Chan*[1], Magdalena Steiner[2], Uwe Kornak[1], Michael Amling[3], Stefan Mundlos[2], Björn Busse[4], Jan Pestka[5], Thorsten Schinke[6], Till Köhne[4], Danny Chan[7]. [1]Charité-Universitaetsmedizin Berlin, Germany, [2]Institut für Medizinische Genetik und Humangenetik, Germany, [3]University Medical Center Hamburg-Eppendorf, Germany, [4]University Medical Center Hamburg-Eppendorf, Germany, [5]Department f.Orthopädie u.Traumatologie, Universitätsklinikum Freiburg, Germany, [6]Department of Osteology & BiomechanicsUniversity Medical Center Hamburg Eppe, Germany, [7]Department of Biochemistry, The University of Hong Kong, Hong Kong

Gerodermia Osteodysplastica (GO) is a premature ageing disorder characterized by wrinkled, lax skin and osteoporosis. It is caused by loss of function mutations in *GORAB*, encoding a golgin with poorly understood function. In order to understand the pathomechanism, a conditional Gorab mouse model was created and crossed with Prx1cre to inactivate Gorab starting from limb bud development. The *Gorab*^{Prx1cre} mutants showed mild growth retardation, a reduction of trabecular and cortical bone volume, mineralization defects, and spontaneous fractures. Histomorphometric analysis revealed a significant increase in osteoblast and osteocyte numbers, but expression analysis showed a block in terminal osteoblast differentiation. This was also mirrored by strongly abnormal osteocyte morphology. There were no significant changes in osteoclast number, suggesting low turnover osteoporosis. *In vitro*, GORAB-deficient fibroblasts exhibited an accumulation of DNA damage and cellular senescence, which was also identified in *Gorab*^{Prx1cre} mutant bone cells. Adding N-acetyl cysteine (NAC) to the culture medium rescued the accumulation of DNA damage after loss of GORAB, suggesting oxidative stress as the cause of DNA damage. Furthermore, NAC treatment also increased the trabecular bone volume and improved the organization of collagen fibers in the cortical bone of *Gorab*^{Prx1cre} mice. Taken together, our results demonstrate that oxidative DNA damage and cellular senescence plays a pivotal role for the pathomechanism of GO and that antioxidants might be a treatment option.

Pathologically increased osteoclastogenesis in a mouse model of MPS-I following bone marrow transplantation. Sonja Kuehn*[1], Thorsten Schinke[2], Michael Amling[3], Till Koehne[3], Thomas Braulke[4], Kerstin Cornils[5], Boris Fehse[5], Sandra Breyer[6], Ralf Stuecker[6], Nicole Muschol[4]. [1]University of Hamburg, Germany, [2]Department of Osteology & BiomechanicsUniversity Medical Center Hamburg Eppe, Germany, [3]University Medical Center Hamburg-Eppendorf, Germany, [4]Department of Biochemistry, Childrens Hospital, University Medical Center Hamburg Eppendorf, Germany, [5]Department of Stem Cell Transplantation, University Medical Center Hamburg Eppendorf, Germany, [6]Childrens Hospital Hamburg-Altona, Germany

Mucopolysaccharidosis-I (MPS-I) is a lysosomal storage disorder associated with various skeletal defects. The disease is caused by inactivating mutations of the *IDUA* gene, encoding the lysosomal enzyme a-L-Iduronidase, which is involved in glycosaminoglycan degradation. Most affected individuals are currently treated by bone marrow transplantation (BMT) in early childhood, and in some cases this is followed by enzyme replacement therapy (ERT). To study bone remodeling in MPS-I we analyzed *Idua*-deficient mice by non-decalcified histology and histomorphometry. We found that bone remodeling was unaffected in 6 weeks old *Idua*-deficient mice, yet at 24 and 52 weeks of age these mice displayed a high bone mass phenotype. Although bone formation was not significantly reduced in 24 weeks old *Idua*-deficient mice, there was a shift in the distribution of osteoblasts at the bone surface, as their average number within the bone-forming units was significantly decreased. Most importantly however, osteoclastogenesis and bone resorption were significantly reduced in 24 weeks old *Idua*-deficient mice, indicative of an osteopetrotic phenotype. In sharp contrast to these findings, a histomorphometric analysis of an iliac crest biopsy from an 8 years old individual with MPS-I revealed low bone mass with pathologically increased eroded bone surfaces. Since this patient underwent BMT at 1 year of age and received ERT for the last three years prior to biopsy, we addressed the question, how these two types of treatment affect bone remodeling in *Idua*-deficient mice. We found that ERT (weekly IDUA injection from 12 to 24 weeks of age) did not significantly influence the bone remodeling phenotype of *Idua*-deficient mice. In contrast, the high bone mass of 24 weeks old *Idua*-deficient mice did not develop after BMT (performed at 8 weeks of age), thereby confirming that it is primarily explained by an osteoclast defect. Most importantly however, the reduced osteoclastogenesis in *Idua*-deficient mice was not only corrected by BMT, but instead, osteoclast number in transplanted mice was more than 4-fold higher compared to non-transplanted or transplanted wildtype mice. Collectively, these findings do not only demonstrate that Idua-deficiency causes an osteopetrotic phenotype, they also show that BMT negatively affects skeletal integrity in MPS-I. It is therefore important to study if a combination of BMT with ERT is the preferable treatment for the affected individuals.

Previously unsuspected defects in the cranial base of a mouse model of Hereditary Multiple Exostoses. Federica Sgariglia*[1], Paul Billings[2], Hyo-bin Um[2], Kevin Jones[3], Eiki Koyama[4], Maurizio Pacifici[4]. [1]Children's Hospital of Philadelphia, USA, [2]Children's Hospital of Philadelphia, USA, [3]University of Utah, USA, [4]Children's Hospital of Philadelphia, USA

Hereditary Multiple Exosostes (HME) is an autosomal-dominant pediatric disorder caused by mutations in *EXT1* or *EXT2* that synthesize heparan sulfate (HS). The patients are HS-deficient and display benign cartilaginous tumors – exostoses- next to, but never within, the growth plates. Exostoses are observed in long bones, ribs and vertebral body and arches, but have never been described in the skull that contains several endochondral structures. Thus, we re-examined the skulls of conditional *Ext1*-deficient mice (*Ext1fl/fl;Col2CreER)* that were tamoxifen-injected at P10, focusing on cranial base synchondroses. These are dual mirror-image growth plates that share a resting chondrocyte zone and sustain cranial base elongation by a combination of chondrocyte proliferation and hypertrophy. Growth in cranial base thickness occurs by chondrocyte apposition from flanking perichondrium. We found that multiple exostoses were present intra-cranially and/or extra-cranially along mutant synchondrosis growth plates at sphenoidal and occipital locations. The initial phase of exostosis formation was often associated with displacement of peripheral prehypertrophic and/or hypertrophic chondrocytes from growth plate into perichondrium, followed by the apparent apposition of immature chondrocytes from the flank. We found also that mutant cranial bases were shorter and thinner than controls, and their growth plates exhibited fewer resting and proliferative chondrocytes, irregular column formation at the periphery, suboptimal subchondral and perichondral bone and fewer osteoblasts. These events were accompanied by decreased expression of genes encoding HS proteoglycan core proteins such as *Perlecan* and *Syndecan 3* particularly in growth plate proliferating zone. To uncover mechanisms, we examined hedgehog signaling, using *Ext1*-deficient mice in a *Gli1LacZ* background. LacZ activity was much stronger and widespread along mutant synchondrosis perichondrium at early stages, thus closely connected to -and possibly triggering- exostosis formation at later time points. In sum, our data reveal that the skull is also affected by the loss of Ext1, displaying large exostoses and other defects, at least in mouse. It will be interesting to re-examine radiographic skull scans and data from HME patients to determine whether exostoses or other skeletal changes are present. If so, the data could lead to new clinical practice principles in the diagnosis, care and prognosis of HME patients.

SDF-1/CXCR4 Axis in Endothelial Progenitor Cells Regulates Both Vasculogenesis and Osteogenesis for Bone Fracture Healing. Yohei Kawakami*[1], Msaaki Ii[2], Tomoyuki Matsumoto[3], Atsuhiko Kawamoto[4], Yutaka Mifune[5], Ryosuke Kuroda[6], Takayuki Asahara[4], Masahiro Kurosaka[6]. [1]Kobe University Graduate School of Medicine, Japan, [2]Department of Pharmacology, Faculty of Medicine, Osaka Medical College, Japan, [3]University of Pittsburgh, USA, [4]Group of Vascular Regeneration, Institute of Biomedical Research & Innovation, Japan, [5]Kobe university, Japan, [6]Department of Orthopaedic Surgery, Kobe University Graduate School of Medicine, Japan

Introduction: CXC chemokine receptor 4 (CXCR4) is a specific receptor for stromal-derived-factor 1 (SDF-1). SDF-1/CXCR-4 interaction is reported to play an important role in vascular development. On the other hand, the therapeutic potential of endothelial progenitor cells (EPCs) for fracture healing has been demonstrated with

mechanistic insight of vasculogenesis and osteogenesis enhancement at sites of fracture. The purpose of this study is to investigate the influence of the SDF-1/CXCR4 pathway in EPCs in bone formation.

Methods: We created CXCR4 gene conditional knockout mice using the Cre/loxP system and set two groups of mice: Tie2-Cre^{ER} CXCR4 knockout mice (CXCR4-/-) and wild type mice (WT).

Results: We report here, in vitro, EPCs derived from CXCR4-/- mouse bone marrow demonstrated severe reduction of migration activity and EPC colony forming activity when compared with those derived from WT mouse. In vivo, radiological and morphological examinations showed fracture healing was delayed in the CXCR4-/- group and the relative callus area at weeks 2 and 3 was significantly smaller in CXCR4-/- group mice. (Fig.1) Quantitative analysis of capillary density at peri-fracture sites also showed a significant decrease in CXCR4-/- group. Especially, CXCR4-/- group mice demonstrated significant reduction of blood flow recovery at fracture sites compared with the WT group in Laser Doppler Perfusion Imaging analysis.(Fig.2) Real time RT-PCR analysis showed that the gene expressions of angiogenic markers (CD31, VE-cadherin, VEGF) and osteogenic markers (osteocalcin, collagen1A1, BMP2) were lower in the CXCR4-/- group. In the EPC incorporation assay, double immunofluorescent staining for isolectin B4 and DiI demonstrated that double stained cells were found in the mice injected EPCs from wild type mice, but not in the mice injected EPCs from CXCR4 KO mice. In the gain-of-function study, the fracture in the SDF-1 intraperitoneally injected WT group healed significantly faster from fracture with enough callus formation comparing them with SDF-1 injected CXCR4-/- group.

Discussion: We demonstrated that an EPC SDF-1/CXCR4 axis plays an important role in bone fracture healing using Tie2-Cre^{ER} CXCR4 conditional knockout mice. This study also suggested that he promotion of EPC CXCR4/SDF-1 axis leads to the acceleration of bone fracture healing for a novel therapeutic application for genetic bone diseases and fracture repair.

MO0123

The FOP R206H ACVR1 mutation is sufficient to cause heterotopic ossification in mouse limbs and is inhibited by a selective RARγ agonist treatment. Salin Chakkalakal*[1], Kenta Uchibe[2], Deyu Zhang[3], Andria Culbert[1], Michael Convente[4], Frederick Kaplan[1], Maurizio Pacifici[5], Masahiro Iwamoto[5], Eileen Shore[1]. [1]University of Pennsylvania, USA, [2]Division of Orthopaedic Surgery, Children's Hospital of Philadelphia, USA, [3]University of Pennsylvania, USA, [4]University of Pennsylvania School of Medicine, USA, [5]Children's Hospital of Philadelphia, USA

Fibrodysplasia ossificans progressive (FOP) is a rare autosomal dominant genetic disorder characterized by extensive heterotopic ossification (HO). Most cases of FOP are caused by the same gain-of-function mutation of the ACVR1/ALK2 type I BMP receptor (R206H). In the present study, we conditionally-activated the ACVR1 R206H mutation in skeletal mesenchymal progenitor (Prrx1^{+}) cells in mice to examine the effects of this cell population on HO and skeletal development. We also tested palovarotene, a phase II selective RARγ agonist, as an inhibitor of ACVR1 R206H-induced heterotopic ossification. Heterozygous Prrx1-Cre;ACVR1 R206H (Prrx1;R206H) mice are viable, but show reduced body length at birth. Histology revealed shorter growth plates with increased proliferative cells and a decreased hypertrophic chondrocyte zone. Consistent with FOP patients, Prrx1;R206H mice at P0 had hind-limb specific great toe malformations and no HO. Soft x-ray and microCT analyses showed that all Prrx1;R206H mice spontaneously developed HO within 2 weeks, with most occurring in the hind limbs. By 4 weeks, HO formation occurs in both hind limbs and fore limbs where Prrx1 is most highly expressed, then progressed to severely impair movement over time. Histological examination confirmed that the HO occurs through endochondral ossification, as in FOP patients. Of note, when the ACVR1 R206H mutation was globally expressed post-natally by a doxycycline-inducible system beginning at P5, all mice developed HO, however the onset and progression were substantially delayed compared to mice with embryonic expression of ACVR1 R206H in Prrx1^{+} cells. Palovarotene, a RARγ agonist that inhibits chondrogenesis, was administered to Prrx1;R206H mice from P3-P14 and significantly reduced spontaneous HO in a dose dependent manner, rescued longitudinal bone growth, and improved limb movement.Our data demonstrate that ACVR1 R206H expression in skeletal progenitor cells supports the induction and progression of heterotopic endochondral ossification as well as being sufficient to induce the characteristic great toe malformations that are characteristic of FOP. While Prrx1^{+} cells appear to be major contributors to HO formation, given the localized expression of Prrx1, additional cell populations likely also contribute to HO in patients. Palovarotene was able to inhibit both the skeletal and HO effects of ACVR1 R206H, providing strong preclinical data for RARγ agonists in clinical trials for FOP.

MO0124

1,25 dihydroxyvitamin D treatment improves bone microarchitecture in Hyp mice. Eva Liu*[1], Adalbert Raimann[2], Daniel Brooks[3], Mary Bouxsein[3], Marie Demay[4]. [1]Brigham & Women's Hospital & Massachusetts General Hospital, USA, [2]Medical University Vienna, Austria, [3]Beth Israel Deaconess Medical Center, USA, [4]Massachusetts General Hospital & Harvard Medical School, USA

X-linked hypophosphatemia (XLH) is characterized by elevated serum FGF-23, which inhibits the 25-hydroxyvitamin D 1-alpha-hydroxylase, resulting in inappropriately low 1,25 dihydroxyvitamin D ($1,25(OH)_2D$) levels. In both mice and humans, this disorder is accompanied by rickets and osteomalacia. Treatment of affected children with $1,25(OH)_2D$ has been reported to increase trabecular, but not cortical, bone density in the radius as assessed by pQCT. $1,25(OH)_2D$ treatment of Hyp mice, the murine homolog of XLH, has been shown to normalize bone ash weight, a surrogate for bone mineral content.

Investigations were undertaken to examine the effect of $1,25(OH)_2D$ therapy on bone microarchitecture in Hyp mice. $1,25(OH)_2D$ (175 pg/g/day) was administered daily to Hyp mice from post-natal day 2 to day 75. Hyp and wild type mouse controls were injected daily with vehicle. $1,25(OH)_2D$ treatment led to a significant increase in serum phosphate relative to Hyp controls (6.3 ± 0.5 mg/dL vs 4.9 ± 0.4 mg/dL, $p<0.05$). Compared to wild type mice, control Hyp mice had shorter femurs, reduced bone cross-sectional size, cortical thickness, and trabecular (Tb) bone volume, as well as increased cortical porosity (Table 1). $1,25(OH)_2D$ treatment of Hyp mice normalized their diaphyseal bone shape, such that femoral midshaft moments of inertia were similar to those of wild type controls. Treatment partially rescued several other parameters including femoral length, cortical thickness, cortical area, and metaphyseal combined cortical and trabecular bone volume (adjacent to the growth plate) ($p<0.05$ vs Hyp controls for all). However, these parameters remained significantly different from those of wild type controls. Neither cortical porosity nor trabecular bone volume in the secondary spongiosa was altered by $1,25(OH)_2D$ treatment of Hyp mice.

These studies demonstrate that $1,25(OH)_2D$ improves femoral diaphyseal shape and cortical microarchitecture in Hyp mice without leading to hypercalcemia or nephrocalcinosis. They also reveal a unique region of increased mineralization adjacent to the growth plate.

Table 1: Bone microarchitecture of Hyp mice treated with daily 1,25 dihydroxyvitamin D

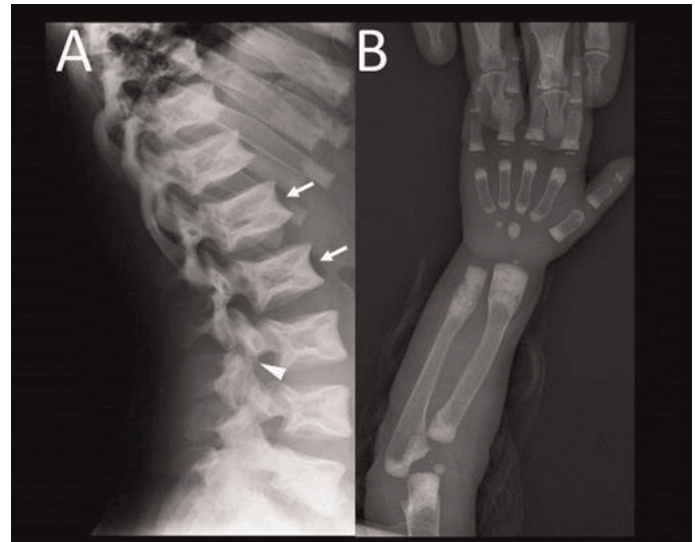
Dysosteosclerosis: Evidence for Genetic Heterogeneity. Gary Gottesman*[1], Steven Mumm[2], William McAlister[3], Serap Turan[4], Katherine Madson[1], Angela Nenninger[5], Murat Bastepe[6], Harald Jueppner[7], Michael Whyte[1]. [1]Shriners Hospital for Children-Saint Louis, USA, [2]Washington University School of Medicine, USA, [3]Washington University School of Medicine, USA, [4]Marmara University Istanbul-Turkey, Turkey, [5]Shriners Hospital for Children-Saint Louis, USA, [6]Massachusetts General Hospital, Harvard Medical School, USA, [7]Massachusetts General Hospital, USA

Dysosteosclerosis (DSS) (OMIM #224300) is the extremely rare (< 25 reports) autosomal recessive disorder characterized during childhood by platyspondyly with diffuse osteosclerosis especially evident in the expanded metaphyses of tubular bones. In 2010, we reported (JBMR 25:2527) that DSS is an "osteoclast-poor'' form of osteopetrosis. In 2012, we discovered mutations in the nucleoside transporter gene, *SLC29A3*, in two unrelated DSS patients (Hum Mol Genet: 21:4904). In 2013, genetic heterogeneity for DSS was suggested by absence of a mutation in *SLC29A3* in a single subject with DSS (Osteoporos Int 24: 2253). Molecular studies of the two patients described below provide evidence for genetic heterogeneity of DSS. Our most recent patient, of Amish descent, showed characteristics of DSS when referred at 15 years of age: short stature, fractures, visual loss, cranial nerve palsies, and oligodontia, but no developmental delay or bone pain. Radiographs revealed a generalized skeletal disorder featuring a sclerotic skull base, broad ribs with sclerotic ends, platyspondyly (Figure-Panel A), long bones with horizontal bands of sclerosis (especially in the metaphyseal regions) bordering hypodensity, failure of modeling at the ends of the long bones, synostosis of the left coronal suture, and absent sinuses. Our second patient, a Turkish child, had the clinical and radiographic phenotype of DSS including: a generalized skeletal disorder with platyspondyly, tubulation failure, sclerosis of regions of endochondral growth with dense metaphyses bordering relatively transparent diaphyses, and thin diaphyseal cortices (Figure-Panel B). Bone biopsies were not performed on either patient. Mutation analysis of coding sequence and exon-intron splice sites did not reveal mutations in *SLC29A3*. In particular, the Turkish patient did not show the mutations found in our previously reported DSS patient of Turkish heritage. Our findings suggest that alterations may lie elsewhere in the *SLC29A3* gene (untranslated regions) or that there is locus heterogeneity involving another gene causing DSS.

*Dr. Gottesman and Dr. Mumm contributed equally to this work.



Panel A: Lumbar spine radiograph shows platyspondyly and sclerosis of the anterior aspect of the vertebral bodies (arrows). Spondylolysis of L3 – L4 is evident (arrowhead) in keeping with DSS as a variant form of osteopetrosis.
Panel B: PA radiograph shows metaphyseal sclerosis, tubulation abnormalities, and diaphyseal osteopenia with thin cortices.

R990G mutation of CASR gene in the autosomal dominant hypocalcemia. JO EUN Kim*[1], Hanseok Choi[2], Sihoon Lee[3], Yumie Rhee[4], Sung-Kil Lim[1]. [1]Yonsei University College of Medicine, South Korea, [2]Dongguk University Ilsan Hospital, South Korea, [3]Gachon University School of Medicine, Rok, [4]Department of Internal Medicine, College of Medicine, Yonsei University, South Korea

Autosomal dominant hypocalcemia (ADH) is a congenital isolated hypoparathyroidism caused by activating mutations in the calcium-sensing receptor (CASR) gene. ADH is characterized by mild-to-moderate hypocalcemia, a tendency towards hyperphosphatemia, low-to-normal serum PTH levels and hypercalciuria. A 35-year-old female patient who diagnosed with hypocalcemia 15 years ago was referred to us for further evaluation. At the time of diagnosis, her serum calcium was 7.6 mg/dL (reference value 8.0-10.5), phosphate was 5.1 mg/dL (2.5-4.5), magnesium was 1.5 mEq/L (1.5-2.4), iPTH was 8.01 pg/mL (10-65), and 24 hour urine calcium was 174.9 mg (70-180). In family history, her farther and her younger brother were also diagnosed with hypocalcemia and hypoparathyroidism, and recently, her new-born baby was suffered from tetany due to hypocalcemia (Baseline of biochemical results for family members are shown in Table 1). She was suspected ADH, thus we sequenced all coding exons and intron-exon junctions of CASR, GNA11 and PTH gene. Direct sequencing of genomic DNA revealed only two nucleotide alterations in the CASR gene, C-to-G transition at nucleotide position 47 and G to A transition at nucleotide position 2968. The 2968G>A transition produces an amino acid change from Arg to Gly at codon 990 (R990G) on exon 7. No mutation was found in GNA11 and PTH gene. R990G was reported as benign polymorphism at first in 1996, but thereafter the evidence of R990G was associated with hypercalciuria, lower levels of serum PTH and ionized calcium have been reported. Moreover, Vezzoli et al. demonstrated that transfection of the 990G variant in HEK-293 cells induced a gain-of-function of the receptor. We are about to study CASR gene analysis in rest of the family members. Our result suggests that the potential role of R990G mutation of CASR gene in autosomal dominant hypocalcemia.

Table1. Baseline of biochemical results for family members at the time of diagnosis

MO0127

An Alignment of ChIP-seq-Defined MEF2C Binding Sites and Genome Wide Polymorphisms Reveals a Risk Genotype Associated with Low Bone Mineral Density (BMD). David Karasik*[1], Jaeyoon Chung[2], Yi-Hsiang Hsu[3], L. Adrienne Cupples[4], Izhak Haviv[5], Douglas Kiel[6], Ching-Ti Liu[4]. [1]Hebrew SeniorLife; Bar Ilan University, USA, [2]Bioinformatics Program, Boston U, USA, [3]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, [4]Biostatistics, Boston U Sch Public Health, USA, [5]Faculty of Medicine, Bar-Ilan University, Israel, [6]Hebrew SeniorLife, USA

MEF2C encodes a Myocyte Enhancer Factor 2C, a transcription factor which fulfills a critical role in the differentiation of vascular smooth muscle cells and is essential for the transcriptional activation of the bone formation inhibitor, SOST. We hypothesized that variation in *MEF2C* regulates binding throughout the genome and this affects skeletal function. Thus we investigated potential epistatic association between genetic variation of *MEF2C* with its binding sites and BMD traits, including femoral neck (FN) and lumbar spine (LS).

We first extracted Chromatin ImmunoPrecipitation Sequencing (ChIP-Seq) data from the ENCODE consortium for MEF2C to characterize its global genomic binding pattern in GM12878 B lymphocytes and K562 CML cell lines. The aligned read density of the sequencing across the reference human genome and peak finder algorithm, produced a total of 6775 MEF2C-binding sites. We analyzed data from 6,624 Framingham Osteoporosis Study participants with Affymetrix 550K array genotype data using regression analysis to model the association between BMD and interactions between 28 tagging SNPs in the *MEF2C* gene and 358 SNPs in MEF2C-binding sites defined in ENCODE (2kb upstream and downstream of the binding site). We implemented linear mixed effects model to account for sample relatedness and adjusted for covariates, including age[2], weight and sex. In addition, we included principal components as covariates to account for population stratification.

There were 10,024 pairwise interactions between the SNPs in the *MEF2C* and MEF2C-binding sites. Interaction between rs13188739 (G/C) and rs7161172 (G/A) was found to be strongly associated with FN-BMD ($p=9.96*10^{-5}$). Both SNPs were common (minor allele frequency 26.7% and 49%, respectively). Participants with the CC/GG genotype (n=109) were similar to the rest of the sample in age, sex, total body lean mass, and BMI, while their BMD was significantly lower for both FN and LS. SNP rs13188739 is located in the intron of *MEF2C*. rs7161172 is 18,620 bps from 5' of *RNASE10* (involved in ribonuclease activity and nucleic acid binding) and 13,844 bps from 3' of *PNP* (purine nucleoside phosphorylase, active in Purine metabolism). Comparing the MEF2C elements that exhibit epistasis with the *MEF2C* gene, over all MEF2C binding elements in the genome, identified an enrichment of the NFkB elements, confirming a role for inflammatory processes in the BMD phenotype.

In conclusion, using ChIP-seq data, we found a suggestion of interaction between the variants in the *MEF2C* and its binding sites. The risk interactive genotype, which corresponds to a significantly lower BMD, needs to be replicated in other cohorts.

MO0128

Characterization of small molecule activators and inhibitors of the mutated $G_s\alpha$ responsible for Fibrous Dysplasia of Bone. Nisan Bhattacharyya*[1], Marek Kucka[2], Catherine Z. Chen[3], Xin Hu[3], Noel T. Southall[3], Andrea Estrada[4], Michael T. Collins[5]. [1]NIDCR, NIH, USA, [2]NICHD, NIH, USA, [3]NCATS, NIH, USA, [4]National Institutes Of Health, USA, [5]NIDCR, NIH, USA

Mutations in *GNAS* (R201C/R201H), the gene encoding for the small G-protein, $G_s\alpha$, (*gsp* oncogene), result in constitutively active $G_s\alpha$, and increased cAMP levels. These mutations cause fibrous dysplasia of bone/McCune-Albright syndrome (FD/MAS). Patients with FD/MAS exhibit ligand-independent over-secretion of growth hormone, prolactin, thyroid hormone, and/or sex steroids and a skeletal dysplasia characterized by fibro-osseous tissue. Identification of small molecule modulators of $G_s\alpha$ may lead to the development of treatments for FD/MAS. To isolate small molecule activators and inhibitors of *gsp*, high-throughput screening (HTS) was performed by measuring cAMP levels in Chinese hamster ovary (CHO) cells stably expressing the wild-type (WT) or mutant $G_s\alpha$ proteins. Chemical libraries comprised of more than $3x10^5$ compounds were screened in CHO and then in patient-derived bone marrow stromal cells. A total of 114 inhibitory and 132 stimulatory compounds were identified. The aim of this study was to develop a hormone-based rat pituitary cell culture model (GH3 cells) for secondary screening of the small molecule modulators identified in the HTS.

GH3 cell lines stably overexpressing either the WT or mutant $G_s\alpha$, were selected based on equivalent $G_s\alpha$ protein expression but low or high cAMP levels, respectively. Cells were treated with varying concentrations of agonists and antagonists using known adenylyl cyclase activators and inhibitors as controls and optimized for prolactin or growth hormone (GH) secretion. 36% of the selected inhibitors could inhibit prolactin secretion; including 7 that reduced prolactin levels by $\geq$ 50% at 10 μM concentrations. Three of these compounds were confirmed to also inhibit growth hormone (GH) secretion. Decreases in prolactin and GH secretion correlated with decreased cAMP levels. Cytotoxicity assays confirmed test compounds had no effect on cell viability. Results from activator studies indicated that 8 compounds increased prolactin levels in both wild-type and mutant protein-expressing cells. *In silico* analyses of activators/inhibitors suggest some compounds may compete for the GTP/GDP binding pocket of $G_s\alpha$. In conclusion, this secondary, orthogonal screening system confirmed that a significant number of the molecules previously identified in HTS have inhibitory activity and that 3 compounds have selective activity on mutant $G_s\alpha$. Further testing is necessary to determine which molecules may have potential for drug development.

Somatic Neurofibromin Deficiency and Transcriptional Dysregulation in Tibial Pseudoarthrosis with Neurofibromatosis Type 1. Nandina Paria[1], Tae-Joon Cho[2], In Ho Choi[3], Nobuhiro Kamiya[4], Kay Kayembe[5], Rong Mao[6], Rebecca Margraf[6], Gerlinde Obermosser[7], Ila Oxendine[1], David Sant[6], Mi Hyun Song[8], David Stevenson[9], David Viskochil[9], Carol Wise[1], Harry Kim[10], Jonathan Rios*[4]. [1]Texas Scottish Rite Hospital for Children, USA, [2]Seoul National University Hospital, South Korea, [3]Seoul National University Children's Hospital, South Korea, [4]Texas Scottish Rite Hospital for Children, USA, [5]Baylor Institute for Immunology Research, USA, [6]ARUP Institute for Clinical & Experimental Pathology, USA, [7]Baylor Institute for Immunology Research, USA, [8]Jeju National University Hospital, South Korea, [9]University of Utah, USA, [10]Scottish Rite Hospital for Children, USA

Neurofibromatosis type 1 (NF1) is an autosomal dominant syndrome caused by mutations in *NF1*. Among the earliest manifestations in individuals with NF1 is tibial pseudoarthrosis and persistent nonunion after fracture. The pathogenesis of pseudoarthrosis was proposed to result from tissue-specific (somatic) loss-of-heterozygosity (LOH) resulting in bi-allelic inactivation of *NF1*, though subsequent studies were inconclusive. We sought to determine the extent of somatic mutation in pseudoarthrosis and to characterize the transcriptional dysregulation potentially underlying the persistent bone remodeling defect in individuals with NF1.

To identify somatic mutations, we performed whole-exome sequencing and genomewide microarray analysis of blood and pseudoarthrosis samples from 16 individuals. Only five (31%) samples had somatic LOH, which encompassed the entire q-arm of chromosome 17 and included the *NF1* gene. Somatic mutations were not identified in four samples. The remaining seven (44%) samples had somatic sequence mutations in *NF1*. In several samples, further genetic analysis confirmed the somatic mutations resulted in bi-allelic *NF1* inactivation and predicted pseudoarthrosis-associated neurofibromin deficiency.

Genomewide transcription was assessed using whole-transcriptome sequencing, and results from pseudoarthrosis- and iliac crest-derived cultured cells from individuals with NF1 as well as control bone samples from individuals without NF1 were compared. Transcriptome analysis identified upregulation of multiple pathways associated with neurofibromin deficiency: phosphoinositol-3-kinase (PI3K) and mitogen-activated protein kinase (MAPK) signaling pathways. Specific upregulation of *EGFR* (2.5-fold, p=4.8e-4), *KITLG* (3.4-fold, p=1.9e-4) and *EREG* (55.7-fold, p=2.49e-11) in pseudoarthrosis cells suggest a tumor promoting, though not tumorigenic, transcriptional profile, and this upregulation was associated with neurofibromin deficiency rather than quantitative differences in ERK activation compared to *NF1*-haploinsufficient iliac crest cells.

The transcriptional profile described in pseudoarthrosis-derived cells and the lack of extensive somatic mutation, other than in the *NF1* gene, suggest a potential for FDA-approved receptor tyrosine kinase (RTK)-inhibitors, which may specifically target neurofibromin-deficient pseudoarthrosis cells, to promote proper bone remodeling and bone union after fracture in individuals with NF1.

MO0130

Targeted sequencing of the Paget's disease associated 14q32 locus identifies several missense coding variants in *RIN3* that predispose to Paget's disease of bone. Maheva Valett[1], Dinesh Soares[1], Sachin Wani[1], Jon Warner[2], Stuart Ralston[3], Omar Albagha*[3]. [1]University of Edinburgh, United Kingdom, [2]south east Scotland Clinical Genetics Service, Western General Hospital, United Kingdom, [3]University of Edinburgh, United Kingdom

Paget's disease of bone (PDB) is a common disorder with a strong genetic component characterised by increased but disorganised bone remodelling. Previous genome-wide association studies identified a locus on chromosome 14q32 tagged by rs10498635 which was significantly associated with susceptibility to PDB in several European populations. Here we conducted fine-mapping and targeted sequencing of the candidate locus to identify possible functional variants. Imputation using 1000 genomes data as reference in 741 PDB patients and 2,699 controls confirmed that the association was confined to a 60 kb region in the RIN3 gene and conditional analysis adjusting for rs10498635 identified no new independent signals. Sequencing of the *RIN3* gene identified a common missense variant (p.R279C) that was strongly associated with the disease (OR=0.64; $P=1.4 \times 10^{-9}$), and was in strong linkage disequilibrium with rs10498635. A further 13 rare missense variants were identified, seven of which were novel and detected only in PDB cases. When combined, these rare

variants were over-represented in cases compared to controls (OR=3.72; P=8.9 x 10^{-10}). Most rare variants were located close to p.R279C in exon 6 in a region that encodes a proline-rich, intrinsically disordered domain of the protein. The common p.R279C variant and many of the rare variants were predicted to have deleterious effects on the protein structure. We conclude that susceptibility to PDB at the 14q32 locus is mediated by a combination of common and rare coding variants in RIN3 and indicate that RIN3 may have a previously unsuspected role in the regulation of bone metabolism.

In non-neuronopathic type 1 Gaucher disease (GD1), mutations in the *GBA1* gene result in glucocerebrosidase deficiency leading to a complex phenotype involving the viscera, bone marrow and skeleton. The prevailing macrophage-centric view, however, does not explain emerging aspects of the disease, including malignancy, autoimmune disease and osteoporosis. To understand the pathophysiology of the multi-system involvement in GD1, we conditionally deleted the *Gba1* gene in hematopoetic and mesenchymal cell lineages using an *Mx1* promoter. The Gba1 mouse fully recapitulated human GD1. Cytokine measurements, microarray analysis, and cellular immunophenotyping revealed widespread dysfunction not only in macrophages, but also in other cell types, notably T- and B-cells, NK cells, and dendritic cells, among others. Moreover, we found that the severe osteoporosis in these mice arose not from osteoclastic defects, but rather from defects in osteoblastic bone formation. Mechanistically, GBA1 deficiency causes the accumulation of two key sphingolipids, glucosylceramide (GL-1) and glucosylsphingosine (LysoGL-1). However, it is not known whether downstream metabolites of GL-1 or LysoGL-1 produced by extralysosomal glucocerebrosidase Gba2 contribute to GD1 pathophysiology. We show that the deletion of *Gba2* significantly rescues the GD1 phenotype, including the reduced bone volume, suggesting that metabolism of GL-1 or LysoGL-1 are major contributors to the bone formation defect. Direct testing revealed a strong inhibition of osteoblast viability by nanomolar concentrations of sphingosine, but not ceramide. These findings are consistent with toxicity of high circulating sphingosine levels in GD1 patients, which we show decline upon enzyme replacement therapy; serum ceramide levels remain unchanged. This study provides direct evidence for the involvement in GD1 of cell lineages other than mononuclear phagocytes and defines sphingosine as an osteoblast toxin, setting forth Gba2 as a viable therapeutic target for inhibitors to ameliorate certain disabling consequences of GD1.

MO0132

Insulin-like Growth Factor Binding Protein 4 in the Development and Metabolism of Bone and Fat Tissues. David Maridas*[1], Victoria Demambro[1], Phuong Le[1], Casey Doucette[1], Clifford Rosen[2]. [1]Maine Medical Center Research Institute, USA, [2]Maine Medical Center, USA

Insulin-like Growth Factor Binding Protein 4 (BP4) is the most abundant BP produced by osteoblasts. While BP4 inhibits IGF actions on pre-osteoblasts *in vitro*, it is unclear whether BP4 enhances or inhibits IGF-I activity *in vivo*. Previous reports showed that locally injected BP4 diminishes IGF-I effects on bone while systemic injection induces bone formation. The purpose of this study was to determine how BP4 mediates adipose differentiation and if this impacts skeletal acquisition. Thus, we investigated the skeletal and adipose phenotypes of BP4 null ($BP4^{-/-}$) mice at 8 and 16 wks of age using DXA, MicroCT, gene expression and protein analysis. At 8 wks, $BP4^{-/-}$ males and females had significant growth retardation ($p<0.05$) compared to $BP4^{+/+}$ littermates. At 16 wks, $BP4^{-/-}$ mice of both genders displayed reductions in femur length, inguinal (iWAT) and gonadal white adipose depots. Interscapular brown fat depots did not differ. Whole body DXA confirmed a marked decrease in fat and lean masses in 8 and 16 wk-old mice of both genders ($p<0.05$). Additionally, areal and femoral BMD and BMC were reduced in females ($p<0.05$) but surprisingly not in males at 16 wks of age. MicroCT revealed decreased BV/TV ($p=0.06$) and trabecular thickness ($p=0.046$) in the femurs of $BP4^{-/-}$ females. However, the males had increases in connectivity density ($p=0.02$) and trabecular number ($p=0.005$) with decreased trabecular spacing ($p=0.02$). Serum IGF-I and BP6 were both increased in $BP4^{-/-}$ females ($p=0.03$). However, in males, serum IGF-I was decreased ($p=0.02$) and BP6 was unchanged. Femoral expression of *SOST* was decreased in $BP4^{-/-}$ males but not in females. *CyclinD1*, *CDKN1a* and *CDKN1b* mRNA were downregulated in iWAT and whole bone of $BP4^{-/-}$ males but only in iWAT for females. *PPARγ* expression was reduced in iWAT of both genders. In sum, our data suggests that BP4 is an important modulator of bone and fat development, but there is clear gender and tissue specificity. Gene expression analysis indicates that the reduction of *SOST* expression may contribute to the preservation of bone in males but not in females. Alterations of serum IGF-I suggest that the skeletal phenotype might be IGF-I independent. Also, impaired adipocyte proliferation and function may partially explain the generalized reduction of WAT. Taken together, our results support the hypothesis that BP4 likely mediates mesenchymal cell progress through several mechanisms, which may be linked to IGF-I and tissue specificity.

Association with Fetuin-A and Ectopic Calcification in Alpha-klotho Mutant Mice. Hironori Yamamoto*[1], Nozomi Yokoyama[2], Rina Onishi[2], Shiori Fukuda[2], Otoki Nakahashi[2], Yuichiro Takei[3], Yutaka Taketani[2], Eiji Takeda[2]. [1]University of Jin-ai, Japan, [2]University of Tokushima School of Medicine, Japan, [3]Hiroshima University, Japan

Background: α-klotho mutant (kl/kl) mice exhibit hyperphosphatemia, hypercalcemia and hypervitaminosis D. These abnormalities are associated with growth retardation and ectopic calcification. Fetuin-A is a hepatic secretory protein acting as a systemic calcification inhibitor. However, it is still unknown about the role of fetuin-A in kl/kl mice. In this study, we examined the expression of fetuin-A in kl/kl mice. Methods: Wild-type (WT) mice and kl/kl mice at 3- or 6-wk-old were used and given free access to regular chow and water. For histology using paraffin sections of kidney, aorta and heart tissues, calcification sites and fetuin-A expression were detected by von Kossa staining and immunohistochemistry (IHC), respectively. Gene expression analysis were performed using western blots (WB) and Real-time RT-PCR methods. Results: Analysis of serial kidney, aorta and heart sections by IHC and von Kossa staining showed a high regional expression of fetuin-A protein in 6-wk-old kl/kl mice and its localization merged with calcifying sites. We also confirmed its co-localization with the calcified lesions in aorta and heart of chronic kidney disease (CKD) rats. Interestingly, the high regional expression of fetuin-A in kidney was also observed at 3-wk-old kl/kl mice without ectopic calcification. Although WB analysis observed markedly high expression of fetuin-A in kidney of kl/kl mice, its renal mRNA levels were no significant differences between WT and kl/kl mice. In contrast, fetuin-A mRNA levels in liver of kl/kl mice were significantly increased than WT mice from 3-wk-old. Moreover, we found that plasma fetuin-A levels in kl/kl mice were significantly higher than WT mice. Conclusions: These results suggest that the up-regulation of hepatic fetuin-A mRNA expression in kl/kl mice contributes to increase plasma fetuin-A levels and co-localize with calcified lesions as an inhibitor of hyperphosphatemia-induced ectopic calcification.

FGF23 deficiency ameliorates progression of chronic kidney disease in mice. Olena Andrukhova*[1], Svetlana Slavic[2], Sathish Kumar Murali[2], Reinhold Erben[3]. [1]INST. OF PHYSIOLOGY, PATHOPHYSIOLOGY & BIOPHYSICS, Austria, [2]1Dept. of Biomedical Sciences, University of Veterinary Medicine, Austria, [3]University of Veterinary Medicine, Austria

Clinical studies have shown that circulating fibroblast growth factor 23 (FGF23) is associated with disease progression, cardiovascular risk, and mortality in patients with chronic kidney disease (CKD). Here, we sought to elucidate further the vitamin D independent role of FGF23 in the pathogenesis of CKD in a mouse model. CKD was induced by 5/6 nephrectomy in 3-month-old wild-type (WT) mice, vitamin D receptor (VDR) mutant mice, and Fgf23/VDR compound mutant mice. Sham-operated (SHAM) WT, VDR, and Fgf23/VDR mice served as controls. Both WT and VDR mutant mice developed progressive CKD by 8 weeks after 5/6 nephrectomy as evidenced by reduced glomerular filtration rate (GFR), increased serum creatinine, increased albuminuria, hypertension, increased serum FGF23 and serum parathyroid hormone (PTH) levels, as well as reduced body weight and increased mortality, relative to SHAM controls. Lack of Fgf23 in Fgf23/VDR mice showed higher GFR and lower urinary albumin but unchanged serum PTH levels as compared to WT and VDR CKD mice. Furthermore, Fgf23/VDR compound mutant CKD mice were partially protected against the CKD-induced weight loss and increase in mortality. In addition, the CKD-induced volume expansion, hypernatremia, hypercalcemia, hyperphosphatemia, hypertension, left ventricular functional impairment, and increase in heart-to-body weight ratio observed in WT mice were ameliorated in Fgf23/VDR compound mutants. Consistent with the recently described function of Fgf23 as a sodium- and calcium-conserving hormone, urinary excretion of sodium and calcium was higher in Fgf23/VDR compound mutant CKD mice as compared to WT and VDR mutant CKD mice. Collectively, our data suggest that elevated FGF23 contributes to the pathogenesis of CKD in VDR-ablated mice, and may provide a mechanistic explanation for the association between circulating FGF23 and disease progression in CKD patients.

HMW FGF2 isoforms mediate renal phosphate wasting by modulating FGF23/FGFR/MAPKinase signaling in kidney. Erxia Du*[1], Liping Xiao[2], Marja Marie Hurley[3]. [1], USA, [2]University of Connecticut Health Center, USA, [3]University of Connecticut Health Center School of Medicine, USA

We previously reported that transgenic mice overexpressing nuclear high molecular weight isoforms of Fibroblast growth factor 2 (HMWFGF2) in osteoblastic lineage cells had phenotypic changes including dwarfism, hypophosphatemia, osteomalacia and increased FGF23 that plays an important role both in bone mineralization and renal phosphate homeostasis. The purpose of the current study was to examine the effect of short-term blocking of FGF23 using FGF23 neutralizing antibody on phosphate homeostasis in kidney of HMWTg mice. One-month-old male HMWTg mice were injected with FGF23 neutralizing antibody (10mg/kg body weight) or Isotype IgG. One-month-old male VectorTg mice were treated with IgG only as control. After 24 hours, mice were sacrificed. DEXA analysis, serum biochemistry, and harvesting of kidneys for mRNA and protein analysis of the genes of interest were performed. Consistent with our previous reports, at baseline, there were significant reductions in bone mineral density and bone mineral content in HMWTg compared with VectorTg mice. In addition, compared with VectorTg, serum phosphate (Pi) was significantly reduced ($P<0.05$) in HMW Tg mice. In HMWTg mice treated with IgG there was no increase in serum Pi. In contrast FGF23 neutralizing antibody significantly increased serum Pi in HMWTg mice (Fig A). There was no statistical difference observed in serum calcium between VectorTg and HMWTg mice. We also examined the effect of FGF23 signaling in kidney of HMWTg mice. We observed that excess FGF23 in HMWTg mice increased protein expression of FGF Receptors (FGFR1&FGFR3), klotho, phospho-Erk (pERK1/2), c-fos and decreased the sodium phosphate transporter (Npt2a) in kidneys to cause Pi wasting. By blocking FGF23 function in kidneys of HMWTg, we observed significantly decreased FGFR1(Fig B), FGFR3, and P-ErK based on immunoflurencent staining. Furthermore Western blot revealed that p-Erk was dramatically reduced and the ratio with total Erk changed from 4.3 to 1.9 (Fig C). There was also a significant reduction in c-Fos mRNA ($P<0.05$), as well as significantly increased Npt2a mRNA ($P<0.05$) (Fig D). Taken together, these data suggests that HMWFGF2 acts on the kidney via FGF23/FGFR/Klotho/MAPK/c-Fos and Npt2a to regulate Pi homeostasis.

Keywords: HMWFGF2, Pi wasting, FGF23, FGF23 neutralizing antibody, MAPKinase signaling.

Calcemic actions of a long-acting PTH analog in PTH knockout mice. Tomoyuki Watanabe*[1], Monica Reyes[2], David Goltzman[3], John Potts[1], Thomas Gardella[1]. [1]Massachusetts General Hospital, USA, [2]Massachusetts General Hospital, USA, [3]McGill University, Canada

Parathyroid hormone (PTH) plays a critical role in regulating blood concentrations of ionized Ca via activation of the PTH receptor 1 (PTHR1). We recently have reported on a series of PTH analogs that bind to the PTHR1 with high affinity, induce sustained cAMP signaling responses in PTHR1-expressing cells, and mediate prolonged calcemic and phosphaturic responses when injected into animals (Maeda et al., PNAS 2013). Given their prolonged duration of action in vivo, such PTH analogs could potentially be used as treatments for hypoparathyroidism. We assessed this possibility for one such long-acting PTH analog, called LA-PTH, in an animal model of hypoparathyroidism. We thus tested the capacity of the analog to modulate blood calcium concentrations in PTH-deficient knock out mice (PTH-KO) mice. The base-line levels of blood ionized Ca in these KO mice are about 10% lower than those in normal mice, consistent with hypoparathyroidism. The mice were injected subcutaneously with either vehicle, LA-PTH (10 nmol/kg) or PTH(1-34) (50 nmol/kg), and blood ionized calcium concentrations were measured at times thereafter. Both LA-PTH and PTH(1-34) injections caused blood Ca++ levels to increase to similar levels (~10% above the levels in vehicle-injected mice), but the duration of the response induced by LA-PTH was significantly greater than that induced by PTH(1-34), despite the five-fold lower dose of LA-PTH. These data support the view that modified PTH analogs can indeed be developed to have prolonged actions on PTHR1 target cells in vivo and to be thus potentially useful as agents for treating hypoparathyroidism.

MO0137

Evolution of a Long-Acting Parathyroid Hormone Analog for the Treatment of Hypoparathyroidism. Henry Bryant*[1], Charles Benson[2], Venkatesh Krishnan[1], Masahiko Sato[3], Ricky Cain[2], Qianqiang Zeng[2], Deborah Robins[2], Nora Yang[4], Yanfei Ma[1]. [1]Eli Lilly & Company, USA, [2]Eli Lilly & Company, USA, [3]Indiana University School of Medicine, USA, [4]NIH, Therapeutics for Rare & Neglected Diseases, National Center for Advancing Translational Sciences, USA

LSN2561553 is a long-acting PEGylated analog of human parathyroid hormone 1-34 (PTH) that was originally developed as a potential once per week bone anabolic therapy for osteoporosis. The peptide binds with high affinity to the PTH1 receptor and activates cAMP signaling in a manner comparable to PTH, although with some in vitro effects distinct from PTH (e.g. PTH1 receptor internalization/recycling dynamics). In 7-month old rats that were osteopenic (4-week post-ovariectomy), once every 6 day dosing of LSN2561553 for 8 weeks produced dose-related bone anabolic effects as demonstrated by increased serum P1NP levels, bone mineral density, bone biomechanics, and a dynamic histomorphometry profile consistent with bone anabolism. These effects on bone were comparable to the bone effects observed with PTH given as once daily injections, but were accompanied by transient hypercalcemia. LSN2561553, subcutaneously administered to postmenopausal osteopenic women at a dose range of 10 – 100 mcg/w over a 4-week period, increased serum P1NP and osteocalcin at the 100 mcg/kg dose. Doses greater than 65 mcg were accompanied by hypercalcemia and its associated clinical symptoms, including nausea, vomiting, headaches and fatigue. These adverse effects were observed after the first and each subsequent weekly dose of LSN2561553 over the 4-week study and led to termination of further development of the molecule for osteoporosis. Follow-up work in parathyroidectomized (PTX) rats suggested potential efficacy of LSN2561553 as replacement therapy. PTX rats confirmed to have low circulating PTH(1-84) and low serum calcium levels were treated with either daily vehicle or various doses of LSN2561553. Subcutaneous LSN2561553 at 10 mcg/kg and higher, elevated serum calcium within 24 hours. Subsequent daily doses of LSN2561553 normalized serum calcium in PTX rats between 36 and 48 hours, which were sustained over a 5 day period. These studies suggested that while LSN2561553 had little value as a bone anabolic therapy for osteoporotic patients with normal PTH status, therapeutic potential was possible for patients deficient in PTH (1-84). This therapeutic potential as a treatment for hypoparathyroidism is being investigated as part of the NIH Therapeutics for Rare and Neglected Diseases program at the National Center for Translational Sciences.

MO0138

Serum Amyloid A3 Secreted by Osteoclasts Inhibits PTH-Stimulated cAMP Production and Osteoblast Differentiation *In Vitro*. Shilpa Choudhary*[1], Thomas Estus[2], Joseph Lorenzo[1], Hector Aguila[1], Carol Pilbeam[1]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut Health Center, USA

Cyclooxygenase-2 (Cox-2) is the major enzyme responsible for prostaglandin (PG) E_2 production in bone. In contrast to wild type (WT) mice, *Cox-2* knockout (KO) mice increase their trabecular bone mass with continuous PTH infusion. *In vitro*, Cox-2 produced PGE_2 inhibits PTH-stimulated osteoblast (OB) differentiation. This inhibition is mediated by a factor secreted from RANKL-stimulated bone marrow macrophages (BMMs). Conditioned medium (CM) from these BMMs inhibits PTH-stimulated cAMP production, cAMP-mediated early gene expression and OB differentiation. The goal of this study was to identify the inhibitory factor in the CM. Microarray analysis of gene expression in RANKL-stimulated BMMs showed that the gene for Serum amyloid a3 (*Saa3*) was the most highly differentially expressed gene in WT BMMs compared to *Cox-2* KO BMMs. In the presence of M-CSF alone, *Saa3* was barely detectable by real time PCR in WT BMMs but was markedly increased by RANKL. Similar results were seen in an osteoclast (OC) progenitor population ($B220^-$ $CD3^-$ $CD11b^{-/low}$ $CD115^+$) isolated by flow sorting. Saa3 protein, measured by ELISA in CM, was detectable only in RANKL-stimulated WT BMMs and OC progenitor cells. Saa3 belongs to the family of four secreted, acute phase apolipoproteins. None of the other *Saa* genes were detectable or induced by RANKL. Addition of recombinant human homolog of Saa3 to primary osteoblasts (POBs) inhibited PTH-stimulated cAMP-mediated early gene expression and OB differentiation. A 99% knockdown of *Saa3* gene and protein expression was achieved in WT

BMMs by lentiviral transduction of shRNA constructs. CM from RANKL-stimulated BMMs with Saa3 knockdown did not inhibit PTH-stimulated cAMP production, cAMP-mediated early gene expression or OB differentiation in POBs. Saa3 has been shown to act via the FPRL-1 receptor, which activates the GPCR/Gαi/o signaling pathway that can be blocked by pertussis toxin (PTX). Addition of PTX to POBs prevented the inhibitory effect of recombinant SAA on PTH-stimulated OB differentiation. We conclude that Saa3 is likely to be the OC-secreted factor that acts on OBs to inhibit PTH-stimulated cAMP signaling and OB differentiation and may act via GPCR/Gαi/o signaling. We speculate that Saa3 may also suppress the bone formation response to PTH when PTH is given continuously *in vivo*.

MO0139

Activity and Gene Expression of Steroid Sulfatase During Differentiation of the Human MG-63 Preosteoblastic Cell Line. Kyle Selcer[1], Natasha Dias*[2]. [1]Duquesne University, USA, [2]Duquesne University, USA

Estrogen plays an important role in regulation of bone turnover by inhibiting osteoclastic bone resorption. Postmenopausal women have low estrogen production, but inactive sulfated steroids, particularly estrone sulfate (E1S) and dehydroepiandrosterone sulfate (DHEAS), are present at considerable levels in postmenopausal circulation. Conversion of these precursors to active estrogens may help maintain bone density in postmenopausal women. The enzyme steroid sulfatase converts sulfated steroids into their active form in peripheral tissues. Steroid sulfatase is known to occur in bone, but little is known about the regulation of this enzyme. In this study, we investigated the activity and expression of steroid sulfatase in a human preosteoblastic cell line (MG-63). MG-63 cells progress through the various stages of bone cell differentiation under the influence of estrogen and osteogenic supplement, passing through a well-defined sequence of proliferation, matrix maturation, and extracellular mineralization. Cells were grown for 21 days in whole medium alone (OS-) or whole medium containing an osteogenic supplement (OS+) known to enhance differentiation. Growth of cells in OS- medium was nearly exponential, whereas that of cells treated with OS+ was considerably slower. Steroid sulfatase activity, as determined by a whole-cell 3H-E1S conversion assay, increased substantially over time in OS- cells, but increased little in OS+ cells. Steroid sulfatase gene expression, as measured by real-time quantitative rtPCR, revealed a 75% increase in steroid sulfatase mRNA expression in the OS- cells over the OS+ cells, across all time points. Alkaline phosphatase activity increased in the OS+ cells over time, but did not increase in the OS- cells. Osteocalcin gene expression was increased in OS- cells on days 5-21, but was increased in OS+ cells on days 2-8. Our data reveals that activity and expression of steroid sulfatase varies during bone cell differentiation, being higher in the early stages. These results suggest that steroid sulfatase is regulated during bone differentiation and may play a role in bone development.

Compartmental, temporal and functional interaction of the *cis*-acting heterogeneous nuclear ribonucleoprotein D_0 (AUF1) and estrogen receptor-α in osteoblasts. Alejandro Garcia*[1], John Adams[2], Martin Hewison[2], Rui Zhou[3]. [1]Univ. of California, Los Angeles, USA, [2]University of California, Los Angeles, USA, [3]University of California, Los Angeles, USA

We analyzed the coupled intermolecular, locational, and functional association among the ERE-interacting heterogeneous nuclear ribonucleoprotein D_0 (hnRNP D_0, AUF1), the estrogen receptor alpha (ERα) and estradiol (E2) in the osteoblastic cell line MC3T3-E1. AUF1, also known as the estrogen response element binding protein (ERE-BP), exerts a dominant–negative effect on ERα–E2-directed transcription and E2 resistance *in vivo.* Co-immunoprecipitation and chromatin immunoprecipitation (ChIP) experiments with AUF-1 and ERα were preformed in the presence or absence of E2 to ascertain association between these two proteins in the cytoplasmic and nuclear compartments of the cell in context with their potential to regulate bone-activating genes *in trans*. Immunoprecipitation of AUF1 from MC3T3-E1 cells treated with 10nM E2 for 5, 15, 30, or 180 min and probing for ERα demonstrated AUF1–ERα association exclusively in the nuclear fraction of the cell before and after E2 stimulation. Maximal nuclear AUF1–ERα association was observed 15 min post introduction of E2, suggesting that nuclear association of AUF1-ERα was due to translocation of E2-ERα complex from the cytoplasm. In synchronized cells prolonged exposure to E2 at 30 min led to a 22% decrease in the association between AUF1 and ERα; this is reminiscent of the liganded ERα's cyclical interaction with regulatory *cis* elements. Suprisingly, immunoprecipitation of AUF1 from the cytoplasmic fraction failed to pull down ERα in the presence or absence of E2. ERα is known to interact with the intracellular estradiol-binding protein (IEBP; hsc70) in the cytoplasm, an event that could obscure the anti-AUF1 binding epitope. ChIP of the ERα or AUF1 followed by quantitative PCR (qPCR) of an enhancer element upstream of the Fas ligand gene (FasL; E2-ERα-induced *FasL* expression in osteoblasts is a direct mediator of osteoclast apoptosis) demonstrated 3.4 fold enrichment of ERα 45 minutes after E2 stimulation and ~300% increase in E2-driven *FasL* mRNA expression after 24 hours of E2 stimulation. This event was reciprocally associated with AUF1 occupancy at the same cis element. These data are the first to show a direct association between AUF1 and the ERα in its E2-activated state in the nucleus and suggest that AUF1 can function as a transacting mediator of bone remodeling in a native *Auf1* expression state.

Prednisolone Treatment Reduces the Osteogenic Effects of Loading in Female Mice. Ingrid Bergstrom*[1], Hanna Isaksson[2], Riccardo Chiusaroli[3], Christina Perdikouri[2], Neashan Mathavan[2], Maria Norgård[4], Antti Koskela[5], Juha Tuukkanen[6], Claes Ohlsson[7], Goran Andersson[8], Sara Windahl[9]. [1]Karolinska Institutet, Sweden, [2]Department of Solid Mechanics & Orthopedics, Lund University, Sweden, [3]Rottapharm Biotech, Italy, [4]Department of Laboratory Medicine, Karolinska Institutet, Sweden, [5]Department of Anatomy & Cell Biology, Institute of Biomedicine, University of Oulu, Finland, [6]University of Oulu, Finland, [7]Center for Bone & Arthritis Research at the Sahlgrenska Academy, Sweden, [8]Karolinska Institute, Sweden, [9]Center for Bone & Arthritis Research, Sahlgrenska Academy, Sweden

Glucocorticoids have deleterious effects on the skeleton leading to osteoporosis and an increased fracture risk while mechanical loading increases bone mass. The aim of the present study was to investigate whether high-dose Prednisolone treatment reduces the beneficial effect of loading on cortical bone mass.

Three-month-old female C57BL/6 mice (n=8-9 in each experimental group) were treated with high-dose Prednisolone (15mg/60d.pellets/mouse) or vehicle. The right tibiae were subjected to short periods of cyclic compressive loading three times a week for two weeks (40 cycles, peak strain 3,000με). Micro-computed tomography was used to assess the osteogenic response in the cortex of the loaded (right) versus the non-loaded (left) tibia. Three-point bending was used to assess the bone strength. Alterations in gene expression were investigated by real-time PCR.

As expected, loading increased the cortical bone area in vehicle treated mice ($11.8 \pm 1.8\%$ vs non-loaded, $p<0.01\%$). Importantly, Prednisolone-treatment substantially reduced the loading response on cortical bone area ($-81.7 \pm 8.0\%$, $p<0.01\%$) compared to vehicle-treated mice. Bone-strength measured by 3-point bending was significantly increased by loading in vehicle-treated mice (force at yield point +37%, $p<0.05$), while no significant effect of loading was observed in Prednisolone-treated mice. The expression of osteoblast-associated genes was significantly reduced by prednisolone-treatment in non-loaded tibia. Several osteoblast and early osteocyte associated genes were induced by loading in vehicle-treated but not in prednisolone-treated mice (Figure 1).

These findings demonstrate that the stimulatory effect of loading on cortical bone mass is reduced by high-dose Prednisolone-treatment. These data suggest that loading may not be beneficial for the skeleton in patients on high dose glucocorticoid treatment.

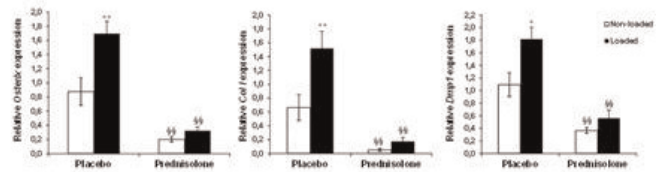

Figure 1. The load-related increase in osteoblast and early osteocyte genes, is blunted in Prednisolone-treated female mice. N=8-9. *p<0.05 and **p<0.01 vs non-loaded tibiae. §§p<0.01 vs placebo control of the same loading regime.

A Reverse J-shaped Association Between Serum 25-hydroxyvitamin D and Cardiovascular Disease Mortality – the CopD Study. Darshana Durup*[1], Henrik L. Jørgensen[2], Jane Christensen[3], Anne Tjønneland[3], Anja Olsen[3], Jytte Halkjær[3], Bent Lind[4], Anne-Marie Heegaard[5], Peter Schwarz[6]. [1]Faculty of Pharmaceutical Sciences, University of Copenhagen, Denmark, [2]2Department of Clinical Biochemistry, Copenhagen University Hospital Bispebjerg, Denmark, [3]Danish Cancer Society Research Center, Denmark, [4]The Elective Laboratory of the Capital Region, Denmark, [5]Faculty of Health & Medical Sciences, University of Copenhagen, Denmark, [6]Glostrup Hospital, Denmark

PURPOSE

Cardiovascular disease is the major cause of death in the Western World, but the association between 25-hydroxyvitamin D levels and the risk of cardiovascular disease mortality remains unclear

METHODS

We examined the association 25-hydroxyvitamin D levels and mortality from cardiovascular disease, stroke and acute myocardial infarct among 161,428 women

and 86,146 men in the Copenhagen vitamin D study (CopD study) in age, time of blood sample and gender-adjusted Cox regression models.

RESULTS

During follow-up between 2004 and 2011 a total of 16.645 subjects died. 5,454 died from cardiovascular disease including 1,574 from stroke and 702 acute myocardial infarct. 25-hydroxyvitamin D level of 70 nmol/L was associated with the lowest cardiovascular disease mortality risk. Compared to that level the hazard ratio for cardiovascular disease mortality was 2.0(95% CI 1.8-2.1) at the lower extreme (~12.5 nmol/L) with higher risk for men 2.5(95% CI 2.2-2.9), than for women 1.7(95% CI 1.5-1.9). At the higher extreme (~125 nmol/L), the hazard ratio of cardiovascular disease mortality was 1.3(95% CI 1.2-1.4), with similar risk among men and women. Results were similar for stroke and acute myocardial subgroups

CONCLUSIONS

In this large prospective study low and high levels of 25-hydroxyvitamin D were associated with cardiovascular disease, stroke and acute myocardial mortality in a non-linear, reverse J-shaped manner, with highest risk at lower levels. Whether this was a causal or associational finding cannot be determined from our data. There is a need for randomized clinical trials which include information on the effects of 25-hydroxyvitamin D levels above 100 nmol/L

MO0143

Adipose Derived Stem Cells Combined With Beta-Tricalcium Phosphate Is a Potential Therapeutic Approach for Bone Defects Under Systemic Administration of $1,25(OH)_2D_3$. Shengyu Lv*[1], Jian Cui[1], Hongrui Liu[1], Wei Feng[1], Juan Li[1], Bao Sun[1], Kefeng Wang[2], Xiong Lu[3], Minqi Li[4]. [1]Shandong University, China, [2]Sichuan University, China, [3]Southwest Jiaotong University, China, [4]The School of Stomatology, Shandong University, Japan

We have examined a new therapeutic approach for the restoration of bone defects. Adipose derived stem cells (ADSC) isolated from adipose tissue of 8-week-old Vista rats were cultured in the osteogenic induction medium. After osteoblastic properties were verified, ADSC were loaded onto beta-tricalcium phosphate (β-TCP) and co-cultured for another 3 days. The ADSC-β-TCP complexes were then implanted into $5 \times 3 \times 5$mm femoral defects of the same ADSC donate rats. Meanwhile, $1,25(OH)_2D_3$ (120ng/kg body weight) was administrated intraperitoneally once every other day. Animals were divided into 4 groups in this study: i. Bone defects restored with β-TCP and treated with normal saline (NS); ii. Bone defects restored with ADSC-β-TCP complex and treated with NS; iii. Bone defects restored with β-TCP and treated with $1,25(OH)_2D_3$; iv. Bone defects restored with ADSC-β-TCP complex and treated with $1,25(OH)_2D_3$. At day 7, 14 and 28 after operation, rats were perfused with 4% paraformaldehyde in 0.1M phosphate buffer (pH 7.4), and their femurs were harvested for histochemical analysis (n=6). The histochemisty of alkaline phosphatase (ALP), Runx2, cathepsin K and tartrate resistant acid phosphates (TRAP) were performed in this study. Groups treated with $1,25(OH)_2D_3$ showed more newly formed bone than the other corresponding two groups treated with NS. The largest volume of new bone was observed in group iv at day 28 (BV/TV: $34.3 \pm 1.3\%$, $49.2 \pm 3.5\%$, $56.1 \pm 2.3\%$ and $65.0 \pm 5.2\%$ for group i, ii, iii and iv respectively). In a respect of osteogenic activity, immunolocalization of ALP and Runx2 were more seen in the bone defects restored with ADSC-β-TCP, especially at the time point of day 7. However, groups treated with $1,25(OH)_2D_3$ showed no obvious effect on the expression of these proteins according to our data. On the other hand, TRAP-positive osteoclasts number showed significant difference at day 7 and day 14 between groups treated with $1,25(OH)_2D_3$ or NS (day 7: 81.80 ± 6.40, 67.70 ± 7.60, 12.10 ± 1.97 and 8.90 ± 1.79; day 14: 88.90 ± 6.98, 105.30 ± 8.34, 31.50 ± 2.59 and 28.40 ± 2.50 in group i, ii, iii and iv respectively, cells/mm2). Importantly, immunolocalization of cathepsin K also revealed obvious decline in the groups treated with $1,25(OH)_2D_3$ at day 7 and day 14 when compared with the corresponding groups treated with NS. Thus, osteogenic-activity-possessing ADSC loaded β-TCP is a potential therapeutic approach for bone defects under systematic administration of $1,25(OH)_2D_3$.

MO0144

Evidence that C/EBP alpha, PU.1 and the SWI/SNF complex are key mediators of 1,25-dihydroxyvitamin D_3 regulation of innate immune responses in lung epithelial cells. Puneet Dhawan*[1], Ran Wei[2], Cheng Sun[2], Adrian F. Gombart[3], H. Phillip Koeffler[4], Gill Diamond[5], Sylvia Christakos[2]. [1]Rutgers - New Jersey Medical School, USA, [2]Rutgers - New Jersey Medical School, USA, [3]Oregon State University, USA, [4]Cedars Sinai Medical Center, USA, [5]University of Florids, USA

Although vitamin D has been reported to have an important role in the regulation of innate immunity, little is known regarding the role of vitamin D in host defense in the airway. We earlier reported that the cathelicidin antimicrobial peptide is induced by $1,25(OH)_2D_3$ in human bronchial epithelial cells with a resultant increase in antimicrobial activity against airway pathogens. In this study we identify key factors that cooperate with the vitamin D receptor (VDR) in the regulation of the human cathelicidin antimicrobial peptide (CAMP) gene. We found that C/EBPα is induced by $1,25(OH)_2D_3$ in human lung epithelial cells and is a potent enhancer of $1,25(OH)_2D_3$ induced CAMP transcription and mRNA and peptide expression. A C/EBP activation domain was identified at -628/-620 within the hCAMP promoter, adjacent to the vitamin D response element (VDRE; -616/-601). Mutation of the C/EBP site markedly attenuated the transcriptional response to C/EBPα as well as to $1,25(OH)_2D_3$, further indicating cooperation between these two factors in the regulation of CAMP expression. C/EBPα has been shown to cooperate with Brm (a component of the SWI/SNF chromatin remodeling complex). Brm dominant negative inhibited the stimulatory effect of C/EBPα and the induction by $1,25(OH)_2D_3$ of CAMP transcription. ChIP/re-ChIP assays showed that Brm functionally cooperates with C/EBPα by direct protein-protein interaction at the C/EBP site in the CAMP promoter. We found that the PU.1 myeloid cell transcription factor is present in lung epithelial cells and cooperates with VDR and C/EBPα to enhance CAMP transcription and mRNA expression. Results of PCR arrays indicate that the two genes most induced by $1,25(OH)_2D_3$ in human bronchial epithelial cells are cathelicidin (38 fold induction) and the TLR4 coreceptor CD14 (46 fold). We found similar cooperative effects between VDR, C/EBPα, PU.1 and the SWI/SNF complex in the regulation of CD14 transcription. These findings indicate that C/EBPα, PU.1 and the SWI/SNF complex are key mediators involved in the regulation by $1,25(OH)_2D_3$ of innate immune responses in lung epithelial cells. The mechanisms involved in the enhanced activation of the CAMP gene suggest potential candidates, including vitamin D, for the development of innate immune responses to augment current therapies to treat or prevent bacterial airway infections.

MO0145

Gene expression profiles identify selective transcriptome responses of the duodenum and distal intestine to modulation by calcium or vitamin D. Vaishali Velduthy*[1], Puneet Dhawan[2], Tanya Seth[1], Kiin Kim[1], Angela Porta[3], Patricia Soteropoulos[1], Saleena Ghanny[1], Sylvia Christakos[2]. [1]Rutgers - New Jersey Medical School, USA, [2]Rutgers - New Jersey Medical School, USA, [3]Kean University, USA

Intestinal calcium absorption is important for maintaining calcium homeostasis. However, as indicated in knock out mice studies, an understanding of the mechanisms responsible for intestinal calcium absorption remains incomplete. To identify key genes involved in the intestinal calcium absorptive process RNA was isolated from the duodenum as well as from distal intestinal segments and studied by Affymetrix microarray. In studies using vitamin D deficient (-D) mice and –D mice injected with $1,25(OH)_2D_3$ (+D) [(1ng/g bw) 3 times over 48h] the genes most strongly affected by $1,25(OH)_2D_3$ in the intestine were CYP24A1, TRPV6 and calbindin-D_{9k}. There was a 5 – 10 fold greater induction of TRPV6 and calbindin-D_{9k} by $1,25(OH)_2D_3$ in the distal intestine compared to the duodenum. Similar findings were observed using RT-PCR and Western blot analysis. Transcript levels for S100A8 and S100A9 antibacterial proteins were induced 3 – 6 fold (2 fold greater induction in the distal intestine). A significant 1.4 fold decrease in gene expression of cadherin-17 (important for cell to cell contact) by $1,25(OH)_2D_3$ was also observed using –D and +D WT mice as well as –D and +D mice null for both calbindin-D_{9k} and TRPV6 (DKO mice). Using WT or DKO mice the transcript levels for claudin-2, claudin-12 and Cav1.3 voltage gated Ca^{++} channel (previously suggested to be involved in vitamin D regulated calcium transport) were unaffected by $1,25(OH)_2D_3$. In previous studies we showed that transgenic expression of VDR restricted to the distal ileum, cecum and colon of VDR KO mice rescues rickets. Microarray analysis indicated that the genes most strongly affected by VDR expression in the distal intestine are TRPV6 (100 -115 fold induction) and calbindin-D_{9k} (10 – 71 fold induction). Transcript levels for claudin-2, 12, and Cav1.3 were similar in VDR KO and transgenic mice. In VDR KO mice that were fed a rescue diet (high in Ca, P and 20% lactose), which normalizes mineral homeostasis, TRPV6 and calbindin-D_{9k} genes were down-regulated in the duodenum. Most notable was the suppression of genes for intra and intercellular matrix proteins including aquaporin 8 and claudin 8 in the ileum under rescue diet conditions. In summary, our findings provide new insight into genes regulated by $1,25(OH)_2D_3$ and high calcium/ lactose in intestine and further emphasize the importance of the distal as well as the proximal intestinal segments in order to understand intestinal effects of calcium and vitamin D.

MO0146

Hypercalcemia and Nephrocalcinosis in Two Infants with Glucose Galactose Malabsorption: The Role of 1,25 Vitamin D. Melissa Fiscaletti*[1], Marie-Jeanne Lebel[2], Nathalie Alos[3], Prevost Jantchou[4], Geneviève Benoit[5]. [1]University of Montreal, Canada, [2]University of Montreal, Canada, [3]CHU Sainte Justine, Canada, [4]Unviersity of Montreal, Canada, [5]Univerity of Montreal, Canada

Hypercalcemia and nephrocalcinosis have been reported in infants with congenital carbohydrate malabsorption - disorders that are potentially fatal if not promptly diagnosed. Yet the mechanisms that produce calcium imbalance in glucose galactose malabsorption (GGM) are incompletely understood.We report two cases of non-related caucasian infants with GGM who both presented with hypercalcemia and nephrocalcinosis. One patient consulted for failure to thrive while the other was first

seen for macroscopic hematuria. In both cases, the osmotic diarrhea was misidentified as polyuria which delayed the diagnosis of malabsorption. The investigations showed hypercalcemia and bilateral nephrocalcinosis in both patients with high levels of 1,25 OH vitamin D despite suppressed PTH and normal 25 OH vitamin D levels. Hypercalciuria was present in one case. After a one-year follow-up, nephrocalcinosis remained stable and hypercalcemia normalized with the introduction of an appropriate diet.

These two cases demonstrate that when hypercalcemia and nephrocalcinosis are detected, the clinician must rule out a malabsorption disorder. Hypercalcemia and nephrocalcinosis in GGM have classically been attributed to dehydration, metabolic acidosis and increase calcium absorption from vitamin D independent pathways. Our cases highlight the possible implication of 1,25 OH vitamine D in this process possibly through the activation of the TRPV6 transcellular pathway. Genotype-phenotype studies are necessary to better understand the variable clinical presentation of GGM.

MO0147

Obese premenopausal women have lower serum total, free and bioavailable 25(OH)D status and higher vitamin D binding protein (DBP) and parathyroid hormone (PTH) concentrations compared to normal weight premenopausal women. Elisa Saarnio*[1], Minna Pekkinen[2], Suvi Itkonen[3], Virpi Kemi[4], Heini Karp[5], Christel Lamberg-Allardt[3]. [1]University of Helsinki, Finland, [2]Folkhälsan Institute of Genetics, University of Helsinki, Finland, [3]University of Helsinki, Finland, [4]Calcium Research Unit, Finland, [5]Calcium Research Unit, Finland

Recent studies have reported lower S25(OH)D mean concentrations in obese subjects than normal weight individuals. However, differences in vitamin D binding protein (DBP) or in free and bioavailable S25(OH)D concentrations between obese and normal-weight persons are not so well studied. We compared 43 obese (BMI >30) and 144 normal-weight (BMI 20-25) women aged 37-47 with mean BMI of 35.7±4.3 kg/m2 (mean +SD) and 22.5±1.6 kg/m2, respectively. Blood samples and data on total vitamin D and calcium intake (from food and supplements) were collected as well as life style habits including sunny holidays. Comparisons between the normal-weight and obese subjects were made with ANCOVA. Logarithmic transformation was applied to non-Gaussian variables and outliers were removed. DBP concentrations were significantly higher in obese compared to normal-weight subjects (388 ± 89 mg/L and 358±88 mg/L, respectively; p= 0.033). Total S-25(OH)D concentrations were 56.7±18.2 nmol/L in normal-weight subjects and 50.4±17.9 nmol/L in obese subjects; p=0.004.The concentration of calculated free 25OHD was lower in obese woman compared to normal-weight women (10.7±4.1 nmol/L and 12.6± 4.3 nmol/L, respectively; p=0.002). Also the calculated bioavailable 25(OH)D (free+albumin bound) was lower in obese persons (p<0.001). Total vitamin D intake, serum parathyroid hormone (SPTH) concentration and sunny holidays were used as covariates. SPTH was higher in obese compared to normal weight subjects (65.1±29.9 and 54.0±23.5 ng/L, respectively; p=0.017).Total vitamin D intake was higher in normal-weight than in obese subjects (15 µg/day and 11µg/day, respectively; p=0.012, which in both groups met the vitamin D recommendation in the Nordic European countries (10 µg/day). In conclusion, obese women had higher DBP concentrations than normal-weight subjects. The concentrations of total, free and bioavailable 25(OH)D were lower than in normal weight women, also after adjustment for total vitamin D intake. Additionally, SPTH concentration was higher in obese women. The observed associations between BMI and total- free-, bioavailable 25(OH)D, DBP and PTH suggests that obesity may modify vitamin D metabolism.

Vitamin D Deficiency and Cardiometabolic |Risks in Arab Adolescents: the "Veiled" Female Advantage. Nasser Al-Daghri*[1], Yousef Al-Saleh[2], Abdulaziz Al-Othman[3], Majed Alokail[3], Omar Al-Attas[3], Abdullah Alnaami[3], Shaun Sabico[3], George Chrousos[4]. [1]King Saud University, Saudi Arabia, [2]King Saud University for Health Sciences, Saudi Arabia, [3]King Saud University, Saudi Arabia, [4]Athens University, Greece

Objective

The recent exponential surge in vitamin D research reflects the global epidemic of vitamin D deficiency and its potential impact on several chronic diseases in both children and adults. Several subpopulations, including Arab adolescent boys and girls, remain understudied. This study aims to fill this gap.

Study Design

A total of 848 apparently healthy adolescent Saudis (334 boys and 514 girls, aged 13-17 years old) were recruited from different public schools within Riyadh, Saudi Arabia. Anthropometrics were taken and fasting blood samples withdrawn to examine serum glucose and lipid profile by routine analysis and 25-hydroxyvitamin D by ELISA.

Results: Almost half of the girls (256/514 or 49.7%) had vitamin D deficiency as compared to only 22.2% (74/334) of the boys (p<0.001). In contrast, there was a significantly higher prevalence of prediabetes in boys than girls (20.8% versus 14.6%;p<0.001). Skin color (R=-0.12;p< 0.001) was strongly inversely associated with vitamin D status in girls, but not in boys. In boys but not in girls, vitamin D status was strongly and inversely associated with BMI (R=-0.17;p<0.001), arm circumference (R=-0.14;p<0.001), systolic blood pressure (R=-0.19;p< 0.001) and triglycerides (R=-0.14;p<0.001). In neither group was fasting blood sugar associated with vitamin D status.

Conclusion: Vitamin D deficiency is more common in Arab adolescent girls than boys. However, vitamin D deficiency is mostly associated with cardiometabolic risk factors in boys, suggesting gender-specific differences that need to be taken into account as to who might benefit the most from vitamin D correction in the adolescent population.

MO0150

An open label study of Zoledronic Acid (*Reclast*/*Aclasta* 5mg iv) in the treatment of Ankylosing Spondylitis. Gavin Clunie*[1], Amel Ginawi[2], Philip O'Connor[3], Philip Bearcroft[4], Steven Garber[5], Shweta Bhagat[6], Andrew Grainger[3], Hill Gaston[7]. [1]Addenbrooke's Hospital, United Kingdom, [2]Basildon University Hospital, United Kingdom, [3]NIHR Biomedical Research Unit, United Kingdom, [4]Cambridge University Hospitals NHS Foundation Trust, United Kingdom, [5]The Ipswich Hospital NHS Foundation Trust, United Kingdom, [6]West Suffolk NHS Foundation Trust, United Kingdom, [7]University of Cambridge Medical School, United Kingdom

Spinal lesions in Ankylosing Spondylitis (AS) include enthesitis, osteitis, and spondylodiscitis. Osteitis occurs frequently and is characterised by high signal on T2w fat-suppressed or STIR Magnetic Resonance (MR). Pamidronate improves spinal symptoms in NSAID-refractory AS but treatment gains are modest. Zoledronic Acid (*Aclasta*/*Reclast; ZA*) is more 'potent' than pamidronate but its unknown whether ZA improves osteitis in AS. The purpose of the study was to establish whether ZA reduces osteitis in AS as defined by MR.

Patients with AS (NY criteria) were recruited from two Rheumatology Units (exclusions: poor dentition, planned dental work, GFR<35ml/min). Written informed consent was obtained. Patients' progression in the protocol required osteitis in ⩾2 discovertebral units (DVUs) Spondylarthropathy Research Consortium of Canada (SPARCC) definition. Eligible patients received ZA. Ethical approval was obtained and protocol authorized (MHRA; 2007-000087-25). Eligible patients had MR scan pre-treatment then 3 and 6 months after ZA. Sagittal plane spine STIR and T1w sequences were obtained. Images were anonymised and coded and scored by 2 radiologists experienced in SPARCC scoring, blinded acquisition of scans and each others' scoring. An average of the scores for each study was taken. Clinical data obtained at baseline and follow-up: Spinal pain visual analogue score (VAS), Composite Clinical Index (BASDAI), MASES enthesitis index (EI).

Of 11 patients recruited, 7 (6m/1f; age 35-54y) qualified for ZA, with the other 4 patients failing to exhibit ⩾2 scorable DVUs on initial MR. Baseline SPARCC scores were between 16-67 (/108). Scores improved in 4/7 patients by 3 months remaining better than baseline at 6 months. Overall 6/7 patients had improved SPARCC scores vs baseline (19-76%) at 6 months. Inter-rater reliability scores were identical for 79% DVUs differing on 21% by maximum of 1 only. Median pain VAS improved 55% (28-63%) at 3 months, sustained in 4/7 patients through 6 months. BASDAI improved 6.3-5.3 by 3 months and to 5.1 by 6 months after ZA. Mean EI improved from 5.1-3.3 at 3 months and to 3.9 at 6 months.

This is the first study in AS to report MR change in osteitis with ZA. Although a small study, the results suggest ZA reduces osteitis in AS. The reduction in SPARCC scores at 6-months mirrors overall clinical improvement over a meaningful period of therapeutic response. ZA treatment was tolerated well and there were no adverse events.

MO0151

Differential expression of inflammation- and regeneration-associated markers of macrophage-polarization (M1 vs. M2) in Bisphosphonate Related Osteonecrosis of the Jaw (BRONJ) and Osteoradionecrosis (ORN). Falk Wehrhan*[1], Manuel Weber[2], Patrick Moebius[2], Raimund Preidl[2], Phillip Stockmann[2], Friedrich W. Neukam[2], Kerstin Amann[3]. [1]University of Erlangen-Nuremberg, Germany, [2]Dept. of Oral & Maxillofacial Surgery, University hospital of Erlangen-Nuernberg, Germany, [3]Institute of Pathology, University hospital of Erlangen-Nuernberg, Germany

Background and Objectives:

Suppression of the local osseous remodeling followed by local inflammation of jaw bone and soft tissue are thought to be involved in the pathogenesis of BRONJ. ORN has been described to be related to chronic inflammation, fibrotic bone remodeling and -destruction. Inflammative processes are mediated by M1-polarized macrophages (CD68-, iNOS-expression), whereas M2 macrophages (CD163-expression) are critical for tissue regeneration. Aminobisphosphonates have been shown to shift macrophage polarization towards the M1-type. Yet it is unknown, if BRONJ and ORN differ regarding the polarization of involved osteoclasts and macrophages.

The aim of this study was to compare the M1- and M2-polarization of osteoclasts and macrophages in BRONJ and ORN by immunohistochemistry analysis compared to healthy jaw bone (NB).

Material and Methods:

15 specimens of BRONJ-associated bone, 15 of ORN-bone and 15 of healty jaw bone were processed for immunohistochemmistry (Peroxidase / DAB+, DAKO Autostainer). A staining of macrophage- and osteoclast-polarization markers (M1: CD 68; iNOS; M2: CD163) was performed. The specimens were completely digitalized in 400x magnification using "Whole-Slide-Imaging" and in each case the three fields of view with the highest expression level within the bone tissue were selected for cell counting (cells/mm^2, ANOVA-Test).

Results:

A significantly ($p<0,05$) increased CD68-expression was seen in ORN compared to BRONJ and NB. Additionally a significantly ($p<0,05$) increased expression of CD163-positive cells was seen in in ORN compared to BRONJ.

The iNOS-expression in BRONJ-specimens was significantly ($p<0,05$) higher than in ORN-samples.

Conclusion:

The results indicate a differential polarization of osteoclasts and macrophages in BRONJ- and ORN-affected bone. Compared to ORN, BRONJ-samples show an increased M1- and a reduced M2-polarization.

These findings are a possible explanation for the clinically and histopathologically observed fibrotic tissue-remodelling processes in ORN compared to the dramatically impaired tissue proliferation and regeneration in BRONJ-affected bone.

MO0152

Regulatory T cells-mediated arrest of inflammatory bone loss involves the chemoattraction of MSCs and the improvement of its pro-reparative and -immunosuppressive phenotype. Gustavo Garlet*[1], Ana Claudia Araujo-Pires[2], Claudia Biguetti[2], Ana Paula Trombone[3], Andrew Glowacki[4], Sayuri Yoshizawa[4], Steven Little[5], Charles Sfeir[6]. [1]School of Dentistry of Bauru, São Paulo University -FOB/USP, Brazil, [2]FOB/USP, Brazil, [3]USC, Brazil, [4]University of Pittsburgh, USA, [5]University of, USA, [6]University of Pittsburgh, USA

Previous studies demonstrate that regulatory T cells (Tregs) chemoattraction arrest experimental periodontitis (ePD), attenuating the inflammatory bone loss that characterize such condition, and promoting the healing (at least partially) of periodontal tissues. Since mesenchymal stem cells (MSCs) are supposed to interact with Tregs towards the generation of a immunoregulatory and regenerative milieu g, in this present study we investigated the potential modulation of MSCs fate and function by Tregs in ePD model in C57Bl/6 mice.

In the absence of functional Tregs (anti-GITR treatment), the levels of MSCs (CD29, CD44, CD73, CD90, CD105, CD106, CD166, NANOG, Stro-1 and CXCR4) and wound healing (SERPINE1, TIMP1, COL1A1, TGFB1, and ITGA4) markers mRNA (qPCR) were significantly reduced, being associated with increased ePD severity (i.e. increased inflammation and bone loss) and increased levels of osteoclasts markers (RANK, RANKL, catepsin K) expression.Conversely, Tregs chemoattraction by a CCL22-releasing formulation, increases the levels of MSCs and wound healing markers expression along the decrease of bone resorption and osteoclast markers expression. Interestingly, the CCL22/Tregs protective effect is significantly diminished by blocking MSCs mobilization with a CXCR4 inhibitor (AMD3100), indicating an active role for MSCs in ePD arrest. MSCs extracted from periodontal tissues (sorted by magnetic beads) in the presence of active Tregs present higher MFI levels of MSCs and healing markers expression (when analyzed by FACS/qPCR), as well increased immunosuppressive properties in vitro, when compared to MSCs from tissues without Tregs. This results were confirmed using a reverse strategy, when MSCs were attracted to periodontal tissues by CXCL12 in the presence or absence of functional Tregs (Tregs disable by anti-GITR treatment or in CCR4KO mice strain), the absence of Tregs resulted in decreased migration of MSCs, as well in decreased levels of healing markers expression (when analyzed by FACS/qPCR) and reduced immunosuppressive properties in vitro.

The results demonstrated that Tregs and MSCs cooperates to suppress inflammatory bone loss in vivo; where the presence of Tregs boosts the chemoattraction of MSCs, as well improves of its pro-reparative and pro- immunosuppressive phenotype, which actively contributes to the attenuation inflammatory bone loss along experimental periodontitis.

MO0153

Bone Geometry and Volumetric Density of Femoral Shaft in postmenopausal Patients with Rheumatoid Arthritis and Bisphosphonate Therapy. Rahel Meinen*[1], Inna Galli-Lysak[1], Daniel Aeberli[2]. [1]Dept. of Rheumatology & Clinical Immunology/Allergology University Hospital, Switzerland, [2]Dept. of Rheumatology & Clinical Immunology/Allergology University Hospital, Switzerland

Background: Rheumatoid Arthritis (RA) leads to synovial hyperplasia, bone erosions, periarticular bone loss, and systemic osteoporosis. Approximately 25% of patients with early RA show osteopenic BMD, and 10% are osteoporotic. There is evidence that postmenopausal women with RA receiving glucocorticoid and bisphosphonate (BP) therapy are at increased risk for atypical subtrochanteric and diaphyseal femoral fracture. To date, the underlying mechanism has not been elucidated. The present study compared femoral shaft bone geometry and volumetric density in postmenopausal RA patients with and without BP therapy using peripheral quantitative computed tomography (pQCT).

Methods: Consecutive postmenopausal RA patients were recruited at the Department of Rheumatology of the Inselspital Bern. PQCT measurements were performed according to a standard protocol at 33% of the femoral bone, and total bone cross-sectional areas (CSA), cortical CSA, and cortical BMD were determined. Primary outcome was cortical thickness, calculated on the basis of a cylindrical model using total CSA and total bone marrow area. Secondary outcomes were cortical BMD and CSA of total bone, cortex, and bone marrow. Mann-Whitney tests were used for group comparisons.

Results: 91 postmenopausal women were recruited for pQCT measurement. Thirty-one patients were excluded due to comorbidities or medications. Of the remaining 60 patients, 20 were on BP and 40 were BP-naïve. Mean disease duration was 14.2 years (range 0–46). Height and weight were comparable between the two groups. Mean age was 62.5 years (range 48–84). On average, women in the BP group were 8.5 years older (p=0.02). Mean cortical thickness was 10.8% lower in the BP group (BP: mean 3.89 mm, 95%CI 2.65–5.12 mm; BP-naïve: mean 4.36 mm, 95%CI 2.90–5.82 mm; p=0.03). Mean cortical CSA was 9.1% lower in the BP group (BP: mean 296.83 mm2, 95%CI 246.37–347.29 mm2; BP-naïve: mean 326.72 mm2, 95%CI: 283.99–414.0 mm2; p=0.01). Differences remained significant when corrected for age. The BP group showed a trend for increased marrow and total femoral shaft CSA (+18% and +2%, respectively), and for lower cortical BMD (-3%).

Conclusion: This cross-sectional pQCT study comparing postmenopausal RA patients with and without BPs supports the hypothesis that BP therapy affects femoral bone shaft geometry and may lead to a lower cortical thickness and area. Further longitudinal prospective pQCT studies are needed.

***In Situ* Osteocyte Modulation of β_3 Integrin in Response to Hindlimb Unloading.** Pamela Zuckerman*[1], Damien Laudier[2], Robert Majeska[3], Stefan Judex[4], Mitchell Schaffler[1]. [1]City College of New York, USA, [2]City College of New York, USA, [3]City College of New York, USA, [4]Stony Brook University, USA

β_3 integrin (β_3) adhesions linking osteocyte (OCY) processes to canalicular walls appear to be critical sites of mechanotransduction. However, the structure and behavior of these complexes *in situ* are incompletely understood. We used Structured Illumination Microscopy (SIM), providing 100nm fluorescence resolution, to i) characterize the number and distribution of β_3 foci along OCY processes *in situ*, ii) test whether the foci contained vinculin (Vin), as a marker for the cytoskeletal linking proteins found in typical focal adhesions, and iii) determine whether the foci are altered due to changes in mechanical loading. Bones of C57Bl/6 mice (4 m.o. male, N=6/grp) subjected to hindlimb unloading (HLU) for 5 or 14 days or left as cage controls were studied. Fixed and demineralized femoral mid-diaphyseal cross sections (5μm) were double stained for β_3 and Vin, and images acquired via SIM. 10 OCYs/animal were analyzed with ImageJ for β_3 cluster number & size in 3 concentric areas (L1-L3) extending 0.5, 2.5 and 3.5mm from the OCY lacunar margins. ANOVA & post hoc Mann-Whitney U-test were used to compare data by distance from cell bodies and by unloading group. In control animals, β_3 staining was punctate and localized in cell processes as previously observed (Fig 1). Focal number and size were highest in L1, closest to the OCY bodies, and 70% and 50%, respectively, in L3 (Fig 2). Vin staining was also punctate, but located exclusively in OCY cell bodies, consistent with earlier findings for paxillin (Fig 1). HLU reduced the number of β_3 foci after 5 and 14 days (by over 50% in L2, $p<0.05$), but did not alter their size. In contrast, the area stained by Vin was unchanged with HLU, though Vin focal size was

reduced at 14 days (Fig3). These results show that β_3 adhesion foci in OCY processes are not typical focal adhesions, and suggest that β_3 mechanotransduction in these sites must be mediated by non-cytoskeletal pathways like ion channels. In addition, β_3 foci *in situ* are dynamic, changing markedly in response to mechanical unloading while Vin foci in the cell body do not. Whether these changes are reversible with remobilization remain to be determined.

Figure 1
SIM Image of Cortical Bone Osteocytes Stained for β_3 Integrin & Vinculin

β_3-integrin (Red) was observed along osteocyte processes throughout the bone matrix (arrows), seen as discrete punctate staining.

Vinculin (Green) staining was present only in osteocyte cell bodies, and not in cell processes.

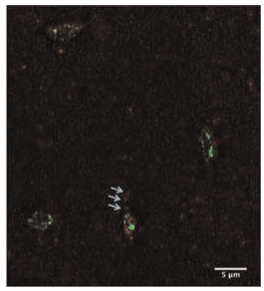

Figure 1

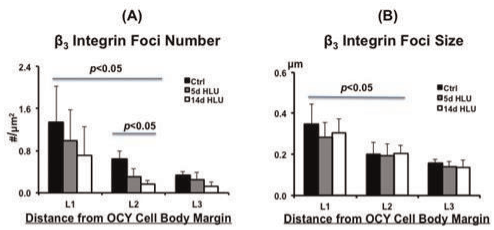

Figure 2
β_3 Integrin in Cortical Bone Tissue Osteocytes of Unloaded Mice

(A) The number of β_3 integrin foci decreased with distance from the lacuna margin and with days of HLU.

(B) Integrin foci size remained unchanged with HLU, plotted as a function of distance from the OCY cell body: L1=0-0.5 μm, L2=0.5-2.5μm & L3=2.5-3.5μm.

Figure 2

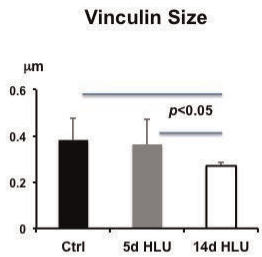

Figure 3
Vinculin in Cortical Bone Tissue Osteocytes of Unloaded Mice

Vinculin was found exclusively within osteocyte cell bodies. Vinculin cluster size was not changed with unloading until after 14 days of HLU, when it was reduced by a third.

Effects of Early Axial Compressive Loading on Cortical Bone Defect Healing in Mice. Robert Carrera*[1], David Wagner[2], Benson George[3], Philipp Leucht[4], Daniel Hunter[3], Gary Beaupre[5], Jill Helms[3], Alesha Castillo[5]. [1]Department of Bioengineering, Stanford University, USA, [2]VA Palo Alto Health Care System, USA, [3]Department of Surgery, Stanford University School of Medicine, USA, [4]Department of Orthopaedic Surgery, Stanford University School of Medicine, USA, [5]VA Palo Alto Health Care System, USA

Introduction: The purpose of this study was to determine the effects of early loading on bone healing. Mechanical stimulation is a known regulator of fracture repair and early weight-bearing is an important aspect of post-surgical care, though very little is known about its effects on the underlying mechanisms of healing. Our hypothesis is that early loading regulates proliferation and differentiation during bone repair. Methods: All procedures were approved by the VAPAHCS IACUC. Under isoflurane anesthesia, bilateral 1-mm monocortical defects were created in anteromedial tibiae in 16 wk-old B6 mice (n=10). The right tibia was subjected to four consecutive days of *in vivo* axial compressive loading (4 N, 2 Hz, 60 cycles) (Fig. 1A) beginning at post-surgery day (psd) 2. Left tibiae served as nonloaded controls. *In vivo* transverse μCT images of bilateral defects were acquired (55 kVp, 300 ms int time, 10.5 μm isotropic voxel) on days 2, 5, 8, 10, and 14. The region of interest included the regenerate and surrounding cortices, and extended up to 50 slices (0.525 mm) on either side of the defect. Percent change in bone volume (BV) at each time point, relative to psd 2, was calculated for each tibia. Groups of animals were euthanized on days 5, 10, and 14. Four-micron longitudinal sections at mid-defect were assessed for histological appearance and proliferation (PCNA, Invitrogen). A linear elastic finite element model of the defect at psd 2 was created (Scanco FE Software), and strains in the longitudinal direction were computed for an applied 4 N point load (Fig 1B). Results: Estimated cortical strains at the edge of the defect reached 800 με in tension (Fig 1B). Percent change in BV was significantly lower in loaded versus control tibias at psd 8 and psd 10 relative the first day of loading (psd 2) (Fig 2) by a Student's t-test. Loaded defects displayed increased proliferation (Fig 3) and greater amounts of cartilage and fibrocartilage (Fig 4) at the periosteum and within the regenerate at psd 10 and 14. Conclusion: Defect-adjacent periosteum and the early regenerate respond to modest levels of cortical bone strain. Loading in the inflammatory and early soft callus phase delays mineralization and remodeling possibly by initiating a robust cartilaginous response and prolonging the proliferative phase. Load-induced increases in callus size may mechanically stabilize the regenerate, which would have implications in clinical rehabilitation protocols.

MO0157

Effects of Mechanical Stimulation on Differentiation of Human Adipose-Derived Stem Cells. Kai Megerle*[1], Whitney Cole[2], Ian Mahaffey[2], Philipp Leucht[3], James Chang[4], Alesha Castillo[5]. [1]Technische Universität München, Germany, [2]VA Palo Alto Health Care System, USA, [3], USA, [4]Department of Surgery, Stanford University School of Medicine, USA, [5]VA Palo Alto Health Care System, USA

Introduction: The goal of this project was to determine the effects of oscillatory fluid flow (OFF) and orbital shaking (OS) on lineage commitment of adipose-derived stem cells (ASCs). Traditional treatment strategies for delayed- and non-union include internal fixation and autologous bone graft, but challenges with donor site morbidity and limited tissue harvest highlight the need for unique sources of osteogenic precursors for orthopaedic applications. We hypothesized that short- and long-term mechanical stimulation enhanced ASC osteogenic differentiation, alkaline phosphatase (ALP) activity, and mineralization. Methods: Human adipose-derived stem cells were obtained from a commercial source and expanded in proliferation media (PM). Passages 1-5 were used for all experiments. At 80% confluence, cells were cultured in either PM or osteogenic media (PM+100nM dexa+10mM b-glycerolphosphate+0.05mM ascorbic acid), and subjected to static conditions or mechanical stimulation (MS). MS consisted of orbital shaking (OS) in a 6-well plate at 200 rpm, 10 dyne/cm^2 or oscillatory fluid flow (OFF), 1 Hz, 20 dynes/cm^2 for given periods. Gene expression, ALP activity, and mineralization were assessed. Data were analyzed by a one-way ANOVA with a Tukey's post-hoc analysis.Results: OFF (3hr, 2Hz) resulted in an increase in Osx and OPN expression and a decrease in PPARγ and Sox9 expression. OS (3hr, 200 rpm) resulted in an increase in Osx, OPN, PPARγ and Sox9 (Fig 1). Runx2 expression did not change in response to OFF or OS. ALP activity of the PM+OS group was not significantly different from the PM group (Fig 2). The OM group exhibited a significant increase in ALP activity compared to PM and PM+OS groups, and the OM+OS group exhibited a significantly lower ALP activity compared to OM alone. Mineralization (RFU 492/520, arbitrary units) was significantly enhanced by OM (140.9 $\pm$ 14.1) compared to PM (2.8 $\pm$ 0.2). Orbital shaking did not affect mineralization of ASCs grown in PM (3.19 $\pm$ 0.4) or OM (131.5 $\pm$ 28.8). Conclusion: OFF is capable of inducing osteogenic differentiation of ASCs. The increase in both osteogenic and adipogenic genes in response to OS suggests that OS may regulate transcription factors involved in unique lineage pathways. Long-term OS either attenuated or had no effect on osteogenic activity suggesting that OS at tested protocols does not represent an effective method for inducing long-term osteogenic lineage commitment of human ASCs.

MO0158

Load-Induced Changes in Corticocancellous Gene Expression, Bone Formation, and Resorption Are Regulated by an Applied Load Threshold and Mechanical Unloading. Haisheng Yang*[1], Whitney A Bullock[2], Alexandra Myhal[2], Daniel Duffy[2], Philip DeShield[2], Maxime Gallant[1], Russell Main[1]. [1]Purdue University, USA, [2]Purdue University, USA

The anabolic cortical tissue response to mechanical stimuli is regulated by a load threshold. To establish the time-dependent cellular basis for the threshold-regulated response in cortical bone and to determine whether corticocancellous tissues respond similarly, successively greater dynamic compressive loads (-3.5N, -5.2N, -7.0N) were unilaterally applied to the tibiae of three groups of 16wk old female C57Bl/6 mice. MicroCT-based finite element analyses were performed to determine the tissue-level strain environments in the diaphyseal cortical and proximal metaphyseal corticocancellous bone at these load levels. Peak principal compressive strains of -1470, -2180, -2940$\mu\varepsilon$ were found at the tibial mid-diaphysis and -1320, -1960, -2640$\mu\varepsilon$ in the proximal cancellous tissues. Load-related changes in gene expression regulating osteoblast and osteoclast function were examined at 3hr and 24hr following a single loading session, following 3 daily loading sessions (3d), and after 2wks of daily loading (5d/wk). The timecourse for the effects of mechanical disuse (unloading) on skeletal gene expression were examined through hindlimb suspension of 16wk old female C57Bl/6 mice for 3hr, 24hr, and 3wks. Dynamic histomorphometry and microCT were used to quantify the mechanobiological response at the cellular and tissue levels, respectively, following 2wks of loading and 3wks of unloading. Short-term downregulation of *Sost* (3hr) and upregulation of *Col1a1* (24hr, 3d, 2wks) at the High Load are consistent with increased mineral apposition rates, bone formation rates, cancellous bone mass, and cortical geometry in the High Load group. The ratio of *Rankl*/*Opg* expression was reduced in corticocancellous tissues 3hr following High Load and increased at all timepoints in the Unload group. Consistent with increased mid-diaphyseal cortical geometry and endocortical bone formation following loading,

diaphyseal *Sost* expression in the Medium Load group decreased following 3d of loading and *Col1a1* expression increased following load (24hr, 2wks), though less than in the High Load group at 2wks. There were no cancellous cellular or tissue level responses observed in the Medium Load group. Taken together, these results suggest that changes in gene expression associated with load-induced bone formation and resorption in cortical and corticocancellous bone are regulated by a load or strain threshold that may differ in magnitude between cortical and cancellous tissues.

Rearing Medaka Fish in International Space Station (ISS) for Bone Metabolism Study. Masahiro Chatani*[1], Akiko Mantoku[2], Kazuhiro Takeyama[2], Kazuhiro Aoki[3], Yasutaka Sugamori[4], Keiichi Ohya[3], Satoko Uchida[5], Hiromi Suzuki[5], Toru Sakimura[5], Yasushi Kono[6], Fumiaki Tanigaki[7], Masaki Shirakawa[7], Keiji Inohaya[8], Dawud Abduweri[4], Yoshiro Takano[4], Akira Kudo[1]. [1]Tokyo Institute of Technology, Japan, [2]Tokyo Institute of Technology, Japan, [3]Tokyo Medical & Dental University, Japan, [4]Tokyo Medical & Dental University, Japan, [5]Japan Space Forum, Japan, [6]Mitsubishi Heavy Industries, Japan, [7]Japan Aerospace Exploration Agency (JAXA), Japan, [8]Tokyo Institute of Technology, Japan

Introduction: Astronaut bone density decreases partially during space flight because of an imbalance between the activities of osteoclasts and osteoblasts. However, the molecular mechanism how these activities change in long-term space flight remains unclear. Medaka fish serve as a model for research of microgravity environment on osteoclasts and osteoblasts. In particular, we have focused on the pharyngeal bone, which is the active bone remodeling tissue.

Aim: To examine the cellular activities related to bone formation and resorption and elucidate the mechanism of decreased mineralization under microgravity.

Method: Medaka fish were rearing in the aquatic habitat for 2 months at ''Kibo'', Japanese experimental module in the ISS. To investigate the bone formation and resorption, we established the TRAP promoter-GFP/Osterix promoter-DsRed double transgenic medaka. Fish were either fixed with 4 % paraformaldehyde at day 16 and day 58, or preserved in RNAlater at day 2 and day 62. Bone mineral density (BMD) was measured by Soft X-ray and μCT. The activity of osteoclasts and osteoblasts was examined by confocal microscopy and histological analysis. The gene expression level was examined by the whole transcriptome analysis using HiSeq.

Results: Medaka fish were sometimes swimming vertically and upside down, indicating unique regulation in swimming position under microgravity. In 58 days-rearing medaka, BMD of the pharyngeal bone region was decreased, compared to 1G control (-30%; 1G control: 213.833 $\pm$ 10.095 mg/cm3 n=6, flight: 149.2 $\pm$ 18.094 mg/cm3 n=5, $p<0.0001$). In 16 days-rearing medaka, the volumes of both GFP and DsRed fluorescence area were decreased (GFP; -49%, DsRed; -68%, $p<0.05$) and the volume of osteoclasts per that of osteoblasts was elevated 1.45 folds, compared to 1G control ($p<0.05$).

Conclusion: These results show that, while osteoclasts and osteoblasts were inactive in 16 days, the ratio of osteoclasts per osteoblasts was increased, compared to 1g control, which is accompanied with the decreased BMD in 58 days. Taken together, the increased bone resorption under microgravity is similar to the low bone-metabolic rotation osteoporosis.

MO0160

Elevation of Glucose to Levels Associated with Type 1 Diabetes Profoundly Diminished Bone Cell Mechanosignaling. Zeynep Seref-Ferlengez*[1], Stephanie Maung[2], Xiaonan Wang[2], Jelena Basta-Pljakic[3], Mitchell Schaffler[4], David C. Spray[2], Sylvia O. Suadicani[2], Mia M. Thi[1]. [1]Albert Einstein College of Medicine, USA, [2]Albert Einstein College of Medicine, USA, [3]City College of New York, USA, [4]City College of New York, USA

Patients with insulin dependent diabetes mellitus (IDDM; Type 1 diabetes) manifest a range of bone problems, including increased risk for bone fractures and defective bone healing. However, the underlying mechanisms are still not well understood. Given that the maintenance of skeletal integrity in response to daily physical activity relies on the regulation of the bone forming cells, osteoblasts, and the primary load sensing cells, osteocytes, we hypothesized that bone loss in Type 1 diabetes is primarily triggered by exposure to high glucose levels which in turn compromises ability of bone cells to perceive and respond to mechanical loading as a result of altered expression of mechanosignaling mediators: specific purinergic receptor (P2Rs) and pannexin 1 (Panx1) channels. To simulate the extracellular glucose levels to which bone cells are exposed in healthy vs. diabetic bones *in vitro*, we cultured MOB-C osteoblasts and MLO-Y4 osteocytes for 10 days in medium (α-MEM) containing 1 or 4.5 g/L glucose. Changes in the expression of P2Rs and Panx1 were determined using Western Blot analysis. Cells were subjected to oscillatory fluid shear stress (OFSS; ? = $\pm$ 10 dyne/cm^2) at 1 Hz in μ-Slide VI$^{0.4}$ chambers (ibidi). We used the ratiometric Ca^{2+} indicator (Fura-2 AM) to image OFSS-induced changes in intracellular Ca^{2+} levels. ATP concentration in each flow sample was measured using the Luciferin-luciferase bioluminescence assay. Cells were also exposed to selective agonists (BzATP, UTP) to evaluate the effects of high glucose (HG) on function of each P2R subtype. The Akita mouse model of Type 1 diabetes (C57BL/6J-Ins2^{Akita}) was used in parallel to evaluate the effects of HG on bone integrity and mechanosignaling system *in situ*. Micro-CT analysis from male Akita (16-week old) and age- and sex-matched wildtype (WT) femurs revealed reduced diaphyseal cross sectional size in Akita compared to WT mice (Fig. 1A). Immunoblots of protein harvested from long bones of Akita (8-week old) and age-matched WT mice (Fig. 1B) and *in vitro* cultures indicated altered expression of P2R (specifically $P2Y_2R$, $P2Y_4R$ and $P2X_7R$) and Panx1 expression in diabetic compared to controls. Moreover, HG exposure blunted normal OFSS-induced Ca^{2+} and ATP signaling. Our findings indicate that Type 1 diabetes impairs the proper response of bone cells to mechanical loads, which is required to maintain bone health.

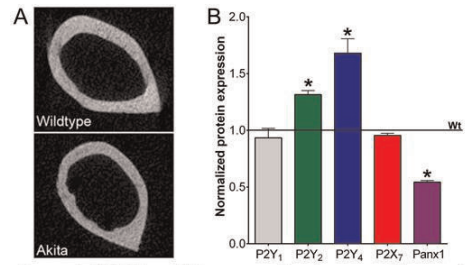

Figure 1. (A) Micro-CT cross-section images of femoral mid-diaphyseal from 16-week old Akita and age-matched wildtype control mice showing reduced diaphyseal cross sectional size in Akita mice. (B) Expression of $P2Y_1R$, $P2Y_2R$, $P2Y_4R$, $P2X_7R$ and Panx1 in long bones of Akita and age-matched wildtype mice. All data are presented as ± SEM. $*P < 0.05$.

MO0161

A Novel In Vivo Loading Model to Study Microdamage in Subchondral Bone Following Acute Knee Injury. Oran Kennedy*[1], Bryan Beutal[2], Matin Lendhey[2]. [1]New York University School of Medicine, USA, [2]Department of Orthopaedic Surgery, New York University School of Medicine, Hospital for Joint Diseases, NY, NY 10003, USA

Introduction:Acute knee injury, such as Anterior Cruciate Ligament (ACL) rupture, may result in microscopic damage in subchondral bone. ACL rupture increases the risk of post-traumatic osteoarthritis (PTOA) within 5-10 years. Whether microdamage plays a specific role in this process is unknown. The presence of microdamage is important since recent data showed that, in cortical bone, it can induce production of pro-resorptive factors in osteocytes following fatigue loading. Also, the unique microarchitecture of the subchondral region, means the spatial distribution of microdamage among Calcified Cartilage (CC), Cortical Plate (CP) and Trabecular Bone (TB) will likely be a crucial factor. If microdamage in this system stimulates an osteoclastogenic response as it does in the fatigue system, this represents a novel paradigm for subchondral bone involvement in PTOA. Here we characterize an in vivo model for ACL rupture, and quantify resultant subchondral microdamage.

Methods: We modified the standard in vivo tibial axial loading configuration to include rotational and valgus components (Fig 1A), which contribute to ACL rupture in humans. Under anesthesia, the knees of female Sprague Dawley rats (n=8, IACUC approved) were fixed at 80-85° flexion and subjected to a loading ramp (rate 0.1 mm/s) until ACL rupture. Animals were sacrificed and knee joints were harvested, with contralateral limbs as controls. Samples were imaged by MRI to confirm rupture, then fuchsin stained for histology.

Results and Discussion: Animal weight was 278.94$\pm$18.4[g] and ACL failure load was 65.8$\pm$11.4 [N] (Fig 1D) with coefficients of variation at 6.6 and 17.3[%]. MRI confirmed rupture of ACL in all tested joints, with no evidence in controls (Fig1 B,E). Microdamage was found in all subchondral compartments (Fig1 C,F) of tested joints and crack density was 6.69$\pm$3.64, 2.65$\pm$0.65 and 2.84$\pm$0.80 [#/mm^2], in CC, CP and TB, regions respectively. This suggests that microdamage in CC, which has not been well described previously, may be a significant consideration in knee injury – and in particular the biological consequences, such as PTOA.

Conclusion: We report a novel animal model for ACL rupture and subchondral bone microdamage. Damage was differentially distributed among the subchondral mineralized tissue zones. This represents a powerful new approach for examining the role of subchondral bone in PTOA following knee injury.

Interrelation between External Oscillatory Muscle Coupling Amplitude and In Vivo Intramedullary Pressure Related Bone Adaptation. Minyi Hu*[1], Jiqi Cheng[2], Neville Bethel[2], Frederick Serra-Hsu[3], Suzanne Ferreri[2], Liangjun Lin[3], Yi-Xian Qin[3]. [1]Stony Brook University, USA, [2]Stony Brook University, USA, [3]State University of New York At Stony Brook, USA

Bone interstitial fluid flow (BIFF) is suggested as a communication media that bridges external physical signals and internal cellular activities within the bone, which thus regulates bone remodeling. Intramedullary pressure (ImP) is one main regulatory factor of BIFF and bone adaptation related mechanotransduction. Our group has recently observed that dynamic hydraulic stimulation (DHS), as an external oscillatory muscle coupling, was able to induce local ImP with minimal bone strain as well as to mitigate disuse bone loss. The current study aimed to further evaluate the interrelationship between DHS's amplitude and *in vivo* ImP induction, as well as this correlation on bone's phenotypic change in conjunction with functional disuse. Simultaneous measurements of ImP and DHS cuff pressures were obtained from the experimental rats under DHS that was driven by loading voltages of 0V ~ 2.4V with a constant frequency of 2Hz. The observed responding trend of the ImP values against DHS cuff pressure amplitudes showed a linear fashion during DHS loading. The ImP reached the peak at 2.4V that was equivalent to 33.75mmHg cuff pressure (Figure 1). The interrelationship between ImP and DHS cuff pressure was evaluated and shown to be proportional, in which ImP was raised with increases of DHS cuff pressure amplitudes. In addition, 4-week *in vivo* experiment using a rat hindlimb suspension model demonstrated that the mitigation effect of DHS on disuse trabecular bone was highly related to DHS's amplitude, where a higher loading dose (30mmHg) led to a more pronounced effect than the lower loading lose (15mmHg). Animals with 15mmHg DHS showed an increase in BV/TV by 80.20% ($p<0.05$) while 30mmHg DHS showed an increase in BV/TV by 100.30% ($p<0.01$). Measures of Conn.D, Tb.N, and Tb.Sp were also significantly affected by DHS treatments with amplitude dependency. There were up to 59.41% ($p<0.05$) and 132.99% ($p<0.05$) increases for Conn.D respected to 15mmHg and 30mmHg of DHS; up to 16.61% ($p>0.05$) and 32.33% ($p<0.001$) increases for Tb.N respected to 15mmHg and 30mmHg of DHS; and up to 21% ($p<0.05$) and 30.99% ($p<0.001$) decreases for Tb.Sp respected to 15mmHg and 30mmHg of DHS (Figure 2). This study provides valuable information for DHS loading optimization, and confirms the regulatory effect of oscillatory DHS on local fluid dynamics.

Load Represses TGFβ Signaling in Bone through a CYLD and PGE2-dependent Mechanism. Jacqueline Nguyen*, Tamara Alliston. University of California, San Francisco, USA

Mechanical load induces an anabolic response in bone through a sequence of steps consisting of mechanical strain detection, signal transduction, regulation of effector cells, and finally bone formation (Duncan R.L. and Turner C.H., 1995). We demonstrated that load-induced bone formation requires intact TGFβ signaling in bone (Nguyen J. et al., 2013). DNTβRII mice, which express a dominant negative TGFβ receptor type II under the control of the osteocalcin promoter, failed to induce maximal bone formation in a hindlimb-loading model. Furthermore, we found that load represses TGFβ signaling through Smad3 in osteocytes within 5 hours after load. Although this rapid mechanosensitive repression of TGFβ signaling is essential for new bone formation, the responsible mechanisms remain elusive. To identify the most proximal steps in mechanoregulation of TGFβ signaling, we examined TGFβ ligand, receptor, and effector mRNA and protein expression in bone at 1, 3, and 5 hours after *in vivo* loading. Load inhibits TGFβ1 and TGFβ2 mRNA expression by 24% and 54% respectively at 1 hour after load ($p<0.05$; t-test). The level and phosphorylation of Smad2 and Smad3 proteins were also reduced (n=4) within 1 hour after *in vivo* loading. Likewise in MLO-Y4 cells, fluid flow shear stress rapidly represses Smad3 stability and phosphorylation. The rapid change in Smad2/3 stability led to the hypothesis that mechanosensitive regulation of TGFβ signaling requires load-dependent regulation of ubiquitin ligases that target Smads for proteosomal degradation. In the lung, the deubiquitinase CYLD induces Smad3 degradation through AKT and GSK3β (Lim JH et al., 2012). We find that CYLD protein expression is induced (2.5 fold; n=3) in cortical bone within 1h of hindlimb loading. Furthermore, CYLD siRNA stabilizes Smad3 protein in MLO-Y4 osteocytes. Using chemical inhibitors of other pathways known to respond rapidly to load, we found that load-induced prostaglandin signaling regulates Smad2 phosphorylation, possibly through a CYLD-dependent mechanism. These studies identify CYLD as a novel mechanosensitive protein and, in particular, a novel pathway in load-mediated regulation of TGFβ and Smad3 signaling in bone. Since CYLD regulates molecular pathways involved in load-induced bone formation, understanding the role of CYLD in bone could yield novel drug targets for low bone mass diseases.

Numerical Characteristics of Overloaded Vertebra L_1. Oleg Ardatov[1], Vidmantas Alekna*[2], Algirdas Maknickas[3], Marija Tamulaitiene[2], Rimantas Kacianauskas[3]. [1]Department of Biomechanics, Vilnius Gediminas Technical University, Lithuania, [2]Faculty of Medicine, Vilnius University, Lithuania, [3]Institute of Mechanics, Vilnius Gediminas Technical University, Lithuania

Aim: Osteoporosis impacts the micro-architectural structure of bone tissue and increases fracture risk. Although osteoporosis affects the entire skeleton, many fragility fractures occur in the lumbar spine. Vertebral fractures in particular result in a high mortality rate. The present study is aimed to investigate the influence of osteoporosis on the mechanical behavior of the vertebra L_1.

Methods: The three-dimensional continuum boundary value problem was formulated and a finite element model (FEM) of L_1 lumbar vertebra was applied. Model was meshed with volume finite elements. The inhomogeneous model consists of two basic parts – cancellous bone and outer cortical shell with anatomical geometry. Impact of osteoporosis on cortical and cancellous bone was modeled by varying transversal elasticity modulus. Cancellous bone and cortical shell are modelled transversally isotropic. Also, two isotropic inter-vertebral disks were modeled on purpose to simulate distributed external load on the boundaries. The value of bending moment was in the range from 3 to 15 Nm. This model was validated according to experimental results of research of healthy lumbar vertebrae.

Results: Model was tested under bending load on both frontal and sagittal planes.A yield stress criterion is chosen to predict the risk of failure of the model. The risk of failure is evaluated according to von Mises stress. It was found, that the critical load for normal bone is 25% higher than for the high degree of osteoporosis (HDO) model and 13% higher for average degree of osteoporosis (ADO) model during forward bending. The highest values of von Mises stress occurred during lateral bending. The critical load for healthy bone is 26% higher than for the ADO model and approximately 60% higher than for HDO model.

Conclusions: Obtained numerical results show large dependence between stress and state of physical properties of cancellous bone. Numerical comparison of frontal and lateral bending showed that during lateral bending stress values in osteoporotic cortical shell are twice greater than in normal cortical shell.

Spontaneous Activity from Access to Running Wheels Stimulates Bone Gain at Multiple Sites in Mice. Robert Brommage*[1], Sabrina Jeter-Jones[2], Andrea Thompson[3], Jeff Liu[3]. [1]Lexicon Pharmaceuticals, USA, [2]Lexicon Pharmaceuticals, USA, [3]Lexicon Pharmaceuticals, USA

Resetting the bone mechanostat in rodents by increasing mechanical forces typically involves forced treadmill exercise or defined cycles of limb compression. Although these procedures are highly successful, they do not perfectly mimic forces acting on bone during normal activity and are usually employed during the daily sleep phase. Rodents voluntarily run several km each day when given access to running wheels and this physiological exercise regimen stimulates bone formation.

Male C57BL/6J-129SvEv hybrid mice were singly housed with (N = 10) or without (N = 8) running wheels (23 cm diameter, MiniMitter system) from 4 through 18 weeks of age. For 5 of 10 running mice, wheel weight was increased by 26% (with a greater increment in moment of inertia) to increase the work required per revolution. Running wheel revolutions were recorded each minute and summed in two hour increments throughout the study. Bone architecture was determined by standard microCT techniques using a Scanco μCT40. Statistical significance was defined as $P < 0.01$.

Mice ran an average of 4.0 (SD = 1.3) km daily with most running occurring nocturnally. There was no effect of running wheel weight on bone parameters and data for these two groups were combined. Femoral length was identical in running and non-running mice.

Running produced a cancellous bone anabolic response in both spine LV5 and distal femur metaphysis, with increases in trabecular bone BV/TV (24% spine, 21% femur) and thickness, but not trabecular number.

The femur responded to running with elevated bone areas in the femoral neck (17%), proximal shaft at the third trochanter (9%) and midshaft (20%). Total areas (diameter) were higher at both femoral shaft sites (10%, 16%) with an elevated cortical thickness (7%) at the midshaft. The tibia midshaft, tibia-fibula junction and distal shaft responded to running with elevated total (19%, 17%, 11%) and bone (20%, 17%, 10%) areas and greater cortical thickness (10%, 7%, 4%). There was no evidence of endocortical bone formation, as marrow cavity areas were consistently elevated and statistical significance achieved for midshaft femur (15%), midshaft tibia (18%) and the tibia-fibula junction (19%).

These results show a consistent beneficial effect of physiological running exercise on bone mass at every site examined, including both cancellous and cortical bone. The cortcal bone respose primarily involved periosteal formation. There was no major effect of running wheel weight.

Using Novel 3D Bone Mimicking Scaffolds to Investigate Tumor-Induced Bone Disease. Ushashi Dadwal*[1], Jonathan Page[2], Alyssa Merkel[3], Michael Kessler[4], Julie Sterling[5], Scott Guelcher[6]. [1]Vanderbilt Center for Bone Biology, Vanderbilt University Medical Center, USA, [2]Department of Chemical & Biomolecular Engineering, Vanderbilt University, USA, [3]Department of Veterans Affairs (TVHS), USA, [4]School for Math & Science, Vanderbilt University, USA, [5]Department of Veterans Affairs (TVHS)/Vanderbilt University Medical Center, USA, [6]Vanderbilt University, USA

Tumor Induced Bone Disease (TIBD) is common in patients with advanced metastatic disease originating from primary breast, prostrate and lung cancer. While many studies have elucidated multiple mechanisms that influence TIBD, most have focused on the interactions between the tumor cells and bone cells (osteoclasts and osteoblasts). Recent studies from our group and others have begun to investigate other facets of the bone microenvironment and demonstrate that both the bone marrow cells and the physical rigidity of bone can influence tumor cell behavior, gene expression, and bone destruction. The majority of these studies have relied on 2D culture, which while valuable, limits our ability to recapitulate complex interactions between multiple cells and physical properties of the bone microenvironment. Therefore we have developed a novel 3D bone mimicking model using polyurethane scaffolds (PURS).

Since our previous 2D data demonstrated that matrix rigidity regulated the expression of genes important in TIBD (TGF-βRII, PTHrP, Integrin β3 and Gli2) in the bone metastatic breast (MDA-MB-231) and lung (RWGT2) cells, we first examined the effect of rigidity in 3D on gene expression. 3D scaffolds were made by printing an inverse mold using a 3D printer (MakerBot). Liquid PUR was then cast into the mold and compressed. The resulting 3D PUR scaffolds have a defined interconnected architecture (Fig. 1a&b) with rigidity ranging from Rigid (2600 MPa: trabecular bone) to Complaint (10 MPa: basement membrane) as determine by nanoindentation (Agilent, g200 nanoindentor).

3D scaffolds were seeded with tumor cells both in vitro (Fig.1c&d) and in vivo. A live cell imaging system was used to track migration of individual cells on rigid and compliant scaffolds to demonstrate tumor cells migrate faster on rigid scaffolds as compared to compliant scaffolds (Fig1e). In vitro data from a bioreactor (3D Biotek) which mimics dynamic cellular environment using physiologically relevant flow rate (2.1 rpm) shows increased expression of PTHrP in rigid vs. compliant scaffolds (Fig.1f) Additionally, In vivo studies were conducted with tumor cells seeded scaffolds implanted into the mammary fat pads of athymic mice. Scaffolds were explanted after 21 days and analyzed for PTHrP expression using RT PCR and histomorphometry (Fig.1h) Thus, we successfully demonstrate 3D PUR scaffolds can be used to analyze the osteolytic potential of tumor cells during TIBD.

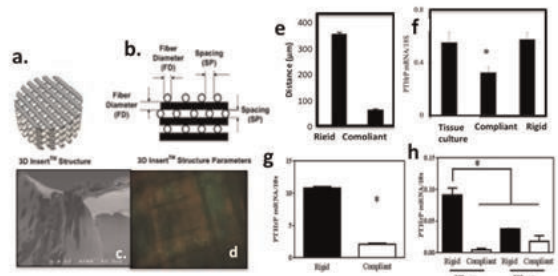

Fig. 1 3D PUR scaffolds have a defined architecture **a.** with interconnected pores and **b.** modifiable Fiber Diameter and Spacing. MDA MB 231 GFP tumor cells were seeded in 3D PUR scaffolds as seen by **c.** SEM imaging that shows cells adhere to the scaffolds and **d.** in vitro using fluorescence imaging seeded inside the scaffolds. **e.** MDA 231 MB cells seeded on rigid scaffolds migrated significantly faster than tumor cells on the compliant scaffolds as determined by live cell imaging. Osteolytic gene expression (PTHrP) measured by RT PCR demonstrates tumor cells have increased expression of PTHrP on rigid scaffolds vs. compliant scaffolds in **f.** static culture as well as **g.** dynamic culture using a perfusion based bioreactor with 2.1 rpm. **h.** In vivo, 10^6 tumor cells were seeded into the scaffolds that were transplanted into mammary fat pads of athymic mice. PTHrP expression is increased on rigid scaffolds.

Bone Regeneration in a Rat Model of Type 2 Diabetes and Aging is Improved by PTHrP Loaded in a Biopolymer-coated Hydroxyapatite. Juan Antonio Ardura*[1], Sergio Portal-Nuñez[1], Irene Gutierrez-Rojas[1], Daniel Lozano[2], Ana Lopez-Herradon[1], Francisca Mulero[3], Maria Vallet-Regi[4], Pedro Esbrit[5]. [1]Instituto de Investigación Sanitaria-Fundación Jiménez Díaz, Spain, [2]Instituto de Investigación Sanitaria-Fundación Jiménez Díaz, Spain, [3]Centro Nacional de Investigaciones Oncológicas (CNIO), Spain, [4]Universidad Complutense de Madrid, Spain, [5]IIS-Fundación Jiménez Díaz, Spain

Type 2 diabetes, which predominates in older individuals, is associated to an increase in fracture risk. The N-(1-37) and C-terminal (107-111) epitopes of parathyroid hormone-related protein (PTHrP) exhibit osteogenic properties. Biopolymer-coated nanocrystalline hydroxyapatite (HA) made as macroporous foams are promising candidates as scaffolds for bone tissue engineering applications. The main aim of this study was to evaluate whether PTHrP (1-37) or (107-111) loading into gelatin-glutaraldehyde biopolymer-coated HA (HAGlu) scaffolds improve bone regeneration in a model of aging and type 2 diabetes.

Type 2 diabetes was induced in male rats by a single dose of streptozotocin intraperitoneally administered on the day of birth. At the age of 18-20 months, those rats showing a glucose disappearance constant below 2.5 x 10^{-2}/minute during a glucose tolerance test were selected. A cavitary defect was performed in both distal tibial metaphysis of diabetic or control aged rats and HAGlu scaffolds with and without PTHrP (1-37) or (107-111) were implanted into the cavitary defects. Animals were sacrificed after 4 weeks and femurs and tibiae were extracted for µ-computerized tomography and histomorphometry analysis.

Femurs from diabetic aged rats showed decreased bone volume/tissue volume (BV/TV) and trabecular thickness and increased trabecular separation compared to control aged rats. No differences in trabecular number and body weight were observed between groups. Four weeks after performing the surgery, the cavitary defect in tibiae of diabetic aged rats presented decreased bone regeneration compared to control aged rats as shown by decreased BV/TV and increased trabecular separation and bone surface/bone volume (BS/BV).In contrast, the bone defect was healed in the presence of PTHrP (1-37) and PTHrP (107-111)-containing HAGlu implant in both diabetic and control rats aged, related to an increase of cortical and trabecular BV/TV, bone thickness and decreased trabecular separation and BS/BV compared to unloaded HAGlu implants.

Our findings suggest the suitability of PTHrP (1-37) and (107-111) loaded into HAGlu scaffolds to produce promising biomaterials as implants in fractures in older adults with type 2 diabetes.

MO0168

Improving Parathyroid Hormone (PTH) Therapy In An Osteoporotic Mouse Model. Joseph Bidwell[1], Paul Childress*[2], Yu Shao[3], Selene Hernandez-Buquer[2], Yongzheng He[2], Daniel Horan[2], Alexander Robling[4], Stuart Warden[5], Feng-Chun Yang[4], Matthew Allen[1]. [1]Indiana University School of Medicine, USA, [2]Indiana University School of Medicine, USA, [3]Indiana University School of Medicine, USA, [4]Indiana University, USA, [5]Indiana University School of Health & Rehabilitation Sciences, USA

Nmp4/*CIZ* (*Nmp4*)-knockout (KO) mice have a normal skeletal phenotype but show an exaggerated response to anabolic parathyroid hormone (PTH). Despite unremarkable bone marrow (BM) and peripheral blood (PB) profiles, KO mice have elevated numbers of BM osteoprogenitors (CFU-F[Alk Phos+] and CD45-/CD105+/CD146+/nestin+ cells), BM CD8+ T cells, and a modest increase in CFU-GM cells, all of which drive PTH-induced bone anabolism. We asked whether the cellular profile and PTH-responsiveness persisted in an osteoporosis model. Wild type (WT) and KO mice were ovariectomized (ovx) at 12wks of age 4wks before therapy initiation (16wks-old, hPTH[1-34] 1µg/kg/day or vehicle). Endpoint parameters were obtained after 4wks (20wks-old) and/or 8wks (24wks-old) of treatment. MicroCT profiles included femoral bone volume/total volume (BV/TV) and connectivity density (Conn D). FACs was employed to obtain BM and/or PB profiles of osteoprogenitors, CD8+ and CD4+ T cells. Histomorphometry for mineralization apposition rate (MAR), mineralizing surface (MS/BS), and bone formation rate (BFR) were evaluated after 4wks of therapy. We employed a two-factor ANOVA for analyses using genotype and treatment as independent variables followed by a Tukey HSD post hoc test. The ovx WT and KO mice showed equivalent bone loss 4wks post-op as we previously reported. The KO mice exhibited a significantly enhanced PTH-induced gain in BV/TV and Conn D at the end of 4wks and 8wks therapies. There was no difference in these parameters between the vehicle-treated genotypes. PTH equally increased WT and KO MAR and BFR after 4wks therapy. The ovx KO mice had an elevated number of BM osteoprogenitors at the end of 4wks therapy but not at 8wks. The ovx null mice had augmented numbers of BM and PB CD8+ T cells compared to WT mice throughout treatment. The CD4+ T cells profiles were similar in both genotypes. PTH had no influence on the T cells with the exception of equally decreasing the number of WT and KO BM CD8+ T cells at 8wks. We conclude that the enhanced PTH response in *Nmp4*-KO mice persists with ovx perhaps sustained by the elevated numbers of osteoprogenitors and CD8+ T cells. This confirms that Nmp4 provides a novel therapeutic target for osteoporosis.

MO0169

Inactivation of Tgfbr2 in osteoclasts causes osteopenia due to impaired coupling of bone formation to bone-resorption. Megan Weivoda*[1], Ming Ruan[2], Christine Hachfeld[2], Larry Pederson[2], Rachel Davey[3], Jeffrey Zajac[4], Jennifer Westendorf[1], Sundeep Khosla[5], Merry Jo Oursler[1]. [1]Mayo Clinic, USA, [2]Mayo Clinic, USA, [3]University of Melbourne, Australia, [4]Austin Hospital, Australia, [5]Mayo Clinic College of Medicine, USA

In the adult skeleton, osteoclast-mediated bone resorption is coupled to osteoblast-mediated bone formation to maintain skeletal mass. While the pathways by which osteoblasts regulate osteoclast differentiation and activity are well established, the mechanisms by which osteoclasts recruit osteoblasts to sites of bone resorption remain unresolved. TGF-ß1 is enriched in the bone microenvironment and is released from the bone matrix during bone resorption. We recently reported that osteoclasts treated with TGF-β1 secrete factors that promote osteoblast migration and mineralization. Using a genetic mouse model, we tested the hypothesis that disrupting TGF-β receptor (Tgfbr) signaling in mature osteoclasts would impair the coupling of bone formation to bone resorption. Transgenic Ctsk promoter Cre mice were utilized to generate animals expressing dominant negative Tgfbr2 specifically in osteoclasts ($Tgfbr2^{OclKO}$). Inactivation of Tgfbr signaling in osteoclasts led to significant reductions in bone mineral density in the spine and femur at 20 weeks of age. Mice were sacrificed at 22 weeks; *ex vivo* microCT analysis showed a significant decrease in bone volume per total volume and trabecular number, with an increase in trabecular spacing in $Tgfbr2^{OclKO}$ femurs. Histomorphometric analysis revealed no change in osteoclast number with inactivation of osteoclast Tgfbr signaling, and serum TRAP levels were unaltered. Of interest, osteoblast numbers were significantly reduced in $Tgfbr2^{OclKO}$ mice. $Tgfbr2^{OclKO}$ mice exhibited significantly decreased bone formation rate (BFR), and a significant decrease in serum P1NP. Mineral apposition rate was unchanged, indicating that the reduced BFR in $Tgfbr2^{OclKO}$ mice is due to reduced osteoblast number, rather than altered osteoblast function. Wnt1 is crucial to normal skeletal development. TGF-ß1 caused a 100-fold increase in osteoclast Wnt1 expression *in vitro*. Immunohistochemistry for Wnt1 showed a significant reduction in osteoclast membrane Wnt1 in $Tgfbr2^{OclKO}$ femurs. These data show that impaired Tgfbr signaling in osteoclasts causes osteopenia by reducing osteoblast numbers and establish a novel paradigm in which TGF-ß stimulated osteoclasts are a key source of factors, such as Wnt1, that promote osteoblastic bone formation at sites of bone resorption.

MO0170

Intermittent PTH after Prolonged Bisphosphonate Treatment Improves Trabecular Bone Microarchitecture and Alleviates Bone Tissue Hypermineralization by Inducing Substantial New Bone Formation. Allison Altman*[1], Carina Lott[2], Wei-Ju Tseng[2], Chantal De Bakker[1], Sy-Dar Liou[2], Tiao Lin[1], Ling Qin[1], Xiaowei Liu[1]. [1]University of Pennsylvania, USA, [2]University of Pennsylvania, USA

Postmenopausal osteoporosis is often treated with bisphosphonates (BP), such as alendronate (ALN). However, long-term BP therapy may lead to hypermineralized bone tissue and atypical femoral fractures. Intermittent parathyroid hormone (PTH) therapy promotes bone formation and reduces tissue mineral density (TMD). We hypothesized that switching from ALN to PTH would improve trabecular bone microstructure and alleviate high TMD.

18 6-mo-old ovariectomized (OVX) rats (OVX at 4 mo-old) were assigned to 3 groups (n=6/group). The Veh+PTH group was treated with saline from wk 0 to 12 and then switched to PTH (40 µg/kg 5x/wk) from wk 12 to 16. The ALN group was treated with ALN (28 µg/kg 2x/wk) throughout wk 0 to 16. The ALN+PTH group received ALN for 12 wks followed by PTH for 4 wks. The right proximal tibia of each rat was scanned by *in vivo* µCT (VivaCT40, 10.5µm) to track changes in trabecular bone over time (Fig 1).

Bone volume fraction (BV/TV) was 0.13 $\pm$ 0.03 at wk 0 across all groups. From wk 0 to wk 12, the BV/TV decreased by 57% ($p < 0.001$) in Veh-treated rats. No bone was lost in ALN-treated rats. From wk 12 to 16, BV/TV increased 40% in the Veh+PTH group, 42% in the ALN+PTH group, and did not change in the ALN group ($p < 0.001$). The increase in BV/TV was accompanied by an increase in trabecular thickness (Tb.Th, 33% Veh+PTH and 25% ALN+PTH, $p < 0.001$). Structure model index (SMI) decreased by 10% and trabecular number (Tb.N) increased by 5% in the ALN+PTH group, indicating more plate-like trabeculae. In contrast, Veh+PTH had no change in SMI or Tb.N from wk 12 to 16. µCT-based *in vivo* dynamic histomorphometry showed a 4-fold increase in bone formation rate in the Veh+PTH group and 3-fold in the ALN+PTH group after 2 wks of PTH treatment. Serum osteocalcin in the Veh+PTH and ALN+PTH groups were 155% and 132% greater than the ALN group.

Left tibia (Tib) and lumbar vertebra L2 were scanned by ex vivo µCT (Tib-6µm, L2-3.5µm). TMD at the trabecular surface was lower in the ALN+PTH group than in the ALN group at both sites (4% $p = 0.07$, and 3% $p < 0.001$).

Our results suggest that intermittent PTH substantially stimulates new bone formation regardless of inhibited osteoclast resorption activities by prior treatment with BP. Pre-treatment with ALN may improve the skeletal response to PTH by promoting plate-like trabeculae. Moreover, switching to PTH after prolonged ALN treatment helped to alleviate hypermineralization of trabecular bone tissue.

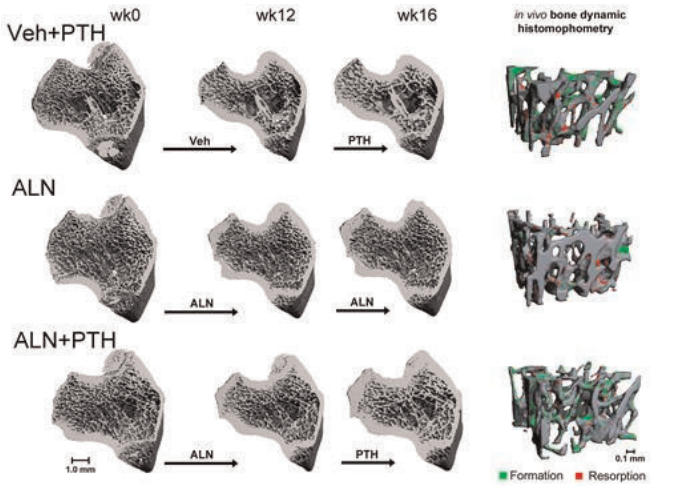

Fig 1. Left: Registered comparison of tibia bone segments at each timepoint with treatment indicated by the arrows between time-points. Right: μCT-based *in vivo* bone dynamic histomorphometry, green indicates areas of new bone (formation), and red indicates lost bone (resorption).

Osteolineage Jagged1 maintains bone homeostasis by regulating osteoblast and osteoclast. Rialnat Lawal*[1], Mary Georger[2], Alexandra Goodman[2], Laura Calvi[3]. [1]University of Rochester Medical Center, USA, [2]University of Rochester, USA, [3]University of Rochester School of Medicine, USA

Notch signaling maintains the progenitor compartment of both osteoblasts and osteoclasts, however a critical Notch ligand in osteoblastic cells is unknown.The Notch ligand Jag 1 is present in osteoblastic cells, where its expression peaks coincidentally with osteocalcin.To determine if osteolineage Jag1 is the critical ligand maintaining the balance of osteoprogenitors and mature bone cells, we examined mice with osteolineage Jag1 deletion (Prx1-cre;Jag1fl/fl: PJ1ko mice). In 2 week old PJ1ko and wildtype (wt) mice there were no skeletal differences by μCT, indicating that osteolineage Jag1 is not required for bone modeling.We next examined 2 month old mice, where lack of osteolineage Jag 1 increased trabecular bone, trabecular number and trabecular thickness by μCT (BV/TV:0.3633 ± 0.03165 N=5 vs. 0.4996 ± 0.04582 N=5 Wt.vs.KO p=0.0400). Quantification of osteoprogenitors by colony forming unit osteoblast (CFU-OB) assay in limiting dilution demonstrated a significant decrease in CFU-OB in PJ1ko mice compared to wt. Conversely, the mature osteoblast pool was increased, as shown by increased osteocalcin+ cells by IHC and increased osteocalcin expression by qRT-PCR in osteoblastic cells (1.011 ± 0.1904 N=9 vs. 1.786 ± 0.2314 N=7 Wt.vs.KO p=0.0206). Since an increase in BV/TV could also be due to decreased osteoclastic cell numbers and/or function, we examined bone resorption and found that marrow CTX was increased significantly in PJ1ko compared to wt (0.7168 ± 0.1034 N=6 vs. 1.514 ± 0.1851 N=5 Wt. vs. KO p=0.0034), while TRAP+ staining multinucleated cells in the metaphyseal region were not increased, suggesting that Jag1 regulates osteoclast function. These data indicate that during peak bone formation Jag1 is a critical Notch ligand, which maintains trabecular bone volume by restricting osteoblastic differentiation, preserving progenitor pools and limiting excess osteoclast function. Since in mice lacking osteolineage Notch signaling the initial bone was succeeded by significant bone loss at 6 mons, we examined PJ1ko and wt at 6-8 mons and found no significant changes in trabecular bone mass. Therefore, loss of Jag1 increases trabecular bone during active skeletal remodeling by enhancing the differentiation of osteoblasts in spite of increased osteoclastic function without age-dependent bone loss by 6-8 mons. These observations may provide a Notch ligand-specific therapeutic strategy for achieving increased bone mass without adverse bone loss.

Sost Antibody Treatment Improves Fracture Healing in Type 1 Diabetes. Cristal Yee*[1], Liqin Xie[2], Deepa Murugesh[3], Sarah Hatsell[4], Aris Economides[5], Gabriela Loots[6], Nicole Collette[7]. [1]University of California, Merced, USA, [2]Regeneron Pharmaceutical company, USA, [3]Lawrence Livermore National Laboratory, USA, [4]Regeneron Pharmaceuticals, USA, [5]Regeneron Pharmaceuticals, Inc., USA, [6]Lawrence Livermore National Laboratory, UC Merced, USA, [7]Lawrence Livermore National Laboratory, USA

Type 1 diabetes mellitus (T1DM) patients suffer from low bone mass, increased fracture risk, and impaired fracture healing due to reduced osteoblast activity. Available treatments can improve bone mineral density (BMD) in T1DM, however, no treatment can adequately restore the fracture healing phenotype. Since over 8% of the US population suffers from T1DM, a great need exists to explore new opportunities to treat orthopedic complications. Sclerostin (*Sost*), a Wnt antagonist, is secreted by osteocytes and inhibits bone formation. *Sost* knockout mice (*Sost KO*) have 3X higher BMD than normal and enhanced fracture healing due to increased Wnt signaling. Hematoxylin and Eosin (H&E) stained paraffin sections of STZ treated *Sost KO* calluses at 21 days post fracture showed enhanced bony bridging compared to *WT* (C57Bl6/J) and *STZ* calluses, confirming the likely positive effects of SostAb treatment in T1DM fracture healing. We hypothesized that elevated Wnt signaling imparted *via* pharmacologic inhibition of Sost with a blocking anti-Sost antibody (SostAb) can improve repair of difficult fractures in Streptozotocin (STZ)-induced T1DM mice. Mid-femoral fractures were generated in a closed Einhorn model and SostAb (25 mg/kg) was administered twice weekly up to 21 days post-fracture (*sham control, STZ*, *sham*+SostAb, and *STZ*+SostAb groups). MicroCT analysis at 21 days post fracture showed *STZ* calluses had a significant ~50% decrease in total volume (p-value 0.0155) in comparison to *sham control,* consistent with delayed healing. Histologically, there was less bridging and woven bone in *STZ* compared to *sham control* calluses, suggesting that *STZ* calluses are smaller with less mineralized bone, similar to published reports of poor osteogenesis. Bone volume/total volume ratios at 21 days post fracture showed that *STZ*+SostAb calluses had significantly increased mineralized bone relative to both *sham control* and *STZ* groups (p-value < 0.0008), suggesting that SostAb treatment is able to rescue the reduced osteogenesis caused by T1DM through a mechanism different from glucose regulation. Further analysis at 42 days post-fracture will determine the long term effects of SostAb on diabetic fractures. Our results suggest that SostAb may potentially help heal problematic fractures associated with T1DM.

The P2X7 Antagonist AFC-5261 rescues Ovariectomy-induced Bone Loss in Mice. Susanne Syberg*[1], Ankita Agrawal[2], Solveig Petersen[3], Jens-Erik Beck Jensen[4], Peter Schwarz[5], Alison Gartland[6], Michael Bös[7], Niklas Jorgensen[8]. [1]Research Centre for Ageing & Osteoporosis, Denmark, [2]The Mellanby Centre for Bone Research, The University of Sheffield, United Kingdom, [3]Research Centre for Ageing & Osteoporosis, Departments of Diagnostics & Medicine, Copenhagen University Hospital Glostrup, Denmark, [4]Department of Endocrinology, Copenhagen University Hospital Hvidovre, Denmark, [5]Glostrup Hospital, Denmark, [6]The Mellanby Centre for Bone Research, The University of Sheffield, United Kingdom, [7]Affectis Pharmaceuticals AG, Fraunhoferstrasse 13, Germany, [8]Copenhagen University Hospital Glostrup, Denmark

The regulatory role of the purinergic receptor P2X7 in bone metabolism is well known, but the effects in bone of pharmacologic modification of P2X7 receptor function in animal models has not yet been reported. Aim: To investigate the influence of a P2X7 receptor antagonist, AFC-5261 (N-[4-Chloro-1-(2-hydroxyethyl)-1H-indol-3-yl]-2-cyclohexylacetamide) on bone cell function and its therapeutic potential in a murine model for osteoporosis (ovariectomy (OVX)-induced bone loss). Method: Primary osteoblasts and osteoclasts were isolated from mice, rat and humans and cultured with AFC-5261 for determination of gene expression of osteoblast markers, ability to produce mineralized bone matrix (AR-S) or perform resorption pits on dentine discs. To evaluate the effect of AFC-5261 in the murine OVX model we measured bone strength, analyzed serum bone markers and performed DXA on female BALB/cJ mice either OVXed or sham-operated. The OVXed animals were treated twice daily with vehicle (PEG) or AFC-5261 (400 mg/kg/day) for four weeks.

Results: *In vitro*, the bone formative activity of the individual osteoblast was stimulated by AFC-5261 in all three species. murine osteoblasts deposited mineralized matrix corresponding to 477.8 nmol Ca^{2+}/well when treated with AFC-5261 (125 nM) compared to 272.1 nmol Ca^{2+}/well in control cultures (p=0.002). AFC-5261 (500 nM) increased gene expression of Runx2 (2.7 fold, p<0.001), ALP (1.7 fold, p=0.004), collagen (2.2 fold, p=0.005) and OPG up to 4.0 fold (p<0.001) in trabecular derived human osteoblastic cells. In opposite, RANKL expression was decreased to a third of the level in control cultures (p=0.022). In murine osteoclast cultures AFC-5261 (400 nM) reduced the area resorbed with 58.5 % (p<0.001), without affecting the number of osteoclasts. *In vivo* BMD increased in the group treated with AFC-5261 to 0.0513 from 0.0488 g/cm^2 (p=0.016) and bone strength was increased at femoral neck from 12.6 to 19.4 N (p<0.001), but not at femoral midshaft (from 22.3 to 22.2 N, p=0.359). AFC-5261 induced bone formation as an increase was seen in both ALP (from 77.7 to 110.0 nmol/ml, p<0.001) and P1NP (from 1.18 to 2.32 ng/ml, p<0.001), while bone resorption (CTX-I) was reduced (from 21.9 to 14.9 ng/ml, p<0.001). Conclusion: AFC-5261 was shown anabolic and anti-resorptive both *in vitro* and *in vivo*. Further studies are necessary in order to determine the potential effects of AFC-5261 on the regulation of human bone metabolism.

The Sirtuin1 Activator SRT3025 Down-regulates Sclerostin in Vivo and in Vitro and rescues OVX-induced bone loss and biomechanical deterioration in mice. Hanna Artsi[1], Einav Cohen-Kfir[2], Irina Gurt[1], Yankel Gabet[3], Ron Shahar[4], Teresita Bellido[5], Rivka Dresner-Pollak*[6]. [1]Hadassah-Hebrew University Medical Center, Israel, [2]HEBREW UNIVERSITY Medicine Faculty, Israel, [3]Department of Anatomy & AnthropologySackler Faculty of Medicine, Israel, [4]The Hebrew University, Israel, [5]Indiana University School of Medicine, USA, [6]Hadassah-Hebrew University Medical Center, Israel

Estrogen deficiency leads to rapid bone loss and skeletal fragility. Sclerostin, encoded by the *sost* gene, is a negative regulator of bone formation, and blocking its action increases bone mass and strength in animals and humans. Sirtuin1 (Sirt1), a major player in aging and metabolism, regulates bone mass and was shown by us to inhibit *sost* gene expression by deacetylating histone 3 at its promoter (*Endocrinology; 152:4514-4524, 2011)*. These findings prompted us to ask if activation of Sirt1 by a synthetic Sirt1-activating compounds (STAC), previously shown to be allosteric activator of Sirt1, can down-regulate sclerostin and reverse ovariectomy (OVX)-induced bone loss and biomechanical deterioration.

Nine-week-old C57BL/6 female mice underwent OVX or SHAM operation and were left untreated for 6 weeks to allow bone loss. SRT3025 at 50,100 mg/kg/day or a vehicle was administered daily by gavage to OVX mice for 6 weeks. Upon sacrifice L4 and one femur were analyzed by microCT, and the 3 point bending test was conducted in the other femur. Trabecular and cortical bone histomorphometry analyses were conducted. Bone markers were determined in serum 1, 6, 9 weeks post OVX. Protein was isolated from whole tibiae extracts. Serum drug levels and uterine weight were determined.

Ovariectomy induced a a rapid bone loss accompanied by a substantial decrease in tibial Sirt1 protein level accompanied by increased sclerostin. SRT3025 administration fully reversed the deleterious effects of ovariectomy on vertebral bone mass, micro-architecture and femoral biomechanical properties-stiffness and the material's Young's modulus of elasticity. Treatment with SRT3025 decreased tibial sclerostin expression and increased femoral cortical periosteal mineralizing surfaces as well as serum P1NP but not CTX, allowing for an anabolic window. In MLO-Y4 osteocyte-like cells SRT3025 down-regulated sclerostin and inactive beta-catenin while a reciprocal effect was observed with EX-527, a Sirt1 inhibitor.

Sirt1 activation by a sirtuin1 activating compound is a potential novel pathway to down-regulate sclerostin and design anabolic therapies for osteoporosis concurrently ameliorating other metabolic and age-associated conditions.

Effect of Green Tea on Socket Repair of Rats Treated with Bisphosphonates. Mariza Matsumoto*[1], Alana Santos[2], Angelica Fonseca[2], Roberto Kawakami[2], Edson Mada[2], Fernando Neves[2], Patrícia Saraiva[2]. [1]Sagrado Coração University, Brazil, [2]Sagrado Coração University, Brazil

A number of systemic disturbances can lead to bone remodeling imbalance demanding treatment with drugs such as bisphosphonates (BP). Due to the popularity of green tea because of its anti-oxidant activity and also on bone tissue, the aim of this study was to evaluate its effects in association with a nitrogenate BP on socket healing repair. Sixty male albinus Wistar rats were divided into 3 groups, according to the treatment: Group C – Control, animals treated with endovenous (EV) 0.9% saline solution, Group GT – treated with 1% green tea in drinking water, Group BP – treated with EV zoledronic acid, and Group BP + GT – treated with EV zoledronic acid and 1% green tea. It was administered 0.035mg/Kg of the drug, every two weeks. After six weeks of the beginning of the BP administration, right upper molars were extracted, and the green tea started to be offered for Groups GT and BP+GT. After 7, 14, and 28 days the animals were euthanized and the maxillas removed for histological analysis. No significant differences were observed among the groups at day 7 when the extraction site was still exposed, with any mucosal coverage. At day 14, while Group C presented granulation tissue inside the sockets, the other groups presented non-viable bone tissue still exposed, covered by a thick layer of bacterial biofilm. At day 28, Group C the extraction site was predominantly covered by the mucosa and primary bone could be seen inside the sockets around a focus of granulation tissue. Specimens from Group GT still presented exposed sockets, covered by biofilm; however, osteoblastic activity resulting in primary bone formation could be seen in the third apical of the socket and granulation tissue in the middle third. Groups BP and BP + GT were very similar, showing thick biofilm covering and invading non viable bone tissue, which was still exposed, associated with neutrophilic infiltrate. An epithelial bridge could be seen under the infected bone fragment coming from the adjacent mucosa. The newly formed bone in deep regions was marked by strong basophilic reversal lines, and evident osteocytes lacunae. Eventual osteoclastic activity was observed when using the BP. From the microscopic morphological results, the association of the green tea had no beneficial effects on socket healing in rats under BP administration.

Effects of Risedronate, Alendronate and Minodronate in Combination with Eldecalcitol in Ovariectomized rats. Hirotaka Wagatsuma*[1], Tetsuo Yano[2], Mei Yamada[2], Daisuke Inoue[3]. [1]Ajinomoto Pharmaceuticals Co., Ltd., Japan, [2]Ajinomoto Pharmaceuticals Co., LTD, Japan, [3]Teikyo University Chiba Medical Center, Japan

Background/Aim: Eldecalcitol (ELD) is a derivative of calcitriol with antiresorptive activity. Although evidence suggests that combined treatment with active vitamin D3 and some bisphosphonates (BPs) is clinically beneficial, combination therapy with ELD and BP has not been validated in the clinical setting. Preclinical studies have shown that simultaneous treatment with ELD and BP is more effective in increasing bone mineral density (BMD) and bone strength than monotherapy. However, relative potency of various BPs, when used in combination with ELD, remains unknown. In this study, we examined effects of treatment with risedronate (RIS), alendronate (ALN) and minodronate (MIN) in combination with ELD on bone mass, microarchitecture and strength in ovariectomized (OVX) rats.

Methods: Female Sprague Dawley rats at 13 weeks old were divided into one sham-operated and eight OVX groups (1: vehicle, 2: RIS, 3: ALN, 4: MIN, 5: ELD, 6: RIS+ELD, 7: ALN+ELD, 8: MIN+ELD). RIS (0.07 μg/kg s.c.), ALN (0.14 μg/kg s.c.), MIN (0.014 μg/kg s.c.) and ELD (0.004 μg/kg p.o.) were given 5 times per week for 16 weeks. Then BMD and bone architecture of the 4th lumbar vertebrae (L4) and the femur were measured by micro-CT, and bone mechanical strength was evaluated by three-point bending of the femur and axial compression of the L4.

Results: Trabecular BMD in the L4 was significantly increased in RIS+ELD, ALN+ELD and MIN+ELD by 56%, 60% and 62%, respectively, compared with the vehicle group. Cortical BMD and connectivity density in the L4 of all BP+ELD combination groups were also significantly increased compared with the vehicle group. On mechanical testing of the L4, the maximum load was significantly decreased in the vehicle group compared with the sham group, and significantly increased in RIS+ELD and ALN+ELD by 59% and 55%, respectively, compared with the vehicle group. MIN+ELD showed a 44% increase without statistical significance. In the femur, every combination therapy significantly improved trabecular BMD and architecture compared with the vehicle group, but no significant inter-group differences were observed in cortical bone mass, architecture and bone strength.

Conclusions: Treatment of RIS, ALN and MIN in combination with ELD improved BMD and bone structural properties to approximately the same extent. And at least RIS and ALN improved bone strength as well. These results suggest that combination therapy of BP and ELD is valid, and further warrant clinical trials.

MO0177

Intermittent interleukin-10 administration prevents early radiation- and combined trauma-induced bone loss by altering RANKL/OPG and Sclerostin. Joshua Swift*[1], Aminul Islam[2], William Danchanko[3], Min Zhai[2], Joan Smith[2], Rossitsa Owens[2], Juliann Kiang[2], Sibyl Swift[1], Matthew Allen[4]. [1]Armed Forces Radiobiology Research Institute, USA, [2]Armed Forces Radiobiology Research Institute, USA, [3]Uniformed Services University of the Health Sciences, USA, [4]Indiana University School of Medicine, USA

Ionizing radiation, when combined with another trauma (i.e. skin wounding), accelerates and prolongs radiation-induced bone loss for at least 120 days post-exposure. These effects arise from early and sustained increases in bone resorption and prolonged suppression of osteoblast activity. The purpose of this study was to determine the efficacy of interleukin-10 (IL-10), an anti-inflammatory cytokine and

potent inhibitor of osteoclastogenesis, to mitigate or prevent negative alterations in bone due to radiation and/or radiation combined with skin wounding (combined injury; CI). Female B6D2F1/J mice (16-wk-old) were exposed to a either a sub-lethal dose of 8 Gy γ radiation (RI) or 0 Gy (SHAM) followed by skin wound (W and CI only), and administered either IL-10 (15 ng/d, s.c.) or an equal volume of sterile saline (VEH; 0.2 mL) 3x/wk for 7 or 30 days. RI significantly lowered distal femur cancellous bone volume fraction (BV/TV; -35% vs. SHAM), trabecular thickness (Tb.Th; -8%), and trabecular number (Tb.N; -29%) by Day 7, which continued to decline through Day 30. CI resulted in similar alterations in bone microarchitecture as RI on Day 7, however these changes were exacerbated by Day 30 (BV/TV: -54% vs. SHAM; Tb.N: -40%). IL-10 treatment after RI and CI resulted in greater BV/TV (+15-16%), Tb.Th (+5%), and Tb.N (+10%) vs. VEH treated mice on Day 7; CI+IL-10 mitigated reductions in BV/TV (+15% vs. VEH) on Day 30. RI and CI significantly reduced mid-diaphysis femur ultimate force (-8% and -19% vs. SHAM, respectively) on Day 7, which was restored by IL-10 administration (+12% and +19% vs. VEH). CI resulted in greater bone tissue concentration (measured by ELISA) of RANKL (+67%), sclerostin (+181%) and RANKL/OPG ratio on Day 7 vs. SHAM. IL-10 treatment after CI reduced RANKL (-68% vs. VEH) and sclerostin (-47%), increased OPG (+52%), and lowered RANKL/OPG on Day 7. On Day 30, increased bone concentrations of RANKL and sclerostin, and reductions in OPG persisted after CI and RI, which were not affected by IL-10 treatment. IL-10 treatment attenuated reductions in cancellous BFR (-40% vs. SHAM) after RI and CI by Day 7 but not Day 30. These data demonstrate the potential involvement of RANKL-OPG signaling in bone loss after irradiation and combined trauma. Furthermore, although IL-10 effectively inhibits early negative effects on bone after these traumas, there does not appear to be a long-term beneficial effect of IL-10 treatment for bone health.

Orally Administered Bisphosphonates Alleviate Colonic Inflammation and Bone Loss in a Mouse Model of Acute Colitis. Maria K. Tsoumpra*[1], Hans-Anton Lehr[2], F. Hal Ebetino[3], Jeffrey D. Neighbors[4], R Graham Russell[5], Sylvie Ferrari-Lacraz[6], Serge Ferrari[7]. [1], Switzerland, [2]Institute of Pathology, Medicine Campus Bodensee, Germany, [3]Structural Genomics Consortium, Oxford University, United Kingdom, [4]Terpenoid Therapeutics Inc., USA, [5]University of Oxford, United Kingdom, [6]Departments of Paediatrics & Internal Medicine & the Transplantation Immunology Unit, Geneva University Hospital, Switzerland, [7]Geneva University Hospital & Faculty of Medicine, Switzerland

Inflammatory bowel diseases arise by altered immune responses to enteric antigens and are characterized by progressive extra-intestinal manifestations that may compromise the quality of life of patients. Bisphosphonates (BPs) may hinder the activation of pro-inflammatory signaling pathways and have been shown to improve bone mineral density (BMD) in colitis animal models. To examine this further, we have evaluated the effects of two novel lower bone affinity BPs, OX14 and digeranyl bisphosphonate (DGBP), on colonic inflammation and bone loss in a mouse colitis model induced by dextran sulfate sodium (DSS) using risedronate (RIS) as a comparator. OX14 has similar anti-resorptive potency to RIS and strongly inhibits farnesyl diphosphate synthase, whereas DGBP selectively inhibits geranylgeranylation. Mice (n=6/group) received RIS or DGBP (25 mg/kg/day) or OX14 (12.5 mg/kg/day) or PBS (control) via oral administration for 10 days, as well as 2% DSS in their drinking water from day 3 onwards. Bone turnover, architecture and mass were evaluated by serum CTX quantification, micro-computed tomography and DXA respectively. The severity of colitis was assessed by blood in stool, body weight and colon length and histology at sacrifice. The anti-inflammatory response was assessed by qPCR on colonic RNA and FACS analysis of bone marrow cells. RIS and OX14 lowered the CTX levels (8.12 ng/ml in RIS, 9.91 ng/ml in OX14 vs 20.38 ng/ml in DGBP, 24.42 ng/ml in control, $p<0.001$) and increased the bone volume fraction at the distal femur metaphysis (9.92% in RIS, 9.65% in OX14 vs 6.62% in control, $p<0.01$). All BPs tested attenuated bone loss in the spine but RIS also increased the femur and body BMD. At sacrifice, colon length was non-significantly greater in OX14 and DGBP treated mice (75 mm in OX14, 72 mm in DGBP vs 68.2 mm in RIS, 65.8 mm in control, ns), in agreement with the histological scoring of decreased inflammation (0 in OX14, 2.5 in DGBP vs 3.3 in RIS, 5 in control, ns). RIS enhanced the expression of the anti-inflammatory cytokine IL10 and decreased the percentage of monocytic and osteoclast progenitors, while OX14 decreased the TNF and IFNγ levels. Collectively, the data indicate that the novel BPs were more potent modulators of local colonic inflammation while RIS better preserved BMD, consistent with its higher affinity for bone. Interestingly, the ability of DGBP to attenuate colonic inflammation was independent of its modest anti-resorptive potency.

MO0179

Targeting osteoclast sealing zone to prevent bone degradation while maintaining bone formation: *in vivo* proof of concept with a small chemical compound. Anne Blangy*[1], Virginie Vives[2], Gaelle Cres[2], Christian Richard[2]. [1]CNRS CRBM Montpellier University, France, [2]CNRS CRBM Montpellier University, France

Current anti-osteolytic medical treatments target osteoclast survival and differentiation. But molecules secreted by the osteoclast or clastokynes are essential to stimulate bone formation by osteoblasts. Suppression of osteoclasts blunts bone turnover, which is suspected to increase the risk of atypical fractures in the long term. A solution to overcome this would be to develop novel therapeutic strategies that target selectively the bone-resorbing activity of osteoclasts without affecting their survival or differentiation.

To reach this goal, we propose here to specifically target the organization of podosomes in osteoclasts. Preventing sealing zone formation by affecting podosome patterning impairs the acidification of the extracellular medium by osteoclasts and renders bone resorption ineffective. We report here the *in vivo* proof of concept that this approach allows to protect against bone resorption while preserving bone formation.

As a model we used C21, a small chemical compound inhibitor of Rac activation by Dock5, which is essential for sealing zone formation. We show here in cultured osteoclasts that C21 destabilizes podosomes organization rapidly and reversibly. We further used C21 in three established mouse models of pathological bone loss: post menopause osteoporosis, rheumatoid arthritis and bone metastases. We demonstrate that administration of C21 efficiently protected mice against bone loss in those three models and that this had no noticeable adverse effect in the mouse. Most interestingly, bone formation parameters (MS/BS, MAR and BFR/BS) were not affected by C21, while they were severely diminished in mice treated with Alendronate.

Our results provide the proof of concept that a chemical compound that destabilizes podosome organization in osteoclasts efficiently protects against pathological bone loss without affecting bone formation. Our findings open new avenues to develop innovative strategies for the treatment of osteolytic bone diseases.

Ablation of Tak1 in monocyte leads to defects in skeletal growth and bone remodeling in mice. Huihuan Liu*[1], Bing Qi[2], Qian Cong[1], Ping Li[1], Micheal Schneider[3], Baojie Li[4]. [1]The Bio-X Institutes, Key Laboratory for the Genetics of Developmental & Neuropsychiatric Disorders, Ministry of Education, Shanghai Jiao Tong University, China, [2]School of Biological Science, Taishan Medical University, China, [3]Cardiovascular Science National Heart & Lung Institute, United Kingdom, [4]Shanghai Jiao Tong University, Peoples Republic of China

Tak1 is a MAPKKK that can be activated by TNFa, RANKL, TGFb, and BMPs. It forms a complex with Tab2 and Tab3 and activates the downstream NF-kB and JNK/p38 MAPK pathways. Tak1 is essential for mouse embryonic development and plays critical roles in homeostasis of tissue such as liver, cartilage, and the immune system. Previous studies have implicated Tak1 as a positive regulator of osteoclastogenesis, yet there lacks a mouse model to study the function of Tak1 in bone remodeling, as mature osteoclast-specific Tak1 deletion resulted in runtedness, postnatal lethality, and severe osteopetrosis, phenotypes that were not even observed in RANK or RANKL deficient mice. Here we generated monocyte-specific Tak1 knockout mice and found that these mice show normal body weight, limb size, and fertility, and osteopetrosis with severity level close to that of RANK or RANKL deficient mice. Mechanistically, Tak1 deficiency altered the signaling of NF-kB, p38MAPK, and Smad1/5/8 and the expression of transcriptional factors required for osteoclastogenesis including PU.1, MITF, c-Fos, and NFATc1, suggesting that Tak1 regulates osteoclast differentiation at multiple stages via multiple signaling pathways. Moreover, the Tak1 mutant mice also showed skull overgrowth, an increase in articulate cartilage thickness, and an increase in the number of mesenchymal stromal/stem cells in vivo. Ex vivo Tak1-/- monocytes also showed enhanced ability in promoting osteogenic differentiation of mesenchymal stromal cells. These findings indicate that Tak1 functions in osteoclastogenesis in cell-autonomous manner and in osteoblastogenesis and chondrogenesis in non-cell-autonomous manners.

Biglycan and fibromodulin deficiency leads to increased bone remodeling that can be rescued by exogenous osteoprotegerin. Vardit Kram*[1], Tina Kilts[2], Kenn Holmbeck[2], Marian Young[1]. [1]National Institutes of Health, USA, [2]NIH/NIDCR, USA

Biglycan (bgn), a class I SLRP, is highly expressed in bone and cartilage and has been shown to play an important role in the proliferation, survival and differentiation of osteoblasts, acting as a positive regulator of bone formation and bone mass. Fibromodulin (fmod), a class II SLRP is also highly expressed in the skeleton, but its function in bone is unclear. In order to examine the combined roles of bgn and fmod in mineralized tissue, double-deficient mice, lacking both *bgn* and *fmod* (*bgn-/0*; *fmod-/-* DKO) were generated. These mice are smaller in size compared to WT, and have reduced bone mass, detectable as early as 3 weeks of age, which becomes more pronounced with age. Morphological differences in femoral bone of DKO mice were observed, which may be the result of abnormal shear forces due to weak tendons and mis-articulation of joints, leading to impaired gait. These mice also develop early onset osteoarthritis as well as ectopic bone formation and tendon ossification. Dynamic histomorphometry showed that the low bone mass phenotype was not the result of decreased bone formation, as the bone formation rate (BFR) of DKO mice was not significantly different from that of WT littermates, implying that the low bone mass was not due to defective osteoblast proliferation or action. Both *in vivo* and *in vitro*, TRAP staining indicated that the DKO mice had increased osteoclast number and activity. Since neither bgn nor fmod is made by osteoclasts, and because decreased levels of the RANKL decoy receptor, osteoprotegerin (opg), which is made by BMSCs and decreased in the serum of the DKO mice, we concentrated on opg as a potential mediator of the increased osteoclast number seen in the DKO mice. Long-term (6 weeks) injections of both WT and DKO mice with rat opg-Fc, a truncated form of opg consisting of the RANKL binding site of opg fused to the Fc domain of IgG, showed it was able to cure the age-related bone loss in the DKO mice, bringing the bone mineral density (BMD) and bone mineral content (BMC) of the DKO mice to comparable levels of the WTs. Thus, while the DKO produce and accumulate less opg, they are able to respond to it when added exogenously. Considering that SLRPs have previously been shown to have roles in binding and regulating extracellular components in bone, we speculate that bgn and fmod may control osteoclast differentiation by potentially mediating the stability and storage of opg in the ECM compartment of mineralized tissue.

Bone Quality Changes in The Streptozocin-induced Diabetes Rat and The Effect of Zoledronic Acid Through Up-regulating The Expression of The Osteogenic Genes. Lingzhi Yu*[1], Min Cui[2], Jing Sun[3]. [1]"shandong University ,jinan Central Hospital", , [2]Shandong University,Jinan Central Hospital, China, [3]Binzhou Medical college,affiliated Hospital, China

Aims:To evaluate the bone quality and the osteogenes changes and the short term effect of zoledronic acid (ZOL) on bone remodeling in the streptozotocin (STZ) induced diabetes rats.Methods:One hundred and twenty female Wistar rats aged 8-10 weeks were randomly divided into four groups: C, D, Z-I and Z-II. C was the control group. Rats in group D were suffered streptozotocin-induced diabetes. Those in group Z-I and Z-II received a bolus injection of zoledronic acid (0.1mg/kg) at the onset of diabetes and 2 weeks later, respectively. Rats were sacrificed at 1, 2, 3, 4 and 5 weeks after diabetes onset. The serum osteocalcin (OC), bone alkaline phosphatase (BALP) and tartarate-resistant acid phosphatase (TRAP) were measured. Real–time PCR and western blot were performed to detect the expression of the mRNAs and their proteins of bone morphogenetic proteins 2 (BMP-2), Runx-2, Osterix and Noggin on the right femur metaphysis. The left femurs were used to measure the bone mineral density (BMD) and the mechanical resistance test. The bone histomorphology of left tibiae were observed.Results: Rats in group D displayed significantly lower serum BALP and OC, higher serum TRAP levels. ZOL administration showed restorative effect on BALP and OC. The expression of Runx-2 and Osterix mRNA in group D had regulated down since the 1st week and BMP-2 mRNA since the 2nd week. Z-I treatment could completely reverse the result. However group Z-II showed only a transient reversing effect on the 4th week and could not be sustainable. The expression of Noggin mRNA regulated up continuously in group D. But the reducing influences began to show until the 4th week both in group Z-I and Z-II. The protein expressions of BMP-2, Runx2 and Osterix in group D lowered at the 5th week to about 64%, 71% and 57% respectively of the control level, while those in group Z-I were obviously higher than all the other groups include Z-II, which was also higher than those of group D. Contrary, Noggin protein expression regulated up markedly than the control level and only Z-I treatment showed a slightly decrease. On the 5th week in group D, the BMD decreased. Z-I treatment restored the alterations. The same trend was observed in Z-II group. Conclusions:Zoledronic acid could prevent the osteopenia. The underlying mechanisms might be associated with its effects of increasing the expression of BMP-2, Runx-2 and Osterix, inhibition of the expression of Noggin.Keywords: Bisphosphonates, diabetic osteoporosis

Combined Treatment with Ascorbic Acid and Thyroid Hormone Promotes Healing of a Non-union Tail Vertebra Defect in Mice. Kevin DeLeon*[1], Hongrun Yu[2], Heather Watt[1], Catrina Alarcon[1], Subburaman Mohan[2]. [1]VALLHCS, USA, [2]Jerry L. Pettis Memorial VA Medical Center, USA

Bone injuries are a serious health problem. Healing is impaired in 10-20% of fractures with seriously delayed union or non-union, causing morbidity for patients and enormous healthcare costs. Thus, there is a compelling need to find novel effective therapies to promote fracture healing. Based on the findings that ascorbic acid (AA) deficiency in mice resulted in spontaneous fractures (Sfx) and that thyroid hormone (TH) deficiency caused impaired skeletal growth both acting via regulating osterix (Osx) expression, we proposed the hypothesis that a combination of AA and TH will produce a synergistic effect on skeletal healing in mice. Treatment of MC3T3-E1 cells with 10 ng/ml of triiodothyronine (T3) or 50 ug/ml AA increased ALP activity less than 3-fold compared to vehicle while combined treatment with both T3 and AA increased ALP activity by 20-fold. Similarly, combined treatment increased Osx expression 20-fold, which was significantly greater than the additive effect of individual treatments. To test if TH and AA play an important role in skeletal healing, we generated gulonolactone oxidase gene disrupted Sfx mutant mice and subjected them to transient AA deficiency (by removing AA from drinking water) and TH deficiency (via methimazole treatment) at 4 wks of age. At 6 wks of age, AA/TH-deficient mice and control wild type (WT) mice were subjected to a 0.8 mm diameter drill hole in the mid-diaphysis of the third tail vertebra. Mice were treated with vehicle, AA (330 μg/ml in drinking water), T3 (1 μg)/T4 (10 μg) via I.P. injection or a combination of AA and T3/T4 for 30 days after the drill hole procedure. At day 1 and 30 after defect, in vivo μ-CT scans of anesthetized mice were performed at 10.5 micron resolution and changes in bone volume (BV) to tissue volume (TV) at the defect site were determined. Bone regeneration was reduced dramatically (56%, $P<0.01$) in vehicle treated Sfx mice with transient AA/TH deficiency compared to WT mice. In WT mice, only the combination of AA/TH produced a significant increase (28%, $P=0.02$) in BV/TV compared to vehicle. In deficient mice, AA, TH and the combination caused a 70%, 106% and 163% increase (all $P<0.01$ vs vehicle; $P<0.05$ in AA/TH vs AA or TH) in BV/TV during the 30 day treatment. Based on these data, we conclude that a combination of AA/TH caused a greater increase in osteoblast differentiation and Osx expression in vitro and bone regeneration ability in vivo compared to individual treatments.

Delay in Fracture Healing by Phosphate Restriction Displays Uniform Recovery in AJ and C57B6 Strains Independent of Genetic Variability. Kyle Lybrand*[1], Brenna Hogue[2], Heather Matheny[2], Amira Hussein[3], Anthony De Giacomo[1], Elise Morgan[4], Thomas Einhorn[5], Louis Gerstenfeld[3]. [1]Boston University Dept of Orthopaedic Surgery, USA, [2]Boston University School of Medicine, USA, [3]Boston University School of Medicine, USA, [4]Boston University, USA, [5]Boston Medical Center, USA

Introduction: Phosphate is essential for bone growth and fracture repair. Although phosphate deficiency has been shown to impair fracture repair, it is unknown how genetic factors interact with this deficiency to affect healing. It is also unknown if healing will be re-initiated once phosphate is replenished, or if initial phosphate deficiency will irreversibly affect healing even after phosphate has been restored. The aims of this project addressed these two questions.

Methods: Closed stabilized fractures were generated in the femora of 3 strains of male mice, A/J (AJ), C57BL/6J (B6), and C3H/HeJ (C3). Phosphate deficiency was initiated 2 days prior to fracture and was maintained for 15 days. Phosphate was then replenished and bone healing was allowed to continue until 35 days. RNA expression for marker genes of chondrogenesis and osteogenesis was assessed by qRT-PCR analysis over this time course. Callus microstructural properties, cartilage content and torsional strength were measured by micro-computed tomography (CT), contrast-enhanced CT and mechanical testing at 21 days post-fracture.

Results: All three strains had impaired expression of cartilage and bone associated genes during the period of phosphate deficiency. Once phosphate was replenished, osteogenic genes showed a burst of late expression in all three strains. Compared to control calluses phosphate deficient calluses were stronger for AJ and B6 strains ($p<0.003$). Even though tissue mineral density (TMD) was lower in these calluses ($p<0.03$), the standard deviation in TMD was lower ($p<0.001$) and for AJ calluses the tissue was located closer to the bone axis ($p=0.03$) indicating a more even distribution of mineralized tissue compared to controls. Further, the phosphate deficient AJ calluses were more brittle than controls ($p<0.02$). No differences in mineralization and mechanical strength were found for C3 calluses ($p>0.30$) suggesting that healing does not recover upon phosphate repletion.

Conclusions: The phosphate restriction in the C3 strain delayed the regain of mechanical strength relative to AJ and B6 strains suggesting that C3 mice respond differently to a rachitic state. These results suggest strain dependent bone repair that is more osteogenic in the C3 strain, which is more effected by phosphate deficiency, while the more chondrogenic strains (AJ and B6) are more responsive to return to the normal metabolic state independent of genetic variability.

MO0185

Differing effects are exerted by the Vitamin E isomers gamma-tocotrienol (GT3) and delta-tocotrienol (DT3) on indices of bone remodeling in mice following exposure to non-lethal ionizing radiation. Sibyl Swift*[1], Joshua Swift[1], Shukla Biswas[2], Merriline Satyamitra[2], Venkataraman Srinivasan[2], Sanchita Ghosh[2]. [1]Armed Forces Radiobiology Research Institute, USA, [2]AFRRI, USA

Exposure of normal skeletal tissue to ionizing radiation, at even low doses similar to those administered for cancer treatment, results in significant bone loss and increased risk of fracture at weight bearing skeletal sites in short periods of time. Vitamin E isomers, such as gamma-tocotrienol (GT3) and delta-tocotrienol (DT3), stimulate osteoblastogenesis and inhibit osteoclast formation and activity. We sought to determine whether the administration of DT3 or GT3 prior to radiation exposure would attenuate radiation-induced bone loss. Male CD2F1 mice (8-10 wk old) were exposed to either a single dose of 7 Gy ionizing radiation (Co^{60}, γ-rays; 0.6 Gy/min) or SHAM (0 Gy). Mice from each group were treated (s.c.) with either VEH (5% Tween-80), DT3 (300 mg/kg), or GT3 (100 mg/kg) 24 hrs prior to radiation exposure or SHAM. Serum biomarkers were assessed 1, 3, 7, 10, 14, and 30 days post-irradiation and compared to sham controls. Radiation injury (RI) resulted in early increases in serum TRACP 5b by Day 7 (+114% vs. VEH), which remained elevated on Days 14 (+121%) and 30 (+69%). This response was diminished with the administration of GT3 at Day 10 (-25%), but did not restore TRACP 5b levels to those of VEH. DT3 had no detectable effect on TRACP 5b levels. RI down-regulated serum osteocalcin levels from Day 7 (-44%) through Day 14 (-56%). DT3 treatment restored osteocalcin levels to those of the VEH group; GT3 treatment had not detectable effect on osteocalcin levels.These data suggest that bone remodeling is initially up-regulated following exposure to non-lethal γ-radiation (7 Gy). These data indicate opposing effects of DT3 and GT3 on bone, when given prior to radiation exposure. The administration of DT3 before RI appears to stimulate overall bone metabolism by increasing TRACP 5b and osteocalcin. However, GT3 treatment in combination with RI, down-regulates RI-induced increases TRACP 5b. Further research into the precise mechanisms by which GT3 and DT3 affect bone after ionizing radiation exposure is necessary to characterize the efficacy of these agents as countermeasures to RI-induced osteoporosis.

Mushroom polysaccharides improve bone microarchitecture and strength in diabetic rats. Chung-Hwan Chen*[1], Hui-Chen Lo[2], Yi-Shan Lin[3], Zai-Jie Wang[3], Lin Kang[4], Chwan-Li Shen[5]. [1]Kaohsiung Medical University Hospital & Kaohsiung Medical University, Taiwan, [2]Fu Jen Catholic University, Taiwan, [3]Kaohsiung Medical University, Taiwan, [4]National Cheng Kung University, Taiwan, [5]Texas Tech University Health Sciences Center, USA

Patients with DM exhibit osteopenia and osteoporosis. Trametes versicolor (L.:Fr.) Pilát (TV), a medicinal mushroom with a wide range of applications, formerly known as Coriolus versicolor, and named Yunzhi in China, has been successfully grown in submerged fermentation as mycelial biomass. Recently, a novel TV strain LH-1, originally collected in Taiwan, has been successfully cultured. Up to now, no study has ever been conducted to show the effects of mushroom polysaccharides on bone health, especially in DM. Therefore, the present study was designed to investigate the potential benefit of TV LH-1 on bone health, in terms of bone microstructure and bone turnover biomarkers, in diabetic rats with impaired glucose tolerance. Male Wistar rats weighing approximately 280 g were used in this study. 27 rats were fed with high fat chow dietand the rest rats (n=10) were fed with normal chow diet during the experimental period served as control (CON) group. The diabetic animals were then divided into 2 groups and intragastrically administered with 0.5 ml of distilled water (the IGT group) (n=12) or TV LH-1 (0.1g/kg of body weight, the TV group) (n=15) daily for 28 days. The rats were sacrificed after treatment. All proximal tibiae were assessed by μ-CT and bending test at the end of study. Bone volume and trabecular number decreased and trabecular separation increased in the IGT group compared with the CON group while TV increased bone volume and trabecular number and decreased trabecular separation compared with the IGT group. The maximal load, stiffness and Young's modulus decreased in IGT group compared with the CON group while TV increased maximal load, stiffness and Young's modulus compared with the IGT group. The anti-hyperglycemic activity of TV LH-1 has also been demonstrated in diabetic rats previously. In this study, bone microarchitecture and bone markers deteriorated after DM induction while TV rescue the deleterious effects of DM on bone microarchitecture and bone marker. This is the first report that TV can improve bone microarchitecture and maximal load, stiffness and Young's modulus of bone in rats with DM. Though DM is a risk factor in osteoporosis, well-control of DM is not exactly known to rescue osteoporosis. The protective effect of TV on bone microarchitecture and bone strength was through the improvement of DM or/and directly on the bone was not elucidated. The protective mechanism of TV in rat with DM on bone required further studies.

MO0187

Role of CCR2+ Cells in the Alveolar Bone Repair Process in Mice. Claudia Biguetti*[1], Andreia Vieira[2], Priscila Maria Colavite[3], Carlos Eduardo Repeke[3], Franco Cavalla[3], Ana Paula Trombone[4], Gustavo Garlet[5]. [1]Universidade de São Paulo, Brazil, [2]Bauru School of Dentistry - University of Sao Paulo (FOB - USP), Brazil, [3]Universidade de São Paulo, Brazil, [4]Universidade do Sagrado Coração, Brazil, [5]School of Dentistry of Bauru, São Paulo University -FOB/USP, Brazil

The bone repair process depends of an initial and transitory inflammatory response, which involves the participation of various leukocytes subsets, as the monocyte/macrophage lineage. The CCR2 receptor is important to macrophage recruitment during inflammatory and immune responses, and play an active role in the regulation of osteoclastogenesis. However, its role in bone repair process remains unknown. Thereby, the purpose of this study was to investigate the role of CCR2+ cells in the alveolar bone repair process in mice, by means of microscopic - histomorphometry, birefringence analysis and immunohistochemistry), tomographic (MicroCT) - and molecular (PCRArray) comparative analysis between C57BL / 6 (WT) and CCR2KO mice during periods of 0 hour, 7, 14 and 21 days post-extraction of the right upper incisor. Our results demonstrated that CCR2 is in fact associated with monocyte/macrophage influx to bone repair site, since the CCR2+ cells are present in the inflammatory infiltrate developed along the alveolar bone repair in WT mice, with a kinetics similar to F4/80+ and CCR5+ cells. Furthermore, F4/80+ and CCR5+ cell number was significantly reduced in CCR2KO mice, suggesting that F4/80+ cells are double positive for CCR2 and CCR5. While CCR5 receptor may account for the remaining (but reduced) migration of the F4/80 + cells in CCR2KO mice, the reduced F4/80+ cells number suggests that CCR2 may be the primary receptor required for its migration. Also, the microscopic analysis demonstrated that CCR2 absence resulted in an increase of inflammatory infiltrate, collagen fibers, osteoblasts and osteoclasts counts and decrease of blood vessels in CCR2KO mice compared to WT mice. Birefringence analysis did not demonstrate major changes in extracellular matrix maturation dynamics in WT vs CCR2KO mice comparison. The molecular analysis demonstrated that CCR2 absence resulted in an altered expression of different markers in CCR2KO mice. While growth factor TGFβ1, bone markers RUNX2 and CTSK, immunological markers TNFα, CCR1 and CCR5, and several MSCs markers (CD106, OCT4, NANOG, CD146, CXCL12 and CD105) were decreased in CCR2KO mice, RANK, RANKL, DMP1, IL6 and CXCR1 mRNA levels were increased. In conclusion, these results indicate that CCR2+ cells play an active role in alveolar bone repair in mice controlling F4/80+ cells migration, which in turn consequently influences inflammatory and healing response events throughout the repair process.

Sheep Model Reflecting Glucocorticoid-induced Osteoporosis in Postmenopausal Women. Christina Andreasen*[1], Søren Overgaard[2], Ming Ding[3], Peter Bollen[4], Thomas Levin Andersen[5]. [1]Odense University Hospital, Institute of Clinical Research, Denmark, [2]Department of Orthopedics & Traumatology, Institute of Clinical Research, University of Southern Denmark, Denmark, [3]Department of Orthopedics & Traumatology, Institute of Clinical Health, University of Southern Denmark, Denmark, [4]Biomedicine Laboratory, University of Southern Denmark, Denmark, [5]Department of Clinical Cell Biology, Institute of Regional Health Services Research, University of Southern Denmark, Denmark

Large animal models are often used for studying orthopedic implants and biomaterial research. In the present study, we investigate whether the bone loss in glucocorticoid treated ovariectomised sheep results from a similar bone remodeling defect as in osteoporotic postmenopausal women treated with glucocorticoids. Ten female sheep were ovariectomised and treated with prednisolone (0.6 mg/kg/day, 5 times weekly) for 7 months. Ten untreated sheep served as control. The bone structure and selected histomorphometric parameters were evaluated in iliac crest biopsies, whereas blood samples were used to evaluate serum levels of bone biomarkers. Ovariectomy and glucocorticoid-treatment induced a significant loss of cancellous bone (19.7 %) after 7 months. During these 7 months the extent of bone surfaces colonized by osteoclasts was unchanged, while the resorption marker carboxy-terminal collagen crosslinks (CTX) on the other hand had a significant periodically elevation that peaked after one month. This suggests that the presence of osteoclasts was unchanged, but that their resorption activities were temporary enhanced or changes. In contrast, the bone formation marker osteocalcin was consistently reduced after one week, and the extent of formative osteoid surfaces was significant reduced after 1 month and almost undetectable after 7 months. The extent of reversal surfaces that reflects the reversal phase coupling bone formation and resorption were significant increased after 1 month, and covered as much as 50% of the bone surfaces after 7 months. Most of these accumulated surfaces were arrested reversal surfaces without any neighboring osteoclasts or osteoid surfaces, supporting that the bone formation and resorption were uncoupled during the reversal phase. As recently described in osteoporotic patients the arrested reversal surfaces had a significantly decreased cell density and reduced immunoreactivity for the osteoblastic markers runx2, osterix, and smooth muscle actin (SMA) when compared to the active reversal surfaces with neighboring osteoclasts and osteoid surfaces. In conclusion, the bone loss in glucocorticoid-treated ovariectomised sheep results from an uncoupling of the bone formation and resorption during the reversal phase, as recently described in osteoporotic postmenopausal women treated with glucocorticoids. This makes it a relevant preclinical model for studying orthopedic implant and biomaterial research under osteoporotic conditions.

MO0189

WISP1/CCN4 controls bone mass by uncoupling osteoblast and osteoclast function potentially by regulation of Wnt signaling. Azusa Maeda*[1], Mitsuaki Ono[2], Tina Kilts[2], Li Li[2], Kenn Holmbeck[2], Pamela Robey[3], Marian Young[1]. [1]National Institutes of Health, USA, [2]National Institutes of Health, USA, [3]National Institute of Dental & Craniofacial Research, USA

WISP1/CCN4 (WISP1) is highly expressed during bone development however, its function in bone is not clear. To study this, we created *Wisp1* knockout (*Wisp1*-KO) mice and results from micro-CT indicated that the bone mass of the *Wisp1*-KO mice was lower and the cortex was thinner compared to wild type (WT) mice. We also previously showed that the osteogenic differentiation of bone marrow stromal cells (BMSCs) was diminished in *Wisp1*-KO-BMSCs.

To learn more about the cellular basis for the phenotypes that we uncovered in the *Wisp1*-KO mice, we next examined the effect of *Wisp1*-deficiency on osteoclastgenesis. When osteoclast progenitors were isolated from bone marrow and cultured with RANKL and M-CSF, more TRAP positive cells were observed in *Wisp1*-KO bone marrow compared to WT. Next, BMSCs were transplanted under the skin of immunocompromised mice in a gelatin vehicle and harvested after 6 weeks. TRAP staining of the transplants showed more osteoclasts in the transplant

containing *Wisp1*-KO-BMSCs. Finally, using 6-month-old ovariectomized mice, we found whole-body bone mineral density was significantly lower in *Wisp1*-KO mice compared to WT, indicating that promotion of osteoclast activity caused by a loss of estrogen is accelerated by *Wisp1*-deficiency. These results suggest that lower bone mass in *Wisp1*-KO mouse is caused by over active osteoclast function.

To further decipher the molecular mechanisms causing lower osteogenesis and higher osteoclastgenesis in the *Wisp1*-KO mouse, we focused on the Wnt pathway since *Wisp1* is a downstream target of this pathway. We measured the differences in expression of genes specifically related to the canonical Wnt pathway and osteogenic differentiation. Our experiment showed the level of mRNAs encoding *β-catenin* (*β-cat*), *Axin2*, *Matrix metalloproteinase 14* (*Mmp14*) and *Cyclin D1* (*Ccnd1*) was significantly lower in *Wisp1*-KO-BMSCs, suggesting that *Wisp1* is not only a target but also an effector of the Wnt pathway. To determine where *Wisp1* functions in the pathway, BMSCs were cultured with osteogenic differentiation media and treated with LiCl which activates the Wnt pathway by inhibiting Gsk3-β. LiCl treatment increased the expression level of *Axin2* mRNA in *Wisp1*-KO-BMSCs but to a lower extent than that found in WT-BMSCs. These results suggest that *Wisp1* could function both up- and downstream of Gsk3-β in the Wnt pathway to regulate bone mass.

COX-1,2 and EP1,2 expression in chronic spinal cord injured patients and healthy controls skeletal muscle tissue. Marco Invernizzi*[1], Manuela Rizzi[2], Claudio Molinari[3], Carlo Cisari[4], Stefano Carda[5], Filippo Renò[2]. [1]University of Eastern Piedmont, Novara, Italy, [2]Innovative Reasearch Laboratory for Wound Healing, Department of Health Sciences, University of Eastern Piedmont "A.Avogadro", Novara, Italy, [3]Human Physiology, Department of Translational Medicine, University of Eastern Piedmont "A.Avogadro", Novara, Italy, [4]Physical & Rehabilitation Medicine, Department of Health Sciences, University of Eastern Piedmont "A.Avogadro", Novara, Italy, [5]Department of Neurorehabilitation & Neuropsychology, Centre Hospitalier Universitaire Vaudois (CHUV), Lausanne, Switzerland

INTRODUCTION: Muscle tissue biology is regulated by a wide array of bioactive compounds among which Prostaglandins (PG), and in particular prostaglandin E_2 (PGE_2) play a pivotal role. PG are a family of active compounds produced by the ubiquitous cyclooxygenase (COX) enzymes (COX 1 and 2) and in skeletal muscle they regulate protein synthesis/degradation, tissue injury recovery and bone-muscle crosstalk. EP1-4 are G protein coupled PGE_2 receptors, and EP1 and 2 represent the most ubiquitous ones. The aim of this study was to evaluate, for the first time, the different expression of COX1,2 and EP1,2 in athrophic skeletal muscle obtained by a new mini-invasive muscle tissue biopsy technique in chronic spinal cord injured (SCI) patients and healthy controls.

MATERIALS AND METHODS: Skeletal muscle biopsies were collected from 6 chronic complete SCI patients and 3 healthy controls vastus lateralis muscle with a tri-axial end cut needle (Biopince© - Angiotech). Correct needle positioning in the target muscle was confirmed by ultrasound guide. All biopsies were performed under local anesthesia. Muscle samples were stained for ATPase to determine fibers composition, while COX1,2 and EP1,2 expression were evaluated by immunofluorescence.

RESULTS: All the bioptic procedures were perfomed easily without failures. Control muscle tissue was macroscopically thicker than SCI one. Moreover SCI sample microscopically displayed some structural degradation (vacuolization). Control specimen displayed an equal distribution of type I and type II fibers, while SCI sample displayed a high prevalence of type II fibers. COX1,2 and EP1 expression in muscle tissue did not display any significant difference between SCI patients and healthy controls. EP2, indeed, was significantly less expressed in SCI patients.

CONCLUSION: The observed shift from type I to type II fibers in SCI specimen was consistent with the results previously described in literature. Moreover in this work, for the first time, attention was focused on PGE_2 synthesis and signalling pathway in human skeletal muscle showing a significant difference in EP2 expression in SCI muscle compared to healthy controls.

GPR55 Regulates Peak Bone Mass and Steroid Hormone Levels in Male Mice. Lauren Whyte*[1], Aysha Khalid[2], Graeme Finnie[2], Selina Chiu[2], David Baker[3], Richard Aspden[4], Ruth Ross[1]. [1]University of Toronto, Canada, [2]University of Aberdeen, United Kingdom, [3]Blizard Institute, Barts & The London School of Medicine & Dentistry, United Kingdom, [4]University of Aberdeen, United Kingdom

Peak bone mass is generally associated with bone mineral density in older age, therefore accrual of bone mass during childhood and adolescence is an important determinant of osteoporosis risk later in life. Previously we characterised an osteopetrotic phenotype in 3 month old male $GPR55^{-/-}$ mice due to a decrease in osteoclast function (Whyte *et al*, 2009). It is not known whether this high bone mass phenotype is maintained with age and equates to increased bone strength. This study investigated the structural and mechanical bone properties of $GPR55^{-/-}$ mice at 3, 5 and 12 months.

μCT analysis of the proximal tibia and distal femur demonstrated a significant increase in trabecular bone volume in male $GPR55^{-/-}$ mice compared to wildtype mice at 3 months ($P<0.05$ tibia, $P<0.01$ femur), 5 months ($P<0.01$ tibia, $P<0.01$ femur) and 12 months ($P<0.0001$ tibia, $P<0.0001$ femur). The increased trabecular volume was associated with significantly increased trabecular number, decreased trabecular separation and increased trabecular connectivity at all ages. Additionally, a significant decrease in structural model index, indicative of a more plate like trabecular structure, was noted at 3 and 12 months. Together these parameters infer increases in bone strength and this was confirmed by mechanical testing of cortical bone. Three point bending demonstrated significantly increased stiffness and increased failure load in 3 and 12 month old $GPR55^{-/-}$ mice.

Although $GPR55^{-/-}$ mice have increased bone mass and strength at 12 months relative to wildtype mice, loss of bone mass still occurs with age. No differences in osteoclast activity were observed between wildtype and $GPR55^{-/-}$ mice at 12 months as determined by measurement of plasma CTx. This likely indicates that the high bone mass phenotype is a result of increased peak bone mass attained in early months, offering protection against the effects of bone loss with age. Interestingly, plasma testosterone levels were significantly increased in $GPR55^{-/-}$ mice at 12 months (wildtype = 26 nmol/L and $GPR55^{-/-}$ = 53 nmol/L ($P<0.01$)). In line with this, epididymal sperm counts revealed a 2.2 fold increase in $GPR55^{-/-}$ mice ($P<0.05$). No changes in estradiol levels were observed. These results suggest that GPR55 may negatively regulate testosterone levels in mice and further extends the therapeutic potential of GPR55 antagonists. Together these data may have implications for understanding the value of GPR55 antagonists to preserve bone loss.

Maternal Myostatin Deficiency Improves Bone Quality of Wildtype Murine Offspring. Arin Oestreich*[1], Marcus McCray[1], William Kamp[1], Laura Schulz[1], Charlotte Phillips[2]. [1]University of Missouri, USA, [2]University of Missouri-Columbia, USA

During fetal development, changes in the uterine environment can have effects on offspring bone quality that persist throughout life; however the biochemical and molecular mechanisms involved remain unknown. Myostatin, a TGF-β family member, is a transcription factor that circulates in the serum and is well known as a negative regulator of muscle mass. Myostatin alters placental glucose transfer and is dysregulated in a model of developmental programming. Additionally, maternal myostatin deficiency increases muscle mass in offspring, but paternal myostatin deficiency does not, suggesting an intrauterine effect of myostatin. The goal of this study was to investigate whether decreased maternal myostatin levels in mice impact adult offspring bone quality. Femora of 4 month old wildtype male offspring from myostatin deficient dams were evaluated by μCT and torsional loading to failure and found to have an 18% increase in torsional ultimate strength compared to genetically identical, age-matched offspring from wildtype dams. Tensile strength, a measure of the bone material strength, was also increased by 20%, suggesting the increased whole bone strength may be due to changes in the bone material. Collagen, the main structural protein in bone, was also increased 8.95% in the offspring from myostatin deficient dams compared to those from wildtype dams, as measured by hydroxyproline content. Taken together, our results suggest that the decrease of myostatin in the maternal environment impacts the developmental programming of bone to increase bone strength and material properties of wildtype mice at 4 months of age.

Musculoskeletal effects of a 246-km ultramarathon race. Peter Pietschmann*[1], Elisabeth Weiss[2], Ursula Föger-Samwald[2], Markus Thalmann[3], Maria Tsironi[4], Katerina Skenderi[5], Katharina Kerschan-Schindl[6]. [1]Department of Pathophysiology & Allergy Research, Medical University of Vienna, Austria, [2]Department of Pathophysiology & Allergy Research, Center for Pathophysiology, Infectiology & Immunology, Medical University of Vienna, Austria, [3]Department of Cardiovascular Surgery, Hospital-Hietzing, Austria, [4]School of Nursing, University of Peloponnese, Greece, [5]Department of Nutrition & Dietetics, Harokopio University, Greece, [6]Department of Physical Medicine & Rehabilitation, Medical University of Vienna, Austria

Background: Although it is commonly accepted that regular physical exercise is beneficial for the skeleton, relatively little is known about musculoskeletal effects of extreme forms of exercise. In previous work [Bone 45 (2009) 1079-1083] we had demonstrated that a 246-km ultra-distance race ("Spartathlon") transiently suppressed bone formation and increased bone resorption. The aim of this study was to analyze effects of the Spartathlon race on novel musculoskeletal markers.

Methods: In 19 participants of the Spartathlon venous blood samples were obtained before and after the race; serum levels of myostatin (an inhibitor of myogenic differentiation), follistatin (an antagonist of myostatin) and markers/

regulators of bone (including the wnt signaling inhibitors sclerostin and dickkopf-1) were determined by ELISA.

Results: After the race a significant four-fold increase of serum follistatin levels was observed; myostatin increased by 12%. Whereas sclerostin levels were not significantly different before and after the race, dickkopf-1 levels had significantly decreased by 15%. In 9 participants also serum samples taken on the day after the race were available; interestingly, at this time point a decrement of sclerostin and dickkopf-1 levels was seen. Serum cathepsin K levels did not differ before and after the ultramarathon.

Conclusion: We speculate that the marked increase of follistatin and the decline of dickkopf-1 after a 246-km ultramarathon race reflect important anabolic signals for muscle and bone.

MO0194

The amino acid tryptophan increases skeletal muscle IGF-1 and follistatin in mice, and induces the expression of exercise-related factors. Mona El Refaey[1], Colleen Davis*[1], Phonepasong Arounleut[2], Sunil Upadhyay[1], Amy Dukes[3], Maribeth Johnson[3], William Hill[4], Carlos Isales[1], Mark Hamrick[5]. [1]Georgia Regents University, USA, [2]Georgia Regents University (formally Georgia Health Sciences University), USA, [3]Georgia Regents University, USA, [4]Georgia Regents University & Charlie Norwood VAMC, USA, [5]Georgia Health Sciences University, USA

Nutrition plays a key role in the maintenance of muscle and bone mass, and dietary protein deficiency has in particular been associated with catabolism of both muscle and bone tissue. One mechanism thought to link protein deficiency with loss of muscle mass is deficiency in specific amino acids that play a role in muscle metabolism. We tested the hypothesis that the essential amino acid tryptophan, and its metabolite kynurenine, might impact muscle metabolism in the setting of protein deficiency. Adult mice (12 mo) were fed a normal diet (18% protein), as well as diets with low protein (8%) supplemented with increasing concentrations (50, 100, and 200 uM) of kynurenine or with tryptophan (1.5 mM). Results indicate that all mice on the low protein diets weighed less than the group fed normal protein (18%) but that the tibialis anterior muscle, relative to body weight, was larger in those mice on the high kynurenine diets. ELISA assays showed significant increases in skeletal muscle IGF-1, leptin, and the myostatin antagonist follistatin with tryptophan supplementation, and the low dose of kynurenine also increased muscle-derived IGF-1. Reverse-phase protein analysis revealed that tryptophan increased activation of several factors known to be induced with exercise in skeletal muscle, including p21 which promotes myocyte terminal differentiation and stat5a, which is involved in IGF-1 and androgen signaling in skeletal muscle. Together, these findings suggest that dietary amino acids can directly impact molecular signaling in skeletal muscle, further indicating that dietary manipulation with specific amino acids could potentially attenuate muscle loss with aging or dietary protein deficiency.

MO0195

The osteogenic effects of swimming, jumping and vibration on the protection of bone quality from disuse bone loss. Mauricio Falcai[1], Ariane Zamarioli*[2], Francisco Jose de Paula[1], Graziela Leoni[3], Manoel Sousa Neto[3], Jose Batista Volpon[1]. [1]School of Medicine of Ribeirao Preto, University of Sao Paulo, Brazil, [2]University of Sao Paulo, Brazil, [3]Dental School of Ribeirao Preto, University of Sao Paulo, Brazil

Purpose: We investigated whether swimming activity associated with a three-week period of unloading could prevent the deleterious effects of disuse on the tibias of hindlimb-suspended rats. Methods: Forty-five Wistar rats were randomly divided into 5 groups: (HS) permanently hindlimb suspended rats; (HS+Swim) rats submitted to unloading interrupted by swimming exercise; (HS+WB) suspended rats with interruption for regular weight bearing for the same length of time as the HS+Swim rats; (Con) control rats; and (Con+Swim): control rats that underwent swimming exercise. Results: The HS rats exhibited a substantial loss of bone quality and uncoupled bone turnover, whence resorption was up-regulated and formation was down-regulated (HS vs Con). In tibias, we observed a significant decrease in BMD (-15%), in bone strength (-28%) and a marked deterioration in the trabecular architecture (-67% in BV/TV, -52% in TbN, -19% in TbTh and -72% in ConnD, $p<0.01$). In femurs, we found a significant reduction of -47% in the number of osteoblasts and a significant increase in bone resorption (i.e. osteoclasts number and eroded surface). We also found a significant decrease in the osteocalcin level (-17%) in the HS rats. Conversely, swimming mitigated bone quality loss induced by hypogravity in the suspended rats submitted to swimming exercise (vs HS). In tibias, swimming significantly increased in +11% the bone mass, in +23% the bone strength, in +32% trabecular thickness, in +50% bone volume and in +89% trabeculae number. In femurs, swimming caused a significant increase of +9.5% in the bone mass, +27% in the bone strength, +12% in the trabecular thickness, +16% in the trabecular volume and a significant reduction in the bone resorption. We found a significant increase of +30% in the osteocalcin serum level and +28% in the IGF-I level. The rats submitted to the suspension interrupted by periods of regular weight-bearing (HS+WB) also showed a slight improvement in bone quality when compared to the permanently suspended rats, but to a lesser degree than those submitted to periods of swimming exercise. Curiously, swimming did not increase bone health in non-osteopenic rats when compared to the control rats, leading to the hypothesis that swimming plays an important role with an osteogenic action in bones ongoing loss. Conclusions: We concluded that swimming activity was shown to be effective at preventing and even reverting the deleterious effects of unloading on the bone quality of osteopenic rats.

A Novel mimetic peptide CK2.1 that induces chondrogenesis and cartilage repair *in vivo*. Hemanth Akkiraju*[1], Jeremy Bonor[2], Padma Srinivasan[2], Catherine Kirn-Safran[1], Randall Duncan[1], Anja Nohe[1]. [1]University of Delaware, USA, [2]University of Delaware, USA

Here we demonstrated the effect of a novel mimetic peptide of Bone Morphogenetic Protein Receptor type Ia (BMPRIa) on cartilage formation and repair. Bone Morphogenetic Proteins (BMPs) are crucial for the formation of articular cartilage and are known to differentiate mesenchymal stem cells to chondrocytes that secrete its extracellular matrix (ECM). The ECM consists of proteoglycans and collagen, including collagen II, IX and XI, and form the functional framework of the articular cartilage. However, a drawback for BMP use as therapeutics is that they also initiate the differentiation of chondrocyte hypertrophy and cartilage degradation. This is evidenced by the up-regulation of collagen X and MMP-13. Recently we identified a new BMPRIa receptor interacting protein, Casein Kinase 2 (CK2). We designed blocking peptides CK2.1, CK2.2, CK2.3 that release CK2 from the BMP receptor type Ia (BMPRIa) isoform activating the downstream BMP signaling pathways in the absence of BMP2. Here we show that CK2.1 alone but not CK2.2 and CK2.3 induced chondrogenesis and the expression of collagens II and IX but not collagen X in adult bovine chondrocytes. This effect was in contrast to BMP2 stimulation which induced collagen X synthesis. Systemic injections of CK2.1 *in vivo* via the tail vein in 8 week old mice resulted in cartilage growth in comparison to controls. Furthermore, Immuno-staining of processed cartilage sections with collagen IX, X and MMP-13 revealed increased collagen IX expression among CK2.1 injected mice, while collagen X and MMP-13 expression was only increased in BMP2 injected mice. We further destabilized the medial meniscus in mice and determined the effect of peptide CK2.1 to repair the damaged cartilage. Intra-articular injections of CK2.1 conjugated to a slow release system resulted in complete regeneration of the damaged tissue. Moreover, immuno-staining of processed samples with collagen IX, X and MMP-13 resulted in the up-regulation of collagen IX synthesis in CK2.1 injected but not in the control. However, more research is required to identify the specific mechanism of CK2.1 in cartilage repair. These data suggests that CK2.1 a novel mimetic peptide could be a possible future therapeutic for cartilage growth and repair.

An Rescue Effect of Altering Subchondral Bone Architecture on the Temporomandibular Joint Cartilage Degradation Induced by an Aberrant Dental Occlusion. Yundong Liu[1], Lifan Liao[1], Kai Jiao[1], Hongyun Zhang[1], Lei Lu[1], Mian Zhang[1], Jing Zhang[1], Jianjun He[1], Yaoping Wu[2], Meiqing Wang*[1]. [1]College of Stomatology, Fourth Military Medical University, China, [2]Xijing Hospital, Fourth Military Medical University, China

Aberrant biomechanical stimulation from abnormal dental occlusion plays an important role in temporomandibular joint (TMJ) OA development. Recently, we developed a unilateral anterior crossbite (UAC) prosthesis in rats and mice and found a significant degenerative change in the TMJ cartilage and subchondral bone loss (1). Subchondral bone remodeling played an important role in the onset and development of osteoarthritis. Therefore it is conceivable to test whether UAC induced TMJ cartilage degradation could be attenuated by administration of a specific classic NF-κB pathway inhibitor and/or strontium via targeting abnormal TMJ subchondral bone resorption.Methods: 6-week-old female C57BL/6J mice were randomly divided into blank control group (withou UAC, without any injection/gavage), and five

experimental (EXP) groups which were treated with UAC and additionally: (1) Saline Group: daily gavage of 0.9% saline; (2) Control Peptide Group: intra-peritoneal injection of control peptide 5 mg/Kg, 1 time/2d; (3) $SrCl_2$ Group: daily gavage of $SrCl_2$, 4 mmol/Kg; (4) NBD Peptide Group: intra-peritoneal injection of NBD peptide, 5 mg/Kg, 1 time/2d; (5) $SrCl_2$ + NBD Peptide Group: combination of daily gavage of $SrCl_2$, 4 mmol/Kg and intra-peritoneal injection of NBD peptide, 5 mg/Kg, 1 time/2d. All UAC additional treatment were appied from day 7 to day 21. The TMJs were sampled and analized 3 weeks after installing of UAC by histomophormetry, histochemistry, real-time PCR, and immunohistochemistry assays.

Results: Thinner and degraded cartilage, reduced cartilage cellular density, decreased expression levels of Collagen II and Aggrecan and increased ADAMTS-5, TNF-α/IL1-β/NFIKBA and NF-κB p-p65, loss of subchondral bone and enhanced osteoclast activity with decreases in OPG/RANKL ratio both in condylar cartilage and subchondral bone were observed in mouse TMJs of Saline Group, Control Peptide Group. However, a mild change were found in mouse TMJs of $SrCl_2$ Group, NBD Peptide Group and $SrCl_2$ + NBD Peptide Group.

Conclusions: The present UAC induced TMJ cartilage degradation could be attenuated via administration of a specific classic NF-κB pathway inhibitor and/or strontium targeting abnormal TMJ subchondral bone resorption, suggesting that inhibiting pathological subchondral bone resorption would be theraputically significant for occlusal original TMJ OA.

Characterization of Monosodium Iodoacetate Induced Osteoarthritis in Rat Knee, Including Tibiofemoral and Patellofemoral Joints. Zhiqi Peng*[1], Jukka Vääräniemi[2], Katja Fagerlund[1], Jukka Rissanen[1], Jenni Bernoulli[2], Jussi Halleen[3], Jukka Morko[1]. [1]Pharmatest Services Ltd, Finland, [2]Pharmatest Services Ltd, Finland, [3]Pharmatest Services Ltd, Fin

Monosodium iodoacetate (MIA) injection in rat knee induces osteoarthritis (OA) symptoms and is used as a preclinical model of OA. Most data of MIA-induced damage in rat knee has been obtained from tibiofemoral joint and not much information is available from patellofemoral junction. In this study, we characterized the effects of intra-articular MIA on entire rat knee, including both tibiofemoral and patellofemoral joints. One mg of MIA was injected into the knee of male Lewis rats in 50 μl of saline. Static mechanical allodynia was used for determining OA-related pain and measured as paw withdrawal threshold. The pain was detected in MIA-injected hind limbs after the injection and continued for 4 weeks until the end of the experiment. X-ray analysis indicated that bone mineral density was decreased in the metaphysis of distal femur and proximal tibia in MIA-injected hind limbs when compared with healthy control limbs. The density of subchondral bone was also decreased in the patella and femoral condyle of MIA-injected knees, whereas their patellofemoral joint space exhibited higher intensity than was observed in the x-rays of control limbs. Histology revealed that eroded or degraded cartilage fragments were distributed in the patellofemoral joint space of MIA-injected knees and that articular cartilage was completely lost at some sites of their patella and femoral condyle. Histological changes were less severe in the tibiofemoral joint, including mainly the loss of proteoglycans in entire articular cartilage and destroyed chondrocytes and collagen matrix in the superficial layer of articular cartilage in the tibial plateau of MIA-injected knees. Double fluorescence labeling demonstrated an endochondral ossification under articular cartilage both in the tibiofemoral and patellofemoral joints of control knees. The endochondral ossification was impaired in the tibiofemoral joint and totally ceased in the patellofemoral joint of MIA-injected knees. When comparing the effects of the same acidic state of the environment on both joints of the knee, the patellofemoral joint exhibited much stronger damage than the tibiofemoral joint. Probably, also the patellofemoral joint plays a substantial role in inducing symptomatic OA pain. This study suggests that the patellofemoral joint should not be ignored when studying the preclinical efficacy of disease modifying OA drugs in the rat MIA model.

Chondroprotective Effects of Salubrinal in a Mouse Model of Osteoarthritis. Kazunori Hamamura*[1], Akinobu Nishimura[1], Akihiro Sudo[2], Hiroki Yokota[3]. [1]Indiana University Purdue University Indianapolis, USA, [2]Mie University Graduate School of Medicine, Japan, [3]Indiana University Purdue University Indianapolis, USA

Salubrinal is a synthetic chemical agent that elevates phosphorylation of eukaryotic translation initiation factor 2 alpha (eIF2α) and alleviates stress on the endoplasmic reticulum. Previously, we reported that in chondrocytes salubrinal attenuates expression and activity of matrix metalloproteinase 13 (MMP13) through downregulation of p38 MAPK and NFkB signaling. In this study, we determined whether administration of salubrinal prevents degradation of articular cartilage in a mouse model of osteoarthritis (OA). We hypothesized that progression of OA is reduced by salubrinal through downregulation of inflammatory responses and activities of proteolytic enzymes including MMP13. In order to test this hypothesis, OA was surgically induced in the left knee of C57/BL6 female mice (approximately nine weeks old) by transecting the medial collateral ligament and removing the medial meniscus. Three animal groups were age-match control, OA placebo, and OA treated with salubrinal. Three days after the induction of OA, administration of salubrinal (1.5 mg/kg) was conducted daily into an intra-articular space of the left knee of the OA salubrinal group, while a solvent for salubrinal (49.5% PEG 400 and 0.5% Tween 80 in PBS) was injected to the OA placebo group. In 3 weeks (N = 6) and 6 weeks (N = 5-8) after the induction of OA, femora and tibiae were isolated and stained with Safranin O. OA progression was quantitatively evaluated based on the scoring system previously reported by Glasson et al. (Grade 0, 0.5, 1, 2, 3, 4, 5, or 6), and data were expressed as mean ± SD. For comparisons among multiple samples, ANOVA followed by post hoc tests was conducted. The results revealed that injection of salubrinal decreased the progression of OA for samples harvested both in 3 and 6 weeks. In particular, compared to the OA placebo group the statistically significant attenuation of OA progression was observed in the 3-week femur samples (3.8 ± 1.2 for placebo and 2.5 ± 0.5 for salubrinal; $p = 0.016$) and 6-week tibia samples (5.3 ± 0.7 for placebo and 3.7 ± 1.8 for salubrinal; $p = 0.041$). The results demonstrate that administration of salubrinal has chondroprotective effects in arthritic joints, and that salubrinal can be considered as a potential agent for alleviating OA symptoms.

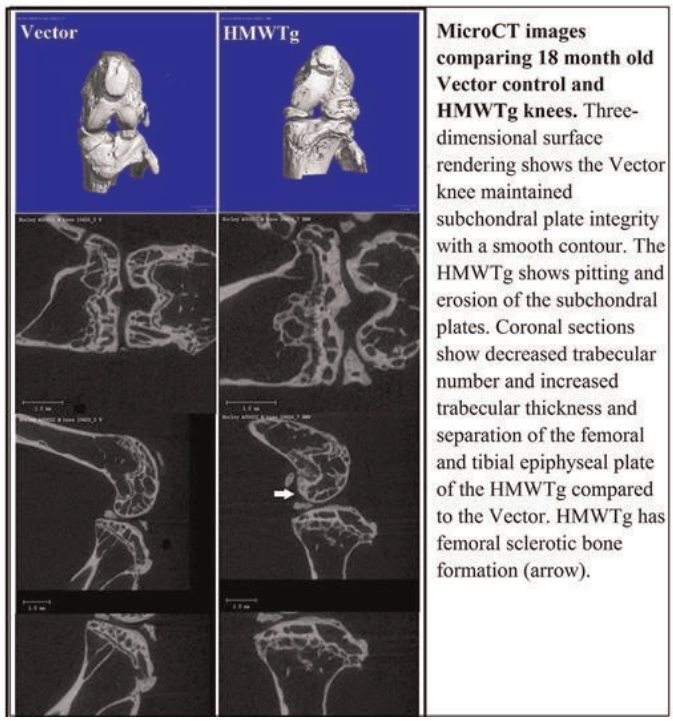
Osteoarthritis in Mice Overexpressing High Molecular Isoforms of FGF2. Patience Meo Burt*[1], Liping Xiao[1], Caroline Dealy[2], Marja Marie Hurley[3]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut Health Center, USA, [3]University of Connecticut Health Center School of Medicine, USA

Osteoarthritis (OA) is a debilitating joint disease that affects over 27 million adults in the U.S., characterized by the loss of articular cartilage and changes in underlying bone. Currently, there is no permanent treatment for OA and a better understanding of the molecular mechanisms that lead to cartilage degradation will be useful in identifying therapeutic targets to help treat the disease. Patients with X-linked hypophosphatemic rickets (XLH) have increased fibroblast growth factor 23 (FGF23) in bone which results in hypophosphatemia, osteomalacia and osteoarthropathy, leading to problems associated with degenerative joint disease. Thus, FGF23 may play a role in OA development. We have developed novel transgenic mice overexpressing nuclear high molecular weight (HMW) isoforms of fibroblast growth factor 2 (HMWTg) in pre-osteoblasts. These mice phenocopy XLH since they have rickets/osteomalacia, hypophosphatemia, and increased FGF23 in serum and bone. We therefore hypothesized that mice overexpressing FGF2 HMW isoforms, in which FGF23 is increased, will develop more severe OA signs than Vector control mice at 18 months of age. To asses for signs of OA, the knee joints from 18 month old HMWTg and Vector male mice were collected. Digital x-ray imaging and microCT analysis were performed to visualize changes in bone. To determine articular cartilage integrity, histological analysis of proteoglycan expression by Safranin-O staining was performed. Immunohistochemistry was used to establish the expression of OA markers, such as metalloproteinases MMP-13 and ADAMTS-5, which are typically increased during joint degeneration. Examination of the knees revealed that HMWTg mice had increased osteophyte formation and subchondral thickening, compared to Vector mice, as indicated by x-ray images. MicroCT analysis of HMWTg revealed that trabecular number in the tibia and femur was decreased, whereas, trabecular thickness and separation were increased while subchondral sclerotic bone was observed. By immunohistochemistry, Safranin-O staining was decreased and metalloproteinase labeling was increased in the knee joint cartilage of HMWTg mice compared to the Vector. These changes imply that the osteoarthritic phenotype is more severe in HMWTg mice. Overall, these results suggest that overexpression of HMWFGF2 leads to signs of severe OA and offers insight into a molecular mechanism that causes the disease, while being a potential therapeutic target to treat it.



MicroCT images comparing 18 month old Vector control and HMWTg knees. Three-dimensional surface rendering shows the Vector knee maintained subchondral plate integrity with a smooth contour. The HMWTg shows pitting and erosion of the subchondral plates. Coronal sections show decreased trabecular number and increased trabecular thickness and separation of the femoral and tibial epiphyseal plate of the HMWTg compared to the Vector. HMWTg has femoral sclerotic bone formation (arrow).

Bone Marrow Lesions Are Characterized by Increased Bone Turnover and Increased Vascularity. Maziar Shabestari*[1], Erik Fink Eriksen[2], Janne Reseland[1], Jarle Vik[3]. [1]University of Oslo, Norway, [2]Oslo University Hospital, Norway, [3]Martina Hansens Hospital, Norway

Bone Marrow Lesions (BMLs), previously denoted Bone Marrow Edema, are detected as water signals on MR scans (low intensity on T1 weighted images and high intensity on T2 weighted scans). Previous histologic studies were unable to demonstrate any edematous changes at the tissue level, which led us to hypothesize that the water signal stems from increased vascularization accompanying a high turnover state in bone. To test this hypothesis we performed tetracycline labeling in addition to T1-weighted and STIR MR scans of 28 patients planned for total hip replacement surgery. Among 14 femoral heads studied so far, 8 revealed BMLs on MR, while 6 were negative. The latter acted as controls in the analysis. On the femoral heads we took out cylindrical biopsies guided by the MR images taken in two perpendicular planes. These biopsies were stored in 70% alcohol prior embedding in methyl methacrylate. Subsequently 7 um sections were prepared and subjected to histomorphometric analysis of the cancellous bone envelope using commercially-available software (BioQuant Osteo). We chose to focus on mineralizing surface (MS/BS) and vascular area (sinusoids + blood vessels), but also evaluated mineral apposition rate (MAR), bone formation rate (BFR/BS), bone volume (BV/TV) and trabecular thickness (Tb.Th).

The analysis revealed that compared to controls bone tissue from patients with BMLs exhibited increased bone turnover: MS/BS (median (95% Confidence interval)) 8.1% (3.41 – 33.29) vs 0.3% (0.06 – 1.64) ($p< 0.0007$) and increased vascular area 0.29 mm2 (0.17 – 1.14) vs 0.03 mm2 (0.004 – 0.16) ($p< 0.03$). None of the other variables of interest were different between the two groups.

In conclusion, this study confirms that Bone Marrow Lesions are characterized by increased bone turnover and increased vascularity in keeping with it being a reparatory process. Thus, the water signal, which is the hallmark of BMLs on MR, is most probably reflecting increased tissue vascularity accompanying increased remodeling activity.

Correlates of Knee Bone Marrow Lesions in Younger Adults. Benny Samuel Eathakkattu Antony*[1], Graeme Jones[2], Alison Venn[3], Lyn March[4], Leigh Blizzard[3], Andrew Halliday[5], Terence Dwyer[6], Flavia Cicuttini[7], Changhai Ding[3]. [1]Menzies Research Institute Tasmania, University of Tasmania, Australia, Australia, [2]Menzies Research Institute, Australia, [3]Menzies Research Institute Tasmania, University of Tasmania, Australia, [4]Institute of Bone & Joint Research, University of Sydney, Australia, [5]Department of Radiology, Royal Hobart Hospital, Australia, [6]Murdoch Childrens Research Institute, Australia, [7]Department of Epidemiology & Preventive Medicine, Monash University, Australia

Purpose: Bone marrow lesions (BMLs) of the knee joint are a key player in osteoarthritis of the knee. However, little is known of their determinants, especially in young adults . The aim of this study was to examine the structural and functional correlates of BMLs in younger adults including physical activity and to determine whether bone mass, cholesterol and hormones measured 5 years prior are associated with current BMLs.

Methods: Subjects broadly representative of the Australian population (n=330, aged 31-41 years, female 48.7%) were selected from the Childhood Determinants of Adult Health study. They underwent T1 and T2-weighted fat- supressed magnetic resonance imaging in their knee. BMLs, cartilage defects, meniscal tears and cartilage volume were measured. Knee pain was assessed by self-administered Western Ontario and McMasters osteoarthritis index (WOMAC) questionnaire. Physical activity was measured by IPAQ questionnaires at the time of MRI. Heel bone mass, lipids and hormone levels (in females) were assessed 5 years prior.

Results: The prevalence of any BMLs in the knee joint was 17%. Cross-sectionally, any BML in the knee was associated with age (PR: 1.09, 95% CI: 1.00, 1.19), previous knee injury (medial tibiofemoral BMLs PR: 2.20, 95% CI: 1.03, 4.71) and total WOMAC knee pain (PR: 1.05, 95% CI: 1.02, 1.09). BMLs were associated with other structural abnormalities such as total knee cartilage defects (PR: 2.65, 95% CI: 1.47, 4.80) and total meniscal tears (PR: 1.70, 95% CI: 0.99, 2.94).

High Density Lipoprotein (HDL) cholesterol measured 5 years prior was negatively associated with any BML (PR: 0.36, 95% CI: 0.15, 0.87). Testosterone measured 5 years prior in females (PR: 0.99, 95% CI: 0.99, 1.00) and speed of sound (bone mass) (PR: 0.98, 95% CI: 0.97, 0.99) were negatively associated with femoral BMLs. Moderate physical activity was protective (PR: 0.93, 95% CI: 0.87, 0.99) while vigorous activity showed a deleterious trend (PR: 1.01, 95% CI: 1.00, 1.02) with BMLs as we reported in older and middle aged adults. All these models were adjusted for age, gender, BMI, duration of follow-up and injury.

Conclusions: BMLs in young adults are associated with increased knee symptoms, a history of injury and other knee structural lesions. Moderate physical activity (not vigorous) may be protective with BML. A higher bone mass and HDL cholesterol in both sexes and testosterone in women may be protective with the devolpment of BMLs in young adults.

MO0204

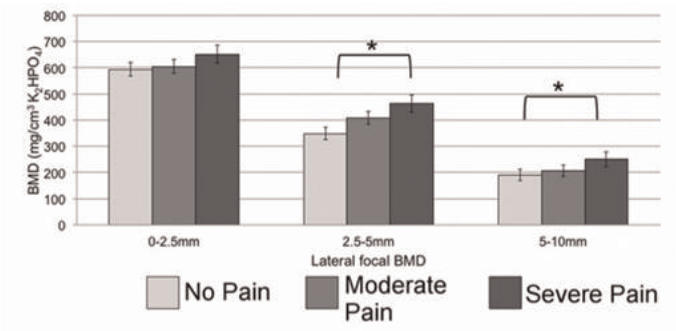
Knee osteoarthritis patients with severe pain while lying down have higher local subchondral tibial bone mineral density. Wadena Burnett*[1], Saija Kontulainen[1], Christine McLennan[2], Diane Hazel[3], Carl Talmo[3], David Hunter[4], David Wilson[5], James Johnston[1]. [1]University of Saskatchewan, Canada, [2]Hebrew SeniorLife, USA, [3]New England Baptist Hospital, USA, [4]University of Sydney, Australia, [5]University of British Columbia, Canada

Introduction: Knee osteoarthritis (OA) is a painful and debilitating joint disease. Knee pain while lying down is of particular concern to patients as it disturbs sleep and quality of life. The subchondral bone is innervated and could be of particular importance in OA-related pain. The objective of this study was to investigate associations between proximal tibial subchondral bone mineral density (BMD mg/cm^3) and pain while lying down in patients with OA.

Methods: The preoperative knee of 42 knee arthroplasty patients was scanned using quantitative computed tomography (QCT). Pain was measured using the Western Ontario and McMaster Universities Arthritis Index (WOMAC) and participants were categorized into three groups: 'no pain', 'moderate pain', and 'severe pain' while lying down. We assessed tibial subchondral BMD at normalized depths of 0-2.5mm, 2.5–5mm and 5-10mm relative to the subchondral surface. Regional analyses of each medial and lateral plateau included total BMD and maximum BMD within a 10mm diameter 'focal' region of interest. The association between WOMAC pain scores and BMD measurements was assessed using Spearman's rank correlation. Regional BMD was compared pairwise between pain and no pain groups using multivariate analysis of covariance with age, sex, and BMI as covariates and Bonferoni adjustment for multiple comparisons.

Results: Lateral focal BMD at the 2.5-5mm depth was related to pain while lying down (ρ=0.388, p=0.011). Lateral focal BMD was 33% higher in participants with 'severe pain' than participants with 'no pain' at the 2.5-5mm depth (adjusted mean difference: 114mg/cm^3; 95%CI: 9.6 to 218mg/cm^3; p=0.028) and 32% higher at the 5-10mm depth (adjusted mean difference: 60mg/cm^3; 95% CI: 0.3 to 120mg/cm^3; p=0.049) (Figure 1). There were no lateral BMD differences at 0-2.5mm from the subchondral surface and no medial BMD differences across all depths.

Conclusion: Higher lateral focal BMD was found in patients with 'severe pain' while lying down compared to patients with 'no pain' at depths of 2.5-5mm and 5-10mm from the tibial subchondral surface. This alteration in lateral plateau BMD may be due to patient self-adjustment in gait or alignment, where actively shifting loading from medial to lateral tibial plateau may help alleviate pain, but may result in higher local lateral BMD at deeper regions from the subchondral surface. This study suggests that local subchondral bone density may have a role in OA-related pain pathogenesis.



Adjusted mean lateral focal BMD of each pain group at three depths from subchondral surface.

MO0205

Structure of Femoral Neck in Hip Osteoarthritis: Texture Analysis Improvement in Cortical Evaluation. Gustavo Davi Rabelo[1], Jean-Paul Roux*[2], Nathalie Portero-Muzy[1], Stephanie Boutroy[3], Roland Chapurlat[4], Pascale Chavassieux[5]. [1]INSERM UMR1033, Université de Lyon, France, [2]INSERM, UMR 1033, Université de Lyon, France, [3]INSERM U1033 & Université de Lyon, France, [4]E. Herriot Hospital, France, [5]INSERM UMR1033, Université De Lyon, France

Cortical porosity (Ct.Po) and cortical thickness (Ct.Th) contribute to the cortical bone strength. When compared to osteoporosis, femoral neck (FN) in hip osteoarthritis (OA) is characterized by thicker cortices, that may contribute to the reduced fracture risk (Blain et al, 2008), with the highest Ct.Th and the lowest Ct.Po in the inferior part, when compared with upperquadrants (Boutroy et al, 2011). However, the isotropic pixel size being 82 µm in the computed tomography images, the smallest cortical bone channels could not been taken into account. The aim of this study was to analyze additional 3D characteristics of the cortices in FN in hip OA and evaluate topological distribution of bone elements in each quadrant.

FN samples were obtained during arthroplasty for hip OA in 18 postmenopausal women (mean age 66±8 yrs). 3D measurements of the bone cortices were assessed from HR-pQCT (Xtreme CT, Scanco Medical) and analyzed by computational routines using Ctan software (Skyscan, Belgium) and Fraclac running in ImageJ (NIH, USA) in the four FN quadrants (Inferior, Superior, Anterior and Posterior). Classical analyses were performed with thresholded methods from binary images to obtain Ct.Th and its heterogeneity (Ct.ThSD), Ct.Po and Fractal Dimension (Ct.FDbin). In addition, texture analysis using unthresholded methods was applied to measure Fractal Dimension (Ct.FDgray) and Lacunarity (Ct.Lac) from gray-scale images.

When compared to the upperquadrants, the inferior quadrants was characterized by a higher and more heterogeneous Ct.Th (Ct.Th $p<0.0001$, Ct.ThSD $p<0.0001$), with a lower Ct.Po ($p<0.0001$). These data were confirmed by higher Ct.FDbin ($p<0.0001$) and Ct.FDgray ($p<0.0001$) and a lower Ct.Lac ($p<0.0009$). There was a significant correlation between Ct.FDbin and Ct.Th ($p<0.001$, $r=0.73$) and Ct.Po ($p<0.009$, $r=-0.60$).

In conclusion, in hip OA, besides a greater thickness and lower porosity, the cortex of the inferior quadrants presents with higher complexity of structure as shown by the Fractal dimension, with more topological homogeneity as shown by the lacunarity in relation to the distribution of bone channels.

The comparison study of quality of sleep(QOS) in rheumatoid arthritis and osteoarthritis. Sang-Hyon Kim*[1], Sang-Il Lee[2]. [1]Chief of Rheumatology, South Korea, [2]M.D., South Korea

Introduction: Patients with musculoskeletal disorders such as rheumatoid arthritis (RA) and Osteoarthritis (OA) suffer from insomnia and other sleep disturbance. However, in the previous study, there was lesser data about comparison of quality of sleep (QOS) in RA and OA. In this study, we aimed to assess (1) the impact of RA on QOS comparing with that of OA patients and control subjects and (2) the impact of these two musculoskeletal disorders on various components of QOS using PSQI (Pittsburgh sleep quality index) Survey. Methods: Ninety three patients with RA, 38 patients with OA, and 126 voluntary control subjects were included in the study. The groups were comparable in terms of demographic characteristics. QOS was evaluated by using PSQI Health survey in all study participants. ESR (Erythrocyte Sedimentation Rate) and CRP (C-Reactive Protein), which is a specific inflammatory marker for RA, was used in RA patients, and McGill Pain Questionnaire be used to evaluate experiencing significant pain in RA and OA. Results: Sleep disturbance, use of sleeping medication, daytime dysfunction score were higher in OA than RA patients and control subjects ($p<0.05$). The between-groups comparisons revealed that RA patients had significantly higher sleep duration scores than OA patients ($0.95\pm$ 1.06 vs $0.61\pm$ 1.05, respectively), ($p<0.05$). The CRP level correlated with PSQI score ($p<0.05$). The parameters of McGill Pain score, sensory pain, affective pain, and VAS score had significantly higher in OA than RA patients ($p<0.05$). Especially, all parameter of McGill Pain score correlated significantly with PSQI score in RA ($p<0.01$), and only sensory pain related to PSQI score in OA ($p<0.05$). Conclusion: Taken together, we need a slightly different approach on evaluating the patients with arthritis suffer from sleep disturbance, either RA or OA. And the CRP level associated with QOS in RA patients.

Connexin45 is Involved in Cancellous but not Cortical Bone Homeostasis. Marcus Watkins*[1], Susan Grimston[1], Bing Wang[2], Xiaowen Zhang[2], Roberto Civitelli[1]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University in St. Louis School of Medicine, USA

Intercellular communication via gap junctions is an important method of coordinating cellular processes. Gap junctions are composed of connexin hexamers that allow passage of small molecules between cells. The biophysical properties of these transcellular channels are dictated by the connexin that forms the gap junction. We and others have previously shown that genetic ablation of connexin43 (Cx43) – the most abundant gap junction protein present in bone – specifically in osteoblasts alters cortical modeling via modulation of both osteoblast and osteoclast activity. Connexin45 (Cx45) is less abundantly expressed in bone cells; and unlike Cx43, whose abundance increases during osteoblast differentiation; Cx45 expression remains relatively stable as osteoblasts differentiate. To examine the role of Cx45 in bone we have induced a conditional deletion of its gene (*Gjc1*) in osteo-chondroprogenitor, using Cre recombinase driven by the *Twist2* (*Tw2*) promoter. $Gjc1^{fl/fl}::Tw2\text{-}Cre$ (cKO) mice were recovered at the expected Mendelian frequency and showed no overt phenotype. Examination of femurs from 2-month-old cKO and control ($Gjc1^{fl/fl}$) mice by µCT revealed an unexpected $60\pm12\%$ ($p<0.05$) increase in trabecular bone volume/tissue volume. This was associated with $20\pm6\%$($p<0.05$) increase in trabecular number and $15\pm7\%$ ($p=0.06$) decrease in trabecular spacing. Cancellous bone mineral density was also increased in cKO mice ($24\pm10\%$) compared to control littermates. By contrast, no significant changes were observed in cortical parameters. Results were consistent among genders. *In vitro* analysis of bone marrow stromal cells (BMSC) using colony forming unit (CFU) assays revealed no change in CFU-fibroblast, CFU-osteoblast nor CFU-adipocyte; thus excluding an abnormality at earlier steps of the osteogenic differentiation program. Thus, Cx45 is involved in cancellous bone homeostasis, whereas Cx43 primarily controls cortical bone modeling. Surprisingly, the function of Cx45 appears to be opposite to Cx43 in modulating skeletal homeostasis.

MO0208

Osterix Has a Critical Role in BMP2-induced Cx43 Promoter Activity in vitro. Dong Jin Chung*[1], Dong Hyeok Cho[2], Jin Ook Chung[2], Min Young Chung[2], Kwang Youl Lee[3]. [1]Chonnam National University Medical School, South Korea, [2]Chonnam National University Medical School, South Korea, [3]College of Pharmacy, Chonnam National University, South Korea

Osterix is a transcription factor specifically expressed by osteoblasts and is important for osteoblast differentiation. Although Osterix has been shown to be induced by BMP2, the molecular basis of the regulation, expression and function during osteoblast differentiation are not fully understood. Connexin43 (Cx43) is a major gap junction (GJ) protein in bone and plays a critical role in osteoblast differentiation. Recessive or dominant disruption of connexin43 function results in osteoblast dysfunction and abnormal expression of osteoblast genes. However, little is known about the functional interactions between Osterix and the Cx43 promoter. Previously, we showed that aminobisphosphonates as well as the pro-osteogenic transcription factors, Runx2, Osterix or Dlx5, increased transcriptional activity of the Cx43 promoter. In this study, we investigated further the relationship between Osterix and Cx43 using the cell lines HEK 293 and C2C12. Osterix increased transcriptional activity of the Cx43 promoter in a dose-dependent manner with peak of 4 and 5 folds in HEK 293 and C2C12 cell lines, respectively. Western blot analysis confirmed that Osterix increased protein expression of Cx43 in a similar pattern. Mutagenesis and chromatin immunoprecipiation assay also showed similar results. These results suggest that Osterix has a critical role in increase in BMP2-induced Cx43 promoter activity.

Pyk2 Isoforms in Osteoblasts: Mechanism of Regulation by Phosphorylation, Translocation, and Pin1 Activity. Pierre Eleniste*, Angela Bruzzaniti. Indiana University School of Dentistry, USA

Deletion of the protein tyrosine kinase Pyk2 in mice results in high bone mass. We previously demonstrated that Pyk2 and the shorter Pyk2-S isoform are highly expressed in osteoblasts (OBs), with Pyk2 mRNA expression declining during OB differentiation, while Pyk2-S mRNA levels increase with time. In addition, deletion of both Pyk2 isoforms promotes OB bone formation. Tyrosine Y402 phosphorylation is important for Pyk2 kinase activity, whereas serine phosphorylation may control subcellular localization. In the current study, we examined the mechanism action of Pyk2 and Pyk2-S by examining tyrosine (pTyr) and serine phosphorylation (pSer), subcellular localization and the activation of OB signaling pathways. Pyk2 and Pyk2-S were transiently expressed in MC3T3-E1 cells, which lack endogenous Pyk2. The pY402 and pSer levels of Pyk2-S were significantly higher than Pyk2 under basal conditions. We also found that the prolyl isomerase Pin1 formed a protein complex with Pyk2 and PyK2-S. Juglone, a Pin1 inhibitor, increased pY402 levels in Pyk2 to a greater extent than Pyk2-S. In contrast, juglone increased the pSer level of Pyk2-S to a much greater extent than Pyk2. Subcellular protein fractionation revealed that Pyk2 is most abundant in the cytoskeleton fraction, followed by the nucleus, membrane and cytosol. Although Pyk2-S was localized mostly in the cytosol under basal conditions, juglone led to the translocation of Pyk2-S to the cytoskeleton. We also examined the effect of Pyk2 and Pyk2-S expression on OB signaling. Western blotting revealed that Pyk2 activated the Notch1 signaling pathway, leading to increased levels of cleaved Notch1. In contrast, Pyk2-S led to the activation of ERK and b-catenin pathways in OBs. Collectively, our studies reveal isoform-specific differences in Pyk2/Pyk2-S phosphorylation, localization and signaling in OBs. Further, Pin1 plays an important role in regulating both the serine phosphorylation and intracellular translocation of Pyk2-S. Serine or tyrosine phosphorylation of the Pyk2 isoforms may also contribute to the activation of specific OB signaling pathways.

MO0210

Adiponectin Enhances Fracture Repair. Liping Wang*[1], Theresa M. Roth[2], Robert Nissenson[3]. [1]VA Medical Center, San Francisco, USA, [2]Endocrine Unit, VA Medical Center, USA, [3]VA Medical Center & University of California, San Francisco, USA

Adiponectin (APN) is the most abundant adipokine secreted from adipose tissue. Clinical studies have shown an inverse relationship between circulating APN levels and total body bone mineral density in humans. Circulating APN is also positively associated with fracture (FX) risk, suggesting a role for APN as a negative regulator of bone mass and strength. However, the influence of APN on FX healing is not known. To investigate this, fracture studies were carried out on male mice with adipocyte-specific overexpression of APN (AdTg) compared with wild type male littermate controls (WT). Four month old mice were subjected to FX at the mid-shaft of the right tibia by three point bending. The analysis of the healing process was carried out using μCT 28 days post FX. AdTg displayed a 59% increase in callus bone fractional volume (BV/TV) (WT vs. AdTg: 28.62 ± 1.45 vs. $45.50 \pm 2.82\%$, $p<0.01$), a 31.9% increase in trabecular thickness (Tb.Th) (WT vs. AdTg: 67.17 ± 2.09 vs. $88.63 \pm 3.99\mu m$, $p<0.01$), and a 31.6% decrease in total callus volume (TV) (WT vs. AdTg: 3.68 ± 0.34 vs. $2.52 \pm 0.40 mm^3$, $p<0.05$). To determine the effects of APN on bone structure and bone formation within the callus, we performed histomorphometry and found that APN over-expression resulted in significantly increased callus BV/TV by 73.8% (WT vs. AdTg: 20.99 ± 3.10 vs. $36.49 \pm 2.14\%$, $p<0.01$), Tb.Th by 49.3% (WT vs. AdTg: 13.15 ± 0.41 vs. 19.63 ± 3.54 μm, $p<0.05$), mineral appositional rate by 43.1% (WT vs. AdTg: 1.19 ± 0.16 vs. 1.71 ± 0.13 μm/d, $p<0.05$), and bone formation rate by 153.7% (WT vs. AdTg: 0.07 ± 0.01 vs. 0.19 ± 0.05 $\mu m^3/\mu m^2$/day, $p<0.05$). Finally, we assessed markers of the osteogenic process by quantitative real time PCR of callus RNA samples at 10 and 28 days after FX. AdTg mice displayed increased expression of the endothelial markers, Tie2 (1.98-fold) and VEGFD (3.0-fold) at 10 days after FX and, at day 28 post FX, increased expression of osterix (1.86-fold) and osteocalcin (2.13-fold), and decreased expression of PPARγ (0.8-fold). Taken together, our results demonstrate that over-expressed endogenous APN produces a positive effect on FX healing by stimulating the function of osteoblasts and callus remodeling. These results raise the possibility that APN or small molecule APN mimetics currently in development for treatment of type 2 diabetes might be effective in promoting FX repair.

Autophagy is the major catabolic process of eukaryotic cells that degrades and recycles damaged macromolecules and organelles. During this process, the cytoplasmic material targeted to degradation is delivered to lysosomes upon sequestration within double-membraned vesicles called autophagosomes. Autophagosomes and their contents are cleared upon fusing with late endosomes or lysosomes, and products of these catabolic reactions can then re-enter anabolic and/or bioenergetic metabolisms. Autophagy occurs at low level in all cells to ensure the homeostatic turnover of long-lived proteins and organelles and is upregulated under stressfull conditions.

In the present work, we analyzed the role of autophagy in osteoblasts (OB). We first show that the autophagic process is induced in OB during mineralization. Then, using knockdown of autophagy-essential genes and OB-specific autophagy-deficient mice, we demonstrate that autophagy deficiency reduces mineralization capacity. Moreover, our data suggest that autophagic vacuoles are used as vehicles in OB to secrete hydroxyapatite crystals. In addition, autophagy-deficient OB exhibit increased oxidative stress and receptor activator of NF-kB (RANKL) secretion, favoring generation of osteoclasts (OC), the cells specialized in bone resorption. In vivo, we observed a 50% reduction in trabecular bone mass in OB-specific autophagy-deficient mice.

Taken together, our results show for the first time that autophagy in OB is involved both in the mineralization process and in bone homeostasis. These findings are of importance for mineralized tissues which extends from corals to vertebrates and uncovers new therapeutics targets for calcified tissue related metabolic pathologies such as osteoporosis.

ECE1 Dependent Endothelin Signaling Regulates the Production of IGF-1, the WNT Signaling Inhibitors Sclerostin and DKK1, and is Critical for Osteogenesis. Michael Johnson*[1], Jasmin Kristianto[2], Baozhi Yuan[1], Everett Smith[1], Luisa Meyer[3], Caitlin Collins[4], Heidi Ploeg[4], Robert Blank[5]. [1]University of Wisconsin, USA, [2]University of Wisconsin–Madison, USA, [3]University of Wisconsin - Madison, USA, [4]University of Wisconsin, USA, [5]Medical College of Wisconsin, USA

Osteoblasts produce, process, and respond to endothelin 1 (ET1), expressing all the proteins required for autocrine ET1 signaling to occur. Previously we demonstrated that exogenous big endothelin (big ET1), increases mineralization by TMOb osteoblasts and acts through increasing production of IGF-1 and decreasing the production of the WNT signaling inhibitors DKK-1 and sclerostin (SOST). Furthermore, the effects of big ET1 supplementation could be blocked by inhibiting endothelin converting enzyme 1 (ECE1) or the ET A type receptor (EDNRA). Earlier studies on the effect of ET1 on bone were done in the context excess ET1 and pathology. It remains unknown whether deficits in ET1 signaling have an impact on bone. To determine the role of ET1 signaling in normal bone physiology we blocked ENDRA and ECE1 using BQ-123 and phosphoramidon, respectively. In both cases, we saw decreased mineralization ($p<0.05$). Concordantly, these treatments also decreased production of IGF-1 ($p<0.001$). While inhibition of EDNRA produced the expected increases of DKK1 and SOST, inhibition of ECE1 either pharmacologically or by transfection with ECE1 specific siRNA led to decreases of both DKK-1 and SOST. In human bone cores exposed to exogenous big ET1, we saw a similar molecular footprint with increased IGF-1 ($p<0.001$), decreased SOST ($p<0.008$) and a trend toward decreased DKK1. These data indicate that ET1 signaling contributes to osteoblasts' developmental program. In addition, they suggest that ECE1 may have additional substrates whose actions are mediated by non-ET1 signaling pathways. Identifying these pathways will require further investigation.

Evidence that adiponectin negatively regulates skeletal homeostasis by direct panacrine effects on osteoblasts. Linh Ho*[1], Marcia J Abbott[2], Dylan O'Carroll[3], Liping Wang[3], Theresa Roth[4], Robert Nissenson[5]. [1]UCSF, USA, [2]SFSU, USA, [3]SF VAMC, USA, [4]SF VAMC, USA, [5]VA Medical Center & University of California, San Francisco, USA

Adiponectin is a regulator of skeletal homeostasis with an inverse correlation between circulating adiponectin levels and BMD. Whether adiponectin systemically regulates bone formation and skeletal homeostasis or these skeletal effects are direct on osteoblasts and site-specific due to local production of the adipokine by marrow adipocytes have yet to be fully understood. To address these issues, we use FVB/N adiponectin transgenic mouse model in which secretion of endogenous adiponectin is increased by adipocytes (AdTg), kindly provided by Philipp Scherer, U. Texas Southwestern Medical School. We found that adiponectin exerts its negative effects on skeletal homeostasis by local regulation and this effect may involve the Beta catenin/ PPARγ signaling axis. Tissue volume (TV) and bone volume (BV) by uCT was significantly lower in female distal femurs in AdTg mice ($P<0.05$). The cancellous TV, BV, and BV/TV at the proximal tibia was significantly lower in AdTg females ($P<0.05$). Proximal tibia in female AdTg mice by dynamic histomorphometry displayed a decrease in mineral apposition rate and bone formation rates at the proximal tibia ($P<0.05$). Cortical thickness was significantly smaller at both the mid shaft of the femur and tibia in female AdTg mice compared to WT ($P<0.05$). In female AdTg mice cortical thickness at the TFJ was significantly smaller than in WT ($P<0.05$). Static histomorphometry analysis revealed a decrease in osteoclast surface in the proximal tibia of female AdTg mice ($P<0.05$). AdTg female mice exhibited increased number of adipocytes in the proximal tibia compared to WT. Treatment with adiponectin on differentiating osteoblastic cells, day 14-28, impaired their ability to fully differentiate ($P<0.05$), reached maximal levels at 2.5 ug/ml. Osterix, runx2, alkaline phosphatase, osteocalcin, and collagen type I were significantly lower in adiponectin treated osteoblastic cells compared to control cells ($P<0.05$). Additionally, the RANKL:OPG ratio was significantly lower in the cells treated with adiponectin compared to the vehicle control cells ($P<0.05$). Adiponectin treatment on mature differentiating osteoblastic cells resulted in increasing in oil red O and Nile red staining ($P<0.05$) and in mRNA levels of PPARγ and C/EBPa ($P<0.05$). Adiponectin treatment on differentiating osteoblastic cells resulted in a decrease in Beta Catenin and cyclin D1 ($P<0.05$). In conclusion, adiponectin has negative effects on bone formation in vivo and in vitro. The in vivo effects are likely to involve direct paracrine actions of adiponectin to suppress osteoblastogenesis and promote adipogenesis.

MO0215

miR-665 Regulates Dentinogenesis by miRNA and Epigenetic Mechanism. Mohammad Hassan*[1], Austin Kemper[2], Harunur Rashid[3], Amjad Javed[2], Austin Kemper[2], Christopher Clarke[4]. [1]University of Alabama, USA, [2]University of Alabama at Birmingham, USA, [3]University of Alabama Birmingham, USA, [4]UNIVERSITY OF ALABAMA, SCHOOL OF DENTISTRY, USA

MicroRNAs (miRNAs or miRs) are evolutionarily conserved, non-coding RNA which regulate gene expression by translational repression or mRNA degradation. Studies have proven the pivotal role miRNA plays in biological processes including tooth development. In our current study, we discovered microRNA-665 (miR-665) to be a potential repressor of odontoblast maturation. Stable overexpression of miR-665 in odontoblast cells inhibits, while knock-down promotes, matrix maturation marker (Col1A1) and mineralization markers Dspp, Dmp1 and osteocalcin. Similar inhibition was observed for the expression of enamelysin (MMP-20) and kallikrein 4 (KLK4), the early and late proteases for dentin and enamel maturation. Consistent with this finding, miR-665 suppressed, whereas anti-miR increased, Runx2 and osterix two essential tooth specific transcription factors. Hence, we determined that miR-665 inhibition of odontoblast maturation could lead to innovative mechanisms that would further our understanding of odontoblast gene function by miR 665. To understand the mechanism by which this miR-665 inhibits odontoblast differentiation, we sought to determine the following mechanisms for miR-665 relevant to dentinogenesis. MiRNA mechanism: Homeodomain gene Dlx3 is highly critical for tooth development. No study of miR regulation of Dlx3 expression during dentinogenesis has been reported to date. We found that miR-665 directly binds to the 3'UTR of Dlx3 mRNA and robustly decreases Dlx3 mRNA and protein in primary and culture odontoblasts cells. Epigenetic mechanism: Analysis of miR-665 guided silencing complex revealed that Kat6A, a MYST family of histone acetyltransferase is endogenously associated with miR-665. Stable expression of miR-665 in odontoblast cells significantly inhibits Kat6A expression (mRNA and protein) and acetylated H3K9 protein level. Kat6A physically interacts with Runx2 and activates tooth specific DSPP promoter activity synergistically. MiR-665 noticeably reduces the recruitment of Kat6A, Runx2, Ing4, osterix and acetylated H3K9 and, induces the recruitment of methylated H3K9 at DSPP promoter close to transcriptional start site (TSS). Regulation of this chromatin remodeling switch (H3K9Ac to H3K9me) by miR-665 clearly demonstrates a repressive state of DSPP gene transcription. When taken together, our results for the first time provide molecular evidence for miR-665 regulation in a miRNA-epigenetic regulatory network to control odontoblast differentiation.

MO0216

Naringenin stimulates mineral formation by human osteoblast-like cells at levels attainable by consuming fruits and vegetables. Bryan D. Johnston*, Dylan W. Johnston, Wendy E. Ward. Centre for Bone & Muscle Health, Faculty of Applied Health Sciences, Brock University, St. Catharines, Ontario, L2S 3A1, Canada

Introduction: A diet high in flavanones, or citrus flavonoids, has been correlated with higher hip and vertebral BMD, and lower bone resorption in perimenopausal women. Naringenin is one of the citrus flavonoids, and by consuming between 2-3 servings of grapefruit juice it is possible to achieve plasma levels of naringenin in the μM range. The stability of naringenin in plasma makes it a good candidate to potentially modulate human osteoblast function. In the present study, naringenin was screened in the long-term culture of human osteoblast-like cells (SaOS-2) for positive effects on the formation of mineral.

Materials/Methods: SaOS-2 cells were seeded at $1.0x10^4$ cells per well in 12 well plates with phenol red free DMEM/F-12 media (10% fetal bovine serum, 1% antibiotics, 10nM dexamethasone (DEX)). The cells were differentiated for 7 days in media supplemented with both 10nM DEX and 50mg/ml ascorbic acid. Naringenin treatment (1, 5, 10, 25, 50, and 75μM) was started after differentiation and the media was supplemented with 10μM β-glycerophosphate to encourage matrix mineralization for 14 days. Media was changed every 2-3 days. To measure mineral formation, cells were fixed in 4% paraformaldehyde (pH 7.4), incubated with Alizarin Red Stain (ARS) (40mM, pH 4.2) and incubated with 10% cetylpyridinium chloride (pH 7.0) to extract the ARS. Since ARS binds to calcium at a molar ratio of 1:2, the amount of calcium per well was determined. The same fixed cell layers were also treated with von Kossa (VK) staining and images of the wells were used to quantify the area of mineral per well. Based on previous research, epigallocatechin-3-gallate (EGCG) treatment at 5μM was used as a positive control.

Results: Naringenin treatment at 1, 5, 10, and 25μM resulted in 12.4%, 25.4%, 25.6%, and 20.5% higher mineral formation compared to control, respectively. These higher levels of mineral formation were similar to the 26.3% higher mineral formation with the positive control, EGCG. The 50μM naringenin treatment resulted in no difference in mineral formation while the 75μM treatment reduced mineral formation. Naringenin treatment at 5 and 10μM and the EGCG control all resulted in higher mineral formation as assessed by VK staining.

Conclusions: At concentrations attainable through diet alone (1-10μM), naringenin stimulated mineral formation by human osteoblast-like cells. Future studies aim to examine the mechanism underlying the observed increase in mineral formation.

N-linked Glycosylation: a Critical Mechanism of PTH-Resistance in Osteoblasts under High Glucose Conditions. Ann-Kristin Picke*[1], Christine Hofbauer[2], Martina Rauner[3], Lorenz Hofbauer[4]. [1]Dresden University Medical Center, Germany, [2]Dresden Technical University Medical Center, Germany, [3]Medical Faculty of the TU Dresden, Germany, [4]Dresden University Medical Center, Germany

Type 2 diabetes mellitus impairs bone quality and increases fracture risk. We showed that diabetic ZDF rats have low bone mass due to impaired osteoblastogenesis, which can be partially reversed with an intermittent parathyroid hormone 1-84 (PTH) therapy. It remains unclear, why PTH treatment does not fully restore osteoblast (OB) function in diabetic conditions. Here, we tested if high glucose (HG) conditions lead to a partial PTH resistance in osteoblasts *in vitro*.

Pre-osteoblastic MC3T3-E1 cells were cultured in osteogenic medium in HG concentrations (100 mM) for 21d. Intermittent PTH treatment was performed by treating the cells with 50 ng/ml PTH for 8h every other day.

HG decreased the production of mineralized matrix by -69% as compared to control cells. Intermittent PTH treatment reversed this effect (+115%), but did not reach the level of control cells. The Ca/P-ratio (quality) of the mineralized matrix was decreased in HG (-83%) compared to control, and PTH treatment increased the Ca/P-ratio by 30% under HG conditions. PTH dose dependently increased cAMP levels up to 2.5-fold, whereas in HG conditions cAMP levels were even decreased after PTH stimulation (4-fold). Similarly, PTH-induced activation of protein kinase A and cAMP response element-binding protein (CREB), the downstream targets of cAMP, were blunted in HG conditions. Gene expression of insulin-like growth factor-1, alkaline phosphatase, osteopontin, connexin43 and RANKL significantly increased after intermittent treatment of PTH in control and HG conditions. To determine whether the blunted cAMP activation was due to a decreased expression of the PTH receptor 1 (PTHR1), we determined protein levels of PTHR1 using Western blot. However, PTHR1 expression was not affected by HG or PTH. Instead N-linked glycosylation was increased in HG. Combined treatment of HG and PTH with tunicamycin to block N-linked glycoprotein synthesis elevated the amount of mineralization in HG-treated cells similarly to PTH treatment alone (4-fold). Interestingly, tunicamycin alone was able to reverse the inhibition of mineralization of HG-treated OB. Tunicamycin treatment also significantly increased gene expression of OB markers.

These results suggest that increased N-linked glycosylation is a critical mechanism of OB function in HG conditions in MC3T3-E1 cells. Thus, preventing these posttranslational modifications may improve OB function and augment the response to PTH treatment in type 2 diabetes mellitus.

Parathyroid Hormone Regulates Osteoblast Bioenergetics Through its Actions on Glycolysis. Anyonya Guntur*[1], Phuong Le[1], Clifford Rosen[2]. [1]Maine medical center research institute, USA, [2]Maine Medical Center, USA

We recently measured the bioenergetic pathways utilized by C57BL/6J neonatal calvarial osteoblasts (COBs) at various stages of differentiation. We reported that differentiating COBs use both Oxidative phosphorylation (OxsPhos, measured via Oxygen Consumption Rates) and Glycolysis (Glyc, measured via Extra Cellular Acidification Rates) for optimal differentiation. Intermittent Parathyroid hormone (PTH) is anabolic to bone through enhancement of osteoblast (OB) differentiation *in vivo,* although *in vitro* chronic exposure may impair differentiation. We hypothesized that PTH would regulate COB bioenergetic pathways. To test this hypothesis, we treated C57BL/6J COBs with Vehicle (VEH) or 20nM PTH for 21 days in the presence of OB differentiation media. In the presence of PTH both OCR and ECAR were inhibited as was nodule formation during *in vitro* osteoblast differentiation. Furthermore, we performed *in vitro* calvarial organ culture from 4 days old C57BL/6J pups in the absence (VEH) or presence (100nM) of PTH added one day after plating the calvariae. Three days after PTH treatment, calvariae were assayed using the Seahorse XF24. PTH treatment led to a significant increase in ECAR levels compared to VEH treated samples. To test whether Glyc plays a key role in regulating osteoblast differentiation, we utilized 2-DeoxyGlucose a specific inhibitor of Glyc at 0.1mM concentration in the presence of OB differentiation media. In the presence of the Glyc inhibitor we observed a dramatic decrease in ECAR and OB nodule formation compared to cells in differentiation media. In sum these data suggest that glycolysis is a critical component in OB differentiation and that chronic PTH treatment can suppress OCR and ECAR *in vitro* but induce ECAR in whole calvaria.

Role for Chloride and Potassium Channels Supporting Na/H Exchange in Bone Formation. Harry Blair[1], Li Liu*[1], Deborah Nelson[2], Peter Friedman[3], Paul Schlesinger[4]. [1]University of Pittsburgh, USA, [2]University of Chicago, USA, [3]University of Pittsburgh School of Medicine, USA, [4]Washington University, USA

We are investigating u*ncharacterized steps of bone mineral synthesis.* Mineral deposition is not fully defined; many cases of osteopenia or osteoporosis have no known cause. Disordered bone formation also contribute to slowly-developing skeletal defects such as kyphoscoliosis. *Bone mineral is precipitated from phosphate and calcium in an isolated extracellular compartment*: the surface layer of osteoblasts is linked by tight junctions. Phosphate and Ca^{2+} cannot move by diffusion because of the tight junctions. Thus, ion transport is obligatory. The bone forming unit, surface cells and osteocytes, is also unified by gap junctions, allowing coordinated bone synthesis. Calcium is transported across osteoblasts by facilitated transport; phosphate is actively produced from ATP and PPi, with high concentrations of free phosphate liberated by phosphatases at the secretory osteoblast surface by alkaline phosphatase and ENPPs. These create a large phosphate gradient. *Formation of mineral from this calcium and phosphate requires H^+ counter-transport*, as seen in the equation of state:

$6\ HPO_4^{2-} + 2\ H_2O + 10\ Ca^{2+} \rightarrow Ca_{10}(PO_4)_6(OH)_2 + 8\ H^+$

Since bone mineral forms in a closed space, as Ca^{2+} precipitates acid accumulates, lowering the pH. This would stop precipitation if H^+ is not removed. This stoichiometry was recognized with experimental evidence of an alkaline bone compartment long ago. But how H^+ transits the osteoblast tight epithelium is uncharacterized. Osteoblasts do have massive basolateral Na^+/H^+ exchange capacity. We recently showed that this is mediated by Na^+/H^+ exchangers (NHEs) 1 and 6. But how H^+ enters the barrier layer of osteoblasts is unknown. We used direct osteoblast membrane transport study to characterize key acid transport mechanisms. This used membrane fragments from mineralizing osteoblasts made by nitrogen cavitation. We show that *osteoblast membranes have massive CLC-type Cl^-/H^+ exchange*, which depends on K^+; thus Cl/H exchange very likely is driven by a membrane voltage from K^+ channels. Studies of mRNA and antibody labeling show massive expression of *both* CLC3 and CLC5 at the secretory membranes of osteoblasts. This expression carries through the entire haversian system. We hypothesize that this allows maintenance of the osteon's mineral by maintaining a slight alkaline gradient during the life of the bone unit. Sudies of CLC3 KO mice show a mild mineralization delay; we hypothesize that CLC3/5 double KO mice will show a severe phenotype.

The Function of MicroRNA miR-23a Cluster in Osteogenesis. Huan-Chang Zeng*[1], Yangjin Bae[1], Jordan Kho[1], Yuqing Chen[2], Terry Bertin[2], Elda Munivez[2], Brendan Lee[1]. [1]Baylor College of medicine, USA, [2]Baylor College of Medicine, USA

MicroRNAs are negative regulators of target genes and are involved in various biological processes. The miR-23a cluster is a group of microRNA which is highly enriched in bone tissues but the function of this cluster during osteogenesis is not yet clear. To study the function of miR-23a cluster in bone development *in vivo*, we generated a transgenic mouse model overexpressing miR-23a cluster using the osteoblast (Ob)-specific Col1a1-2.3kb promoter. Micro-computed tomography (uCT) and histomorphometric analysis showed that transgenic mice exhibited low bone mass with decreased Ob number and decreased mineral apposition rate. Interestingly, we also found that osteocytes were significantly increased in transgenic mice supporting dysregulation of both early Ob fate commitment and late Ob terminal differentiation into osteocytes. To study the loss of function of miR-23a cluster *in vivo*, we also generated transgenic mice expressing decoys for miR-23a, miR-27a or miR-24-2 individually driven by the Col1a1-2.3kb promoter. Mice with the miR-23a decoy and miR-27a decoy showed dental fractures and low bone mass by μCT while miR-24 decoy lines had no apparent abnormalities. RNASeq analysis of mouse models showed that TGF-β signaling pathway may be directly regulated by the miR-23a cluster.

MO0221

Transgenic Over-expression of Vitamin D Receptor in Mature Osteoblasts Enhances Anabolic and Catabolic Activities Depending on Dietary Calcium and Phosphate Levels. Rahma Triliana*[1], Howard Morris[2], Paul Anderson[3]. [1]SA Pathology/IMVSthe University of Adelaide., Australia, [2]SA Pathology, Australia, [3]Musculoskeletal Biology Research, University of South Australia, Australia

1,25-dihydroxyvitamin D (1,25D) action in osteocytes has been reported to actively inhibit mineralisation in mice in addition to its actions to enhance RANKL-mediated bone resorption. However, osteocalcin-promoter driven over-expression of vitamin D receptor (VDR) in mature osteoblasts and osteocytes (OSVDR mice) has also been demonstrated to enhance bone formation as well as reduce bone resorption. While these complex observations are not easily reconciled, the physiological conditions which determine the nature of vitamin D activity is likely to be an important factor. To address this, 3-week-old female OSVDR and WT mice were fed standard semi-synthetic diet containing either 1% calcium and 0.625% Phosphorus (NCaP) or 0.03% calcium and 0.08% phosphorus (LCaP) until 20 weeks of age, at which time they were killed for subsequent analyses. When compared to NCaP fed WT mice, LCaP fed WT mice exhibited marked reduction in femoral cortical bone volume (24%, $P<0.001$) due to increased endosteal circumference and reduced metaphyseal trabecular bone volume (70%, $P<0.001$) due to reduced trabecular number, which is consistent with osteopenia due to enhanced bone resorption. Consistent with previous findings, OSVDR mice fed NCaP diet demonstrated increased cortical (8%, $P= 0.056$) and trabecular (64% $P=0.003$) bone volumes when compared to WT fed NCaP diet. However, OSVDR mice fed LCaP diet demonstrated markedly reduced femur length, reduced trabecular bone volume and cortical thinning which was splayed towards the metaphyseal region. In addition, these mice frequently demonstrated disturbed growth plate structure, marked intra-cortical porosity which was associated with pronounced osteoclastic activity. The pronounced catabolism of bone in OSVDR mice fed LCaP occurred despite normocalcemia and normophosphatemia. However, serum FGF23 levels were 2-fold lower and serum 1,25D levels were 2-fold higher in OSVDR mice when compared with WT mice fed LCaP suggesting that the enhanced catabolism mediated by 1,25D activity may be due, at least in part to altered feed-back on renal 1,25D synthesis. These findings support the notion that 1,25D activity in osteoblasts/osteocytes mediates anabolic and catabolic activities depending on the physiological challenge of calcium and phosphate demand.

Membrane-bound prostaglandin E synthase (mPGES)-1-mediated prostaglandin E_2 (PGE_2) production plays a critical role in the ligand for toll-like receptor 2 heterodimer (TLR1/2, TLR 2/6) induced bone resorption. Chiho Matsumoto[1], Tsukasa Tominari[2], Michiko Hirata[3], Chisato Miyaura[1], Masaki Inada*[1]. [1]Tokyo University of Agriculture & Technology, Japan, [2]Tokyo University of Agriculture & Technology, Japan, [3]Tokyo University of Agriculture & Technology, Japan

Toll-like receptors (TLRs) play critical roles in innate immunity, and various ligands for TLRs are thought to regulate the host defense mechanisms against pathogens. TLR2 generally forms heterodimers with TLR1 or TLR6. TLR2 heterodimers have different biological response, the TLR2-TLR1 heterodimer recognizes triacylated lipopeptides from gram-negative bacteria, whereas the TLR2-TLR6 heterodimer recognizes diacylated lipopeptides from gram-positive bacteria. We have reported that bone resorption associated with inflammation such as bacterial infection of periodontitis was attenuated in prostagrandin E2 synthethase deficient mice (*mPges*1-/-) due to the lack of PGE_2 production by osteoblasts. In this study, we examined the roles of PGE_2 in various TLR2 ligands induced bone resorption using the models of *mPges*1-/-. TLR1/2 and TLR 2/6 synthetic ligands markedly increased bone resorbing activity in wild-type derived calvarial organ cultures, and that the activity was attenuated in the cultures derived from *mPges*1-/-. In the cultures of *mPges*1-/- osteoblasts, both PGE_2 production and the following RANKL expression were attenuated. The activation of NFkB in osteoblast is critical for the induction of various inflammation related genes, such as COX-2 and mPGES-1. In luciferase assay, TLR1/2 and TLR2/6 ligands induced NFkB activation in wild type derived osteoblasts.

To examine the direct effects of TLR1/2, 2/6 ligands on the survival in mature osteoclasts, we used the models of RANKL induced osteoclasts derived from bone marrow macrophage. Mature osteoclasts expressed RANK, cathepsin K, NFATc1, and the treatment of TLR 2/6 ligand enhanced NFATc1 expression and osteoclast life span. Finally we investigated the possible roles of a gram positive bacteria derived native TLR2 ligand in bone resorption. Lipoteichoic acid from gram positive bacteria stimulated bone resorption in the calvarial cultures with increased production of PGE2. These results suggest that synthetic and native ligands for TLR2 heterodimer promotes RANKL expression via mPGES-1-mediated PGE_2 synthesis, leading to bone resorption. mPGES-1 may play a key role in the inflammatory bone destruction via TLR2 heterodimer signaling pathway.

MO0223

Osteoblast-Speci R⩾c IGF-1 signaling deficiency causes delayed endochondral bone formation during fracture healing. Tao Wang*[1], Yongmei Wang[2], Candice GT Tahimic[3], Chak Fong[4], ALICIA MENENDEZ[4], Daniel Bikle[3]. [1]University of California, San Francisco, SAN FRANCISCO, CA, USA, [2]Endocrine Unit, University of California, San Francisco/VA Medical Center, San Francisco, CA, USA, [3]Endocrine Research Unit, Division of Endocrinology UCSF & VAMC, San Francisco, CA, USA, [4]University of California, San Francisco, San Francisco, California, USA

Insulin-like Growth Factors (IGFs) are important local regulators during fracture healing. Although IGF signaling deficiency is known to increase the risk of delayed union or non-union fractures in the elderly population, the mechanism has received little attention. We hypothesize that the loss of the IGF-1 receptor (IGF-1R) results in decreased bone formation and impaired healing following fracture. To test this hypothesis, we mated conditional knockout (CKO) mice harboring a tamoxifen-inducible Cre under the control of the osteoblast-specific promoter, 2.3-kb fragment of α1(I) collagen, with floxed IGF-IR mice. Using the inducible Cre-LoxP system, disruption of the IGF-1R gene in osteoblasts at the time of fracture impaired both autocrine/paracrine and endocrine IGF-1 effects on osteoblasts only during fracture healing. Gene disruption was induced by 5 i.p. injections of tamoxifen in oil (2mg per mouse), and fracture was performed after the second tamoxifen injection. A unilateral closed tibial fracture was made in CKO mice and IGF-IR $^{flox/flox}$ (CON) mice aged 12 weeks. Non fractured tibial diaphysis (basal line control) and fracture callus samples were collected and analyzed by micro-CT, histomorphometry and gene expression. The results demonstrated that non fractured tibia in CKO mice were not significantly different from CON mice,but smaller callus size, decreased bone formation and a higher percentage of cartilage were found in the callus of CKO mice at day 10 post-fracture ($p<0.05$). Gene expression analysis showed that levels of osteoblast differentiation markers (OCN, Col1α1) were significantly reduced in the CKO callus compared to CON at day 10, 15, 21 post-fracture ($p<0.05$). Relative gene expression of Col2a1 and Col10a1, early and late markers of chondrocyte differentiation, showed that Col2a1 was significantly upregulated at day 10, 15, 21 and 28, and Col10a1 was significantly increased in the CKO callus at day 15 and 21 post-fracture. Two key osteoblast transcription factors, Runx2 and Osterix, acting sequentially to initiate osteoblast differentiation and highly expressed in the preosteoblast and immature osteoblast population, were significantly increased in the CKO callus at day 15 and 21 post-fracture ($p<0.05$). Our data indicate that IGF-1 signaling deficiency in this transgenic mouse model hindered osteoblast formation and maturation, and delayed endochondral ossification at the early stages of fracture healing. Enhancing IGF-I signaling may provide a means to enhance endochondral bone formation resulting in improved fracture healing.

Use Of MC3T3 Cells For Native High-Level Production Of Carboxylated Mouse Osteocalcin. Patricia Buckendahl*[1], Daniel Benjamin[2]. [1]Rutgers University, USA, [2]Cenoxys Corporation, USA

Studies of *in vitro* and *in vivo* function of fully carboxylated native osteocalcin (OC) in the mouse require greater quantities of pure protein than are available commercially. Purification of native OC from mouse bone can be complicated by extensive glycation of the protein, as indicated by MALDI-TOF analysis, particularly from bone of older mice. To avoid this problem we cultured MC3T3-E1 cells and harvested the media. MC3T3-E1 cells were obtained from ATCC, plated in proliferation conditions in αMEM, 10% FBS, without ascorbic acid in 75 cm^2 culture flasks. When cells were confluent, flasks were changed to serum free advanced MEM containing ascorbic acid, 10 mM β-glycerophosphate, and 10 μM vitamin K1 to promote differentiation. To stimulate a further increase of OC production, we exposed some cultures to bioactive glass conditioned medium (GCM). Serum free medium was exposed to 45s5 Bioactive glass (MO-SCI Healthcare, Rolla MO), 100 mg/50 ml, for at least 3 days, to leach Si^{4+} and Ca^{2+} into the medium. Plain or GMC media were harvested every 3 to 7 days, frozen and lyophilized prior to purification. Under these conditions, cells continued to secrete OC for more than 5 months. Separation of OC from the media initially followed Sephadex G25 gel filtration and ion-exchange protocols. However, this was hampered because several red to yellow colored components, including phenol red, vitamin B12 and riboflavin co-eluted with the OC. These bound irreversibly to the ion-exchange resin (Biorad Macro-Prep High Q Anion Exchange), rendering separation unreliable. A preliminary step of separation of reconstituted media on a bulk C18 reverse phase column was added. Elution with 30% methanol eliminated most of the phenol red and vitamins as well as some unwanted proteins. Additional protein, including OC, was then eluted with 80% methanol. After evaporation of the methanol and lyophylization, the protein was dissolved and assayed for OC content by RIA. At this stage, media from cells cultured without GCM yielded about 3 ng OC/ml of culture media. Cultures with GCM yielded a 10 to 20-fold increase in OC secretion into the media, up to 60 ng OC/ml of media after 7 days. Presence of GLA in chromatographic fractions was confirmed qualitatively by reaction with diazobenzene sulfonic acid. Culture of MC3T3 cells with GCM can be easily scaled up to yield large quantities of native mouse OC and purified by standard chromatographic methods.

Cation activation of G-class signalling in human osteoblasts. Mark Rybchyn[1], Wendy Green[1], Arthur Conigrave[2], Rebecca Mason[3], Tara Brennan-Speranza*[4]. [1]Bosch Institute, Physiology & School of Medical Sciences, University of Sydney, Australia, [2]University of Sydney, Australia, [3]University of Sydney, Australia, [4]University of Sydney, Australia

We have previously shown that treatment of primary human osteoblasts (HOBs) with pharmacologically relevant concentrations of divalent cations including Ca^{2+} and Sr^{2+} resulted in an increase in osteoprotegerin (OPG) release, whilst decreasing the expression of membrane-associated receptor activator of NFκB Ligand (RANKL) (1,2). The present study investigated whether the calcium-sensing receptor (CaSR) and/or a related class C GPCR, GPRC6A, mediate these responses.

HOBs were transfected with siRNA directed at the CaSR (HOB/$CaSR^{kd}$) or GPRC6A (HOB/GPR^{kd}) or with a scrambled sequence (HOB/SCR) for 24h. Transfected cells were then exposed to zero or 1 mM strontium in the presence of 1 mM calcium for 24h. OPG and RANKL mRNA were measured by qRT-PCR. Strontium induced ~2-fold increase in OPG expression and ~2.5-fold decrease in RANKL expression in HOB/SCR cells ($p<0.05$; $p< 0.01$) but had little effect in HOB/$CaSR^{kd}$ cells. There was no significant difference in the strontium-induced increase in OPG mRNA expression between HOB/SCR and HOB/GPR^{kd} cells. However, the strontium-induced reduction in RANKL mRNA expression was not observed in HOB/GPR^{kd} cells and, instead, a paradoxical increase in RANKL expression was observed when compared to HOB/SCR cells ($p<0.001$). PI-3-kinase inhibitor wortmannin inhibited strontium-induced changes in both OPG and RANKL, but only changes in RANKL were inhibited by ERK-inhibitor peptide. Furthermore, Co-IP investigations show that treatment of HOBs with Ca^{2+}, the natural ligand for CaSR, results in dimerization of the CaSR with GPRC6A. GPRC6A also appears to support *osteocalcin*-sensing in at least some tissues. However, recent results in Chinese Hamster Ovary (CHO) cells that stably express GPRC6A, have raised doubts regarding its role in osteocalcin sensing while confirming the role of GPRC6A in sensing basic amino acids and divalent cations. Our studies show that it might be necessary for the GPRC6A to dimerize with the CaSR or another receptor in order for it to signal to downstream pathways.

HIF-1α Dependent Metabolic Reprogramming of Periosteal Cells Improves Bone Repair. Steve Stegen*[1], Nick Van Gastel[2], Guy Eelen[3], Annelies Quaegebeur[4], Riet Van Looveren[5], Peter Carmeliet[4], Geert Carmeliet[3]. [1]Laboratory of Clinical & Experimental Endocrinology, KU Leuven, Belgium, [2]Laboratory of Clinical & Experimental Endocrinology, KU Leuven, Belgium, Belgium, [3]Katholieke Universiteit Leuven, Belgium, [4]Angiogenesis & Neurovascular Link, Vesalius Research Center, KU Leuven, Belgium, [5]KU Leuven, Belgium

Cell-based bone tissue engineering represents a promising strategy for the treatment of large bone defects. However, the low survival rate of the osteogenic cells implanted in an environment deprived of oxygen and nutrients remains a therapeutic challenge. We hypothesized that metabolic preconditioning by activation of the hypoxia signaling (HIF) pathway may protect these cells from cell death and hereby improves bone repair.

To stimulate the HIF-pathway, the PHD2 oxygen sensor was genetically inhibited in murine periosteum derived cells (*Phd2*^{low} mPDC). The bone formation (ectopic model) and bone repair capacity (large bone defect model) was assessed by implanting mPDC-seeded calcium phosphate-collagen scaffolds in nude mice. Histomorphometric and microCT analysis revealed enhanced bone formation, especially within the

scaffold center, in the *Phd2*^{low} mPDC-seeded scaffolds 8 weeks after implantation compared to control. In addition, we observed an increase in the number and size of blood vessels closely associated with the sites of bone formation.

In contrast to the later time points, blood vessels were absent in both control and *Phd2*^{low} mPDC-seeded scaffolds 3 days after implantation. However, *Phd2*^{low} mPDC survived better in the hypoxic center of the scaffold and showed reduced oxidative stress, suggesting the involvement of metabolic reprogramming. Indeed, several metabolic adaptations contributed to this prosurvival effect *in vivo*. We observed a redistribution of metabolic intermediates necessary for supplying energy and regulating redox homeostasis during cell stress. Furthermore, inhibition of enzymes responsible for maintaining these processes significantly reduced the prosurvival capacity of *Phd2*^{low} mPDC *in vitro* and *in vivo*.

Lastly, the effects of *Phd2* inactivation were HIF-1α dependent, as inhibition of *Hif-1α* transcription using a shRNA approach completely abrogated the prosurvival and bone forming properties of *Phd2*^{low} mPDC.

In conclusion, activation of the HIF-pathway in periosteal cells by genetic inactivation of *Phd2* preserves cellular bioenergetics and redox homeostasis during stress and hereby improves cell survival and ultimately bone formation in a tissue-engineered construct.

Induction of single nucleotide polymorphisms in the purinergic P2X7 receptor and subsequent investigation of changes in function and gene expression of specific bone markers. Barakat Ali Nasir Ali[1], Jan Rune Larsen*[2], Solveig Petersen[2], Niklas Jorgensen[3], Ole Vang[4], Susanne Syberg[5]. [1], Denmark, [2]Research Center for Ageing & Osteoporosis, Diagnostic Department, Glostrup Hospital, Denmark, [3]Copenhagen University Hospital Glostrup, Denmark, [4]Department of Science, Systems & Models, 18.1 Roskilde University, Denmark, [5]Research Centre for Ageing & Osteoporosis, Denmark

The investigation of bone is an interesting field in research involving crosstalk between several cells of different origins including several pathways of which many are still to be discovered and characterised. Through this system, a constant remodelling of the skeleton throughout the lifespan of a human is administered. If this system is no longer in homeostasis, it can lead to osteoporosis – a very invasive disease of which many elderly people suffers, in particular post-menopausal women. Involvement of the purinergic P2X7 receptor in regulation of bone formation has been reported. In addition, a subsequent identification of several single nucleotide polymorphisms (SNPs) within its gene has also been documented. This project has its basis in indicative findings of the negative and positive effect from SNPs in the P2X7 receptor gene and the subsequent risk of developing osteoporosis.

As a result, it is the aim of this report to investigate the cellular effect of three selected SNPs transfected into an osteoblastic cell line in order to determine functional changes in the receptor followed by an analysis of the pattern of expression in selected bone markers. This was approached by inducing a single point mutation using site directed mutagenesis in the P2X7 receptor gene whilst it sits in a plasmid. This is followed by transfection of the plasmid into ROS 17/2.8 cells using Lipofectamine 2000 and a subsequent examination of change in receptor function by looking at changes in intracellular calcium concentration using calcium assay. In addition, seven bone markers are tested for change in gene expression by RT-qPCR.

A functional change of the P2X7 receptor observed by a change in intracellular calcium concentration was found for two SNPs according to their gain- or loss-of-function character when compared to WT. In contrast, the third SNP induced no significant change in function of the P2X7 receptor when compared to WT.

For the seven bone markers, although significant differences between SNPs and WT was observed, no tangible patterns of increase or decrease in boneformation seen as a result of change in bone markers was observed.

Mice Deficient in Osteoblast Smad4 Exhibit Impaired Collagen Fibrillogenesis. Cynthia Brecks*[1], Gabriel Mbalaviele[2], Roberto Civitelli[2]. [1]Washington University In St Louis, USA, [2]Washington University in St. Louis School of Medicine, USA

Previous work from our lab demonstrates that Smad4, a key component of the TGF-β and BMP pathways, regulates skeletal development. Indeed, osterix (OSX)-Cre-driven osteoblast-specific ablation of *Smad4* (cKO) causes stunted growth, spontaneous fractures and a combination of features seen in osteogenesis imperfecta and cleidocranial dysplasia. Here, we further explored the nature of the collagen matrix abnormalities caused by osteoblast *Smad4* deficiency. All markers of osteoblast differentiation downstream of Osx, measured by qPCR in calvaria cells, were significantly decreased in bone extracts from cKO mice relative to wild type (WT) littermates, including type I collagen. We have also shown that fibrillar collagen organization is abnormal in cKO bones by picrosirius red staining. This was corroborated by transmission electron microscopy, showing significantly larger cross-sectional diameter of collagen fibers in cKO relative to WT mice, suggestive of aberrant collagen fiber assembly and processing. This is consistent with our previous observation of reduced *Lox* expression by *Smad4* deficient cells. Indeed, we observed reduced deposition of collagen into the extracellular matrix in cKO mice relative to WT mice. Except for *Lox*, other collagen processing enzymes were not altered in cKO mice. However, collagen fiber assembly is also regulated by small leucine-rich proteoglycans (SLRPs) such as biglycan, as they are associated with collagen fibrils and contribute to their assembly. Indeed, biglycan protein expression was significantly down-regulated in the calvaria of cKO compared to WT mice, consistent with published data showing that biglycan expression is Smad4-dependent. Thus, Smad4 is a key regulator of organic bone matrix, by modulating collagen synthesis, post-translational modification and assembly in a proper fibrillar structure; its absence recapitulates matrix abnormalities found in some forms of osteogenesis imperfecta.

Odd-skipped related 1 transcription factor modulates skull closure and cranial bone formation. Shinji Kawai*[1], Masashi Yamauchi[1], Ikumi Michikami[2]. [1]Osaka University Graduate School of Dentistry, Japan, [2]Osaka University Graduate School of Dentistry, Japan

The odd-skipped gene is initially identified as a Drosophila segmentation gene, and contains three DNA-binding C2H2-type zinc fingers in the C-terminal half of the molecule as a pair-rule transcription factor. Mammalian homologues, Odd-skipped related 1 (Osr1) and Osr2, are cloned from both mice and humans. Human OSR1 is detected in fetal lungs, adult colon, small intestine, prostate, and testis. Osr1 is known to play important roles in embryonic, heart, and urogenital development. To elucidate the in vivo function of Osr1 in bone formation, we generated transgenic mice overexpressing full-length Osr1 under control of 2.8kb Osr1 promoter. Osr1 transgenic mice were smaller than wild-type littermates. Especially, abnormality was found in skull of Osr1 transgenic mice by soft X-ray analysis, skeletal preparation, and morphological analysis. Round skull and cranial dysraphism were observed in transgenic mice. Further, primary calvarial cells obtained from Osr1 transgenic mice showed increased proliferation and increased expression of chondrocyte markers, but decreased expression of osteoblast markers. BMP2 reduced Osr1expression and Osr1 knockdown by siRNA induced ALP and osteocalcin expressions in mesenchymal and osteoblastic cells. Thus, Osr1 negatively functioned in bone formation. Our genetic observations show that the Osr1 gene plays a role in appropriate skull closure and cranial bone formation.

Osteoblast differentiation causes a switch in the primary mechanism that regulates activity of the cAMP/PKA signaling pathway. Bryan Hausman*[1], Xin Chen[1], Guang Zhou[1], Guangbin Luo[2], Shunichi Murakami[1], Edward Greenfield[1]. [1]Case Western Reserve University, USA, [2]Case Western Reserve University, USA

The cAMP/Protein Kinase A (PKA) pathway is essential for regulation of many genes and cellular processes and is therefore tightly controlled by multiple mechanisms including secretion/degradation of the initiating hormones, activity of their cognate receptors, cAMP production/degradation, levels of the PKA regulatory subunits and their binding to A-kinase anchoring proteins, nuclear import/export of the PKA catalytic subunit, transcription factor phosphorylation/dephosphorylation, production of inhibitory transcription factors, and histone acetylation/deacetylation. However, we previously showed that inhibition of nuclear PKA activity by Protein Kinase Inhibitorγ (PKIγ) is the primary mechanism that regulates activity of the cAMP/PKA pathway in mesenchymal precursor cells and in osteoblast-like ROS17/2.8 cells. Thus, PKIγ terminates PKA activity and expression of primary response genes (*c-fos*, *LIF*, and *IL6)* induced by parathyroid hormone (PTH) or isoproterenol. As a result, PKIγ reduces production of LIF protein and thereby restrains osteogenesis and enhances adipogenesis by mesenchymal precursor cells. In our current studies, we investigated the effects of PKIγ in mature osteoblasts *in vitro* and *in vivo*. Before and after differentiation into osteoblast-like cells (7 days with ascorbic acid and β-glycerol phosphate), wild-type murine embryonic fibroblasts (MEFs) exhibit equivalent forskolin (Fsk)-induced increases in nuclear PKA activity and expression of *c-fos*, *LIF*, and *IL6* mRNAs. In contrast, undifferentiated PKIγ$^{-/-}$ MEFs exhibit greater Fsk-induced increases in nuclear PKA activity (3-fold, $p<0.001$) and expression of the mRNAs (2- to 10-fold, $p<0.05$). However, upon differentiation into osteoblast-like cells, the effects of PKIγ deficiency are compensated as wild-type and PKIγ$^{-/-}$ MEFs are indistinguishable. This compensation occurs in the absence of major up-regulation of PKIα or PKIβ mRNAs. Similar to MEFs after differentiation into osteoblast-like cells, no differences are detected between wild-type and PKIγ$^{-/-}$ calvarial osteoblasts in PTH- or Fsk-stimulated gene expression. Similarly *in vivo,* PTH-induced gene expression in femoral osteoblasts is not different between PKIγ$^{-/-}$ and wild-type littermates; and no major skeletal phenotype is detected in adult or embryonic PKIγ$^{-/-}$ mice. These data suggest that PKIγ is most important early in the osteoblastic lineage and that other mechanisms to regulate cAMP/PKA signaling predominate in mature osteoblasts.

Osteoclast-derived coupling factor Cthrc1 stimulates osteoblast differentiation through Rac1/PKCδ/ERK. Kazuhiko Matsuoka[1], Kyoji Ikeda[2], Sunao Takeshita*[2]. [1]National Center for Geriatrics & Gerontology, Japan, [2]National Center for Geriatrics & Gerontology, Japan

Various regulatory molecules relaying between bone resorption and formation have been reported, including matrix-derived growth factors, secreted and membrane factors derived from osteoclasts themselves. We have recently reported that Cthrc1 secreted from active bone-resorbing osteoclasts stimulates bone formation and acts as a coupling factor in vivo. In this study, we examined signal transduction pathways of Cthrc1 to clarify the mechanism how it transmits anabolic signals to osteoblasts using ST2 cells that are induced into osteoblastic differentiation by recombinant Cthrc1.

We found that recombinant Cthrc1 phosphorylates PKCδ, ERK and JNK, and activates Rac1 on ST2 cells. Cthrc1 induces alkaline phosphatase (ALP) activity in ST2 cells, which is dose-dependently reduced by the addition of pharmacological inhibitors of PKCδ, ERK and Rac1, i.e. Rottlerin, U0126 and EHop-016, respectively. PLC and JNK inhibitors, U73122 and SP600125, however, did not affect ALP activity by Cthrc1 stimulation. Knockdown of PKCδ by siRNA abrogated the stimulation of ALP activity induced by Cthrc1. Cthrc1 dose-dependently inhibited β-catenin dependent signals assessed with a TOP Flash system. These data suggest that Cthrc1 may cross-talk with not only Wnt/PCP pathway, but also canonical Wnt/β-catenin pathway. In order to search for a Cthrc1 receptor, ST2 cell lysates were applied to an affinity column of recombinant Cthrc1 protein, and a membrane protein was identified by mass spectrometry.

Taken together, these results suggest that Cthrc1 stimulates osteoblast differentiation through Rac1/PKCδ/ERK pathways.

RUNX2 O-GlcNAcylation Links Osteogenesis and Nutrient Metabolism in Mesenchymal Stem Cells. Alexis Nagel*[1], Lauren Ball[2]. [1]Medical University of South Carolina, USA, [2]The Medical University of South Carolina, USA

The *runt*-related transcription factor 2 (RUNX2) is the master switch controlling osteoblast differentiation and formation of the mineralized skeleton. The post-translational modification (PTM) of RUNX2 by phosphorylation, ubiquitinylation, and acetylation modulates its activity, stability, and interactions with transcriptional co-regulators and chromatin remodeling proteins downstream of osteogenic signals. We report for the first time novel sites of O-linked N-acetylglucosamine (O-GlcNAc) modification on human type II RUNX2 identified by tandem mass spectrometry, as well as interaction of RUNX2 with the nutrient responsive enzyme O-GlcNAc transferase (OGT) which modulates the action of numerous transcriptional effectors. Mass spectrometric characterization also revealed novel sites of arginine methylation, as well as sites of lysine acetylation. A chemoenzymatic labeling approach demonstrated that ~ 40% of RUNX2 isolated from nuclei of osteogenic bone marrow derived mesenchymal stem cells (BMMSCs) treated with the pharmacological OGA inhibitor, Thiamet G, was O-GlcNAc modified. Levels of O-GlcNAcylated RUNX2 were increased in BMMSCs after 1 and 2 days of rhBMP2/7-treatment (50 ng/mL), and the presence of rhBMP2/7 significantly decreased activity of the O-GlcNAcase (OGA) cycling enzyme by 39.0% after 8 days. Differentiation of BMMSCs in the presence of Thiamet G enhanced expression (24.3%) and activity (65.8%) of alkaline phosphatase (ALP) after 6 days, and rhBMP2/7-induced effects on ALP activity were enhanced by 35.6% in the presence of Thiamet G. These data suggest that decreased OGA activity is associated with increased activity of the early osteogenic marker ALP and that the effects of BMP2/7 are mediated in part by modulation of protein O-GlcNAc modification. These findings support a role for the nutrient responsive O-GlcNAc PTM in the regulation of osteoblast function, and have implications for pathological bone loss observed under conditions of altered nutrient metabolism such as type I and type II diabetes.

Sr stimulating effect on mineralization is modified by calcimimetic R568 in UMR 106.1 osteoblast like cells. Nicole Nijs-De Wolf*[1], Rafik Karmali[2], Pierre Bergmann[3]. [1]Université Libre de Bruxelles, Belgium, [2]CHU Brugmann, Université Libre de Bruxelles, Belgium, [3]Centre Hospitalier Universitaire Brugmann, Belgium

Introduction: Strontium ranelate is used to treat osteoporosis and acts on bone resorption, which is inhibited, while it stimulates bone formation. Sr^{++} increases the mineralization of UMR106.1 OB like cells cultivated in mineralizing conditions. Osteoblasts express PTHrP, a bone anabolic agent, and the expression of PTHrP in osteoblasts is stimulated by divalent cations. We have shown previously that Sr^{++} increased the relative abundance of the mRNA of PTHrP in UMR 106.1 osteoblast like cells and that PTH 7-34, an inhibitor of PTH action on the parathyroid hormone receptor 1 (PTHR1) decreased the stimulating effect of Sr^{++} on OB-like cells mineralization. To get more insight into the mechanism of action of Sr^{++}, we investigated in this work if its effect on UMR106.1 mineralization was modified by agents which modulate the sensitivity of the calcium sensing receptor (CaSR) to divalent cations.

Methods: UMR-106.1 were cultivated in MEM containing 10 % FCS. At confluence, the cells were trypsinized, plated at 10^5 cells/cm^2 density and cultivated in mineralizing conditions for 6 days without $SrCl_2$ or with $SrCl_2$ 0.25, 0.5, 1.0, 1.5 or 2 mmol/L. The calcimimetic R568 (generous gift of Amgen) was added from the beginning at a concentration 0, 100, 300 and 1000 nmol/l. Control experiments were performed with the enantiomer S568. In some experiments, the calcilytic NPS 2143 (purchased from Sigma) was added at the concentrations 100 and 1000 nmol/L. At the end of the culture, alizarin 2% was added for 15 min; the plates were washed and the color dissolved in cetyl pyrimidin-HCl 10%. The optical density of the supernatant was measured at 562 nm.

Results: Sr^{++} increased significantly mineralization for concentrations $\geqslant$ 0.5 mmol/L. The calcimimetic R568 had no effect per se on mineralization except at the highest concentration, for which mineralization was maximally stimulated. The effect of Sr^{++} on mineralization was sensitized, with a significant increase for a concentration of 0.25 mmol/L of Sr at a R568 concentration of 100 nmol/L, and a maximal effect of this low Sr concentration when the calcimimetic was added at a concentration of 300 nmol/L. With the enantiomer or the calcilytic NPS 2143, we observed a moderate increase of mineralization in the absence of Sr, but the stimulatory effect of Sr was abolished.

Conclusion: Our data show that the stimulating effect of Sr^{++} on UMR 106.1 mineralization is at least in part transduced through the CaSR.

MO0234

Alternative Splice Variants Of The Osteogenic Cytokine SDF-1 Differentially Mediate CXCR4 and CXCR7 Expression in Bone Marrow MSCs. Alexandra Aguilar*[1], Samuel Herberg[2], Sudharsan Periyasamy-Thandavan[3], Brian Volkman[4], Galina Kondrikova[5], Xing-Ming Shi[6], Mark Hamrick[7], Carlos Isales[6], William Hill[8]. [1]UCC School of MedicineGeorgia Regents University, USA, [2]Case Western Reserve University, USA, [3]Georgia Regents University & Charlie Norwood VAMC, USA, [4]Medical College of Wisconsin, USA, [5]Georgia Regents University, USA, [6]Georgia Regents University, USA, [7]Georgia Health Sciences University, USA, [8]Georgia Regents University & Charlie Norwood VAMC, USA

Purpose: Stromal cell-derived factor-1 (SDF-1/CXCL12) has six known alternative mRNA splice variants. SDF-1α and SDF-1β are the main isoforms. SDF-1a has been implicated in bone marrow-derived stem/stromal cell (BMSC) mobilization and osteogenic differentiation. We have previously shown that SDF-1b, the second most abundant splice variant, is also important for regulating osteogenesis. It is unclear whether there is a difference in the activation of gene expression and signaling pathways between these two constitutively expressed isoforms in BMSCs. We assessed the effects of SDF-1α & β on the expression of SDF-1 ligands and receptors using a dose range know to differentially affect CXCR4 signaling by SDF-1α due to ligand biased GPCR activation. Hypothesis: SDF-1 splice variants have different affects on BMSC SDF-1 ligand & receptor expression. Materials: BMSCs were derived from 18-month-old male C57BL/6J mice. Cells were treated for 24 and 48 h with increasing doses (50, 100, 200, 400 and 800ng/mL) of rhSDF-1a or SDF-1b. mRNA expression of SDF-1a, SDF-1b, CXCR4 and CXCR7 were analyzed by qRT-PCR. SDF-1a protein levels in cell lysates and supernatants were assessed by ELISA. Results: mRNA levels of SDF-1a and SDF-1b at 24 and 48 h were comparable, independent of the exogenous stimulus. SDF-1a treatment induced expression of CXCR4 at 24 h in a dose-dependent manner. In contrast, BMSCs responded to SDF-1b treatment only at a higher dose (400ng/mL) to increase CXCR4 levels. At 48 h, SDF-1b still did not increase CXCR4 expression below 200ng/ml. Both isoforms induced the expression of CXCR7 in a similar fashion at both time points; however, SDF-1b significantly increased the overall mRNA level at 48 h. SDF-1a protein levels in cell lysates significantly increased ($p<0.01$) with SDF-1b treatment at 24 h relative to controls and decreased with both isoforms at 48 h. SDF-1a levels in the supernatant increased significantly ($p<0.0001$) with SDF-1a treatment at both time points. SDF-1b treatment also increased the expression of SDF-1a at 24 h ($p<0.05$) and 48 h, however, to a lesser extent compared to SDF-1a treatment. Conclusions: Our data suggest that there is a distinct difference in the mechanisms by which the expression of CXCR4 and CXCR7 is induced in BMSCs depending on the SDF-1 splice variant, and dose, cells are exposed to. This suggests potentially a difference in GCPR ligand biased signaling between SDF-1 isoforms that may alter BMSC osteogenesis.

MO0235

IRE1a,forming a control loop with BMP2 and GEP,regulates osteoblastogenesis. Fengjin Guo*[1], Zhangyuan Xiong[2], Peng Zhang[3], Xiaofeng Han[4], Meiling Li[4], Fei Xia[4]. [1]Chongqing Medical University, Peoples Republic of China, [2]Department of Cell Biology & Genetics,Core Facility of Development Biology, Chongqing Medical University, China, [3]Department of Cell Biology & Genetics,Core Facility of Development Biology, Chongqing Medical University, Chongqing 400016,China, China, [4]Department of Cell Biology & Genetics,Core Facility of Development Biology, Chongqing Medical University, Chongqing 400016,China, China

Osteoblast differentiation is a multi-step process where mesenchymal cells differentiate into osteoblast lineage cells including osteocytes.All is known that the differentiation of uncommitted mesenchymal cells to osteoblasts is a fundamental process in embryonic development and the repair of bone defect.The BMPs are

important regulators of this process and play a key role in the BMP-induced osteogenic differentiation and bone formation.Recently,BMP2 is known to activate unfolded protein response(UPR) signaling molecules,such as BiP,PERK,IRE1α.IRE1a,as one of three unfolded protein sensors in UPR signaling pathways,can be activated during ER stress.

GEP is an autocrine growth factor that has been implicated in embryonic development,tissue repair,tumorigenesis,and inflammation.We previously reported that GEP induced chondrocyte differentiation,endochondral bone formation and cartilage repair.GEP was reported to promote bone regeneration and bone formation.However,little is known about the modulation and physiological significance of IRE1a in osteoblast differentiation.Specifically,whether IRE1a influences GEP mediated osteoblastogenesis have not been delineated,the molecular mechanism on how to regulate GEP-mediated osteoblastogenesis by IRE1a is also remains unknown.Herein,we demonstrate that overexpression of IRE1a inhibits osteoblast differentiation,as revealed by reduced activity of ALP and OCL.Mechanistic studies revealed that the expression of IRE1a during osteoblast was a consequence of JunB transcription factor binding to several AP1 sequence(TGAG/CTCA) in the 5'-flanking regulatory region of the IRE1a gene,followed by transcription.In addition,GEP induces IRE1a expressions and this induction of IRE1a by GEP depends on JunB;Furthermore,IRE1a inhibition GEP-induced osteoblastogenesis relies on JunB;Besides,GEP is required for IRE1a inhibition of BMP2-induced bone formation.Collectively,these findings demonstrate that (1)IRE1a Inhibits the BMP2-mediated Osteogenic Differentiation;(2)JunB upregulates endogenous IRE1a expression and enhanced this inhibition; (3)GEP induces IRE1a expressions and this induction depends on JunB; (4)GEP is required for IRE1a inhibition of BMP2-induced bone formation;(5)IRE1a inhibition of GEP induced osteoblastogenesis is,at least partially,mediated by the transcription factor JunB.Thus,IRE1a,BMP2,GEP,and JunB constitute a regulatory feedback loop and act in concert during osteoblast differentiation and bone formation.

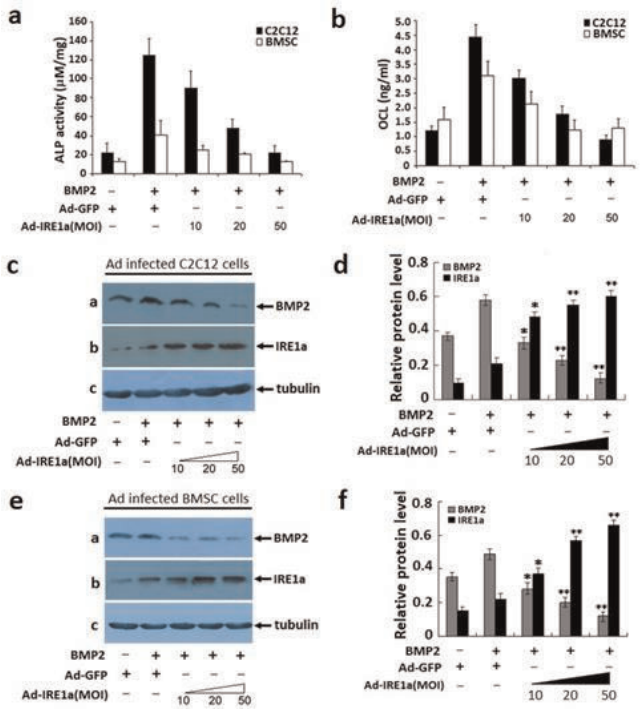

Figure 1. IRE1a inhibits the BMP2-induced osteogenesis assayed by ALP and OCL.

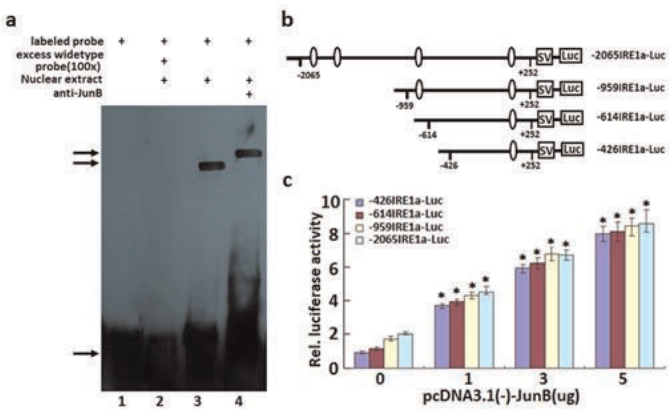

Figure 2. JunB binds to the AP1 of the IRE1a promoter and upregulation of IRE1a reporter constructs.

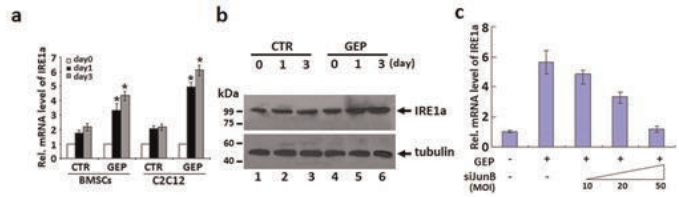

Figure 3. IRE1a expression induced by GEP is depended on JunB.

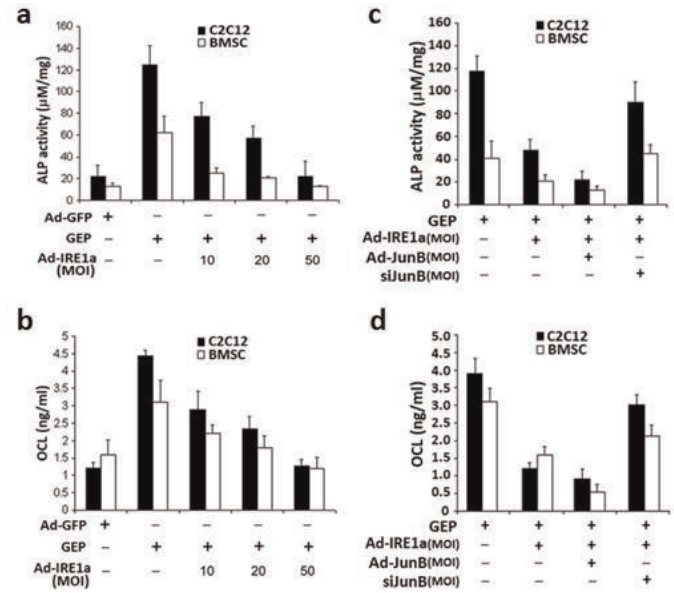

Figure 4. IRE1a inhibits GEP-mediated osteogenesis assayed by ALP and OCL.

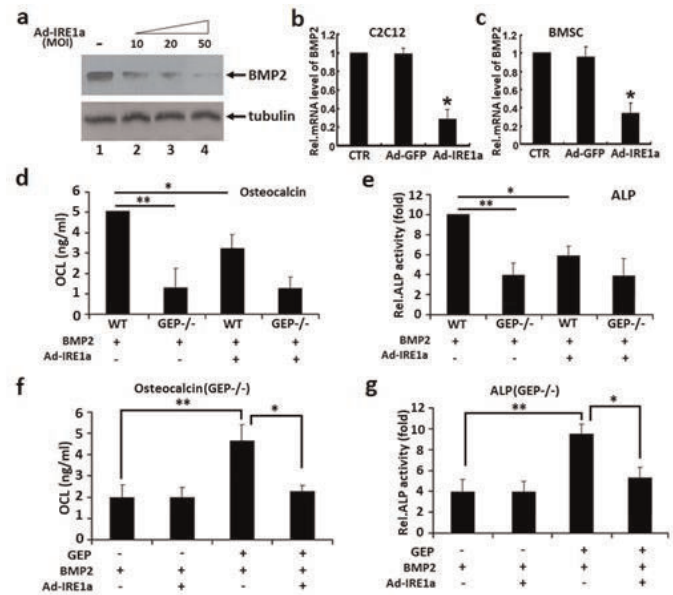

Figure 5. GEP is required for BMP2-induced osteoblastogenesis and IRE1a inhibition in vitro.

The canonical Wnt/β-catenin signaling improves osteoblast and osteocyte survival by enhancing DNA repair. Abhishek Chandra*[1], Tiao Lin[1], Ji Zhu[2], Wei Tong[3], Xiaowei Liu[1], Keith Cengel[4], Bing Xia[5], Ling Qin[1]. [1]University of Pennsylvania, USA, [2]University of Pennsylvania, School of Medicine, USA, [3]Perelman school of medicine, USA, [4]University of Pennsylvania, USA, [5]Rutgers Cancer Institute of New Jersey & Robert Wood Johnson Medical School, USA

Focal radiotherapy for cancer patients has detrimental effects on tumor adjacent bones and currently there is no curative treatment available. We previously reported that focal radiation causes massive cell death in osteoblasts and a modest reduction of osteocyte number in rat bone, and that daily injection of parathyroid hormone (PTH, 1-34) alleviates radiation-induced bone loss by promoting the survival of osteoblasts and osteocytes. Osteoblastic cell culture and calvarial organ culture experiments demonstrated that the anti-apoptotic effect of PTH on osteoblast lineage cells after radiation is mainly mediated through the β-catenin pathway. Consistently, we found that Wnt3a, a canonical Wnt ligand, almost completely mitigated the 10-fold increase in radiation-induced apoptosis in osteoblasts and osteocytes by activating β-catenin. Radiation exposure rapidly generates DNA lesions, among which DNA double strand break (DSB) is the most deleterious form that causes cell death. Using immunofluorescence staining of γ-H2AX and the comet assay, we found that Wnt3a greatly reduced the number of nuclear γ-H2AX foci (a DSB marker) and the percentage of comet tail (corresponding to damaged DNA) in irradiated osteoblasts and osteocytes and that Dkk1 abolished both effects of Wnt3a, suggesting that canonical Wnt pathway promotes the DSB repair. Most radiation-induced DSBs are repaired through non-homologous end-joining (NHEJ), which requires the binding of Ku70/80 heterodimer to DSB ends. Interestingly, we found that Wnt3a modestly elevated Ku70 amount and remarkably stimulated nuclear heterodimer formation of Ku70/80 by activating the b-catenin pathway. In addition, Wnt3a suppressed the activation and nuclear localization of cleaved caspase-3, a main effector caspase responsible for cell death. Osteoblast and osteocyte apoptosis is also the major cause for glucocorticoid-induced osteoporosis. We found that dexamethasone greatly stimulated ostebolast apoptosis accompanied by a strong increase in γ-H2AX foci number and that addition of Wnt3a completely reversed such DNA damage and cell death. In conclusion, we have demonstrated a strong anti-apoptotic effect of canonical Wnt/β-catenin on osteoblasts and osteocytes and a novel role of this pathway in regulating DSB repair machinery. Our data also suggest that Wnt agonist, such as Sclerostin neutralizing antibody, could be a potential therapeutic treatment for radiation- and steroid-induced osteoporosis.

A Glimpse into MicroRNA 23a~27a~24-2 Regulation of Bone Development. Austin Kemper*[1], Mohammad Hassan[2]. [1]University of Alabama at Birmingham, USA, [2]University of Alabama, USA

Previously we have shown that miR 23a~27a~24-2 (miR-cluster) is involved in a regulatory network with Runx2 and Satb2, two key transcription factor for osteoblast differentiation. During differentiation of osteoblasts we have observed reciprocal expression levels of miR-cluster and Hoxa5, Hoxa10, and Hoxa11; spatially and temporally regulated transcription factors. Further investigations have uncovered regulation of these Hox factors by miR-cluster. Reporter and ChIP assays revealed binding of these factors to the promotors of Runx2 and Osteocalcin to promote osteogenesis. These experiments have indicated a regulatory role for miR-cluster in skeletal and craniofacial development. Recently we have developed two mouse lines for studying this cluster. The first is a global knockout mouse for the cluster and the second is a drug inducible anti-miR-cluster (miR-ZIP) transgenic knockdown mouse to investigate how loss of the miR-cluster impacts embryonic and postnatal development. We found that heterozygous knockout mice have higher bone mineralization, narrower cranial sutures, and extended zygomatic arches in alcian blue and alizarin red stained skeletal preparations at birth. MicroCT has revealed higher cortical bone volume, bone mineral density and cortical thickness in these mice. RNA sequencing in MC3T3 mouse preosteoblast cells overexpressing miR-cluster has revealed many potential targets of the cluster including many chromatin binding transcription factors such as Phf10 and Lin9. Validation of Phf10 in miR-cluster overexpression cells revealed significantly increased expression. Overexpression of Phf10 was found to increase expression of p21, an important regulator of cell cycle progression and an inhibitor of cellular proliferation. Further characterization and identification of the molecular mechanisms involving miR 23a~27a~24-2 contributing to regulation of bone and craniofacial development could have a strong impact on research into osteoporosis and other human diseases.

Bisphosphonate Suppress Mesenchymal Cells Proliferation and Differentiation into Osteoblast via Attenuation of Wnt Signaling. Seungwoo Han[1], Hye-Ri Park*[2], Min-Su Han[2], Youn-Kwan Jung[2], Eun-Ju Lee[2], Ji-Ae Jang[2], Gun-Woo Kim[2]. [1]Daegu Fatima Hospital, South Korea, [2]Laboratory for arthritis & bone biology, Fatima research institute, South Korea

Bisphosphonates (BPs) are widely used for osteoporosis, but its long term use can cause a femoral insufficiency fracture which is mainly responsible for decreased bone turnover by BP-mediated suppression of osteoclast. As a farnesyl pyrophosphate synthase inhibitor, BP can attenuate various farnesylated and geranylgeranylated GTPase proteins, such as Rab, Rac, Rap, Ras and Rho. Among them, especially Rho GTPase signaling is critical in mesenchymal cell commitment into osteoblast by RUNX2 induction, but the role of BP in osteoblast differentiation is still controversial. We investigated the effect of BP on osteoblast and bone marrow stromal cells in vivo and underlying mechanisms. Mice with zolendronate (ZA) administration (0.1 mg/kg intraperitoneal weekly) showed higher bone mass and decreased osteoclast number per bone surface. Further, ZA-administrated mice revealed an attenuated mineral deposition rates and decreased expression of osteogenic marker such as Runx2, osterix, and osteocalcin in RNA and protein level. ZA significantly decreased the number of fibroblast colony-forming units (CFU-F) from bone marrow stromal cells (BMSCs), suggesting the decreased proliferation of BMSCs by ZA. That was repeated in vitro BrdU incorporation assay using mouse mesenchymal cell line, C3H10T1/2 cells and BMSCs. In addition, ZA diminished the osteoblast differentiation in both C3H10T1/2 cells and BMSCs. ZA significantly decreased the expression of canonical Wnt target protein, Lef1, and increased Dkk2 expression. Furthermore, the nuclear translocation of β-catenin was markedly decreased by ZA, suggesting that the inhibition of canonical Wnt signaling is associated with reduced mesenchymal commitment to the osteoblast lineage by BPs. Together, these results provide the evidence of BPs-induced impairment of mesenchymal cell proliferation and osteoblast differentiation, and a mechanistic insight into how BPs lead to the impaired bone quality causing insufficiency fracture.

Bobby Sox homology regulates osteogenic/odontogenic differentiation of human dental pulp stem cells. Eui Kyun Park[1], Young-Ae Choi*[2], Hye Jung Ihn[3], Jiwon Lim[2], Ju Ang Kim[2]. [1]Kyungpook National University, South Korea, [2]Department of Oral Pathology & Regenerative Medicine, School of Dentistry, Kyungpook National University, South Korea, [3]Department of pharmacology, School of medicine, Kyungpook National University, South Korea

Transcription factors have been implicated in regulating the differentiation of odontoblasts from dental pulp stem cells (DPSCs) but their regulatory network is not completely understood. In this study, new transcription factors that control the odontoblast differentiation of human DPSCs were identified using a microarray. The results revealed bobby sox homolog (BBX) was expressed most strongly during odontoblast differentiation. Validation using RT-PCR revealed the strong expression of BBX during the odontoblast differentiation of DPSCs. BBX expression was also detected in adult molar odontoblasts and other tissues, including the heart, kidney, testis and bone marrow. To understand the role of BBX in odontoblast differentiation, BBX variant 1 and 2 cDNAs were cloned and overexpressed in DPSCs. The overexpression of BBX cDNA in DPSCs induced substantial mineralization and expression of the odontoblast marker genes, such as alkaline phosphatase (ALP), osteopontin (OPN), bone sialoprotein (BSP), dentin matrix acidic protein 1 (DMP1), and Dentin sialophosphoprotein (DSPP). Moreover, the knock-down of BBX using shRNA substantially decreased the expression of ALP and DSPP. Overall, these results suggest that BBX plays an important role during the odontoblast differentiation of human DPSCs.

Comprehensive profiling of gene expression temporal dynamics during osteoblastogenesis in the context of differing genetic backgrounds. Kwangbom Choi[1], Dana Godfrey[1], Matthew Hibbs[2], Cheryl Ackert-Bicknell*[3]. [1]The Jackson Laboraotry, USA, [2]The Jackson Laboratory, USA, [3]University of Rochester, USA

The proper maturation and function of osteoblasts is critical for maintaining bone mass. However, the differentiation of osteoblasts is inadequately characterized at a molecular level and the impact of genetic background on this process is largely unknown. To address this, we measured whole genome transcriptional dynamics using RNA-seq throughout differentiation from the pre-osteoblast stage to mature osteoblasts. Specifically, neonatal mice were generated by breeding male C57BL/6J (B6) mice expressing cyan florescent protein (CFP) under the control of the Col3.6 promoter to female mice of each of four inbred strains: B6 itself, 129S1/SvImJ, C3H/

HeJ and CAST/EiJ. Calvarial cells were obtained via standard protocols, cells cultured for 4 days, and the FACS sorted to enrich for pre-osteoblasts based on the presence of CFP. CFP+ cells were returned to culture, differentiated into osteoblast by culturing in the presence of 50 mg/ml ascorbic acid, 4 mM beta-glycerol phosphate and RNA was collected at 2, 4, 6, 8, 10, 12, 14, 16 and 18 days post differentiation. mRNA profiles for each time point for each of the four strains were generated by Next-Gen RNA sequencing, using an Illumina HiSeq 2000. The alignments for abundance estimation of transcripts was conducted using Bowtie (0.12.9) and expression level per gene was calculated using RSEM (1.2.0). In order to identify co-expressing genes based on temporal expression pattern, we utilized Weighted Gene Co-expression Network Analysis and hierarchical clustering. We were able to find only two groups (or modules) of genes, whose expression levels monotonically increase or decrease within the measured time frame. A logistic growth model was fit to each gene in these two modules and the time of maximal increase or decrease was estimated. This allowed us to order genes relative to one another across osteoblastogenesis with regards to when expression increased or decreased and this temporal ordering was compared between strains. We observed that the major impact of genetic background was on the pace of differentiation, and that the ordering of genes was only minimally influenced by strain with some notable exceptions. These outliers in gene expression timing may be potential drug targets and should be further evaluated. From this data we can, in detail, define the gene expression steps associated with the maturation of pre-osteoblasts to mature mineralizing osteoblasts thus increasing our understanding of the process.

COUP-TFII suppression by miR-194 determinates fate of mesenchymal stromal cells. Jeong-Tae Koh*[1], Byung-Chul Jeong[2], In-Hong Kang[3], Hyuck Choi[4], Sin-Hye Oh[5], Yu-Ri Kim[3]. [1]Chonnam National University, South Korea, [2]Chonnam National University School of Dentistry, South Korea, [3]Department of Pharmacology & Dental Therapeutics, School of Dentistry, Chonnam National University, South Korea, [4]Research Center for Biomineralization Disorders & Dental Science Research Institute, School of Dentistry, Chonnam National University, South Korea, [5], South Korea

Mesenchymal stromal cells (MSCs) have the capacity to differentiate into adipocytes and osteoblasts. Differentiation of MSCs is tightly controlled by various growth factors, transcriptional factors, and other intracellular molecules. The chicken ovalbumin upstream promoter-transcription factor II (COUP-TFII) has been introduced to be a regulator of MSC fate. In this study, we aimed to investigate if microRNAs targeting COUP-TFII can determinate the fate of MSCs. In the present study, we observed that miR-194 was involved in the reciprocal regulation of osteoblast and adipocyte differentiation from MSC lineage cells. In the cultures of mesenchymal lineage C3H10T1/2 and bone marrow stromal cells, osteogenic stimuli increased miR-194 expression with the decreases in COUP-TFII expression, whereas adipogenic stimuli reduced miR-194 expression with the increases in COUP-TFII expression. A luciferase assay with COUP-TFII 3′-UTR reporter plasmid, including miR-194 binding sequences, showed that miR-194 reduced the luciferase activity. However, miR-194 did not affect the activity of mutated COUP-TFII 3′-UTR reporter. Enforced expression of miR-194 significantly enhanced osteoblast differentiation, but inhibited adipocyte differentiation with decreasing COUP-TFII mRNA and protein level. In contrast, inhibition of the endogenous miR-194 reduced matrix mineralization in the MSC cultures, and promoted the formation of lipid droplets by rescuing COUP-TFII expression. Furthermore, overexpression of COUP-TFII reversed the effect of miR-194 on the cell fates. Taken together, our data demonstrated that miR-194 acts as a critical regulator of COUP-TFII and can determinate the fate of MSCs into osteoblasts.

Genome-wide DNase hypersensitivity analysis reveals novel transcriptionally active regions during osteoblastogenesis. Phillip Tai*[1], Hai Wu[2], Jonathan Gordon[2], Troy Whitfield[3], Andre Van Wijnen[4], Jane Lian[5], Gary Stein[6], Janet Stein[7]. [1]University of VermontCollege of MedicineDepartment of Biochemistry, USA, [2]University of Vermont, USA, [3]University of Massachusetts Medical School, USA, [4]Mayo Clinic, USA, [5]University of Vermont College of Medicine, USA, [6]University of VermontCollege of Medicine, USA, [7]University of Vermont, USA

The discovery and characterization of regulatory sequences that control bone-related genes during development have been limited by the classical approaches for identifying *cis*-regulatory modules. These approaches relied primarily on sequence conservation in promoters and the identification of disease-causing, non-coding mutations near critical genes. New technologies have revealed the extent to which regulatory sites can reside far beyond promoter regions. To identify novel and dynamic *cis*-regulatory modules, we probed the presence of open chromatin using DNase hypersensitivity analysis on a genome-wide scale during MC3T3 osteoblast differentiation using high-throughput sequencing. We demonstrate that DNase hypersensitivity profiling can accurately define the boundaries of active regulatory sequences across the genome. More than 220,000 unique DNase hypersensitive sites (DHSs) were identified, with a majority being highly dynamic throughout differentiation. DHSs that overlap promoters are generally constitutive throughout differentiation, while dynamic DHSs are found predominantly in intronic and intergenic regions. This observation coincides with the regulatory nature of intronic and intergenic enhancer regions.

To understand the function of dynamic DHSs, we examined the representation of osteogenic regulatory motifs within these regions, revealing specific motif rules for osteoblast-related transcription factors. One striking finding is that at peak levels of *Runx2* expression in committed osteoblasts (d9), RUNX2 binds distinct motifs according to preference rules defined by genomic position. Intronic sequences enriched for RUNX2 are overrepresented by both TGTGGT and TGCGGT motifs at equal ratios, while in intergenic sequences, only the TGTGGT motif is over-represented, suggesting a functional distinction between intronic and intergenic recruitment of RUNX2. Some of these RUNX2 enriched regions appear to precede DHS regions that emerge later during differentiation. The importance of position-dependent motif preferences is under investigation. In summary, DHS profiling of the osteoblast genome has identified highly dynamic regulatory modules at non-promoter regions. Additionally, the discovery of distinct binding patterns of bone-essential transcription factors in intronic versus intergenic sequences further enriches our understanding of the concerted regulatory network that drives bone differentiation.

MO0243

High Osteogenic Potential of fibroblast from FOP Patients. Nathalie Bravenboer*[1], Dimitra Micha[2], Huib van Essen[3], Coen Netelenbos[4], Gerard Pals[2], Marelise Eekhoff[5]. [1]VU University Medical Center, The Netherlands, [2]Department Clinical Genetics, VU University Medical Center, Netherlands, [3]Department Clinical Chemistry, VU University Medical Center, Netherlands, [4]VU Medical Center, The Netherlands, [5]Deparment Internal Medicine, VU University Medical Center, Netherlands

Fibrodysplasia ossificans progressiva (FOP) is a rare, extremely disabling genetic disorder characterized by progressive heterotopic ossification preceded by episodic inflammatory soft tissue swellings, leading to early death. There is no effective treatment. We have developed an in vitro system to investigate trans-differentiation towards the osteogenic cell lineage using platelet lysate (PL). PL contains many growth factors and cytokines important for cell growth and differentiation. Since osteogenic potential is high in FOP, we hypothesize that lower concentrations of PL are necessary for osteogenic differentiation of cells from FOP patients compared to control cell lines.

Skin biopsies were obtained from four patients with FOP. Sub-dermal fibroblasts were cultured in Ham F10 media. Fibroblast cell lines from 4 age- and sex-matched healthy individuals were used as controls. Osteogenic trans- differentiation was induced by culturing in osteogenic medium containing beta glycerol phosphate, ascorbic acid and different concentrations of PL (2%, 1%, 0.5%) or FCS (10%). Osteogenic differentiation was determined by mRNA expression of runx2, alkaline phosphatase and osteocalcin at day 0,3, 7, 14 and 21. Mineralization capacity was detected at day 21 by alizarin red staining.

In all four cell lines the classical mutation in the activin receptor-like kinase2 (Alk2) receptor was confirmed. Runx2 and alkaline phosphatase mRNA expression started to increase 3 days after addition of osteogenic medium with a maximum increase at day 7, both in control and FOP cell lines with all PL concentrations. Runx2 was significantly higher in FOP cell lines compared to controls at t=7 for 2% PL, at T=14 for all PL concentrations and at t=21 for 1% PL. Alkaline phosphatase was not different in FOP cell lines compared to controls. Osteocalcin mRNA expression was not increased osteogenic medium, but the mRNA expression was higher in FOP cell lines compared to controls at t=0 for 2%PL. After 21 days of culture calcium deposits were detected with alizarin red staining in FOP cell lines, similarly to the control cell lines.

We demonstrated osteogenic differentiation both in fibroblasts from FOP patients and controls. The concentration of platelet lysate required to trigger the cells into the osteocytic lineage is not relevant. FOP cell lines express higher amounts of runx2 during the trans-differentiation process which suggests a higher osteogenic potential.

IL-17 inhibits osteoblast differentiation and bone regeneration in rat. Youngkyun Lee*[1], Yong-Gun Kim[2], Jae-Young Kim[3]. [1]Kyungpook National University School of Dentistry, South Korea, [2]School of Dentistry, Kyungpook National University, South Korea, [3]Kyungpook National University, South Korea

Objective: The interleukin-17 (IL-17) family is a group of pro-inflammatory cytokines that are produced by a subset of helper T cells. IL-17 family members are not only involved in the immune response of tissues but also play a role in bone

metabolism. Although the role of IL-17 in osteoclast-mediated bone resorption has been extensively studied, its role during osteoblast-mediated bone formation has rarely been investigated. In this study, we examined the effect of IL-17 on osteogenesis in rats both *in vitro* and *in vivo*.

Design: To evaluate osteogenesis *in vitro*, rat calvarial osteoblast precursor cells were cultured for 14 days in osteogenic medium with or without 50 ng/mL IL-17. Osteogenic activity was evaluated by alkaline phosphatase and alizarin red staining. The mRNA expression of alkaline phosphatase, osteocalcin, and osterix was also measured by using real-time PCR. To test whether IL-17 affects bone formation *in vivo*, bone filling was examined by micro-computed tomography and histological observations at 8 weeks after critical-sized defects were made in rat calvaria.

Results: Rat calvarial cells expressed distinct IL-17R isoforms compared with human mesenchymal stem cells and mouse calvarial cells. The presence of IL-17 significantly reduced alkaline phosphatase and alizarin red staining and the expression of alkaline phosphatase, osteocalcin, and osterix *in vitro*. IL-17 also significantly inhibited the filling of calvarial defects *in vivo*.

Conclusion: IL-17 exerted a negative effect on osteogenesis in a rat model. In contrast to the previously reported beneficial effect on osteogenic differentiation of human mesenchymal stem cells, our results suggest a species or cell type-specific role for IL-17 in bone formation.

MO0245

Inhibition of Adipogenic and Osteogenic Differentiation of hBM-MSCs by FGF1 and FGF2 in 3D Collagen Gels. Solange Le Blanc*[1], Meike Simann[2], Franz Jakob[3], Norbert Schuetze[4], Tatjana Schilling[5]. [1]University of Wuerzburg, Orthopedic Center for Musculoskeletal Research, Germany, [2]University of Wuerzburg, Orthopedic Center for Musculoskeletal Research, Germany, Germany, [3]University of Wuerzburg, Orthopedic Center for Musculoskeletal Research, Germany, [4]University of Wuerzburg, Orthopedic Center for Musculoskeletal Research, Germany, [5]University of Wuerzburg, Germany

Existing evidence suggests that there is an inverse relationship between osteogenesis and adipogenesis in the bone marrow; enhanced differentiation in one pathway results in a diminished differentiation in the other. This is particularly relevant in the pathogenesis of osteoporosis, the most prevalent disorder of bone remodeling, in which the loss of bone is accompanied by a parallel increase of adipose tissue in the bone marrow.

Previous results of our group suggested that fibroblast growth factor 1 (FGF1) signaling might act as a molecular check point and switch of differentiation. Based on this, the main objective of this work was to study the effect of FGF signaling on adipogenic and osteogenic differentiation of primary human bone marrow mesenchymal stem cells (hBM-MSCs) in 3D type I collagen gels, in order to better mimic the environment of native bone marrow.

hBM-MSCs embedded in 3D collagen gels were chemically induced to differentiate into adipocytes or osteoblasts in the absence and presence of recombinant FGF1 or FGF2. Differentiation was evaluated by histochemical staining of cryosections for lipid vesicles, alkaline phosphatase activity, and matrix mineralization and by measuring the expression levels of differentiation markers by quantitative PCR.

Both, FGF1 and FGF2 exerted a dose-dependent negative effect on adipogenic differentiation. A reduction in lipid droplet formation and in the gene expression of adipogenic markers was observed for FGF-treated samples. Similarly, FGF1 and FGF2 had got a dose-dependent negative effect on osteogenic differentiation in 3D. Alkaline phosphatase activity and matrix mineralization were inhibited by high concentrations of FGFs, as was the gene expression of osteogenic markers.

Taken together, these results indicate that the continuous stimulation with FGFs during the differentiation induction of hBM-MSCs in 3D collagen gels results in the inhibition of both, adipogenesis and osteogenesis.

Microarray Analysis of Pulsed Electromagnetic Field (PEMF) Stimulatory Effects on Human Bone Marrow Stromal Cells. Nicola Partridge[1], Zhiming He*[2], Nagarajan Selvamurugan[3]. [1]New York University College of Dentistry, USA, [2]New York University, USA, [3]University of Medicine & Dentistry of New Jersey, USA

The fundamental mechanism of the osteogenic effect of pulsed electromagnetic field (PEMF) is currently not fully understood. We proposed that it is caused by the regulation of gene expression by an extracellular signal. Thus, in this study we performed Affymetrix microarray and RT-PCR analyses to systematically investigate the patterns of gene expression with PEMF using human bone marrow stromal cells (hBMSCs). Fresh bone marrow from a 27 year old healthy female donor was purchased (Lonza) to obtain hBMSCs. PEMF (Cervical-Stim by Orthofix, Inc.) treatment was initiated 24 h after BMSCs were seeded, with 4 h daily exposure every day throughout the experimental period. Cell samples from both PEMF and sham (control) groups were collected simultaneously at different time points corresponding to pre-osteoblast proliferation, differentiation and mineralization phases. Total RNAs were analyzed using Affymetrix Human U133 plus 2.0 Gene Chips and qRT-PCR. ERK/MAPK activation was observed after 30-60 min of PEMF exposure on day 5 of culture and paralleled by stimulation of cyclin D1 at 2h which was chosen for the subsequent microarray analysis. After fully evaluating PEMF-regulated gene expression and intense gene ontology analysis, our results indicate that PEMF stimulation of hBMSCs' proliferation mainly affect genes of cell cycle regulation, structure and some growth receptors or kinase pathways. There were a total of 114 known genes up regulated and 17 known genes down regulated at this time point. During the differentiation (day 23) and mineralization (day 33) stages, a total of 37 and 173 known genes, respectively, were identified as significantly regulated. In these two stages, PEMF-regulated osteoblast gene expression mainly involved down regulation of transcriptional regulators, metabolism, proteases and regulators, and also cell adhesion and binding proteins, cytoskeletal and structural proteins. Notably, the transforming growth factor beta (TGF-β) signaling pathway seems to be most highly regulated by PEMF. TGFB2 gene expression was up regulated at both stages, while TGF-β regulator-1(TBRG1) was increased at 23 days. PEMF also affected Fibrillin-2 (FBN2) expression which regulates osteoblast maturation through binding to TGF-β and controlling its bioavailability. Taken together, our results provide insights into PEMF-regulated gene expression of the entire human genome, which provides the fundamentals to reveal the mechanism of action of PEMF therapy.

***Connective Tissue Growth Factor* Reporter Mice Label a Subpopulation of Mesenchymal Progenitor Cells that Reside Around Trabecular Bone.** Peter Maye*[1], Wen Wang[2], Sara Strecker[3], Yaling Liu[3], Mark Kronenberg[1], Spenser Smith[1], Liping Wang[1], Fayekah Assanah[3]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut, USA, [3]University of Connecticut Health Center, USA

Few gene markers selectively identify skeletal progenitor cells inside the bone marrow. We have investigated a cell population located in the mouse bone marrow labeled by *Connective Tissue Growth Factor* reporter expression (CTGF-EGFP). Bone marrow flushed from CTGF reporter mice yielded an EGFP+ stromal cell population. Interestingly, the percentage of stromal cells retaining CTGF reporter expression decreased with age and was half the frequency in females compared to males. Relative to past fate mapping strategies to mark bone marrow skeletal progenitors *in vitro*, including Twist2-Cre and Osterix-Cre approaches, CTGF reporter expression and endogenous CTGF expression marked largely overlapping cell populations in culture. Consistent with this past work, sorted EGFP+ cells displayed multipotent skeletal potential being able to differentiate into osteoblasts, chondrocytes, and adipocytes *in vitro* and osteoblasts, adipocytes, and stromal cell lineages after transplantation into a calvaria defect. Examination of CTGF reporter expression in bone tissue sections showed that EGFP+ cells were highly localized to regions around trabecular bone and were rarely detected in the periosteum, endocortical surfaces, or the central marrow space. Comparison of CTGF and Osterix reporter expression in bone tissue sections indicated an inverse correlation between strength of CTGF expression and osteoblast maturation. Down regulation of CTGF reporter expression also occurred during in vitro osteogenic differentiation. Collectively, our studies indicate that CTGF reporter mice selectively identify a subpopulation of bone marrow skeletal progenitor cells that reside around trabecular bone.

3D Scaffolding with Adipose Derived Mesenchymal Stem Cells – Their Osteogenicity and Osteoblast Mineralization. Morten Dahl*[1], Susanne Syberg[2], Niklas Jorgensen[3], Else Marie Pinholt[4]. [1], Denmark, [2]Research Centre for Ageing & Osteoporosis, Denmark, [3]Copenhagen University Hospital Glostrup, Denmark, [4]Department of Maxillofacial Surgery, Denmark

Purpose: Adipose derived mesenchymal stem cells (ADMSCs) can differentiate into mineralizing osteoblasts and may generate neoangiogenesis. Three-dimensional (3D) scaffolds like titanium granules and dense collagen matrix may be suitable carriers for these cells. The aim of the current in vitro experiment was to demonstrate the osteogenic potential of ADMSCs seeded on 3D titanium granules and 3D dense collagen matrix.

Materials and methods: ADMSCs were isolated, cultured in osteoblast-differentiating medium and evaluated with alkaline phosphatase (ALP) assay, osteogenic gene expression, and ALP staining. ADMSC-derived osteoblasts were seeded on oxidized and non-oxidized titanium granules (TiO_2 and Ti granules) and dense collagen matrixes and the cultures were evaluated for in vitro mineralized matrix formation (Alizarin Red assay) and gene expression of osteoblast-related genes. Results are presented as mean ± SEM.

Results: ADMSCs expressed osteoblastic lineage genes, CBFA-1 and stained strongly for ALP. Mineralization measured as absorbance was significantly higher for cells seeded on TiO_2 granules on day 10 (0.1883 ± 0.0342), 14 (0.2738 ± 0.0854) and 17 (0.3152 ± 0.1077) than on cells seeded on Ti granules (0.0421 ± 0.0213, 0.473 ± 0.0143

and 0.478±0.0102, respectively) or cells alone (0.0129±0.0046, 0.0275±0.0189 and 0.0230±0.0057, respectively) after correcting for controls (empty wells, TiO_2 and Ti granules without cells). Relative ALPL expression was significantly higher for cells seeded on TiO_2 granules on day 1 (1.90±0.18) compared to cells alone (1.04±0.07). On day 4 relative ALPL expression was significantly higher for cells seeded on Ti granules (1.20±0.10) compared to cells alone (0.88±0.05). Relative RUNX2 expression was significantly higher for cells seeded on TiO_2 granules on day 1 (2.48±0.27) compared to cells seeded on Ti granules (1.35±0.23) and cells alone (1.41±0.13). Relative COL1α1 expression was significantly higher for cells alone on day 1, (5.60±0.78), 4 (2.12±0.42) and 8 (1.69±0.43) than for cells seeded on TiO_2 granules (1.35±0.36, 0.17±0.02 and 0.14±0.01, respectively) and Ti granules (1.02±0.31, 0.45±0.07 and 0.56±0.07, respectively).

Conclusion: ADMSCs have osteogenic potential especially when seeded on TiO_2 granules evidenced by increased mineralization. TiO_2 granules may be used as carrier for ADMSCs from laboratory bench to the patient within bone defects in maxillofacial surgery.

Loss of Notch Signaling in Skeletogenic Mesenchymal Stem Cells Results in Fracture Nonunion. Cuicui Wang*[1], Jason Inzana[2], Michael Zuscik[3], Regis O'Keefe[4], Hani Awad[1], Matthew Hilton[5]. [1]University of Rochester Medical Center, USA, [2], USA, [3]University of Rochester School of Medicine & Dentistry, USA, [4]University of Rochester, USA, [5]Duke University Musculoskeletal Research Center, USA

Although the vast majority of the fractures progress to union, fracture non-union develops in 10-20% of all patients. It is believed that fracture non-union or inappropriate fracture repair is due to the inadequate regenerative potential of the tissue on the cellular level. This regenerative potential is largely dictated by stem cell populations that reside in the bone marrow and periosteal tissue surrounding the bone. Recently, our laboratory identified the Notch signaling pathway as a critical maintenance factor for bone marrow derived mesenchymal stem cells (BMSCs) during development. To determine whether Notch signaling in MSCs or more mature osteoblasts is required during the process of bone fracture repair, we preformed open, non-stabilized tibial fractures on *Prx1Cre;RBPjk$^{f/f}$*, *Col1Cre(2.3Kb);RBPjk$^{f/f}$*, and control mice. Following injury, bone fractures were analyzed via radiographs, biomechanical torsion testing, histology, immunohistochemistry, TRAP staining, and real-time qPCR at multiple time-points post fracture. We also assessed the number of BMSCs present in mutant and control mice. Our data demonstrate that *Prx1Cre;RBPjk$^{f/f}$* mutant mice display characteristics most commonly observed in human hypertrophic non-unions, while *Col1Cre(2.3Kb);RBPjk$^{f/f}$* and control fractures heal normally. Although the *Prx1Cre;RBPjk$^{f/f}$* mutants did form a substantial external callus involving periosteal stem cells, they did not develop an appropriate internal callus which ultimately resulted in fracture non-union. Furthermore, *Prx1Cre;RBPjk$^{f/f}$* mutants exhibited a dramatic reduction in the pool of BMSCs. We also performed stabilized or rigidly fixed femur fractures on *Prx1Cre;RBPjk$^{f/f}$* mutants to determine whether fracture instability was required for fracture non-union. Stabilized femur fractures of *Prx1Cre;RBPjk$^{f/f}$* mutants also resulted in fracture non-union, suggesting that insufficient fracture stabilization is not absolutely required for fracture non-union in these mutant mice. Therefore, all fracture non-unions observed in *Prx1Cre;RBPjk$^{f/f}$* mutants likely resulted from BMSC pool depletion or loss of Notch signals within BMSCs. Collectively, our data reveal that BMSCs are a vital component of fracture repair and act to form the internal callus providing stability to the fracture and promoting healing, and that loss of Notch signaling in MSCs and depletion of BMSCs results in bone fracture non-unions.

Aging Effects of Advanced Glycation End Products on Osteoclast Resorption on Human Bone. Xiao Yang*[1], Chintan Gandhi[2], Rahman Md mizanur[3], Mark R. Appleford[4], Lian-Wen Sun[5], Xiaodu Wang[6]. [1]University of Texas at San Antonio & Beihang University, USA, [2]Department of Mechanical Engineering, University of Texas at San Antonio, USA, [3]Department of Medicine - Clinical Immunology & Rheumatology, University of Texas Health Science Center at San Antonio, USA, [4]Department of Biomedical Engineering, University of Texas at San Antonio, USA, [5]School of Biological Science & Medical Engineering, Beihang University, China, [6]UTSA, USA

Advanced glycation end-products (AGEs) are products of non-enzymatic glycation and oxidation of long-lived proteins (e.g. collagen) and lipids [1]. AGEs are reported to accumulate in extracellular matrix as seen in bone tissues of elderly people and affect bone resorption/formation during remodeling process, thus leading to skeletal fragility [2]. However, it has been controversial in the previous studies regarding the age-related influences of matrix AGEs on osteoclastic resorption activities in bone.

In this study, we collected bone slices from mid-diaphysis of human cadaveric femurs of three age groups: young, middle-aged and elderly group, respectively. The bone slices were polished and sterilized, and then human osteoclast precursor cells (Lonza Walkersville Inc., MD) were seeded onto the bone slices. The precursor cells were activated with medium supplemented with M-CSF and RANKL and differentiated into osteoclasts. After terminating the cell culture in 14 days, osteoclastic resorption pits on the bone slices were stained and imaged. Next, the bone slices were demineralized to determine the areal AGEs distribution based on its autofluorescence intensity. The local resorption pit number and area were measured in regions with different AGEs concentrations. Moreover, the matrix AGEs distribution (autofluorescence intensity) in interstitial and osteonal regions was also measured for the three age groups.

The results showed that 1) AGEs concentration in both osteonal and interstitial bone regions was significantly less in young bone than in middle-aged and elderly bones, suggesting that matrix AGEs accumulation is related to donor age; 2) the total resorption pits number/area were similar for all bone slices irrespective of age-related differences in local AGEs concentrations, suggesting that the average osteoclastic resorption activities are not dependent on matrix AGEs concentrations; 3) the resorption pit number/area in the interstitial bone regions were significantly less in young group than in elderly group, while such differences were not observed in the osteonal regions, thus suggesting that age-related changes in osteoclastic resorption activities were manifested only in biologically older bone tissues (interstitial bone). In summary, donor age induced changes in osteoclast resorption activities occur only in biologically older bone tissues.

Effect of Zoledronate on Particle-Induced Osteolysis In Vitro and In Vivo. Yue Ding*[1], Maolin Zhang[2], Huiyong Shen[2], Changchuan Li[2], Chi Zhang[2]. [1]Sun Yat-sen Memorial Hospital, , [2]Sun Yat-sen Memorial Hospital, China

Aseptic loosening is a key factor that causes implant failure of joint replacement. This study was aimed to investigate the effect of zoledronate on particle-induced osteolysis in vitro and in vivo. First, osteoclast precursors were isolated from the long bones of six-week-old C57BL/6J mice and assigned into 6 groups with different component: in Group A, the culture solution was added; in Group B, the macrophage colony stimulating factor(M-CSF), the receptor activator of nuclear factor kappa ligand(RANKL) and culture solution was added; in Group C, the titanium particles and culture solution was added; in Group D, the solution(the supernatant of cultured mouse macrophages induced by titanium particles after 24h) and culture solution was added; in Group E, the M-CSF, RANKL, ZOL and culture solution was added; in Group F, the solution, ZOL and culture solution was added. After 10 days coverslips were stained by the tartrate-resistant cultured acid phosphatase (TRAP). And the activity of the osteoclast cells was detected with the area of osteo-assay surface resorption. The TRAP positive multinucleated cells and the resorpion lacunae were observed in group B, group D, group E and group F. In group F(5.54%±1.25%), the area of resorption lacunae was smaller than that in group D(10.34%±1.69%, $P<0.01$,$t=5.61$).It suggested that the zoledronate could inhibit the activation of osteoclasts induced by the titanium particles in vitro. On the other hand, the model of particle-induced osteolysis in mice skull was established, and then a single dose of zoledronate was locally administered to investigate its effect on particle-induced osteolysis. Ninety-six 12-week-old C57BL/6J mice were equally allocated into eight groups, and different dosages of zoledronate were added. Fourteen days after operation, the animals were sacrificed in CO_2. According to the CT scan and Micro-computed Tomography, it showed an inverse correlation between dosage of zoledronate and the extent of bone resorption. According to these results, zoledronate may have the potential to be a therapeutic target for particle-induced osteolysis.

MO0252

Glucocorticoids Enhance Mature Osteoclast Activity Without Affecting RANKL Induced Osteoclast Formation. Ulf Lerner[1], Petra Henning*[2], Jan Tuckermann[3], Howard Conaway[4]. [1]Sahlgrenska Univesity Hospital, Sweden, [2]Centre for Bone & Arthritis Research, Sahlgrenska Academy, University of Gothenburg, Sweden, [3]University of Ulm, Germany, [4]University of Arkansas for Medical Sciences, USA

Glucocorticoid (GC) therapy is the greatest risk factor for secondary osteoporosis. Pathogenetic mechanisms involve an initial increase in bone resorption followed by decreased bone formation. In an effort to gain a better understanding of the resorptive activity of GC, we have used mouse bone marrow macrophages (BMM) to determine if GCs can directly modulate RANKL stimulated osteoclast formation and/or activity. Experiments performed in plastic wells showed that GCs (dexamethasone, hydrocortisone, and prednisolone) inhibited osteoclast number and size during the initial phases of RANKL stimulated osteoclastogenesis. In more prolonged cultures, escape from GC induced inhibition occurred and an enhanced number of osteoclasts was formed, many with an increased area. These changes were not associated with any effect by dexamethasone on RANKL stimulated mRNA expression of several osteoclastic genes. When BMM cells were seeded on bone slices, no inhibition or

stimulation by GCs of RANKL induced osteoclast formation was observed, nor was the release of Trap5b affected. However, GCs (dexamethasone, hydrocortisone, and prednisolone) robustly enhanced RANKL stimulated formation of resorption pits and release of CTX. Release of CTX was concentration dependent, occurring at and above 1 nM of dexamethasone. The stimulation of pit formation was not associated with an effect on the mRNA expression of several osteoclastic genes (Acp5, Ctsk, Oscar) or osteoclastogenic transcription factors (c-fos, Nfatc1). The potentiation of RANKL induced CTX release by dexamethasone was significantly less in BMM cells from mice with conditional knockout of the glucocorticoid receptor (GRLysMCre). No effect by dexamethasone on CTX release was observed in RANKL stimulated BMM from GRdim mice, which are unable to dimerize the GC receptor. These data suggest that: 1. GCs do not have a direct effect on RANKL stimulated osteoclast formation, and 2. a direct enhancement of RANKL mediated resorption is stimulated by the dimeric GC receptor.

MO0253

Kinase Activity of Leucine Rich Repeat Kinase 1 (LRRK1) Is Essential for Osteoclast Resorptive Activity. Weirong Xing*[1], Bo Liu[2], Shaohong Cheng[3], Robert Brommage[4], Subburaman Mohan[5]. [1]Musculoskeletal Disease Center, Jerry L. Pettis Memorial Veteran's Admin., USA, [2]VALLHCS, USA, [3]VA Loma Linda Health Care Systems, USA, [4]Lexicon Pharmaceuticals, USA, [5]Jerry L. Pettis Memorial VA Medical Center, USA

LRRK1 belongs to the ROCO protein family, and contains ankyrin repeats and leucine-rich repeats, a GTPase-like domain of Roc, a COR domain, and a serine/threonine kinase domain. We have shown that knockout (KO) of Lrrk1 in mice causes severe osteopetrosis. Precursors derived from Lrrk1 KO mice differentiate normally into multinucleated osteoclasts (OCs) in response to M-CSF/RANKL treatment, but these OCs fail to resorb bone due to defects in cytoskeletal rearrangement, peripheral sealing zones and ruffled borders. While bone resorption in KO mice is reduced dramatically, bone formation is not significantly affected. Lrrk1 KO mice have normal teeth, are healthy through one year of age and respond to anabolic PTH treatment, but are resistant to ovariectomy-induced bone loss. We characterized calvarial and mandibular bones of 6-wk old male Lrrk1 KO mice and control WT littermates (N = 4 pairs) by μCT analyses. In contrast to dramatically elevated trabecular BV/TV in long bones and vertebra (2- to 5-fold), deficiency of Lrrk1 had only a mild effect on the skull. Calvaria from Lrrk1 KO mice had normal TV, 20% higher BV and 17% higher BV/TV than control mice (all $P < 0.05$). For the mandible, TV, BV and BV/TV in Lrrk1 KO mice were increased 25%, 34% and 7%, respectively (all $P < 0.01$). To determine if LRRK1 regulation of OC function depends on kinase enzymatic activity, OC precursors derived from Lrrk1 KO mice were transduced with lentivirus containing 3xFlag/hLRRK1, 3xFlag/K650A hLRRK1 that abolishes GTP/GDP binding and kinase activity or GFP control. Transduced cells were differentiated to OCs on bone slices in the presence of M-CSF/RANKL before determining resorptive activity by pit formation. Comparable expression of WT hLRRK1 and K650A mutant hLRRK1 proteins in transduced OCs was confirmed by Western blot analyses with a Flag tag antibody. Ectopic expression of full length WT hLRRK1/Flag fusion protein in Lrrk1 null OCs completely rescued resorptive activity. In contrast, OCs with the kinase dead K560A hLRRK1/Flag mutant protein had no enhanced resorptive activity as compared to GFP expressing cells. Conclusions: 1) The modest skull and mandible phenotypes of Lrrk1 KO mice compared to long bones and vertebra are consistent with evidence that regulation of OC function is different in membranous and endochondral bone. 2) The requirement for LRRK1 in functional OCs depends upon its enzymatic kinase activity in addition to presumed scaffolding functions.

WASH complex subunit FAM21 is required for efficient osteoclast formation. Jian Zuo[1], Edgardo Toro[2], John Neubert[1], Kevin McHugh[2], Lexie Holliday*[3]. [1]University of Florida College of Dentistry, USA, [2]University of Florida, USA, [3]University of Florida College of Dentistry, USA

Our previous studies have suggested that binding between the vacuolar H^+-ATPase (V-ATPase) and microfilaments is vital for osteoclast function. Recent work in *Dictyostelium discoideum* showed that the Wiscott Aldrich and Scar Homolog (WASH) complex is involved in a process that sorts V-ATPases between membrane compartments which involves V-ATPase binding to microfilaments. In mammalian cells the WASH complex is known to function by regulating actin polymerization and is linked to vesicle sorting by the retromer complex. The purpose of this study was to test the hypothesis that the WASH complex plays a role in osteoclast function which may be tied to specialized sorting of V-ATPases.

We found by quantitative real time PCR and Western blotting that multiple subunits of the WASH complex were upregulated up to 3-fold during osteoclastogenesis. FAM21, a subunit of the WASH complex, was localized to a tubulovesicular network and, surprisingly, to the plasma membrane-associated actin rings of resorbing osteoclasts. This is the first description of FAM21 (or any subunit of the WASH complex) being localized to a plasma membrane domain. FAM21 co-localized with V-ATPase after treatment of resorbing osteoclasts with wortmannin, which stimulates internalization of V-ATPases from the ruffled plasma membrane into cytosolic vesicles. Immunoaffinity purification using an anti-V-ATPase antibody pulled down FAM21 only after treatment of osteoclasts with wortmannin. This association remained even when actin filaments were depolymerized with latrunculin A, a result consistent with a direct interaction between the WASH complex and V-ATPase as was reported in *Dictyostelium*. Knockdown of FAM21 by RNA interference in RAW 264.7 cells resulted in reduction of osteoclast formation by 85% even though it had no effect on the viability of the cells.

These data support the hypothesis that the WASH complex has a role that is vital for osteoclast formation, and may be crucial for specialized membrane trafficking required for bone resorption. As in *Dictyostelium,* the WASH complex may be involved in sorting V-ATPases between membrane compartments. This idea is supported by co-precipitation of FAM21 with V-ATPase during the retrieval of V-ATPases from the ruffled plasma membrane, but further studies are required to test this concept. These studies are the first to identify FAM21 and the WASH complex as important components of the bone resorptive machinery of osteoclasts.

Exosome-encapsulated miR-214 secreted from osteoclast to inhibit osteoblastic activity. Defang Li*[1], Chao Liang[2], Baosheng Guo[2], Jin Liu[2], Lei Dang[1], Liang Xu[3], Xiaojuan He[4], Zicai Liang[5], Aiping Lu[1], Ge Zhang[1]. [1]Institute for Advancing Translational Medicine in Bone & Joint Diseases, School of Chinese Medicine, Hong Kong Baptist University, Hong Kong SAR, China, [2]Institute for Advancing Translational Medicine in Bone & Joint Diseases, School of Chinese Medicine, Hong Kong Baptist University, Hong Kong SAR, China, [3]nstitute for Advancing Translational Medicine in Bone & Joint Diseases, School of Chinese Medicine, Hong Kong Baptist University, Hong Kong SAR, China, [4]Institute of Basic Research in Clinical Medicine, China Academy of Chinese Medical Sciences, Beijing, China, [5]Academician Chen Xinzi Workroom for Advancing Translational Medicine in Bone & Joint Diseases, Kunshan RNAi Institute, Kunshan Industrial Technology Research Institute, Kunshan, Jiangsu, China

Introduction

A number of miRNAs have been found to be present in body fluids of humans (mice) and mediate intercellular communication, suggesting that the potential role of miRNAs in mediating intercellular communication from osteoclasts to osteoblasts deserves intense investigation. Exosomes (50-100 nm) can function as efficient vectors to protect miRNAs from RNase-induced degradation to mediate intercellular communication. However, the functional role of exosomes in miRNAs transfer between osteoclasts and osteoblasts is unknown. Recently, our study implied that the increased miR-214 could regulate osteoblastic activity (Wang XG, et al., Nat Med, 2013), and miR-214 was abundant in primary osteoclasts other than primary osteoblasts. Therefore, it is highly desirable to study the role of exosomes in miR-214 transfer from osteoclast to osteoblast.

Methods

Experimental Design: (1) Study 1: The influence of miR-214 within osteoclasts in regulating the osteoblastic activity was investigated *in vitro*. (2) Study 2: The transferred miR-214 from osteoclasts to osteoblasts encapsulated in exosomes was confirmed *in vitro.* (3) Study 3: The role of DNM3, which was implicated in pinch off of exosomes and co-expressed with miR-214, in exosome-mediated miR-214 transfer from differentiating osteoclasts was investigated *in vitro*. Refer to http://sdrv.ms/1ay09xO for experimental protocols online.

Results

In study 1, the mRNA expression levels of osteoblast marker genes (*Bglap*, *Alp*, *Collagen-I*, *Opn*, *Runx2*, *Osx* and *Atf4*) in osteoblasts were down-regulated by increased miR-214 with osteoclasts. In study 2, the miR-214 levels in exosomes were increased after increasing the miR-214 level in differentiating osteoclasts by transfer of miR-214-expressing lentiviral vector (LV-miR-214), which could be inhibited by an exosome inhibitor GW4869. Further, flow cytometry data and confocal microscope analysis demonstrated that the exosomes from osteoclasts could be internalized into osteoblasts. In study 3, *DNM3* silencing by transfection of LV-DNM3 siRNA attenuated extracellular transfer of miR-214 in osteoclasts and promoted the expression of bone formation marker genes (*Bglap* and *Osx*) in osteoblasts *in vitro.*

Conclusions

The *in vitro* experiments demonstrated that miR-214 was transferred from osteoclast to osteoblast in exosome-encapsulated form, and DNM3 participated in the intercellular transfer of exosome-encapsulated miR-214.

MO0256

Interleukin-1 receptor-associated kinase-4 (IRAK4) promotes inflammatory osteolysis by activating osteoclasts and inhibiting formation of foreign body giant cells. Eri Katsuyama*[1], Takeshi Miyamoto[2], Yoshiaki Toyama[3]. [1]Keio University, Japan, [2]Keio University School of Medicine, Japan, [3]Keio uni., Japan

[objective and methods]

Foreign body giant cells (FBGCs) and osteoclasts, both of which are derived from bone marrow macrophages (BMMs), have been implicated in osteolysis and implant failure associated with inflammation or microbial infection. FBGCs are induced following implantation of biomaterials, however, we have little understanding about the regulation of FBGC differentiation. In this study, we focused on interleukin-1 receptor-associated kinase-4 (IRAK4), which plays a role in IL-1R/TLR signaling, and examined the differentiation of FBGCs and osteoclasts in IRAK4-deficient mice under an inflammatory condition.

[results and discussion]

FBGCs from wild-type (WT) BMM did not have bone resorbing activity but rather expressed *yellow mottled (YM)* and *arachidonate 15-lipoxygenase (Alox15)*, M2 macrophage-like wound-healing and inflammation-terminating molecules. By adding IL-1β, FBGC and osteoclast formation were significantly inhibited and promoted, respectively; however, such effects were cancelled when FBGCs and osteoclasts were generated from IRAK4-deficient BMMs. Furthermore, calvarial bone resorption promoted by LPS, an infection mimetic of a gram-negative bacteria, was abrogated in IRAK4-deficient mice *in vivo*. IRAK4-deficiency did not alter physiological osteoclast formation *in vitro* and bone mineral density *in vivo*. In contrast, IRAK4-deficiency restored FBGC formation and M2 macrophage like molecule expression in condition with LPS *in vivo*.

[conclusion]

Our results identify IRAK4 as a therapeutic target to inhibit the stimulated osteoclastogenesis and to rescue the inhibited FBGC formation under an inflammatory and an infectious condition without affecting physiological bone resorption.

Lhx2 regulates bone remodeling in mice by modulating RANKL signaling in osteoclasts. Jung Ha Kim*[1], Bang Ung Youn[2], Kabsun Kim[3], Nacksung Kim[4]. [1], South Korea, [2]Chonnam National University, South Korea, [3]Chonnam national university, South Korea, [4]Chonnam National University Medical School, South Korea

The LIM homeobox 2 transcription factor Lhx2 has a variety of functions, including neural induction, morphogenesis, and hematopoiesis. Here we show the involvement of Lhx2 in osteoclast differentiation. Lhx2 was strongly expressed in osteoclast precursor cells but its expression was significantly reduced during receptor activator of nuclear factor-kB ligand (RANKL)-mediated osteoclastogenesis. Overexpression of Lhx2 in bone marrow-derived monocyte/macrophage lineage cells (BMMs), which are osteoclast precursor cells, attenuated RANKL-induced osteoclast differentiation by inhibiting the induction of nuclear factor of activated T cells c1 (NFATc1). Interestingly, interaction of Lhx2 proteins with c-Fos attenuated the DNA binding ability of c-Fos and thereby inhibited the transactivation of NFATc1. Furthermore, Lhx2 conditional knockout mice exhibited an osteoporotic bone phenotype, which was related with increased osteoclast formation *in vivo*. Taken together, our results suggest that Lhx2 acts as a negative regulator of osteoclast formation *in vitro* and *in vivo*. The anti-osteoclastogenic effect of Lhx2 may be useful for developing a therapeutic strategy for bone disease.

MO0258

The elementary fusion modalities of osteoclasts. Kent Soe*[1], Anne-Sofie Hobolt-Pedersen[2], Jean-Marie Delaisse[3]. [1]Vejle Hospital, University of Southern Denmark, Denmark, [2]Vejle Hospital, University of Southern Denmark, Denmark, [3]Vejle Hospital, IRS, University of Southern Denmark, Denmark

The last step of the osteoclast (OC) differentiation process is cell fusion. Most efforts to understand the fusion mechanism have focused on the identification of molecules involved in cell fusion. Surprisingly, the basic fusion modalities, which are well known for fusion of other cell types, are not known for the OC. Here we characterize the partners involved in a fusion event with respect to their mobility, number of nuclei, and differentiation level.

OCs were generated from buffy coat monocytes exposed to RANKL. Time-lapse videos were recorded on OC preparations of three donors. A total of 174 videos, representing 3,468h, 656 fusion events, and 100 mm2 were analyzed by two observers. Fusion partners were categorized according to number of nuclei and mobility. Furthermore, nucleus tracing tests were performed by co-culturing cells from male and female donors, at early or late differentiation stages.

Fusions between a mobile and immobile partner were most frequent. They represented 62% of the fusion events, while fusion between two mobile or two immobile partners represented only 26% ($p<0.001$) and 12% ($p<0.001$), respectively. The immobile fusion partner contained on average significantly more nuclei than the mobile one ($p<0.01$). Enrichment in nuclei of an OC with three or more nuclei resulted from fusion with a mononucleated cell in 67% of the cases ($p<0.001$), while mononucleated cells fused with a multinucleated cell in 61% of the cases ($p<0.05$). This observation suggests that fusion is more likely to occur between a more mature (multinucleated) fusion partner and a less mature (mononucleated) partner. This hypothesis was supported by an independent approach based on nucleus tracing. These experiments showed that more differentiated cells have a higher propensity to fuse with less differentiated cells mixed at a 1:1 ratio ($p=0.002$), when compared to conditions where cells of male and female donors had been exposed to RANKL for the same amount of time.

We conclude that OCs most often gain nuclei by addition of one nucleus at a time, and that this nucleus is most often delivered by a moving cell to an immobile cell. This conclusion appears relevant to the in vivo situation where mononucleated cells migrating from the bone marrow fuse with more mature OCs on the bone surface. These results also fit the fusion modalities reported for other cell types and may in addition help to elucidate how hyper-nucleated OCs are generated in some clinical situations.

MO0259

Connexin 43 Hemichannels are Important Regulators of Osteoclast Differentiation. Danielle Callaway*[1], Manuel Riquelme[2], Jean Jiang[1]. [1]University of Texas Health Science Center at San Antonio, USA, [2]University of Texas Science Center, San Antonio, USA

Connexin 43 (Cx43) is a membrane protein that forms gap junctions and hemichannels for communication between the cell and adjacent cells or the extracellular environment, respectively. Although the function of Cx43 in osteocytes and osteoblasts has been extensively investigated, its role in the osteoclast remains largely unknown. In this study, we found that Cx43 is expressed in the osteoclast and macrophage precursors, localized on the cell surface in mononuclear cells during

osteoclastogenesis. Conversely, in the osteoclast, Cx43 was found in the cytoplasm. In order to evaluate the function of Cx43 during the differentiation process, gap junction and hemichannel activity were assessed. Gap junction activity was analyzed with the dye coupling assay where we failed to detect dye transfer between cells during differentiation. However, both osteoclasts and precursors possessed functional hemichannels that could be blocked by the Cx43(E2) antibody developed by our laboratory that is specific for Cx43 hemichannels. Dye uptake analysis measuring hemichannel activity revealed that upon RANKL addition, Cx43 hemichannels were opened suggesting that hemichannels could serve as regulators during the osteoclast differentiation process. In agreement with the previous results showing a lack of Cx43 at the cell surface, dye uptake in the osteoclast was significantly attenuated compared to mononuclear precursors. Next, we assessed whether Cx43 plays a role in osteoclast differentiation with models of reduced Cx43 including RAW264.7 cells with Cx43 knockdown by siRNA and the heterozygous ($Cx43^{+/-}$) mouse model. In both models, there was a significant decrease in total numbers of osteoclasts formed compared to controls. In order to determine whether hemichannels were important in osteoclast differentiation, we applied Cx43(E2) antibody during differentiation, which led to a reduction in total osteoclast numbers and TRAP activity. Levels of nuclear factor of activated T-cells, cytoplasmic 1 (NFATc1), which activates mature osteoclast and pro-fusion genes, were then evaluated to assess if it could be regulated by hemichannels. However, because there was no evident reduction in NFATc1, the mechanisms mediating Cx43 hemichannel activity and its impact on osteoclastogenesis could be downstream of NFATc1 or part of a separate pathway. In total, this data indicates that Cx43 hemichannels have important contributions as regulators of osteoclast differentiation.

Duffy Antigen Receptor for Chemokines (DARC) Modulates Inflammation-induced Recruitment of Osteoclast Precursors. Mohamed Elgendy[1], Yan Hu[1], Subburaman Mohan[2], Bouchra Edderkaoui*[2]. [1]Jerry L Pettis Memorial Veterans Administration Medical Center, USA, [2]Jerry L. Pettis Memorial VA Medical Center, USA

Inflammatory reactions observed after many, if not all, bacterial infections have been shown to be powerful activators of monocytes and macrophages and potent inducers of pro-inflammatory cytokines and chemokines. Because Duffy antigen receptor for chemokines (Darc) is known to bind to a number of the pro-inflammatory chemokines of the CC and CXC families and because chemokines are known to regulate osteoclast (OC) trafficking, we have predicted that Darc regulates OC recruitment to the sites of inflammation by modulating chemokine actions. We have used mice that lack Darc expression (Darc-KO) and wild type (WT) mice to assess the role of Darc in the response to bacterial Lipopolysaccharide (LPS) infections. Animals were administered with subcutaneous LPS injections on mouse calvaria bone. Five hours post-LPS injection, the expression of CD14 which is a marker of inflammatory monocytes, was found to be increased significantly in response to LPS injection. Histological sections were prepared at the injection sites, and the sections were stained for tartrate-resistant acid phosphatase (TRAP), 3 days post-LPS injection. The percentage of bone surface covered by OCs (Trap stained surface) was measured. As expected, LPS injection caused a significant increase in the percentage of bone surface covered by OCs in both lines of mice compared to the saline injected animals at three days post-LPS injection. While, the % TRAP labeled OC surface was significantly reduced in KO mice compared to WT mice in saline injected animals, the magnitude of increase in OC surface in response to LPS was greater in Darc-KO mice compared to WT mice. Based on these data and the previous data that showed Darc mediates trancytosis of chemokines to vascular lumen promoting chemokine-mediated leukocyte transmigration, we predicted that blocking Darc function enhances the response of OC precursors to bacterial infections. To test this hypothesis, we evaluated the expression levels of CD11b, an established marker of OC precursors, around the injection site for the two lines of mice and found greater increase in the expression of CD11b in response to LPS injection in KO mice compared to WT mice. Based on these findings, we conclude that Darc regulates recruitment of OC precursors at the inflammation site, probably through regulation of chemokines transcytosis that consequently regulate leukocytes migration.

Loss of HDAC7 in Osteoclasts Increases Bone Mass Through Interactions with MITF and PU.1. Melissa Stemig[1], Kristina Astleford[2], Ann Emery[2], Tsang-hai Huang[3], Janice Cho[2], Raj Gopalakrishnan[4], Kim Mansky*[4], Eric Jensen[4]. [1]University of Minnesota School of Dentistry, USA, [2]University of Minnesota, USA, [3]National Cheng-Kung University, Taiwan, [4]University of Minnesota, USA

We recently identified histone deacetylase 7 (HDAC7) as a novel regulator of osteoclast formation. Our in vitro data indicated that suppression of HDAC7 enhanced differentiation of osteoclasts from bone marrow macrophage cultures, while overexpression of HDAC7 inhibited osteoclast formation. In reporter assays, HDAC7 repressed the activity of the microphthalmia-associated transcription factor, MITF. Physical interaction between MITF and HDAC7 was attenuated by stimulation with RANK Ligand (RANKL), a factor that enhances MITF activity.

To further characterize the role of HDAC7 in osteoclast differentiation in vivo, we created mice null for HDAC7 expression in osteoclasts using LysM-CRE. Micro-CT at 1, 3 and 6 months indicates that mice null for HDAC7 expression are osteopenic at 3 and 6 months compared to their wild type littermates, with increased osteoclast activity as measured by CTX ELISA but with no significant change in the rate of bone formation. When osteoclasts from the HDAC7 null mice are cultured in vitro, they are larger in size and display increased resorption activity. They also exhibit increased expression of MITF/PU.1 target genes including *DC-STAMP*, *OSCAR*, *cathepsin K* and *v-ATPase V_0 subunit d2*. New biochemical studies show that HDAC7 interacts with both MITF and PU.1 transcription factors. Deletion analysis identifies a specific region in the HDAC7 amino-terminal domain that mediates MITF and PU.1 binding. Further, we found by ChIP analysis that HDAC7 is located at MITF-responsive promoter elements. These data suggest a model in which HDAC7 regulates bone resorption and the onset of osteoclast differentiation by repressing the activities of MITF and PU.1 at target gene promoters. Unexpectedly, targeted mutations in HDAC7 reveal that consitutively nuclear, constitutively cytoplasmic, as well as deacetylase inactive forms of HDAC7 all can inhibit osteoclast differentiation. Thus, the mechanism(s) used by HDAC7 to regulate osteoclast formation represent an active area for ongoing investigations.

RANK cytoplasmic IVVY535-538 motif activates C/EBPα which plays a crucial role in osteoclast lineage commitment. Joel Jules*, Wei Chen, Xu Feng, Yi-Ping Li. University of Alabama at Birmingham, USA

The receptor activator of NF-κB (RANK) ligand (RANKL) plays an essential role in osteoclast (OC) formation by stimulating its receptor, RANK, leading to the activation of many critical OC transcription factors (TFs), such as FBJ osteosarcoma oncogene (c-fos), SFFV proviral integration 1 (PU.1), Runt-related transcription factor 1 (Runx1), and CCAAT/enhancer binding protein α (C/EBPα). However, it is not fully known whether all of these factors are essential for OC lineage commitment. In this study, we first confirmed that the expression of C/EBPα, Runx1, cFos or PU.1 was significantly up-regulated by transient stimulation of bone marrow macrophages (BMMs) with RANKL and macrophage-colony stimulating factor (M-CSF) to induce osteoclastogenesis, suggesting the potential involvement of these factors in OC lineage priming. In addressing this issue, we found that whereas overexpression of all four TFs in BMMs could stimulate the expression of many OC marker genes in the absence of RANKL, C/EBPα played a more striking role in mediating OC formation when attended by permissive levels of RANKL. This finding indicates that C/EBPα may play a stronger role than the other 3 in OC lineage commitment. RANK contains an IVVY (535-538) motif which plays a critical role in OC formation by committing BMMs into OC lineage. Hence, we investigated the role of the IVVY motif in the activation of these four TFs during OC lineage commitment via a mutational strategy. We utilized a chimeric receptor system containing the human Fas external domain linked to transmembrane and cytoplasmic domain of normal mouse RANK (ChA) or mouse RANK bearing an inactivating mutation in the IVVY motif (ChB), which were activated by a specific human-Fas activating antibody. We showed that the IVVY motif plays a dispensable role in the activation of PU.1, cFos, and Runx1, but it is critical for C/EBPα activation during OC lineage priming. Consistently, the ChA, but not the ChB, expressers could mediate osteoclastogenesis. Finally, despite its critical role in OC lineage commitment, we found, unexpectedly, that overexpression of C/EBPα in the ChB expressers failed to rescue osteoclastogenesis, indicating that C/EBPα may not be the sole factor responsible for OC lineage commitment. Collectively, these findings reveal C/EBPα is the most critical of the known OC TFs for OC lineage commitment. Significantly, C/EBPα has the potential to serve as a therapeutic target for bone loss from excessive OC formation.

MO0264

RANKL Enhances TNF Induced Osteoclast Differentiation by Degrading TRAF3 in the Absence of TRAF6. Zhenqiang Yao*[1], Yanyun Li[2], Bryant Darnay[3], Lianping Xing[1], Brendan Boyce[4]. [1]University of Rochester, USA, [2]University of Rochester Medical Center, USA, [3]University of Texas M.D. Anderson Cancer Center, USA, [4]University of Rochester Medical Center, USA

TNF receptor associated factors (TRAFs) regulate osteoclastogenesis. For example, TRAF6 is essential for RANKL-induced osteoclast (OC) formation, while TRAF3 limits both RANKL- and TNF-induced OC formation by promoting proteasomal degradation of NF-κB-inducing kinase thereby negatively regulating NF-κB signaling. We have used TRAF6-/- and generated TRAF3-Cathepsin K conditional KO (cKO) mice to further investigate the roles of TRAF6 and TRAF3 in RANKL- and TNF-induced osteoclastogenesis. We confirmed that RANKL does not induce OC formation from TRAF6-/- OC precursors (OCPs), but surprisingly it significantly increased OC formation induced by TNF alone from these cells (135+/-14 vs. 51+/-6/well). Also surprisingly, RANKL induced OC formation (152+/-21/slice) and bone resorption when TRAF6-/- OCPs were cultured on bone slices (resorption pit 0.07+/-0.02 mm2/slice). This effect was blocked by a TNF inhibitor, but not by a TGFbetta1 neutralizing antibody or an IL-1 receptor antagonist. WT and TRAF6-/- spleen cells cultured on bone slices with OC-inducing medium produced equal amounts of TNF (169+/-43 vs. 151+/-17 pg/ml) and these were significantly higher than those from cells cultured on plastic (26+/-4 vs 19+/-2 pg/ml). TRAF3 protein levels increased in TRAF6-/- OCPs in response to TNF, similar to WT cells, and these levels were significantly reduced by concomitant RANKL treatment. OC formation induced by RANKL+TNF from TRAF6-/- OCPs (65+/-7/well from GFP vector infected cells) was blocked by TRAF3 over-expression (3+/-1/well) and dose-dependently by an antagonist of cellular inhibitor of apoptosis proteins (cIAPs), which function along with TRAF2 to degrade TRAF3 in B cell. Consistent with this, the cIAP antagonist inhibited RANKL-induced TRAF3 degradation in TRAF6-/- OCPs. Finally, TNF induced significantly more OCs from TRAF3-CatK cKO OCPs (157+/-9/well) than from WT cells (43+/-5/well), and TRAF6 levels were low in cKO OCPs and, unlike in WT cells, they did not increase in response to RANKL or TNF. We conclude that OCP interaction with bone matrix increases their expression of TNF to stimulate OC formation and that RANKL enhances TNF-induced osteoclastogenesis by promoting degradation of TRAF3, both through a TRAF6-independent mechanism, while TRAF3 appears to be required for induction of TRAF6 by these cytokines. Thus, strategies to increase TRAF3 levels in OCPs should inhibit RANKL- and TNF-induced osteoclastogenesis.

Regulation of Osteoclastogenesis by Integrated Signals from Toll-Like Receptors. Tamar Krisher*[1], Zvi Bar-Shavit[2]. [1]Hebrew University of Jerusalem, Israel, [2]Hebrew University of Jerusalem Faculty of Medicine, Israel

Toll-like-receptors (TLRs) in immune cells sense and are activated by pathogen-derived molecules to initiate the innate immune response. TLRs are also expressed by osteoclasts (OCs) and modulate their differentiation in a dual manner: stimulation of committed precursors which is the mechanism by which pathogen-induced bone loss occurs and inhibition of early precursors that could serve as a mechanism for down-regulating excessive resorption, and as a switch for promoting the differentiation of common precursor cells into inflammatory cells. TLRs 3, 4 and 9 are activated by viral double stranded RNA, LPS and bacterial DNA, respectively. Since infections may contain more than one pathogen we studied the simultaneous stimulation of different TLRs on OC differentiation. The TLR ligands used were Poly-IC (P), LPS (L) and CpG-ODN (C) activating TLRs 3, 4 and 9, respectively. To examine a synergy among the TLR ligands we used suboptimal doses of the ligands. Combinations of L+C and L+P, but not of C+P resulted in a synergistic effect on the inhibition of osteoclastogenesis (reduction of RANKL-induced TRAP + multinucleated cells). The role of induction of cFos in RANKL-induced OC differentiation is well documented, and consistent with the differentiation data, the combinations of L+C and L+P, but not of C+P resulted in a synergistic effect on inhibition of RANKL-induced cFos expression. Similar conclusions were obtained when the induction of the expression of the osteoclastogenesis inhibitory cytokine, IL-12 was examined. In contrast, all 3 combinations exhibited synergistic effects on inhibition of MCSF-receptor expression. We then examined the stimulatory effect. Combinations of L+C and C+P, but not of L+P exhibited synergy in stimulation of osteoclastogenesis, in increase of cFos expression, its downstream target NFATc and in the expression of the osteoclastic genes, MMP9 and cathepsin K. MCSF receptor expression was not altered significantly in stimulation protocols. Finally, the effects of each ligand on the 3 TLRs were examined. The 3 ligands increased the expression of TLR3 and TLR9, while no significant effects were observed on the expression of TLR4. In summary, cFos plays a role in the two effects while MCSF receptor plays a role only in the inhibitory effect. Increasing TLRs expression by other TLR ligands may cause part of the synergy. The synergism between TLR ligands enables the individual to initiate response at a lower level of pathogen.

SUMOylation of NEMO Differentially Regulates Osteoclastogenesis and Bone Loss. Yousef Abu-Amer[1], Kyuhwan Shim*[2], Kuljeet Seehra[3], Yi-Ping Li[4]. [1]Washington University in St. Louis School of Medicine, USA, [2]Washington University school of medicine, USA, [3]Washington University School of Medicine, USA, [4]University of Alabama at Birmingham, USA

The role of NF-κB in osteoclastogenesis (OCG) has been established. However, the role of IKKγ/NEMO; the NF-κB essential modulator, in this process and in bone development has not been studied. Based on clinical case reports, wherein various mutations in *nemo* gene elicit Incontinentia Pigmenti and skeletal defects in humans, we surmised that this gene may regulate skeletal development. Indeed, conditional deletion of *nemo* from the myeloid compartment caused osteopetrosis owing to defective OCG. To unveil the molecular mechanism underlying this phenotype, we performed domain structure-functional analysis of NEMO. The function of NEMO is governed by oligomerization which is regulated by Ubiquitination (UB) and SUMOylation events at multiple lysine residues occurring in cell and signal specific manners. To this end, we identified lysine (K)-270 and K302, known as SUMOylation sites, as critical differential regulators of NEMO function during OCG. Specifically, expression of K270A-NEMO (K270 SUMOylation-deficient) elicited higher OCG in NEMO-null compared to wild type NEMO expressing cells. In contrast, expression of the mutant K302A-NEMO in NEMO-null cells failed to restore OCG, indicating that K302-modification is essential for NEMO stability and function. More prominently, introduction of K302A mutation in concert with K270A abrogated the robust OCG observed by the latter form. Consistently, localization of WT and mutant NEMOs in HEK cells shows that K270A-NEMO forms condensed multimer in perinuclear compartments whereas K302A-NEMO was diffusely distributed throughout the cytoplasm. Importantly, introduction of K302A mutation in concert with K270A significantly disrupted the multimeric appearance of NEMO. These findings suggest that K270A increases oligomerization and OCG, a gain of function, and K302A impairs oligomer formation and impedes OCG, a loss of function mutation. Because K270 and K302 are SUMOylation sites for SUMO2/3 and SUMO1, respectively, we examined their effect directly by co-expression with the various forms of NEMO WT and mutants. Our findings indicate that SUMO1 coexpression enhances NEMO function and OCG whereas SUMO2 acted as a negative regulator. Additional experiments show that SUMO2 acts in a K270 site-specific manner whereas SUMO1 has no site preference and can still function when c-terminally fused with NEMO. Thus, we provide evidence that SUMO1 and SUMO2/3 differentially regulate OCG and maybe viable to regulate bone resorption.

The Notch modulators Lnx2, Tspan5/10, and Msi2 play a critical role in osteoclast differentiation. Toshifumi Fujiwara*[1], Jian Zhou[2], Shiqiao Ye[1], Haibo Zhao[1]. [1]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [2]UAMS, USA

Genetic studies in human and mice have pinpointed an essential role of Notch signaling in osteoblast and osteoclast proliferation and differentiation during skeletal development and remodeling. However, the factors and pathways regulating Notch activation in bone cells remain largely unknown. Each Notch receptor is present at the cell surface as a heterodimer. When the cognitive ligand binds to the extracellular domain of Notch, a disintegrin and metalloprotease (ADAM), such as ADAM10, cleaves the juxtamembrane S2 proteolysis site of the Notch receptor. The γ-secretase subsequently cleaves the S3 site within the transmembrane domain and releases the Notch intracellular domain (NICD). NICD then translocates to the nucleus, where it functions as a transcriptional co-activator of Notch target genes, including Hes and Hey. Numb, a membrane-associated adaptor protein critical for cell-fate determination, inhibits Notch signaling through the regulation of Notch endocytosis/recycling and the ubiquitin/proteasome degradation of NICD. In this study, we demonstrate that the expression of Notch activators, Lnx2 (Ligand of Numb protein X2), Tspan 5, Tspan 10 (Tetraspanin 5 and 10), and Msi2 (Musashi 2), are up-regulated during osteoclast differentiation as measured by quantitative real-time PCR. Lnx2, an E3 ubiquitin ligase, promotes Notch signaling by lowering the level of Numb. Tspan5 and 10, two of the TspanC8 subfamily members of tetraspanins, regulate ADAM10 maturation and cell surface expression. Msi2 is a mRNA binding protein and may inhibit Numb gene translation. Knocking down the expression of these four genes in bone marrow macrophages by lentivirus-mediated shRNAs markedly inhibits osteoclast formation, as exhibited by decreased $TRAP^+$ multinucleated osteoclasts and declined mRNA and protein expression of osteoclast markers, TRAP, Cathepsin K, and NFATc1. Mechanistically, loss of these Notch activators in osteoclast precursors diminishes intracellular level of NICD, especially NICD2, and attenuates the expression of Notch targeting gene Hes1 and Hey1. Thus, Lnx2, Tspan 5, Tspan 10, and Msi2 are previously unidentified Notch modulators in osteoclast lineage cells that play a critical role in osteoclast differentiation.

The stimulation-dependent internalization of RANK is crucial for osteoclast differentiation. Yuu Taguchi*[1], Jun-ichiro Inoue[2]. [1]The Inst. of Med. Sci., Univ. of Tokyo, Japan, [2]The Inst. of Med. Sci., Univ. of Tokyo, Japan

Bone remodeling involves bone formation by osteoblasts and bone resorption by osteoclasts. Excess formation of osteoclasts leads to pathological bone resorption observed in osteoporosis and rheumatoid arthritis. Therefore, elucidating the molecular mechanisms of osteoclastogenesis is crucial for developing drugs and therapeutic strategies to treat such diseases. Osteoclast differentiation requires activation of the signal transduction emanated from RANK expressed on cell surface of osteoclast-precursor cells, whish are differentiated from hematopoietic stem cells upon M-CSF stimulation. We have previously demonstrated that RANK has the unique domain, HCR, essential for osteoclastogenesis. The HCR domain works as a platform for forming the long-termed signal complex that links to the PLCγ2-Ca^{2+} pathway, which together with the RANK signal to activate NFATc1, a master transcriptional factor for osteoclastogenesis. Here we report a novel mechanism for the HCR-mediated activation of the osteoclastogenic signal. Our immunofluorescence analysis revealed that RANK was located only on cell surface before RANKL-stimulation, but that subpopulation of RANK subsequently became internalized and localized to peri-nuclear region at 48 hours after stimulation. However, RANK mutant lacking the HCR-region remains on cell surface even at 48 hours after stimulation, indicating that HCR mediates the RANK internalization. More importantly, inhibition of RANK-internalization by treating with Dynasore, an inhibitor of the dynamin-dependent receptor internalization, blocked osteoclast differentiation. Similarly, treatment with Methyl-β-cyclodextrin, a selective inhibitor of lipid-raft formation, and that with Pitstop2, a specific inhibitor of clathrin, inhibited the RANK-internalization, and resulted in failure of osteoclastogenesis. These results suggest that RANK-internalization is crucial for osteoclastogenesis. Interestingly, the inhibition of RANK-internalization by treatment with such drugs had no effect on the RANK-mediated activation of NF-κB and MAPKs and the induction of NFATc1 expression. Taken together, these results strongly suggest the HCR-mediated novel signal pathway that is coupled with the RANK internalization and involved in the osteoclastogenic signal.

A Microfluidic System to Study the Effects of Mechanically Loaded Osteocytes on Osteoclast recruitment and formation. Kevin Middleton*[1], Lidan You[2]. [1]University of Toronto, Canada, [2]Mechanical & Industrial Engineering, University of Toronto, Canada

Introduction

It has been well established that bone remodels to accommodate the mechanical loads under which it is placed [1]. This remodeling process occurs through the action of a basic multicellular unit (BMU) that consists of a head of bone resorbing osteoclasts, a tail of bone matrix secreting osteoblasts, and an axially aligned blood vessel supplying precursor cells, signals, and nutrients [2]. However, the mechanisms that link macro-scale mechanical loading to the activation and development of this BMU have yet to be fully elucidated. One cell of particular interest is the osteocyte, which is a mechanosensing cell that is well distributed throughout the bone matrix [3]. In this work we have developed a microfluidic system to overcome the limitations of current in vitro studies [4] and test the hypothesis that unloaded osteocytes promote osteoclast precursor migration and osteoclastogenesis in a physiologically relevant environment.

Methods

MLO-Y4 and RAW264.7 cells were seeded in a microfluidic device consisting of three cell seeding channels (16mm long x 1mm wide x 60μm high), separated by side channels (200μm long x 50μm wide x 60μm high). One channel of MLO-Y4 cells is exposed to a stimulatory fluid shear stress for 1 hour every day, while the other channels are exposed only to a perfusion flow to replace waste media. Every day cells are imaged to determine any net change in the location of cell populations. At the end of 7 days, RAW cells are TRAP stained to quantify the degree of osteoclastogenesis across the width of the central channel.

Results

Using a computational model of our device, we show that our system can produce a stimulatory flow to one channel while keeping the other channels in static conditions. Additionally, we demonstrated that signals produced in one channel are able to diffuse to a neighbouring channel, generating a concentration gradient across that channel. Furthermore, preliminary data shows that RAW cells preferentially migrate towards a RANKL source as compared to a control. Additionally, increased osteoclastogenesis was found closer to the RANKL supplying channel, validating the existence of a chemical gradient across the channel width.

Connexin 43 Hemichannels are Important in Maintaining Normal Bone Structure and Osteocyte Viability. Huiyun Xu[1], Sumin Gu[2], Manuel Riquelme[3], Sirisha Burra[4], Danielle Callaway[5], Hongyun Cheng[2], Teja Guda[6], James Schmitz[4], Roberto Fajardo[7], Sherry Abboud Werner[5], Hong Zhao[8], Peng Shang[9], Mark Johnson[10], Lynda Bonewald[11], Jean Jiang*[5]. [1], Peoples Republic of China, [2]University of Texas Health Science Center at San Antonio, USA, [3]University of Texas Science Center, San Antonio, USA, [4]University of Texas Health Science Center, USA, [5]University of Texas Health Science Center at San Antonio, USA, [6]University of Texas at San Antonio, USA, [7]UT Health Science Center, San Antonio, USA, [8]University of Missouri, USA, [9]Northwestern Polytechnical University, Peoples Republic of China, [10]University of Missouri, Kansas City Dental School, USA, [11]University of Missouri - Kansas City, USA

Connexin (Cx) 43 plays important roles in bone function and development. Targeted deletion of Cx43 in osteoblasts or osteocytes leads to increased osteocyte apoptosis, osteoclast recruitment, and reduced biomechanical properties. Cx43 forms both gap junctions and hemichannels, which mediate the communication between adjacent cells or between cytoplasm and extracellular environments, respectively. Two transgenic mouse models driven by a 10 kb-DMP1 promoter with the overexpression of dominant negative Cx43 mutants were generated to dissect the functional contribution of Cx43 gap junctions as compared to hemichannels in osteocytes. The R76W mutant blocks gap junction, but not hemichannel function, and the ?130-136 mutant inhibits activity of both types of channels. ?130-136 mice showed a significant increase in bone mineral density compared to WT and R76W mice. MicroCT analyses revealed a significant increase in total tissue and bone area in midshaft cortical bone of ?130-136 mice. The bone marrow cavity was expanded, whereas the cortical thickness was increased and associated with increased bone formation along the pericortical area. Histologic sections of the midshaft showed increased numbers of empty osteocyte lacunae and apoptotic osteocytes in ?130-136, but not in WT and R76W, mice which correlated with altered biomechanical and estimated bone material properties. There was a trend for reduced osteoblasts along the endosteal surface in ?130-136 mice. Osteoclasts were increased along the endosteal surface in both transgenic mice with a greater effect in ?130-136 mice which likely contributed to the increased marrow cavity. These findings suggest that osteocytic hemichannels play a dominant role in regulating osteocyte survival and balance between endocortical bone resorption and periosteal apposition that is crucial for maintaining bone mass and strength.

Estrogen loss causes mitochondrial stress in Osteocytes in vivo. Dorra Frikha-Benayed*[1], Jelena Basta-Plajkic[2], Robert J Majeska[3], Mitchell Schaffler[4]. [1]The City University of New York, USA, [2]City Collage New York, USA, [3]City Collage New York, USA, [4]City College of New York, USA

Estrogen loss was shown to cause osteocyte (OCY) apoptosis that triggers bone resorption. The mechanism by which estrogen loss leads to osteocyte death is not clear. However, studies from our laboratory and others suggest that increased oxidative damage could play a role, since estrogen was reported to exhibit anti-oxidant effects that can attenuate harmful effects of reactive oxygen species (ROS). Mitochondrial (Mt) oxidative metabolism is a major source of ROS, and we previously showed that hypoxia-induced oxidative stress in OCY leads to impaired Mt function and NADH accumulation that could be monitored in situ by multiphoton microscopy (MPM). In this study, we tested the hypothesis that estrogen loss results in a similar stress response in OCY in vivo. We adapted our previous approach to assess OCY NADH levels in situ after estrogen withdrawal. OVX or Sham surgery was performed on C57BL/6J mice (17 wk old, n=6, IACUC approved). OCY NADH levels were investigated at 2 days post-OVX from metatarsal diaphyses of anesthetized mice using *in vivo* MPM (40X Objective; Excitation: 833 nm; Emission: 460 nm). In separate studies, OCY mitochondrial content was also assessed by IHC in metatarsals mid-diaphyses of control mice by staining with antibody to mitochondrial ATPase V. Results: NADH fluorescence was absent from OCY in Sham animals, consistent with our previous findings for OCY at baseline conditions in vivo. In contrast, OCY in OVX bones showed high levels of NADH fluorescence (Fig 1). NADH accumulation was greatest in OCY located with approximately 40 μm of the periosteal surface (Fig 2). IHC studies revealed that the more NADH responsive cells closest to the periosteal surface also expressed high levels of ATPase V, indicating greater Mt content. This study shows that estrogen loss causes dramatic and region-specific NADH accumulation in OCY in vivo. The increase in NADH is consistent with impaired mitochondrial electron transport, such that NADH produced by cellular catabolic pathways cannot be re-oxidized to NAD+. How estrogen regulates mitochondrial is not yet clear; however, OCY express estrogen receptors and estrogen has been shown to act directly on mitochondrial DNA (in nonskeletal systems), so multiple mechanisms are possible.

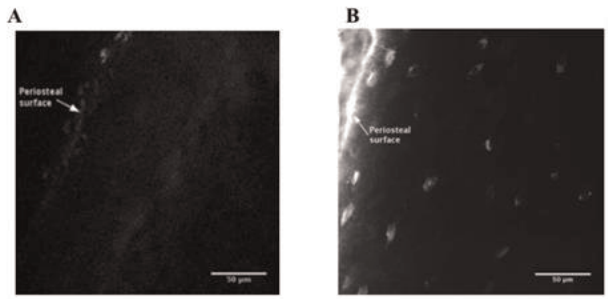

Figure1: (A) In vivo imaging of metatarsal cortex of Sham operated animal shows no NADH fluorescence in osteocytes. **(B)** Strong NADH fluorescence seem in osteocytes near periosteum at 48 hours post OVX.

IDG-SW3 early osteoblasts in mineralising 3D collagen gels differentiate to osteocytes that respond to mechanical loading. Nicole Scully*[1], Lynda Bonewald[2], Sam Evans[3], Deborah Mason[4], Bronwen Evans[4]. [1]Cardiff University, United Kingdom, [2]University of Missouri - Kansas City, USA, [3]cardiff university, United Kingdom, [4]Cardiff University, United Kingdom

Osteocytes *in vivo* are derived from osteoblasts, embedded in mineralised matrix and mechano-sensitive. They are difficult to isolate and models for *in vitro* osteocyte studies are limited. IDG-SW3 mouse early osteoblasts differentiate (35 days) in monolayer to mature osteocytes expressing sclerostin and FGF-23.[1] These are DMP1-GFP$^{(-)}$ under immortalizing conditions but DMP1-GFP$^{(+)}$ under osteogenic conditions. We investigated osteocytic differentiation of IDG-SW3 in mineralising 3D gels, thus mimicking osteocytes *in vivo*, and assessed their responses to mechanical loading.

Cells were set up in 3D type I collagen gels (48-well plates), incubated at 33°C (4 days), then placed in osteogenic medium at 37°C (22 days). Cell number/viability and phenotype (trypan blue, qRTPCR, confocal), and VEGF and IL-6 protein secretion (ELISA) were quantified over time. Following mechanical loading (10 Hz, 5 mins, 2.5 N, day 10), putative mechano-sensitive factors (DMP1, VEGF, IL-6, RANKL, LRP-5) were measured at 0.5–48 hrs (qRTPCR, ELISA). All results presented are combinations from3 independent experiments.

Cells were viable (>90%) but did not proliferate in osteogenic medium. They were DMP1 GFP$^{(+)}$ from day 2 (confocal microscopy), and DMP1 mRNA steadily increased, peaking at day 21 ($p<0.05$). Phalloidin labelling confirmed actin organisation and osteocytic processes (day 21). E11 and PHEX mRNA both peaked at day 14 ($p<0.01$, $p<0.001$ respectively) before decreasing, whilst MEPE expression was the same throughout. Sclerostin expression peaked at day 7 with little expression at other timepoints. VEGF and IL-6 protein increased during differentiation (IL-6, day 21, $p<0.001$). Following mechanical loading, DMP1 (48 hrs, $p<0.05$), VEGF (30 mins, $p<0.05$), IL-6 (24 hrs $p<0.01$), LRP-5 (48 hrs, $p<0.05$) and RANKL (24 hrs, $p<0.01$) mRNA, as well as VEGF and IL-6 protein secretion increased (IL-6, 24 hrs $p<0.01$) compared to unloaded controls.

This mineralising 3D collagen gel model enables differentiation of osteoblasts to osteocytes in an environment akin to osteocytes *in vivo*. Differentiation is accelerated in 3D compared to monolayer, with sclerostin detected after 7 days. The 3D model enables mechanical loading of osteocytes, as demonstrated by up-regulation of putative mechano-sensitive factors. This model will further our understanding of mechano-sensitive pathways in osteocytes and could also be applied to human primary osteoblasts.

Local Bone Tissue Mechanical Properties Change Without Remodeling: A Study Of Lactating Mice. Serra Kaya*[1], Jelena Basta-Pljakic[2], Zeynep Seref-Ferlengez[2], Wing-Yee Cheung[1], Robert Majeska[3], Susannah Fritton[4], Shoshana Yakar[5], Mitchell Schaffler[1]. [1]City College of New York, USA, [2]City College of New York, USA, [3]City College of New York, USA, [4], USA, [5]New York University COLLEGE OF DENTISTRYDavid B. Kriser Dental Center, USA

Introduction: Osteocytes can dynamically remodel their pericellular bone matrix through osteocytic osteolysis, leading to increases in lacunar and canalicular size. Furthermore, these increases are reversible. It is well established that cortical bone modulus depends strongly on its vascular porosity, but whether the resulting changes in osteocyte pericellular void space can also alter local material properties of bone is unknown. In the current study, we tested whether bone elastic modulus and lacunar-canalicular space (LCS) change at the microscopic level in response to lactation and post-lactation recovery.

Methods: C57/B6 mice (n=15, 3 m.o.) were mated and allowed to nurse their pups. After 2 wks of lactation (Lac), mice were divided into three groups. *Group 1* was sacrificed after 2 wks Lac; *Groups 2* and *3* were allowed to recover for 1 wk and 4 wks post-Lac (after forced-weaning), respectively. Age-matched controls (n=5/group) were also examined. Femurs were stored at -20°C until testing. Tissue level elastic modulus (Ei) was measured using microindentation on femoral mid-diaphyseal cross-sections. For osteocyte LCS studies, femoral cross-sections were imaged using super resolution microscopy (100 nm resolution fluorescence imaging) and lacunar and canalicular areas measured.

Results: Two weeks of Lac caused marked reductions in bone Ei (10% and 15% at Posterior and Anterior regions, respectively) compared to controls. After 1 wk post-Lac, Ei returned to pre-Lac levels and did not increase further at 4 wks post-Lac (Fig 1). Lac did not cause intracortical resorption or increases in vascular spaces. Lacunar and canalicular areas increased by 2 wks Lac (19% and 15%, respectively) and retuned to baseline levels after 1 wk post-Lac (Fig 2).

Conclusion: These results reveal that tissue-level cortical bone material properties are reversibly modulated in response to physiological challenge without bone remodeling. Small changes in LCS appear sufficient to alter local material. In addition, these studies demonstrate that Lac-induced reductions in Ei and increased in LCS void space reverse quickly once Lac stops. The precise mechanisms underlying osteocytic osteolysis and lacunar/canalicular are as yet unknown. Nevertheless, our studies reveal that bone possesses an intrinsic ability for rapid and dynamic regulation of its material properties, accomplished by the action of osteocytes.

MO0274

Osteocyte Signaling and Perilacunar Remodeling during Exercise. Joseph Gardinier*[1], Alexander Khmaladze[2], Michael Morris[1], David Kohn[1]. [1]University of Michigan, USA, [2]University of Michigan, USA

The ability to improve the quality of bone, as defined by its mechanical properties, reduces the risk of fracture and development of musculoskeletal diseases later in life. The mechanical properties of cortical bone gained during exercise despite no significant changes in bone geometry are often attributed to local adaptation of existing tissue. Given that osteocytes are ideally located to modify the intrinsic properties of bone during exercise, the purpose of this study was to determine if exercise increases osteocyte remodeling of the perilacunar matrix and identify changes in their gene expression. Under the University Committee on Use and Care of Animals approval, 16 week old male mice were weight-matched and assigned to sedentary or exercise groups. Exercise involved 30 minutes of treadmill running at 12 m/min on a 5° incline. After 6 consecutive days of exercise, mice were sacrificed and the tibia extracted, cleaned, and flushed of excess tissue to reduce the presence of non-osteocyte cells for qRT-PCR. Additional mice were subjected to 21 days of exercise and then sacrificed to extract tibia samples for mechanical testing and Raman spectroscopy, which consisted of a locally constructed microprobe with a line focused laser beam. After 6 days of exercise, tartrate-resistant acid phosphatase (TRAP), matrix metalloproteinases (MMP), and SOST expression were significantly reduced, while FGF-23 significantly increased by 3.5 fold. Raman spectroscopy revealed a higher mineral-to-matrix ratio after 21 days of exercise (15.8 $\pm$ 0.8 vs. 14.1 $\pm$ 0.6) that was predominately located within the perilacunar matrix (tissue within 5μm of the lacunae wall) compared to non-perilacunar matrix (tissue 15μm away from any lacunae wall). In sedentary controls, the carbonate-to-phosphate ratio of the perilacunar tissue was larger compared to non-perilacunar (0.156 $\pm$ 0.002 vs. 0.150 $\pm$ 0.003), while exercise demonstrated an opposite trend (0.160 $\pm$ 0.001 vs. 0.165 $\pm$ 0.003). The changes in composition coincided with an increase in stiffness (95 $\pm$ 4.7 N/m vs. 83 $\pm$ 4.6 N/m) and ultimate strength (206 $\pm$ 6 MPa vs. 180 $\pm$ 6 MPa) compared to sedentary controls. Overall, these data demonstrate that exercise suppresses TRAP and MMP expression, which osteocytes can utilize to alter the perilacunar tissue composition. As a result, the perilacunar remodeling observed during exercise is considered a key determinate of the mechanical properties gained without changes in tissue geometry.

MO0275

Pigment epithelium derived factor reduces sclerostin expression by osteocytes. Feng Li*[1], Na Song[2], Joyce Tombran-Tink[2], Christopher Niyibizi[3]. [1]Penn State College of Medicine, USA, [2]Penn State College of Medicine, USA, [3]The Pennsylvania State University College of Medicine, USA

Pigment epithelium-derived factor (PEDF) encoded by serpinf1 is a strong antiangiogenic factor found in a variety of fetal and adult tissues. Lack of PEDF expression has been reported to be the cause of a recessive form of osteogenesis imperfecta type VI whose hallmark is a defect in mineralization (1, 2). The mechanisms by which PEDF leads to defective mineralization are not known. We and others reported that PEDF enhances mesenchymal stem cell (MSCs) differentiation and osteoblastic mineralization in osteogenic cultures(3, 4). Reduction or absence of PEDF expression by MSCs resulted in the inability of the cells to efficiently mineralize bone matrix upon differentiation. The mechanisms by which PEDF regulates matrix mineralization however, remain unclear; in present study, weexamined expression of factors that play a role in matrix mineralization in osteoblastic osteogenic cultures. Osteoblasts harvested from human bone and maintained in osteogenic medium to day 14 expressed PHEX, MEPE and Sost/sclerostin suggesting that the cells differentiated into osteocytes at this time point (Fig 1). Supplementation of the cultures with PEDF reduced expression Sost and MEPE while promoting expression of Collagen I indicating that PEDF regulates factors that play a role in matrix mineralization. We then focused on sclerostin expression and its suppression by PEDF. Osteoblasts incubated in osteogenic medium to day 7 did not show any sost expression, however by day 14, sost/sclerostin expression was observed confirming the data that at this time point osteoblasts giverise to osteocytes in osteogenic cultures (Fig. 2). Presence of PEDF in osteogenic cultures reduced production of sclerostin by osteocytes in culture to 50% in comparison to the protein produced by osteocytes in osteoblastic cultures incubated in absence of PEDF (Fig. 2). To confirm that PEDF reduced expression of sost/sclerostin by osteocytes, primary osteocytes were isolated from human bone. Isolated cells expressed DMP-1 and sclerostin; incubation of the cells with PEDF for 48, reduced expression of sost/sclerostin confirming the data that PEDF suppresses expression of sost by osteocytes. Sclerostin is a known potent inhibitor of bone formation through its inhibition of Wnt signaling. Taken together, these data suggest that reduction in Sost expression by osteocytes as a result of exposure to PEDF may be one of the mechanisms by which PEDF increases mineralization of bone matrix. The mechanisms by which PEDF regulates sclerostin expression by osteocytes are currently under investigation.

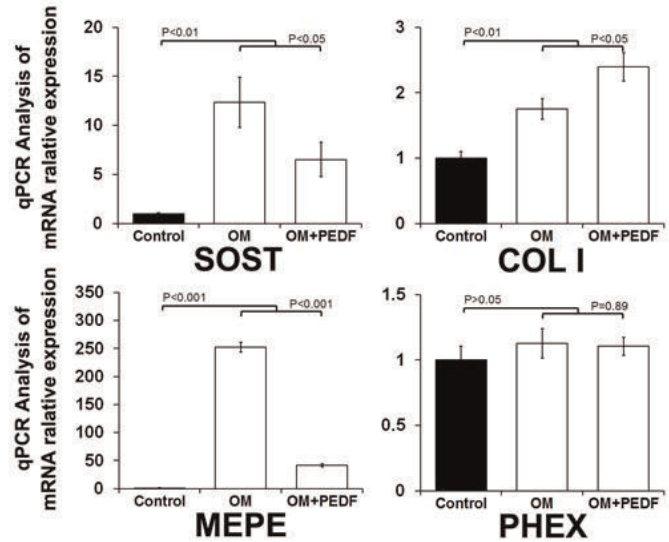

Figure 1. Supplementation of osteoblastic culture with PEDF regulated mRNA expression of osteoblasts and osteocytes related genes at 2 weeks.

Figure 1. Supplementation of osteoblastic culture with PEDF regulated mRNA expression

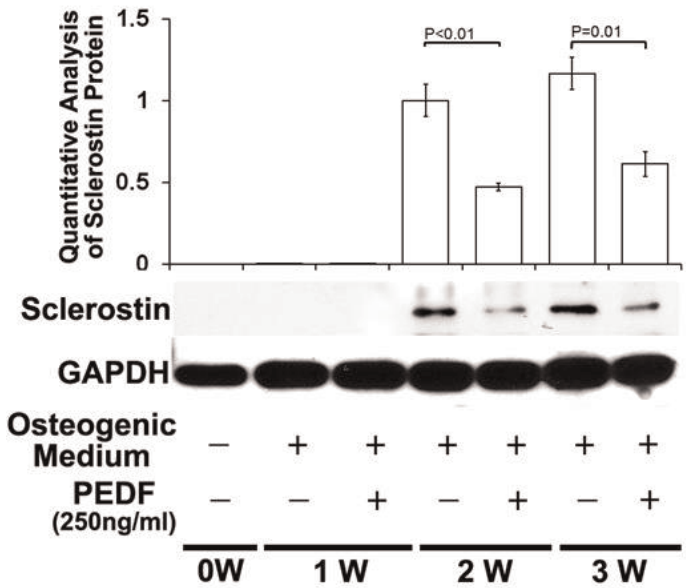

Figure 2. Presence of PEDF in osteogenic cultures reduced production of sclerostin by osteocytes in culture to 50% in comparison to the protein produced by osteocytes in osteoblastic cultures incubated in absence of PEDF.

MO0276

E11 protein stabilisation promotes osteocyte differentiation and protects against osteoarthritis pathology. Katherine Staines*[1], Matt Prideaux[2], Nigel Loveridge[3], David Buttle[4], Andrew Pitsillides[5], Colin Farquharson[6]. [1]The Roslin Institute & R(D)SVS, The University of Edinburgh, United Kingdom, [2]University of Adelaide, Australia, [3]University of Cambridge, United Kingdom, [4]University of Sheffield, United Kingdom, [5]Royal Veterinary College, United Kingdom, [6]Roslin Institute, University of Edinburgh, United Kingdom

The mechanisms which govern osteoblast-to-osteocyte transitions are yet to be elucidated, however their dysregulation are likely to contribute to osteoarthritic (OA) subchondral bone (SCB) sclerosis. The transmembrane glycoprotein E11 is critical in early osteocytogenesis, however its function and regulatory mechanisms are still unknown. Here we established the regulation of E11 expression during osteocytogenesis and examined whether this expression is compromised in OA. Using the late osteoblast MLO-A5 cell line we reveal increased expression of E11 protein/mRNA ($P<0.001$) concomitant with extensive osteocyte dendrite formation and matrix mineralisation ($P<0.001$). Whilst overexpression of E11 significantly increased mRNA expression ($P<0.001$), western-blotting failed to detect any correlative increases in protein expression, suggestive of post-translational regulation. We therefore treated E11-overexpressing cells with calpeptin and ALLN, inhibitors of calpains (cysteine proteases) and found that both promoted E11 protein expression, with ALLN having the greatest effect. However, whilst exogenous treatment of MLO-A5 cells and osteocytic IDG-SW3 cells with 10μM ALLN induced a profound increase in stellate cell morphology (50%, $P<0.001$) and increased E11 protein expression (69%), treatment with calpeptin failed to promote similar osteocytogenesis; the calpain inhibitors E64d/Z-FA-FMK also failed to modify MLO-A5 cell morphology or gene/protein expression. Similarly, the protein expression of calpain 1 and 2 remained unchanged over a 15-day MLO-A5 time course. Due to the dual roles for ALLN in calpain and proteasome inhibition, this characterised proteasomal degradation as the key pathway in E11 post-translational targeting and degradation. This was supported by studies using proteasomal-selective inhibitors (MG132/lactacystin) which produced similar dose-dependent increases in E11 expression in MLO-A5 cells. These data implicate proteasome degradation in controlling E11 stability which will be confirmed using the therapeutic proteasome inhibitor Bortizomib in MLO-A5, and human osteoblast cultures. In a natural model of OA (STR/Ort mouse) we reveal decreased E11 protein expression in the SCB osteocytes in regions of the joint where OA pathology is observed. Together these data suggest that proteasome-mediated E11 protein degradation limits acquisition of the osteocyte phenotype and this contributes to the SCB sclerosis observed in OA.

MO0277

Deletion of ephrinB2 in osteocytes leads to increased trabecular bone mass, but reduced bone strength. Christina Vrahnas[1], Stephen Tonna[2], Huynh Nguyen[3], Mark Forwood[4], T John Martin[5], Natalie Sims*[6]. [1], Australia, [2]St Vincent's Institute, Australia, [3]Griffith University, Australia, [4]Griffith University, Australia, [5]St. Vincent's Institute of Medical Research, Australia, [6]St. Vincent's Institute of Medical Research, Australia

EphrinB2 is a receptor tyrosine kinase expressed by osteoblasts and osteocytes; in these cells its production is stimulated by parathyroid hormone (PTH) and IGF-1. Osteoblastic ephrinB2 signalling has been reported to prevent osteoblast apoptosis, and is required for osteoblast maturation and their support of osteoclast formation. Furthermore, we have reported that the bones of mice lacking ephrinB2 throughout the osteoblast lineage (Osx1Cre.efnB2$^{f/f}$) displayed greater compliance in 3 point bending tests compared to controls, indicating that osteoblastic ephrinB2 maintains cortical modelling during growth. The present study examined the effect of targeted deletion of ephrinB2 in osteocytes on bone mass and strength.

Bones were collected from 12-week-old female mice with ephrinB2 deleted in osteocytes (Dmp1Cre.efnB2$^{f/f}$) and littermate controls (Dmp1Cre.efnB2$^{w/w}$);n=7-12/group. Tibiae were analysed by histomorphometry and femora by both microCT and 3-point bending tests. Dmp1Cre.efnB2f/f mice showed significantly greater tibial trabecular bone volume (BV/TV by 40%, $p<0.01$), trabecular thickness (by 10%, $p<0.05$) and trabecular number (by 20%, $p<0.01$). Both femoral and tibial trabecular separation were significantly lower (by 12% and 23% respectively, $p<0.01$, $p<0.05$). While neither osteoblast number nor bone formation rate were significantly altered, osteoclast surface/bone surface (OcS/BS) and osteoclast size were both ~12% greater in Dmp1Cre.efnB2$^{f/f}$ mice compared to control ($p<0.01$), without any significant change in RANKL or OPG mRNA levels. The combination of a high OcS/BS with normal bone formation rate and increased BV/TV suggests impaired bone matrix destruction in mice lacking osteocytic ephrinB2.

Dmp1Cre.efnB2$^{f/f}$ femora also had significantly thinner cortices ($p<0.01$) and were more brittle than controls when assessed by 3 point bending tests. They showed a significant reduction in post-yield deformation (by 24%, $p<0.01$), toughness (33%, $p<0.001$), yield stress (10%, $p<0.05$), ultimate deformation (20%, $p<0.001$) and energy absorbed to failure (35% less, $p<0.001$) compared to controls. This indicates increased brittleness of the bone matrix.

These data indicate that although ephrinB2 in osteoblasts is required for their ongoing differentiation, osteocytic ephrinB2 does not mediate this effect. Rather, osteocytic ephrinB2 provides signals that limit osteoclastogenesis, stimulate osteoclast function, and maintain compliance of the bone matrix.

Osteocyte differentiation is delayed by low dose TNF. Mark Nanes*[1], Linda Gilbert[2]. [1]VA Medical Center & Emory University, USA, [2]Atlanta VA Medical Center, USA

Inflammation causes bone loss in arthritis, menopause, and aging. TNF contributes to systemic bone loss by suppressing osteoblast (Ob) differentiation. We reported that low levels of TNF in TgTNF mice (2-5 pg/ml) suppress osteoblast numbers and diminish bone accrual at 4 weeks of age without affecting osteoclasts or bone resorption. By 12 weeks of age TgTNF and WT mice had the same number of Ob [Gilbert *et al.* Bone 56(1):174-183 2013]. Despite the similarity of Ob number between TgTNF and WT mice at at12 weeks of age, TgTNF show persistently less bone by micro computed tomography.

Since it is known that osteocytes (Ot) play a key role in regulating bone formation and resorption, we examined the effect of TNF on the appearance of Ot in young TgTNF mice. At 4 weeks of age TgTNF mice had 40% fewer Ot vs. WT by histomorphometry. By 6 weeks of age Ot number was not different between groups and by 12 weeks TgTNF had a trend for more Ot than WT mice. Thus, delayed appearance of Ob was followed by delayed appearance in Ot that later catch up to that observed in Wt.

To determine the effect of TNF on expression of Ot phenotypic markers, IDG-SW3 osteocyte-like cells (gift from Dr. Lynda Bonewald) were treated with TNF either beforeor after their consecutive differentiation to the Ob and Ot phenotype. Real time RT-PCR of cultured IDG-SW3 cells showed early expression of the Ob markers alkaline phosphatase (AP), osteocalcin (OC), and bone sialoprotein (BSP) followed by the Ot markers dentin matrix acidic phosphoprotein 1 (DMP1), phosphate regulating endopeptidase homolog, X-linked (Phex), and sclerostin (SOST). TNF dose-dependently inhibited expression of the Ot markers even after cells had achieved expression of the Ob phenotype (days 9-12). IC_{50} for the Ot markers (DMP1, Phex, SOST) was 2.3 ng/ml and IC_{50} was 1 ng/ml for the Ob markers (AP, OC, BSP). Interestingly, IDG-SW3 cells did not respond to TNF with increased expression of SOST as reported in other cells lines and in TgTNF mice. TNF inhibited expression of Dickkopf-related protein 1. Cell viability throughout the 12 day culture period was demonstrated by TNF stimulation of RANKL and Alamar Blue assay. These results suggest that Ot are extremely sensitive to TNF. Ot may mediate chronic inhibitory effects of TNF on bone formation.

Sclerostin Expression can be Induced by Enforced Expression of Defined Transcription Factors in Human Fibroblasts. Makoto Fujiwara*[1], Wei Wang[2], Yasuhisa Ohata[2], Kouji Miura[2], Taichi Kitaoka[3], Takuo Kubota[4], Yasuji Kitabatake[2], Noriyuki Namba[3], Toshimi Michigami[5], Keiichi Ozono[6]. [1]Osaka University graduate school of medicine, Japan, [2]Osaka University Graduate School of Medicine, Japan, [3]Osaka University Graduate School of Medicine, Japan, [4]Osaka University Graduate School of Medicine & Dentistry, Japan, [5]Osaka Medical Center & Research Institute for Maternal & Child Health, Japan, [6]Osaka University Graduate School of Medicine, Japan

Background: Sclerostin, coded by *SOST*, is a secretory protein expressed specifically in osteocytes and suppresses osteogenesis by inhibiting the Wnt signaling. Regulatory mechanism of *SOST* expression remains unclear mainly due to difficulty in using osteocytes in vitro.

Purpose: We aim to induce sclerostin expression in human fibroblasts, which are easily available, by retroviral gene transduction.

Methods: Human sarcoma cell line SaOS-2, which expresses *SOST* during long-term differentiation culture, was cultured in differentiation medium or maintenance medium. We compared and analyzed RNA expression pattern in each medium by RNA microarray and searched for candidate transcription factor (TF) genes which increased more than two-fold higher in differentiation medium than maintenance medium. Furthermore, we narrowed down the TFs by (1) IPA upstream regulator analysis which expects effective causal TFs on the microarray data in reference to empirical gene expression data, (2) prediction of binding ability to *SOST* promoter and enhancer with TRANSFAC database, and (3) previous reports that showed some association between the TF and osteogenesis. After determining the candidate TFs, we cloned these genes into retrovirus pMXs vector, induced them into human fibroblasts, and analyzed *SOST* expression by real time PCR on day 7. Finally, we measured screlostin concentration in conditioned medium by ELISA.

Results: Twenty TFs were selected from 70 candidates. Among them, enforced expression of the seven TFs, ATF3, DLX3, IRF7, MXI1, KLF4, PAX4 and SP7, induced *SOST* expression in fibroblasts. Gradual reduction of the number of TFs

demonstrated significantly high *SOST* expression, approximately 200 folds than control at four TFs. Sclerostin secretion was also confirmed in conditioned medium by ELISA.

Conclusion: We have established the method to induce sclerostin expression in human fibroblasts by inducing defined TFs. The method is applicable to analyze the pathological role of sclerostin in bone metabolic disorders such as various kinds of hereditary rickets.

Sclerostin is Mechanically and Hormonally Regulated in a Novel *in vitro* Osteocyte Model. William Thompson*[1], Gunes Uzer[1], Sherwin Yen[2], Buer Sen[3], Zhihui Xie[4], Kaitlyn Brobst[2], Maya Styner[5], Janet Rubin[5]. [1]University of North Carolina, USA, [2]University of North Carolina, USA, [3]University of North Carolina At Chapel Hill, USA, [4]University of North Carolina, USA, [5]University of North Carolina, Chapel Hill, School of Medicine, USA

Osteocytes modulate bone density through both osteoblast and osteoclast effectors, and "reach out" to interact with cells in the marrow compartment. The stellate morphology and spatial organization of osteocytes are optimal for sensing force and transmitting biochemical signals through their interconnected lacuno-canalicular system. In addition to the paracrine effects of sclerostin and RANKL on bone effector cells, osteocytes secrete endocrine signals including DMP1 and FGF23, which alter matrix mineralization and renal phosphate homeostasis. To understand how osteocytes respond to hormonal and physical signals there is a need for cell models that faithfully replicate the *in vivo* osteocyte phenotype. Current osteocyte cell lines present limitations that inaccurately represent *in vivo* conditions. We have developed a novel osteocyte model expressing the defining markers of these cells while displaying a stellate morphology within a mineralized matrix. Primary polyclonal murine marrow-derived mesenchymal stem cells were grown in osteogenic medium. Within 15 days, expression of early osteocyte markers E11, DMP1, and Phex were significantly increased compared to culture day 10. Genes found later in osteocyte differentiation, including Dmp1 and Fgf23, were also measurable at 15 days. Importantly, Sost rose approximately 100 fold, plateauing at d15. At this time, electron microscopy revealed osteocyte-like cells encased in matrix with a defined pericellular space and dendritic extensions. Staining for actin or with an anti-E11 antibody revealed numerous cellular projections connecting adjacent cells. Mimicking *in vivo* osteocyte secretory responses, our cell model responded to PTH and $1,25(OH)_2D_3$. PTH treatment significantly repressed Sost, Dmp1, and Opg mRNA expression, and reductions in sclerostin protein were also observed. Exposure to $1,25(OH)_2D_3$ increased expression of Fgf23, Dmp1, and Rankl, and decreased that of Opg. As it is known that mechanical loading suppresses osteocyte Sost *in vivo*, we tested whether twice daily low intensity vibration treatment reduced Sost production *in vitro*. After two days of LIV, Sost mRNA expression was decreased by $23 \pm 8\%$, while Dmp1, E11 and Phex were unaffected. In summary, we have developed a novel osteocyte model that faithfully replicates the morphology, gene expression profile, and hormonal and mechanical responses of osteocytes observed *in vivo* that will enable molecular and biochemical studies of sclerostin regulation.

FREE CIRCULATING miRNAS AND BONE TISSUE miRNAs ARE NOVAL BIOMARKERS FOR OSTEOPOROSIS. Mohammed-Salleh Ardawi*[1], Mohammed Qari[2], Talal Bahksh[3], Abdulrahman Sibiani[4], Ali Ahmad[5], Mohammad Noaman[5], Abdulrahim Rouzi[6]. [1]Center of Excellence for Osteoporosis Research & Department of Clinical Biochemistry & KAU Hospital, Faculty of Medicine, King Abdulaziz University, Saudi Arabia, [2]Center of Excellence for Osteoporosis Research & Department of Haematology & KAU Hospital, Faculty of Medicine, King Abdulaziz University, Saudi Arabia, [3]Center of Excellence for Osteoporosis Research & Department of General Surgery, Faculty of Medicine & KAU Hospital, King Abdulaziz University, Saudi Arabia, [4]Center of Excellence for Osteoporosis Research & Department of General Surgeryand KAU Hospital, Faculty of Medicine, King Abdulaziz University, Saudi Arabia, [5]Center of Excellence for Osteoporosis Research, King Abdulaziz University, Saudi Arabia, [6]Center of Excellence for Osteoporosis Research & Faculty of Medicine, Saudi Arabia

Background: Many patients at risk of osteoporosis or osteoporotic fracture will be missed based on bone mineral density (BMD) assessment alone. Accordingly, there is a need to identify new biomarker(s) independent of BMD to improve fracture prediction. The identification of specific micro-RNA (miRNA) signatures is considered as possible new diagnostic and therapeutic targets. Several free circulating extracellular miRNAs identified as biomarkers that were associated with various types of cancer. The objective of the present study is to identify specific miRNAs in patients with osteoporotic fractures compared with non-osteoporotic fractures.

Methods: Isolated miRNAs were examined from the serum of 26 patients with hip fractures that were transcribed and the samples were studied among 15 osteoporotic and 15 non-osteoporotic samples. With each pool of samples, human serum and plasma miRNA PCR Arrays were performed. A total of 90 different miRNAs were identified. miRNA samples were isolated from the serum and bone tissues of 45 osteoporotic and 45 non-osteoporotic patients and studied. Two-tailed Mann-Whitney test was used to compare between the groups. ROC-curve analysis was used to determine diagnostic miRNAs appility.

Results: A total of 13 miRNAs that were regulated were identified following the validation analysis including: miR-19b, miR-21, miR-221, miR-23a, miR-24, miR-93, miR-100, miR-122a, miR- 124a, miR-125b and miR-148a. These were significantly up-regulated in the serum of osteoporotic patients. In the bone tissue of osteoporotic patients, the following were identified: miR-21, miR-23a, miR-24, miR-25, miR-27a, miR-93, miR-100 and miR-125b that were significantly highly expressed. A total of 7 miRNAs displayed an up-regulation both in serum and bone tissue.

Conclusions: The present study demonstrates a significant role for several miRNAs in patients with osteoporosis and suggests that they may be useful biomarkers for diagnostic purposes and possible target(s) for treating bone loss and optimizing fracture healing among osteoporotic patients.

Very Early Responses of Biochemical Markers of Bone Turnover to Teriparatide. Deborah Robins[1], Benjamin Leder*[2], Kelly Krohn[3], Jahangir Alam[4], Heather Murphy[5], Alan Chiang[6], John Krege[6]. [1]Eli Lilly & Company, USA, [2]Massachusetts General Hospital Harvard Medical School, USA, [3]Lilly USA, LLC, USA, [4]Lilly USA, LLC, USA, [5]inVentiv Health Clinical, LLC, USA, [6]Eli Lilly & Company, USA

Purpose: Few data are available on the early response of biochemical bone turnover markers (BTMs) to teriparatide. This open-label, single-site study in healthy postmenopausal women measured immediate and short-term effects of single and multiple doses of teriparatide on serum PINP, osteocalcin (OC), CTX, and NTX. Methods: 18 women enrolled and completed the study. Mean age was 57 yrs (range 47-77 yrs); 2 were of African descent and 16 were Caucasian. In Period 1, subjects received a single subcutaneous (SQ) dose of 40 mcg teriparatide. In Period 2 (after a 3-4 week washout), subjects received daily 20 mcg teriparatide SQ injections for 28 days. In both periods, serum for BTM evaluations was collected at 4 timepoints throughout the day prior to dosing. In Period 1, BTMs were measured postdose at 0, 2, 6, 10, and 24 hrs, and at 3 and 7 days. In Period 2, BTMs were measured at 0, 2, 6, 10, and 24 hrs following the first dose, and then every week pre-dose for the remaining 28-day dosing period. Comparisons used paired t-test. Results: Prior to teriparatide treatment, PINP and OC showed little change in diurnal variation or food effect when compared with baseline, whereas significant decreases were observed in CTX and NTX ($p<0.001$, compared with baseline). In Period 1, two significant increases in bone formation markers were noted: PINP increased from 53 ± 18 (mean $\pm$ SD) at baseline to 56 ± 19 mcg/L at 24 hrs postdose ($p=.002$); OC increased from 23 ± 11 at baseline to 26 ± 13 ng/ml at 3 days postdose ($p=.017$). In Period 2, PINP increased steadily, reaching 102 ± 34 mcg/L at 28 days ($p<0.001$), and OC levels increased to 40 ± 20 ng/ml ($p<0.001$). Both 40 and 20 mcg of teriparatide partially blocked the decrease in NTX and CTX otherwise observed with food and diurnal variation in the absence of treatment. Serial fasting concentrations of BTMs showed progressive increases in bone formation markers (PINP and OC) but not bone resorption markers (CTX and NTX) through 28-day dosing. No new or serious adverse events were reported during this study. Conclusions: Teriparatide increased PINP and OC, while preventing decline of CTX and NTX normally observed with food and diurnal variation. These findings suggest early anabolic effects of teriparatide may involve progressive stimulation of bone formation and an acute, but not progressive, stimulation of bone resorption. This study also supports PINP as a useful early formation marker to assess the bone anabolic effect of teriparatide.

We Are Not On The Same Page: Variation of PTH and Vitamin D Binding Protein Measurement in 2014. Neil Binkley*[1], Gretta Borchardt[2], Diane Krueger[1], Ravinder Singh[3], Donald Wiebe[4]. [1]University of Wisconsin, Madison, USA, [2]University of Wisconsin, USA, [3]Mayo Clinic, USA, [4]University of Wisconsin, USA

Standardization of 25(OH)D measurement is recognized as necessary to define vitamin D (D) status. However, other related analytes, e.g., PTH and vitamin D binding protein (DBP), may also require standardization. PTH measurement is often used to determine D adequacy and recent work suggests that bioavailable 25(OH)D (Bio-25D) measurement may be needed to define D status. Methodologic differences exist for both PTH and DBP. We hypothesized that standardization of PTH and DBP

is currently inadequate and thus compared current PTH and DBP measurements. Common PTH methods were compared with a nominal gold standard, liquid chromatography tandem mass spectroscopy (LC-MS/MS). DBP results from 3 commercially available kits were compared.

PTH comparability was assessed in a QA study of 14 plasma pools derived from clinical lab residual specimens selected to span from low to high PTH values. Seven clinical labs measured PTH in routine manner (6 by automated immune-based methods, 1 by LC-MS/MS). DBP was measured in 30 serum specimens (10 in duplicate) with 3 commercial kits. Results were compared using linear regression and Bland-Altman analyses.

Immunoassay based PTH results were consistently higher than a LC-MS/MS method (mean bias of +18-28 pg/mL). Good correlation was observed between LC-MS/MS and the other labs (R^2 = 0.90 to 0.94) and between the immune based assays (R^2 from 0.99 to 1.00) with mean bias of -2 to +12 pg/mL. However, the normal range for the laboratories differed; the reported upper limit of normal ranged from 53.5 to 90 pg/mL. As a result, a variable number (from 5 to 10) of these 14 specimens were classified as ''high'' by the various labs. The 3 DBP assays were quite reproducible (%CV from 4 to 7%). However, there was no significant correlation between results from the 3 DBP kits (R^2 = 0.003 to 0.022).

In conclusion, there is good between-lab correlation of PTH results, suggesting that harmonization of these assays is possible. However, if the LC-MS/MS values are correct, all clinical labs tested here report PTH results that are variably ''too high.'' As PTH measurement will likely continue to assist in defining D sufficiency, development of a reference measurement procedure and subsequent standardization (along the lines currently being undertaken for 25(OH)D by the Vitamin D Standardization Program) is necessary. Similarly, standardization of DBP and Bio-25D measurement will be needed if this analyte is validated to have clinical utility.

Abnormal Trabecular Plates and Cortical Thinning at the Distal Radius and Tibia in Postmenopausal Women with Vertebral Fractures. Ji Wang*[1], Emily Stein[2], Bin Zhou[1], Kyle Nishiyama[1], Elizabeth Shane[2], X Guo[1]. [1]Columbia University, USA, [2]Columbia University College of Physicians & Surgeons, USA

Postmenopausal women with fragility fractures have deterioration of trabecular microstructure and cortical thinning, independent of areal BMD by DXA. In postmenopausal women with vertebral fractures, lower volumetric BMD, fewer and more widely separated trabeculae, thinner cortex and reduced stiffness have been observed at the distal radius and distal tibia by HR-pQCT. While previous studies have demonstrated the importance of trabecular plates in mechanical integrity of trabecular bone, whether vertebral fracture is associated with deficiencies in trabecular plate microstructure is unknown. Postmenopausal women with vertebral fractures (n=40) and non-fracture controls (n=40) were scanned by HR-pQCT. Trabecular and cortical compartments were separated by an automatic segmentation algorithm. Trabecular type, orientation and connectivity were measured by individual trabecula segmentation (ITS) analysis. Cortical thickness, porosity and area were measured by a customized cortical evaluation script (Nishiyama et al. 2013). Whole bone and trabecular bone stiffness were estimated by finite element analysis. The fracture and control groups were similar in age (69 ± 8 and 69 ± 7 yrs), race (82.5% and 92.5% Caucasian, respectively), and body mass index (27 ± 6 and 26 ± 5). Group differences in microstructure and stiffness are shown in Figure 1. Compared to controls, women with vertebral fractures had lower cortical thickness, smaller cortical area, and larger trabecular area. Cortical porosity and pore size did not differ. By ITS, fracture subjects had lower plate bone volume, fewer trabecular plates, less axially aligned trabeculae and less trabecular connectivity. Group differences in trabecular microstructure were greater at the radius than at the tibia, while cortical differences were more pronounced at the tibia. Whole bone stiffness and trabecular bone stiffness were lower in women with vertebral fractures by 17% and 25%, respectively at the radius, and by 18% and 19% at the tibia. In summary, postmenopausal women with vertebral fractures had both trabecular and cortical microstructural deterioration at the peripheral skeleton, with preferential loss of trabecular plates and cortical thinning. These microstructural deficits translated into lower whole bone and trabecular bone stiffness at the radius and tibia. Our results suggest that abnormalities in trabecular plate and rod microstructure may be important mechanisms of vertebral fracture in postmenopausal women.

Advanced *In Vivo* Bone Quality Assessment Using the Next Generation of HR-pQCT. Sarah Manske*[1], Ying Zhu[2], Clara Sandino[3], Steven Boyd[1]. [1]University of Calgary, Canada, [2]University of Calgary, Canada, [3]Faculty of KinesiologyBone Imaging LabUniversity of Calgary, Canada

While HR-pQCT scanners have been readily adopted for 3D bone quality assessment, the spatial resolution (82 μm) was insufficient for direct morphological assessment of trabecular thickness (Tb.Th) and separation (Tb.Sp). The second generation scanner (HR-pQCT2, XtremeCTII, Scanco Medical) can perform *in vivo* scans at 61 μm nominal isotropic resolution using a shorter acquisition time and similar radiation dose as the previous generation. We assessed whether the HR-pQCT2 can provide results similar to the original HR-pQCT (XtremeCT) in order to support ongoing longitudinal studies, and whether the accuracy of HR-pQCT2 is sufficient to perform a direct assessment of trabecular bone microarchitecture.

We evaluated 20 human cadaveric radii (mean age 70 yrs, 9 male). We compared a standard patient evaluation performed on the HR-pQCT system (X1, 82 μm) and a mimicked HR-pQCT evaluation performed on the HR-pQCT2 system (X1M, 82 μm). We also compared an HR-pQCT2 patient evaluation (X2, 61 μm), and a gold standard, high resolution *ex vivo* protocol on HR-pQCT2 (HR, 30 μm). Additionally, we scanned a microCT spatial resolution phantom (mCTP610, Shelley Automation). All scans were 3D registered to ensure a common region of analysis. For X1 and X1M we applied the manufacturer's standard patient evaluation to assess total BMD (Tt.BMD), trabecular BMD (Tb.BMD), trabecular number (Tb.N), and derived $Tb.Th^d$ and $Tb.Sp^d$. For X2 and HR we applied a direct morphological assessment of Tb.N, Tb.Th, and Tb.Sp.

X2 could resolve the coil spaced at 100 μm (Figure 1A) better than X1 (Figure 1B), with a 30% improvement in spatial resolution. All outcomes of X1 agreed well with X1M scans (R^2 = 0.93 to 0.99). In our setup, Tt.BMD and Tb.BMD were significantly higher in X1M than X1, which resulted in significantly higher $Tb.Th^d$ in X1M than X1. In contrast, Tb.N and $Tb.Sp^d$ did not differ between X1 and X1M. Directly assessed Tb.N and Tb.Sp were highly correlated (R^2 = 0.93 to 0.98) and did not differ between HR and X2. However, despite an excellent association for Tb.Th (R^2 = 0.97), differences in spatial resolution caused systematic overestimation by X2.

Our results suggest that compatibility between X1 and X1M scans will require accurate density calibration. Importantly, spatial resolution of HR-pQCT2 is sufficiently accurate to assess trabecular microarchitecture directly, which opens new possibilities for understanding of bone microarchitectural changes with aging and treatment.

Comparability of HR-pQCT Bone Quality Measures Improved by Scanning Anatomically Standardized Regions. Serena Bonaretti[1], Margaret Holets[2], Isra Saeed[3], Louise McCready[2], Thomas Lang[1], Sundeep Khosla[4], Andrew Burghardt*[1]. [1]University of California, San Francisco, USA, [2]Mayo Clinic College of Medicine, USA, [3]University of California, San Francisco, USA, [4]Mayo Clinic College of Medicine, USA

Current HR-pQCT protocols do not account for limb length despite tremendous variation in bone density and geometry along the radius and tibia. Consequently, limb length adds considerable variability that confounds the interpretation of biological effects and increases scatter in cross-sectional and normative data. We measured the variability in bone quality parameters due to limb length and propose a protocol for scanning anatomically-standard regions based on measured limb-length. HR-pQCT scans covering twice the typical length of the distal radius and tibia were acquired in adult men (n=17) and women (n=13). Percutanous limb length was measured using standard anthropometric protocols. Bone parameters were calculated for three subvolumes equivalent to the normal scan length (110 slices) based on the following positioning scenarios: (1) the standard fixed distance from the jointline; (2) the average % location of the standard position based on measured limb-length; (3) the average % location of the standard position estimated from height data of previous HR-pQCT population studies in the literature. The standard deviation of differences between fixed and anatomic positions, and percent difference for representative bone parameters (BMD, Tb.BMD, Ct.Th, Tb.N) measured in subvolumes based on the default and either anatomic scan position, were calculated. The average anatomic position in the study population was $4.0 \pm 0.5\%$ in the radius and $7.2 \pm 0.6\%$ at the tibia, corresponding to a variance of ± 1.1 and ± 2.2 mm in the scan position, respectively. The height-estimated anatomic position for optimal comparability to previous HR-pQCT population data was 4.1% and 7.4%. Average differences in bone measurements between fixed and anatomic scan regions were minimal by design; however individual differences exhibited substantial variability (Table 1). The large distribution of differences between bone parameters measured at a fixed distance from the joint and an anatomically relative distance indicates limb length contributes significant variance to bone quality measurements. This strongly recommends the use of scan protocol that is adjusted for measured limb length, particularly for cross-sectional studies and normative database generation. The minimal average differences between fixed distance scanning and the literature-derived relative distance suggest that anatomically-standardized scan positioning can maintain a high degree of comparability to legacy population data.

Table 1: Summary of variability in HR-pQCT measures associated with limb length

	Relative position based on limb length measured in current study participants [Radius: 4.0% | Tibia: 7.2%]		Relative position estimated from height of existing HR-pQCT population data in the literature [Radius: 4.1% | Tibia: 7.4%]	
	Difference vs. Fixed: Population Averages	Variance and Range of Differences	Difference vs. Fixed: Population Averages	Variance and Range of % Differences

Focal Osteoporosis in the Trabeculae of the Femoral Head in Hip Fracture. Linda Skingle[1], Fjola Johannesdottir[2], Paul Mayhew[2], Karen Blesic[1], Kenneth Poole*[2]. [1]Cambridge University Hospitals NHS Foundation Trust, United Kingdom, [2]University of Cambridge, United Kingdom

Objective: In cases of femoral neck fracture there is thinning of the femoral cortex in a focal patch near the anterolateral head-neck junction compared with the rest of the femoral head (Poole et al. PLoS One 2012). We took femoral heads at operation from this hip fracture population and tested whether the volume of trabecular bone beneath the thinned cortex was also osteoporotic by histomorphometric criteria. We used microCT to calculate bone volume/tissue volume (BV/TV) and compared it with another subcortical site within the same femoral head.

Method: Sixteen femoral heads were obtained at hip replacement (with appropriate ethics approval) following femoral neck fracture. The heads were halved and a core was taken from each half: one through the focally thin patch of the head and the other from the opposite, subfoveal, part of the head. These two cores were microCT scanned (XTEK HMX CT 300 - 23µm/pixel). Measurements of BV/TV were made using Image J/Bone J (Doube et al. Bone 2010) along the length of the core starting at the endocortical trabeculae and progressing through in 100x23µm slice segments through the core. Paired t tests were performed to compare the BV/TV in 100 slice segments for the subfoveal and focally thin areas (Fig.1).

Results:The results show a significant difference between the first hundred slices of each pair of cores, after this point in the core no significant difference was found between the two sites (Fig.1).Conclusion: We conclude that there is focal osteoporosis (by histomorphometric criteria) in the trabecular bone immediately beneath the focally thin areas of cortex (identified previously using in vivo CT imaging (Poole et al. PLoS One 2012)). In cases of femoral neck fracture this may be a factor in fracture initiation and propagation. We plan to elucidate the mechanism (be it disuse or fatigue) for this focal osteoporosis with further histological studies on these same core biopsies.

Intra- and Inter-Operator Variability in HR-pQCT Scan Positioning. Serena Bonaretti*[1], Margaret Holets[2], Nicholas P. Derrico[3], Kyle Nishiyama[4], Danmei Liu[5], Stephanie Boutroy[6], Roland Chapurlat[7], Heather McKay[5], Elizabeth Shane[8], Mary Bouxsein[9], Thomas Lang[1], Sundeep Khosla[10], Andrew Burghardt[1]. [1]University of California, San Francisco, USA, [2]Mayo Clinic College of Medicine, USA, [3]Beth Israel Deaconess Medical Center, USA, [4]Columbia University, USA, [5]University of British Columbia, Canada, [6]INSERM U1033 & Université de Lyon, France, [7]E. Herriot Hospital, France, [8]Columbia University College of Physicians & Surgeons, USA, [9]Beth Israel Deaconess Medical Center, Harvard Medical School, USA, [10]Mayo Clinic College of Medicine, USA

The role of the operator in HR-pQCT precision has not been evaluated and may be critical for multicenter cross-sectional studies. At scan time, the operator acquires a 2D projection of the limb (scout image) and manually identifies an anatomic landmark, which determines the scan region. Variability in landmark identification impacts bone measurements, especially in the radius where morphological variations are greater. In this study, our goal was to quantify long-term and short-term intra-operator precision of landmark placement, variability among operators at multiple imaging centers, and the corresponding effect on bone measurements.

We reproduced the acquisition interface of the HR-pQCT system (XtremeCT, Scanco Medical AG) to simulate the process of identifying anatomic landmarks in the scout image. To evaluate intra-and inter-operator precision, 56 double stack scans (220 slices, centered on the standard scan region) and corresponding scout images were acquired at two imaging centers. We were thus able to virtually localize standard 110-slice sub-volumes for analysis, based on landmark positions retrospectively identified in the simulation environment. For both radius and tibia, we evaluated (1) long-term intra-operator variability for 2 operators (over 6-24 months); (2) short-term intra-operator precision for 7 operators in a subset of 15 images, positioned three times in a random order; (3) inter-operator precision for 5 operators. For each experiment, we calculated standard deviation of the landmark position (SDRMS) and coefficient of variation (CVRMS) of primary bone densitometric and structure parameters.

Precision results are in Table 1. Positioning for the tibia was highly reproducible, even across multiple operators (CVRMS<1.8%). In contrast, errors for the radius were significantly greater ($p<0.05$), and particularly high across multiple operators (SDRMS=0.56mm, CVRMS=6.6% for Ct.Th). At both sites, Ct.Th was considerably more sensitive to position variability than density and structure measures.

In conclusion, we found that HR-pQCT scan positioning for the tibia is highly reproducible over time and across operators. Greater positioning variability is observed for the radius, leading to relatively high precision errors. Efforts to define more reproducible landmarks, establish more rigorous operator training procedures, and develop automated scan positioning methods should be pursued to minimize the effects of operator variability in the radius.

RADIUS	Scout Positioning Precision	Impact on Bone Parameter Measurements					
	SD_{RMS} [mm]	BMD CV_{RMS} [%]	Ct.BMD CV_{RMS} [%]	Tb.BMD CV_{RMS} [%]	Ct.Th CV_{RMS} [%]	Tb.N CV_{RMS} [%]	Tb.Sp.SD CV_{RMS} [%]

Is TBS different in healthy European Caucasian men and women ?: Creation of normative spine TBS data for men. Vladyslav Povoroznyuk*[1], L. Del Rio[2], S. Di Gregorio[2], F. Michelet[3], N. Dzerovych[4], A. Musiienko[4], R. Winzenrieth[5]. [1]Institute of Gerontology AMS Ukraine, Ukraine, [2]Cetir Group Mèdic, Spain, [3]R&D department, Med-Imaps, France, [4]Institute of Gerontology NAMS, Ukraine, [5]R&D department, Med-Imaps, Ukraine

Introduction: Trabecular Bone Score (TBS, Med-Imaps, France) is an index of bone microarchitectural texture extracted from antero-posterior spine DXA. In this cross-sectional analysis from two facilities in Ukraine and Spain, we have investigated the age-related changes of the lumbar vertebrae microarchitecture assessed by TBS in a cohort of Caucasian men and compare the results to TBS reference data for Caucasian women.

Methods: Subjects in the study were Ukrainian and Spanish men aged 40 and older with a BMD Z-score at spine L1-L4 within ± 2SD. Individuals were excluded if they had fractures, were on any osteoporosis treatment and/or had any illness that would be expected to impact bone metabolism. All data have been obtained from GE-Lunar DXA devices (Prodigy and iDxa, Madison, WI, USA). Cross-calibration between the two centers was performed for TBS. TBS was evaluated at spine L1-L4 but also for all possible vertebrae combinations.

Results: A database of 368 men aged 40 to 90 years was created. TBS and BMD values at L1-L4 were poorly correlated with BMI (r=0.16 and 0.22). TBS was poorly correlated with weight (r=-0.1) and height (0.03) whereas higher correlations were obtained for BMD (r=0.3 and 0.2). TBS values obtained for all lumbar vertebral combinations decreased significantly with age (see figure below, at L1-L4 for men and women). There was a linear decline of 13.5% (~-1.75 T-score) in TBS at L1-L4 between 40 and 90 years of age in men whereas a decline of 16.7% (~-2.58 T-score) was observed in women *(Dufour et al.,OI 2012)*. Conversely to women, there is no modification of TBS decline rate after 65 years in men.

Conclusion: This study established for the first time TBS age related curve in European men at lumbar spine. The decrease seen in lumbar TBS reflects age-related micro-architecture texture changes at spine. Within 40-65 age range, similar TBS decline was observed in both European Caucasian men and women (p=0.8). After 65, TBS decline rate is significantly higher for women than for men ($p<0.01$). This study confirms the need for using gender dedicated reference data.

Static postural stability and hip fracture in elderly individuals. Hua Lin*[1], Changchang Liu[2], Brian Lin[3], Xiufen Zhu[2]. , [2]Center of Bone Metabolic DiseasesAffiliated Drum Tower Hospital of Nanjing University Medical School, China, [3]Johns Hopkins University, USA

Objective: To study the effect of static postural stability and its correlation with hip fracture in elderly individuals.

Methods: We carried out a retrospective study comprising 141 elderly individuals aged more than 60 years old. Static postural stability was assessed in participants with or without prior history of hip fracture.

Results: The mean age of participants was 71.12 ± 7.08. There were 65 participants (46.10%) with history of hip fracture. The logistic regression analysis showed significantly positive correlation between NO-WDI (OR=8.458,P=0.004) or HF-F4 (OR=6.883,P=0.009) and history of hip fracture incidence.

Conclusion: In elderly individuals with history of hip fracture, the ability to remodel the body's center of gravity and the ability of lower-extremities to maintain balance were both decreased. The data suggest NO-WDI and/or HF-F4 may be effective parameters in early prediction and rehabilitation for hip fracture in elderly individuals.

MO0292

Acromegaly induces bone microarchitectural alteration as assessed by TBS (Trabecular Bone Score) at lumbar spine without impacting bone mineral density (BMD). Giuseppe Guglielmi[1], Claudia Battista[2], Francesca di Chio[1], Antonio Salcuni[2], Michelangelo Nasuto[1], Renaud Winzenrieth[3], Alfredo Scillitani*[4]. [1]Department of Radiology, University of Foggia, Italy, [2]Department of Endocrinology, Scientific Institute Hospital "Casa Sollievo della Sofferenza", Italy, [3]Department of Clinical Research, Medimaps Group, Switzerland, [4]Casa Sollievo Della Sofferenza Scientific Institute, Italy

Subjects with acromegaly (AG) were more susceptible to sustained fractures. It has been reported in the literature that subjects suffering from AG have a high prevalence of vertebral fractures even for subjects with normal BMD. Sparse information exists on the effect of AG on bone microarchitecture and no at axial sites. The aim of our study was to examine bone quality and quantity assessed by TBS (Trabecular Bone Score) and BMD in subject with AG at lumbar spine.

We present a cross-sectional study on 46 subjects with AG (26 women and 20 men) with mean age and BMI of 54.9 ± 11.5years and 29.3 ± 4.2 Kg/m^2 respectively. Among them, 41% were in active phase of the disease, 74% suffered from hypogonadism (Hy) and 22% sustained at least a fracture (Fx). BMD and TBS were evaluated at PA Spine (L1-L4) using an iDxa DXA device (GE-Lunar) and TBS iNsight® (v2.1, Med-Imaps, France).

BMD and TBS were correlated together ($p<0.0001$), with 49% of TBS explained by spine BMD. Subjects with Hy have a significant lower BMD and TBS ($p<0,002$). Those with fracture have a lower TBS ($p=0.02$) whereas no difference has been observed on spine BMD ($p>0.5$). TBS was associated with the presence of the fracture with an odd-ratio per one SD decrease of 2.64 [1.1-6.3] and an area under the ROC curve of 0,71 [0.56-0,84]. BMD, Age, presence of Hy, or duration of Hy were not associated with the presence of fractures. Compared to normative TBS values, AG subjects have a significant TBS impairment (-6%, $p<0,001$). Those with Hy or the presence of the fractures have a lower TBS values when compared to normative values: -8% ($p<0,001$) and -13% ($p<0,02$) respectively.

The present study is the first to report data on changes in spine BMD and TBS at lumbar spine in Subject with acromegaly. AG induces bone microarchitectural texture impairment at lumbar spine. Presence of hypogonadism or fractures worsens such ann impairment. As previously obtained, TBS seems to be more sensitive to bone modification than BMD.

Association Between the Risk of Distal Ulnar Fracture Complicated with Low-Energy Distal Radial Fracture among Postmenopausal Women and Bone Mineral Density of the Forearm Shaft. Kayoko Furukawa*[1], Akinori Sakai[2]. [1], Japan, [2]University of Occupational & Environmental Health, Japan

Background: The presence or absence of distal ulnar fracture as a complication with distal radial fracture greatly influences the surgical procedure employed and the patient's postoperative course. In the present study, we aimed to compare the bone mineral density (BMD) following low-energy distal radial fracture among Japanese postmenopausal women aged >65 years who also had distal ulnar fracture with those women who did not.

Method: In total, 78 postmenopausal women aged >65 years who experienced distal radial fractures after a fall were enrolled in this study. Of these patients, 10 had distal ulnar fractures as a complication with distal radial fractures (ulnar fracture group), whereas the remaining did not (non-ulnar fracture group). Along with the patient characteristics, we compared the BMD at 6 sites—lumbar, proximal hip, entire forearm, ultra distal forearm, mid distal forearm, and forearm shaft—between the groups. No significant differences in age, body height, and weight were noted between the 2 groups. The ulnar fracture group had a significantly greater body mass index than the non-ulnar fracture group.

Result: The BMDs of the proximal hip and the entire forearm were significantly lower in the ulnar fracture group than in the non-ulnar group. Stepwise regression analysis indicated that the BMD of the forearm shaft was the most significant factor associated with ulnar distal fracture; moreover, MID, UD, entire forearm BMD, and lumbar BMD were significantly associated with ulnar distal fracture complicated with distal radial fracture, in decreasing order.

Normative Spine TBS Data For Latin American Women. Bruno Camargos*[1], Luis Jaime Elizondo-Alanís[2], Ben-Hur Albergaria[3], Patricia Clark[4], Carlos Eduardo Magro[5], Fidencio Cons-Molina[6], Jorge Morales-Torres[7], Renaud Winzenrieth[8]. [1]Hospital Mater Dei, Brazil, [2]Centro de Investigación Clínica, Mexico, [3]CEDOES, Brazil, [4]Laboratorios Clinicos De Puebla, Mexico, [5]Clinica Densito, Brazil, [6]Centro de Investigacion en Artritis y Osteoporosis, Mexico, [7]Hospital Aranda de la Parra, Mexico, [8]Med-imaps, Hôpital X. Arnozan, PTIB, Pessac, France, France

Introduction: Trabecular Bone Score (TBS, Med-Imaps, France) is an index of bone microarchitecture texture extracted from postero-anterior spine DXA. In this cross-sectional analysis from six facilities in Mexico and Brazil, we have investigated the age related changes of the lumbar vertebrae micro-architecture assessed by TBS in a cohort of Latin American women. METHODS: Subjects in the study were Mexican and Brazilian women (LAVOS cohort, Mexican and Brazilian centers) aged 30 and older with a BMD Z-score at spine L1-L4 within $\pm$ 2SD. LAVOS MEXICO included patients from Puebla Mexico and the data source for this TBS values were from Mexicali Baja California, Ciudad Obregon Sonora and Leon, Guanajuato. LAVOS BRAZIL included patients from Vitoria. Individuals were excluded if they had fractures or were on any osteoporosis treatment and/or had any illness that would be expected to impact bone metabolism. All data have been obtained from Prodigy DXA devices (GE-Lunar, Madison, WI, USA). Cross-calibrations between the six centers were performed for TBS and BMD. BMD and TBS (TBS insight v2.1) were evaluated at spine L1-L4 but also for all possible vertebrae combinations.RESULTS: A database of 941 women ages 30 to 90 years was created. TBS and BMD values at L1-L4 were not correlated with BMI r=0.02 and r=0.1 respectively, both non significant. TBS and BMD values obtained for all lumbar vertebral combinations decreased significantly with age (see figure below). There was a linear decline of 20% (-3.2 SD) in the micro-architectural texture at L1-L4 between 45 and 90 years of age whereas a decline of 27% (-3.3 SD) was observed in BMD. Before 45 years old, TBS is slightly increasing (+0.95% between 30 and 45 years). Similar results were obtained for other ROIs of the lumbar spine.CONCLUSION: The decrease seen in lumbar TBS reflects age-related micro-architectural texture changes at spine. These findings suggest that TBS normative data can be used in clinical practice to assess bone micro-architectural texture deterioration over time and improve patient management.

MO0295

Bone structure assessed by TBS reflects trabecular microarchitecture of transiliac bone biopsies in idiopathic osteoporotic females with fragility fractures. Christian Muschitz*[1], Heinrich Resch[2], Roland Kocijan[3], Olivier Lamy[4], Angela Trubrich[5], Dieter Pahr[6], Wolfgang Schima[7], Fritz Lomoschitz[7], Stylianos Kapiotis[8], Didier Hans[9]. [1]St. Vincent's Hospital, Austria, [2]Medical University Vienna, Austria, [3]St. Vincent Hospital Vienna, Austria, [4]University Hospital, Switzerland, [5]BHS, Austria, [6]Institute of Lightweight Design & Structural Biomechanics, Vienna University of Technology, Austria, [7]Department of Diagnostic & Interventional Radiology, St. Vincent Hospital Vienna, Austria, [8]Labcon – Medical Laboratories Ltd., St. Vincent Group, Austria, [9]Lausanne University Hospital, Switzerland

Purpose:Trabecular Bone Score (TBS) is a novel grey-scale textural analysis used in estimating trabecular structure from the lumbar spine DXA. It has been shown that TBS correlates well with direct measures of bone microarchitecture independent of BMD in human cadaver vertebrae.

Methods:The aim of this cross-sectional study was to evaluate correlations between TBS of the spine and microarchitectural parameters of transiliac bone biopsies in females with idiopathic osteoporosis and fragility fractures. As a result, the

clinical impact and precision of TBS in bone quality assessment was evaluated. The following structural parameters of transiliac bone biopsies from 12 consecutive treatment-naïve and otherwise healthy females (mean 47; range 34 to 69.5 years) with recent fragility fractures were analyzed by a microtomographic imaging system: Bone volume/total volume (BV/TV), trabecular thickness (TbTh), trabecular separation (TbSp), number of trabeculi (TbN), connectivity density (ConnD) and structure model index (SMI). Spine BMD was assessed by DXA and site-matched spine TBS parameters were extracted from the DXA image using the TBS iNsight calculator.

Results:Laboratory tests did not reveal any evidence of metabolic disorder in any of our subjects. There was a correlation between TBS and the following 3D parameters: TBS and BV/TV: r=0.70 ($p<0.01$), TBS and TbSp: r=-0.70 ($p<0.01$), TBS and TbN: r=0.58 ($p<0.05$), and TBS and SMI: r=-0.75 ($p<0.01$). Even after adjustment for spine BMD, the correlation between TBS and BV/TV, TbN, TbSp and SMI remained significant. Using the stepwise regression approach the best models combining density and microarchitecture predicted 97% of the TBS parameters.

Conclusion:The association between TBS and microarchitectural parameters indicated that low TBS showed a marked deteriorated microarchitecture related to low TbN, high TbSp, altered SMI as well as low BV/TV. Hence, TBS is a feasible non-invasive surrogate technique for the assessment of bone mircorarchitecture texture from DXA scans in clinical routine that would not satisfy the definition of osteoporosis when solely based on T-scores or BMD values.

MO0296

Characterization of the osteocyte lacuno-canalicular network using ptychographic X-ray nanotomography. Cameron Kewish[1], Antonia Ciani*[1], Manuel Guizar-Sicairos[2], Ana Diaz[2], Mirko Holler[2], Stephane Pallu[3], Zahra Achiou[4], Rachid Jennane[5], Hechmi Toumi[5], Eric Lespessailles[6], Claude Laurent Benhamou[7], Jean-Pierre Samama[1]. [1]Synchrotron Soleil, France, [2]Paul Scherrer Institut, Switzerland, [3]EA 4708 - I3MTO Orléans, France, [4]Univ Orléans, I3MTO, Ea 4708, France, [5]Univ Orléans, I3MTO, Ea 4708, France, [6]Centre Hospitalier Regional Orleans, France, [7]CHR ORLEANS, France

Osteocytes are the last differentiated state of the osteoblast lineage, the longest living cells in the skeleton, and they play various functions including a crucial role in the mechanotransduction pathway. The osteocyte network, a system of extra cellular spaces, including lacunae and lacuno-canalicular network (LCN) is implicated in perilacunar mineralization and localized changes in bone strength. Thus, the geometrical three-dimensional (3D) characterization of this network might be of crucial importance in understanding bone pathologies. [1]

The recent development of ptychographic X-ray nanotomography exploits the penetrating power of hard X-rays and the high resolution of coherent lensless imaging to produce quantitative 3D images of the electron density within objects. [2] This has provided biomedical science with a new tool for characterization of the LCN with a resolution of tens of nanometers, for bone specimens currently up to 100 micrometers in diameter. We present here the application of ptychographic nanotomography for the morphometric characterization of the LCN, and nano-densitometry within the vicinity of the osteocyte lacunae. Tibial diaphysis cortical bone samples were taken from glucocorticoid-induced osteopenic, and control rats.

Results from this study can offer critical information on how osteoporosis and current drug treatments alter a measure of matrix quality and, ultimately, may provide insight into why drug treatments have shown variable clinical effectiveness across different studies. The shape of the lacunae and morphological parameters of the LCN have been extracted from 3D images using a newly developed data processing method. Network changes are discussed in connection with the biological impact.

MO0297

Cushing Disease: Gain in Bone Mineral Density and also Bone texture assessed by Trabecular Bone Score after cure of Cushing Disease. Eugenie Koumakis*[1], Renaud Winzenrieth[2], Laurence Guignat[3], Catherine Cormier[4]. [1]Hôpital Cochin, France, [2]Med-imaps, Hôpital X. Arnozan, PTIB, Pessac, France, France, [3]Service d'Endocrinologie, Hôpital Cochin, France, [4]AP-HP Groupe Hospitalier Cochin, France

Cushing disease (CD) is considered as a true model of a glucocorticoïds (GCs) effects on bone metabolism because of the minimization of confounding factors. Hypercortisolism frequently induces bone loss which is more pronounced at the lumbar spine than at the femoral neck due to a higher content in trabecular bone. This bone loss results in osteoporosis and leads to an increase in fracture risk. Several studies have shown bone mass restoration in patients with CD after treatment. The aim of our study was to examine treatment effects on bone mineral density (BMD) and on bone texture assessed by TBS in subjects with CD.

Patients and methods. We present a longitudinal study on 31 subjects (20 women and 11 men) with CD with mean age and BMI of 36.8 ± 12.4 years and 27.8 ± 4.0 Kg/m^2, respectively. Mean 24h urinary cortisol before treatment was 589 ± 1301µg/24h. All subjects were completely cured, i.e. 24h urinary cortisol normalization after treatment. Cure of CD was obtained following transsphenoidal surgery (TSS) only (n=17), TSS in combination with medical treatment (n=3), TSS and bilateral surrenalectomy (n=8), bilateral surrenalectomy (n=1), medical treatment only (n=1). BMD and TBS were evaluated at AP Spine (L1-L4) with DXA prodigy (GE-Lunar), QDR 4500 (Hologic), and TBS iNsight® (Med-Imaps) before and after treatment. Both DXA were cross-calibrated using a custom-made phantom. Linear regression was used to evaluate TBS and BMD modifications over time. Results were normalized at 1 and 2 years after treatment. BMD and TBS gains were expressed in % in comparison to baseline.

Results. Absolute TBS and BMD gains were significant ($p<0.0001$, and $p<0.01$, respectively). Normalized gains of TBS and BMD in % are presented figure 1 (mean + SEM). After treatment, BMD and TBS increased by 3.1 and 6.9% respectively after 1 year, and by 6.2 and 13.8% after 2 years. Before treatment, BMD and TBS were not correlated ($p=0.43$). After treatment, this correlation remained non significant ($p=0.53$). TBS gain was correlated with BMI and weight before treatment: r=0.46 ($p=0.009$) and r=0.44 ($p=0.01$).

Conclusion. The absence of correlation between TBS and BMD and the more significant improvement of microarchitecture assessed by TBS than BMD suggest qualitative rather than quantitative bone alterations in hypercorticism-induced osteoporosis. Bone microarchitecture assessment could therefore be a useful and supplementary tool for fracture risk evaluation in GC induced bone loss.

MO0298

Diagnosis of vertebral fractures by the EOS X-ray imaging system. Karine Briot*[1], Jacques Fechtenbaum[2], Adrien Etcheto[3], Sami Kolta[2], Antoine Feydy[3], Christian Roux[4]. [1]Paris Descartes University, Cochin hospital, Rheumatology Hospital, France, [2]Centre D'Evaluation, Des Maladies Osseuses, France, [3]Paris Descartes University, Cochin Hospital, France, [4]Hospital Cochin, France

Vertebral fractures (VF) are independent risk factors for both vertebral and peripheral fractures. However, for both cost and radiation concern, spine radiographs cannot be done neither as a screening method for at risk patients, nor as a follow-up tool. Vertebral fracture assessment (VFA) is a reliable technique with low radiation (3 µSv) to assess vertebral deformities but with a poor visualization of the upper thoracic spine. EOS® X-ray imaging system allows the acquisition of biplane images while the patient is in an upright weight-bearing position with a low radiation dose (80µSv).The objective of the study was to evaluate the sensitivity and specificity of EOS radiographs compared to VFA for the diagnosis of VF.

We conducted a cross sectional study in subjects aged above 50 years with indication for spine radiograph (risk factors for postmenopausal osteoporosis, height loss,..). EOS radiographs and VFA of the spine from T4 to L4 using DXA were performed the same day. EOS images were independently compared with VFA scans by two rheumatologists, for the diagnosis of VF. We assessed the sensitivity, specificity, predictive values and the interobserver precision of EOS compared to VFA images.Two hundred patients (mean age of 66.2 years were included; 62.5% were osteoporotic (T≤-2.5 at at least one site) and 38% has scoliosis with a mean BMI of 23.7 (3.8) kg/m^2 . At the vertebral level (n=5200), the percentage of unreadable vertebrae was 2.4% and 3.6% using EOS radiographs and VFA, respectively ($p=0.0007$). Unreadable vertebrae were located at T4, T5, T6. The legibility of spine was significantly affected by scoliosis (OR=2.845, $p<0.0001$,for EOS radiographs and OR= 1.85, p= 0.0041, for VFA). Using VFA, 66 patients (33.0%) had at least one VF whereas 69 patients (34.5%) had at least one VF using EOS radiographs. At the patient level, sensitivity, specificity and VPN for the diagnosis of VF of EOS radiographs were 0.797, 0.916 and 0.895, respectively. At the vertebral level, sensitivity, specificity and VPN were 0.657, 0.994 and 0.987, respectively. Concordance between both observers was very good for EOS radiographs (kappa-score=0.89), higher than for VFA (κ= 0.67).

This study shows that EOS X-rays have a good diagnostic value for the diagnosis of VF with a better legibility of upper thoracic spine and a higher concordance between readers compared to VFA, suggesting that this method could improve screening and follow-up of patients.

MO0299

Effects of Glucocorticoid Treatment on Bone BMD and TBS in Men. Edward Leib*[1], Renaud Winzenrieth[2]. [1]University of Vermont, USA, [2]Center of Bone diseases, Lausanne University Hospital, Lausanne, Switzerland, France

Aim: The aim of the study is to evaluate whether microarchitectural texture changes as measured by Trabecular Bone Score (TBS) can identify those male patients exposed to glucocorticoid (GC) therapy who are more likely to fracture.

Material and Methods: This mono-centric study involves US white men aged 45 and older who at the time of bone density testing gave a history of present or past use of GC. They were compared to a group of control subjects. Control subject exclusions included one or more historical fractures, or a past or present treatment or illness influencing bone metabolism. Subjects included in the GC treated group received prednisone ⩾ 5mg/day for ⩾3months or equivalent treatment. BMD was assessed at the lumbar spine (L1-L4) using a Prodigy device (GE-Lunar, Madison, USA). TBS was calculated at L1-L4 using the TBS iNsight® (Medimaps, France). Clinical data, presence of osteoporotic fracture (OPF), GC treatment and common clinical risk factors (CRFs) were documented.

Results: From the database, 73 men treated with GC and 90 control men were matched for age and BMI ($p>0.4$). Characteristics of the patients are shown in table. No correlation was observed when comparing spine TBS, spine BMD and BMI in either treated or cont. groups ($-0.16 \leq r \leq 0.23$). When compared to normal values, no TBS difference was observed in the control group whereas the GC group had a significantly lower TBS value (see table). GC subjects had a lower TBS compared to healthy subjects ($\Delta TBS = -4.1\%$, $p<0.02$) whereas no significant difference was observed for BMD ($p>0.07$). The negative effects of GCs was even more marked when fracture status was taken into account. We observed a TBS decrease of 9.3% in GC-patients with fracture ($p<0.01$) compared to control group whereas no differences was observed for BMD ($p>0.5$).

Conclusion: GC induces a microstructural texture impairment whereas no effect was observed on BMD. This result is consistent with previous TBS studies on GC treatment in women. Presence of an osteoporotic fracture worsens the GC effects on microarchitectural texture. TBS outperformed BMD in its ability to identify a population at risk for fracture and therefore should be a reliable tool for management of glucocorticoid-treated men.

Table: Characteristics of patients and controls

	GC-treated group	Control group
No. Of subjects	73	90
No. Of subjects with OP fracture	10 (13.7%)	0%
Age (years)	62.6±10.7	63.4±9.9

MO0300

Evaluation of Patients' Intervention Following Osteoporosis Screenings at Health Fairs. Frances Tepolt*[1], Susan Hassenbein[2], Edward Fox[3]. [1]Penn State Hershey Bone & Joint Institute, USA, [2]Penn State Bone & Joint Institute, USA, [3]Pennsylvania State Hershey Medical Center, USA

Introduction: Osteoporosis, a systemic skeletal disease resulting in the deterioration of the micro architecture of bone tissue, affects 15-20 million people in the U.S. Screening methods, although improving, remain inadequate, leaving the disease underdiagnosed and undertreated. The purpose of this study is to determine the effectiveness of calcaneal quantitative ultrasound (US) scanning in prompting osteoporosis evaluation with a health care provider. Similar studies investigating the utility of heel US in the community setting to promote bone health are lacking in currently published research.

Materials and Methods: Male and female subjects 18 years of age or older presenting at health fairs/ community events May 2012 - October 2013 were asked to participate in the study, providing consent for US scanning of the calcaneus and future telephone contact. Interested subjects with abnormal scan results (T-score less than or equal to -1) were contacted via telephone at least three months post-screening and asked a series of questions regarding their health and follow-up with a care provider.

Results: 67 subjects provided consent for participation and qualified for the study (T-score by heel US less than or equal to -1). 48/67 (71.6%) had phone screenings completed, and, of those, 42/48 (87.5%) were female and 6/48 (12.5%) male, mean age 53.9 years (range 29-84 years). 23/48 (47.9%) had follow-up with a health care professional. The average T-score of those with follow-up (-1.7 +/- 0.4) was significantly lower ($p=0.03$) compared to those without follow-up (-1.4 +/- 0.3). There was no significant difference in age. Of those who sought follow-up, 21/23 (91.3%) did so with a primary care physician, and 19/23 (82.6%) received recommendation for further evaluation/treatment. Recommendations included calcium/Vit D supplementation (12/19, 63.2%), DEXA scan (12/19, 63.2%), laboratory testing (2/19, 10.5%), or pharmacotherapy (2/19, 10.5%). None of the patients contacted for follow-up (0/48) suffered a fracture between time of heel US and phone screening.

Conclusions: Osteoporosis screening with heel US effectively prompts patients at high risk for osteoporosis to seek further osteoporosis workup from a health care professional in near half (47.9%) of cases and, of those, further evaluation/treatment in the vast majority (82.6%). Heel US screenings are therefore highly effective in improving the diagnosis and treatment of osteoporosis in the community.

HR-pQCT, Finite Element Analysis, and Machine Learning with Support Vector Machines Improved Classification of Postmenopausal Women with Fragility Fractures. Kyle Nishiyama*[1], Emily Stein[2], Stephanie Sutter[3], Donald McMahon[2], Edward Guo[4], Elizabeth Shane[2]. [1]Columbia University, USA, [2]Columbia University College of Physicians & Surgeons, USA, [3]Columbia University Medical Center, USA, [4]Columbia University, USA

Measurement of areal bone mineral density (aBMD) by dual-energy x-ray absorptiometry (DXA) is the current standard for diagnosis of postmenopausal osteoporosis. However, the majority of fractures occur in women who do not have osteoporosis by DXA criteria. Fracture is a complex, multifactorial event affected by many factors not measured by DXA, such as age, race, height, weight, falls, as well as bone structure and strength. The interaction among these factors is not well understood. We hypothesized that high-resolution peripheral quantitative computed tomography (HR-pQCT) combined with DXA and demographic data would improve classification of women with and without prior fragility fracture. To account for the complex interactions among measurements, we used support vector machines (SVM), in which models are trained on a subset of data and tested on the remaining data. We studied 101 women with previous low-trauma fracture (age 68 ± 8) and 101 fracture-free controls (age 68 ± 7). Demographic data and historical information were obtained by questionnaire. We measured aBMD by DXA at the spine, total hip, femoral neck, 1/3 and ultradistal radius. We also measured bone microarchitecture and volumetric BMD by HR-pQCT and estimated bone strength by finite element (FE) analysis at the radius and tibia. We compared a logistic regression model based on DXA parameters with five different models using SVM's and 10-fold cross validation. These included: 1) demographic data only, 2) DXA only, 3) HR-pQCT and FE only, 4) demographic and DXA data, and 5) all parameters. We also classified participants with wrist fractures only (N=40) and spine fractures only (N=35) compared to controls using all parameters. Sensitivity, specificity, accuracy, kappa, and area under the ROC curve (AUC) are presented (Table). The highest performance was achieved using all parameters and SVM models (AUC=0.71). The lowest was achieved with DXA only and logistic regression (AUC=0.56). DXA only slightly outperformed the model based on demographics alone. HR-pQCT alone outperformed both of these models. Performance was high for forearm fractures only, using all parameters (AUC=0.76). We conclude that SVM models that integrate information from DXA, demographics, HR-pQCT and FE perform better at discriminating fracture. Such models may be used as a basis to identify critical parameters for assessing fracture risk and to predict individuals at increased risk of fracture in future prospective studies.

Model	AUC	Accuracy (%)	Sensitivity (%)	Specificity (%)	PPV (%)	NPV (%)	Kappa
Logistic: DXA only	0.560	55.4	55.6	55.3	54.5	56.4	0.11
SVM: Demographics	0.579	57.9	58.2	57.7	56.4	59.4	0.16
SVM: DXA	0.609	60.9	59.2	63.4	70.3	51.5	0.22
SVM: demographics and DXA	0.649	64.9	63.2	67.0	71.3	58.4	0.29
SVM: HR-pQCT	0.658	65.8	64.5	67.4	70.3	61.4	0.32
SVM: all parameters	0.708	70.8	69.1	72.8	75.2	66.3	0.42
SVM: forearm fx only	0.757	77.1	64.1	84.8	71.4	80.0	0.5
SVM: spine fx only	0.647	71.3	59.1	75.4	44.8	84.5	0.31

Multimodality Radiographic Characteristics and Complications of Atypical Femoral Fractures: the Ontario AFF Cohort. R Bleakney*[1], Linda Probyn[2], Jonathan Adachi[3], Leon Lenchik[4], Aliya Khan[5], Earl Bogoch[6], Robert Josse[7], Catherine Lang[8], Angela M. Cheung[9]. [1]Mount Sinai Hospital, Canada, [2]University of Toronto, Sunnybrook HSC, Dept. of Medical Imaging, Canada, [3]St. Joseph's Hospital, Canada, [4]Wake Forest University, USA, [5]McMaster University, Canada, [6]St. Michael's Hospital, Canada, [7]St. Michael's Hospital, University of Toronto, Canada, [8]University of Toronto, Canada, [9]University Health Network-University of Toronto, Canada

Background: Atypical femoral fractures (AFFs) are increasingly recognized in patients on long term bisphosphonate therapy. There are many complications of AFFs including delayed healing, progression from incomplete to complete fractures, and fracture of the contralateral femur. Hardware fixation may be performed prophylactically or for management of complete AFFs and hardware complications are important to recognize.

Objective: To demonstrate characteristic radiographic findings using multimodality imaging (SE-femur, conventional radiographs, CT femur, MRI and bone scintigraphy scans) so as to aid clinicians with the diagnosis of AFFs and their complications.

Results: Included are images showing delayed healing, progression of incomplete to complete fractures, bilateral fractures, surgical management with complication and other cases. (See figure)Conclusion: AFFs and their complications have characteristic radiographic findings. Radiologists and clinicians should familiarize themselves with these findings so as to better diagnose AFFs and their complications.

MO0303

Normative Data of TBS for Healthy Postmenopausal African American Women. John Aloia[1], Mageda Mikhail[2], Gianina Usera*[1], Ruban Dhaliwal[3], Shah Islam[4]. [1]Winthrop University Hospital, USA, [2]Winthrop University Hospital, USA, [3]SUNY Upstate Medical University, USA, [4]Winthrop University Hospital, USA

Purpose: African American women have fewer incidences of fractures than do their Caucasian counterparts, for any given bone density. Studies conducted on TBS have used data from Caucasian women. The purpose of this study is to provide a reference range for postmenopausal African American women.

Methods: Baseline data of 418 healthy postmenopausal African American women was obtained from two clinical trials, one previously conducted and one ongoing, conducted at the Bone Mineral Research Center at Winthrop University Hospital. Exclusion criteria included bone disease or any co-morbidity that impacts bone metabolism. Health status was determined through medical history, physical exam, and screening laboratory tests. Spine BMD was obtained with DXA Hologic (model Discovery A) scans. TBS was calculated for L1-L4 as those used for BMD using TBS iNsight software by Med-Imaps (Version 2.0). All calculations were performed using SAS 9.3. Results were considered significant if $p<0.05$.

Results: The correlation coefficient was 0.40 for the relationship between spine BMD and TBS (L1-L4) (p-value$<$0.0001). Mean(SD) age of the subjects was 66(7) years. Mean(SD) TBS was 1.304(0.101), and mean(SD) spine BMD was 1.009(0.159). Significant correlations were found between TBS and age (p-value$<$0.003), as well as BMI (p-value$<$0.0001). There were no significant correlations found between TBS

and bone-specific alkaline phosphatase, parathyroid hormone, C-terminal telopeptide, 24-hr urine calcium, and serum 25(OH) D.

Conclusion: TBS, which is a measure of the micro architecture of bone, may indicate structural differences not apparent from BMD. Here we provide a reference range of TBS for healthy postmenopausal African American women.

Selected model R-Square: 0.34

Osteoporosis assessment at hip with Bindex®. Janne Karjalainen*[1], Ossi Riekkinen[2], Heikki Kroger[3]. [1]Bone Index Finland Ltd., Finland, [2]Bone Index Finland, Ltd., Finland, [3]Kuopio University Hospital, Finland

Currently, majority of the osteoporotic patients are not diagnosed (1). Efficient osteoporosis diagnostics would require novel approaches at primary healthcare. An ultrasound based device (Bindex®) has been recently introduced for osteoporosis screening and diagnostics. Bindex measures cortical thickness and determines parameter called density index (DI). Thresholds for DI in osteoporosis assessment have been determined in Finnish Caucasian population (n= 448) along the International Society of Clinical Densitometry (ISCD) guidelines (2,3). In this study, these thresholds are tested in Finnish caucasian female population.

A total of 100 females were recruited from private primary healthcare centers (Suomen Terveystalo Ltd., Finland) to the study (age 61.5 $\pm$ 8.1 years). Subjects were measured with dual energy x-ray absorptiometry (DXA) to determine bone mineral density (BMD) at proximal femur . Further, the cortical thickness was measured at three locations (distal radius, distal and proximal tibia) with Bindex. Subjects were diagnosed with osteoporosis when T-score at femoral neck or total proximal femur was below -2.5. Density index was calculated either by using measurement at one location (DI_1, proximal tibia) or all three locations (DI_3). By using the diagnostic thresholds, subjects were classified as healthy, osteoporotic or in need of DXA examination to verify diagnosis.

An average of 27% of the patients would require additional axial DXA examination when using thresholds and triage approach with DI_1 and DI_3. Sensitivity in osteoporosis diagnostics was 71.4% and 85.7% for DI_1 and DI_3, respectively. Specificity was 90.3% and 89.1% for DI_1 and DI_3, respectively. Osteoporosis at the hip was diagnosed in 7 and osteopenia in 40 subjects by DXA.

In this study, preliminary findings suggest good performance of previously determined thresholds in the current population. More data is needed to verify findings, especially more osteoporotic patients need to be included in the study.

The better prediction of vertebral fractures using Trabecular Bone Score and FRAX than Bone Mineral Density in postmenopausal diabetic women. Yoon-Sok Chung*[1], So Young Ock[2], Yong Jun Choi[2]. [1]Ajou University School of Medicine, South Korea, [2]Ajou University School of Medicine, South Korea

Background: Increased fracture risk in diabetes is related to bone quality rather than bone mineral density (BMD). The trabecular bone score (TBS) derived from the dual x-ray absorptiometry (DXA) image is proposed as an index of bone microarchitecture that associated with bone quality. The aim of this study is to investigate whether TBS improves the prediction of radiographic vertebral fractures compared to BMD or FRAX alone.

Methods: Total 118 Korean postmenopausal diabetic women were enrolled. Lateral plain radiographs of the thoracolumbar spine, and lumbar vertebral BMD (GE Lunar) were obtained. The FRAX® probability was computed using the algorithm available online at http://www.shef.ac.uk/FRAX (South Korea version). We classified the subjects with and without radiographic vertebral fracture. TBS was obtained by TBS iNsight Software program with BMD DXA images (GE Lunar). We compared the performance of TBS, BMD, FRAX and the combination with TBS and FRAX, by using receiver operator characteristics (ROC) analysis with area under the curves (AUCs).

Results: Among the subjects, 55 women (46.6%) had vertebral fractures and 63 women (52.5%) not. The TBS was lower in subjects with VFs (1.28$\pm$0.11) than without VF (1.33$\pm$0.10), (p=0.10). However, there was no difference in BMD between the subjects with VFs (1.00$\pm$0.18) and without VFs (1.03$\pm$0.14), (p=0.241). For radiographic vertebral fractures, TBS and lumbar spine (LS) BMD had similar predictive power (AUC: 0.381 versus 0.407) but the combination of TBS and lumbar spine BMD increased the performance over LS BMD alone (AUC: 0.619). FRAX score for major osteoporotic fracture showed good predictive power (AUC: 0.642). Furthermore, the prediction improved with the combination of TBS and FRAX score (AUC: 0.667).

Conclusion: These results suggest that combination of TBS with FRAX or BMD improves the performance of LS BMD or FRAX alone for the prediction of radiographic vertebral fractures in postmenopausal diabetic women.

MO0306

A Trans-ethnic Genome-wide Association Study Identifies Gender Specific Loci Influencing Pediatric BMD and BMC at the Distal Radius. Alessandra Chesi*[1], Jonathan Mitchell[2], Heidi Kalkwarf[3], Jonathan Bradfield[4], Joan Lappe[5], Shana McCormack[4], Vicente Gilsanz[6], Sharon Oberfield[7], Hakon Hakonarson[4], John Shepherd[8], Andrea Kelly[4], Babette Zemel[1], Struan Grant[9]. [1]Children's Hospital of Philadelphia, USA, [2]University of Pennsylvania, USA, [3]Cincinnati Children's Hospital Medical Center, USA, [4]Children's Hospital of Philadelphia, USA, [5]Creighton University Osteoporosis Research Center, USA, [6]Children's Hospital Los Angeles, USA, [7]Columbia University Medical Center, USA, [8]University of California, San Francisco, USA, [9]Children's Hospital of Philadelphia / University of Pennsylvania, USA

Osteoporosis, a condition with a strong heritable component, likely has origins in childhood when bone accrual is rapid. Childhood fractures are common, with the forearm being the most common site. Genome-wide association studies (GWAS) have identified >70 loci associated with BMD in adults but less is known about genetic influences specific to bone in childhood. To identify novel genetic factors that influence pediatric bone strength at the one-third distal radius, we performed a GWAS of BMC and BMD expressed as sex-, age-, population ancestry (black vs. non-black) specific Z-scores, adjusted or unadjusted for height Z-score, in a multicenter, multi-ethnic cohort of 1,399 healthy children (720 girls and 679 boys; 53% Caucasian, 22% African American, 14% Hispanic) aged 5-20y from the Bone Mineral Density in Childhood Study. BMC/BMD was measured using Hologic bone densitometers, with scans analyzed centrally. Biospecimens were genotyped using the Illumina OmniExpress BeadChip. We performed a sex-stratified analysis on ~16.43 million SNPs (directly genotyped or imputed) using a univariate linear mixed model as implemented in the software GEMMA to account for population stratification. Among females, variation at one locus (*CPED1,* also known as *C7orf58*) yielded association at the level of genome wide significance (rs7797976, P=1.2x10^{-10}, β=0.34; BMD-Z height-adjusted). In males, one locus on 9p21.3 yielded suggestive association (rs7035284, P=2.8x10^{-7}, β=-0.28; BMC-Z height-adjusted). Results were tested for replication in an independent, same-age cohort of 486 Caucasian children (245 girls and 241 boys). Both loci achieved at least nominal significance in this cohort within the relevant gender (rs7797976; P=0.047; rs7035284; P=0.015), and reached genome-wide significance when combining the cohorts (rs7797976; combined P=2.4x10^{-11}; rs7035284; combined P=1.2x10^{-8}).

Signals in the *CPED1* region were previously associated with BMD at other skeletal sites in adults and children. Our result at the distal radius underscores the importance of this locus at multiple skeletal sites. The 9p21.3 is within a gene desert, with the nearest gene flanking each side being *MIR31HG* and *MTAP*, neither of which has been implicated in BMD or BMC previously.

In summary, we report a novel locus for pediatric BMC at the distal radius in males, and implicate the *CPED1* locus in pediatric radius BMD in females. The difference in genetics between genders warrants further investigation.

MO0307

Association between osteoporosis susceptibility genes and bone mineral density in Vietnamese population. Lan T Ho-Pham*[1], Bich Tran[2], Sing Nguyen[3], Tuan Nguyen[2]. [1]Pham Ngoc Thach University of Medicine, Vietnam, [2]Garvan Institute of Medical Research, Australia, [3]Garvan Institute of Medical Research, Australia

Background and Aim: Bone mineral density (BMD) is under strong genetic control. However, it is not clear which specific genes are involved in the genetic regulation. Moreover, data on the genetics of osteoporosis in Asian population are very limited. This study sought to determine the contribution of osteoporosis genes discovered by genome-wide association studies in Caucasian populations to the variation in BMD in the Vietnamese population.

Methods: The study involved 564 Vietnamese men and women aged 18 years and over (average age: 47 years) who were randomly recruited from the Ho Chi Minh City (formerly Saigon). Demograpic data and clinical history were obtained by a structured questionnaire. BMD at the femoral neck, lumbar spine, total hip and whole body were measured by DXA (Hologic QDR4500, Bedford, MA, USA). Thirty-two single nucleotide polymorphisms (SNPs) in 29 genes were genotyped using Sequenom MassArray technology. We used the Bayesian Model Average (BMA) method to identify a set of SNPs that are independently associated with BMD.

Results: The distribution of genotypes of all SNPs included in this analysis was consistent with the Hardy-Weinberg's equilibirum law. After adjusting for age, gender and weight, 3 SNPs were associated with BMD: rs2016266 (SP7 gene), rs7543680 (ZBTB40 gene), and rs1373004 (MBL2/DKK1 gene). Among the three genetic variants, the SNP rs2016266 had the strongest association, with each minor allele being associated with ~0.02 g/cm2 increase in BMD at the femoral neck and whole body. Each of these genetic variant explained about 0.2 to 1.8% variance of BMD. All other SNPs were not significantly associated with BMD.

Conclusion: These results suggest that genetic variants in the SP7, ZBTB40 and MBL2/DKK1 genes are associated with BMD in the Vietnamese population, and that the effect of these genes on BMD is likely to be modest.

MO0308

Association between polymorphisms in Glucose-dependent insulinotropic polypeptide (GIP) and GIP receptor (GIPR) genes and bone quality in young and elderly Swedish women. Gaurav Garg*[1], Jitender Kumar[2], Fiona McGuigan[3], Mattias Callréus[4], Maria F. Gomez[5], Paul Gerdhem[6], Holger Luthman[7], Valeriya Lyssenko[8], Leif Groop[9], Kristina Akesson[10]. [1]Clinical Research Center, Lund University, Sweden, [2]Dept of Medical Sciences, Molecular Epidemiology & Science for Life Laboratory, Uppsala University, Sweden, Sweden, [3]University of Lund, Malmö, Skane University Hospital, Malmö, Sweden, [4]Skåne University Hospital, Sweden, [5]Department of Clinical Sciences, University Hospital Malmö, Lund University, Sweden, [6]Dept of Clinical Science, Intervention & Technology, Karolinska Institutet, Sweden, [7]5Medical Genetics Unit, Dept. of Clinical Sciences Malmö, Lund University, Sweden, [8]Department of Clinical Sciences, Diabetes & Endocrinology, University Hospital Malmö, Lund University, Sweden, [9]Department of Clinical Sciences, Diabetes, & Endocrinology, University Hospital Malmö, Lund University, Sweden, [10]Skåne University Hospital, Malmö, Sweden

Introduction: Glucose-dependent insulinotropic polypeptide (GIP) is an anabolic gastro-intestinal hormone that potentiates glucose-induced insulin secretion thereby stimulating bone formation and mineralization. Hormone activity is induced via GIP binding to the GIP receptor (GIPR). GIPR gene is widely expressed including on osteoblasts. Mice studies have shown that deficiency in GIP or GIPR leads to low bone mass and bone strength. To date, only one genetic association study for GIPR gene with bone phenotype in human has been published.

The aim of this study was to determine the age-related association between genetic variation in the GIP and GIPR genes and bone strength and bone mineral density (BMD) in young and elderly women and investigate relationship between serum GIP and bone.

Methodology: Two SNPs rs229172_GIP and rs10423928_GIPR were studied in two cohorts of Swedish women: PEAK-25 (all 25 yrs, n=1061) and OPRA (all 75 yrs, n=1044) and analyzed for their association with BMD, bone mineral content (BMC), ultrasound measures, trabecular bone score (TBS), body composition parameters and serum GIP levels. We also analyzed the association between serum GIP and bone related phenotypes.

Results: Women with the minor 'A' allele of rs10423928_GIPR had significantly lower ultrasound values (BUA: TT: 117.1 vs. AA: 115.4, p=0.011; SI: TT: 97.8 vs. AA: 94.5, p=0.03) after adjustment (p=0.004; 0.014) in PEAK-25 only. No association was observed with BMD and BMC in either cohort. rs10423928_GIPR was associated with lower serum GIP levels (β value = -6.93) (unadj. p=0.019; adj p=0.03).

In the OPRA cohort, women with minor 'A' of rs2291725_GIP had lower ultrasound values (SoS: TT: 1525.3 vs AA: 1516.2, p = 0.03; SI: TT: 71.2 vs. AA: 69.0, p = 0.04) at baseline as well as at 10 years follow-up (SoS: GG: 1516.9 vs. AA: 1507.7, p = 0.02; SI: GG: 64.9 vs. AA: 57.0, p = 0.018). rs2291725_GIP was associated with FN BMD, TB BMC and FN BMC after adjusting for fat mass (p=0.016; 0.02; 0.03) in the OPRA cohort only. No association was found between SNPs in either genes with TBS in PEAK-25 and fracture incidence in the OPRA cohort. No relation was found between serum GIP and bone phenotypes.Conclusion: This is a first genetic study where we have identified the genetic association between rs2291725_GIP and rs10423928_GIPR with lower bone strength. However, the association appears to be age-dependent, suggesting the involvement of yet unknown gene-environment interaction

MO0309

Association of VDR, COL1A1 and LCT gene polymorphisms with bone mineral density in Lithuanian women with postmenopausal osteoporosis. Pavel Marozik[1], Marija Tamulaitiene*[2], Irma Mosse[1], Vaidile Strazdiene[3], Vidmantas Alekna[2]. [1]Institute of Genetics & Cytology NAS Belarus, Belarus, [2]Faculty of Medicine, Vilnius University, Lithuania, [3]National Osteoporosis Center, Lithuania

The purpose of this study was to investigate the frequency of genes predisposing to osteoporosis (OP) in postmenopausal Lithuanian women.

Methods. This case-control study included 73 women from National Osteoporosis Center, Lithuania. Dual-energy X-ray absorptiometry (iDXA, GE Lunar) was used to measure bone mineral density (BMD). DNA was extracted from bloodspots dried on special NucleoSafe cards (Macherey-Nagel, Germany). OP predisposition gene polymorphisms (VDR *ApaI, BsmI, TaqI* and *Cdx2,* COL1A1 *G2046T* and LCT *T-13910C*) were determined using PCR analysis.

Results. Case group included 28 postmenopausal women with severe OP (age 74.1±1.2 years in average), the control group included 45 women (average age 72.9±0.9 years, p>0.05). Genotyping results showed that the total frequency of unfavorable risk alleles (predisposing to OP) in case group (52.1%) was higher comparing to controls (48.6%). The analysis of *Cdx2* polymorphism of VDR gene did not reveal any statistically significant difference between groups analysed, although the frequency of protective A allele in control group was 1.6 times higher compared to patients with OP. The frequency of risk allele *B* (42.9%, 1.6 times) and *BB* homozygotes (17.9%, 1.4 times) of VDR *BsmI* gene polymorphism was higher in

patients with OP compared to controls (p>0.05). The same was found for COL1A1 *G2046T* and LCT *T-13910C* polymorphisms.

In further analysis, control Lithuanian population was compared with control Belarusian population. No statistically significant difference was shown between them, and both were in correspondence with the one expected from the Hardy-Weinberg equilibrium. This allows us to compare Lithuanian patients with Belarusian control population. Statistically significantly higher risk allele *C* (OR=2.38, 95% CI, 1.39–4.07) and homozygotes *CC* (OR=3.32, 95% CI, 1.53–7.22) of LCT *T-13910C* gene polymorphism were found in patients compared to control group.

The analysis of the relationship between gene polymorphisms and BMD in Lithuanian population revealed a statistically significantly higher BMD at lumbar spine in *CT* heterozygotes of LCT *T-13910C* gene polymorphism compared to unfavorable *CC* homozygotes (1.06 ± 0.03 and 0.98 ± 0.02, correspondingly, p=0.05).

Conclusion. The findings of this study suggest that analysed gene polymorphisms are associated with postmenopausal OP in Lithuanian women, and insufficient statistical power may be due to small number of investigated subjects.

Genome-wide Association Study of Trabecular Bone Score Reveals Several Candidate Loci for Bone Quality. Hyung Jin Choi*[1], Jung Hee Kim[2], Nam H Cho[3], Chan Soo Shin[2]. [1]Chungbuk National University Hospital, South Korea, [2]Seoul National University College of Medicine, South Korea, [3]Preventive Medicine, Ajou University School of Medicine, South Korea

Several large-scale genome-wide association studies of bone mineral density have been performed. However, genetic factors influencing bone quality has not been investigated. To identify genetic factors for bone quality, we conducted a genome-wide association study in 2,987 samples from a community-based cohort. After sample quality control, 2,587 samples were analyzed. The discovery analysis revealed several candidate loci for trabecular bone score ($P<1\times10^{-5}$). One locus in chromosome 13 near SERP2 showed highest statistical significance ($P=1.0\times10^{-6}$) in combined analysis. Another loci in chromosome 1 near SLC4A1 and chromosome 9 near KLF4 were associated with trabecular bone score in combined analysis ($P=1.8\times10^{-6}$ and $P=3.7\times10^{-6}$). One locus in chromosome 9 near DBC1 showed highest statistical significance ($P=6.0\times10^{-7}$) in female specific analysis. Our result reveals several candidate loci for bone quality.

Polymorphisms in Cannabinoid Receptors Genes and Bone Mineral Density in Postmenopausal Korean Women. Jung-Gu Kim*[1], Jae Hee Woo[2], Hoon Kim[3], Jong Hak Kim[2]. [1]Seoul National University Hospital, South Korea, [2]Department of Anesthesiology & Pain Medicine, School of Medicine, Ewha Womans University, South Korea, [3]Department of Obstetrics & Gynecology, Seoul National University College of Medicine, South Korea

Purpose: The purpose of this study was to investigate the association between single nucleotide polymorphisms (SNPs) in cannabinoid receptor genes and bone mineral density (BMD) in postmenopausal Korean women.

Methods: The seven polymorphisms (CNR1c.*2394A>G, c.*3475A>G, c.1359C>A, rs2023239 C>T, rs2180619A>G, rs7766029C>T, rs806379A>T) in CNR 1 gene and sixteen polymorphisms (CNR2 c.188A>G, c.189A>G, c.465C>T, c.660G>A, c.751T>C, c.846T>C, c.946C>T, c.999G>A, c.1014C>G, rs2229583, rs2229584, rs229585, and rs229586, CNR2 rs4237, rs7530595, and rs16828926) in CNR2 gene were analyzed in 405 postmenopausal Korean women. Serum levels of osteoprotegerin (OPG), soluble receptor activator of the nuclear factor-κB ligand (sRANKL) and bone turnover markers were measured and BMDs at the lumbar spine and femoral neck were also examined.

Results: The CNR2 c.465C>T, c.660G>A, c.946C>T, and c.*263G>A polymorphisms among polymorphisms measured in CNR genes, were associated with BMD of lumbar spine. The AA genotype of thec.660G>A, and c.*263G>A polymorphism in the CNR2 gene was found to have significantly lower BMD of the lumbar spine compared to non AA genotype. BMD of lumbar spine in the TT genotype of CNR2 c.465 C>T, and c.946C>T polymorphism was lower, compared to non TT genotype. The TT genotype of the CNR2 c.946C>T polymorphism (OR, 3.43; 95% CI, 1.28-9.19) and the AA genotype of and CNR2 c.*263G>A polymorphisms (OR, 1.74; 95% CI, 1.03-2.95) had an increased risk of osteoporosis of the lumbar spine and/or femoral neck compared with other genotype respectively. The adjusted serum levels of bone turnover markers, OPG, sRANKL, or $sRANKL\times1{,}000/OPG$ ratios were not associated with the CNR polymorphisms.

Conclusion: Our results suggest that the CNR2 c.465C>T, c.660G>A, c.946C>T, and c.*263G>A polymorphisms may be genetic factors affecting BMD in postmenopausal Korean women.

Funding Support: This research was supported by Basic Science Research Program through the National Research Foundation of Korea (NRF) funded by the Ministry of Education, Science and Technology (2013052650), and by grant funded by the Seoul National University Hospital Research fund (04-2013-0320).

MO0312

Bone Mineral Density Changes Among Women Initiating ACE Inhibitors , Beta Blockers, and Thiazide Diuretics: Results from the SWAN Bone Study. Daniel Solomon*[1], Kristine Ruppert[2], Zhenping Zhao[2], YinJuan Lian[2], Gail Greendale[3], Joel Finkelstein[4]. [1]Harvard Medical School, USA, [2]University of Pittsburgh, USA, [3]University of California, Los Angeles, USA, [4]Massachusetts General Hospital, USA

Introduction: There has been substantial controversy over the potential role of several medications used to lower blood pressure and their potential effect on bone mineral density (BMD). Thiazide diuretics have been found to improve BMD in several small randomized controlled trials. As well, observational studies suggest improvement in BMD in some but not all beta-blocker analyses. The purpose of these analyses was to examine the effect of different antihypertensive agents on BMD using rigorous pharmacoepidemiologic methods.

Methods: we examined data from the Study of Women's Health Across the Nation (SWAN). 2365 women were followed for a median of 7.1 years at five SWAN sites with annual BMD assessments performed. In addition, medication use and other potential confounders – body mass index, diabetes, menopausal status, and comorbidities – were assessed annually. We performed a matched propensity score analysis examining annual rates of BMD change, comparing new users of thiazide diuretics, beta blockers, and ACE inhibitors with nonusers of any anti-hypertensive.

Results: Among the 2365 eligible women we found 1305 new users of any of the anti-hypertensive agents of interest. Propensity scores were calculated between each of the anti-hypertensive categories and non-users and then matched sets were created. 76 users of thiazide diuretics were matched with an equal number of nonusers, 69 ACE inhibitor users were matched with a similar number of nonusers, and 88 beta blocker users were matched with a similar number of nonusers. Baseline characteristics were very similar across users and nonusers for all three sets of matched cohorts. As expected, thiazide diuretic users gained bone mineral density or had a slower rate of decline compared to nonusers (Table 1). In contrast, rates of BMD loss in beta blocker(Table1) and ACE inhibitor users were similar to rates in non-users (data not shown).

Conclusions: Matched propensity score analysis of new users of thiazide diuretics produced the expected increase in BMD. The loss in BMD observed among new users of beta blockers and ACE inhibitors suggests that prior observational studies may be confounded. These methods may be helpful for estimating the effects of medications on BMD in observational cohorts.

Table 1. Annual within group change in BMD for SWAN participants starting thiazide diuretics or beta blockers

	Annual BMD Change (95% Confidence Interval)		
	Spine	Femoral Neck	Total Hip
Base Model[a]			
Thiazide user	***+0.43% (-0.10, 1.0)***	***-0.28% (-.80, .30)***	+0.22% (-.20, 0.70)
Non-user	+0.09% (-0.5, 0.7)	-0.59% (-1.2, -0.03)	+0.22% (-0.30, 0.60)
Full Model[b]			
Thiazide user	***+0.42% (-0.16, 0.99)***	***-0.30% (-0.87, 0.27)***	+0.34% (-0.10, 0.78)
Non-user	+0.08% (-0.49, 0.65)	-0.64% (-1.20, -0.07)	0.18% (-0.26, 0.62)
Base Model[a]			
Beta blocker user	-0.66% (-1.10, -0.20)	-0.42% (-0.78,-0.05)	-0.49% (-0.80,- 0.18)
Non-user	-0.69% (-1.1, -0.20)	-0.63% (-1.0,-0.26)	-0.49% (-0.80,- 0.18)
Full Model[b]			
Beta blocker	-0.60% (-1.1, -0.14)	-0.42% (-0.79,-0.06)	-0.51% (-0.81,- 0.20)
Non-user	-0.65% (-1.1, -0.20))	+0.63% (-1.0,-0.27)	-0.50% (-0.80,- 0.19)

[a] Base Model is adjusted for age, race, site, BMI and menstrual status. [b] Full model is Base Model + physical activity, # comorbid conditions, and propensity score. ***Bold italics indicate that the annualized rate of loss of BMD in the medication-using group is statistically significantly different from that of the matched, non-using comparison group; p-values range between p= 0.01 to p=0.04.***

MO0313

Explaining gender difference in fracture risk: the role of volumetric bone mineral density. Hanh Pham*[1], Nguyen Nguyen[2], Mei Chan[3], Jacqueline Center[2], John Eisman[2], Tuan Nguyen[2]. [1]Garvan Institute of Medical Research, Australia, [2]Garvan Institute of Medical Research, Australia, [3]Osteoporosis & Bone Biology, Australia

It has been suggested that men and women with the same age and areal bone mineral density (aBMD) have the same risk of a fragility fracture. However, such a relationship is not always true for all types of fractures. The present study aimed to determine the gender difference in fracture risk using volumetric and areal bone mineral density.

The study was designed as a population-based prospective investigation that involved 2279 women and 1379 men aged 57+ years (median: 68) who had been followed for a median of 9 years (range 1 – 25 years). Femoral neck aBMD, expressed as g/cm2, was measured by dual energy X-ray absorptiometry (GE-Lunar) at baseline. Femoral neck volumetric bone mineral density (vBMD), expressed as g/cm3, was estimated from aBMD and bone mineral content using a published algorithm. Low-trauma fracture was ascertained from X-ray reports. Hazard ratio (HR) of fracture

was estimated from the Cox's proportional hazards model to compare fracture risk between groups by BMD, age and gender.

Baseline vBMD in men is 0.31 ± 0.06 g/cm3, which was not significantly different from women (0.32 ± 0.07 g/cm3). However, baseline aBMD in men (0.93 ± 0.15 g/cm2) was significantly higher than women (0.81 ± 0.14 g/cm2). During the follow-up period, a significantly higher proportion of women (31.9%; n = 728) sustained fragility fractures compared to men (16.5%; n = 227). For a given aBMD and age, women had a higher risk of any fracture compared to men (HR: 1.4; 95%CI: 1.18 to 1.62), but not for hip or vertebral fracture. However, for a given vBMD and age, the risk of fracture was consistently greater in women than men for any fracture (HR 2.04; 95%CI: 1.76-2.36), for hip fracture (HR: 2.02; 95%CI: 1.37-2.96), and for vertebral fracture (HR: 1.93; 95%CI: 1.51-2.45).

These results indicate that women have higher risk of fracture than men for a given age and vBMD. The data also suggest that vBMD migh be a better predictor of fracture risk than aBMD, and that the diagnosis of osteoporosis should be based on vBMD rather than aBMD.

MO0314

Influence of degenerative disorders on the lumbar spine BMD and TBS with age: the Cohort OsteoLaus. Olivier Lamy*[1], Ivan Padlina[2], Berengère Aubry-rozier[2], Delphine Stoll[3], Marie Metzger[2], Didier Hans[4]. [1]Chief of the Bone Unit, Switzerland, [2]Bone Unit, Switzerland, [3]Centre a bone diseases, Che, [4]Lausanne University Hospital, Switzerland

Introduction: After menopause, lumbar spine (LS) BMD and TBS decrease with age. In practice, we are often faced with values of LS BMD "relatively" high for the age, which can lead to erroneous interpretations. Preliminary studies have shown that osteoarthritis (oa) does not influence TBS. The aim of this study was to measure changes in LS BMD and TBS values in women 50 to 80 years, taking into account the impact of fractured vertebrae (VFx) and oa (Voa).

Material and Methods: The 1'500 women 50 to 80 years old included in the cohort OsteoLaus (Lausanne, Switzerland) have had LS BMD and TBS, and VFA. All exams were analyzed independently by two experts following the ISCD guidelines, excluding VFx and vertebra with > 1 SD difference with the vertebra immediately adjacent.

Results: We included 1'443 women: age 66.7±11.7 y, BMI 25.7±4.4. Participants were divided into six age groups: 50-55, 55-60, 60-65, 65 -70, 70-75 and 75-80 years. BMD was increased from 1.2 to 3.2 % before excluding VFx and Voa ($p < 0.001$). TBS didn't change after excluding VFx and Voa (0.0% to 0.8%, ns). BMD (Vfx and Voa excluded) was for the six age groups: 0.953±0.141 g/cm2, 0.916±0.155, 0.909±0.158, 0.917±0.167, 0.918±0.168 and 0.933±0.188, respectively. Loss between 52.5 and 77.5 y. was 2.10 %, or 0.09 %/y with a loss of 0.46%/y from 52.5 to 62.5 y, followed by a gain of 0.18 %/y between 62.5 and 77.5 y. The change in BMD between two consecutive age gr was significant only between gr1 and gr2 ($p < 0.02$). TBS (Vfx and Voa excluded) was for the six age groups: 1.357±0.093, 1.317±0.099, 1.289±0.092, 1.269±0.099, 1.253±0.101 and 1.235±0.105, respectively. Loss between 52.5 and 77.5 y. was 8.99 %, or 0.36 %/y with a loss of 0.50 %/y between 52.5 and 62.5 y, and 0.26%/y between 62.5 and 77.5 y. Changes in TBS between 2 consecutive age groups was highly significant ($p < 0.02$ - $p < 0.0001$). These results are more pronounced in a sub-analysis including only women with Voa (with and without exclusion of Voa).

Conclusion: This study shows a double interest in TBS, particularly in the older population: 1) on average, TBS is not affected by fractures or oa disorders, 2) while BMD increases after 65 years (moderate degenerative disorders cannot be excluded from the analysis), TBS continues to decline. For the LS evaluation, TBS should play a leading role not only for diagnosis but also for treatment monitoring in view of its independence to oa.

MO0315

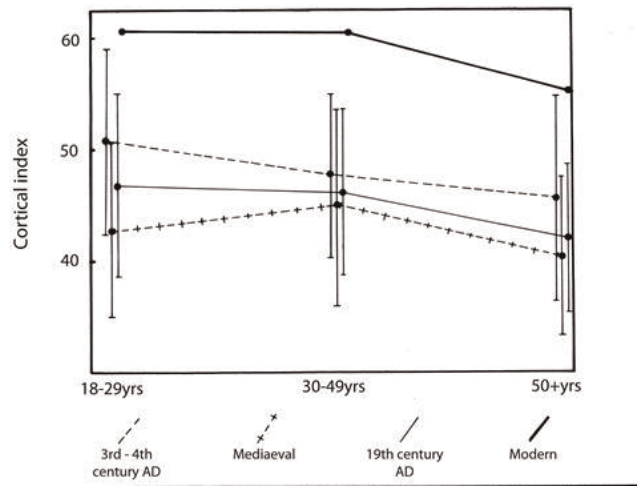
Age-Related Loss of Cortical Bone in Males: Trends from the 3rd century AD to the Present Day in North-West Europe, a Study Using Archaeological Skeletons. Simon Mays*. English Heritage, United Kingdom

Background: Osteoporosis has been increasingly recognised as a health threat in the ageing male. Studies of osteoporosis in archaeological skeletons are useful to our understanding of the disease, particularly the impact of enviromental risk factors, because they allow comparisons to be made with populations of similar genetic make-up to the present day but with very different livestyles. To date, most studies of osteoporosis in ancient skeletons have focused on the disease in females. The aim of this study is to investigate age-related loss of cortical bone in male skeletons. British archaeological populations from three different time periods, ranging from the 3rd century to the 19th century AD, are investigated, and comparisons drawn with modern data. Over this 1600 year period there was an increase in exposure to risk factors such as cigarette smoking, sedentary lifestyle and vitamin D deficiency, which are commonly held to exacerbate osteoporotic loss of bone mass. It was thus hypothesised that there should be an increase in the severity of age-related loss of cortical bone in later compared with earlier populations.

Methods: Bone status was evaluated using measurement of cortical thickness at the midshaft of the the second metacarpal from radiographs (N=215 male skeletons). The cortical thickness was expressed as the cortical index (100 x combined cortical thickness / bone width).

Results: peak cortical index in young male adults was less in the archaeological populations than today ($p<0.001$). Two-factor analysis of variance indicated no difference in age-patterning in cortical index between the three archaeological populations ($F=0.54$, $p=0.71$), and in each case the pattern of age-related loss of cortical bone in resembled that in a large modern reference group (Fig. 1). No fragility fractures were found in the archaeological populations.

Discussion and conclusions: The lesser peak cortical bone in ancient populations may reflect the poorer nutrition characteristic of earlier populations, although other unidentified factors may also be involved. There was no difference in age-related patterns of cortical bone loss between the different time periods, despite the time-progressive increase in exposure to risk factors commonly held to exacerbate loss of bone mass. The current results suggest that such factors may not exert very great effects on age-related cortical bone loss in males.



Metacarpal cortical index versus age in males from different time periods

MO0316

Osteopenia and Osteoporosis in Adult Females with Type 1 Diabetes: Results from the T1D Exchange Registry. Ruban Dhaliwal*[1], Nicole Foster[2], Linda Dimeglio[3], Katherine Manseau[4], Viral Shah[4], Julie Kittelsrud[5], Jill Simmons[6], Lucy Mastrandrea[7], Maya Styner[8], Roy Beck[9], Ruth Weinstock[10]. [1]SUNY Upstate Medical University, USA, [2]Jaeb Center for Health Research, USA, [3]Indiana University School of Medicine, USA, [4]Barbara Davis Center for Childhood Diabetes, USA, [5]Avera McKennan Hospital & University Health Center, USA, [6]Vanderbilt University Medical Center, USA, [7]SUNY at Buffalo, School of Medicine, USA, [8]University of North Carolina, Chapel Hill, School of Medicine, USA, [9]Jaeb Center for Health Research, USA, [10]State University of New York Health Science Center, USA

To obtain a better understanding of the relationshp between type 1 diabetes (T1D) and osteopenia/osteoporosis (OP), factors associated with bone health were examined in adult females aged 26-92 years from 38 centers in the T1D Exchange clinic registry (median age 45 years, median duration of diabetes 23 years, 91% non-Hispanic white).

Diagnoses were obtained from medical record review. Since the diagnosis of osteoporosis could not be distinguished in the registry from the diagnosis of osteopenia, the conditions were grouped for analyses into one entity (OP). Individuals with end stage renal disease or history of transplantation were excluded. Multivariable logistic regression models evaluated associations of demographic and clinical factors with OP.

Of 2582 adult females, 295 (11%) overall; 38% ⩾65 years) had an OP diagnosis. Those with OP were more likely to be older (mean 62 vs 45 years, $p<0.001$) and have lower BMI (mean 27 vs 34 kg/m^2, $p=0.05$) compared with participants without OP. Among 76 participants with a history of celiac disease (CD), 17% had OP compared with 11% of those without CD (unadjusted $p=0.12$). Only 27 of the 295 with OP were <50 years old. OP status was not associated with recent HbA1c ($p=0.42$), diabetes duration ($p=0.90$), youth vs later (> 18 years of age) onset T1D ($p=0.62$), and presence of CD ($p=0.09$), thyroid disease ($p=0.77$), and known microvascular complications of T1D ($p=0.22$). Use of supplements was more common in those diagnosed with OP: 86% vs 52% took vitamin D; 76% vs 32% took calcium. Limitations of these data include lack of systematic screening for OP, of bone mineral density data, and of fracture data. In conclusion, in the T1D Exchange, OP is common, particularly in older women. Further studies are needed to better understand contributing factors, impact of OP on fracture risk, and optimal approaches for prevention.

MO0317

A small population-wide increase in BMD is associated with substantial reduction in fracture incidence. Mei Chan*[1], Dana Bliuc[2], Jacqueline Center[2], John Eisman[2], Tuan Nguyen[2]. [1]Osteoporosis & Bone Biology, Australia, [2]Garvan Institute of Medical Research, Australia

It is not clear whether a shift in the population distribution of bone mineral density (BMD) could have an impact on the fracture incidence in the general population. The present study sought to determine the effect of change in population-based BMD on fracture incidence in the elderly population.

The study involved two cohorts recruited from the City of Dubbo (Australia). The first cohort, DOES1, included 2204 participants who were recruited from 1990. The second cohort, DOES2, included 1516 participants who were recruited from 2000. All participants were aged 60 years and above at the time of study entry. Baseline anthropometric and demographic characteristics were ascertained at baseline by a structured questionnaire. BMI was calculated from measured height and weight. BMD at the femoral neck and lumbar spine was measured by DXA (GE-LUNAR Corp, Madison, WI). Osteoporosis was defined as femoral neck BMD T-score $\leq$ -2.5. Low trauma and non-pathological fractures were ascertained from X-ray reports during the follow-up (from study entry till 31/12/2013).

The prevalence of obesity (BMI$\geqslant$30) increased during the follow-up period: in women, from 18% in DOES1 to 30% in DOES2. In men, the corresponding prevalence increased from 7% and 33%. During the same period, for a given age and BMI, women in DOES2 had a greater BMD (~6%) than their counterparts in DOES1. Femoral neck BMD changes were also observed in men but with a smaller magnitude (3%). In the DOES2 cohort, the prevalence of osteoporosis by BMD was 9%, a reduction of ~20% compared with the DOES1 cohort. In women, the age-standardised annual fracture incidence decreased from 3.2% in DOES1 to 2.5% in DOES2, a relative decline of 28% ($P < 0.001$). In men, there was a similar decline of fracture incidence: from 1.7% to 1.3% per year, a reduction of 24% ($P = 0.006$). Most of this reduction was in non-vertebral fractures. There was no change in the uptake of anti-osteoporosis treatment during the follow-up period. These data suggest that a modest population-wide secular increase in BMD was associated with a substantial reduction in fracture risk in the general population.

These results support the concept that a population-based approach to improve BMD distribution could be as or more effective than focusing on those at high-risk, e.g. post fracture) in reducing the community burden of fracture incidence. One aspect of these findings suggests how a modest increase in BMD induced by anti-resorptive therapy could bring larger-than-expected reduction in fracture risk reduction. An important but conflicting aspect to these findings is that an intervention that could bring substantial benefit to the population may not necessarily bring benefit to an individual.

MO0318

Correlation of Other Fracture Types with Hip Fracture: Toward a Rational Combined Hip Fracture Endpoint. Cathleen Colon-Emeric*[1], Carl Pieper[2], Janet Grubber[3], Courtney VanHoutven[3], Joanne LaFleur[4], Kenneth Lyles[5], Robert Adler[6]. [1]Duke University Medical Center, USA, [2]Duke University, USA, [3]Durham VA Medical Center, USA, [4]University of Utah, USA, [5]Duke University Medical Center, USA, [6]McGuire VA Medical Center, USA

Background: With ethical requirements to enroll lower risk subjects, recent osteoporosis trials are underpowered for change in hip fractures. Different anatomical sites have varying properties which confer different levels of fracture risk and response to treatment.

Objective: To identify anatomical sites which cluster with hip fracture at higher than expected frequency. If treatment is associated with similar risk reductions within the cluster, subsequent trials can use a combined endpoint to increase power.

Design: Cohort study using administrative data from Veterans Affairs and Centers for Medicare and Medicaid Services.

Population: U.S. Male Veterans (n=5,036,536) aged 50 years and over receiving primary care in the VA system between 1999-2009.

Methods: Fractures were ascertained using ICD9 and CPT codes and classified by fracture type; hip, forearm, spine, shoulder, pelvic, rib/clavicle, distal femoral, tibial/fibular, and other. To avoid double counting due to repeated coding of the same event over time, each individual was counted only once for each fracture type, and femur fracture codes must have occurred at least 6 months away from hip fracture codes. Pearson correlation coefficients for each pair of fracture types were calculated, and logistic regression was used to calculate the odds ratios and kappa statistic for each fracture type with hip fracture. Latent class analysis was used to identify clusters of highly correlated fractures.

Results: Over the study period 595,579 (11.8%) men suffered 1 or more fractures and 140,905 (2.8%) suffered 2 or more fractures. Hip fracture was the most common specific fracture type (49% of individuals with fracture), followed by spine (31%), femur (26%) and shoulder (21%). The fracture types most highly correlated with hip fracture were pelvic/acetabular (Pearson coefficient 0.25, $p<0.0001$), femur (0.16, $p<0.0001$), and shoulder (0.11, $p<0.0001$). Odds ratios and kappa statistics (reflecting the proportion of potential agreement above chance) for each fracture type with hip fracture are reported below. Latent class analysis revealed good loading onto a single factor (rho estimates <0.10 or >0.90).

Conclusions: Pelvic, acetabular, femur, and shoulder fractures cluster with hip fractures within individuals at greater than expected frequency. If subsequent analyses confirm similar treatment risk reductions within that cluster, then a combined endpoint could be used in subsequent trials to better estimate the effect of new therapies on hip fracture risk.

Fracture Types	Odds Ratio (95% CI)	Kappa
hip * femur	10.1 (46.5, 48.6)	0.16
hip * forearm	5.1 (5.0, 5.2)	0.06
hip * pelvic/acetabular	47.6 (46.5, 48.6)	0.20
hip * rib	4.5 (4.4, 4.6)	0.08
hip * shoulder	9.1 (8.9, 9.3)	0.10
hip * spine	5.4 (5.3, 5.5)	0.09
hip * tibia	4.7 (4.5, 4.8)	0.05

MO0319

Fall in Elderly Cared by Undegraduate Medical Students Belonging to The Internal Medicine Academic League. Fabiana Fonseca[1], Layla Bonfim Faleiros*[2], Renan Rodrigues Neves Ribeiro do Nascimento[2], Stéfano Franco Minohara Minohara[2], Estela Mion Petrillo Mion Petrillo[2], Tiago Marques Agostinho Marques Agostinho[2], Egidio Lima Dórea Lima Dórea[2]. [1]PUC - SPUNICID, Brazil, [2]UNICID, Brazil

INTRODUCTION

Fall in elderly represents a serious problem in public health. Its impact has not been properly discussed in academic circles. Furthermore, many professionals believe that fall is inevitable with aging. Approximately 30% of the older populatiom fall, that figure rises to 50% above 80 years of age. This makes falling a representatuve fraction of morbidity rates and causes of death. Therefore, it raises the attetion the lack of studies about fall in elderly cared by medicine students.

OBJETIVE

To assess the number of patients cared by undergraduate medicine students belonging to an Internal Medicine Academic League that have suffered a fall, comparing to literature data and characterize the methods of fall porevetion in the studied population.

MATERIALS AND METHODS

Retrospective study, encompassing 106 medical records of patients cared in LACM between 2007 and 2013. Information was retrived about the presence of falls in the last year of visits of all patients. The results were compiled in an Excel spreadsheet and analyzed as data tables.

RESULTS

Approximately 22,45% of patients cared by LACM have suffered falls, with a slight bias to the male population (54,1%). The average age was 70 yeaes of age. The patients reporting falls used in average 5 different medicines. 20,8% of the patients reporting falls did not present concurrent comorbidity, while 3 (12,5%) had two and 16 (66,7%) three or more.

CONCLUSION

The study enabled us to identify that the data of patients cared by LACM are in agreement with the literature. The use of multiple medicines was an important factor in patients that suffered falls, as well as the presence of comorbidity. Therefore, the assessment of medication and proposal for education in fallprevetion is important to reduce the incidence of falls. Furthemore, the training in fall prevention for professionals involved in elderly care can reduce fall rates and promote quality of life.

MO0320

High Body Mass Index Is a Risk Factor for Low Trauma Fractures in Women Who Have Sustained an Upper Arm or Lower Leg Fracture. Claudia Beaudoin*[1], Sonia Jean[2], Louis Bessette[1], Louis-Georges Ste-Marie[3], Jacques P. Brown[4]. [1]CHU de Quebec Research Centre, Canada, [2]Institut National De Santé Publique Du Québec, Canada, [3]CHUM, University of Montreal, Canada, [4]CHU de Québec Research Centre, Canada

Purpose: To investigate the relationship between body mass index (BMI) and the level of trauma in a cohort of fractured women aged 50 and older. Methods: In the Recognizing Osteoporosis and its Consequences in Quebec programme, a cohort of recently-fractured women was recruited. Information on circumstances of fracture and skeletal sites were collected at baseline, and fractures were classified as low or high-energy trauma fractures. A low-energy trauma fracture was defined as occurring spontaneously, from a fall from standing height, sitting, lying (<1m high), missing three or fewer steps, coughing or sneezing or from a movement outside of the normal

range of motion. All other fractures were classified as high-energy trauma fractures. Six to eight months following fracture, women were contacted to complete a follow-up questionnaire detailing personal and clinical characteristics related to osteoporosis. Femoral neck bone mineral density (FN-BMD) of participants who reported having had a BMD measurement within 2 years of the fracture event were obtained from patients' clinics. BMD data was imputed for women who did not have a FN-BMD result available (1250/2633). To evaluate the association between BMI and the level of trauma, a multivariate logistic regression model including adjustment variables and an interaction between BMI and fracture site was constructed. Results are presented by fracture site category. Results: The analysis included 2633 women who suffered a fracture. The number of women who suffered a low and high trauma fracture is presented in Table 1 according to fracture site and BMI. Women who suffered a foot, ankle, tibia or fibula fracture were more likely to have experienced a low-energy trauma fracture if they were overweight (O.R. [95% C.I.] = 1.80 [1.20; 2.70]) or obese (O.R. [95% C.I.] = 2.91 [1.85; 4.58]) than if they had a normal BMI (Table 2). In women who suffered an upper arm fracture, those with an obese BMI tend more to have experienced a fracture following a low- than a high-energy trauma (O.R. [95% C.I.] = 2.08 [1.22; 3.55]). No significant association was detected between BMI and the level of trauma in women who suffered a hip/pelvis/femur or wrist/forearm fracture. Conclusions: This study suggests that the association between BMI and level of trauma differs depending on the fracture site. In women who have suffered an upper arm or lower leg fracture, high BMI is a risk factor for low trauma fractures.

Fracture site n_1/n_2	Body mass index (m/kg²)			
	Underweight (<18.5)	Normal (18.5-24.9)	Overweight (25-29.9)	Obese (≥30)
Foot, ankle, tibia/fibula	6/2	164/77	240/70	223/44
Hip, pelvis, Femur	18/2	121/24	71/16	34/8
Upper arm	3/3	120/57	118/44	119/33
Wrist, Forearm	13/3	351/87	277/79	159/47

Table 1: Number of women who suffered a low- (n1) and high- (n2) energy trauma fracture

Fracture site O.R. [95% C.I.]	Body mass index (m/kg²)			
	Underweight (<18.5)	Normal (18.5-24.9)	Overweight (25-29.9)	Obese (≥30)
Foot, ankle, tibia/fibula	0.95 [0.17; 5.27]	1.00 (Ref)	**1.80** [1.20; 2.70]	**2.91** [1.85; 4.58]
Hip, pelvis, femur	1.67 [0.34; 8.29]	1.00 (Ref)	1.02 [0.49; 2.13]	1.28 [0.49; 3.34]
Upper arm	0.46 [0.08; 2.59]	1.00 (Ref)	1.27 [0.77; 2.08]	**2.08** [1.22; 3.55]
Wrist, forearm	0.79 [0.20; 3.07]	1.00 (Ref)	0.94 [0.65; 1.35]	1.01 [0.66; 1.56]

MO0321

Is Fall Risk Indirectly Captured by FRAX?. Shreyasee Amin*[1], Kenton Kaufman[2], Jeremy Crenshaw[2], Sara Achenbach[2], Elizabeth Atkinson[2], Sundeep Khosla[3], L. Joseph Melton[1]. [1]Mayo Clinic, USA, [2]Mayo Clinic, USA, [3]Mayo Clinic College of Medicine, USA

Falls precipitate most fragility fractures, which increase with advancing age and tend to be more common in women. Many risk factors incorporated into the fracture risk assessment score, FRAX, are also associated with falls. Thus, it may be that fall risk is indirectly captured through FRAX. If not, fall risk would be important to assess separately when determining individual fracture risk.

We studied an age-stratified cohort of 125 ambulatory, community-dwelling women age ⩾ 65 yrs (body mass index [±SD], 27.3 ± 5.0 kg/m^2). All except one woman had femoral neck bone mineral density (FN BMD, g/cm^2) measured and FRAX scores (% 10-year risk), for both major osteoporotic (OP) fractures and hip fractures, determined. Self-reported history of falls within the last year was recorded. Subjects completed various assessments for fall risk, unless prior injury or surgery precluded safe participation, including the Activities-specific Balance Confidence (ABC) Scale (0-100%) [N=125], Functional Reach Test (FRT, cm) [N=124], and maximum unipedal stance (1-Leg Stance) (0-30 s) [N=121], where higher scores are associated with lower fall risk. In a motion analysis laboratory, we also assessed the dynamic stability margin (DSM, m) [N=119], a measure of gait stability captured while subjects performed unobstructed level walking. Negative DSM values quantify the dynamic instability that an individual allows during undisturbed gait. Using Spearman's correlation, we examined the relation between each fall risk tool with age, FN BMD and FRAX and then assessed the association between each fall risk tool with FN BMD and FRAX, adjusted for age.

The median (range) for age, FN BMD and the two FRAX scores of these women was 77 (65-92 yrs), 0.81 (0.54-1.20 g/cm^2), 14.2 (3.3-56.9%, major OP fracture risk) and 3.5 (0.1-45.8%, hip fracture risk), respectively. There were 47 women who reported at least 1 fall within the prior year. The median (range) for ABC, FRT, 1-Leg Stance and DSM was 92 (43-100%), 26 (5-38 cm), 11 (1-30 s) and -0.41 (-0.65 to -0.18 m), respectively. Most assessments of fall risk were associated with age. After adjusting for age, none of the fall risk tools was associated with FN BMD or either of the two FRAX scores (Table).

In the assessment of individual fracture risk, our results suggest that fall risk would need to be considered separately from either FN BMD or FRAX score.

	Spearman Correlation Coefficient (Unadjusted/Age-adjusted)			
Fall Risk Tool	Age	FN BMD	FRAX Major OP Fractures	FRAX Hip Fractures
ABC Scale	-0.44*/--	0.18*/0.07	-0.34*/-016	-0.38*/-0.15

Low Rate of Osteoporosis Treatment in Nursing Home Men at High-risk for Fractures. Alexandra Papaioannou*[1], Carly Skidmore[2], George Ioannidis[3], Courtney Kennedy[4], Denis O'Donnell[5], Hrishikesh Navare[5], Lora Giangregorio[6], Sharon Marr[4], Sid Feldman[7], Angela M. Cheung[8], Richard Crilly[9], Sophie Jamal[10], Robert Josse[11], Sadhana Prasad[3], Anne Braun[2], Ravi Jain[12], Lehana Thabane[2], Jonathan Adachi[13]. [1]Hamilton Health Sciences, Canada, [2]McMaster University, Canada, [3]McMaster University, Canada, [4]McMaster University, Canada, [5]Medical Pharmacies Group Limited, Canada, [6]University of Waterloo, Canada, [7]Baycrest, Canada, [8]University Health Network-University of Toronto, Canada, [9]University of Western Ontario, Canada, [10]The University of Toronto, Canada, [11]St. Michael's Hospital, University of Toronto, Canada, [12]Osteoporosis Canada, Canada, [13]St. Joseph's Hospital, Canada

Introduction: Our previous work in LTC has shown that awareness and use of clinical practice guidelines in Long-Term Care (LTC) are low. Clinicians practicing in LTC face unique challenges caring for elderly individuals including co-morbidities and prescribing contraindications. To address these challenges, the Gaining Optimal Osteoporosis Assessments in Long-Term Care (GOAL) knowledge translation initiative was implemented to improve identification and treatment. In this analysis, we examined baseline prescribing rates in residents identified as high-risk. Methods: GOAL is a stepped wedge cluster randomized controlled trial currently underway in 50 LTC homes in Ontario, Canada. De-identified clinical/prescribing data were downloaded from the database of a large pharmacy provider that services all study homes. Chart audits were performed to determine residents at high risk of fractures. Based on Osteoporosis Canada clinical practice guidelines, high-risk was defined as individuals who had at least one spine/hip fracture, 2 or more other fractures, or taking corticosteroids (>7.5 mg/d Prednisone equivalent). We calculated the proportion of high-risk residents who were receiving osteoporosis medications (including alendronate, risedronate, zoledronic acid, denosumab or parathyroid hormone), and average total daily vitamin D and calcium supplementation. Results: In 1740 residents from 13 LTC homes [mean age = 83 (standard deviation (10), 70% (1130/1607) women] randomized to the first wave, 12.2% (58/477) of men and 17.8% (201/1130) of women were identified as high-risk. Overall, 17.2% (10/58) of high-risk men and 42.3 % (85/201) of high risk women were taking an osteoporosis medication. Average total daily vitamin D and calcium supplementation in high-risk residents was 1189 IU/day (SD 857) and 306 mg/day (SD 432) respectively. Conclusion: Our results demonstrate that men, in particular, may be a group not being considered for fracture prevention. In the high-risk cohort, greater than 80% of men and 50% of women were not prescribed osteoporosis medication. Several factors contribute to low rates of treatment in nursing home elderly and the GOAL initiative aims to reduce this care gap.

MO0323

Real-World Evidence on Fragility Fractures and Treatment in Canadian Osteoporotic Patients. Marie-Claude Meilleur*[1], Martin Cloutier[2], Jimmy Royer[2], Arun Krishna[3]. [1]Merck Canada Inc, Canada, [2]The Analysis Group, Canada, [3]Merck, USA

OBJECTIVES: Patients with osteoporosis (OP) are at high risk of fragility fractures, although some treatments may help reduce that risk. This study aims to assess the prevalence of fractures in patients with OP in Quebec (Canada) and describe the use of antiresorptive agents (AAs) among patients who had a fragility fracture.

Methods: Patients ⩾50 years of age with an OP-related event, defined as either a diagnosis for OP, a fragility fracture, or a prescription fill for an AA were identified in Quebec's healthcare database, *Régie de l'assurance maladie du Québec (RAMQ)* between 06/2005 and 06/2013. Patients with a diagnosis for Paget's disease or a neoplasm were excluded. The date of a patient's first OP-related event was defined as the index date. Patients were required to be continuously enrolled in the RAMQ healthcare plan for ⩾36 months following the index date. Patients were observed from the index date until the end of their continuous RAMQ healthcare plan enrollment or end of data availability (observation period). Incident fractures were defined as either a newly diagnosed fragility fracture or a subsequent diagnosis of a fragility fracture occurring ⩾6 months after a previous diagnosis for the same type of fracture.

Results: A total of 63,784 patients met the selection criteria. Most patients were female (82.6%) and ⩾65 years old (64.3%). At the index date, 54.8% of the patients had a diagnosis for OP, 24.2% had a fragility fracture, and 21.0% had a prescription fill for an AA as their first OP-related event. The median follow-up time after index date was 5 years. Over the observation period, 19,498 (30.6%) patients experienced ⩾1 fragility fracture. Among these patients, 13,064 (67.0%) did not use any AA over the entire observation period. Among the 13,064 patients with a fragility fracture and no use of AA, 37.9% had ⩾2 fragility fractures, 14.3% had ⩾3 fragility fractures, and 5.7% had ⩾4 fragility fractures. Among patients previously treated with an AA or diagnosed for OP, 9.7% of them experienced ⩾1 fragility fracture.

CONCLUSIONS: Despite available treatment options, a large proportion of OP patients experienced fragility fractures and a majority of these patients were untreated prior to their first fragility fracture and remained untreated. Further studies are warranted to better understand the rationales for not prescribing/using AAs.

MO0324

The Epidemiology of Distal Forearm Fractures in Austria Between 1989 and 2010. Hans P. Dimai*[1], Axel Svedbom[2], Astrid Fahrleitner-Pammer[3], Thomas Pieber[4], Heinrich Resch[5], Christian Muschitz[6], Heinrich Thaler[7], Michael Szivak[8], Karin Amrein[1], Fredrik Borgström[9]. [1]Medical University of Graz, Department of Internal Medicine, Division of Endocrinology & Metabolism, Austria, [2]OptumInsight, Sweden, [3]Medical University Graz, Austria, [4]Medical University of Graz , Department of Internal Medicine, Division of Endocrinology & Metabolism, Austria, [5]Medical University Vienna, Austria, [6]St. Vincent's Hospital, Austria, [7]Trauma Center Meidling, Austria, [8]Austrian Worker's Compensation Board (AUVA), Austria, [9]Quantify Research, Sweden

Purpose

To estimate the incidence of distal forearm fractures and assess trends in the entire Austrian population aged ⩾50 years, from 1989-2010 for inpatient fractures, and from 1999 to 2010 for all fractures (outpatient and inpatient).

Methods

The number of inpatient forearm fractures was obtained from the Austrian Hospital Discharge Register (AHDR) for the entire population ⩾ 50 years from 1989 to 2010. The total number of forearm fractures (i.e. including outpatient fractures) was modeled using patient level data on 36,327 patients with forearm fractures. The model estimated the proportions of patients treated in outpatient care based on sex, age and calendar year. The adjusted proportions were applied to the AHDR data to estimate the total number of forearm fractures in Austria. Age-standardized incidence rates (cases per 100,000) were estimated in 5-year age intervals. To analyze the change in incidence of forearm fractures over time, average annual changes expressed as incidence rate ratios (IRR) were calculated.

Results (Figure 1)

Age-standardized incidence

The age-standardized incidence rate per 100,000 person years of inpatient forearm fractures in women in 1989, 1999, and 2010 were estimated at 84, 155, and 192. The age standardized incidence of inpatient forearm fractures in men the same years were estimated at 24, 41, and 37. Overall, approximately 27% of all fractures were treated in an inpatient setting.

For all distal forearm fractures, the age standardized incidence in women in 1999 and 2009 were estimated at 709 (95% CI: 675-743), and 607 (578-637) respectively. The age standardized incidences in men the same years were estimated at 171 (156-185), and 162 (151-174) respectively.

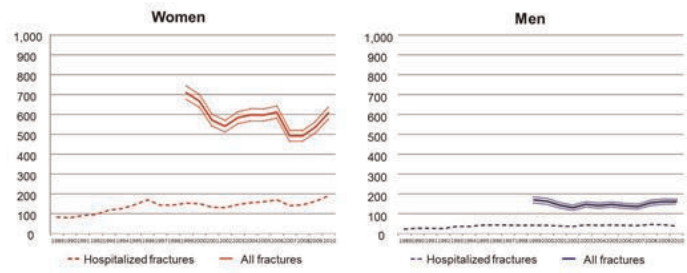
Trend analyses

For inpatient fractures, the IRR analysis showed statistically significant increases in the incidence of inpatient fractures per year for both men (2.0% per year, $p<0.01$) and women (2.9%, $p<0.01$) over the entire time period (1989-2010) and the first ten years (1989-1998) (7.6%, $p<0.01$ in men; and 8.1%, $p<0.01$ in women). However, for the last twelve years (1999-2010) the increase was only significant for women (2.2%, $p<0.01$).

For all distal forearm fractures, the IRR analyses showed a significant decrease in women (-1.1%, $p<0.01$) but not in men (-0.8%, $p>0.05$) over the last twelve years (1999-2010).

Conclusion

The incidence of distal forearm fractures in the entire Austrian population is comparable to hip fracture incidence which is known to be among the highest worldwide. However, trend analyses reveal a significant decrease for all distal forearm fractures in women, but not in men, over the last 12 years. It is noteworthy that similar trends have been observed for hip fracture incidence in several countries of the so-called Western World (including Austria) in the past few years.



Age-standardized incidence rates of distal forearm fracture

What is the Bone Metabolic State of Patients With High Energy Trauma Fractures. Debra Sietsema*[1], Michael Koets[2], Clifford Jones[1]. [1]Orthopaedic Associates of Michigan; Michigan State University, USA, [2]Wayne State University School of Medicine, USA

Purpose: Osteoporosis is a metabolic bone disorder affecting 9 million adults in the United States, resulting in nearly 2 million fractures annually from low energy falls. This disease causes low skeletal mass and a decrease in bone remodeling leading to fragility and fracture. The cause of this decline in bone strength is a physiological imbalance of metabolites, most importantly calcium and Vitamin D. Yet, little is known regarding bone health of those experiencing high-energy fractures. The purpose of this study was to determine the bone metabolic health of patients with a high-energy trauma fractures.

Methods: From 2011 through 2012, 522 consecutive adults with high-energy trauma fractures were initially treated at a Level I Trauma Center, were seen in an outpatient clinic for bone health, and retrospectively evaluated. 96 patients were excluded due to insufficient chart data, resulting in 426 patients in the study. Patients had a full work up consisting of mechanism of traumatic fracture(s), health and medication history, physical exam, bone health laboratory values, and DXA.

Results: There were 231 (54%) males and 195 (46%) females with a mean age of 54 (18-90) and BMI of 27.7 (15.3-70.6) and predominance of Caucasians (405, 95%). Mechanism of injury was MVA (149, 35%), fall from height (106, 25%), MCA (53, 12%), and other (118, 28%). 19/426 (5%) had previous fracture(s) after age 50. Comorbidities included: diabetes (45, 11%), hypothyroidism (45, 11%), COPD (23, 5%), and RA (17, 4%). 92/426 (22%) were smokers and 67 (16%) were past smokers. Medication history included: bisphosphonate (10, 2%), PPI (64, 15%), Estrogen (52, 12%), Glucocorticoids (7, 2%). Lab values included: Calcium 8.9 (6.5-11.1), Vitamin D 25 (OH) 27.5 (3-65) with 262 (62%) less than 30 ng/ml. Bone turnover markers were: P1NP 52 (1-231) and CTX 0.5 (0.09-1.77). DXA T-score was -1.7 (0.4 to -4.8). Decreased T score was related to increased age ($r=-0.318$, $p<0.001$).

Conclusions: Despite having a high-energy mechanism, patients presenting with fractures at a Level 1 Trauma Center were found to have risk factors for poor bone health similar to patients presenting with low energy fractures. Vitamin D insufficiency occurred in a majority and bone turnover markers demonstrated poor bone remodeling. Previously undiagnosed osteoporosis was noted, especially with increased age. Consistent screening criteria should be implemented for all patients presenting with fractures to improve the bone-healing environment.

MO0326

Assessment of the Fracture Risk by Age Distribution in Korean Using FRAX with and without BMD. JI WAN Kim*[1], Young-Jee Jeon[2], Jae Suk Chang[3]. [1]Haeundae Paik Hospital, Inje University, South Korea, [2]Department of Family Medicine, Haeundae Paik Hospital, Inje University, South Korea, [3]Department of Orthopedic Surgery, University of Ulsan, College of Medicine, Asan Medical Center, South Korea

*Introduction*This study estimated the fracture risk according to age distribution in Korean by FRAX model and the correlation was assessed between the fracture risk with and without bone mineral density (BMD).

Methods Data collected from the 2010 Fifth Korean National Health and Nutrition Examination Survey, a cross-sectional survey of the general South Korean general population, were analyzed. The 10-year fracture risk was calculated in Korean aged 50 years or older using FRAX model with and without BMD. The correlation in relation with BMD was analyzed by evaluating the Pearson correlation.

Results The average 10-year risk was 3.9±2.4% for osteoporotic fracture and 1.3±1.4% for hip fracture in men over 50 years of age, while it was 8.1±4.9% and 2.9±3.2% respectively in women over 50 years of age. The 10-year fracture risk calculated without BMD was 4.3±14.2% for osteoporotic fracture and 1.3±1.2% for hip fractures in men, and those was not statistically different from the result with BMD (p=0.385, 0.591). There was a linear correlation between the risk of hip fracture with and without BMD (p<0.001), but the risk of osteoporotic fracture wasn't correlated (p=0.126). In women, the 10-year fracture risk calculated without BMD was 7.6±4.3% for osteoporotic fracture and 2.6±3.1% for hip fractures. The results were lower than that with BMD (p<0.001, p=0.001), and there were strong positive correlation between the risk of osteoporotic and hip fracture with and without BMD (p<0.001).

Conclusion The fracture risk was increased with age, but the increase was converted in age over than 80 years old in Korean population. The fracture risk using FRAX model without BMD was highly correlated with that with BMD, and it had a tendency to underestimate the 10-year fracture probability in women. However the FRAX risk calculator without BMD was well calibrated to hip fracture but not to major osteoporotic fracture in men.

MO0327

Association of serum uric acid concentration with bone: Roles of age and vitamin C intake. Shivani Sahni*[1], Katherine Tucker[2], Caroline Fox[3], Douglas Kiel[4], Marian Hannan[5]. [1]Hebrew SeniorLife, Institute for Aging Research & Harvard Medical School, USA, [2]University of Massachusetts Lowell, USA, [3]Framingham Heart Study, National Heart, Lung, & Blood Institute, Harvard Medical School, USA, [4]Hebrew SeniorLife, USA, [5]HSL Institute for Aging Research & Harvard Medical School, USA

Rationale: Serum uric acid (UA) has been linked with higher areal bone mineral density (BMD) but at elevated concentrations UA can act as a pro-oxidant, thus contributing to inflammation. The trabecular bone compartment may be a more sensitive indicator of changes due to inflammation-mediated osteopenia; hence, examination of associations between UA and Quantitative Computed Tomography (QCT) bone measures may provide insights into UA's metabolic effects. Further, UA increases with advancing age and vitamin C intake increases UA excretion. Yet, little is known about the role of UA on bone, accounting for these factors.

Objective: To examine the cross-sectional association of UA with QCT volumetric measures of bone [vBMD(g/cm^3), integral and trabecular vBMD] and cross-sectional area (CSA, cm^2) at the L3 level of the spine in men and women from the Framingham 3rd Generation Cohort. We further examined if these associations were modified by age and vitamin C intake.

Methods: 966 men and 800 women [mean age: 45 (31-72y] had UA (mg/dl) and QCT measures in 2002-2005. Sex-specific multivariable linear regression was used to calculate the association of UA with each of the QCT measures, adjusting for age, BMI, smoking, calcium intake, alcohol intake, physical activity, serum creatinine, vitamin C intake, and post-menopausal status (in women). Interactions with age and vitamin C intake were tested. If significant (P<0.10), then sub-groups of age (<50y; 50+y) and vitamin C intake (at median) were examined.

Results: The mean ages were 44(±6) y in men and 46(±6) y in women. Mean UA concentrations were 6.30 (±1.24) mg/dl in men and 4.47(±1.10) mg/dl in women. UA was not significantly associated with bone measures (Table, P range: 0.07-0.98).

Significant interactions by age (men, P=0.06) and vitamin C intake (women, P=0.08) were observed for CSA. Higher UA was associated with lower CSA (P=0.02) in men ⩾50 y of age, but not in men <50, Higher UA tended to be associated with lower CSA (P=0.1) in women with low vitamin C intake, but not in those with high vitamin C intake.

Conclusions: While UA was not associated with bone overall, it appeared to be important for bone in sub-sets of age in men and vitamin C intake in women. In women, vitamin C intake may modify the effect of UA on CSA, suggesting that vitamin C may protect against negative effects of elevated UA under some conditions.

Associations between Serum Vitamin K1 and Risk of Hip Fractures in Elderly Norwegian Men and Women. A NOREPOS Study. Trine Elisabeth Finnes*[1], Cathrine M Lofthus[2], Haakon E. Meyer[3], Anne Johanne Søgaard[4], Grethe Tell[5], Ellen M Apalset[6], Clara Gjesdal[7], Guri Grimnes[8], Berit Schei[9], Rune Blomhoff[10], Sven Ove Samuelsen[11], Kristin Holvik[12]. [1]Sykehuset Innlandet Thrust, Norway, [2]Department of Endocrinology, Oslo University Hospital, Norway, [3]Norwegian Institute of Public Health/University of Oslo, Norway, [4]Department of Chronic Diseases, Division of Epidemiology, Norwegian Institute of Public Health, Norway, [5]Department of Global Public Health & Primary Care, University of Bergen, Norway, [6]Department of Global Public Health & Primary Care, University of Bergen & Department of Rheumatology, Haukeland University Hospital., Norway, [7]Haukeland University Hospital, Norway, [8]University Hospital of Northern Norway, Norway, [9]Department of Public Health & General Practice Norwegian University of Science & Technology, Norway, [10]Department of Nutrition, Faculty of Medicine, University of Oslo, Norway, [11]Department of Mathematics, University of Oslo, Norway, [12]Norwegian Institute of Public Health, Norway

BACKGROUND: Low vitamin K concentrations are associated with a higher proportion of under-carboxylated osteocalcin, and are suggested a risk factor for osteoporotic fractures. The relationship between circulating vitamin K1 and the risk of fractures is not established, and few larger studies have included both men and women.

AIM: To investigate the association between the levels of serum vitamin K1 (phylloquinone) and the risk of subsequent hip fractures in elderly men and women.

MATERIALS AND METHODS: In this case cohort study 21,774 men and women aged 65 to 79 years who attended four community based health studies during 1994-2001 were followed with regard to hip fractures for a median follow up time of 8.2 years. Hip fractures were identified through electronic discharge registers. Vitamin K1 was determined in frozen serum samples obtained at baseline in all hip fracture cases (n=1090) and in a randomly selected subcohort (n=1241). The relation between quartiles of vitamin K1 and risk of hip fracture was investigated in a Cox proportional hazards regression adapted for the case-cohort design.

RESULTS: Serum vitamin K1 levels ranged from 0 to 11.7 ng/mL (median 0.72 ng/mL). In a model adjusted for age, sex, and study centre, HR for hip fracture in the 1st (lowest) quartile of vitamin K1 compared to the 4th (highest) quartile was: 1.47 (95% CI: 1.15 – 1.87). The corresponding figures for the 2nd and the 3rd quartiles were 1.29 (95% CI: 1.01 – 1.64) and 1.09 (95% CI: 0.85 – 1.40), respectively. P for trend across quartiles was <0.001. The same pattern was seen in sex stratified analyses, and no interaction between sex and vitamin K was found. In a model also adjusting for body mass index and serum concentrations of 25OH-vitamin D, α-tocopherol and retinol, HR for hip fracture in the 1st compared to the 4th quartile was 1.30 (95% CI: 1.01 – 1.67).

CONCLUSION: Low serum concentrations of vitamin K were associated with a higher risk of hip fractures. Intake of vitamin K1 may be a surrogate marker of a healthy life style. However, the higher risk for hip fracture was still evident after adjusting for common confounders, and other fat soluble vitamins. The possible protective effect of vitamin K1 provides a preventive opportunity, which should be investigated in well-designed randomized controlled trials.

MO0329

Brown adipose tissue (BAT) activity is inversely associated with bone mineral density (BMD) in healthy young adults. Robert McLean*[1], Lauren Weiner[2], Aaron Cypess[2], Douglas Kiel[3]. [1]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA, [2]Joslin Diabetes Center & Harvard Medical School, USA, [3]Hebrew SeniorLife Institute for Aging Research & Harvard Medical School, USA

While white adipose tissue stores energy, BAT generates energy through calorie consumption (thermogenesis), which can be activated in response to cold exposure. BAT depots have recently been identified in adults. It has been hypothesized that BAT in the bone marrow may regulate osteogenesis, or that reduced BAT activity may indirectly contribute to bone loss through increased sympathetic activity. In humans, BAT volume was positively correlated with BMD in women with anorexia, and in women, but not men, in a study of healthy adults. Identification of BAT activity as a mechanism for bone loss would suggest that activation BAT may be a potential intervention for maintaining bone. The objective of this study was to determine the association between BAT activity and BMD in healthy adults. Nine (4 men, 5 women) young (mean age 25 years, range 20-31), healthy volunteers were recruited from the community. Height and weight were measured and body mass index (BMI, kg/m^2) was calculated. Total body BMD, fat-free mass and fat mass were measured by DXA (Discovery A, Hologic). BAT activity (BAT volume [mL] x mean standard uptake value [g/mL]) was determined by ^{18}F-fluorodeoxyglucose (FDG) PET-CT (Discovery LS, GE Medical Systems) after 2 hours of cold exposure (14℃) using a cooling vest. Unadjusted correlations (r) among study variables were calculated, and linear regression was used to calculate the age- and multivariable-adjusted association between BAT activity and BMD. Mean BMI was 23 kg/m^2 (range 19-29) and mean BMD was 1.188 g/cm^2 (SD 0.122). Unexpectedly, BAT activity was negatively correlated with BMD (r=-0.72, P=0.03; Figure). BAT was also negatively correlated with age (-0.58, P=0.09), but was not correlated with BMI, fat-free mass or fat mass. BMD was positively correlated with age (r=0.74, P=0.02). After age adjustment, there was no statistically-significant association between BAT activity and BMD (β=-0.0009, P=0.18), and results were similar after adjustment for BMI, fat mass and fat free mass. These results suggest that increased BAT activity may be associated with lower BMD in young, healthy adults. Larger studies of longitudinal changes in BMD that include adults across a wider age range are needed to determine whether BAT may have a mechanistic role in bone loss.

Figure. Association of brown adipose tissue (BAT) activity after cold exposure with total body BMD among healthy volunteers (4 men, 5 women) aged 20 to 31 years.

Cancer Rates in Men With and Without Osteoporosis in a US Healthcare System. Cynthia O'Malley*[1], Nguyet Tran[2], Carol Zapalowski[3], Nadia Daizadeh[4], Thomas Olenginski[5], Jane Cauley[6]. [1]Amgen Inc., USA, [2]Amgen Inc., USA, [3]Amgen, USA, [4]Amgen Inc, USA, [5]Geisinger Medical Center, USA, [6]University of Pittsburgh Graduate School of Public Health, USA

Introduction: Osteoporosis (OP) and cancer are common age-related diseases which share some similar risk factors such as smoking and alcohol use. Moreover, bone-sparing therapies are approved to counter the bone loss associated with a number of cancer treatments. Given the co-occurrence of these common conditions, we describe the incidence of cancers in men by OP status.

Methods: We identified 3,600 men with OP (evidence of OP diagnosis, fragility fracture or OP medication order) and 3,600 age-matched controls with no evidence of OP in the electronic health records from an integrated healthcare system (2004-2009). Men were also matched by length of follow-up to allow equal opportunity to develop an incident cancer. For each cancer type, exposure time began at index until the first of the following events: a diagnosis of that cancer, death, disenrollment, end of study. For each cancer type, incidence rates (IR) were calculated by dividing the number of men with the cancer by the total follow-up person-years (P-Y) at risk for that cancer. Exact Poisson 95% confidence intervals (CI) were also generated. For comparison, we present SEER age-adjusted rates for white men age ⩾65.

Results: The matched groups had a mean age of 70.9 years (standard deviation [SD], 9.0) with an average follow-up time of 2.2 years; 98% were white. The mean (SD) body mass index (BMI) was 28.1 (5.4) in the 91.4% of the OP subjects with known BMI. In the control group, the mean (SD) BMI was 29.1 (5.5); BMI was known for 67.7% of these subjects. BMI could not be calculated in men with missing height. For all malignancies combined, the IRs were similar between the OP subjects and controls, at 29.3 per 1,000 P-Y and 30.4 per 1,000 P-Y, respectively. IRs by OP status were similar for the most common cancers including prostate, lung, colorectal and bladder cancers (see table). Carcinoma in situ of skin was common in both the OP and control groups (7.1 and 6.2 per 1,000 P-Y, respectively). SEER IRs were similar to those reported here, falling within the observed CIs. The exceptions were lung/bronchus and brain tumors which were higher in our study, regardless of OP status.

Conclusion: This assessment describes the cancer burden in older men by OP status. While there were slight variations in IRs by OP status, the rates were similar overall in this study population and comparable to those reported for older men in the SEER registry.

Table. Cancer rates in men by osteoporosis status, 2004–2009

Co-morbidities in patients with a recent fracture at the Fracture Liaison Service. Lisanne Vranken*[1], Caroline Wyers[2], Robert Van Der Velde[3], Heinrich Janzing[4], Wim Morrenhof[5], Marcel Janssen[6], Piet Geusens[7], Joop Van Den Bergh[8]. [1]VieCuri Medical Centre, The Netherlands, [2]Maastricht University, The Netherlands, [3]VieCuri Medical Center Venlo, the Netherlands, The Netherlands, [4]VieCuri Medical Centre, Department of Surgery, Netherlands, [5]VieCuri Medical Centre, Department of Orthopedic Surgery, Netherlands, [6]VieCuri Medical Centre, Laboratory of Clinical Chemistry & Haematology, Netherlands, [7]University Hasselt, Belgium, [8]VieCuri MC Noord-Limburg & Maastricht UMC, The Netherlands

Purpose

To evaluate co-morbidities and medication use in patients with a recent fracture (fx) at the Fracture Liaison Service (FLS).

Methods

Retrospective chart review of all consecutive patients with a recent fx visiting the FLS for fracture risk evaluation. Data were analysed using Chi-square tests, Fisher's Exact Test and logistic regression analysis adjusting for age, sex, BMD (normal vs. osteopenia vs. osteoporosis) and fx classification (finger & toe vs. minor vs. major vs. hip).

Results

1359 consecutive patients (⩾50 yrs) were evaluated at the FLS (72% women; mean age 65 years), 57% with a minor, 29% major, 8% hip and 6% finger or toe fx. Osteoporosis was diagnosed in 30%, osteopenia in 47% and a normal BMD in 23%. In 83% one or more co-morbidities were reported in medical history; cardiovascular disease (CVD) in 27%, COPD in 7%, diabetes mellitus type 2 (DM2) in 7%, rheumatic disease in 4% and psychiatric disorders in 4%. CVD was significantly more present in men (p=0.001) at higher age (p=.000), COPD with lower BMD (p=.002), DM2 with

higher age (p=0001) and psychiatric disorders with lower BMD (p=.035) and severe fx (p=.008). In addition, in 28% of patients we detected ⩾ 1 contributors to secondary osteoporosis with laboratory testing (men: 22%, women 30%); monoclonal proteinemia in 0.5%, renal insufficiency grade ⩾ 3 in 11.2%, primary hyperparathyroidism in 3.0%, secondary hyperparathyroidism in 15.7%, hyperthyroidism in 5.1% of patients and hypogonadism in 1.6% of men. The presence of these contributors was significantly higher in women (p=.002) at higher age (p=.000). Medication was used by 74% of patients; 54% used 1-4 drugs and 20% used ⩾ 5 drugs (polypharmacy); cardiovascular medication was used by 45%, antidepressant by 8%, benzodiazepine by 7%, proton-pump inhibitor by 17% and antiepileptic by 4%. Polypharmacy was reported more frequently in patients with higher age (p=0.000), lower BMD (p=.015) and severe fx (p=.001). After adjustments, only age was significantly related with polypharmacy.

Conclusion

One or more co-morbidities were present in 83% of patient with a recent fracture after age 50 and 74% use one or more drugs, 20% with polypharmacy. Furthermore, in 28% new contributors to secondary osteoporosis were diagnosed. Therefore careful evaluation of medical history, medication use and laboratory testing should be performed for optimal management of bone and fall related co-morbidities and risk factors.

High Prevalence of Vitamin D Insufficiency and Deficiency among Post-menopausal Women in China: Preliminary Results of a Chinese Multicenter Study. Zhongjian Xie[1], Zhenlin Zhang[2], Eryuan Liao[1], Wen Wu[3], Chunyan Lu[4], Shuqing Tao[5], Lijun Wu[6], Julie Chandler[7], Senaka Peter[8], Ting Wu[9], Weibo Xia*[10]. [1]Institute of Endocrinology & Metabolism, the second Xiangya Hospital of Central South University, China, [2]Department of Osteoporosis & Bone Diseases, Shanghai Jiao Tong University, Affiliated Sixth People's Hospital, China, [3]Department of Endocrinology, Guangdong General Hospital, China, [4]Department of Endocrinology, West China Hospital, Sichuan University, China, [5]Department of Orthopedics, the Second Affiliated Hospital of Garbin Medical University, China, [6]Department of Rheumatism & Immunology, People's Hospital of Xinjiang Uygur Autonomous Region, China, [7]Merck Research Laboratories, USA, [8]Department of Epidemiology, Merck Research Laboratories, USA, [9]Department of Epidemiology, Merck Research Laboratories, China, [10]Department of Endocrinology, Key Laboratory of Endocrinology, Peking Union Medical College Hospital, Chinese Academy of Medical Sciences, China

Purpose: Previous small studies exploring the prevalence of low serum Vitamin D [25(OH)D] levels among postmenopausal women in China reported inconsistent findings. The aim of this study was to determine the prevalence of low 25(OH)D levels in a large cohort of post-menopausal women in China.

Methods: This cross-sectional study recruited 960 women with a mean age of 65.8 years (55-93) from urban (N=481) and rural (N=479) areas of 7 geographically distinct regions during the summer in China. Each woman was evaluated for total serum 25(OH)D using liquid chromatography-tandem mass spectrophotometry, fracture risk using Osteoporosis Self-Assessment Tool for Asians (OSTA), and bone mineral density (BMD) using Dual energy X-ray absorptiometry. Demographic and clinical data were obtained and a questionnaire assessing general health, lifestyle habits and sun exposure was completed. Published definitions of vitamin D deficiency range from 25(OH)D < 10ng/ml to < 20ng/ml, and insufficiency from < 20ng/ml to <30ng/ml. For the present study, prevalence is reported using 25(OH)D cut-off points of < 15 ng/ml, < 20ng/ml and < 30ng/ml.

Results: Overall, 43.8 % of women had a serum 25(OH)D < 20 ng/ml, with a higher prevalence (48.1%) in women over 75 years and a lower prevalence (38.5%) in women 55-59 years.. The overall prevalence was 86.5% for 25(OH)D < 30 ng/ml and 17% for 25(OH)D < 15 ng/ml. Using a cut-off point of 25(OH)D <20 ng/ml, the prevalence was significantly higher among urban than rural dwellers (51.1% vs. 36.3%. respectively). Prevalence of low vitamin D levels increased with decreasing BMD. The prevalence of low vitamin D varied by region, but not necessarily latitude, with lower prevalence (19.2-25%) found in the Middle and Northeast regions, and higher prevalence (46.7-56.7%) found in Northwest, North, East, Southwest and South regions. There was no correlation between the prevalence of low vitamin D and fracture risk score determined by OSTA.

Conclusions: Our results show that the prevalence of Vitamin D deficiency and insufficiency, by any definition, is common among postmenopausal women in China, even during the summer, and especially among those living in urban areas. Higher prevalence of low Vitamin D is associated with lower BMD. Increased awareness of Vitamin D deficiency and insufficiency among post-menopausal women in China is necessary, and dietary and other intervention strategies should be undertaken to correct this problem.

MO0333

Hip Fracture Vital Signs: Simple Observations at a Medical Visit Estimate Hip Fracture Risk in Women and Men. Steven Cummings*[1], Lily Lui[2], Peggy Cawthon[3], Jane Cauley[4], Susan Diem[5], Teresa Hillier[6], Kristine Ensrud[7]. [1]San Francisco Coordinating Center, USA, [2]UCSF, USA, [3]California Pacific Medical Center Research Institute, USA, [4]University of Pittsburgh Graduate School of Public Health, USA, [5]University of Minnesota, USA, [6]Kaiser Center for Health Research, USA, [7]University of Minnesota & Minneapolis VA Health Care System, USA

We developed a simple assessment of a patient's risk of hip fracture that can be counted while taking vital signs and walking the patient to the exam room. Hip fracture risk would be available when the physician begins to talk with the patient.

We included 9495 women enrolled in the prospective community-based Study of Osteoporotic Fractures (SOF) and 5921 men enrolled in the companion MrOS. The two studies made similar measurements of weight and height (BMI), pulse rate, walking speed over 6 meters, and ability to rise from a chair without needing one's arms. Incident hip fractures were validated by radiographs over 12 years of 98 and >99% complete follow-up. We generated separate multivariable proportional hazards models for women and men but the associations were very similar so we pooled the data into one multivariable model. Points were based on the coefficients for each term in the multivariable model (multiplying by 2 and rounded to the nearest digit) to create a simple additive score. We then calculated the relative hazards and absolute risks of hip fracture for categories of total scores. The scores and rates warrant validation and calibration in other cohorts.

Every factor was significantly and independently associated with risk of hip fracture (Table 1). Each added point strongly increased a patient's risk of hip fracture (Table 2). 23.0% of women and 5.5% of men had a score ⩾ 5 points indicating at least an 18.6% 10-year risk of hip fracture. We conclude that a patient's risk of hip fracture can be easily estimated at the beginning of any medical visit. Start with points for gender and age. From vital signs, add points for BMI and pulse rate. Then add points as the patient walks a timed distance on the way to the exam room and then sits then rises from the chair. This quickly generates a risk of hip fracture that physician sees along with other vital signs to stimulate discussion about how to reduce that risk.

Table 1. Association of individual vital signs with relative risk of hip fracture and points

Sign	Points	HR (95% CI)
Female	1	1.8 (1.5, 2.1)
Age ≥ 75	2	2.9 (2.5, 3.3)
BMI <25	1	1.6 (1.4, 1.8)
Pulse ≥80	1	1.3 (1.1, 1.5)
Gait ≤1.0 m/s	2	2.4 (1.9, 2.9)
or >1.0-1.2 m/s	1	1.5 (1.3, 1.9)
Unable to rise	1	2.1 (1.6, 2.6)

Table 2. Total points and hip fracture risk

Total	10-yr risk %	HR (95% CI)	Prevalence (%)
0	1.1	1	9.4
1	2.3	2.0 (1.2, 3.5)	12.6
2	3.8	3.4 (2.1, 5.4)	20.9
3	5.0	4.4 (2.8, 7.1)	25.4
4	9.7	8.9 (5.5, 14)	15.5
≥5	18.6	18 (11, 28)	16.3

Tables of vital signs and risk of hip fracture

MO0334

Lack of concordance among vitamin D binding protein assays and effect on bioavailable 25OHD estimates. Carrie Nielson*[1], Priya Srikanth[2], Ying Wang[1], Christine Swanson[2], Christine Lee[1], Rene Chun[3], Martin Hewison[4], John Adams[4], Dirk Vanderschueren[5], Roger Bouillon[5], Jodi Lapidus[2], Jane Cauley[6], Eric Orwoll[1]. [1]Oregon Health & Science University, USA, [2]Oregon Health & Science University, USA, [3]UCLA/ Orthopedic Hospital Research Center, USA, [4]University of California, Los Angeles, USA, [5]Katholieke Universiteit Leuven, Belgium, [6]University of Pittsburgh Graduate School of Public Health, USA

Vitamin D binding protein (DBP) is an important determinate of vitamin D activity. Bioavailable 25OHD (bioD) varies by circulating DBP level, and DBP haplotype affects binding affinity for 25OHD. Multiple DBP assays are available, but their concordance has not been determined. We compared results of three DBP assays and evaluated their effect on resulting bioD estimates.

In a random sample of 610 men in the Osteoporotic Fractures in Men (MrOS) cohort (age ⩾65), we measured DBP by 3 assays (R&D Systems, Genway, and Leuven). 25OHD was measured by GCMS. DBP genotyping was done for two nonsynonymous SNPs, rs4588 (Thr436Lys) and rs7041 (Asp432Glu), and these were combined into six previously characterized haplotypes, corresponding to those with the highest (1F1F) to lowest affinity (22) for 25OHD. From these, bioD was estimated using previously validated equations. Correlations and plots were used to assess concordance across the range of DBP and bioD. Differences in mean DBP and bioD by DBP haplotype were tested by ANOVA.

Mean DBP levels were similar across all three assays (4.8-5.1 μM), and SD were similar for Genway and Leuven assays (0.8 and 0.7, respectively); the R&D assay had a much broader distribution (SD=1.7). All had low CVs (2-4%). Correlations among DBP assays were generally poor: they were highest between Genway and Leuven ($r=0.60$) and weak for R&D and Genway ($r=0.29$) and R&D and Leuven ($r=0.39$, all $p<0.0001$). Correlations among calculated bioD estimates were high for those incorporating DBP from Genway and Leuven ($r=0.95$), but were lower for those incorporating R&D (with Genway, $r=0.65$; with Leuven, $r=0.66$; all $p<0.001$). All DBP assay results differed by DBP haplotype (Figure, $p<0.001$); for Genway and Leuven assays, DBP was lower among higher affinity haplotypes, and for the R&D assay, DBP was lowest in the highest affinity (1F1F) haplotype. Assay differences were most pronounced in the 1F1F and 1F2 haplotypes, those common in persons of African descent. These differences resulted in higher mean bioD for 1F1F and 1F2 haplotypes when R&D was used than when Genway or Leuven were used.

These results have important implications for assessing biological effects of DBP and bioD, and for understanding racial differences in vitamin D physiology. Understanding the reasons for assay discordance will be necessary before conclusions can be drawn regarding DBP and calculated bioD associations with skeletal and other outcomes.

Figure. DBP distributions differ by DBP by haplotype. Left side is Genway, and distributions are similar for Leuven (not shown); right side is R&D. All p for ANOVA < 0.001.

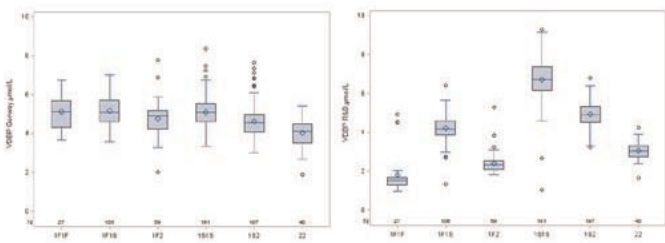

Figure. DBP distributions differ by DBP by haplotype.

MO0335

Risk factors for hip fracture in older men: The Osteoporotic Fractures in Men Study (MrOS). Jane Cauley*[1], Peggy Cawthon[2], Kathy Peters[3], Steven Cummings[4], Kristine Ensrud[5], Douglas Bauer[6], Brent Taylor[7], James M. Shikany[8], Andrew Hoffman[9], Nancy Lane[10], Deborah Kado[11], Eric Orwoll[12]. [1]University of Pittsburgh Graduate School of Public Health, USA, [2]California Pacific Medical Center Research Institute, USA, [3]California Pacific Medical Center Research Institute, USA, [4]San Francisco Coordinating Center, USA, [5]University of Minnesota & Minneapolis VA Health Care System, USA, [6]University of California, San Francisco, USA, [7]University of Minnesota, USA, [8]University of Alabama, Birmingham, USA, [9]Stanford University, USA, [10]University of California, Davis Medical Center, USA, [11]University of California, San Diego, USA, [12]Oregon Health & Science University, USA

Risk factors for hip fracture have been extensively studied in women have but less is known about risk factors for hip fracture in men. We performed a comprehensive overview of risk factors for hip fracture and tested whether these risk factors are independent of femoral neck bone mineral density (FN BMD).

MrOS is a prospective study of 5,994 men, age 65+. Among 5,876 men not reporting osteoporosis treatment at baseline, 178 men suffered an incident hip fracture confirmed by radiographic report during a mean of 8.64 ± 2.5 years of 99% complete follow-up. Follow-up time was truncated to 10 years. All risk factors and measurements were assessed at the baseline exam. Cox Proportional Hazards models were used to calculate the hazard ratio (HR) and 95% confidence intervals (CI).

Older age (⩾ 75 years), poor chair stand performance, comorbidity, current smoking, positive fracture history since age 50 , greater height and lower mental health scores were all associated with an increased risk of hip fracture, Table. Body mass index was not associated with an increased risk of hip fracture after adjustment for FN BMD. One standard deviation decrease in FN BMD was associated with 3-fold increased risk of hip fracture after adjusting for BMD most associations remained statistically significant although the magnitudes of the HRs were attenuated. Two or more major comorbidities were associated with > 2-fold risk of hip fracture. Specific comorbidities associated with an increased risk of hip fracture in a secondary multivariate + BMD model were history of myocardial infarction, HR=1.57 (1.03, 2.39), hyperthyroidism, HR=2.57 (1.18, 5.61), stroke, 1.99 (1.25, 3.16) and Parkinson's disease, HR=4.12 (1.64, 10.36). Tricyclic antidepressant use was also associated with an increased risk of hip fracture, HR=2.73 (1.26, 5.91). Education, health status, weight change, family history of fracture, diabetes, RA or OA, physical activity, alcohol, cognitive function and visual impairments were unrelated to hip fracture. Several variables unrelated to hip fracture e.g., rheumatoid arthritis and corticosteroids likely reflected low power.

Older men who smoke and have multiple comorbidities, low BMD, greater height, a positive fracture history and have poor chair stand test performance have an increased risk of hip fracture. Targeting these high risk men for intervention could prevent hip fractures.

Table: Multivariate Models of Risk Factors for Hip Fracture with and without adjusting for FNBMD

	Referent/ Unit for HR	Multivariate Model HR(95% CI)	Multivariate Model + BMD HR(95% CI)
Age(y)	65-69		
70-74		1.51 (0.84, 2.71)	1.43 (0.79, 2.57)
75-79		3.63 (2.13, 6.20)	2.76 (1.62, 4.73)
80-84		6.37 (3.65, 11.13)	4.80 (2.74, 8.39)
85+		7.98 (4.01, 15.88)	5.39 (2.70, 10.79)
FN BMD g/cm^2	0.13 g/cm^{2+}	-------	3.21 (2.61, 3.95)
BMI(kg/m^2)	≥ 30		
25- < 30		1.20 (0.76, 1.87)	0.80 (0.51, 1.25)
< 25		1.85 (1.15, 2.98)	0.78 (0.48, 1.28)
Chair Stand	Quartile 1		
Quartile 2		1.78 (1.02, 3.11)	1.55 (0.89, 2.71)
Quartile 3		1.91 (1.10, 3.32)	1.71 (0.98, 2.98)

MO0336

Systematic evaluation of loss of renal function over 10 years in elderly Swedish women. Linnea Malmgren*[1], Fiona McGuigan[2], Sofia Berglundh[1], Kerstin Westman[1], Anders Christensson[1], Kristina Akesson[3]. [1]Skane University Hospital, Sweden, [2]University of Lund, Malmö, Skane University Hospital, Malmö, Sweden, [3]Skåne University Hospital, Malmö, Sweden

Introduction: Chronic kidney disease (CKD) has been shown to be associated with bone mineral density (BMD), bone loss and fracture, therefore identifying women at risk of CKD is an important element in fracture prevention. There is a natural decline in renal function with age, but longitudinal studies investigating the pattern of decline in elderly women are scarce. We estimated renal function using the most commonly used creatinine based algorithms in 1011 women from the population based OPRA cohort consisting of 75-year-old Swedish women, at baseline, 3-, 5- and 10 years and investigated the association with mortality and comorbidities.

Materials and methods: Serum creatinine was measured at age 75 (N=1011), age 78 (N=849) age 80 (N=679) and age 85 (N=362). Estimated glomerular filtration rate (eGFR) was calculated using each of the equations; Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI), the revised Lund-Malmö (LM-rev), the Modification of Diet in Renal Disease (MDRD), the Berlin Initiative Study (BIS-1) and the Cockcroft-Gault (CG) study equations. CKD was staged as 1-5 and mortality and comorbidity compared between women with CKD stage 3 or worse and all others using Cox proportional hazard and regression.

Results: Approximately 95% of women aged 75-85 years had an eGFR equivalent to CKD stage 2-3 from CKD-EPI, with a continuous progression towards stage 3 during the follow-up. During the 10y follow-up, an overall loss of 22% of eGFR was observed, with an accelerated loss between ages 80-85y. Mean loss per decade was 16.5 mL/min (SD 12.2). Women with advanced CKD (stage 3-5) had an almost doubled risk of dying (adjusted hazard ratio 1.9 (95%CI 1.3-2.8) during the follow-up and an increased risk of comorbidities.

Conclusion: In 75-85 year old women the majority has reached CKD stage 2-3 and that it is essential to use a formula appropriate for age. Loss of renal function is not uniform over time and is related to eGFR level at baseline. The twenty percent reduction in renal function over 10 years is considerably higher than previously estimated. These studies indicate reduced kidney function is associated with impaired health and mortality, whereas the implications for bone loss and fracture will be further evaluated.

MO0337

A Fracture Liaison Service specifically designed to address local government concerns can be effective. Diane Theriault*[1], Carla Purcell[2]. [1]Dartmouth General Hospital, Canada, [2]Dartmouth General Hospital, Canada

There is no Fracture Liaison Service (FLS) in Nova Scotia, Canada. The Dartmouth General Hospital (DGH) Fracture Navigator Program (FNP) was designed as a prototype that might be endorsed by government for on-going funding. Accordingly, the prototype is aligned with the 2010 Osteoporosis Canada (OC) Guidelines, uses a nurse working through protocols with minimal on-going input from physicians, lessens duplication of services and recommends limited referrals to osteoporosis specialists (only as per the indications listed in the 2010 OC Guidelines). The FNP focuses on high risk patients and ensuring that they receive effective osteoporosis medication to reduce their risk of repeat fracture.

The FNP sees fragility fractures of hip, spine, wrist, shoulder and pelvis at DGH. Initially, the patient's fracture risk is determined as per 2010 OC Guidelines: BMD and spine X-rays performed and CAROC tool used. A letter is sent to the family physicians of high risk patients recommending osteoporosis treatment. To see if effective medication has been started, these patients are contacted by phone 3 months later.

We show results for the non-spine fractures only. Fracture risk assessment is described for patients who had initial fractures from Feb 19, 2013 to Jan 13, 2014; treatment rates are described for patients who had initial fracture from Feb 19 to Dec 31, 2013. A total of 204 non-spine fractures were seen up to Jan 13, 2014. Exclusions include under the care of an osteoporosis specialist (5), bilateral total hip replacement (1), subtrochanteric femoral fracture (2), palliative care (2). 19 patients declined enrollment and 3 have yet to undergo the prescribed investigations. Of the 173 non-spine fracture patients who completed the fracture risk assessment, 123 (71.1%) were deemed at high risk and 50 (28.9%) were deemed at moderate risk as per CAROC. For the period of Feb 19 to Dec 31, 2013, there were 101 patients who were at high risk ready for phone follow-up, of which 34 could not be reached by phone by Apr 7, 2014, 1 was deceased, 1 declined further assessment and 2 were discharged as per protocol (having been referred to an osteoporosis specialist). Of the 63 remaining high risk patients, 53 (84.1%) had been initiated on treatment, 9 (14.3%) were not initiated on treatment and 1 was unsure.

Conclusion: An FLS can be designed to respond to local government concerns and still be effective at closing the post-fracture osteoporosis care gap.

MO0338

Clinical evaluation of the appropriateness of referrals for dual energy X-ray absroptiometry: differences by physician specialty. Alp Cetin*. Proffessor, Turkey

OBJECTIVES

It is well established that who should be tested for dual energy X-ray absorptiometry (DXA) scan and for this purpose International Society for Clinical Densitometry (ISCD) recommendations for DXA referrals are most widely accepted guidelines. However, appropriateness of referrals for DXA has not been extensively studied so far. This study was conducted to investigate the ordering practices of physicians and appropriateness of DXA referrals in Hacettepe University Hospitals.

MATERIALS AND METHODS

The indications for DXA testing were prospectively recorded in 200 consecutive patients (174 females, 26 males) who referred for DXA scan. Indications were categorized as appropriate or inappropriate according to the ISCD recommendations; the specialty of the ordering physician was also noted.

RESULTS

DXA indications were found appropriate in 108 patients (54%) and inappropriate in 92 patients (46%). As expected most appropriate DXA scans (100%) were observed in patients referred from the department of geriatrics. This was followed by the department of physical medicine and rehabilitation (77%), rheumatology (66%), endocrinology (43%), internal medicine (42%), and obstetrics and gynecology (23%).

CONCLUSION

In this preliminary evaluation of the appropriateness of DXA testing, a considerable number of studies was classified as inappropriate. There was a great variation among different specialities who deals with osteoporosis. Educational programs should be implemented to reduce the rate of less appropriate examinations.

MO0339

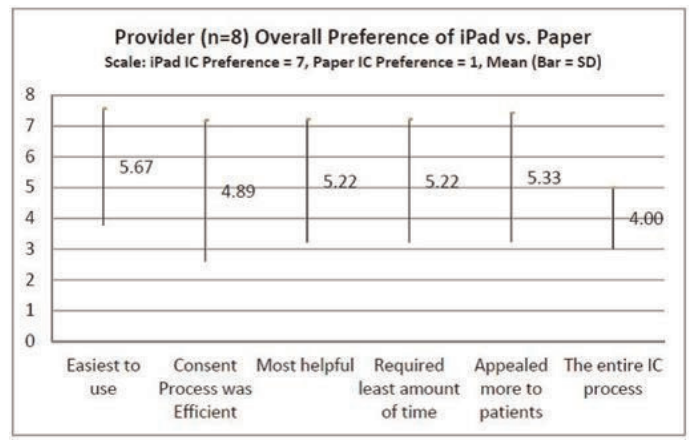
Effectiveness and feasibility of an iPad based Patient administered informed consent (IC) vs. Paper Consent for Osteoporosis Pragmatic Clinical Trials (PCT). Amy Warriner*[1], P. Jeffrey Foster[2], Nicole Wright[1], Amy Mudano[1], Cora Lewis[1], Sebastian Sattui[2], Mary E. Melton[2], Wilson Pace[3], Walter Calmbach[4], Laura Nichols[3], Susan Booth[5], T. Michael Harrington[2], Jeffrey Curtis[1], Kenneth Saag[1]. [1]University of Alabama At Birmingham, USA, [2]University of Alabama at Birmingham, USA, [3]University of Colorado Denver, USA, [4]University of Texas San Antonio, USA, [5]Mytrus, Inc., USA

Purpose: Pragmatic clinical trials (PCTs) comparing osteoporosis therapeutic options require large numbers of investigative sites for sufficient sample size and generalizability. Conducting Informed Consent (IC) constitutes a major barrier to performing PCTs in practice settings due to time and resource limitations. There is a need to improve efficiency and effectiveness of IC. To address this, we compared a patient-administered iPad IC tool to traditional paper IC in community practices and evaluated their feasibility for a mock future osteoporosis PCT of bisphosphonate discontinuation vs. continuation.

Methods: In collaboration with a software vendor experienced in direct-to-patient studies (Mytrus, Inc.), we developed an interactive iPad IC tool that included an animated video summarizing the PCT, the complete IC, and a quiz to assess and reinforce comprehension. We recruited community-based practices (n=9) from the Alabama Practice Based Research Network and the American Academy of Family Physicians National Research Network. Practices aimed to recruit 3 participants for each IC approach. Practices were randomized to start with the iPad IC, or with the paper IC. After completing 3 patient enrollments, practices were switched to the other IC process. Patient inclusion criteria included $\geq$1 year alendronate use and willingness to use an iPad for IC. Patients' comprehension and satisfaction were collected on surveys (7-point Likert scale) following the IC process. We surveyed practice staff to assess satisfaction and perceived time demands following each phase and at the end of study. Patient and provider satisfaction and patient comprehension for the 2 IC processes were compared using non-parametric methods.

Results: To date, 8 clinics have enrolled 31 women (n= 14 iPad, mean age 69.9$\pm$6.5years, and n= 17 paper, mean age 72.3$\pm$8.3years). Overall satisfaction and comprehension with both consent methods was high, with the iPad participants trending towards greater satisfaction and understanding of key concepts but not reaching significance (Table). Among providers, we saw similar trends in satisfaction despite a slightly longer perceived time to complete (Table). When comparing the iPad with Paper IC, providers consistently favored the iPad (Figure).

Conclusion: Patients and providers appeared more satisfied with the iPad delivered IC than traditional paper IC. Use of patient administered iPAD has potential to improve IC effectiveness in PCTs.



Figure

SURVEY RESPONSES (1-7, 7=EXTREMELY SATISFIED), mean (SD)	iPad	Paper

Secondary prevention of osteoporotic fractures: evaluation of the Amiens University Hospital's fracture liaison service between January 2010 and December 2011. Nassima Dehamchia-Rehailia[1], Daciana Ursu[1], Isabelle Henry-Desailly[1], Patrice Fardellone*[2], Julien Paccou[3]. [1]Department of Rheumatology, Amiens University Hospital, France, [2]Service de rhumatologie, CHU Hôpital Nord, France, [3]University of Picardie Jules Verne, Amiens, France

Purpose: The main goal of the present study was to assess the performance and results of the Fracture Liaison Service (FLS) at Amiens University Hospital, France.

Methods: This was an observational, single-center, ambispective study. All patients admitted to Amiens University Hospital between January 2010 and December 2011 for a low-trauma fracture (vertebral and non-vertebral fractures) were identified by a FLS nurse. Patients willing to enter the study were assessed for their osteoporosis risk factors, daily calcium intake, bone mineral density (BMD) by DXA, and clinical chemistry parameters. When necessary, the patients received a prescription for osteoporosis medication. The participation rate, osteoporosis medications, initiation rate and osteoporosis treatment persistence were assessed 12 and 18 months later.

Results: Of the 1,439 patients contacted, 872 were eligible for inclusion. A total of 335 patients (participation rate: 38.4%) were included in the study (mean age: 63.3 years; 71.9% female). All patients underwent BMD measurement and more than 90% of them were assessed for osteoporosis risk factors and daily calcium intake. Osteoporosis medication was prescribed in 182 patients (75.5% of the patients in whom it was indicated [n=241]). Bisphosphonates were the mainly prescribed osteoporosis medications (83.5%). 74.1% and 67.4% of patients were still under treatment at 12 and 18 months respectively. The main cause of treatment discontinuation was non-renewal of the prescription by the patient's general practitioner.

Conclusion: Secondary prevention of osteoporosis in Amiens University Hospital has improved since the creation of the FLS, with encouragingly high treatment initiation and persistence rates.

What Percentage of Patients in UK Nursing Homes are Suitable for and Require IV Zoledronate? Results of a Structured Nursing Home Review Programme. Eamonn Brankin*[1], Wendy Feeney[2], Robin Munro[3]. [1]NHS Lanarkshire / University of Glasgow, United Kingdom, [2]NHS Lanarkshire, United Kingdom, [3]NHS Lanarkshire / University of Glasgow, United Kingdom

Over a 2 year period all nursing homes in NHS Lanarkshire were visited by an osteoporosis specialist nurse with a view to assessing patients' fracture risk, medication compliance and suitability for IV zoledronate if appropriate. A paucity of information remains about who might be suitable for and require IV bisphosphonate therapy in this high risk population and who in particular, if intolerant of oral therapy or contraindicated, might be precluded from receiving IV therapy due to impaired renal function. Over the 2 year period 64 nursing homes were visited and all residents assessed for the above parameters. A total of 1555 patients were assessed, of whom 268 had already had a hip fracture.477 were on calcium & vitamin D, 31% of the relevant patient population.177 were found to be already on oral alendronate.

Compliance overall with oral bisphosphonate therapy was 100% (ie those documented to be on the drug were actually taking it) although further assessment identified that there was great variation in knowledge among nursing home staff re the importance of adhering to the specific drug regime of oral bisphosphonate medication and as a result this medication was not given correctly.

Through a programme of patient and staff education a significant number of patients were actually subsequently able to take oral bisphosphonates. 52 educational sessions have been undertaken to date. After completing the programme we initiated a process of evaluation to assess the effectiveness of these sessions.

Very surprisingly only 2 of those who had been tried on oral bisphohsponate therapy were truly intolerant of this and therefore could be considered for IV therapy and / or denosumab

No patients have so far been commenced on denosumab.Two patients have been successfully treated with IV bisphosphonate therapy, with zero requiring denosumab.

Conclusions: By instituting a structured nursing home review programme, we successfully managed to review a large percentage of patients in nursing homes within the county for fracture risk, compliance and suitability for alternative therapies for those unsuitable for oral bisphosphonate therapy. Of those assessed for '2nd line' therapy, only 2 were found to be suitable for and subsequently treated with IV zoledronate and none required densoumab. Through structured staff education far more patients were found to be able to take oral alendronate than had been previously thought.

MO0342

Zoledronic Acid and Denosumab Use in Ontario, Canada. Andrea Burden*[1], Mina Tadrous[2], Andrew Calzavara[3], Suzanne Cadarette[1]. [1]University of Toronto, Canada, [2]University of Toronto, Canada, [3]Institute for Clinical Evaluative Sciences, Canada

Residents aged 65 or more years in Ontario Canada receive full coverage for medications listed on the public drug formulary. Two novel extended dosing osteoporosis medications were added to the public drug formulary for the treatment of osteoporosis in the last decade: annual zoledronic acid in 2006 (access changed in 2012), and semi-annual denosumab in 2012. The objectives of our study were to: 1) describe the use of zoledronic acid and denosumab by physicians and patients over time, and 2) examine the impact of the 2012 formulary change that opened access (less restricted) to zoledronic acid. We identified new users of zoledronic acid and denosumab from 2006 to 2013 using Ontario pharmacy claims data. The number of new patients and physicians were plotted by month and examined over time. Descriptive characteristics of patients and prescribers were summarized pre- and post-formulary change for zoledronic acid; and overall for denosumab. We identified 1,508 zoledronic acid users 2006/09-2013/03 (896 pre-formulary change: 81% female, 41% prior osteoporosis treatment, mean age=76 [SD=7.0]; and 612 post-formulary change: 91% female, 26% prior osteoporosis treatment, mean age=77 [SD=6.9]) treated by 630 physicians (420 pre-formulary change), and 16,736 denosumab users 2012/02-2013/03 (79% female, 55% prior osteoporosis treatment, mean age=79 [SD=7.5]) treated by 2,904 physicians. We identified a rapid uptake of denosumab (>450 new physicians and >1,200 new patients) in contrast to zoledronic acid (<6 new physicians and <6 new patients) in the first two months on the drug formulary. Zoledronic acid use increased significantly post-formulary change with >80 new physicians and >200 new patients within 2 months of the formulary change. We document a slow increase in use of zoledronic acid over 7 years of observation, and a rapid increase in the use of denosumab in just over 1 year of observation. Drug formulary listing status and restrictions impact drug prescribing and patient characteristics. The impact of formulary restrictions on drug utilization and the study of drug effects (safety and effectiveness) deserves close attention. We anticipate that use of denosumab and zoledronic acid will continue to increase, yet the ability to compare the effects of these agents will require novel study designs given the inherent time trends and drug policy-induced selection bias.

MO0343

Comparisons of Osteoporotic Fracture Incidence and Anti-osteoporotic Medication Expenditures after Changes of Reimbursement Policy. Rong-Sen Yang[1], Li-Wei Hung*[2]. [1]National Taiwan University Hospital, Taiwan, [2]National Taiwan University Hospital, Taiwan

Objective

Osteoporosis is a public health burden for aging society. Prevalence of osteoporosis-related fracture in Taiwan is the highest over Asia. With increasing use of anti-osteoporotic medications, our previous analysis showed concomitant decline in hip fracture prevalence with dramatic increase in anti-osteoporotic medications from 1999 to 2010 in Taiwan. However, National Health Insurance (NHI) launched a policy to restrict osteoporosis medication use since 2011. This study

aimed to analyze the prevalence of osteoporosis and its related fracture for calculate the expenditure on anti-osteoporotic medication between 2009 and 2011.

Materials and Methods

We used 2009-2011 National Health Insurance Research Database (NHIRD) to evaluate the prevalence of osteoporosis and its related fracture. Patients with a diagnosis of osteoporosis (ICD-9-CM code: 733.XX) and osteoporotic related fractures (ICD-9-CM code: hip fracture: 820.XX; vertebral fracture: 805.2, 805.4, 805.8, 806.2, 806.4; proximal humerus fracture: 812.0, 812.1, 812.2; forearm fracture: 813.4, 813.5) were identified. Using the pharmaceutical audit from IMS health, Taiwan, the expenditure of anti-osteoporotic drugs, including calcitonin, alendronate, raloxifene, teriparatide, ibandronate, zoledronic acid, strontium ranelate and denosumab, were analyzed.

Results

During the study period, prevalence of osteoporosis was slightly decreased from 3,823 to 3,509 per 100,000 people. However, the prevalence of osteoporosis-related fracture was increased from 2,258 to 2,315 per 100,000 people. The prevalence of fracture at spine and hip elevated (1,115 to 1,186 per 100,000 and 537 to 558 per 100,000 respectively) whereas the prevalence of fracture at shoulder or forearm reduced (267 to 253 per 100,000 and 475 to 459 per 100,000 respectively). Compared to the expenditure of anti-osteoporotic medication in 2009, an 11.6% decrease was found in 2011. All medication expenditure has been declined except zoledronic acid. Among them, teriparatide declined to 80% of its expenditure in 2010.

Conclusions

Between 2009 and 2011, the prevalence of osteoporosis slightly decreased. However, its related fracture increased as well as the prevalence of spin and hip. The anti-osteoporotic medication expenditures declined sharply. Further study on the prevalence of osteoporosis and its related fracture and its related expenditures is needed to evaluate the impact of the policy which restricted anti-osteoporotic medication use.

MO0344

Calcium alleviation of oxidative stress. Active Absorptive Algal Calcium decreases total peroxides in blood. Takuo Fujita*[1], Mutsumi Ohue[2], Ryuji Aoyama[2], Tomohiro Tanaka[2], Yoshio Fujii[3], Tsuyoshi Jotoku[4], Akimitsu Miyauchi[5], Yasuyuki Takagi[6]. [1]Katsuragi Hospital, Japan, [2]Katsuragi Hospital, Japan, [3]Calcium Research Institute Kobe Branch, Japan, [4]Dept of Orthopedic Surgery, Osaka Medical College, Japan, [5]Miyauchi Medical Center, Japan, [6]National Hyogo Chuo Hospital, Japan

Background Severe cell injury occurs in response to oxidative stress on reperfusion as in calcium deficiency, PTH hypersecretion, Ca release from bone and osteoporosis leading to universal rise of cytosolic Ca and cell death. In an attempt to find a link between these two common phenomena, effect of Ca supplementation to overcome calcium paradox on oxidative stress was tested.

Methods Twenty postmenopausal women consulting Osteoporosis and Osteoarthritis Clinic of Katsuragi Hospital volunteering to participate the study were randomly divided into 2 equal groups : A (mean age 67 $\pm$ 9) and B (mean age 72 $\pm$ 4) without significant difference in age (p=0.2055). A but not B was supplemented with 900mg / day Active Absorptive Algal Calcium (AAACa) with a high intestinal absorbability (Nutrients 2010). To estimate the total oxidizing activity (dROMs), 20µl diethyl p-phenylendiamine and 2 ml acetate buffer at pH4.8 was added to 20µl serum and incubated for 5 min at 37C. Biological Antioxidant Potential (BAP) was measured as the total reducing activity. BAP / dROMs was calculated to evaluate antioxidant activity against the given oxidizing activity. This study was approved by the IRB of Katsuragi Hospital.

Results In contrast to a rise of dROMs by 6.2 $\pm$ 13.9 % (Mean $\pm$ SD) per month in B, it fell distinctly by -15.5 $\pm$ 13.0 % characterizing A, indicating a marked alleviation of oxidative stress in response to AAACa (p=0.0020). BAP/dROMs significantly increased in A by 27.4 $\pm$ 26.8, over B by 1.8 $\pm$ 2.4 (p=0.0335), suggesting a significant antioxidant activity of calcium. BAP failed to change significantly.

Discussion Rise of intracellular free calcium, an inevitable consequence of calcium paradox, initiates oxidative stress with increase of reactive free radical formation possibly through mitochondrial Ca accumulation. Oxygen free radicals, on the other hand, aggravate cell Ca overload through promotion of Ca entry by changing membrane phospholipid composition (Zhou et al 2009). Oxygen paradox and calcium paradox thus appears to promote each other causing a negative spiral in cell destruction, unless prevented by an effective Ca supplementation.

Conclusion Distinct alleviation of oxidative stress demonstrated in response to Ca supplementation with AAACa appears to support an important role of calcium to counteract the harmful effect of oxidative stress.

MO0345

The effect of calcium and vitamin D supplementation on bone mineral density in healthy males: A meta-analysis. David Greene*[1], Leslie Silk[2], Michael Baker[2]. [1]Australian Catholic University, Australia, [2]Australian Catholic University, Australia

Musculoskeletal diseases is an Australian national health priority however, osteoporosis remains an under-diagnosed and under-treated disorder, particularly in men. Despite the known benefits of vitamin D and dietary calcium on bone density, it is estimated that 31% of Australian adults are vitamin D deficient (<50 nmol/L) and a similar proportion of adults have inadequate dietary calcium intake [(1,2)]. Calcium and vitamin D supplementation has previously shown a small, but positive effect on bone strength and a reduction in fracture risk. However, research has focused on children and females with the preventative effects of vitamin D and/or calcium supplementation on male bone remaining largely unexplored. The aim of this meta-analysis is to examine the efficacy of calcium and vitamin D supplementation on improving bone mineral density in healthy males. Medline, EMBASE, SPORTDiscus, Academic Search Complete, CINHAHL Plus and PubMed databases were searched for all studies including healthy males which provided participants with vitamin D and/or calcium supplementation and used changes to bone mineral density (BMD) as the primary outcome measure. From 3,930 possible references, a meta-analysis was performed using 8 references. Results demonstrated significant pooled effects size (ES) for comparison between supplementation and placebo/control groups at all sites included in the meta-analysis. The largest effect was found in total body (ES=0.644; 95% CI=0.406 to 0.883; p=0.001), followed by total hip (ES=0.483, 95% CI= 0.255 to 0.711, p=0.001) and femoral neck (ES=0.402, 95% CI=0.233 to 0.570, p=0.001). The smallest impact was observed on the lumbar spine (ES=0.290, 95% CI=0.164 to 0.415, p=0.001). Evidence appears to support the use of calcium and vitamin D supplementation for improving BMD in older males however, there is a need for high quality randomised controlled trials in younger age cohorts.

MO0346

Supplementation with Beetroot Juice Does Not Affect Bone Microarchitecture of the Femur or Lumbar Vertebrae of OVX Rats. Amanda Longo*[1], Bryan Johnston[1], Paul LeBlanc[1], Sandra Peters[1], Gregory Wohl[2], Wendy Ward[3]. [1]Brock University, Canada, [2]McMaster University, Canada, [3]Brock University, Canada

Postmenopausal osteoporosis is characterized by a decline in the production of endogenous estrogen resulting in a decrease in skeletal mass and changes to bone microarchitecture. Hormone replacement therapy protects bone microstructure in postmenopausal women and estrogen-deplete rodent models through estrogen receptor modulated signaling. The beneficial effects of estrogen can also be mediated, in part, through the nitric oxide pathway. Moderate levels of nitric oxide result in a net positive bone balance. Flux through this pathway has been show to decrease in response to estrogen withdrawal. With digestion, dietary nitrates are converted to the bioactive ion nitric oxide, a known regulator of local osteoblast and osteoclast activity. Thus, dietary nitrates, a component found in high concentrations in beetroot, may provide an alternative therapy for the maintenance of bone microarchitecture in response to estrogen withdrawal. Three-month, ovariectomized (OVX) Sprague-Dawley rats (n=14/group) were randomized to control (no treatment), 17β-estradiol replacement (1.5mg 90-day release subcutaneous pellet from Innovative Research of America, positive control), or beetroot juice (once daily, 18.75mg nitrates, James White Drinks) for 12 weeks. Femur and lumbar vertebrae were excised and imaged using high-resolution micro-computed tomography (SkyScan 1176). Images of the femur mid-shaft, femoral neck, and third lumbar vertebrae (L3) body were acquired at a voxel size of 9µm and bone morphometry was analyzed using SkyScan CT-Analyser, v.1.13. As expected, estrogen-replacement provided significant ($p<0.05$) benefits to trabecular bone structure outcomes (femoral neck, L3) including BMD, percent bone volume, trabecular number, and separation compared to OVX control. For all trabecular bone outcomes at the femoral neck and L3, the beetroot group was similar to control. Beetroot intervention resulted in a lower ($p<0.05$) cortical area fraction of the femur mid-shaft compared to other groups. Cross-sectional thickness, bone area, tissue area, and BMD of the femur mid-shaft or L3 body were similar among all groups suggesting no change in surrogates of cortical bone structure. In summary, 12-week intervention with nitrate-concentrated beetroot juice did not preserve bone microarchitecture in the femur mid-shaft, femoral neck, or L3 body.

MO0347

Development and validation of a food frequency questionnaire for assessment of vitamin D and calcium intake in Finnish adults. Suvi Itkonen*[1], Maijaliisa Erkkola[2], Essi Skaffari[3], Pilvi Saaristo[3], Elisa Saarnio[4], Christel Lamberg-Allardt[1]. [1]University of Helsinki, Finland, [2]Division of Nutrition, Department of Food & Environmental Sciences, University of Helsinki, Finland, [3]Calcium Research Unit, Department of Food & Environmental Sciences, University of Helsinki, Finland, [4]University of Helsinki, Finland

Adequate vitamin D (vitD) intake is important for bone health, and a low vitD status may increase the risk of many common chronic diseases. The aim of this study was to update and develop a food frequency questionnaire (FFQ) to assess dietary and supplemental vitD and calcium (Ca) intake in a Finnish population. VitD-enrichment of almost all fluid dairy products has increased vitD intake during recent years. These are now the main vitD sources, other important sources are fish products and vitD-enriched margarines. For the development of the FFQ, data on the use and supply of vitD-enriched products in the markets was examined. An interviewer-driven 98-item FFQ, including also Ca sources, was developed. The foods were divided into 8 categories, including detailed questions on the use of supplements. In addition, short questions on possible sunlight exposure were included. Trained interviewers collected information of vitD intake of 69 healthy Caucasian adults aged 20-37-years by the FFQ. Serum 25-hydroxy-vitamin D (S-25OHD) concentration, the major biomarker of vitD status, concentrations was assessed by EIA (IDS). Validity was assessed using Spearman correlation coefficients and cross-classification into quartiles of vitD intake and S-25OHD. The mean (SD) intakes of vitD were 9.8 μg/d (5.0 μg/d) from food, 9.4 μg/d (15.0 μg/d) from supplements, 19.1 μg/d (15.7 μg/d) in total, respectively. The mean concentration of S-25OHD was 68.9 nmol/L (23.9 nmol/L). A strong correlation between total vitD intake (from FFQ and supplements) and S-25OHD was observed ($r=0.560$, $p<0.001$), which did not improve when adjusted for sunny holidays ($r=0.544$, $p<0.001$). Cross-classification analyses demonstrated no major misclassification of participants into intake quartile; 83% percent of subjects were classified into the same or adjacent quartile, and 1% into the opposite quartile. In those not using vitD supplements (n=32), the correlation between the two methods was good ($r=0.351$, $p=0.049$), and 84% of subjects were classified into the same or adjacent quartile, and 9% into the opposite quartile. This FFQ provides promising validation evidence and a reasonable estimation of vitamin D intake in healthy young Caucasian adults during winter season. The validity and reproducibility of the FFQ will further be assessed with repeated measurements and with comparison to food records by triad method, and also Ca intake assessment by these two methods will be compared.

MO0348

Evaluating Effects of Supplemental Vitamin D on Incident Fracture Risk in the VITamin D and OmegA-3 TriaL (VITAL). Amy Yue[1], JoAnn Manson[2], Julie Buring[2], Nancy Cook[2], Douglas Bauer[3], Peggy Cawthon[4], Dennis Black[3], Meryl Leboff*[5]. [1]Brigham & Women's Hospital, USA, [2]Brigham & Women's Hospital Professor of Medicine, Harvard Medical School, USA, [3]University of California, San Francisco, USA, [4]California Pacific Medical Center Research Institute, USA, [5]Brigham & Women's HospitalProfessor of Medicine, Harvard Medical School, USA

Although there is widespread use of supplemental vitamin D to promote bone health, data from large, randomized, placebo-controlled trials of the effects of supplemental vitamin D *alone* on fracture outcomes are sparse and inconsistent; these trials show benefit, no effect, or increased risk of supplemental vitamin D on fracture outcomes. We are conducting an ancillary bone study to the large *VIT*amin D and Omeg*A*-3 Tria*L* (VITAL) to test the safety and efficacy of high-dose supplemental vitamin D in the primary prevention of incident fractures (all, non-vertebral, and hip).

The parent VITAL is a 2x2 factorial, double-blind, placebo-controlled trial testing the effects of daily, high-dose supplemental vitamin D3 (cholecalciferol, 2000 IU/d) and/or omega-3 fatty acids (EPA+DHA; 1 g/d) in the primary prevention of cancer and cardiovascular disease (CVD). After completing a 3-month placebo run-in, men aged ⩾50 and women aged ⩾55 were randomized to receive either high-dose, supplemental vitamin D or placebo, permitting up to 800 IU/d of supplemental vitamin D and an intake of 1200 mg/d of elemental calcium. Randomization closed March 24, 2014. VITAL includes approximately 26,000 participants (exceeding the target of 20,000), with an oversampling of blacks (n>5,100) and high minority representation (~26% non-white).

Among VITAL participants enrolled in the parent trial, 580 reported at least one fracture event in year 1 post-randomization. Fractures reports were examined separately and according to annual questionnaires, medical record review, and fracture adjudication including review of radiological images of hip and femur fractures. Participants who fractured were older and more likely to be women than men. The cohort has broad U.S. geographic diversity. Questionnaires at run-in and baseline assessed demographic, lifestyle, physical activity, nutritional and clinical risk factors related to osteoporosis, CVD, cancer, and other health outcomes. Assessments will be repeated on an annual basis. Baseline levels of serum 25-hydroxyvitamin D, PTH, and calcium will also be measured using blood samples collected from a subset of >16,000 participants. Determination of treatment effects will be based on intent-to-treat and other analyses. Results from this large study will inform clinical and public health recommendations and clarify the role of high-dose, daily supplemental vitamin D in the primary prevention of fractures in the U.S.

MO0349

High prevalence of vitamin D deficiency in patients with xeroderma pigmetosum (XP)- A under strict sun-protection. Akiko Kuwabara*[1], Naoko Tsugawa[2], Kiyoshi Tanaka[3], Yasuyo Uejima[1], Junko Ogawa[1], Natsumi Otao[1], Nanae Yamada[1], Taro Masaki[4], Chikako Nishigori[5], Shinichi Moriwaki[6], Toshio Okano[7]. [1]Department of Health & Nutrition, Osaka Shoin Women's University, Japan, [2]Kobe Pharmaceutical University, Japan, [3]Kyoto Women's University, Japan, [4]Division of Dermatology, Clinical Molecular Medicine, Graduate School of Medicine, Kobe University, Japan, [5]Division of Dermatology, Clinical Molecular Medicine, Graduate School of Medicine, Kobe University, Japan, [6]Department of Dermatology, Osaka Medical College, Japan, [7]Kobe Pharmaceutical University, Japan

Purpose: Xeroderma pigmentosum (XP) is a rare autosomal recessive disease characterized by defective repair of ultraviolet (UV) irradiation-induced DNA damage and resultant high risk of skin cancer. Thus, these patients need photoprotection through minimization of daytime outdoor activity and constant sunscreen use. Since DNA repair is most severely impaired in XP group A (XP-A), such restrictions are most strictly applied to XP-A patients. Considering the UV-mediated cutaneous vitamin D production, rigorous photoprotection would be associated with vitamin D deficiency. Reports have been scarce, however, on the vitamin D status of patients with XP. Then, we have studied the vitamin D status in XP-A patients under most strict photoprotection.

Methods: Twenty-two XP-A patients (male;12, female;10, aged 6 to 44) were evaluated for their vitamin D intake, serum levels of 25-hydroxy-vitamin D (25OHD) and parathyroid hormone (PTH). Vitamin D intake was assessed by 2-day food weighing method.

Results: Median dietary vitamin D intake was 4.7μg/day. In 40% of the subjects, vitamin D intake was below the adequate intake (AI) of Dietary Reference Intakes (DRIs) in Japan. The median concentrations of serum 25OHD and PTH were 8.0ng/mL and 46.5pg/mL, respectively. In 73% of patients, serum 25OHD level was lower than 10ng/mL, strongly indicating vitamin D deficiency. Vitamin D intake was not significantly correlated with serum 25OHD concentration. Vitamin D intake and serum 25OHD level were significantly lower in patients under enteral nutrition (EN) than those with oral intake (OI). Multivariate analyses revealed that EN was a significant predictor of decreased serum 25OHD level.Conclusions: We have found that vitamin D deficiency is highly prevalent in XP-A patients under strict photoprotection. The implication of our finding would be two-fold. First, supplementation should be considered to avoid unfavorable skeletal consequences in these patients. Second one is related to the DRIs. Determination of dietary vitamin D requirement has been an annoying issue in the decision of DRIs because of its cutaneous production. Recently published DRIs for calcium and vitamin D 2011 from Institute of Medicine adopted the comparison of serum 25OHD level and dietary vitamin D intake in subjects from arctic region. Data from XP patients would shed light on the dietary vitamin D requirement and yield useful information on the DRIs determination.

MO0350

Measurement of Serum 1,25-dihydroxyvitamin D Levels: An Excercise in Utility or Futility?. Tarlisha Holsey*[1], Sudhaker Rao[2], Arti Bhan[1]. [1]Henry Ford Hospital, USA, [2]Henry Ford Hospital, USA

Background: With growing interest in vitamin D nutrition (VDN), it has become common practice to assess VDN status with measurement of vitamin D metabolites. Although the best available index of VDN is serum 25-hydroxyvitamin D (25-OHD) level, the difference between 25-OHD and 1,25-dihydroxyvitamin D (1,25-DHD) measurements, and the clinical indication and relevance of each measurement is not well appreciated in clinical practice.

Methods: As part of continuous quality improvement process in the Bone and Mineral Research Laboratory (BMRL), we conducted an audit of the number of serum 1,25-DHD measurement requests in a 3-month period (01/01/2014 to 03/31/2014). For each serum 1,25-DHD measurement, a review of the patients' records and/or personal phone contact with the ordering provider was conducted by the BMRL director (DSR) to clarify which vitamin D metabolite the provider intended to measure, and to educate the provider about the appropriate metabolite to assess VDN. In almost all instances, the intention of the providers was to measure serum 25-OHD, and not 1, 25-DHD.

Results: During the 3-month audit period, 449 serum 1,25-DHD measurements were requested: 55 came from 2 community based hospitals owned by the Henry Ford Health System (HFHS), 64 from community providers that use BMRL as reference laboratory, 246 from providers within the HFHS, and 84 from the Henry Ford Hospital inpatient setting (reasons for the latter source were not readily apparent).

The mean serum 1, 25-DHD level for the entire cohort was 61.7 ± 26.9 (range: 6-141 pg/ml). Only 71 of the 441 (or 16%) requests included simultaneous serum 25-OHD requests. Unfortunately, no provider simultaneously assessed renal function or measured serum calcium.

Conclusions: Isolated measurement of serum 1,25-DHD to assess VDN, as with 25-OHD (ASBMR Annual Meetings 2010 and 2012) appears quite pervasive, despite the well-established and publicized guidelines to measure 25-OHD to assess VDN. Many providers are ordering serum 1, 25-DHD to assess VDN when in fact they intended to measure serum 25-OHD, the best available index of VDN. Increased education and computerized "stop-gaps" is urgently needed to avoid unnecessary (and perhaps irrelevant) testing of serum 1, 25-DHD level, which is needed only in rare circumstances, and to avoid considerable health care costs, as implied in the "Choose Wisely" campaign!

MO0351

Rational Assessment of Vitamin D. Arthur Chausmer*. C/A Informatics, LLC, USA

There is some controversy regarding the use of 25 hydroxycalciferol as an assessment of vitamin D status. The aim of this presentation is to provide literature evidence based suggesting this is only a marginally viable surrogate and that it is vastly overused to justify unnecessary treatment with pharmacologic doses of vitamin D The physiology of calcium and vitamin D are reviewed and discussed in the light of decision making regarding the need and advisability of therapeutic intervention and concurrent risk of potentially life threatening hypervitaminosis D.

There is no data in any animal model regarding the measurement of the total body burden of vitamin D as calciferol, 25 OHD or 1,25 OH2D, consequently there is no test which has been demonstrated to reflect the total body stores of any element of the metabolic pathways. The measurement of an inactive metabolite, 25 OHD, although commonly used for the diagnosis of D deficiency, has some weak statistical relationship with the active metabolite, but no causal relationship with any aspect of calcium homeostasis. Multiple confounding factors are presented which make this a poor choice for determination of clinical vitamin D sufficiency.

While it is more costly than simple measurement of 25 OHD, it is concluded that the actual evaluation of vitamin D status requires different testing. This includes elements of it's interaction with calcium metabolism as a whole, which cannot be assessed by the simplistic approach of a single 25 OHD value. Rather a true assessment of vitamin D status includes measurement of 1,25 dihydroxycalciferol in concert with PTH, calcium, phosphorus and renal function testing. Simply measuring 25 OHD should not be the basis for treatment with potentially toxic doses of vitamin D.

MO0352

The Effect of High-Dose Vitamin D Supplementation on Bone Mineral Density and Bone Turnover Markers in Subjects with Type 2 Diabetes and Hypovitaminosis D – a Randomized Controlled Trial. Hanne Gulseth*[1], Cecilie Wium[2], Erik Fink Eriksen[3], Kåre I. Birkeland[4]. [1]Norwegian Institute of Public Health/ Oslo University Hospital, Norway, [2]Department of Endocrinology, Morbid Obesity & Preventive Medicine, Oslo University Hospital /University of Oslo, Norway, [3]Oslo University Hospital, Norway, [4]Department of Endocrinology, Morbid Obesity & Preventive Medicine, Oslo University Hospital/ University of Oslo, Norway

Low levels of 25 hydroxy-vitamin D (25OHD) are common, and associated with increased bone turnover, risk of fractures and possibly adverse glucose metabolism. We tested whether vitamin D supplementation could improve bone mineral density (BMD) and bone turnover markers in subjects with type 2 diabetes, and if the effects of vitamin D supplementation depended on ethnicity.

In a 6-month, parallel group, placebo-controlled, double-blind randomized trial, patients of South-Asian and Nordic ethnicity, with type 2 diabetes and hypovitaminosis D (25OHD < 50 nmol/L) received oral vitamin D_3 or placebo. A dose of 400,000 IU vitamin D_3 was given at baseline, followed by 200,000 IU after 5 weeks if 25OHD <100 nmol/L. We measured 25OHD, PTH, CTX1, P1NP and osteocalcin as well as BMD of the hip and spine. Data are mean (SD).

Subjects (n=62, 48% females) of Nordic (n=43) and South Asian (n=19) ethnicity with age 57.7 (9.6) years, BMI 31.9 (5.2) kg/m2, HbA1c 7.8 (1.4)%, diabetes duration 10.3 (6.2) years and 25OHD 37.4 (12.1) nmol/L participated in the trial. After 3 and 6 months 25OHD increased significantly in the D_3 group, by 35.5 (19.4) and 14.9 (12.2) nmol/L respectively, compared to the placebo group: 6.1 (15.7) and 1.5 (15.3) nmol/L, p<0.001 and p=0.001 . The changes in bone turnover markers and BMD did not differ significantly between groups (table 1). However, in subjects of South Asian ethnicity PTH decreased (-2.0 (0.8) pmol/L, p=0.036) and spine BMD increased (0.034 (0.013) g/cm^2, p=0.032) significantly in the D_3 group compared to placebo. There were no significant changes in the Nordic group.

In conclusion, in a 6-month, placebo-controlled, double-blind, randomized trial of oral vitamin D_3 versus placebo, subjects with type 2 diabetes and hypovitaminosis D did not change bone turnover markers or BMD. In subjects of South Asian ethnicity PTH concentrations fell and spine BMD improved after vitamin D supplementation.

	Vitamin D_3		Placebo		
	Baseline	Change	Baseline	Change	p-value
BMD spine (g/cm^2)	1.26 (0.17)	0.014 (0.04)	1.20 (0.20)	0.001 (0.04)	0.086
BMD hip (g/cm^2)	1.16 (0.13)	-0.003 (0.02)	1.09 (0.16)	0.02 (0.10)	0.18
PTH (pmol/L)	4.3 (1.9)	-0.5 (2.1)	3.7 (2.1)	0.6 (2.3)	0.13
Osteocalcin (nmol/L)	0.50 (0.38)	-0.04 (0.3)	0.53 (0.31)	0.06 (0.6)	0.62
CTX1 (µg/L)	0.26 (0.14)	-0.01 (0.11)	0.26 (0.14)	0.01 (0.10)	0.20

MO0353

Three doses of vitamin D on bone mineral density and structural analysis in postmenopausal women: a double-blind randomized controlled pilot study. L. Claudia Pop*[1], Deeptha Sukumar[2], Christopher Gordon[3], Stephen Schneider[4], Yvette Schlussel[1], Theodore Stahl[4], Sue Shapses[5]. [1]Rutgers University, USA, [2]Drexel University, USA, [3]McMaster University, Canada, [4]Rutgers-Robert Wood Johnson Medical School, USA, [5]Rutgers University, USA

Background: Studies examining bone due to vitamin D supplementation, in a dose-dependent manner, are currently lacking. Postmenopausal women undergoing weight control to improve health outcomes, are particularly at risk for bone loss, and might benefit from additional vitamin D intake.

Objective: This one year-long study addressed whether vitamin D supplementation, in healthy overweight/obese older women, attenuates bone structural parameters with modest weight loss.

Design: Fifty-nine women (age, 58 ± 6 years; body mass index, 30.2 ± 3.8 kg/m^2, serum 25-hydroxyvitamin D (25OHD), 27.3 ± 4.4 ng/ml), were randomly assigned to one of 3 daily doses of vitamin D_3 (A, 600 IU; B, 2000 IU; C, 4000 IU) with total calcium intake (diet and supplement) of 1.2 g/d while counseled for weight control. Serum was analyzed for 25OHD, parathyroid hormone and bone turnover markers. Areal bone mineral density was measured by dual energy x-ray absorptiometry. Geometry, strength, and trabecular and cortical BMD and microarchitecture by high resolution three dimensional peripheral quantitative computed tomography.

Results: After one year, serum 25OHD levels increased to 26.5 ± 4.4, 35.9 ± 4.5 and 41.5 ± 6.9 ng/ml, in groups A, B and C, respectively, and the groups were different (p<0.01). Weight change was similar between groups (-3.0 ± 4.1%). Trochanter aBMD decreased more in group A (-1.5 ± 3.9%) than group B (+0.9 ± 2.8%) (p<0.05) and did not differ from C. No other BMD parameters differed between treatments. However, femoral neck aBMD decreased in the A group (-1.0 ± 2.8%) compared to baseline (p<0.05). Cortical thickness changed differently between groups, by: -1.5 ± 5.2%, +0.6 ± 3.2% and +2.0 ± 4.8% in groups A, B and C, respectively (p < 0.05). Also, compared to baseline, trabecular separation increased (+2.6 ± 5.2%) and trabecular number decreased (-1.6 ± 3.0) in group A (p < 0.05), but there was not change in thickness or bone volume/tissue volume.

Conclusion: There is no effect of vitamin D_3 supplementation at any dose on BMD in older women over 1 year, but a decrease in cortical geometry and the age-related changes in trabecular microstructure are attenuated with higher vitamin D supplementation.

MO0354

Vitamin D replacement in patients undergoing bariatric surgery: a systematic review and meta-analysis. Marlene Chakhtoura*[1], Ghada El-Hajj Fuleihan[2], Elie Akl[3], Nancy Nakhoul[3], Bassem Safadi[3]. [1]American University of Beirut, Lebanon, [2]American University of Beirut-Medical Center, Lebanon, [3]American University of Beirut, Lebanon

Background:

Bariatric surgery is the most effective measure for weight loss. Vitamin D deficiency is common in patients undergoing bariatric surgery (1). Specific risk factors related to obesity include sedentary lifestyle and vitamin D sequestration in adipose tissue. In addition, limited intake of dairy products due to dietary intolerance and bypass of the primary absorption sites of vitamin D at the jejunum and ileum concur to result in hypovitaminosis D. This would contribute to bone loss following bariatric surgery (2). Major clinical practice guidelines on vitamin D supplementation in patients undergoing bariatric surgery are mostly based on expert opinion (3-5).

Aim:

Assess the benefits and harms of different doses of vitamin D replacement therapy in patients undergoing bariatric surgery.

Outcomes measures:

The main outcome of this study is the mean difference in serum 25-hydroxyvitamin D level reached between three vitamin D dose categories: low (≤ 800IU), moderate (800-3500 IU) or high (>3500IU) daily dose of vitamin D, or placebo/no vitamin D supplementation.

Other outcomes include mortality, change in bone mineral density and muscle strength, diabetes, hypertension and dyslipidemia resolution, incidence of fracture, hypercalcemia - hypercalciuria and kidney stones, in addition to quality of life and cost economics.

Eligibility criteria:

We included randomized controlled trials (RCTs) and controlled clinical trials (CCTs) administering different oral doses of vitamin D or placebo in bariatric surgery patients.

Search methods:

We searched Medline, PubMed, Embase and the Cochrane Library for eligible trials. No time or language limitations were applied. We searched clinicaltrial.gov, ICTRP and ICRCTN for registered trials. References retrieved were reviewed in duplicate by 2 independent reviewers. Authors were contacted for unpublished data. The protocol will be submitted to the Cochrane Collaboration Group.

Results:

The search yielded 1339 articles. After duplicate removal, we screened 996 articles by title and abstract, and retained a total of 86 articles for full text screening. We also identified 8 ongoing clinical trials. The data abstraction and analysis are currently under progress, to be completed by September 2014.

Keywords: vitamin D, bariatric surgery

MO0355

Higher bone resorption across the menopause may impair trabecular micro-architecture – the prospective OFELY study. Elisabeth Sornay-Rendu*[1], Pawel Szulc[2], Stephanie Boutroy[3], Olivier Borel[4], Roland Chapurlat[5]. [1]INSERM UMR1033, Université de Lyon, France, [2]INSERM UMR 1033, University of Lyon, Hopital E. Herriot, Pavillon F, France, [3]INSERM U1033 & Université de Lyon, France, [4]INSERM UMR 1033, France, [5]E. Herriot Hospital, France

Median values of bone turnover markers (BTM) are higher in post- than in premenopausal women. As many skeletal traits track - follow in a trajectory established early in life through young adulthood to advanced age, we hypothesized that BTM levels will also track in their percentile location established before menopause into the postmenopausal years.

Seventy women aged 38±4 yr had blood collected 13±4 yr before the menopause and then, 6±4 yr after the menopause, when they were 57±4 yr. At the end of the follow-up, bone microarchitecture was assessed at the distal radius and tibia by high resolution peripheral quantitative computed tomography (XtremeCT SCANCO, Scanco AG, Brüttisellin, Switzerland).

Of women who were in the highest tertile of serum CTX-I levels before the menopause, 58% remained in the highest tertile after the menopause. Of women who were in the lowest premenopausal tertile, 63% remained in the lowest tertile after the menopause. Overall, 51% of women remained in the same tertile across menopause (weighted k= 0.40, 95% confidence interval: 0.23-0.56, $p<0.001$). Premenopausal CTX-I levels explained 24% of variability of CTX-I levels after menopause ($p<0.001$). Women from the highest premenopausal tertile had higher average CTX-I level and variance after the menopause compared with women from the lowest premenopausal tertile (0.62±0.20 vs 0.39±0.11 ng/mL, $p<0.001$).

Women who were in the highest CTX-I tertile before and after the menopause had 20% fewer trabeculae (Tb.N) at the distal tibia (1.5SD, $p<0.001$) than women who were in the lowest CTX-I tertile before and after the menopause (p for trend <0.001). Similar results were found for Tb.N at the distal radius (14%, 0.9SD, $p<0.05$, p for trend <0.05). Furthermore, trabecular distribution (Tb.Sp.SD) at the distal tibia was more heterogeneous in women in the highest CTX-I tertile before and after the menopause compared with women in the lowest CTX-I tertile before and after the menopause (42%, 2.1SD, $p<0.01$, p for trend <0.01). No difference were detected for cortical parameters or volumetric bone mineral density.Remodeling marker CTX does not consistently track, but tracking in the higher CTX-I levels across the menopause is associated with poorer trabecular microarchitecture, a feature that can assist in rational targeting of therapy.

MO0356

Model Development in Ovariectomized Rabbits to Translate the Increased Bone Remodeling Associated with the 3-mg Dose of the Odanacatib Phase II Study. Tara Cusick*[1], Le Duong[2]. [1]Merck & Co., Inc., USA, [2]Merck Research Laboratories, USA

Odanacatib (ODN) is a selective and reversible CatK inhibitor currently developed for osteoporosis treatment. Results from the dose-ranging ODN phase II study revealed modest bone loss in spine and hip from patients treated with the lowest dose of ODN 3-mg once-weekly (OW) for 2-yrs. Both biochemical formation and resorption markers were elevated in these patients above baseline. The goal of this study is to develop a preclinical model to further our understanding of the mechanism of bone loss associated with this 3-mg dose. Based on pharmacokinetic (PK) profiles, we modeled the 3-mg (Cmax=64nM, Cmin=15nM) and fully efficacious 50-mg OW (Cmax=337nM, Cmin=47nM) clinical doses in ovariectomized (OVX) rabbits using food formulations. Adult rabbits received sham- (N=18) or OVX (N=47) surgery 9-mo. prior to dosing. OVX-rabbits were randomized into 4 groups (N=11-12) and fed food containing: vehicle (Veh), high dose ODN (1.5mg/kg) once-daily (OD-H) or once-wkly (OW-H) and low dose ODN (0.45mg/kg) once-wkly (OW-L). Note, ODN-food was fed only the first day of the week in the OW regimens. Study endpoints included PK, bone resorption (uHP) and formation (BSAP) biomarkers and longitudinal BMD scans at 0, 3, 6, 9 and 12 mo. Rabbits fed 1.5 or 0.45mg/kg ODN daily achieved plasma exposures of ~263 and 66nM, respectively. Hence, OD-H maintained ODN mean exposure above the IC90 at all times. To mimic the 3-mg clinical dose, OW-H achieved Cmax=83nM and Cmin=7nM and OW-L had Cmax=22nM and Cmin=2nM in rabbits over the week. Comparing Veh, OD-H showed sustained reduction of uHP 65-78% ($p<0.001$) at all-time points and increased BSAP up to 24.2% ($p<0.05$) by 9 mo. However, OW-H and OW-L regimens significantly reduced uHP up to 80% ($p<0.05$) early in the week and rebounded to Veh levels toward weeks end. The OW groups maintained BSAP at Veh levels at all-time points. Versus baseline, OD-H increased LV5-6 aBMD up to 12.1% ($p<0.05$) after 12 mo. In contrast, LV5-6 aBMD of OW-H and OW-L were unchanged or tended to decrease compared to Veh. Thus, by mimicking the PK of the 3-mg human dose, we demonstrated that cyclic intermittent dosing of ODN at sub-/clinical exposures accelerated bone remodeling rate that tended to favor modest net bone loss in OVX-rabbits. The results from this preclinical model supports the clinical finding that maintaining optimal inhibition of CatK is necessary to achieve full benefit of ODN for the treatment of osteoporosis.

Regulating osteogenesis via Bcl6. Takeshi Miyamoto[1], Yoshiaki Toyama[2], Atsuhiro Fujie*[3]. [1]Keio University School of Medicine, Japan, [2]Department of Orthopaedics Surgery, School of Medicine, Keio University, Japan, [3]Department of Orthopaedic Surgery, School of Medicine,Keio University, Japan

The aim of the present study is to explore a single molecule, which simultaneously regulates both osteoclasts and osteoblasts. The pathophysiology of osteoporosis is based on the imbalance between bone resorption and bone formation, which two arms are regulated by the activities of osteoclasts and osteoblasts, respectively. Because these two arms are linked each other through coupling factors, treatment with anti-resorptive agents promotes simultaneous suppression of bone formation, which frequently results in limited increment of bone volume. Myriad of therapeutic agents for osteoporosis had been developed for decades, yet no agent which can regulate both bone resorption and bone formation, had been developed. In this study, we show that B cell lymphoma6 (Bcl6) KO mice exhibited significantly reduced bone mass due to accelerated osteoclastogenesis and altered osteoblastogenesis.

Bcl6 KO mice and control littermates were necropsied at 6 weeks of age. Removed hindlimbs were fixed with 70% ethanol, and were subjected to dual-energy X-ray absorptiometry analysis to measure bone mineral density and for bone-histomorphometric analysis. Primary osteoblasts isolated from the calvarial bones of the newborn (1-3d) mice were cultured, and mRNA was extracted to perform RT-PCR, to analyze expression of osteoblast-specific genes. Expression of osteoblast-specific genes in Bcl6 over-expressed MC3T3E1 cells was also analyzed.

Bcl6 KO mice exhibited severe osteoporosis compared with WT littermates. Enhanced osteoclast development while altered bone formation by osteoblasts was simultaneously seen in Bcl6KO mice, and Bcl6 KO mice showed decreased BV/TV(%), Ob.S/BS(%),Tb/N(/mm) compared with WT littermates. Primary osteoblasts derived from Bcl6 KO mice showed inhibited expression of osteoblast-specific genes after BMP2 stimulation. On the contrary, primary osteoblasts from Bcl6 over-expressed MC3T3E1cells showed accelerated expression of osteoblast-specific genes after BMP2 stimulation. Bcl6 inhibits osteoclast differentiation, while promotes osteoblastic bone formation.Bcl6 can be a potent therapeutic target, which simultaneously regulates both osteoclasts and osteoblasts.

RNA Seq-based Gene Expression in Mouse Cortical and Cancellous Bone. Natalie Kelly*[1], John Schimenti[2], F Patrick Ross[3], Marjolein Van Der Meulen[1]. [1]Cornell University, USA, [2]Cornell University, USA, [3]Hospital for Special Surgery, USA

Osteoporotic fractures occur predominantly at corticocancellous sites [1]. Mechanical loading is a promising approach for recovery of bone mass. Cortical (Ct) and cancellous (Cn) bone respond differently to mechanical loading, dependent on waveform [2]. The ability to quantitate differential changes in gene expression separately in Ct and Cn bone, in the absence of contaminating marrow cells, would be an important advance. We aimed to isolate high quality RNA from Ct and Cn bone in the absence of marrow cells and to examine differential gene expression between these tissues with RNA-seq.

Tibiae from 11-wk-old female C57Bl/6 mice were used for histology (left leg, H&E) or RNA isolation (right leg). Tibial bone marrow was not removed, flushed with PBS, or centrifuged (n=10/group). A Cn core was removed from the Ct shell of the metaphysis and RNA was isolated from these samples and from bone marrow (n= 3). Bone- (*Col1a1*, *Bglap*) and marrow-associated genes (*Icam4*) were assayed by qPCR and normalized to *Gapdh*. mRNA from cortical and cancellous bone of 4 10-wk old female mice mouse was processed for RNA-seq (100bp, single-end). Sequences were aligned with TopHat, and differential expression (>2-fold) was determined with Cuffdiff [3].

Marrow was visible in H&E stained intact Ct and Cn bone, removed incompletely by flushing, and barely detectable in centrifuged samples. Centrifuged Ct bone had 11- and 12-fold higher expression of *Col1a1* and *Bglap* than bone with marrow, while centrifuged Cn bone values were 26- and 29-fold higher. The expression of *Col1a1* and *Bglap* was significantly lower in Cn than Ct bone. Marrow had very low expression of bone-related genes compared to intact bone (80- to 990-fold less). Centrifugation, but not flushing, decreased the expression of *Icam4.* Marrow and intact Ct and Cn bone had similar expression of *Icam4* (Figure 1). On average 76% of the 18 million reads per library were mapped to the mouse genome, 95% uniquely. After removal of 11 contaminating muscle genes [4], 136 genes were over 2-fold increased (81) or decreased (55) in Cn versus Ct bone. These included osteocrin (–26-fold), Wnt16 (–10-fold), Sost (–3-fold), and Wnt10b (–2-fold).

The ability to examine gene expression by RNA-seq in marrow-free mouse Ct and Cn bone separately has the potential to impact osteoporosis and mechanotransduction research.

Tissue Heterogeneity Determined by FTIR Imaging Decreases with Increasing Fracture Count. Adele Boskey*[1], Lyudmila Spevak[2], Patrice Watson[3], Susan Bare[3], Robert Recker[4]. [1]Hospital for Special Surgery, USA, [2]Hospital for Special Surgery, USA, [3]Creighton University, USA, [4]Creighton University, USA

Fourier transform infrared imaging (FTIRI) can provide a "chemical photograph" of bone composition. We previously used FTIRI to define compositional parameters that vary with fracture risk [JBMR 29:24,1565]. We also showed that the full-width at half maximum of the pixel distribution (heterogeneity) of FTIRI parameters decreased if patients were treated with bisphosphonates [JBMR 2013;28;150; JBMR 2012; 27:172]. Increased heterogeneity is believed to retard crack propagation suggesting that a more homogeneous bone would have an increased risk of fracture. In the present study we examined FTIRI means and heterogeneities from 80 iliac crest biopsies from patients with and without prior self-reported fractures. The study objective was to test the hyothesis that tissue heterogeneity decreased with increased number of fractures. FTIRI spectra were collected from 3 sections of each biopsy with cortical and cancellous bone examined separately. Mean and standard deviation for 5 FTIRI parameters (mineral/matrix; CO_3/PO_4, crystallinity, acid phosphte content, and collagen maturity) and their respective mean heterogeneities were compared by linear regression analysis. Fracture data was initially segregated by number with 0 (n=33), 1 (n=11), 2 (n=17), 3 (n=13), and 4-7 (n=6) fractures and later, 3 groups of ~ equal size were studied. Mean age and BMD were not significantly different in these groups. FTIRI analysis showed no significant difference in any of the mean cortical or cancellous parameters with fracture number, although there was a significant linear decrease in coritcal CO_3/PO_4 ratio and a significant linear increase in collagen maturity with number of fractures for both cortical and cancellous bone. To facilitate comparion of heterogeneities, we normalized each heterogeneity values, dividing each by its parameter mean, combined cortical (co) and cancellous (ca) bonesand compared groups with 0, 1&2, and 3-7 fractures. This gave several trends but only CO_3/PO_4heterogeneity decreased with fracture number. Regression analysis of fracture number vs. heterogeneity (Fig 1) showed small but significant negative slopes for most parameters. These data, while limited due to the reliance on patient reported fracture incidence, support our hypothesis that heterogeneity decreases with increasing number of fractures. Decreased heterogeneity is associated with weaker materials, decreased energy dissipation and ability to retard microcracks, contributing to fracture risk.

MO0360

Improving bone metabolism by pomegranate seed oil in bone cells culture and in a preclinical mice model of postmenopausal osteoporosis. Mélanie Spilmont*[1], Yohann Wittrant[2], Veronique Coxam[3], Laurent Rios[4]. [1]Equipe Alimentation, Squelette et Métabolisme, France, [2]Equipe Alimentation, Squelette et Métabolismes, INRA, UMR 1019, UNH, CRNH Auvergne, France, [3]INRA Theix, France, [4]GREENTECH SA Biopôle Clermont-Limagne, France

In the current context of longer life expectancy, the prevalence of osteoporosis is increasingly important. This is why development of new strategies of prevention is highly suitable. Some dietary fats and particularly conjugated linoleic acid have a positive impact on bone formation leading to improved bone mineral density (BMD). Pomegranate seed oil (PSO) and its major component: punicic acid, a conjugated linolenic acid specific to this fruit, have potent anti-inflammatory and anti-oxidative properties both *in-vitro* and *in-vivo*, two process strongly involved in osteoporosis establishment. In this study, we demonstrated that PSO consumption (5% of the diet) improved significantly bone BMD and prevented trabecular microarchitecture impairment in ovariectomized (OVX) mice C57bl6j, compared to OVX controls animals. Those findings are associated with transcriptional changes in bone tissue, suggesting involvement of both osteoclastogenesis inhibition and osteoblastogenesis improvement. In addition, thanks to an *ex-vivo* experiment, we provided evidence that serum from mice fed pomegranate seed oil (5% by gavage) had the ability to significantly down-regulate the expression of specific osteoclast differentiation markers and RANK-RANKL downstream signaling targets in osteoclast like cells (Raw264.7). Moreover, in osteoblast like cells (MC3T3-E1) it elicited significant increase in ALP activity, matrix mineralization and transcriptional levels of major osteoblast lineage markers involving the Wnt/β-catenin signaling pathways may. Our data also reveal that PSO inhibited pro-inflammatory factors expression, while stimulating anti-inflammatory ones. These results demonstrate that PSO is highly relevant regarding osteoporosis. Indeed, it offers promising alternatives in the design of new strategies in nutritional management of age-related bone complications.

MO0361

Bone Loss in a New Rodent Model Combining Spinal Cord Injury and Cast Immobilization. Joshua Yarrow*[1], Fan Ye[2], Alexander Balaez[3], Jillian Mantione[3], Dana Otzel[3], Cong Chen[4], Luke Beggs[2], Celine Baligand[4], Jonathan Keener[3], Wootaek Lim[4], Ravneet Vohra[4], Abhinandan Batra[4], Stephen Borst[2], Prodip Bose[2], Krista Vandenborne[4]. [1]VA Medical Center, University of Florida, USA, [2]VA Medical Center, University of Florida, USA, [3]VA Medical Center, USA, [4]University of Florida, USA

Rodent contusion spinal cord injury (SCI) models are commonly used to assess preclinical interventions designed to restore musculoskeletal integrity. However, unlike humans, rodents exhibit spontaneous recovery of hindlimb function after contusion SCI, which complicates the interpretation of musculoskeletal outcomes. We have previously reported that hindlimb immobilization (IMM) subsequent to SCI exacerbates muscle atrophy in rodents due to the complete inhibition of hindlimb loading. Herein, we characterize bone loss in our newly developed SCI+IMM model and determine the influence of muscle contractility on skeletal integrity after SCI. Female Sprague-Dawley rats aged 16 weeks were randomized into the following groups: (a) Controls, (b) severe contusion SCI sacrificed at 7 days (SCI-7), (c) SCI sacrificed at 21 days (SCI-21), (d) 2 weeks IMM-alone, (e) SCI+IMM, or (f) SCI+IMM plus 2 weeks quadrupedal treadmill training (SCI+IMM+TM). SCI-7 and SCI-21 exhibited a >20% reduction in distal femoral and proximal tibial cancellous volumetric bone mineral density (vBMD) measured via μCT ($p \leq 0.01$), characterized by reductions in cancellous bone volume (cBV/TV%), trabecular number, and trabecular thickness. IMM-alone induced no observable bone loss. However, SCI+IMM exacerbated cancellous vBMD deficits with values being 25-45% below Controls ($p \leq 0.01$) and SCI-21 ($p \leq 0.05$) resulting from reduced cBV/TV% and reduced trabecular number. Similarly, SCI+IMM produced the greatest cortical bone loss within the distal femoral cortical region with cortical area and cortical thickness being 14-28% below Control ($p \leq 0.01$). SCI+IMM+TM partially alleviated cancellous vBMD deficits with values being 21% above SCI+IMM ($p \leq 0.01$), resulting from higher cBV/TV% and increased trabecular number, and also ameliorated cortical bone deficits at the distal femur; although, SCI+IMM+TM did not restore cancellous or cortical bone to Control or SCI-21 levels. Our findings indicate that residual and/or facilitated muscle contractility ameliorate bone decrements after SCI and suggest that our novel SCI+IMM model represents a clinically-relevant means of assessing strategies to prevent SCI-induced musculoskeletal deficits.

MO0362

Effects of alendronate for bone loss and pain-related behavior in the hindlimb-unloaded mouse model of osteoporosis. Taro Nakagawa*[1], Hiroki Wakabayashi[2], Yohei Naito[2], Takahiro Iino[2], Sho Kato[2], Akihiro Sudo[2]. [1]Mie University Graduate School of Medicine, Japan, [2]Department of Orthopaedic Surgery, Mie University Graduate School of Medicine, Japan

Background/Purpose: Factors of chronic pain due to hemiplegia or prolonged immobility are varied, there is osteoporosis (a rarefaction due to bone atrophy) as the cause. However, there have been few reports regarding the correlation between osteoporosis and pain-related behavior. We investigated the effects on bone mass and pain-related behaviors in osteoporosis model mice with hindlimb unloading, and investigated the effect of alendronate (ALN) on pain-related behaviors.

Methods: Male ddY mice (8 weeks old) were tail-suspended for 2 week and assigned to 3 groups; hindlimb-loaded mice treated with vehicle (control), hindlimb-unloaded mice treated with vehicle (HU), hindlimb-unloaded mice treated with ALN (HUA)(n=8/group). Starting immediately after tail-suspension, vehicle or 40μg/kg ALN was injected subcutaneously twice a week for 2 weeks. The bilateral femoral distal metaphyses and proximal tibial metaphyses were analyzed three-dimensionally by micro-computed tomography (μCT) 2 weeks after tail-suspension. The frequency of the withdrawal response and the withdrawal threshold to the application of von Frey filaments to the planter surface of the hindpaws was examined as mechanical hyperalgesia 2 weeks after tail-suspension.

Results: μCT analysis of the femoral distal metaphysis (Fig. 1) and the proximal tibial metaphysis showed that bone volume/tissue volume (BV/TV) and trabecular number (Tb.N) were significantly less in the HU group than in the control group, whereas trabecular separation (Tb.Sp) was significantly greater in the HU group than in the control group. In the HUA group, BV/TV and Tb.N were significantly greater than in the HU group, whereas Tb.Sp was significantly less than in the HU group. The paw-withdrawal-frequency stimulated by von Frey filaments with strength of 0.4~2.0 gwas significantly higher in the HU group than in the control group. Whereas it was significantly lower in the HUA group than in the HU group (Fig. 2). The withdrawal threshold was significantly lower in the HU group than in the control group, whereas it was significantly higher in the HUA group than in the HU group. There was no significant difference between the HUA group and the control group in μCT analysis and hyperalgesia of hindlimbs.

Conclusion: In this study, ALN prevented bone loss and mechanical hyperalgesia in hindlimbs induced by unloading. The results suggest that bone resorption is one of the causes of osteoporotic pain.

MiRNAs Involved in the Osteoblastic Function are Altered in Human Osteoporotic Bone. Natalia Garcia-Giralt*[1], Laura De-Ugarte[2], Susana Balcells[3], Sergi Ariño-Ballester[4], Guy Yoskovitz[5], Santos Martinez-Diaz[6], Robert Guerri Fernandez[7], Leonardo Mellibovsky[8], Roser Urreizti[3], Xavier Nogues[9], Daniel Grinberg[10], Adolfo Diez-Perez[11]. [1]IMIM, Spain, [2]MSRU,IMIM (Institut Hospital del Mar d'Investigacions Mèdiques), Spain, [3]Departament de Genètica, Universitat de Barcelona, IBUB, Centro de Investigación Biomédica en Red de Enfermedades Raras (CIBERER), ISCIII, Spain, [4]MSRU,IMIM (Institut Hospital del Mar d'Investigacions Mèdiques), Spain, [5]IMIM, Parc de salut Mar, RETICEF, Spain, [6]Department Orthopaedic Surgery & Traumatology, Hospital del Mar, Spain, [7]Fundacio IMIM, Spain, [8]Servei de Medicina Interna, Hospital del Mar, Universitat Autònoma de Barcelona, Spain, [9]Institut Municipal D'Investigació Mèdica, Spain, [10]The University of Barcelona, Spain, [11]Servei de Medicina Interna, Hospital del Mar, Universitat Autònoma de Barcelona,IMIM (Institut Hospital del Mar d'Investigacions Mèdiques), Red Temática de Investigación Cooperativa en Envejecimiento y Fragilidad (RETICEF), Spain

It is well known that osteoblastic function is abnormal in osteoporotic bone. Moreover, we have observed by Real-time PCR that fresh human bone from fractured hips expresses low levels of osteoblastic markers (Alkaline phophatase, BMP2, osteocalcin and COL1A1). Our aim was to identify miRNAs differentially expressed in bone samples of fractured compared to healthy individuals. Additionally, we performed a miRNA profiling of primary osteoblasts (hOB) to assess the origin of the differentially expressed miRNAs. Total RNA was extracted from fresh femoral neck trabecular bone from women undergoing hip replacement due to either osteoporotic fracture (n=6) or osteoarthritis in the absence of osteoporosis, according to BMD measurements (n=6), age and BMI-matched, and from hOBs at passage 0, obtained from knee replacement due to osteoarthritis (n=4). Samples were hybridized to the miRCURY LNA™ microRNA Array 7th (Exiqon, Denmark), in the manufacturers' facilities. For comparison of expression levels, the threshold was set at log fold change > 1.5 and a p-value < 0.05 (Benjamini and Hochberg corrected).

Overall, 790 miRNAs were detected in fresh bone samples, from which 292 (35.89%) were also detected in hOBs. A subset of 82 microRNAs was found to be significantly differentially expressed between osteoporotic and control samples. Upon validation of 8 miRNAs with the lowest p-values, and for which a validated assay was available (miRCURY LNATM Universal RT microRNA qPCR assay), two of them were confirmed: miR-320a and miR-483-5p. They were both found over-expressed in the osteoporotic samples (and expressed in hOBs). The intersection pathways involving genes targeted by miR-320a and miR-483-5p are mainly prostate cancer (4.496403e-14), PI3K-Akt signalling (5.614388e-08) and focal adhesion (6.000918e-07). It is noteworthy that these three pathways share many genes, such as: SOS2, IGF1R, PDK1, PDGFD, PIK3CA, AKT3, PTEN and MAPK1. Most of these genes are involved in cell proliferation and survival signalling, suggesting that a dysfunction in the osteoblastic cell renewal is occurring in the osteoporotic bone.

In conclusion, osteoporotic bone has an altered widespreadly osteoblast function at both key osteoblast gene expression as well as miRNAs expression levels.

MO0364

Understanding Low Bone Mass In Down Syndrome Patients. Archana Kamalakar*[1], Diarra Williams[2], Nisreen Akel[1], Tristan Fowler[3], Frances Swain[4], Kent McKelvey[4], Dana Gaddy[1], Larry Suva[1]. [1]University of Arkansas for Medical Sciences, USA, [2]University of Arkansas for Medical Sciences, USA, [3]Universität Wien, Aut, [4]Department of Orthopaedic Surgery, University of Arkansas for Medical Sciences, USA

Down Syndrome (DS), trisomy of human chromosome 21, is the most common chromosomal abnormality that affects live infants, with a prevalence of around 1:700 in the US. There are currently approximately 5.6 million people with DS world-wide. DS females have ovaries containing reduced numbers of small follicles with greatly increased rates of atresia, whereas DS males are often well-masculinized, but infertile. We and others have reported an increased prevalence of low bone mass in men and women with DS. However, we have shown (in both DS mice (Ts65Dn) and humans) that the mechanism of low bone mass in DS involved low bone turnover, in the face of overt hypogonadism. In an effort to resolve this conundrum in a series of 18 euthyroid, and vitamin D and calcium replete men with DS (mean age 29 ± 7 years), we measured BMD as well as serum bone turnover markers (NTx, P1NP) and a marker of bone formation, sclerostin. NTx and P1NP were significantly decreased compared with age-matched normals, yet serum sclerostin levels were not different between DS and normals. To determine the potential influence of reproductive hormones in the Hypothalamic-Pituitary-Gonadal-Skeletal axis on low BMD, we also measured serum levels of the gonadotropins (LH, FSH) and testosterone (T). Interestingly, LH and FSH levels were both significantly elevated compared with the normal reference ranges. In all patients, BMD Z-score was less than -2.0, confirming the expected low BMD. All 18 males with DS had serum T levels within the low normal reference range. We next examined the expression of sclerostin and RANKL in the long bones of DS mice (Ts65Dn and TC1) by immunohistochemistry. RANKL staining was difficult to detect but unchanged compared with littermate controls. In addition, although more robust, sclerostin immunostaining was not different between WT and DS. In culture, the low bone turnover was replicated with decreased numbers of TRAP+ multinucleated cells as well as osteoblasts in whole bone marrow cultures. In osteoclast motility assays, a significant increase was observed in precursor motility of bone marrow macrophages from Ts65Dn mice compared to WT type mice. These data suggest that the decreased bone turnover in the face of hypogonadism in these DS patients maybe accompanied by a compensatory increase in the motility of TRAP+ osteoclast precursors. In sum, the low bone mass in these patients remains unexplained by decreased sex steroids or elevated LH and FSH levels.

MO0365

The effects of androgens on cortical bone mass do not result from direct actions on osteoblasts or osteoclasts. Semahat Serra Ucer*[1], Shoshana Bartell[2], Ha-Neui Kim[3], Srividhya Iyer[2], Li Han[2], Aaron Warren[4], Julie Crawford[4], Maria Jose Almeida[2], Stavros Manolagas[2]. [1]University of Arkansas for Medical Sciences, USA, [2]Central Arkansas VA Healthcare System, Univ of Arkansas for Medical Sciences, USA, [3]Univ. Arkansas for Medical Sciences, Central Arkansas VA Healthcare System, USA, [4]Center for Osteoporosis & Metabolic Bone Diseases, Central Arkansas Veterans Healthcare System, University of Arkansas for Medical Sciences, USA, USA

Global deletion of the androgen receptor (AR) in male mice causes high bone turnover, increased resorption, and decreased cortical and trabecular bone mass. Targeted AR deletion in the entire osteoblast lineage, on the other hand, decreases trabecular, but not cortical, bone mass. It remains possible, therefore, that direct actions of androgens on cells of the osteoclast lineage mediate their protective effects on the cortical compartment and/or contribute to their effects on cancellous bone in males. To explore this possibility, we have generated mice with selective deletion of AR in cells of the monocyte/macrophage lineage by crossing mice harboring a floxed AR allele (exon 2) with mice expressing the Cre recombinase under the control of regulatory elements of the LysM gene (AR flox;LysM-Cre mice). Analysis of genomic DNA extracted from cultured bone marrow-derived macrophages and osteoclasts revealed >90% reduction of the AR conditional allele. The number of myeloid cells (CD11b+) were similar between AR flox;LysM-Cre and LysM-Cre littermate control mice, as determined by flow cytometry. At 12 and 26 weeks of age femoral and spinal DEXA BMD, trabecular bone volume in the distal femur and L5 vertebra, and cortical thickness in femoral mid-shaft, by μCT were also indistinguishable between the AR flox;LysM-Cre mice and their littermate wild-type controls. We next orchidectomized (ORX) AR flox;LysM-Cre and LysM-Cre controls at 20 weeks of age and examined their skeletons 6 weeks later. ORX decreased cortical thickness, trabecular bone volume and trabecular number to the same extent in both genotypes, compared to their respective sham-operated littermates. These findings indicate that the osteoclast AR plays no role in the protective effects of androgens on cancellous or cortical bone. Taken together with the evidence that the osteoblast AR affects only cancellous bone, our results also indicate that neither the osteoblast nor the osteoclast AR are involved in the protective effects of androgens on cortical bone mass. Hence, the effect of androgens on cortical bone mass must be exerted indirectly, perhaps via effects on muscles and mechanical strains and/or changes in growth factor production.

Transmenopausal changes in cortical bone quality. Sonja Gamsjaeger*[1], Wolfgang Brozek[1], Robert Recker[2], Klaus Klaushofer[3], Eleftherios Paschalis[4]. [1]Ludwig Boltzmann Institute of Osteology at the Hanusch Hospital of WGKK & AUVA Trauma Centre Meidling, 1st Medical Department, Hanusch Hospital, Austria, [2]Creighton University, USA, [3]Hanusch HospitalLudwig Boftzmann Institute of Osteology, Austria, [4]Ludwig Boltzmann Institute for Osteology, Austria

Hormonal changes due to menopause are considered to be among the culprits of postmenopausal osteoporosis. These changes are believed to result in bone tissue loss and decrease in bone mineral density (BMD), mainly through alterations in bone remodeling rates. Specifically, bone remodeling rates (based on activation frequency of new remodeling sites) in women 1 year after cessation of menses are roughly twice those of healthy premenopausal women.

Bone strength depends on its amount and quality. Bone quality includes its structural and material properties. Bone material properties are dependent on bone turnover rates. Remodeling rates are significantly increased immediately following menopause.

We have previously reported that menopause results in changes in bone quality of human iliac crest trabecular bone. In the present study we used Raman microspectroscopic analysis of double iliac crest biopsies with a spatial resolution of 1 μm obtained before and immediately after menopause (1 year after cessation of menses) in healthy females, to investigate changes in material properties due to menopause in cortical bone. In particular, the mineral / matrix ratio, the relative proteoglycan and lipid content, the mineral maturity / crystallinity, and the relative pyridinoline collagen cross-link content were determined in cortical bone as a function of tissue age (freshly deposited bone in osteons and at endosteal surfaces based on the presence of fluorescent double labels, and older cortical interstitial bone). 2-way ANOVA statistical analysis indicated that although all monitored bone quality parameters were significantly dependent on tissue age, no significant differences due to menopause were evident at any of the cortical microanatomical locations examined, unlike what we have previously described in trabecular bone.

The results of the present study suggest that menopause does not affect the bone quality of cortical bone. Moreover, they emphasize the need to consider cortical separately from the trabecular compartment (most likely due to different turnover rates and specific surface area). Finally, these results help in understanding changes due to aging hallmarks such as menopause, which in turn facilitates the discrimination from changes due to diseases such as osteoporosis.

MO0367

Long-term low-molecular-weight heparin and bone health in non-pregnant patients: A systematic review. Olga Gajic-Veljanoski*[1], Chai W. Phua[2], Prakesh S. Shah[3], Angela M. Cheung[4]. [1]University Health Network, Canada, [2]Division of Hematology, Dept of Medicine, University of Toronto, Canada, [3]Departments of Paediatrics & IHPME, University of Toronto, Canada, [4]University Health Network-University of Toronto, Canada

Introduction: Patients who require long-term anticoagulation with low-molecular-weight heparin (LMWH) such as cancer patients or the elderly may be at increased risk of fractures. However, it is unclear whether long-term use of LMWH has any deleterious effect on bone health.

Objective: To determine if LMWH therapy of at least 3 months' duration adversely affects bone outcomes in non-pregnant adult populations.

Methods: We systematically searched Medline, EMBASE, the Cochrane Library, conference proceedings and bibliographies until February 2014. We included comparative studies, published in English, conducted in non-pregnant adult populations, reporting the long-term effect of LMWH (>= 3 months) on fractures or bone mineral density (BMD). Two reviewers independently extracted the data and assessed methodological quality of the included studies. We used a tool developed by the Cochrane Collaboration Back Review Group to evaluate the method quality of clinical trials and the Newcastle Ottawa Scale to evaluate the quality of observational studies. We qualitatively synthesized evidence from all studies and used random-effects meta-analysis to quantify the effect of LMWH on fractures.

Results: Of 2726 identified records, we excluded 2603 citations based on the title and abstract screening and examined 123 citations in full. Sixteen articles reporting 14 studies were included: 10 clinical trials (4865 patients) and four observational cohort studies (251 patients). Majority of studies had high risk of bias. In most studies, BMD and fractures were assessed as secondary outcomes. In a random-effects meta-analysis of the five trials (2280 patients), LMWH for 3-6 months did not significantly increase the relative or absolute risk of all fractures (pooled risk ratio=0.58, 95%CI: 0.23 to 1.43, I2=12.5%; risk difference=0.00, 95%CI: -0.02 to 0.02), when compared to unfractionated heparin, vitamin K antagonists or placebo. Qualitative synthesis of the

prospective cohort studies (166 patients) suggested that LMWH for 3-24 months decreased the mean BMD by 2.8-4.8% (depending on the BMD site) compared to vitamin K antagonists that decreased the mean BMD by 1.2-2.5%.

Conclusions: The long-term use of LMWH may not increase the risk of fractures, but may adversely affect BMD. The strength of evidence is weak and further well-designed studies are warranted.

The Association Between Use of Antidepressants and Bone Quality Using Quantitative Ultrasound. Päivi Rauma*[1], Julie Pasco[2], Michael Berk[3], Amanda Stuart[4], Risto Honkanen[1], Heli Koivumaa-Honkanen[5], Jason Hodge[6], Lana Williams[7]. [1]University of Eastern Finland, Finland, [2]Deakin University, Australia, [3]Deakin University; The University of Melbourne, Australia, [4]Deakin University, Australia, [5]University of Eastern Finland; Kuopio University Hospital; University of Oulu, Finland, [6]Deakin University; The Geelong Hospital, Australia, [7]The University of Melbourne, Australia

Osteoporosis and depression are major public health problems worldwide. Studies have reported an association between antidepressant use, mainly selective serotonin reuptake inhibitors (SSRIs) and bone density, but the issue remains unclear.

Altogether 849 Australian men (aged 24-98 years) from the Geelong Osteoporosis Study (GOS) completed a comprehensive questionnaire in 2006-2011 and had quantitative ultrasound (QUS) heel measurements. Bone quality was indexed by Broadband Ultrasound Attenuation (BUA), Speed of Sound (SOS) and Stiffness Index (SI). The cross-sectional associations between these parameters and use of antidepressants were studied using multivariate linear regression adjusted for anthropometric, medication and lifestyle factors. The study was approved by the Human Research Ethics Committee at Barwon Health and all participants provided written, informed consent.

At the time of assessment, 61 (7.2%) men were using antidepressants, of which 44 (72.1%) used SSRIs. Mean SI values were 95.4% and 100.2% (p=0.076), BUA 115.7 dB/Mhz and 120.8 dB/MHz (p=0.020) and SOS 1566.9 m/sec and 1572.5 m/sec (p=0.32) for antidepressant users and non-users, respectively. After adjustments antidepressant use was associated with lower SI (p=0.002), SOS (p=0.010) and BUA (p=0.053). However, body weight was identified as an effect modifier; QUS values were lower for antidepressant users with low weight (<90kg) only.

In conclusion, use of antidepressants was associated with lower bone quality measures of QUS for men with low body weight. Thus, osteoporosis should be considered among men with light body weight when antidepressants are prescribed.

MO0369

Bone Marrow Fat (BMT), Energy Metabolism and Bone Mineral Density (BMD) in Young Women with Cushing Disease (CD). Sergio Luchini Batista*[1], Marcello Henrique Nogueira-Barbosa[2], Iana Mizumukai de Araújo[2], Adriana Lélis Carvalho[2], Carlos Ernesto Garrido Salmon[3], Ayrton Custódio Moreira[2], Margaret de Castro[2], Francisco José Albuquerque de Paula[2]. [1]School of Medicine of Ribeirao Preto, University of Sao Paulo, Brazil, [2]School of Medicine of Ribeirão Preto, University of São Paulo, Brazil, [3]Faculty of Science & Letters, University of São Paulo, Brazil

Introduction: Glucocorticoid-induced osteoporosis (GIO) is a multifactorial disorder involving systemic (hypogonadism, impaired GH/IGF-I and PTH secretion and decreased vitamin D action) as well as tecidual alteration in bone cells crosstalk (i.e., increased RANKL, decreased osteoprotegerin). Osteocyte and osteoblast apoptosis has also been considered an important mechanism for bone loss in this condition. Although rare, Cushing Disease is the most important cause of endogenous hypercortisolism. It typically differs from GIO due to the maintenance of adrenal androgen secretion (e.g., S-DHEA, DHEA and androstenedione). Our aim was to measure Bone Marrow Fat (BMF), Bone Mineral Density (BMD) and some energy metabolism parameters in young women with CD. Material and Methods: The study comprised 28 young women, 14 with CD and 14 controls (C), matched by age (C=35.4±10.3 vs CD= 34.5±9.2years) and height (C=1.65±0.08 vs CD=1.62±0.05m). Blood sample was collected after overnight fast for measurement of glucose, insulin, IGF-I, osteocalcin, and CTX. BMD was evaluated in L1-L4, femoral neck, total hip. ^{1}H magnetic resonance spectroscopy (1.5T) in lumbar spine (L3) was used to evaluate BMF. Results: Body weight (C=60.3±8.8 vs CD=89.2±17.3Kg), waist circumference (C=79.5±10.0 vs CD=111.8±11.6cm) and BMI (C=22.4±2.9 vs CD=33.9±5.9Kg/m^2) were higher in CD ($p<0.05$). CD patients showed alteration in the circadian rhythm of salivary cortisol (9am=2510±1182ng/dl, 23h=1784 ±989ng/dl) and in response to 1mg-dexamethasone suppression test (1786±1861ng/dl). CD group exhibited greater serum levels of alkaline phosphatase (C=150±30 vs CD=190±40U/L), glucose (C= 86±7 vs CD=136±59mg/dl), insulin (C=7.9±3.7 vs CD=29.7±25.2µIU/ml) and HOMA-IR (C=1.68±0.84 vs CD=10.31±9.22). The serum levels of creatinine, calcium, phosphorus, albumin, PTH and 25-OHD (C=22.8±9.6 vs CD=17.3±8.4ng/mL) were similar in both groups. Despite higher BMI, BMD in L3 was slightly lower in CD group (C=1.000±0.101 vs CD=0.945±0.086g/cm^2), but 57% of CD patients showed Z-score lower than -1.0, whereas this figure was 21% in C. Bone marrow fat was significantly higher in CD than in C (37.1±8.7 vs 20.8±8.2%; $p<0.05$). Conclusion: Endogenous hypercortisolism due to CD impacts trabecular bone even in young women. While trabecular bone is negatively affected, bone marrow fat is significantly enhanced in these patients. Our results encourage further studies to unveil the role of insulin resistance and BMF into bone deterioration in CD.

MO0370

Ineffective fracture prevention by bisphosphonate in patients undergoing high dose glucocorticoid therapy with a FRAX ten year probability greater than 5.8%. Goichi Kageyama*[1], Takaichi Okano[2], Kousaku Tsuda[2], Yuzuru Yamamto[3], Daisuke Sugiyama[4], Goh Tsuji[5], Shunichi Kumagai[5], Akio Morinobu[6]. [1]Kobe University Hospital, Japan, [2]Kobe University Hospital, Japan, [3]Kobe University Hospital, Japan, [4]Keio University, Japan, [5]Shinko Hospital, Japan, [6]Kobe University Hospotal, Japan

(Background) High dose glucocorticoid (GC) therapy (PSL>0.8mg/kg/day) is often provided to patients with systemic rheumatic disease. GC induced osteoporosis (GIO) is a common complication of high dose GC therapy and bisphosphonate(BP) is frequently used as a first-line prevention of GIO and fragile fractures. However, some patients are still at high risk of bone fractures despite bisphosphonate administration. The World Health Organization fracture risk assessment tool (FRAX) is used to calculate the 10-year probability of major (hip, clinical spine, humerus or wrist fracture) fractures and has been recently adopted to the treatment guidelines for GIO and for assessment of fracture risk. Drugs more effective than BP have recently become available, but it is unclear which patients with high dose GC therapy should be given the newer drugs for GIO prevention.

(Aim) To identify patients with high dose GC therapy at a high risk of developing fragility fracture despite bisphosphonate treatment.

(Method) We conducted a retrospective study on systemic rheumatic disease patients who were treated with PSL>0.8mg/kg/day at Kobe University Hospital from April 1988 to March 2012. The fracture risk at the start of high dose GC therapy was assessed by FRAX. Comparison between patients who remained fracture-free for over 5 years and those who suffered fractures within 5 years despite taking bisphosphonate were focused in particular.(Results) 229 (SLE 76, Vasculitis syndrome 58, PM/DM 51, AOSD 12, MCTD 7, others 25) patients were included and the mean observational period was 1819 days (95% CI 1653-1989). 57 patients (52 clinical spinal, 3 hip, 1 humerus, 1 wrist) suffered from fracture. 28 patients suffered from fracture within 5 years despite taking BP. 94 patients were fracture-free for over 5 years with or without BP. Receiver operating characteristic (ROC) analysis revealed that the optimal cut-off of FRAX ten year probability failing to prevent fracture over 5 years despite bisphosphonate treatment was 5.8% (Sensitivity 89.3%, Specificity 74.5%, Area under the curve 0.885). Kaplan-Meier analysis also revealed that bisphosphonate had no effect in reducing fractures in patients with FRAX?5.8%.

(Conclusion) BP is ineffective for preventing fractures in high-risk patients (FRAX>=5.8%) undergoing high dose GC therapy. Thus, these patients require alternative prophylactic measures for fragility fractures.

Serum Levels of Growth Differentiation Factor (GDF)-15 Are Elevated, And Decreased After Introduction of Oxygen Therapy in Japanese Male Subjects with COPD-Associated Osteoporosis. Reiko Watanabe*[1], Takeshi Tanaka[2], Keisuke Aita[2], Masaaki Hagiya[2], Nobuyuki Tai[2], Junko Hirano[2], Kyoko Yokosuka[3], Hisami Yamakawa[4], Tsutomu Yarita[3], Toshiaki Homma[2], Ryo Okazaki[1]. [1]Teikyo University Chiba Medical Center, Japan, [2]Teikyo University Chiba Medical Center, Japan, [3]Yarita Hospital, Japan, [4]Yaria Hospital, Japan

Background&Aim: We have reported a high prevalence of vertebral fractures in male COPD patients in Japan. The mechanism of COPD-associated osteoporosis, however, still remains unclear. The aim of the present study is to investigate bone metabolism in COPD and its change after introduction of oxygen therapy. We also examined a role for GDF-15, a marker of congestive heart failure that has recently been shown to be induced by hypoxia in osteocytes through HIF-1α.

Subjects&Methods: In this cross-sectional study, 52 Japanese male COPD subjects (mean age 70.0 ± 8.3, BMI 21.3 ± 3.9 kg/m^2) were enrolled. The number and severity of existing vertebral fractures was assessed by lateral spine x-rays, and bone mineral density was measured by DXA. Bone metabolic markers and parameters of calcium metabolism were measured by standard assays. Serum levels of GDF-15 was measured by ELISA.

Results: We found prevalent vertebral fractures in 38 (73.1%), multiple fractures in 25 (48.1%), and SQ Grade 2 or 3 fractures in 11 (21.2%). Lumber spine and femoral neck BMD T scores were −1.13±1.49 and −1.83±1.26, respectively. Mean 25(OH)D levels were 23.7±11.0 ng/ml, which showed no correlation with PTH levels. Mean GDF-15 levels were 1747 pg/mL (healthy male mean: 1020 pg/mL (59 years)) and correlated positively with age, creatinine, interleukin-6, pyridinoline 1CTP, and negatively with albumin, hemoglobin(Hb) and LDL-cholesterol. In multivariate linear regression analysis, Hb was the only independent determinant of GDF-15 (R^2=0.250,β=-0.459, p=0.007). When the subjects were divided into four groups according to the PTH and 25(OH)D levels, GDF-15 was significantly elevated (2714 pg/mL, p=0.024) and Hb was decreased (12.1 g/dl, p=0.00001) in subjects with PTH <42 pg/mL and 25(OH)D <20 ng/ml. Interestingly, in 4 patients who were introduced to the oxygen therapy, GDF-15 dramatically decreased (mean 6047→1779 pg/mL) within one month, while PTH tended to increase (39.5→48.5 pg/mL) and Tracp-5b significantly increased (131→379 mU/dL, p=0.030) without any appreciable changes in Hb.

Conclusions: GDF-15 was shown, for the first time, to be elevated and immediately decreased after oxygen therapy in COPD subjects. The results further suggest that systemic hypoxia affects bone metabolism at least in part indirectly through suppression of PTH secretion. Further examination is needed to elucidate pathophysiological roles of GDF-15 and PTH in COPD-associated osteoporosis.

MO0372

Differential effects of teriparatide (TPTD) and zoledronic acid (ZOL) on bone mineralization density distribution (BMDD) at 6 and 24 months in the SHOTZ study. David Dempster*[1], Paul Roschger[2], Barbara M. Misof[3], Hua Zhou[4], Eleftherios Paschalis[5], Fangqiu Zhang[6], Jahangir Alam[7], Valerie A. Ruff[8], Klaus Klaushofer[9], Kathleen Taylor[10], For the SHOTZ Investigators [11]. [1]Columbia University, USA, [2]L. Boltzmann Institute of Osteology, Austria, [3]Ludwig Boltzmann Institute of Osteology, Austria, [4]Helen Hayes Hospital, USA, [5]Ludwig Boltzmann Institute for Osteology, Austria, [6]inVentiv Health Clinical, Canada, [7]Lilly USA, USA, [8]Eli Lilly & Company, USA, [9]Hanusch HospitalLudwig Boftzmann Institute of Osteology, Austria, [10]Eli Lilly & Company, USA, [11], USA

Purpose: SHOTZ assessed the progressive effects of TPTD and ZOL on bone remodeling and material properties in postmenopausal women with osteoporosis. Previously, we reported that bone formation indices were significantly higher in patients receiving TPTD versus ZOL. In this analysis, we report BMDD results − a measure that reflects bone matrix mineralization. This is the first head-to-head study to compare the effects of an anabolic versus an antiresorptive agent on BMDD over time.

Methods: Subjects from the 12-month randomized study were eligible to enroll in a 12-month extension and assigned open label to their original treatment regimen: TPTD 20 µg/d (sc injection) or ZOL 5 mg/y (IV infusion). Biopsies were obtained at month 6 (TPTD, n=28 and ZOL, n=31) and month 24 (TPTD, n=10 and ZOL, n=10). Quantitative backscattered electron imaging was used to obtain BMDD measurements from the same bone samples used for histomorphometric analyses.

Results: In cancellous bone, CaMean (mean calcium concentration), CaWidth (width of the distribution peak), and CaLow (percentage of low mineralized bone) provided the clearest distinction between TPTD and ZOL at months 6 and 24 (Table). CaMean was significantly higher while CaLow and CaWidth were significantly lower in the ZOL group at both time points, indicating higher mineralization density and more homogeneous mineral content with ZOL. Compared to TPTD, mean BMDD curves (Figure) show that bone matrix mineralization in the ZOL group increases (peak shift to the right) and becomes more homogeneous (narrower peak width) over time. Within the ZOL group, significant changes were seen in all parameters from month 6 to 24, indicating a progressive increase in mineralization density. In sharp contrast, mineralization density did not increase over time in the TPTD group, reflecting ongoing deposition of new bone. Similar within- and between-group differences were observed in cortical bone.

Conclusions: In this study, TPTD stimulated new bone formation, producing a bone mineral matrix that remained relatively heterogeneous with a stable mean mineral content. ZOL slowed bone turnover rate and prolonged secondary mineralization, producing a more homogeneous and, over time, a more highly mineralized bone matrix. While both TPTD and ZOL increase clinical measures of bone mineral density (BMD), this study shows that the underlying mechanism for the BMD increase with each drug is fundamentally different.

[a]**CaMean** = Mean calcium concentration in the area of bone measured.
[b]**CaPeak** = The most frequent calcium concentration occurring in the area of bone measured.
[c]**CaWidth** is a measure of the variability of mineralization density (heterogeneity).
[d]**CaLow** is a measure of the area of bone with the least amount of calcium.
[e]**CaHigh** is a measure of the area of bone with the most amount of calcium.
Values are shown as mean (SD). *P* values are for 2-sample t-test. *P<0.05 Month 24 vs Month 6.
BMDD=bone mineralization density distribution; TPTD=teriparatide; ZOL=zoledronic acid.

Table

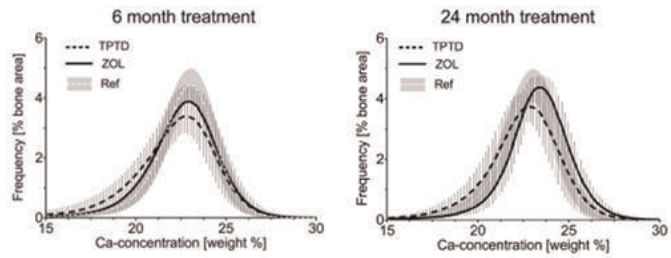

Figure. Changes in cancellous BMDD with type and duration of treatment.
The mean BMDD curves (±1SD) of treatment groups (TPTD and ZOL) show a progressively increasing difference with treatment duration. Compared to TPTD, the bone matrix mineralization becomes more homogeneous (narrower peak width) and higher (peak shift to the right) for ZOL treatment. Reference data (historical) were obtained from 52 healthy adults (Roschger et al. *Bone* 2003;32:316-23).

MO0373

Early increases in IGF-1 receptor density on circulating osteogenic progenitor cells predict responsiveness to teriparatide. Adi Cohen*[1], J. Sanil Manavalan[2], Stavroula Kousteni[1], Robert Recker[3], Joan Lappe[4], David Dempster[5], Donald McMahon[6], Mariana Bucovsky[7], Mafo Kamanda-Kosseh[7], Julie Stubby[8], Elizabeth Shane[6]. [1]Columbia University Medical Center, USA, [2]Columbia University, USA, [3]Creighton University, USA, [4]Creighton University Osteoporosis Research Center, USA, [5]Columbia University, USA, [6]Columbia University College of Physicians & Surgeons, USA, [7]Columbia University, USA, [8]Creighton University, USA

In an open-label pilot study of teriparatide (TPTD; 20 mcg daily for 2 yrs) in 21 premenopausal women with idiopathic osteoporosis (IOP), we found substantial

increases in lumbar spine (LS; mean ± SD: 10.8 ± 8.3%), total hip (TH; 6.2 ± 5.6%) and femoral neck (FN; 7.6 ± 3.4%) BMD. However, LS BMD response to TPTD varied from -1% to +20%. Lower pre-TPTD bone turnover by serum bone turnover markers (BTM) and bone biopsy, smaller 1M increases in BTM, and higher BMI and body fat predicted lower responsiveness to TPTD. Since IGF-1 is low in obesity and is also critical for TPTD action on osteoblasts, we investigated whether differential TPTD responsiveness was mediated by IGF-1 related mechanisms. Serum IGF-1 and IGFBP3 did not change in response to TPTD. However, baseline serum IGF-1 was inversely associated with TPTD response. Prompted by these findings, we measured IGF-1 receptor (IGF-1R) density on circulating osteogenic progenitor (COP) cells. We obtained peripheral blood mononuclear cells (PBMCs) at baseline and 1, 3 and 18M of TPTD in 11 women who participated in the pilot study (38 ± 7 yrs, BMI 20.9 ± 3.0 kg/m^2). Following exclusion of hematopoietic lineage cells, COPs were identified by flow cytometry with antibodies against osteocalcin and Runx2 and designated as %COP, meaning % of PBMCs expressing these markers. IGF-1R density on COPs was measured by mean channel fluorescence (MCF) of antibodies to IGF-1R. At baseline, %COP correlated directly with cancellous wall width (r;p: 0.85;0.0008) and mineral apposition rate (0.76; 0.006) on transiliac biopsies. %COP increased with TPTD, peaking at 3M by 221% (p=0.02). IGF-1R MCF increased by 128% (p=0.009) at 3M (Figure). Baseline %COP and the increase in COP at 3M did not predict BMD response to TPTD (Table). In contrast, the increase in IGF-R MCF in COPs (3M %change) correlated directly with early BMD response to TPTD. Although baseline IGF-1R MCF did not correlate with BMI and body fat, IGF-1R increase (3M %change) correlated strongly and inversely with BMI and body fat by DXA. We conclude that both %COP and IGF-1R density on COPs rise markedly in IOP women in response to TPTD. The increase in IGF-1R density on COPs correlates inversely with body fat and directly with early BMD response. These results suggest that body fat may be inversely associated with responsiveness to TPTD mediated via the IGF-1 axis. An early increase in IGF-1R density on COPs may play an important role in the osteoanabolic response to TPTD.

Effectiveness of Teriparatide in the Treatment of Osteoporosis, Data from Real-World Clinical Practice George O. Tsoukas1, Alaa Dekis2, Philip H. Tsoukas3, Louise Ullyatt1, Fiona Vickers, George M. Tsoukas1 1 Division of Endocrinology, 2 Division of Rheumatology, McGill University Health Center; 3 Department of Medicine, University College Dublin. Georges Tsoukas*. McGill University, Canada

Although the efficacy of teriparatide in bone metabolism has been demonstrated in multiple controlled clinical trials, data from longitudinal observational studies are limited. Such studies are essential in understanding real-world effectiveness of therapeutic interventions. In this study, we aim to demonstrate true population-based benefits of teriparatide in a clinical practice setting.

We conducted a retrospective chart review on a total of 286 patients seen at 4 different osteoporosis clinics in Montreal, Canada. All patients were treated according to Canadian Osteoprosis Guidelines. Fracture data were available on 240 of these patients. All fractures were clinical and reported according to Canadian guidelines.

51% of the patients received teriparatide for 18 months, 38% for 24 months and 11% for other duration of treatment.The mean follow up after cessation of teriparatide was 36 months ranging from 5 to 106 months. All patients after teriparatide therapy received an antiresorptive.

During teriparatide treatment, new fractures occured in 9 patients, all fractures were non-hip and non-vertebral. After cessation of teriparatide, new fractures occured in 17 patients, 3 patients had 2 fractures each, with a total of 20 fractures. Of these, 15 were non-vertebral fractures, 3 vertebral and 2 hip. After 24 months, teriparatide increased the bone mineral density by 9% in the lumbar spine and 5% in the hip. the alkaline phosphatase, osteocalcin and c-terminal telopeptide increased by 26, 111 and 107% respectively at 18 months. Compliance to therapy was reported to be 85% at 18 months.

Our results suggest that treatment of osteoporosis with teriparatide significantly increased spinal bone mineral density. The fracture outcome evaluation in this retrospective review of the clinical practice data indicated that the occurence of fracture incidence during teriparatide therapy was low (3.7%) with no new vertebral fractures. In the post teriparatide therapy follow up period, an increase in the incidence of fractures was observed with most (85%) being non-vertebral.

Effects of Recombinant Human Parathyroid Hormone on Bone Structure in Premenopausal Women with Lower Extremity Stress Fractures: A Pilot Study. Ellen Almirol*[1], Lisa Gao[2], Shelley Hurwitz[3], Meryl Leboff[4]. [1]Brigham & Women's Hospital, USA, [2]Case Western Reserve University School of Medicine, USA, [3]Brigham & Women's Hospital, USA, [4]Brigham & Women's HospitalProfessor of Medicine, Harvard Medical School, USA

Stress fractures are repetitive motion injuries of the lower extremities, which are more common in women than men. Although Teriparatide (TPD) has advanced osteoporosis care, there are no randomized, placebo (PBO)-controlled trials on effects of TPD on bone structure in adults with stress fractures. In this pilot study, we evaluated the effects of TPD vs PBO on structural changes according to peripheral quantitative computed tomography (pQCT) in women with lower extremity stress fractures. We recently found early and robust rises in bone formation markers and a larger anabolic window in women treated with TPD vs PBO (ASBMR 2013). Premenopausal women (aged 21-45) with lower extremity stress fractures were randomized to daily TPD (20μg s.c.) or placebo injections for 8 weeks; women received calcium and vitamin D to achieve daily intakes of 1000 mg of calcium and 400 IU vitamin D3. To assess changes in bone structure, pQCT (XCT 3000 Stratec Germany) at the distal radius (4, 33%) and unaffected tibia (4, 38, 66%) were measured at 0, 8 and 12 weeks. Serum biomarkers of bone formation [amino terminal propeptide of type 1 collagen (P1NP) and osteocalcin (OC)] and resorption (C-telopeptide) were measured at 0, 4 and 8 weeks. Groups were compared using the Wilcoxon Rank-Sum Test or Chi Square test, as appropriate. Of 101 women screened, 13 were randomized to TPD (n=6) or PBO (n=7). Compared with PBO, the TPD-group at the 38% tibial site showed an increase in cortical thickness (TCT) and cortical area (TCA) at 8 weeks ($p \leq 0.01$). In the PBO-treated group, there was an increase at the tibial 38% cortical density (TCD) site at 8 weeks (p=0.01), with no change in the TPD-treated group, possibly related to the increase in TCA. No significant differences were observed between groups at the distal radius over the study period. Changes in P1NP and OC with TPD were positively correlated with changes at the 38% tibial TCA (p=0.03 and 0.01) and TCT (p=0.01 and 0.02) site at 8 weeks. This short-term study in women with stress fractures treated with TPD or PBO showed increases in TCA and TCT at the 38% tibial site, with an unexpected rise in the TCD in the PBO group; changes in bone formation biomarkers were positively correlated with changes in TCA and TCT, but not TCD. This 8-week pilot study showed some potential benefit of TPD on bone structure, although larger PBO-controlled studies are needed to assess the systemic effects of TPD on bone in adults with stress fractures.

Er-Xian Decoction stimulates osteoblastic differentiation of bMSCs in OVX mice and its gene profile analysis. Qin Bian*[1], Yongjun Wang[2]. [1], USA, [2]Othopedic Surgery, Peoples Republic of China

Er-Xian Decoction (EXD), a traditional Chinese herbal formula, has been widely used for the treatment of postmenopausal osteoporosis. To evaluate osteogenetic effect of EXD on bMSCs in OVX mice and to search for its genes and pathways targets. Six-month-old ICR mice that underwent OVX were treated with EXD. After 3 months, bone mass was evaluated by microcomputed tomography, histological and immunohistochemical detection. The bone mesenchymal stem cells (bMSCs) from femurs and tibiaes were harvested to observe the self-renewal and differentiation capacity by Colony. forming unifibroblastic (CFU-F), Colony. forming adipocyte (CFU-Adipo) and alkaline phosphatase (ALP) staining. In addition, the expression of 26991 genes of bMSCs ex vivo at 2 weeks after EXD-treatment or of bMSCs in vitro after exposure to conditioned serum from EXD-treated rats was measured and analyzed using NimbleGen Gene Expression Profiling, Cluster and pathway analysis. Micro-CT displayed a decrease in bone mass at 3 month after OVX. EXD treatment increased bone mass, elevating osteocalcin (OC) protein levels in vivo and facilitating the self-renewal and osteoblastic differentiation of bMSCs ex vivo. Gene expression profile analysis revealed that EXD rescued several gene expressions that were dyregulated by OVX. These genes overlapped and concentrated upon ten pathways between ex vivo and in vitro experiments. EXD exerts an osteogenetic effect on bMSCs in OVX induced osteoporotic mice. Our results contribute to further study of its molecular mechanism and traditional use in the treatment of postmenopausal osteoporosis.

MO0377

First in Man Studies of Pharmacokinetic Profiles of a Novel Oral PTH(1-34). Jonathan Tang*[1], Hillel Galitzer[2], Christopher Washbourne[3], Isabelle Piec[4], Naifang Wang[5], Gregory Burshtein[6], Phillip Schwartz[7], Yoseph Caraco[8], Ehud Arbit[6], William Fraser[3]. [1]University of East Anglia, Norwich, UK, United Kingdom, [2]Entera Bio, Israel, [3]University of East Anglia, United Kingdom, [4]BioAnalytical Facility, University of East Anglia, United Kingdom, [5]Enter Bio, Israel, [6]Entera Bio, Israel, [7]Entera Bio, Israel, [8]Hadassah Hospital, Israel

Background: PTH(1-34) (Teriparatide) is an anabolic agent used in treatment of osteoporosis. It promotes bone formation and reduces the risk of vertebral and some non-vertebral fractures. The route of administration by daily subcutaneous (sc) injection can cause problems in certain patients. A new oral delivery system for human PTH(1-34) has been developed as a possible treatment option. Galitzer *et al.* presented pre-clinical data (ASBMR 2012, MO0402) and first-in-human results (ASBMR 2013, FR0378) on safety, tolerability and absorption dynamics of oral PTH(1-34) in various dosages. We now describe the pharmacokinetics (PK) of oral PTH(1-34) compared to sc and placebo in healthy subjects.

Objective: A single-center, double blinded, triple crossover study was designed to compare the 1.8 mg optimal dose of oral PTH(1-34) against standard dosage of teriparatide injection and oral placebo.

Method: The study was conducted following and in accordance with the Hadassah Medical Center ethical approval committee.12 healthy volunteers (6m/6f), 18-50y, received three treatments: single sc injection of 20µg FORTEO®, 1.8 mg oral PTH(1-34), or placebo. Blood samples were collected at time 0, 10, 15, 20, 30, 45, 60, 75, 90, 120, 180, 240, 300 minute post dose. Plasma concentration of PTH(1-34) (IDS, Tyne and Wear, UK) and cyclic adenosine 3',5'monophosphate (cAMP) were measured on all samples.

Results: All 12 subjects on oral PTH(1-34) showed rapid, post dose increase then decrease of PTH(1-34), from baseline mean (±SD) of 5.9 (1.8) pg/mL to peak mean of 185.3 (±128.8) pg/mL. Pharmacokinetic profiles of oral PTH(1-34) showed Cmax (pg/mL), Tmax (mins), $AUC_{0\text{-last}}$ of 238.3 (110.8), 17.5 (5.4) and 6161.7 (2726.7), respectively; whereas sc showed mean Cmax (pg/mL), Tmax (mins), $AUC_{0\text{-last}}$ of 172.3 (55.7), 20.8 (8.7) and 13965.9 (2984.8), respectively. Plasma cAMP increased in all subjects in response to oral PTH(1-34) and sc treatment. Serum adjusted calcium in all subjects remained within normal limits throughout the studies.

Conclusion: Pharmocokinetic profiles showed a single oral dose of 1.8 mg PTH(1-34) is rapidly absorbed, and no significant difference in Cmax and Tmax when compared with 20µg of sc teriparatide. A significant difference in the rate of plasma clearance and $AUC_{0\text{-last}}$ value was observed (fig.1). These differing profiles and modality of administration of PTH(1-34) could offer unique advantages in the treatment of calcium and metabolic bone disorders.

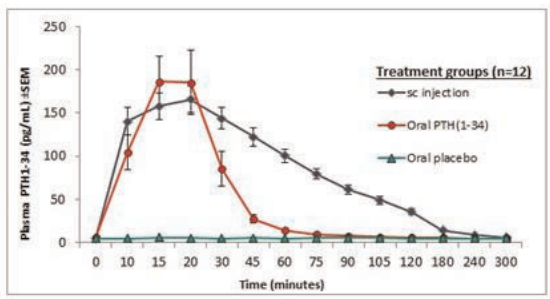

Figure 1: Pharmacokinetic profile showing changes in plasma PTH(1-34) levels in response to treatments.
One-way ANOVA analysis showed no significant difference in Cmax value achieved between oral PTH(1-34) and sc treatment. Plasma PTH (1-34) concentration declined more rapidly after oral treatment. Significant difference ($p<0.05$) in plasma PTH(1-34) was observed 20 minutes post treatment.

Figure1: Pharmacokinetic profile showing changes in plasma PTH(1-34) levels in response to treatment

Flavonoid class compounds abrogating sclerostin induced inhibition of Wnt/beta catenin signaling. Sung-Kil Lim[1], Eun Jin Kim*[2], Bo Mi Park[2], Dongdong Zhang[2], Nam Hee Kim[2], Joohyun Bae[2]. [1]Yonsei University College of Medicine, South Korea, [2]Yonsei University, South Korea

Sclerostin, the key negative regulator of Wnt signaling in bone, has been spotlighted as a potential target for osteoporosis because of its specific expression in osteocytes. Recent studies on anti-Sclerostin antibody treatment in mouse and phase II clinical trials revealed dual effects on bone; enhancement of bone formation and inhibition of bone resorption. Our group and others identified that loop2 region is the functional domain of Sclerostin for the interaction with Lrp5/6, and the NXI motif, and its neighboring residues play an important role for the inhibition of Sclerostin on canonical Wnt/beta catenin signaling. If NXI motif of sclerostin is a part of active binding site to LRP5/6, NXI motif mimic chemicals would abrogate sclerostin inhibition for the Wnt/beta-catenin signaling. Recently we found two flavonoid compounds abrogated sclerostin induced inhibition of Wnt/beta catenin signaling pathway. The compounds bound to E1 domain of LRP5 (IC50:39 uM). They stimulated ALP expression in ST2 stromal cells and also enhanced BMP2 induced ALP expression in C2C12 cells. In ex vivo analysis, they enhanced calvaria bone formation dose dependently. We are planning to perform in vivo bone formation analysis in OVX mouse model.

Inceased Serum Undercarboxylated Osteocalcin in use of Teriparatides could be reduced with concurrent use of vitaminK. Yoichi Kishikawa*[1], Taro Mawatari[2]. [1]Kishikawa Orthopedics, Japan, [2]Hamanomachi Hospital, Japan

BackgroundPreviously we reported changes in serum bone metabolism markers after 4 months of daily teriparatide (Forteo20µ/day) and weekly teriparatide (Teribone56.5µ/week) in treatment of vertebral fracture.

Concerning as the bone formed when teriparatide was used in the treatment of vertebral fracture, it is possible that bone with relatively increased ucOC was formed. It is expected that bone of better quality could be formed using vitaminK as an attended medicine.

A weekly chemically synthesized teriparatide (Teribone) has become available only in Japan.

Methods

162 patients with vertebral fracture were treated conservatively using soft Corset with administration of two types of Teriparatides.

Changes in serum TRACP 5b, ucOC, OC and ucOC/OC at 0, 4 and 8 months were analyzed. Intially vitamin D (alphacalcidole 0.25µ) was used for all the patients as a concurrent medicine besides Teriparatide. If ucOC increased too much in comparison to OC at 4months, switched from vitamin D to vitaminK (menateterenone45mg).

Results

Four subgroups devided by two factors are compaired statisitically, daily or weekly Teriparatide, alphacalcidole or menateterenone as a concurrent medicine. Daily with vitaminK 42 or vitaminD 50 cases, Weekly with vitaminK 21 or vitaminD 49 cases.

ucOC increased at 4months and clearly decreased at 8 months by switching from vitaminD to vitaminK. That tendency was obvious in daily Teriparatide than weekly one.

On the other hand OC was not affected by that switching.

Discussion

The meanig of ucOC icreasing after Teriparatide is not well known, but is suspected representing not only activating Osteoblasts but also lack of vitaminK when it makes a lot of new bone.

Concurrent use of vitamin K would be neccecery and could make good quallity bone when Teriparatide is used. An Animal study is expected rveal the effect of vitaminK attended.

MO0380

Increased Endocortical Formation and Periosteal Resorption at the Distal Tibia in Premenopausal Women with Idiopathic Osteoporosis Treated with 18 Months of Teriparatide. Mary Beth Tribble*[1], Adi Cohen[2], Chantal De Bakker[3], Joan Lappe[4], Robert Recker[5], Kyle Nishiyama[6], Mishaela Rubin[6], John Bilezikian[7], Elizabeth Shane[7], Xiaowei Liu[3]. [1]University of Pennsylvania, USA, [2]Columbia University Medical Center, USA, [3]University of Pennsylvania, USA, [4]Creighton University Osteoporosis Research Center, USA, [5]Creighton University, USA, [6]Columbia University, USA, [7]Columbia University College of Physicians & Surgeons, USA

Idiopathic osteoporosis (IOP) in premenopausal (PreM) women is characterized by abnormal bone microarchitecture and reduced bone stiffness. We've reported that teriparatide (TPTD) treatment improves trabecular bone quality at the distal radius and tibia, but little is known about TPTD's effect on cortical bone. We hypothesized that significant bone remodeling occurs at both the periosteal (PS) and endosteal (ES) surfaces in IOP patients treated with TPTD.

PreM women (n=18; 41±6 years) with a history of fragility fractures and/or low BMD received 20 µg of TPTD daily for 18 months. The distal tibia was scanned using high-resolution peripheral QCT (HRpQCT, Scanco) at 0, 6, and 18 months. A novel image registration technique was applied to precisely align the baseline and follow-up scans. PS, ES, and intracortical area (IC) envelopes were isolated (Fig 1A), and the follow-up scans were subtracted from the baseline to generate a BMD differential map (ΔBMD, Fig 1B). Regional ΔBMD, bone mineral content (BMC), and cortical structure were quantified. Reproducibility of all parameters was determined in a separate group of subjects (n=15) who were scanned twice in one week.

Over 18 months, compared to ΔBMD of the IC (-2 mg HA/cm^3), ΔBMD at the PS (-57 mg HA/cm^3) indicates significant mineral loss ($p<.001$), and ΔBMD at the ES (48 mg HA/cm^3) indicates significant mineral gain ($p<.001$, Fig. 1B). BMC decreased 14% ($p<.001$) at the PS and increased 7% ($p<.001$) at the ES, with no change in the IC (Fig

1C). There were 0.2% ($p<.01$) and 0.4% ($p<.05$) decreases in PS and ES perimeters, respectively, leading to a 1% increase in Ct.Area ($p<.01$) and a 0.9% increase in cortical thickness (Ct.Th, $p<.05$). No change in polar moment of inertia (pMOI) was observed over time (Fig 1D). Reproducibility was 1-5% for BMC and 0.1-0.5% for structural measures.Our results indicate that TPTD preferentially improves new bone accrual at the ES and accelerates bone resorption at the PS of the distal tibia in PreM women with IOP. In contrast, an earlier study showed that TPTD stimulates bone accrual at both the ES and PS of the iliac crest in postmenopausal women, suggesting TPTD's effect on cortical bone is site-specific. Although both ES and PS perimeters decrease at the tibia, Ct.Th and Ct.Area significantly increase, and the cortex's mechanical function is maintained. The preferential mineral deposition at the ES may help to improve bone's resistance to endocortical trabeculation.

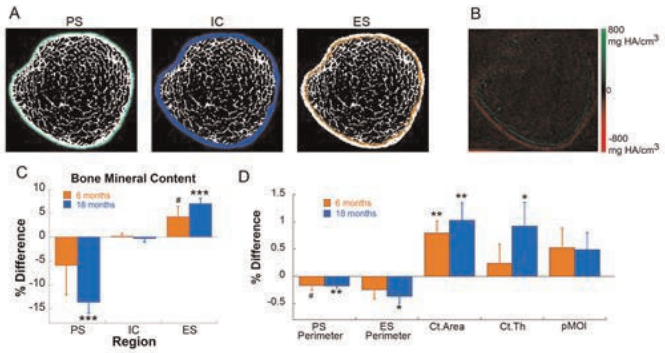

Fig. 1 (A) Regions identifying the periosteal surface (PS), intracortical area (IC), and endosteal surface (ES); (B) ΔBMD differential map: green indicates increased BMD while red indicates reduced BMD over time; (C) % difference in bone mineral content (BMC) at different cortical regions; (D) % differences in cortical structure. #p<.1; *p<.05; ** p<.01; *** p<.001

Once-weekly Teriparatide Increases Bone Mineral Density in the Distal Radius using The Correction Method of Dual-energy X-ray Absorptiometry Images. Yukihiro Isogai[1], Nobuo Urushibara[2], Harumi Nakayama[3], Ryutaro Adachi[4], Shigeru Kitagawa[4], Naoto Kato*[5], Tatsuhiko Kuroda[5]. [1], Japan, [2]Nukada Memorial Hospital, Japan, [3]Harumi clinic, Japan, [4]Hitachi Aloka Medical, Ltd, Japan, [5]Asahi Kasei Pharma Corporation, Japan

Purpose

Teriparatide increases bone mineral density (BMD) in lumbar vertebrae and femur. In radius, few study have investigated the effect of daily teriparatide on the changes of BMD, however, there are no reports of once-weekly teriparatide. In this study, the effect of once-weekly teriparatide in increasing BMD was examined in the distal 1/10 of the radius and the distal 1/3 of the radius using the correction method to avoid rotation and inclination of hands in dual-energy X-ray absorptiometry (DXA) images.

Methods:

This study is retrospective study at 2 medical sites which included the data of postmenopausal women who had a vertebral fracture and were diagnosed with primary osteoporosis with BMD of ≤70% of the young adult mean in the healthy Japanese population. The DXA scan images of the radius were taken at the start of once-weekly 56.5 μg teriparatide administration and after administration for 6, 12, and 18 months. Percentage changes of BMD from baseline in the radius (distal 1/10 and 1/3 radius) with correction method were evaluated.

Results

(Medical site 1)

9 subjects (mean age: 80.4 years) who had been not used bisphosphonates or had taken washout times if patients were used bisphosphonates were treated by once-weekly teriparatide administration for 6 months. When the corrections were made, significant increase of BMD at 6 months was found in the distal 1/10 radius (1.98 %, $p = 0.001$), but not in the distal 1/3 radius (0.98%, $p = 0.272$).

(Medical site2)

17 subjects (mean age: 77.7 years), who had been used bisphosphonates were subsequently treated by once-weekly teriparatide for 18 months. When the corrections were made, significant increase of BMD at 12 months was found in the distal 1/10 radius (2.05%, $p = 0.045$) and the efficacy was lasting until 18 months (2.18%). No significant increase in BMD was observed in the distal 1/3 radius, but BMD were maintained during teriparatide treatment (1.32% (6 months), 1.17% (12 months), 0.99% (18 months)).

Conclusion

Once-weekly teriparatide significantly increased BMD in the distal 1/10 radius and maintained BMD in the distal 1/3 radius. A correction method to avoid irrelevant measurement of BMD produced by in adequate arm positioning was also useful tool to detect the efficacy of teriparatide. However, further studies are needed to provide clear evidence of the pharmaceutical efficacy of once-weekly teriparatide due to small number of patients.

Sclerostin Antibody Administration Activated Bone Formation in Ovariectomized Rats with Concurrent Mechanical Unloading. Dongye Zhang*[1], Minyi Hu[1], Timothy Chu[2], Liangjun Lin[3], Xiaodong Li[4], Hua Zhu (David) Ke[5], Yi-Xian Qin[3]. [1]Stony Brook University, USA, [2]Stony Brook University, USA, [3]State University of New York at Stony Brook, USA, [4]Amgen, Inc., USA, [5]Amgen Inc., USA

Severe bone loss occurs when postmenopausal osteoporosis patients had concurrent immobilization and it is challenging condition to manage. Sclerostin antibody (Scl-Ab) increased bone formation and bone mass, and decreased bone resorption in postmenopausal osteoporosis. The current study was to examine the effect of Scl-Ab in mitigating the conditions in ovariectomized (OVX) rats with concurrent hindlimb suspension (HLS). Four-month-old female Sprague Dawley rats were divided into 7 groups (n=11 per group) as shown in Figure 1, HLS was introduced 2 weeks after sham and OVX. Scl-Ab (25 mg/kg) or vehicle was injected sc twice weekly for 5 weeks starting at the time of HLS. Histomorphometry analyses were performed at metaphyseal trabecular bone of the distal femurs. OVX alone, but not HLS resulted in significant decrease in BV/TV (-36%) in comparison to sham control. HLS plus OVX showed more bone loss than OVX alone. Scl-Ab significantly increased bone mass in all three conditions (HLS, OVX alone and OVX with concurrent HLS) with relative BV/TV increase of 37%, 87% and 87% compared with respective controls (Fig. 1 & 2a). Similar trend was observed in Tb.Th (Fig. 1 & 2b). Trabecular mineralizing surface/bone surface (MS/BS), mineral apposition rate (MAR) and bone formation rate (BFR/BS) were significantly increased in Scl-Ab treated rats (HLS alone, OVX alone and HLS+OVX) compared with respective controls. In summary, Scl-Ab prevented trabecular bone loss in OVX rats with concurrent HLS. Histomorphometric analyses reveal that Scl-Ab promoted bone formation in OVX rat model with concurrent HLS. The data suggest that sclerostin antibody represents a promising therapeutic approach for osteoporosis induced by estrogen deficiency with concurrent mechanical unloading.

MO0384

Sequential anti-osteoporotic therapy against recurrence of fragility fractures: the positive clinical effects of an osteo-anabolic first choice. Costantino Corradini*[1], Francesca Boisio[2], Vittorio Macchi[2], Francesca Ingegnoli[2]. [1]State University of Milan Department of Human Science, Italy, [2]State University of Milan, Italy

Introduction - Fragility fractures daily treated in orthopaedy of general hospitals or specialized institutes represent a common problem of healing and prevention of recurrence. In particular in osteoporotic women femoral, vertebral, humeral and wrist fractures continue to be the controversy over the type of treatment and their duration, especially given the possible adverse effects of long-term use. Furthermore, pharmaceutical spending review has conditioned the treatment and social choices. In this scenario the combined or sequential use of anti-osteoporotic drugs is actually debated. Objective - To evaluate the clinical outcome of femoral and vertebral fragility fractures after sequential treatment using teriparatide (TPTD) and risedronate (RIS) or denosumab (DMAB) following the guidelines of Italian Drug Agency (AIFA). Materials and methods - 124 postmenopausal women with femoral and/or vertebral fragility fractures received teriparatide (20-µg daily) for 24 months and then risedronate (35mg weekly) or denosumab (60-mg every 6-months), for other 24 months. They were undergone at the beginning, 3rd month and variably every six months to lumbar and femoral BMD and X-ray, serum markers of bone turnover, functional ability, SF-36, EQ-5. Results: Osteocalcin increased significantly at 3rd month maintaining high levels till to 24th month in TPTD group; while it declined more in the RIS group than the DMAB group. CTX I were equally suppressed in both groups. The X-ray between 3rd and 6th evidenced fracture healing in all cases. During TPTD assumption all patients detect positive effects on quality of life; whereas in the first six month of antiresoptive agents they reduced. At 24th month in all groups any recurrence of fragility fractures was detected. At 2nd year lumbar spine BMD increased in the TPTD (8.7±4.8%), DMAB (7.3±2.8%,) and RIS (5.6±3.4%) groups; femoral neck BMD also increased the TPTD (3.6±2.9%), DMAB (4.1±3.8%) and RIS (2.6±1.9%) groups. Conclusions- The initiation of anti-osteoporotic treatment with anabolic agent in the fragility fractures permits to enhance fracture healing and to restore BMD with reduced functional disability and better quality of life.The treatment with an osteo-anabolic agent needs to be followed by anti-resorptive treatment in order to maintain the bone restored. The different clinical outcomes revealed in two periods of treatment suggest the need by fractured patients to have further anabolic windows.

MO0385

The Long Term Effects Of Abaloparatide (BA058) On Bone Histomorphometry in Osteopenic Rats. Luc Chouinard*[1], Elisabeth Lesage[2], Susan Y. Smith[3], Gary Hattersley[4]. [1]Charles River Laboratories, PCS Montreal, Canada, [2]Charles River, Canada, [3]Charles River Laboratories, Canada, [4]Radius, USA

Abaloparatide (ABL) is a novel analog of PTHrP(1-34) currently being developed for the treatment of osteoporosis. This study was conducted to evaluate the effects of daily subcutaneous injection of ABL for 12 months on bone histormorphometry in ovariectomized (OVX) female Sprague-Dawley (SD) rats. Six-month old SD rats (10/sex/dose) underwent OVX or Sham surgery. Following a 3-month bone depletion period, daily subcutaneous injection of vehicle (Sham and OVX controls) or ABL at 1, 5 or 25 µg/kg, was given for 52 weeks. Rats were injected subcutaneously with fluorochrome labels 10 and 3 days prior to euthanasia. Histomorphometry of the cancellous bone was performed on the proximal tibia and lumbar vertebrae while the cortical bone histomorphometry was conducted on the tibia at mid-diaphysis. OVX induced high bone turnover by the end of the bone depletion period, that progressed to osteopenia at the cortical and both cancellous bone sites after 12 months. In cortical bone, ABL treatment resulted in a dose-related increase of periosteal formation rate and endosteal mineralizing surfaces. At the endosteal level, the effects of ABL were limited to increases in the endocortical labeled surfaces at 25 µg/kg. The increases in periosteal and endosteal formation indices, combined with the absence of effect on endosteal resorption, resulted in a reduction of the medullary area and endocortical perimeter that lead to cortical thickening despite the minimal periosteal perimeter expansion at all dosed groups, compared to OVX and Sham controls. In cancellous bone, treatment of OVX rats with ABL at ⩾ 1µg/kg resulted in increases of all bone formation parameters. These effects, combined with the lack of effect on the osteoclast surface, resulted in dose-related increases in trabecular number and thickness that resulted in increased bone volume, decreased trabecular separation and complete reversal of the OVX-induced osteopenia in the tibia and L3. Additionally there was no abnormal cell proliferation, marrow fibrosis, osteoid accumulation and/or mineralization defect observed in the examined bone sections. Thus, the administration of abaloparatide to OVX female rats at ⩾ 1µg/kg/day completely reversed the OVX-induced cancellous and cortical bone changes.

MO0386

A RCT Study to Compare the Short-term Biochemical Bone Metabolism Outcome of Weekly Alendronate Treatment in Osteopenic Women with or without Vibro-Therapy Intervention. Emilio Roldan*[1], Ricardo Capiglioni[2], Victor Montangero[2], Alicia Marino[2], Claudia Gomez Acotto[2]. [1]Gador S.A., Argentina, [2]Maimonides Univ, Argentina

Gómez Acotto C, Capiglioni R, Marino A, Montangero V, Roldán EJA.gomez-acotto.claudia@maimonides.edu

Phospho-Calcium Unit, Maimonides University, Buenos Aires, Argentina

The outcome of alendronate treatment of osteoporosis in practice is variable depending on many factors, as therapy compliance and persistence, among the main ones. The addition of a comfortable and periodical physical program may help in many ways. In addition, the subsequent skeletal impact may favor the enlargement of the bone active surface, which in turn is the alendronate arrival area to the bone; and given the exercises in adequate "doses" it may improve the muscle driven skeletal properties, even in aged people (Bone mechanostat theory). To test the above a group of 53 postmenopausal women having little physical activities, which give consent to be randomized and receive or not 3 weekly, 15 minutes sessions of passive interventions with a vibrio-therapy (VT) equipment (Galileo(R), a footplate developing a frequency range up to 30 Hertz), during 12 months. Osteoporosis was diagnosed by standard DEXA methods, and pQCT assessments quantified muscle/bone variables. As alendronate absorption is a further bias variable we treat all the patients with a drinkable formulation of 70mg weekly alendronate, from commercial resources, as the administration of soluble alendronate reduces variations in digestive transit and absorption, and may avoid serious GI unwanted effects. Blood D-pyridinoline was used as bone resorption marker, it was reduced in both groups but was found significantly more depressed among the VT users after 6 and 12 months (from average [range] 0.905 [1.215-0.780] to 0.640 [0.860-0.500] and 0.610 [0.810-0.490] in non-VT users vs. 0.908 [1.205-0.637] to 0.510 [0.660-0.370] and 0.510 [0.660-0.365] in VT users; $p<0.05$). Other variables as Ca/creatinine, AlkPh, and glycaemia did not evolve differently between groups. We conclude that a VT intervention increases the benefit of alendronate therapy in postmenopausal women with customary low level of activity by achieving a more effective suppression of bone metabolism after 6 months, and further maintaining the difference steady during the year of this observation. In some other studies the value of this therapeutic approach has not been clearly distinguished, but with close monitoring of patient adherence and the administration of soluble alendronate may remark the above described benefit. We continue working in this program to assess changes in bone density and structure.

MO0387

A Study of Women with Osteoporosis who are at High Risk for Fracture despite Benefits of Oral BisphosphonateTreatment. Arun Krishna[1], Debra Eisenberg[2], Tao Gu[2], Hillary Placzek[2], Ankita Modi*[3]. [1]Merck, USA, [2]Healthcore, USA, [3]Merck & Co., Inc., USA

Background: Bisphosphonates (BIS) have been shown to significantly reduce the risk of osteoporotic fracture in women with post-menopausal osteoporosis (OP). However, there are a substantial proportion of women who remain at high risk despite being compliant to BIS therapy.

Objective: To estimate the proportion of osteoporosis patients who remain at high risk for fracture despite being compliant to BIS treatment and to estimate their disease burden in terms of healthcare resource use and costs.

Methods: This was a retrospective claims and medical chart study, focusing on women ⩾55 years of age with OP and ⩾2 years of oral BIS treatment identified from the HealthCore Integrated Research Environment (HIRE) between 01/01/2007-06/30/2009. Initiation date of BIS was set as the index date. The pre-index period was 6 months prior to index date and the post index period was 25-36 months after index date. Patients were designated as high risk if they were compliant (defined as Medication Possession Ratio (MPR = days supply/365 days) ⩾ 70%) to BIS treatment for ⩾ 24 months, had a pre-index fracture or BMD test, and were considered as high risk of fracture if they met ⩾ 1 of the following criteria: a) patients experiencing a fracture or b) have a subsequent BMD score of $t<-2.5$ during post-index period.

Results: The total study sample was n=4,021. Of these, a total of 4.6% (n=185) experienced a fracture between index date and 36 months post-index. And a total of 1.5% (n=58) experienced a fracture during 25-36 month post index period. Also, of those with pre-index fracture (5.5%, n=220), 30% (n=66) experienced a subsequent post-index fracture despite compliance to BIS treatment. Of the total 330 charts reviewed to validate BMD test results, 124 (38%) were identified as high risk through the chart review (BMD of $t<-2.5$) in the post-index 25-36 months period. Within the high risk claims cohort, 38% (n=71) had an OP-related office visit during the 25-36 month post-index time period with a mean cost of $135. Among the high risk chart cohort, 69% (n=86) had an OP-related office visit during the 25-36 month post-index time period with a mean cost of $218.

Conclusions: In this study, a large proportion of women adherent to bisphosphonates for 2 years remain at high fracture risk. Although these women may have benefited from their therapy and have a lower fracture risk than if they had remained untreated, alternative treatments for osteoporosis could be considered for such patients

Alendronate Improves Bone Material Level Properties in Paired Human Transiliac Bone Biopsy Specimens. Patrick Ammann*[1], Rene Rizzoli[2]. [1]Division of Bone Diseases, Switzerland, [2]Geneva University Hospitals & Faculty of Medicine, Switzerland

Bone strength, hence fracture risk, is dependent on bone geometry, microstructure and bone material level properties. Alendronate treatment maintains bone mass, prevents further microarchitecture deterioration and increases the mean degree of mineralization. This latter effect could potentially modify bone material level properties. We investigated the effects of Alendronate treatment on bone material level properties and bone microarchitecture of transiliac bone biopsy from postmenopausal osteoporotic patients. In a longitudinal study, 38 paired biopsies were obtained at baseline and after 6 or 12 months of treatment with Alendronate 70 mg once weekly. Elastic Modulus, Hardness and Working Energy were blindly analyzed by nanoindentation at the level of the interstitial and haversian bone of the cortex and of trabecular nodes and remodeling units under humid conditions. Parameters of microarchitecture were evaluated by microCT (Scanco Medical). Bone microarchitecture and bone mass were not influenced by Alendronate treatment. Changes in bone material level properties were observed at the level of the interstitial cortical bone at the two time points and only by 12 months in haversian bone, but not at the level of the trabecular bone. In another group of the same study, patients were treated with Strontium Ranelate which changed bone material level properties after 6 and/or 12 months at the level of the trabecular bone and cortical bone. The significant changes were of similar magnitude for both treatments. The positive effect on bone material level properties of Alendronate could be partially explained by the known increase of mean degree of mineralization and could contribute to the known improvement of bone strength since no modification of bone mass was observed. Interestingly this study indicates that bone material level properties could be selectively improved by two anti-osteoporotic treatments like Alendronate and Strontium Ranelate.

MO0389

Differentiating effects of treatments on TBS. Renaud Winzenrieth*[1], Luis Del Rio[2], Silvana Di Gregorio[3], E Bonel[3], M Garcia[3]. [1]Med-imaps, Hôpital X. Arnozan, PTIB, Pessac, France, France, [2]Cetir Centre Medical, Spain, [3]Cetir Grup Medic, Spain

Purpose:. The objective of the study is to assess longitudinal effects of different osteoporosis treatments on TBS and BMD at lumbar spine.

Method: We analyzed 337 patients (men: 61; women: 276; Age range: 29 to 89 years; Follow-up: 23.5 ±13.9 months, BMI<29 kg/m^2). We stratified the cohort by treatments: No treatment (NT,n=82), Vitamin D+Calcium (VC, n=75), Testosterone (T,n=24), Biphosphonate (B,n=104), Denosumab (D,n=30), PTH (n=11), Raloxifene (R,n=11). The follow-up changes were analyzed by T-Test. Variation in % from baseline were assessed and normalized at 24 months. (Statistical significance was set at p< 0.05).

Results (See table): After 24 month, TBS NT group decreased by 2.4% (p<0.01) whereas a non significant decrease was observed for spine BMD (Δ=-0.3%). Compared to NT group, significant improvement (p<0.05) have been observed in both ΔTBS and ΔBMD for T, B, D, PTH groups. Significant variations have been observed in the V and R group for TBS whereas no significant variations were observed for BMD when compared to T group. At the end of the follow-up, significant improvement have been observed for BMD in T(+4.0%), B(+2.3%), D(+7.3%) and PTH(+8.5%) groups. Significant improvement was only observed in the D group (+2.1%) for TBS whereas a improvement tendency was observed in the PTH group (+1.9%).Conclusion: Non correlated effects have been observed on BMD and TBS irrespectively to the treatment. As expected from the literature, TBS of NT subjects decreased with age. When compare to NT subjects, significant differences have been observed for TBS in all treatment groups whereas BMD underdiagnoses the follow-up changes in V and R group. As expected TBS remained stable under Biphosphonate. Significant TBS increasing was observed under Denosumab whereas a positive tendency has been observed under PTH. TBS could be a useful tool to monitor treatment effects.

Efficacy and Safety of Bazedoxifene in Postmenopausal Latino Women with Osteoporosis. Jose A. Hernández Bueno[1], Lizbeth Arias[2], Ching-Ray Yu[3], Robert Williams[4], Barry S. Komm*[4]. [1]Unknown, Mexico, [2]Pfizer Inc, Mexico, [3]Pfizer Inc, USA, [4]Pfizer Inc, USA

Introduction: After menopause, declining estrogen levels contribute to accelerated bone loss, increasing risk of osteoporosis and fracture. Bazedoxifene (BZA), a selective estrogen receptor modulator, reduces fractures and bone turnover rate in postmenopausal women with osteoporosis.Purpose: Evaluate safety/efficacy of BZA on vertebral fractures, bone mineral density (BMD), and bone turnover markers (osteocalcin, C-telopeptide [cTX]) in women from Latin American (LA) sites in the global pivotal trial.Methods: In the 3-year, phase 3, randomized, double-blind trial, healthy postmenopausal women with osteoporosis (N=7492) received BZA 20 mg/d (BZA20) or 40 mg/d (BZA40), raloxifene 60 mg/d (RLX), or placebo (PBO). This post hoc analysis included participants (n=3036) from Argentina, Chile, Brazil, and Mexico.Results: In the ITT population, incidence of new vertebral fractures at month 36 with BZA20 (1.87%) and BZA40 (1.9%) was comparable to RLX (1.43%;) and lower than PBO (2.83%); differences were not statistically significant. BZA20 and BZA40 reduced new vertebral fractures by 39% (HR, 0.61; 95% CI, 0.30-1.26) and 32% (HR, 0.68; 95% CI, 0.34-1.36) respectively vs PBO. Compared with PBO, BZA20 and BZA40 were associated with greater (P<0.001) adjusted mean % increases from baseline to month 36 in BMD (lumbar spine: 1.26%, 2.49%, 2.79%; total hip: -0.41%, 0.40%, 0.95%; femoral neck: -0.59%, 0.88%, 1.78%; trochanter: -0.25%, 0.90%, 1.26%). Adjusted mean % BMD changes with BZA40 were comparable to RLX (lumbar spine, 3.18%; total hip, 1.11%; femoral neck, 1.68%; trochanter, 1.43%). Except for the trochanter, BMD changes were greater (P<0.05) with RLX vs BZA20. Compared with PBO, BZA20 and BZA40 produced greater (P<0.001) adjusted median % reductions in osteocalcin (-27.0%, -43.0%, -44.1%) and cTX (-32.1%, -50.7%, -53.4%) by month 12. Except for osteocalcin in the BZA40 group, the reductions were statistically significantly smaller for BZA vs RLX (osteocalcin, -46.9%; cTX, -57.6%). There were no significant differences between groups in overall incidence of TEAEs, serious AEs, or AEs leading to study withdrawal. There were significantly higher rates of somnolence, rhinitis, vaginitis, elevated alkaline phosphatase, and hypercholesterolemia with BZA20 and vascular disorders, depression, accidental injury, hypercholesterolemia, elevated liver enzymes, and vaginitis with BZA40 vs PBO.Conclusion: BZA is effective and safe in postmenopausal LA women with osteoporosis.

Evolution of Subject Characteristics in FREEDOM and its Extension for Up to 8 Years. JD Adachi*[1], PR Ho[2], CJF Lin[2], MA Bolognese[3], HG Bone[4], P Hadji[5], S Papapoulos[6], C Recknor[7], NS Daizadeh[2], P Dakin[2], RB Wagman[2], S Ferrari[8]. [1]McMaster University, Canada, [2]Amgen Inc., USA, [3]Bethesda Health Research Center, USA, [4]Michigan Bone & Mineral Clinic, USA, [5]Philipps-University of Marburg, Germany, [6]Leiden University Medical Center, Netherlands, [7]United Osteoporosis Centers, USA, [8]Geneva University Hospital, Switzerland

Purpose: Changes in study population demographics enrolled in long-term osteoporosis clinical trials may affect interpretation of efficacy/safety outcomes. Denosumab (DMAb) is being evaluated for up to 10 years in the 3-year FREEDOM trial and 7-year Extension (EXT). DMAb for up to 8 years is associated with low fracture incidence, continued BMD increases, and adverse event profile similar to what has previously been reported (Papapoulos et al., *JBMR.* 2013;28:S1). We compare the FREEDOM and EXT populations at baseline and in the EXT to assess potential selection bias that might influence long-term treatment outcomes.

Methods: In FREEDOM, women were randomized to placebo (PBO) or DMAb 60 mg Q6M. All FREEDOM subjects who had not missed >1 dose of investigational product, completed the 3-year visit, and consented to enroll were eligible to receive open-label DMAb in the EXT. We assessed whether older age and incident fractures contributed to attrition at Year 5 of the EXT, representing 8 years of follow-up.

Results: In FREEDOM, 6478/7808 (83%) subjects completed the trial. Of 5928 subjects eligible for the EXT, 4550 (77%) enrolled. Through Year 5 of the EXT, 3004 (66%) remained on study. While baseline characteristics were similar in FREEDOM and EXT, all subjects were 3 years older at EXT baseline, prevalent vertebral fracture rate in PBO-treated subjects was higher at EXT baseline compared with FREEDOM baseline (25% vs 22%), and DMAb-treated subjects had higher mean BMD at EXT baseline. Age distribution after 5 years of EXT remained consistent with the antecedent 3 years in FREEDOM, with no preponderance of younger subjects (Figure). As expected, older subjects were more likely to discontinue, however, 62% of subjects who were ⩾75 years at EXT baseline remained on study through Year 5. While subjects who fractured were more likely to discontinue in FREEDOM and in the EXT, 88% and 83% of PBO and DMAb fractured subjects, respectively, completed the 3-year FREEDOM trial, and 72% of fractured subjects in the EXT remained enrolled through Year 5.

Conclusion: In this large-scale, long-term study of DMAb, EXT population maintained similar characteristics to the original FREEDOM cohort. During EXT, a high percentage of subjects at increased risk for fractures due to older age and incident fracture remain on study. This suggests that the low fracture incidence and consistent safety profile reflect the long-term DMAb treatment effect.

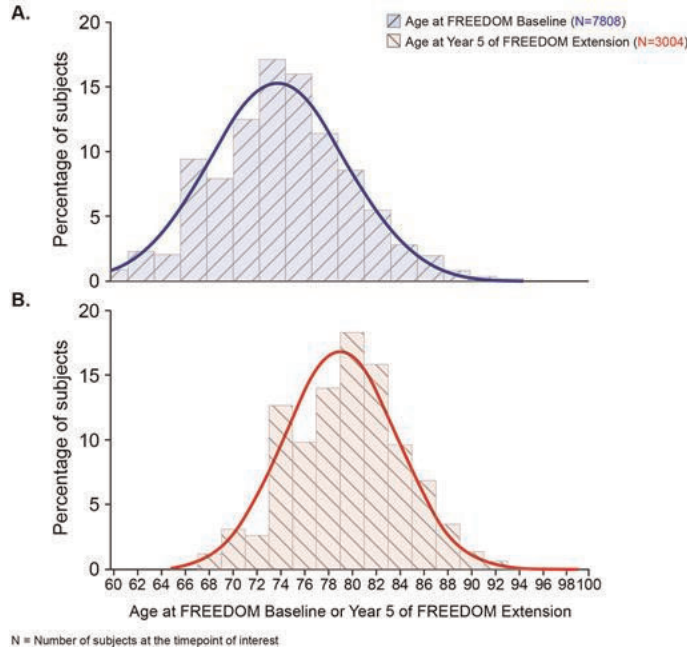

Figure. Age Distribution at FREEDOM Baseline (A) and Year 5 of FREEDOM Extension (B)

NSAID Efficacy in Acute-Phase Reaction Management in Chinese Postmenopausal Osteoporosis Patients after Zoledronic Acid Infusion: A Subgroup Analysis. Fuxing Pei*[1], Xun Liu[2], Yingxu Gao[2]. [1]West China Hospital, Sichuan University, Peoples Republic of China, [2]Novartis Pharmaceuticals (China), China

Objective: To evaluate short-term safety and access the acute phase response (APR) (fever and body pain) in an observational setting during first 4 weeks post zoledronic acid (ZOL) 5 mg single infusion in postmenopausal osteoporosis (PMO) patients of mainland China.

Methods: This was a 4-week, prospective, multicenter, open-label, non-interventional study in 2601 PMO patients. The primary outcome was the rate and severity of fever (temperature increases 1 ? compared with baseline) and body pain. The secondary outcome was efficacy of antipyretic-analgesic and anti-inflammatory drugs (NSAIDs) for treatment with APR. Patients with an APR were separated into 3 groups: prevention group (patients using NSAIDs to prevent APR on infusion day irrespective of APR); control group (patients using NSAIDs for symptom control when fever or pain severity aggravated); no therapy group (no NSAIDs usage).

Results: Data from 2583 patients with complete body temperature records and 2601 patients with pain severity data were analyzed, with an average age of 68.14 ± 9.89 years old and baseline body temperature of 36.51 ± 0.31?. There were740 (28.65%) patients experienced fever within 1st week and 456 (17.53%) patients pain severity aggravated within 2 weeks post ZOL infusion. Within 2 weeks of infusion, 1187 patients used NSAIDs, 50.72% (602) of them used NSAIDs to prevent APR, the other 49.28% (585) patients used NSAIDs for symptom control.

Subgroup analysis showed the fever rate in patients with preventive NSAIDs usage was 8.71% less than that of patients without preventive NSAIDs (21.76% vs 30.47%) within 1st week post ZOL infusion. The percentage of patients with pain severity aggravated with preventive NSAIDs usage was 12.00% less than that in group without preventive NSAIDs usage (8.31% vs 20.31%) within 2 weeks after ZOL infusion. The detail changes of body temperatures and fever recovery time was showed in the table. There was no statistically significant result on the efficacy of NSAIDs for pain relief in patients with the severity aggravation.Conclusion: Comparing symptom control post ZOL infusion, preventive NSAID treatment could effectively reduce the rate of patients experiencing fever or body pain aggravation. Patients with preventive NSAID treatment experienced mild symptom with a shorter period. Our results could provide guidance for APR management in clinical practice.

Items		Prevention group (n=131)	Control group (n=487)	P value
Patients with elevated body temperature	1℃-≤2℃	104(79.39%)	359(73.72%)	<0.0001
	>2℃	27(20.61%)	128(26.28%)	<0.0001
Average elevated body temperature (LSMean) (℃)		1.73	1.82	<0.0001
Average fever recovery time (LSMean) (Day)		1.51	1.83	<0.0001

MO0393

Oral alendronate is associated with gastro-intestinal reflux disease and voice alterations irrespective of the presence of esophagitis. Sirley Vasconcelos*[1], Francisco Bandeira[2], Alyne Loureiro[3], Ana Catarina Araújo[3], Severino dos Santos[4], Larissa Pimentel[5]. [1]Hospital Agamenon Magalhães - Recife, Brazil, [2]University of Pernambuco, Brazil, [3]Agamenon Magalhães Hospital, Brazil, [4]Osvaldo Cruz Hospital, Brazil, [5], Brazil

Bisphosphonates (BPS) are considered first-choice drugs for the treatment of osteoporosis, and due to its low cost, alendronate is the most widely used. Esophagitis is one of the main side effects of this drug and little is known about gastroesophageal reflux disease (GERD) with its atypical features such as voice problems, as a consequence of oral BPS. The aim of this study was to identify GERD and vocal changes in postmenopausal women with osteoporosis taking alendronate, compared to a control group. One hundred eighteen postmenopausal women were studied, of whom 59 were on alendronate and 59 were not using it. The diagnosis of GERD was made by the presence of dyspeptic symptoms and signs of esophagitis on endoscopy. The presence of voice disturbances was evaluated by the Perceptual Assessment of Voice and Acoustic Evaluation of Voice. The mean age was 66.87 ± 7.78 years (range 52 – 85), mean BMI= 27.38 ± 4.63 and age of menopause was 45.35 ± 7.04 years. Regurgitation and pyrosis were more frequent in the treatment group (88.14 %) than in the control group (77.97 %), with OR = 2.09 (95% CI 0.77 to 5.71), although these differences were not statistically significant . There were significant differences for the following atypical manifestations in the cases x controls: globus pharyngeal (55.93 % vs. 33.90%, p=0.010), dysphagia (35.59 % vs. 18.64%, p=0.041), discomfort in the upper airways (23.73 % x 8.47 %, p=0.030) and odynophagia (22.03 % vs. 6.78 %, p=0.025). Voice changes were also noted more frequently in treatment group than in the control group (89.83% x 72.88 %), adjusted OR 4.4 (95% CI 1.48-13.1, p = 0.022). The most prevalent changes were vocal hoarseness (72.03 %, p = 0.154), vocal fatigue (44.07 % vs. 27.12%, p = 0.056), and difficulty in speaking (30.51 % vs. 15.25% p=0.052). Esophagitis was more prevalent in the control group (15.25 % vs. 3.39 %, p = 0.042), suggesting an independent effect of BPS on atipical GERD symptoms. Our data suggested that alendronate may be implicated in generation of laryngeal GERD symptoms.

MO0394

Osteoporosis Treatment with Denosumab: Our Experience in the Real Clinical Practice. Diana González*[1], Beatriz Oliveri[2], Alicia Bagur[3], Carlos Mautalen[4]. [1]Mautalen Salud e Investigación, Argentina, [2]Mautalen, Salud e Investigación, Argentina, [3]Mautalen Salud e Investigacion, Argentina, [4]Centro de Osteopatías Médicas, Argentina

Randomized controlled trials have demonstrated that subcutaneous denosumab (DNB), a fully human monoclonal antibody against the receptor activador of nuclear factor $_k$B ligand (RANKL), ensures an effective anti-osteoporotic treatment. In the pivotal trials previous use of IV bisphosphonate was an exclusion criterion while previous oral bisphosphonates were allowed after a long wash out period. Other trials showed DNB effectiveness in patients previously treated with bisphosphonates without wash out period. The aim of this study was to report our experience with DNB in the real clinical practice in patients with osteoporosis. Subjects and Methods: osteoporotic women who received one or two doses of DNB during the period from 2011 to 2013 were included. The following issues were analyzed: a) Biochemical markers of bone turnover: serum Crosslaps (sCTX), Bone Gla Protein (BGP) and Bone Remodeling Index (BRI) at baseline, 6 (range: 5-7) months after the first dose of DNB, and at one year of treatment (six months after the second dose of DNB). b) Bone mineral density (BMD) of the lumbar spine (LS), femoral neck (FN) and total femur (TF) at baseline and one year of treatment. Results: Seventy-five postmenopausal women with mean (X ± SD) 67.0+9 years-old were included. Seven out of 75 women were naive of bisphosphonate treatment. Sixty-eight patients had been treated with bisphosphonates during 5.8 ± 4 years. The 41.3% of the patients had history of fragility fractures. Biochemical determination and BMD values at baseline, 6 months and 12 months of treatment with DNB are shown in the table. The percent change from baseline in BMD was +6.5% (p<0.0001), +8.0% (p<0.0001) and +5.6% (p<0.0001) in LS, FN and TF respectively. S-CTX and BRI showed a very significant decrease at 6 months: sCTX -77.3% (p<0.0001), and BRI -57.3% (p<0.0001) and at 12 months: sCTX -65.9% (p<0.0001), and BRI -34.25% (p<0.05). Although mean values of BGP were in the lower normal range at baseline and during treatment, they decreased 17 % at the 6th month after DNB (p<0.01) . The change of BGP at 12 months was not significant. A negative correlation between the percent changes BMD of TF and sCTX corresponding to 6 months (r=-0.36; p<0.01) was observed. No patients suffered new fractures during the study period. DNB was well tolerated and no adverse events were recorded. Conclusion: DNB has been an effective and safety anti-osteoporotic treatment even in those patients previously treated with other antiosteolytic treatments.

Table: Biochemical markers of bone turnover values at baseline, after first and second doses of DNB. BMD values at baseline and after second doses of DNB.

	Biochemical markers of bone turnover			BoneMineral Density		
	sCTX (80-590ng/ml)	BGP (15-43ng/ml)	BRI (100-300)	L2-L4 (g/cm²)	FN (g/cm²)	TF (g/cm²)
Baseline	292.34±185	13.64±10.7	110.54±105	0.880±0.15	0.656±0.19	0.708±0.13
After 1st doses DNB	66.37±53*	11.34±16.7#	46.50±38*	-	-	-

MO0395

Relationship between Response to Treatment with Risedronate and Baseline Characteristics Including Age, BMD, and Serum 25(OH)D Level - Subanalyses of Japanese Risedronate Phase III Trials-. Taro Mawatari*[1], Ryoichi Muraoka[2], Yukihide Iwamoto[3]. [1]Hamanomachi Hospital, Japan, [2]Ajinomoto Phamaceuticals Co, Ltd., Japan, [3]Dept. of Orthopaedic Surgery, Kyushu University, Japan

Purpose: Risedronate (RIS) increases bone mineral density (BMD) and reduces fracture risk. However, the response to the treatment may depend on the subjects' characteristics, such as baseline BMD, age, and Serum 25(OH)D Level. In this study, Japanese Phase III trials of RIS were subanalyzed to consider these issues.

Subjects and Methods: A total of 1447 subjects whose baseline BMD, serum 25(OH)D level were measured prior to RIS treatment were included in this study. RIS was administered for 12 months without vitamin D supplementation in those trials. Relationship between baseline characteristics (BMD, serum 25(OH)D level, and age) and response to RIS treatment (BMD change and new fracture) were evaluated.

Results: Subjects with a baseline 25(OH)D levels below 20ng/mL were 44.7%, and only 10.8% were above 30ng/mL. Student's t-test showed that the percent change in BMD was significantly higher when initial BMD (T-score) was < -2.5 than when it was ⩾ -2.5 (mean ± SE was 5.80 ± 0.13% and 4.59 ± 0.28%, respectively; P=0.0003), and lower when baseline 25(OH)D level was < 21 ng/mL than when it was ⩾ 21 ng/mL (mean ± SE was 5.39 ± 0.18% and 5.99 ± 0.17%, respectively; P=0.0138). (Figure) When subjects were divided into tertiles of age at start of RIS treatment, the percent change in BMD showed no significant difference among groups. Irrespective of baseline BMD, fracture rate was 1.5% in the population with a endpoint T-score < -2.5 and 0.8% in the population with a endpoint T-score ⩾ -2.5.

Conclusions: These results suggest that bone density increases in response to RIS treatment even when the initial BMD is low, but early initiation of treatment would be more effective from the standpoint of preventing fracture. BMD response to RIS was smaller when 25(OH)D was less than 21 ng/mL than when it was not less than 21 ng/mL, suggesting the importance of vitamin D supplementation.

MO0396

Closing the Gap in Osteoporosis Management: Implementation and Outcome Analysis of Secondary Fracture Prevention Programs. Kirtan Ganda*[1], Markus Seibel[2]. [1]Concord Hospital, Australia, [2]Bone Research Program, ANZAC Research Institute, University of Sydney, Australia

In the majority of patients with fragility fractures, the underlying osteoporotic bone disease remains undiagnosed and untreated. We present three analyses (1) establishing the characteristics of effective Secondary Fracture Prevention programs (SFPP), (2) optimising follow-up after treatment initiation, and (3) determining factors associated with increased risk of re-fracture in patients managed within a SFPP.

(1) Systematic review and meta-analysis of 42 reports on SFPPs published between 1996-2011: Outcome measures extracted included bone mineral density (BMD) testing and osteoporosis treatment initiation rates. Studies were grouped into 4 models of care, from most intensive (Type A = assessment & treatment) through to type D (patient education only). Meta-analyses demonstrated increased BMD testing (p=0.06) and treatment initiation rates (p=0.03) with increasing intensity of intervention. Thus, fully coordinated, intensive SFPPs were more effective in improving patient outcomes than approaches involving patient education only.

(2) A 2-year RCT of 102 patients initiated on oral bisphosphonate therapy at the Concord SFPP, randomised to 6-monthly follow-up with the SFPP (group A) or primary care physician follow-up (group B). Compliance & persistence were measured using claims data and their predictors analysed. At 24-months, medication possession ratio (MPR) and persistence were high and similar in both groups. In the adjusted analysis, patients in group A were not more likely to be compliant or persistent than those in group B, indicating that initiation of therapy within an SFPP is associated with high long-term therapeutic adherence.

(3) In a 7-year prospective study, we determined the predictors of re-fracture amongst 234 subjects managed by the Concord SFPP. In multivariate analysis, co-morbidity (HR 2.04 if >3, 95%CI 1.10-3.79), corticosteroid use (HR 1.75, 95%CI 1.12-2.73), total hip BMD (HR 1.36 per 0.1g/cm^2 decrease, 95%CI 1.08-1.70) and a MPR of less than 50% (HR 3.36, 95%CI 1.32-8.53) were significantly associated with re-fracture, indicating patients who fulfil these criteria are at very high risk of refracture, requiring intensive management.

These results demonstrate that intensive SFPPs (i.e.Type A) are effective in raising treatment rates, and that following treatment initiation by the program, patients are likely to adhere to therapy outside the SFPP. However, therapeutic compliance remains the major determinant of re-fracture risk.

MO0397

DEVIDE-Study: DEnosumab Versus Intravenous IbanDronatE – a 24 months retrospective head to head real life study – Baseline Data. Astrid Fahrleitner-Pammer*[1], Christian Muschitz[2], Doris Wagner[3], Karin Amrein[3], Thomas Pieber[3], Heinrich Resch[4], Hans Dimai[5]. [1]Medical University Graz, Austria, [2]St. Vincent's Hospital, Austria, [3]Medical University, Austria, [4]Medical University Vienna, Austria, [5]Medical University of Graz, Austria

Purpose: Effective treatment of postmenopausal osteoporosis (PMO) is frequently compromised by poor persistence and adherence to short-term medications. Aim of this study which has been performed in a real-life setting, is to investigate the effect of parenteral ibandronate (IBN) compared to denosumab treatment in a cohort of IBN pretreated patients.

Methods: Retrospectively 808 patients with PMO who did not tolerate oral BP therapy were analyzed. All were treated with quaterly IBN injections for 27+3mos and were regularly monitored at a osteporosis outpatients clinic. After Denosumab was launched 366 women were switched to receive this therapy whereas the remaining 422 preferred to stay on IBN. Effectiveness in terms of fracture incidence, BMD, BTM as well as adherence and safety of the two treatments will be analyzed.

Results: The baseline characteristics are given in table 1. There were no differences in any of the parameters investigated including renal and liver function, vitamin D, PTH and bone turnover markers. Laboratory testing , recording of adverse events was done every 6 months, BMD readings, soinal X-ray and fracture assessment were performed at baseline and after 12 and 24 months of ongoing IBN or Denosumab therapy.

Conclusion: The results of this study not only will provide clinicans with insights into persistence with denosumab in comparison to quarterly IBN therapy, bit will also compare the effect of denosumab for the first time with a parenteral administered bisphosphonate in respect to safety, changes in BMD as well as fracture incidence and changes in spine deformity index over a time period of 2 years.

tab1:

Characteristics	Denosumab (n=366)	Ibandronate (n=442)
Age (years)	67.2 + 7	67.5 + 6
Years since menopause	22 + 3	21 + 4
Weeks on ALN	5 + 2	5 + 2
Total Hip BMD T-Score	-1.8 + 0.7	-1.7 + 0.8
Femoral neck BMD T-score	-2.1 + 0.9	-2.0 + 1
Lumbar spine BMD T-score	-2.8 + 1.2	-2.7 + 1.4
Non vertebral fracture, n (%)	26 (7.1%)	34 (7.7%)
Vertebral fracture, n (%)	69 (18.9%)	84 (19%)

MO0398

Persistence With Prolia® (Denosumab) for 1 Year in Relation to Patient-reported Data: Interim Results From a Prospective Observational Study of Postmenopausal Women With Osteoporosis. SL Silverman*[1], E Siris[2], DL Kendler[3], D Belazi[4], JP Brown[5], DT Gold[6], EM Lewiecki[7], A Papaioannou[8], C Simonelli[9], G Quinn[10], A Balasubramanian[11], FM Mirza[11], P Ho[11], S Siddhanti[12], B Stolshek[12], C Recknor[13]. [1]Cedars-Sinai Bone Center for Excellence, UCLA School of Medicine, & OMC Clinical Research Center, USA, [2]Columbia University Medical Center, USA, [3]University of British Columbia, Canada, [4]AlchemiPharma LLC, USA, [5]Laval University & CHU de Québec Research Centre, Canada, [6]Duke University Medical Center, USA, [7]New Mexico Clinical Research & Osteoporosis Center & University of New Mexico School of Medicine, USA, [8]McMaster University, Canada, [9]Health East Osteoporosis Care, USA, [10]Sarnia Statistics LTD, United Kingdom, [11]Amgen Inc., USA, [12]Amgen Inc., USA, [13]United Osteoporosis Centers, USA

Purpose: Persistence with osteoporosis therapy is important for optimal reduction of fracture risk. In a randomized clinical trial in women with low BMD, persistence with denosumab (DMAb) was >90% (Freemantle *Osteoporos Int* 2012). Patients who had greater perceived necessity for an osteoporosis drug had lower odds of nonadherence (Kendler *Menopause* 2013). We are conducting a prospective observational study to evaluate persistence with DMAb in routine clinical practice in Canada (CAN) and the United States (US).

Methods: In this ongoing, multicenter, observational, 2-year study, women were enrolled within 4 wk after the 1st injection of DMAb, recommended for administration every 6 mo for the treatment of osteoporosis per the local product label. Clinical sites include primary care and specialty practices. No clinical procedures, assessments, or changes to routine management of patients were required. Persistence with DMAb for 12 mo was defined as receipt of the 2nd injection no more than 6 mo+8 wk from the baseline injection. Patients completed questionnaires at baseline that included Beliefs About Osteoporosis Medicines (BMQ 11; necessity and concern), the Patient Satisfaction Questionnaire, and other questions about accessing the provider and treatment. We report interim results of 1-year persistence with DMAb in relation to these patient-reported data.

Results: Of the 935 women enrolled (CAN 303, US 632), 82% were persistent with DMAb for 1 year (CAN 88%; US 79%). Median scores (on a scale of 0.00 to 5.00) for the BMQ 11 were 3.00 for necessity of the medication and 2.33 for concern about the medication. Patients were very or quite satisfied with the frequency (87%), mode (85%), and convenience (87%) of DMAb administration. Persistence for 1 year was slightly higher in patients who perceived a higher necessity, had lower concern, or had a higher necessity-concern ratio (Table 1). There was a suggestion of increased persistence among patients who were satisfied with DMAb (Table 2). Other patient-reported data suggest that copayment >$100 (US) and payment by patient (CAN) but not household income, educational level, distance travelled, or patient-support programs might have a relationship with persistence.

Conclusion: In this study of routine clinical practice, 82% of patients persisted on therapy for 1 year. Patients' perceived need for the drug and satisfaction with the drug may lead to better overall persistence.

Preferences for Osteoporosis Treatment in Japan. Ikuko Tanaka*[1], Marco DiBonaventura[2]. [1]NAGOYA Rheumatology Clinic, Japan, [2]Kantar Health, USA

Introduction: Nearly 15 million people experience osteoporosis in Japan and, although there are a number of treatment options available, they all vary on a range of different attributes. Understanding patient preferences in each country is important because these can differ based on societal and cultural backgrounds as well as medical and insurance systems. The aim of this study was to investigate patient preferences for osteoporosis treatment in Japan and how these preferences might vary based on prior treatment experience. METHODS: The current study included data from an online survey that was administered to respondents of the Japan National Health and Wellness Survey, an annual general health survey of the adult Japanese population. Only those diagnosed with osteoporosis and who had osteoporosis treatment experience were included in the analyses (N=655). Patients were categorized into one of four groups based on two dimensions (bisphosphonate experience or not; currently on treatment or not). Respondents evaluated medication attributes and reported their level of agreement with various statements for a hypothetical treatment which had varied dosing frequencies of daily, weekly, or monthly. RESULTS: All attributes were considered important in absolute terms. Efficacy was rated as the most important followed by side effects, the administration process (e.g., food and posture restrictions), and dosing frequency. Cost was not considered an important attribute. In forced choice rankings, efficacy, safety, and dosing frequency were the most highly ranked attributes. Both current and former bisphosphonate users had a significant preference for weekly dosing over daily dosing. All patient groups perceived daily dosing as the most burdensome and monthly dosing to be most highly associated with missed doses. DISCUSSION: Patients place particular value on efficacy and side effects, though dosing frequency is considered the next most important attribute. There was a preference for weekly dosing over daily dosing among those with bisphosphonate experience, primarily because of the perceived burden of daily dosing as well as a greater perceived likelihood of missing doses for monthly dosing. Overall, weekly dosing was evaluated as the best balance between frequency and ease of remembering to take the medication. Physicians should be aware of patient preferences as aligning medications with preferences may be associated with better health outcomes.

MO0400

Preventing breaking bad: The impact of DXA and FRAX results on physicians' treatment decisions in a large multispecialty group practice. Meg Durbin*[1], Miriam Rotman[2], Bradley Stolshek[3], Harold Luft[2]. [1]Palo Alto Medical FoundationSutter Health, USA, [2]Palo Alto Medical Foundation Research Institute, USA, [3]Amgen, USA

Background: Osteoporosis and related fractures cause significant morbidity, mortality, and expense, but medications recommended by groups such as the National Osteoporosis Foundation (NOF) to prevent fracture (fx) are inconsistently prescribed. FRAX calculations added to dual energy x-ray absorptiometry (DXA) reports estimate fx risk, but few studies assess the impact of such reports on physician prescribing patterns.

Objective: To describe prescribing patterns for women age ⩾ 50 years after 1) DXA showing low BMD (T score < -1.0) with or without FRAX (15362)- 1^0 prevention or 2) fx suspicious for osteoporosis (2748) -2^0 prevention.

Methods: All data were obtained from electronic health records (EHR) in a large multispecialty group. In the 1^0 prevention group, DXA and FRAX reports from 2009-10 were reviewed. High FRAX score is defined as 10 yr risk > 3% for hip or > 20% for any osteoporosis related fx. In the 2^0 prevention group, fxs were identified from 2009-10, with any DXAs done between 2 y before through 6 mo after fx. Prescription medication to treat low BMD (''Rx'') was identified in medication lists from 6 mo before through 6 mo after DXA date (1^0 prevention) or fx (2^0 prevention).

Results: Most women with osteoporosis had Rx (71%), but Rx rates differed by FRAX score - 73% with high or no FRAX vs. 61% with low FRAX, p <0.01 (Fig. 1). Only 34% of all women with osteopenia had Rx, but greater Rx was strongly related to high FRAX and lower T scores: 46% with osteopenia and high FRAX had Rx vs. 28% with low FRAX (p <0.01), and Rx rates rose as T scores fell from the highest to lowest subgroups: 23% vs. 32% vs. 44% (Fig. 2) (test for trend, p <0.01). In women with suspicious fx, 42% overall had Rx, but Rx rates were higher in the subset with DXA: 79% with T score < -2.5 vs. 42% with higher T score vs. 37% without DXA (p <0.01) (Fig. 3).

Conclusion: Most women with osteoporosis had NOF guideline-consistent treatment. Treatment rates in osteopenia were low overall but rose with higher FRAX scores and lower BMD. Most women with osteoporosis-suspicious fractures were not prescribed Rx. However, in the subset with fracture and DXA-confirmed osteoporosis, most were prescribed Rx, even though DXA to confirm low BMD is not required before starting Rx after osteoporosis- suspicious fx. Opportunities exist to increase both physicians' recognition of fracture risk stemming from low BMD and to raise their rates of prescribing medication to prevent such fractures.

MO0401

Understanding Physicians Perceptions of Patients Barriers to Osteoporosis Medication Intitiation. Stuart Silverman*[1], Haiyan Qu[2], Jeffrey Curtis[3], Susan Greenspan[4], Sarah Morgan[3], Jeri Nieves[5], Ryan Outman[3], Richard Shewchuk[2], Ethel Siris[6], Amy Warriner[3], Nelson Watts[7], Kenneth Saag[3]. [1]Cedars-Sinai/UCLA, USA, [2]University of Alabama at Birmingham, USA, [3]University of Alabama at Birmingham, USA, [4]University of Pittsburgh, USA, [5]Columbia University & Helen Hayes Hospital, USA, [6]Columbia University College of Physicians & Surgeons, USA, [7]Mercy Health Osteoporosis & Bone Health Services, USA

Purpose: Despite international guidelines, osteoporosis treatment rates remain low. A better understanding is needed on how to organize and address barriers to medication initiation. We derived a cognitive map of how physicians perceive patient-identified barriers for the purpose of developing minimally invasive interventions aimed at increasing treatment initiation.

Methods: To elicit barriers to initiating osteoporosis medication, we conducted 4 nominal groups with 18 postmenopausal women with a history of fracture who were not currently receiving osteoporosis treatment. Each woman then independently ranked her 3 most important barriers creating a final list of 25 barriers. Next, physician osteoporosis experts (n=26) independently grouped these barriers into clusters of at least 2 barriers each. The data were analyzed using multidimensional scaling and hierarchical cluster analysis. The physicians also used a 5-point Likert scale to indicate their level of agreement or disagreement of the ability of each barrier to be addressed by an intervention.

Results: The physicians included 11 rheumatologists, 9 endocrinologists, 3 general internists and 3 others with significant osteoporosis management experience. A sorting exercise identified 5 distinct clusters (Figure): 1) concerns about side effects, 2) experience of side effects, 3) lifestyle changes, 4) medication access and complexity, and 5) patient uncertainty about treatment and trust in provider. Barriers were mapped along 2 dimensions: the x-axis represented patient uncertainty about osteoporosis treatment with medication side effect concerns on the left and uncertainty in trust of care providers on the right. The y-axis represented patient belief and expectations about osteoporosis treatment with lifestyle change at the top, and access and complexity of medications at the bottom. The project team named the clusters and axes based on common features. Based on the average mean ratings within clusters, physicians agreed that the concerns about side effects cluster could be addressed as elements of an intervention (M+SD, 3.9+0.9) while the uncertainty of medication and providers cluster could not be addressed easily (M+SD, 2.7+1.1).

Conclusion: The identified clusters generated by physician agreement using cognitive mapping provide a basis for a theoretical framework from which to develop future tailored interventions to address the barriers to initiating osteoporosis treatment.

Two Years of Osteoanabolic Treatment to Heal a Non-union Fracture in a Patient with Multiple Co-Morbidities. Elliott Schwartz*[1], Patricia Schwartz[2], George Tischenko[3]. [1]Northern California Institute for Bone Health, Inc., USA, [2]Northern California Institute for Bone Health, Inc., USA, [3]Muir Orthopaedic Specialists, USA

Non-union of a fracture is defined as permanent failure of healing following a fracture, usually, by 6 months. The FDA defines non-union for investigative purposes as a fracture 9 months old that has shown no signs of healing for 3 months. Non-unions occur in 10-20% of the 6,000,000 annual fractures in the United States. The morbidity of non-unions is extensive and expensive. The treatment of non-unions is, usually, surgical. However, the development of osteoanabolic agents suggests there may be another approach. However, the duration of time of treatment to "heal" a non-union is unknown. Numerous individuals suggest that this treatment may take weeks to a few months.

We evaluated a 66 year old morbidly obese white male who fractured his right medial malleolus after weeks in an exercise class without obvious trauma. A CT scan of the ankle 5 months later showed a non-union. Because of morbid obesity and chronic obstructive pulmonary disease, surgical repair was deemed inadvisable. A "secondary" osteoporosis laboratory work-up showed pre-diabetes and hypogonadism. A DXA showed normal bone density. He was started on low dose pulsed ultrasound. A month later, he was started on teriparatide 20mcg subcutaneously daily. A month later, he was started on a Heart Healthy Diet and testosterone gel. He was followed with appropriate laboratory monitoring and serial CT scans at appropriate intervals. The CT scan performed at one year showed an incompletely healed medial malleolar fracture. A CT scan of the ankle performed 23 months after initiation of osteoanabolic treatment showed complete healing of the medial malleolar fracture.

Conclusion: Current osteoanabolic therapy can heal fracture non-unions but the length of time to do so may be prolonged.

MO0403

Combination therapy Denosumab and Alfacalcidol in Postmenopausal Osteoporosis - tree years experience. Corina Galesanu*[1], Andra Iulia Loghin[2]. [1]University of Medicine & Pharmacy, Romania, [2]University of Medicine & Pharmacy, Romania

Background: Analysis of data from the FREEDOM trial confirmed that Denosumab significantly improved bone mineral density, mass and strength besides significantly reducing the risk for fractures. Denosumab is a full human monoclonal antibody targeting the RANK Ligant, an essential regulator of osteoclast formation, function and survival.

Objectives: The purpose of this study was to investigate the effect of the Denosumab on change Bone Mineral Density (BMD) in postmenopausal osteoporotic women.

Methods: Twenty seven postmenopausal women with BMD T-score at lumbar spine (LS), total hip(TH) or femoral neck (FN) less than -2.5 received Denosumab 60 mg subcutaneous injection at every 6 months , plus 1000 mg calcium and alfacalcidol 1 µg/d. Mean age of our patients was 63 years old and mean age of menopause was 49.5 years old. BMD was measured by Dual-energy X- ray Absorptiometry (DXA) at baseline and 1, 2, 3 years. Adverse events were monitored.

Results: At baseline mean BMD at LS was 0.727 g/cm2 and increased to 0.781 g/cm2 (+7.8%), 0.825 g/cm^2 (+5.6%), 0.852g/cm^2 (+3.2%) after 1,2,3 years. For FN mean BMD at baseline was 0.556 g/cm2 and increased to 0.572 g/cm2 (+2.8%), 0.607g/cm^2 (+6.1%), 0.632g/cm^2 (+2.4%) after 1,2,3 years. BMD at TH increased from 0.725 g/cm2 to 0.754 g/cm2 (+4.0%), 0.792g/cm^2 (+5.0%), 0.806g/cm^2 (+1.7%) after 1,2,3 years. No adverse events or fractures under the therapy.

Discussions: Regarding combination therapy there are no studies showing that combination treatment with 2 or more osteoporosis drugs has a greater effect on fracture reduction than treatment with a single agent. Additive effects on BMD and bone turnover have been observed with combinations of 2 antiresorptive agents. We consider that the combination between Denosumab and Alfacalcidol explaned the increase of BMD more than in monotherapy.

Conclusion: Denosumab and Alfacalcidol treatment significantly increased BMD at the LS, FN and TH in our patients with postmenopausal osteoporosis. It was well tolerated by the women.

Effect of Eldecalcitol on Bone Metabolism Following Alendronate Treatment in Ovariectomized Rats. Satoshi Takeda*[1], Sadaoki Sakai[2], Yoshihito Tashiro[3], Michinori Hirata[4], Ken-ichi Serizawa[4], Kenji Yogo[4], Koichi Endo[5]. [1]"chugai Pharmaceutical Co., Ltd.", Japan, [2]Chugai Pharmaceutical Co., Ltd., Japan, [3]Chugai Pharmaceutical Co.,Ltd, Japan, [4]Chugai Pharmaceutical Co.,Ltd., Japan, [5]Chugai Pharmaceutical Co., Ltd., Japan

Although treatment with bisphosphonate (BP) reduces the risk of osteoporotic fractures, concerns have recently emerged that long-term BP therapy is associated with an increased risk of atypical femoral fractures and osteonecrosis of the jaw. These concerns highlight the need for a drug holiday or switching to other drugs after long-term BP therapy. Eldecalcitol (ELD), an active vitamin D_3 derivative, is used to treat osteoporosis in Japan. ELD has been shown to inhibit osteoclastic bone resorption more potently than alfacalcidol, a prodrug of the active vitamin D_3, and stimulate bone minimodeling, a type of focal bone formation without prior bone resorption, in ovariectomized (OVX) rats. In this study, we examined the effects of ELD on bone mineral density (BMD), bone biomechanical strength, and bone turnover following alendronate (ALN) treatment in OVX rats.

Wistar-Imamichi rats (6-month old) were ovariectomized and treated with ALN (1µg/kg, s.c., 5 times/week) for 12 weeks. Thereafter, rats were treated with ALN (A→A group), ELD (20 ng/kg, p.o., 5 times/week; A→E group) or vehicle (A→V group) for another 12 weeks. Lumbar BMD was measured by DXA, and the biomechanical strength of the L5 vertebra was tested by the compression test. Bone histomorphometry was performed using the L3 vertebra.

The OVX-induced reduction of lumbar BMD was inhibited in the A→A, A→E, and A→V groups. BMD of the A→E group was higher than that of either the A→A or A→V group. The maximum load of L5 in the A→E group was higher than in the disease control (DC), A→A, and A→V groups. N.Oc/BS, ES/BS, N.Ob/BS, OS/BS, BFR/BS, and Ac.f were elevated by OVX and were suppressed in the A→A, A→E, and A→V groups. N.Oc/BS and ES/BS in the A→E group were lower than in either the A→A or A→V group. N.Ob/BS and OS/BS in the A→E group were higher than in the A→A group. Bone minimodeling in the A→E group was higher than in the DC group.We demonstrated that switching to ELD following 12-week treatment with ALN was more beneficial than continuing or discontinuing ALN in terms of increasing BMD and bone biomechanical strength in OVX rats. Because ALN is known to remain in bone even after treatment has been terminated, the effects of ELD following ALN treatment observed in this study may be caused by a combination effect of ELD and ALN. Bone minimodeling action of ELD may contribute to increasing BMD and bone biomechanical strength after ALN treatment.

MO0405

Intrinsic bone mineral quality in postmenopausal osteoporotic women treated for 12 months with strontium ranelate or alendronate. Camille Ponçon*[1], Delphine Farlay[2], Georges Boivin[3]. [1]INSERM U1033 Université de Lyon, France, [2]INSERM, UMR1033; Université De Lyon, France, [3]INSERM, UMR1033 ; Universite De Lyon, France

Strontium ranelate (SrRan) and alendronate (ALN) are anti-osteoporotic treatments reducing fracture risk. However, the mechanism of action of SrRan on bone remains partially elucidated. Its active agent, strontium ion (Sr), is exclusively fixed in bone mineral formed during treatment (1). In order to better understand its mechanism of action, early effects of SrRan were compared to those of ALN. Our goal was to analyze the intrinsic properties of bone mineral in the newly deposited tissue. One hundred twenty iliac bone biopsies were performed in postmenopausal osteoporotic women, before (M0) and after a 12 months (M12) treatment (SrRan or ALN), i.e., 30 pairs of biopsies for each treatment. After methylmethacrylate embedding, 2 µm-thick sections were analyzed by Fourier transform infrared microspectroscopy (FTIRM). The intrinsic mineral bone quality was assessed by 4 variables: mineralization index, mineral maturity, crystallinity index and carbonation. FTIRM was performed on the newest bone tissue, at M0 and M12, on the surface of trabeculae or on endocortical layer or in cortical osteons with wide Haversian canals. In SrRan group M12, Sr was localized by X-ray microanalysis to identify the recent bone formed during treatment. After SrRan (M12 vs M0), mineralization index, mineral maturity and crystallinity index were not significantly changed. Only mineral carbonation decreased significantly in cortical and trabecular sites. After ALN, only mineralization index and carbonation increased significantly in the two sites. These effects were coherent with the inhibitory action of ALN on bone remodeling, and indicated that mineral crystals were more numerous after ALN. However the mineral maturity remained unchanged at M12, suggesting the precipitation of new crystals instead of growth of the old ones. The decreased carbonation observed after SrRan, could be due to the Sr ion steric hindrance altering the incorporation of carbonates into crystals. This effect is independent of an action on bone remodeling. Our study underlined that SrRan and ALN have distinct modes of action on bone tissue. A decrease of bone mineral carbonation may be a variable contributing to the decrease of fracture risk.

MO0406

The Effects of Pulsed Electromagnetic Field (PEMF) and/or Bisphosphonate Treatments on Vertebral Bone Mass in a Long-Term Osteoporosis Model. Caroline Androjna*[1], Erik Waldorff[2], James Ryaby[3], Maciej Zborowski[4], Ronald Midura[5]. [1]Lerner Research InstituteCleveland Clinic, USA, [2]Orthofix, USA, [3]Orthofix Inc, USA, [4]Cleveland Clinic, USA, [5]Lerner Research Institute of Cleveland Clinic, USA

Cervical-Stim® (Orthofix, Lewsville, TX) PEMF treatment has been shown to provide clinical benefits as an adjunct to spinal fusion in patients with risk factors for failed fusion. However, the effect on osteoporotic patients currently undergoing bisphosphonate treatments has not been established. The objectives of this study was to determine if the commercial Cervical-Stim PEMF waveform and a combinatorial treatment approach with a bisphosphonate could mitigate osteoporosis bone loss in the lumbar spine to reduce vertebral compression fracture risk in at risk patients. 120 skeletally mature (6-7 month old) ovariectomized (OVX) female Sprague-Dawley rats were equally divided into 6 cohorts being treated with a combination of alendronate (ALN, 3 s.c. injections/week at 10μg/kg BW) and/or PEMF (Cervical-Stim, 3 hrs/day, 7 days/week): age-matched normal rats (Sham OVX), Sham OVX+PEMF, OVX, OVX+ALN, OVX+PEMF, and OVX+PEMF+ALN. In-vivo microCT imaging (20 μm resolution), of the L4 vertebrae, was performed at baseline (5-7 days post OVX), 6, 12, 18 and 24 weeks post initiation of PEMF/ALN treatment. Outcome measures included bone volume fraction (BV/TV), bone mineral content (BMC), and bone mineral density (BMD). Injections of Alizarin Red and Calcein injections were done at 22 and 24 weeks, respectively, for end-point histomorphometry assessment of trabecular bone remodeling rates. Preliminary BV/TV, BMD and BMC results from the first 60 animals (10 rats/cohort) indicate that bone losses in the spine were minimal for the Sham OVX group while the OVX group experienced continual bone loss over the 24 weeks. ALN slows down bone loss as expected, but cannot prevent it. Intermediate results indicate that PEMF appears to partially mitigate OVX bone losses: analyses shows a trend of 23% and 18% mitigation at 18 and 24 weeks, respectively as compared to no treatment. While PEMF was shown to not be as effective as ALN treatment, co-treatment of OVX rats with PEMF and ALN did not demonstrate interference with ALN's effectiveness. Histomorphometric data are currently being completed. In conclusion, intermediate results suggest that daily PEMF treatment partially mitigates cancellous bone loss in the spine of long-term osteoporotic rats but not as effectively as ALN treatment. In addition, PEMF does not alter the effectiveness of ALN, and could therefore potentially be used as an adjunct treatment for osteoporotic patients currently undergoing bisphosphonate treatments.

MO0407

The role of the renin–angiotensin system in the bone metabolic response to mental stress. Norman Pollock*[1], Laura Carbone[1], Monique Bethel[2], Yanbin Dong[3], Luiz Ortiz[3], Obioma Nwobi[3], Coral Hanevold[4], Deborah Stewart[3], Gregory Harshfield[3]. [1]Georgia Regents University, USA, [2]Indiana University School of Medicine, USA, [3]Georgia Regents University, USA, [4]Seattle Children's Hospital, USA

Although increasing evidence suggests that mental stress may contribute to osteoporosis, it is unclear how the two comorbidities are linked. Because animal and co-culture models indicate that activation of renin-angiotensin system (RAS) causes abnormal bone metabolism, we postulate that the stress-related hormone angiotensin II (Ang II) may be a contributing factor linking mental stress to poor bone health. We tested this hypothesis in a randomized, double-blind, placebo-controlled crossover study, which examined the effect of an Ang II receptor blocker (Irbesartan, Avapro®) on the bone turnover and pressure natriuresis response to one hour of mental stress in sodium retainers and excreters. Fifteen healthy normotensive adults (7 men and 8 women; mean age, 25 y; range, 18-46 y) were randomized to either a 4-day standardized sodium diet and Irbesartan tablets (50 mg daily for 7 days) or the same diet and identical placebo tablets, each for 1 week, after a washout period of 1 week. On day 5 of each testing week, a 3-hour mental stress protocol was administered, which included 1-hour of rest, 1-hour of mental stress (competitive video game), and another 1-hour of rest. Blood pressure was collected at 15-minute intervals during the 3-hour protocol. Blood was collected hourly for assessment of procollagen type 1 amino propeptide (P1NP; bone formation marker) and C-terminal telopeptide α-1 chain of type 1 collagen (CTX; bone resorption marker). Hourly urine specimens were collected to determine urinary sodium excretion. An individual was designated as a sodium retainer if urinary sodium excretion decreased during the stress protocol in the placebo condition. In the sodium retainers, Irbesartan increased urinary sodium excretion during stress and had a beneficial effect on blood pressure levels throughout the protocol (all $p < 0.05$). During stress, Irbesartan also had a beneficial effect on P1NP, CTX, and the P1NP/CTX ratio in the sodium retainers (all $p<0.05$). In the sodium excreters, there was no effect of Irbesartan on change in urinary sodium excretion during stress or changes in blood pressure or bone turnover markers during the 3-hour protocol (all $p>0.05$). Our data suggest that in individuals who retain sodium under stress, suppression of Ang II inhibits sodium retention and improves bone metabolism, providing evidence of RAS in the bone metabolic response to mental stress.

MO0408

Long-term Improvements in Bone Mineral Density and Health Related Quality of Life in Osteoporosis Patients Treated with Teriparatide. Herman Bami*[1], Adrian Budhram[2], Raymond Chu[3], George Ioannidis[4], Alexandra Papaioannou[5], Arthur Lau[1], Jonathan Adachi[6]. [1]McMaster University, Canada, [2]Michael G. DeGroote School of Medicine, McMaster University, Canada, [3]Faculty of Medicine, University of Toronto, Canada, [4]McMaster University, Canada, [5]Hamilton Health Sciences, Canada, [6]St. Joseph's Hospital, Canada

Purpose: To investigate the effect of Forteo ® (teriparatide) therapy on bone mineral density (BMD) and health-related quality of life (HRQL) during and up to 2 years after completion of teriparatide therapy.

Methods: We retrospectively reviewed consecutive osteoporosis patients treated with teriparatide in a Canadian rheumatology outpatient practice. We included patients that received teriparatide therapy with baseline and follow-up BMD results up to two years after completion of 18 or 24-month treatment. Patient information was reviewed via electronic medical system records (EMR). If EMR data was unavailable, paper copies of patient files were reviewed. Baseline information collected included age, gender, height and weight as well as BMD and Mini-Osteoporosis Quality of Life Questionnaire (OQLQ) data. Medications taken prior, during, and post-teriparatide therapy were also recorded. Repeated measures mixed-model analyses were used to compare baseline and follow-up measurements for BMD at the femoral neck, lumbar spine and total hip as well as each of the ten questions of the OQLQ questionnaire (five domains). The analyses were adjusted for sex and baseline age, height and weight.

Results: 167 patients were included in this study including 143 women. The baseline characteristics were: mean (standard deviation) age 65.1 (11.4) years, height 159.8 (9.1) centimeters and weight 63.0 (13.1) kilograms. Statistically significant improvement in BMD at the femoral neck, lumbar spine and total hip were demonstrated up to 2 years after teriparatide treatment (see table 1). Significant improvements were also observed at the second follow-up post-teriparatide treatment in the OQLQ domains of pain symptoms, emotional functioning and physical functioning ($p < 0.05$ for the first 6 questions) as well as a trend towards significance in the domains of activities of daily living and leisure.

Conclusion: This study demonstrates the efficacy of teriparatide treatment in osteoporosis patients to improve both BMD, particularly in the lumbar spine, and HRQL. Furthermore, these findings are suggestive of maintained improvement in BMD up to 2 years after completion of teriparatide therapy.

	Baseline (T-score)	1st follow-up Change in T-score From baseline	P-value*	3rd follow-up Change in T-score From baseline	P-value**

Differences in bone status between type 1 and type 2 diabetes mellitus patients. Jakob Linde*[1], Søren Gregersen[2], Ellen Hauge[1], Bente Langdahl[3], Peter Vestergaard[4]. [1]Aarhus University Hospital, Denmark, [2]Aarhus University Hospital, Denmark, [3]Aarhus University Hospital, Dnk, [4]Aalborg University Hospital, Denmark

Background: Diabetes Mellitus are associated with an increased fracture risk and underestimation of fracture risk by common predictors.

Aim: To investigate whether bone status differs between type 1 diabetes mellitus (T1D) and type 2 diabetes mellitus patients (T2D).

Methods: Ongoing cross-sectional study. Diabetes patients were consecutively recruited from diabetes outpatient clinics at Aarhus University Hospital and Aalborg University Hospital. Diabetes was diagnosed according to international guidelines. Only patients aged 50 years or more, with a recent eGFR ⩾50 mL/min, and HbA1c ⩾ 49 mmol/mol during the last six months were included. Unpaired t-test and multiple linear regression were used. Included patients were evaluated using hip, spine and forearm DXA (Hologic^{TM} (n=112) and Lunar^{TM}(n=14)), and a subset evaluated at forearm and ankle by HRpQCT (Scanco^{TM}) (n=112). Patients suffering from conditions and/or using medications affecting bone metabolism were excluded.

Results: 126 diabetes patients (60 T1D, 66 T2D) were included. T2D were older (mean difference: 4.54 years, P<0.01) and had a larger body mass index (BMI) (mean difference: 5.04 kg/m^2, P<0.01) than T1D. No gender differences were apparent (P=0.78). Hip T-score was -0.45 (p=0.03) lower among T1D. Spine and radius T-score did not differ between T1D and T2D (p=0.10 and 0.39, respectively).

Neither cortical nor trabecular parameters evaluated by HRpQCT differed between T1D and T2D, although the tibial cortical area tended to be lower among T1D (P=0.07).

Multiple linear regression revealed that diabetes type did not influence hip (P=0.21), spine (P=0.54), and radius (P=0.33) T-score or tibial cortical area (P=0.01) significantly after adjustment for BMI, age and gender.

Conclusion: Bone structure did not differ between T1D and T2D when evaluated by DXA and HRpQCT scans. Although T1D and T2D differ in etiology, treatment and other characteristics, these findings support that T1D and T2D share the same structural characteristics in regard of bone status and possible bone fragility.

FRAX Underestimates Fracture Risk in Patients with Type 1 Diabetes Mellitus. Tayyab Khan*[1], Tamara Spaic[2], Lisa-Ann Fraser[3]. [1]Department of Medicine, Western University, Canada, [2]Western University, Canada, [3]Western University, Canada

Individuals with type 1 diabetes (DM1) have over a 6-fold increased risk of sustaining a hip fracture compared to the general population. The WHO Fracture Risk Assessment Tool (FRAX) incorporates DM1 into its fracture risk assessment by including it as a cause of "secondary osteoporosis". We aimed to assess how well FRAX identifies fracture risk in a real-world population of patients with DM1.

We studied bone health in a sequential population of patients with known DM1 being followed by Endocrinologists at an academic centre. Patients filled out a bone health questionnaire which was used to up-date their electronic medical record (EMR). De-identified data was extracted from the EMR for all patients with DM1 over age 40. Fracture risk scores were calculated using FRAX (without BMD).The study was approved by the local Research Ethics Board.

There were 201 individuals with DM1 identified, with mean age of 53.9 years (40-82). Prior fracture was reported by 29.9% of patients, and 19.9% of these were confirmed fragility fractures (defined as a fall from standing height or less). Despite this, only 25 patients (12.4%) were identified as "high risk" for future fracture by their calculated FRAX score (>20% risk of major osteoporotic fracture or >3% risk of hip fracture over the next 10 years), and 19 (9.5%) were in the "moderate risk" category (10-20% risk). Out of the 40 patients who had sustained at least one fragility fracture, 15 (37.5%) were at "high risk" and 10 (25%) were at "moderate risk" of fracture according to their FRAX score.

We found that FRAX systematically underestimated fracture risk in a population of patients with DM1. The pathogenesis of the increased bone fragility caused by DM1 is thought to be multifactorial and complex. Our results suggest that this risk is not adequately accounted for by the FRAX tool, and highlights the limitations of using conventional fracture assessment tools in the diabetic population.

MO0411

Young and middle aged male with type 1 diabetes have lower vBMD and strength in femoral bone and have aging structure of the femoral neck assessed by Quantitative CT. Koji Ishikawa*[1], Takashi Nagai[2], Tomoyasu Fukui[3], Takuma Kuroda[4], Katsunori Inagaki[4]. [1]Department of Orthopeadic Surgery, Showa University School of Medicine, Japan, [2]Department of Orthopeadic Surgery, Showa University School of Medicine, Japan, [3]Department of Internal Medicine, Division of Diabetes & Endocrinology, Showa University School of Medicine, Japan, [4]Department of Orthopeadic Surgery, Showa University School of Medicine, Japan

Several previous studies have reported osteoporosis measured by dual-energy X-ray absorptiometry (DXA) in younger patients with type 1 diabetes (T1D). DXA, however, is unsuitable for precise measurements of bone mineral density and strength because of the limitations of two-dimensional (2D) imaging. Our group used 3D quantitative computed tomography (QCT) to obtain more precise information about bone fragility in T1D. Seventeen male T1D patients aged from 19 to 48 years, and eighteen age-matched control males (C) were studied. Patients with diabetic nephropathy (proteinuria and eGFR<60) were excluded. In QCT measurements, T1D patients had a significantly lower cortical volumetric bone mineral density (vBMD) in the femoral neck, significantly lower total vBMD and cortical cross-sectional area (CSA, an estimator of compression strength) in the inter-trochanter. Bone strength estimated by the bucking ratio (an index of cortical instability) of the inter-trochanter was significantly higher in T1D. We also measured QCT parameters (cortical thickness, cortical vBMD, trabecular vBMD, integral vBMD) in anatomic quadrants [supero-anterior (SA), infero-anterior (IA), infero-posterior (IP), supero-posterior (SP)] of the femoral neck to reveal the structure more precisely. In IA and IP area, there were not significant difference between T1D and controls. But T1D patients had significant lower cortical thickness in SP, and cortical BMD in SA. This quadrant data suggest that structure of the femoral neck in T1D was aging bone. Bone metabolic markers were also comparable between T1D and C. There were not significant difference between T1D and C. Biochemical measurements including IGF-1 were collected too. The IGF-1 values were significantly lower in T1D than in C (130 ± 35 *vs* 158 ± 34 mg/dl). Furthermore, IGF-1 values were positively correlated with the total vBMD of the neck and the serum bone formation markers (r=0.49~0.71, respectively) in T1D. Indeed, in quadrant, IGF-1 values were positively correlated with cortical thickness in SA, trabecular vBMD in SP, respectively.In conclusion, young and middle-aged T1D patients had cortical weakness of the femoral inter-trochanter lesions with lower vBMD. Moreover, there already exist more aging structures at the femoral neck in T1D. Perhaps more importantly, low IGF-1 might be a causative factor for skeletal abnormality in T1D.

Prospective study of bone loss after spinal cord injury (SCI). Role of osteocyte markers. Laia Gifre*[1], Joan Vidal[2], Josep Lluís Carrasco[3], Xavier Filella[4], Silvia Ruiz-Gaspà[5], Enric Portell[2], Ana Monegal[6], Africa Muxi[7], Nuria Guanabens[8], Pilar Peris[9]. [1]Hospital Clinic Barcelona, Spain, [2]Guttmann Neurorehabilitation Institute, Spain, [3]Public Health Department. University of Barcelona, Spain, [4]Department of Biochemistry & Molecular Genetics. Hospital Clinic, Spain, [5]CIBERehd. Hospital Clínic, Spain, [6]Hospital Clinic Barcelona, Spain, [7]Nuclear Medicine Department. Hospital Clínic, Spain, [8]Universitat De Barcelona, Spain, [9]Hospital Clínic of Barcelona, Spain

Background: SCI has been associated with a marked increase in bone loss and bone remodeling. The absence of mechanical load, probably mediated by osteocyte mechanosensory function, seems to be a determinant factor related to bone loss in this condition. However, the pathogenesis and clinical management of this process remains unclear.

Aim: To analyze the effect of recent SCI on osteocyte function and its relationship with bone turnover and bone mineral density (BMD) evolution.

Methods: We prospectively included 42 patients (40M:2F, aged 35 ± 14yrs) with a recent (<6months) complete SCI (ASIA A 39:B 3). Osteocyte markers (serum sclerostin, Dkk-1 and FGF23), bone turnover markers (bone formation: P1NP, bone ALP; resorption: sCTx) and BMD (lumbar spine, proximal femur, total body and lower extremities [DXA]) were assessed in all patients at baseline, and at 6 and 12 months. The results were compared with a healthy control group of similar age and sex.

Results: 22/42 patients completed the 12-month follow-up period. At baseline SCI patients showed a marked increase in bone markers (PINP and CTx) which remained significantly increased at up to 6 months of follow-up (Table). In addition, they presented significantly increased Dkk-1 values throughout the study (Table). Sclerostin or FGF23 values did not significantly change. BMD markedly decreased at the proximal femur (-13 ± 5% at 6 months, p<0.01; -20 ± 5% at 12 months, p<0.01), total body (p<0.01 at 6 months, p<0.01 at 12 months) and lower extremities (p<0.01 at 6 months, p<0.01 at 12 months), with no significant changes at the lumbar spine. As a result, 59% of patients developed densitometric osteoporosis at 12 months. Bone markers were negatively correlated with proximal femur BMD (bone ALP: r=-0.33, p<0.01; P1NP: r=-0.26, p<0.01, adjusted for age and BMI) with a decreasing negative association throughout the study period.

Conclusions: Marked bone loss associated with increased bone turnover and increased Dkk-1 serum levels is observed shortly after complete SCI. Maintenance of increased Dkk-1 levels throughout the study coinciding with continuous BMD loss further suggest a regulatory role of this osteocyte mediator in this process.

Parameters	Healthy controls	SCI at baseline	SCI at 6 months	SCI at 12 months
	Mean (CI, 95%)	Mean (CI, 95%)	Mean (CI, 95%)	Mean (CI, 95%)

Bone Turnover Markers and Different Dialysis Procedures. Vladimir Palicka*[1], Sylvie Dusilova Sulkova[2], Magdalena Holeckova[2], Roman Safranek[2], Ladislava Pavlikova[2]. [1]Fakultni Nemocnice, Czech Republic, [2]Charles University, University Hospital, Czech Republic

Introduction: The role of P1NP and CTx in patients with ESRD and dialysis is not well established. Data comparing hemodialysis (HD) with on-line hemodiafiltration (HDF) are lacking. We aimed (1) to assess the relation between bone turnover markers and traditional markers of CKD-MBD in dialysis patients and (2) to compare effect of HD and HDF on serum concentrations of P1NP and CTx.

Methods: 96 clinically stable dialysis patients were studied. Regime has been stable for at least three previous months, using dialysate calcium 6 mg/dL. 54 patients were on high-volume on-line HDF; 42 patients were treated by conventional HD. Serum Ca, P, B-ALP, 25-hydroxyvitamin D, 1-84 PTH, CTx and P1NP were measured before and after single HD or HDF procedure. Results are expressed as median (interquartile range); p value < 0.05 was considered statistically significant.

Results: Only twelve patients had pre-dialysis B-ALP above the reference range for given age and sex, while P1NP was elevated in 92 patients and CTx in 94 patients, indicating a possibility of retention of P1NP and CTx in serum due to kidney failure. However, significant correlation between serum B-ALP (15.6; 10.9-23.1) and P1NP (323; 189-441) was found ($r = 0.492$; $p<0.001$). Similarly, CTx (2.05; 1.6-2.47) significantly correlated with B-ALP ($r = 0.470$; $p<0.001$) and 1-84PTH (18; 11.2-26.7) correlated with P1NP ($r = 0.415$, $p<0.001$) as well as with CTx ($r = 0.420$; $p<0.001$). All these correlations indicate that P1NP and CTx reflect bone turnover in dialysis patients.

Both dialysis procedures influenced P1NP and CTx differently. Conventional HD did not change either P1NP or CTx. HDF, on the contrary, decreased CTx by 80% (from 2.26; 1.99-2.85 to 0.53; 0.33-0.70), $p<0.001$ and P1NP by 32% (from 395; 255-509 to 288; 168-396), $p<0.001$. Serum Ca and P levels did not differ between HD and HDF procedures. Serum 25-D did not correlate with any of the bone turnover markers.

Conclusion: Serum CTx and P1NP are markedly elevated in dialysis patients, which may reflect not only the missing renal elimination, but also their high bone turnover. Different elimination strategies may be associated with procedure-dependent acute changes in bone turnover indicators. As there was no pre-dialysis difference in P1NP and CTx between HD and HDF patients, the effect of HDF is probably only temporary. However, the long-term consequences of these findings deserve further studies.

Increased marrow adipose tissue following Spinal Cord Injury. Tiffiny Butler*[1], Thomas Schnitzer[2], William Edwards[3], Karen Troy[1]. [1]Worcester Polytechnic Institute, USA, [2]Northwestern University, USA, [3]University of Calgary, Canada

Spinal cord injury (SCI) all but eliminates loading from the paralyzed regions, resulting in rapid loss of both bone and muscle mass. Suboptimal loading from decreased muscle mass may alter the muscle-bone crosstalk resulting in increased medullary adiposity and decreased bone mass. Marrow adipose tissue (MAT) negatively regulates bone formation and may play a synergistic endocrine related role in the loss of bone following SCI. However, the exact function of MAT and its effect on other diseases is not well understood.

Our purpose was to determine factors related to tibial MAT accumulation following spinal cord injury in acute and chronic SCI subjects. We previously exploited clinical CT data to quantify visceral and intermuscular adipose tissue in the torso. Here, we established a similar technique to quantify MAT using quantitative CT. Computed tomography (CT) data of the proximal 15 mm of the non-dominant tibia were acquired on 49 subjects with acute (13 subjects) and chronic (36 subjects) SCI (41 male), age 22-65 years, duration of injury of 0–42.5 years. A calibration phantom with known hydroxyapetite concentrations was included in each scan and was used to establish a linear relationship between Hounsfield units (Hu) and tissue mineral density. Quantitative image analysis was performed to determine integral BMD (g/cm3) and MAT volume, defined as voxels within the periosteal envelope having Hu [-205 to -50]. Pearson's correlations were used to determine relationships between MAT volume (cm^3) and: BMD, duration of injury (years), age (years) and body mass (kg).

MAT volume was 31.1 ± 23.9 cm3 for all subjects combined, 8.7 ± 6.9 cm3 for acute subjects and 38.3 ± 22.9 cm3 for chronic subjects. MAT showed an inverse relationship with BMD ($r=-0.734$, $p<0.001$) and increased with duration of SCI ($r=0.51$, $p<0.001$; Figure 1) but not with age ($r=0.13$, $p=0.42$) or body mass ($r= -0.02$, $p=0.89$).

Although few studies have investigated changes in long bone MAT in individuals with SCI, others have linked increased marrow adiposity with decreased bone mineral density and cortical bone area. MAT and osteoblasts share common precursors, and low magnitude mechanical vibration has been shown to inhibit adipogenesis in mice. Similarly, resistance exercises and whole body vibration have been shown to prevent increases in vertebral marrow fat during prolonged bed rest. Further study of MAT in SCI patients may lead to improved understanding of the role MAT plays in bone health.

Proximal Femur Strength and Cortical Thickness Estimates in Klinefelter Syndrome and Post-Menopausal Women. Enrico Schileo*[1], Ilaria Palmadori[2], Fulvia Taddei[3], Alessandro Coran[4], Sigurur Sigursson[5], Vilmundur Gudnason[6], Tamara Harris[7], Carlo Foresta[4]. [1]Istituto Ortopedico Rizzoli, Bologna, Italy, Italy, [2]Istituto Ortopedico Rizzoli, Italy, [3]Istituto Ortopedico Rizzoli, Italy, [4]Università di Padova, Italy, [5]Icelandic Heart Association, Iceland, [6]Icelandic Heart Association Research Institute, Iceland, [7]Intramural Research Program, National Institute on Aging, USA

The structural basis of the reported low bone mass in Klinefelter Syndrome patients (KS), and its consequences on bone strength are poorly understood.

In a very recent HRpQCT study KS exhibited, at the distal tibia (load-bearing bone), compromised bone microstructure and strength, suggesting an analogy with aging women [1].

The aim of the present QCT study was to test if proximal femur strength and bone structure of KS patients and post-menopausal women are actually similar.

Methods

QCT-based Finite Element estimates of proximal femur strength (FE-strength) were obtained for: KS patients (n= 18, aged 44 ± 8), post-menopausal women (n=83, aged 76 ± 6, composed of VPHOP (n=12) and Ages (n=71) cohorts), and aging men (Ages, n=39, aged 79 ± 5).

FE-strength was calculated with a validated procedure [2], retaining the minimum strength among a range of plausible fall directions.

In KS and VPHOP women cohort, cortical density (Ct.D) and cortical thickness (Ct.Th.) were estimated [3]. In the superior aspect of the femoral neck (i.e. the most critical as from FE results) Ct.Th. was further mapped to nine regions (cross-combinations of head-neck junction, mid-neck, trochanteric fossa levels in anterior, central, and posterior sectors).

Results

The FE-strength of KS and women was similar (KS: 2981 ± 514 N; Women: 2822 ± 627 N, % diff. $< 3\%$, not significant, Mann-Whitney $p = 0.29$).

Conversely, the FE-strength of older men (4176 ± 985 N) was significantly higher compared to KS ($p < 0.001$), and, as expected, to similarly aged women ($p < 0.001$).

The women for whom CT.D and Ct.Th. were analyzed did not differ in FE-strength (2710 ± 386 N, $p=0.11$) from KS.

Cortical density was equivalent ($p=0.38$) in KS (1.128 ± 0.055 g/cm^3) and women (1.146 ± 0.054 g/cm^3).

Bone cortex was instead significantly thinner in KS [Figure], reaching a three-fold thinning in the posterior and central sectors of the head-neck junction, a site of fracture-related cortical thinning traits [4].

Discussion

We confirmed, for proximal femur strength, the analogy between KS and post-menopausal women. This analogy was not reflected in bone structure, being Ct.Th. much thinner in KS. This low Ct.Th. could be a starting point to explain compromised bone strength, in future studies on larger cohorts, including trabecular and metabolic parameters.

The relationship between sclerostin, bone mineral density and vascular calcification in rheumatoid arthritis. Julien Paccou*[1], Cedric Renard[2], Sophie Liabeuf[2], Said Kamel[2], Patrice Fardellone[3], Ziad Massy[2], Michel Brazier[4], Romuald Mentaverri[5]. [1]University of Picardie Jules Verne, Amiens, France, [2]Amiens University Hospital, France, [3]Service de rhumatologie, CHU Hôpital Nord, France, [4]University of Picardie, France, [5]INSERM U1088, France

Introduction

Recent data indicate that serum sclerostin could be involved in vascular calcification (VC). The present study tested the hypothesis that serum sclerostin levels are associated with VC in patients with rheumatoid arthritis (RA) and control subjects matched for age and gender.

Methods

In this cross-sectional study, 75 RA patients were compared to 75 control subjects matched for age and gender. Demographic and clinical characteristics, bone mineral density (BMD) measured by DXA, cardiovascular risk factors and serum sclerostin (ELISA) were assessed. Coronary artery calcium (CAC) and abdominal aortic calcification (AAC) scores were evaluated by computed tomography in patients free of clinical evidence of coronary artery disease. Analyses were performed to identify determinants of serum sclerostin and VC.

Results

Coronary artery calcification was more prevalent in patients with RA (65.3%) than in controls (49.3%) (p=.04). The mean CAC score was 197 $\pm$ 470 in patients with RA and 109 $\pm$ 297 in controls (p=.07). However, AAC was also more prevalent in patients with RA (71.2%) than in controls (54.7%) (p=.04). The mean AAC score was 1.0 $\pm$ 1.3 in patients with RA and 0.7 $\pm$ 1.4 in controls (p=.02). Higher AAC scores (P=.02) and higher lumbar BMD (P=.03) were identified as independent determinants of higher serum sclerostin levels in RA patients, whereas male gender (P=.03), higher lumbar BMD (P<.0001) and low estimated glomerular rate (eGFR) (P<.001) were identified in controls. In RA patients, multivariate logistic regression analysis identified older age (OR per year of 1.10 [1.03-1.18]; P<0.01) and male gender (OR=6.79 [1.33-34.62]; P=.02) as independent determinants of CAC, and older age (OR=1.16 [1.07-1.27]; P<.001) as an independent determinant of AAC. For controls, independent determinants were older age (OR=1.19 [1.06-1.35]; P<.01), hypertension (OR=7.31 [1.98-26.96]; P<.01) and lumbar BMD (OR per 30 mg/cm2 of 1.14 [1.01-1.29]; P=.03) for CAC and older age (OR=1.11 [1.02-1.20]; P=.01) for AAC.

Conclusion

Circulating sclerostin was significantly and independently associated with AAC in RA patients.

MO0417

Adverse Changes in Bone Mineral Density and FRAX Score 100 Days Post Allogeneic Bone Marrow Transplant. Monika Pawlowska*[1], Basia Pajerski[2], Qun Yang[3], Indy Sekhon[2], David Kendler[4], Raewyn Broady[5]. [1], Canada, [2]University of British Columbia, Canada, [3]Prohealth Clinic Research, Canada, [4]Associate Professor University of British Columbia, Canada, [5]Clinical Associate Professor University of British Columbia, Canada

Purpose: Bone loss following allogeneic bone marrow transplant (allo-BMT) is a common complication and is multifactorial. Previous studies have demonstrated bone loss occuring 6 months after allo-BMT but few studies address earlier changes in bone mineral density (BMD). Furthermore, there are no data quantifying the impact of changes in BMD on fracture risk as calculated by FRAX. Determining BMD and performing a fracture risk assessment at baseline and 100 days after allo- BMT could identify patients with rapid bone loss and allow for early therapeutic intervention.

Methods: Patients who underwent allo-BMT (2011-2013) and had BMD testing before and 100 days post BMT were analyzed. FRAX risk factors were prospectively determined and a FRAX score was calculated at baseline and day 100.

Results: 98 patients (59 males, 39 females), mean age 49, were included. A BMD decline of 3% or more, the least significant change on many DXA instruments, was seen in 46 patients at the lumbar spine, 56 at total hip, and 55 at femoral neck at 100 days post transplant. The mean decline in lumbar spine, total hip, and femoral neck BMD was 3.27%, 4.43%, and 4.53%, respectively (P < 0.001 for all). Following transplant, 47 patients had long-term, high dose glucocorticoid exposure. The mean FRAX 10 year risk of major osteoporotic fracture was 4.2% at baseline, and 5.7 % at 100 days (p < 0.001). This represents a 1.5% increase in 10 year fracture risk over 100 days. The mean 10 year risk of hip fracture was 0.5% at baseline, and 0.8% at 100 days (p< 0.001), for a 0.3% increase in risk. Prior to BMT, 4 patients met the North American menopause society criteria for osteoporosis pharmacotherapy and at 100days, 9 patients met this threshold; 2 of whom sustained vertebral fractures during this time.

Discussion: Allo-BMT recipients have a rapid, and statistically significant, decline in hip and spine BMD, even in the first 100 days post transplant. These changes in BMD, and frequent high dose glucocorticoid use post transplant, confer a significant rise in fracture risk. Although FRAX has not been validated previously in the post transplant population, femoral neck BMD and steroid exposure are important components of risk assessment using this tool, and in this cohort, the main contributors to the significant increase in 10 year fracture risk. This new information strengthens the argument for preventive strategies to reduce bone loss subsequent to BMT.

MO0418

BMD Changes after Kidney Transplantation. Nicolas Segaud[1], Isabelle Legroux[2], Marc Hazzan[3], Christian Noel[3], Bernard Cortet*[4]. [1]Service de Rhumatologie, France, [2]Service de Rhumatologie, France, [3]Service de Néphrologie, France, [4]Service de Rhumatologie, France

Introduction: Renal transplant patients may have bone loss related to the drugs taken but also to their past history of chronic kidney disease. The objective of the present work was to study changes in BMD 2 years after the first assessment.

Methods: This longitudinal study included patients who underwent renal transplantation realized between 2005 and 2011 and followed at the University-Hospital of Lille. Patients were included if they had a first bone evaluation (including bone densitometry, spine X-rays and biological assessment) and at least another BMD assessment. The first assessment was done on average 9 months after transplantation and 2 years later.

Results: 259 patients satisfied to the inclusion criteria, (96 women) with a mean age of 49.7 $\pm$ 12.1 years at transplantation. The mean duration of dialysis was 3.2 $\pm$ 3.3 years. 75 patients (29.0%) withdrew corticosteroid 7 days after transplantation without new introduction during follow-up. Vertebral fractures were found in 28 patients (10.8%). According to the WHO classification, 101 patients had osteoporosis and 125 had osteopenia at the first evaluation (at least at one site). Osteoporosis treatment with bisphosphonates (alendronate or risedronate) was initiated for 95 patients. In all patients, BMD gains compared with baseline were significant : 3.9 $\pm$ 6.6%, 2.6% $\pm$ 7.6, 3.0 $\pm$ 7.2% at the lumbar spine, femoral neck and the total hip respectively (p <0.0001). The gains were significant for patients treated with bisphosphonates compared with baseline: 5.0% respectively (p <0.0001), 2.5% (p = 0.012) and 2.7% (p = 0.004) at the lumbar spine, femoral neck and total hip respectively. BMD gains were higher for patients treated by bisphosphonates for all the sites (p<0.015) than for patients without bisphosphonates. There was no difference in terms of BMD gains between alendronate and risedronate (p = 0.457). The patients who withdrew corticosteroids early had higher gains in BMD than patients with more prolonged corticosteroid therapy: difference between groups for the overall population = 2.1% for the lumbar spine (p = 0.019) and 2.0% for the total hip (p = 0.044). The stepwise regression analysis (patients without bisphosphonates) showed associations between BMD changes (femoral neck) and the duration of corticosteroid therapy, the level of bone alkaline phosphatase at baseline, the lack of vertebral fracture. No correlation was found between the change in BMD and the duration of dialysis or renal function.

Conclusion: Kidney transplant recipients have a pre-existing increased bone fragility. Bisphosphonates and early corticosteroid withdrawal can improve BMD.

Bone Quality at the Time of Lung Transplant in Cystic Fibrosis. Louis-Georges Ste-Marie*[1], Natalie Dion[1], Pasquale Ferraro[2], Caroline Albert[3], Nathalie Bureau[2], Audray Fortin[2], Valérie Jomphe[2], Larry Lands[4], Genevieve Mailhot[5]. [1]CHUM, University of Montreal, Canada, [2]CHUM, University of Montreal, Canada, [3]CHUM, Canada, [4]MUCH, McGill University, Canada, [5]Research Center CHU Sainte-JustineUniversity of Montreal, Canada

In the past 20 years, cystic fibrosis patients (CF) have dramatically extended their survival due to advances in care. As CF get older, age-related complications such as fragility fractures, known to seriously undermine their quality of life, have emerged. Despite its high prevalence, pathogenesis of CF-related bone disease remains poorly understood and predicting individuals at increased risk of fracture is still difficult. Bone strength is determined by bone quantity and quality. Knowing that bone mineral density (BMD) is a poor predictor of fractures in CF, it is reasonable to postulate that alterations in bone quality will likely contribute to their propensity to fracture. In order to assess bone quality in CF, a 2 cm segment of rib was recovered during lung transplantation. For the control group, a rib sample has been taken from simlarly aged lung donors without chronic diseases (D). To date, 25 specimens were collected [12 CF: 28 ±8yo and 13 D: 34 ±11yo; p=0.14] which exclude CF under bisphosphonate treatment. These specimens were analysed with various techniques to evaluate: BMD by DXA, microstructure by micro-CT, bone remodelling by histomorphometry and quality of bone strength by calcein staining of microcracks. *Ex vivo* rib BMD tended to be lowered in CF compared to D (CF: 0.16 ±0.05 vs D: 0.19 ±0.03g/cm^2; p=0.08) as well as cortical tissue mineral density measured by micro-CT (CF: 0.84 ±0.09 vs D: 0.93±0.16g HA/cm^3; p=0.12). Interestingly, trabecular BMD determined by micro-CT was significantly lower in CF than in D (CF: 0.06 ±0.5 vs D: 0.11 ±0.06g HA/cm^3; p=0.03). As shown in Table I, no major differences in microstructural indices (by micro-CT and by histomorphometry) were found between CF and D. Compared to D, osteoid parameters, OV/BV and OS/BS, tended to be lowered in CF whereas mean osteoid thickness was significantly reduced. Eroded surfaces were significantly decreased in CF than in D. Presence of microcraks in trabecular bone (Cr.D) was four times higher in CF than in D (p=0.009). These preliminary results suggest a possible decrease in bone remodeling in CF (both formation and resorption),which could contribute to the accumulation of micro-damage leading to the weakening of bone strength. This exploratory study confirmed the use of rib specimens as a precious tool to assess bone quality and ultimately, to better understand fracture risk in end-stage CF patients.

Table I	CF	D

Effect of Risedronate on Bone Mineral Density and Trabecular Bone Score in Liver Postransplantation patients after one year of follow-up. Gonzalo Allo Miguel[1], María Soledad Librizzi[2], Sonsoles Guadalix Iglesias[1], David Lora[3], Guillermo Martinez Diaz-Guerra[4], Federico Hawkins*[5]. [1]12 de Octubre, University Hospital., Spain, [2]12 de Octubre, University Hospital, Spain, [3]Clinical Epidemiology Unit, 12 de Octubre University Hospital., Spain, [4]University Hospital 12 Octubre, Esp, [5]Hospital Universitario, Spain

Introduction: Patients with organ transplantion have higher risk of osteoporosis and related fractures. Aminobisphosphonates are the mainstay of anti-resorptive treatment for them.Risedronate (RIS) seems to have an early and positive effect, reducing these complications. In addition to bone loss, bone quality alterations are involved in bone strength and could be assessed by the trabecular bone score (TBS).

Aim: Evaluate the effect of RIS (35 mg/weekly) on TBS and BMD in patients with liver transplantation, during one year follow-up.

Material and methods: 81 patients with liver transplantation and low BMD at baseline were randomized to RIS plus calcium and vitamin D (RIS group) vs. calcium and vitamin D (control group, CON) and followed over 1 year. LS and FN DXA (Hologic Discovery W) was perfomed at baseline, 6 and 12 months. Site matched LS TBS data was obtained using TBS iNsight 2.0 software (Medimaps, Swiss). Serum PTHi, 25(OH)D, β-CTX and P1NP were determined at baseline, 6 and 12 months. Bivariate comparisons were performed using Student's *t* test and Pearson's X^2 analysis for continuous variables.

Results: 62/19 (male/female) patients were randomized in two groups (RIS and CON). Baseline characteristics (mean±SD) were similar between groups in age (56.04±8.41), IMC (24.96±4.41), TBS (1.29±0.12), except in LS T-score (RIS -2.57±0.87; CON -2.13 ±0.73, p=0.016). TBS was low in both groups at baseline (RIS 1.29±0.12; CON 1.30±0.12, p=0.84), 6 months (RIS 1.27±0.13; CON 1.30±0.10, p=0.75) and 12 months (RIS 1.27±0.11; CON 1.29±0,12, p=0.98). LS BMD increased in both groups at 12 months vs. baseline; RIS: +4.81±8,81%; CON +3,35±5,76% (p=0.385).There were no significant differences between groups in BMD at any site at 6 or 12 months. No correlations were found between BMD and TBS values, at any follow-up time point. No significant differences were found between patients with (n=6) or without vertebral fractures in their TBS values. A positive correlation (r=0.34; p=0.009) was found between β-CTX and TBS at 6 months. No correlations were found between TBS and age, sex, PTHi, 25 (OH)D and P1NP.

Conclusions: After 12 months of treatment, BMD improved at LS in both groups. We found persistenly low TBS values during the follow-up, in both groups, without significant changes after RIS treatment. Our results point towards 1 year of immunosuppressive therapy does not induce bone microarchitecture degradation in liver transplant patients.

Inkjet-based biopatterning of SDF-1β augments BMP-2-induced repair of critical size mouse calvarial defects. James Cray*[1], Samuel Herberg[2], Galina Kondrikova[3], Sudharsan Periyasamy-Thandavan[4], R. Nicole Howie[3], Mohammed Elsalanty[5], Lee Weiss[6], Phil Campbell[7], William Hill[8]. [1]Medical University of South Carolina, USA, [2]Case Western Reserve University, USA, [3]Georgia Regents University, USA, [4]Georgia Regents University & Charlie Norwood VAMC, USA, [5]Georgia Regents University, USA, [6]Carnegie Mellon University, USA, [7]Carnegie Mellon University, USA, [8]Georgia Regents University & Charlie Norwood VAMC, USA

Purpose: A major problem in craniofacial surgery is non-healing bone defects. Autologous reconstruction remains the standard of care in the treatment of these cases, however bone morphogenetic protein-2 (BMP-2) therapy has proven its clinical utility, although non-targeted adverse events occur due to the high milligram-level BMP-2 doses used. Ongoing efforts explore the use of different growth factors, cytokines, or chemokines as well as co-therapy strategies to augment healing.

Methods: Here we utilize inkjet-based biopatterning technology to controllably load acellular DermaMatrix delivery matrices with nanogram-level doses of BMP-2, stromal cell-derived factor-1β (SDF-1β), transforming growth factor-β1 (TGF-β1), or co-therapies thereof. We tested the hypothesis that bioprinted SDF-1β co-delivery enhances BMP-2- and TGF-β1-driven osteogenesis both *in vitro* and *in vivo* using a mouse calvarial critical size defect (CSD) model.

Results: Our data showed that BMP-2 bioprinted in low-doses induced significant new bone formation by four weeks post-operation. TGF-β1 was less effective compared to BMP-2, and SDF-1β therapy did not enhance osteogenesis above vehicle control levels. Co-delivery of BMP-2 + SDF-1β was shown to augment BMP-2-induced bone formation compared to BMP-2 alone. In contrast, co-delivery of TGF-β1 + SDF-1β decreased bone healing compared to TGF-β1 alone. This was further confirmed *in vitro* by osteogenic differentiation studies using MC3T3-E1 pre-osteoblasts.

Conclusions: Our data indicates that delivery of a low-dose growth factor therapy based on biopatterning technology can aid in healing CSD injuries. SDF-1β augments

the ability for BMP-2 to drive healing, a result confirmed *in vivo* and *in vitro*; however, because SDF-1β is detrimental to TGF-β1-driven osteogenesis, its' effect on osteogenesis is not universal. We are continuing work specifically investigating dose and delivery technologies within this paradigm.

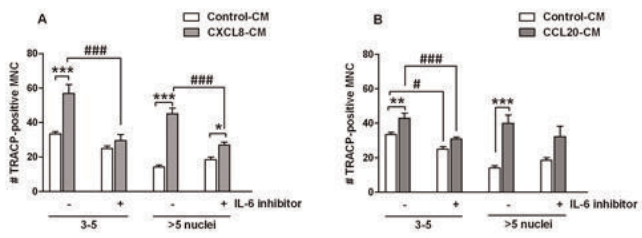
CXCL8 and CCL20 Enhance Osteoblast-Mediated Osteoclastogenesis. Janak L Pathak[1], Astrid D Bakker[2], Patrick Verschueren[3], Willem F Lems[4], Frank P Luyten[3], Jenneke Klein-Nulend*[5], Nathalie Bravenboer[6]. [1]Department of Oral Cell Biology, Academic Centre for Dentistry Amsterdam (ACTA), University of Amsterdam & VU University Amsterdam, MOVE Research Institute Amsterdam, Netherlands, [2]Department of Oral Cell Biology, Academic Centre for Dentistry Amsterdam (ACTA), University of Amsterdam & VU University Amsterdam, Netherlands, [3]Skeletal Biology & Engineering Research Center, KU Leuven, Belgium, [4]Department of Rheumatology, VU University Medical Center, MOVE Research Institute Amsterdam, Netherlands, [5]ACTA-VU University AmsterdamDept Oral Cell Biology (Rm # 11N-63), The Netherlands, [6]VU University Medical Center, The Netherlands

Introduction: Osteoporosis is common in rheumatoid arthritis. CXCL8 and CCL20 are chemokines, which are produced by inflammatory cells around the inflamed joints in rheumatoid arthritis, and which are found at elevated levels in synovial fluid and serum. Since osteoblasts express receptors for CXCL8 and CCL20 we hypothesized that CXCL8 and CCL20 contribute to osteoporosis in rheumatoid arthritis by affecting osteoblast proliferation, differentiation, and osteoblast-osteoclast communication. The purpose of this study was to indicate a role for the chemokines CXCL8 and CCL20 in osteoclastogenesis through their effect on osteoblasts.

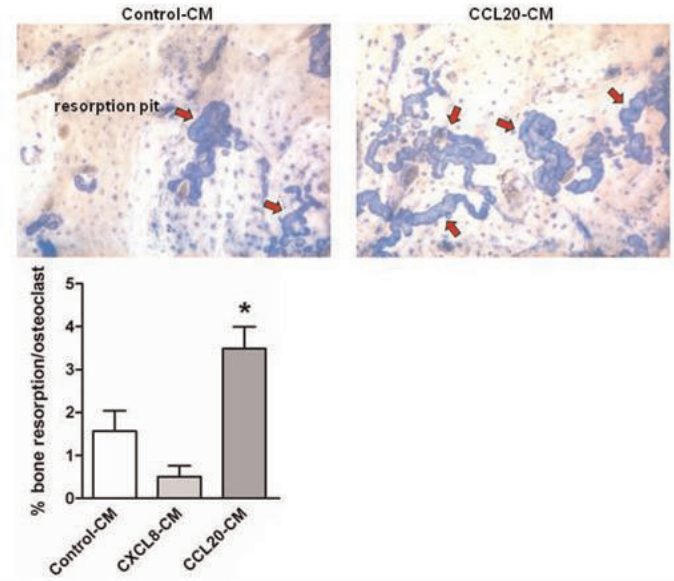
Methods: Primary human osteoblasts were cultured in the presence or absence of CXCL8 (2-200 pg/ml) or CCL20 (5-500 pg/ml) for 14 days. Osteoblast proliferation and differentiation were analyzed, as well as cytokine gene expression. IL-6 protein production was quantified by ELISA. Human peripheral blood mononuclear cells were cultured with conditioned medium (CM) from CXCL8 and CCL20-treated osteoblasts in the presence or absence of IL-6 inhibitor for 21 days. The number of tartrate-resistant acid phosphatase-positive osteoclasts was counted, and osteoclast activity was determined by the resorption pit assay.

Results: CXCL8 (200 pg/ml) enhanced mRNA expression of Ki-67 up to 2.7-fold, alkaline phosphatase by 1.7-fold, and IL-6 protein production by 1.2-fold in osteoblasts. CXCL8-CM enhanced the number of osteoclasts by 1.7-fold (3-5 nuclei), and 3.0-fold (>5 nuclei) (Fig. 1A). IL-6 inhibition reduced these osteoclast numbers by ~40% (Fig. 1A). CCL20 (500 pg/ml) enhanced mRNA expression of Ki-67 up to 2.5-fold, alkaline phosphatase by 1.6-fold, and IL-6 protein production by 1.3-fold in osteoblasts. CCL20-CM enhanced the number of osteoclasts by 1.3-fold (3-5 nuclei), and 2.8-fold (>5 nuclei), while IL-6 inhibition reduced these osteoclast numbers by ~30% (Fig. 1B). CCL20-CM increased osteoclast activity by 2.2-fold (Fig. 2). Neither CXCL8 nor CCL20 directly affected osteoclastogenesis.

Conclusion: CXCL8 and CCL20 did not negatively affect osteoblast proliferation or differentiation. However, both CXCL8 and CLC20 enhanced osteoblast-mediated osteoclastogenesis, partly via stimulation of IL-6 production, suggesting that CXCL8 and CCL20 contribute to localized and generalized osteoporosis in rheumatoid arthritis.



CXCL8-CM and CCL20-CM enhanced osteoclastogenesis, and inhibition of IL-6 reduced this effect



CCL20-CM, but not CXCL8-CM, enhanced osteoclastic bone resorption

Targeted inhibition of the Parathyroid Hormone related Protein (PTHrP) 1-173 isoform in human triple negative breast cancer (TNBC) reproduces all the effects of simultaneous inhibition of all three PTHrP isoforms on tumor growth *in vitro* and *in vivo* . Aimee-Lee Luco*[1], Dao Chao Huang[2], Ibtihal Fadhil[3], Benoit Ochietti[3], Xian Fang Huang[3], Anne Camirand[3], Richard Kremer[2]. [1]McGill University, Canada, [2]McGill University, Royal Victoria Hospital, Canada, [3]McGill University Health Center, Canada

In humans PTHrP exists in three isoforms including PTHrP 1-139, 1-41 and 1-173.PTHrP 1-173 is uniquely expressed in human tissues but its biological role remains elusive. Most human cancer tissues express the three isoforms but their specific role in breast cancer progression has not been examined. In this study we raised specific monoclonal antibodies against PTHrP 1-173 and compared their effects to monoclonal antibodies directed at all three isoforms in human triple negative breast cancer (TNBC) models. *In vitro* we examined the following PTHrP producing TNBC cell lines: MDAMB231, BT549 and MDAMB435.We also used the PTHrP negative TNBC cell line MDAMB468 as a negative control. Monoclonal antibodies were raised against PTHrP1-33(P158 and M45), PTHrP140-173(P108) and PTHrP 150-169(P6 and M18).Expression of PTHrP isoforms was examined with real time PCR and Western Blots. Cells were grown in DMEM 10% FBS and cell growth over time determined using the alamar assay. A dose dependent growth inhibition with the monoclonal antibodies was observed in PTHrP positive TNBC but not in the PTHrP negative TNBC or in PTHrP positive TNBC treated with IgG/IgM controls. A maximal growth inhibition of ⩾80% was achieved with all monoclonal antibodies tested in PTHrP positive cells with no significant difference was observed between cells treated with monoclonal antibodies directed against PTHrP 1-173 (P108, P6 and M18) compared to cells treated with monoclonal antibodies raised against all three isoforms (P158 and M45) .In contrast treatment with Tamoxifen or Herceptin had no effect on TNBC growth. We next examined *in vivo* the efficacy of two monoclonal antibodies directed either at the three isoforms (M45)or specifically directed at the PTHrP1-173 isoform (M18) in female nude mice transplanted with MDAMB435 cells in the mammary fat pad. Animals received intra-peritoneal injections of 200 micrograms of antibodies three times a week for 6 weeks and tumor growth examined overtime. A significant inhibition of tumor growth (~60%, $p \leq 0.01$) was observed but was not significantly different between animals treated with M45 or M18 monoclonal antibodies. Tumor examination at sacrifice revealed significant inhibition of cell cycle and mitogenic markers (cyclinD1 and Ki67) and of the chemokine receptor CXCR4.

Detection of sonic hedgehog in a patient with orthognathic surgery. Tsuyoshi Shimo[1], Yuki Kunisada*[2], Naito Kurio[3], Masanori Masui[2], Norie Yoshioka[2], Soichiro Ibaragi[2], Tatsuo Okui[2], Akiyoshi Nishiyama[2], Akira Sasaki[4]. [1]Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sci, Japan, [2]Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sciences, Japan, [3]Japan, Japan, [4]Okayama University, Japan

Introduction: Previously, we have reported that sonic hedgehog (SHH) is expressed at the site of a bone fracture spatiotemporally, and activate bone remodeling. In this study, we investigated the involvement of SHH in the fractured healing processes during the perioperative period for orthognathic surgery.

Methods: Between 2012 and 2013, 34 patients (24 female and 10 male, mean age was 23.4 (16-42) years) were admitted to our institution for the orthognathic surgery (22 maxillary and mandibular, 12 mandibular). Human serum from peripheral venous and local drainage was isolated from patient at the different time points during the perioperative period. The levels of SHH, soluble receptor activator of nuclear factor-κB ligand (sRANKL) and osteoprotegerin (OPG) were assayed by ELISA and the relationship between them was analyzed. Approval for this study was obtained from the human ethics committee of Okayama University.

Results: Local serum SHH, sRANKL and OPG levels at 1 day after surgery was increased more than those of peripheral serum. The ratio of SHH/OPG in peripheral serum were decreased after 1 days of surgery, and increased on day 3 and 7. Similarly the ratio of sRANKL/OPG in peripheral serum were decreased after 1 and 3 days of surgery, and increased on day 7. SHH/OPG ratio in local serum was unchanged at 0, 1, and 2 days after surgery. On the other hand, the sRANKL/OPG ratio in local serum was decreased 2 days after surgery.

Conclusion: The level of SHH in the local serum was increased after the osteotomy. There should be further evaluation of use of SHH as a biomarker of fracture healing.

MO0426

Novel ELISA for the Quantitative Measurement of Free, Bioactive, Soluble RANKL - A New Highly Sensitive Tool for Bone Research. Andreea Suciu[1], Andreas Breitwieser*[2]. [1], Austria, [2]Biomarker Design Forschungs GmbH, Austria

RANKL, the receptor activator of nuclear factor kappa B ligand is a key regulator in bone metabolism (1) and acts through binding to the transmembrane receptor RANK. RANKL is a membrane-bound protein that can be segregated to a soluble, bioactive (2) form (sRANKL). Through competitive binding to the naturally occurring decoy receptor Osteoprotegerin (OPG), the RANKL/RANK interaction can be blocked at the ligand/receptor level.

One of the biggest challenges in measuring free soluble RANKL are its low circulating levels and its nature to bind to OPG, making it difficult to measure: the accuracy of sRANKL measurement is compromised by the very low or undetectable levels, as observed in some patient cohorts (3).

Our goal was to develop a highly sensitive and specific assay that enables the direct measurement of free, bioactive, soluble RANKL in serum and plasma samples by taking advantage of the high affinity and specificity protein-protein interaction between sRANKL and OPG. Immobilized, recombinant OPG was used to capture free sRANKL, which subsequently is detected with a biotin labeled anti-sRANKL antibody.

We could show that nearly all samples (98%) from an unselected healthy population (n=210) had detectable free sRANKL values within the calibration range of the assay (0 - 2 pmol/l). The median of serum samples (prepared immediately after blood collection and stored at -25℃) was 0.14 pmol/l, with a lower limit of quantification (LLOQ) of 0.01 pmol/l. Assay characteristics, such as intra/inter-assay precision, dilution linearity and spike/recovery as well as sample stability have been analyzed and will be presented.

Our novel ELISA provides a reliable and accurate tool for the quantitative determination of free, soluble, bioactive RANKL in human samples and could help to understand the underlying regulatory mechanisms of various diseases such as rheumatoid arthritis, inflammatory bowel disease, multiple myeloma, and cardiovascular disease. Future analyses of free soluble RANKL with this highly sensitive assay could also range from drug efficacy studies to screening for the early detection of diseases.

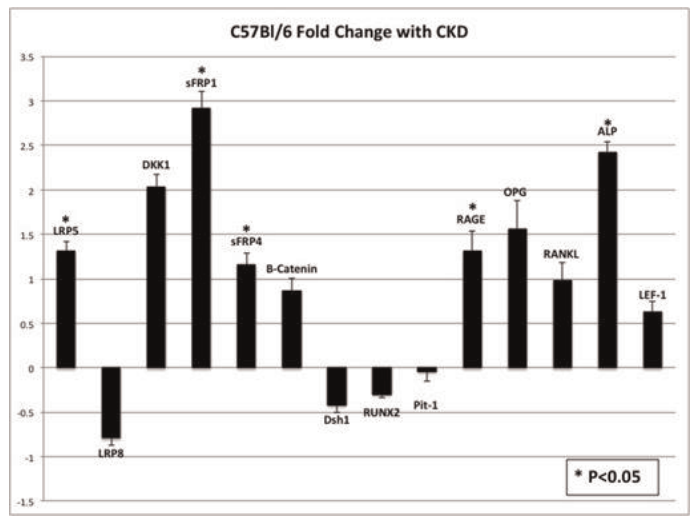
Baseline Bone Density Modulates the Wnt Signaling Pathway in a Murine Kidney Disease Model. Ryan Clark*[1], Laura Shum[1], Xiaoxin Wang[1], Moshe Levi[2], Karen King[3]. [1]University of Colorado, USA, [2]University of Colorado Denver, USA, [3]University of Colorado School of Medicine, USA

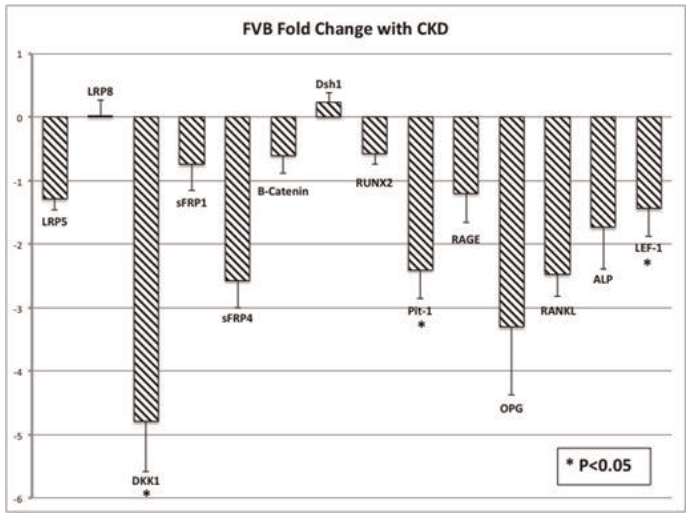
Purpose: Chronic kidney disease (CKD) often leads to decreased bone quality. However, the mechanisms involved are not clear. One potential mechanism linking CKD to bone metabolism is the Wnt signaling pathway. We measured Wnt pathway gene expression changes due to CKD in two strains of mice: C57Bl/6, a *low* bone density strain, and FVB, a *high* bone density strain. The purpose was to answer the following: 1) Does CKD affect Wnt signaling in bone?, and 2) Does baseline bone density modulate the effect of CKD on Wnt signaling?

Methods: This study was IACUC approved. In a two-stage surgery on 10 wk. old mice, one kidney and the cortical portion of the second were removed (''5/6 Nx'' N = 12 mice/strain). Control surgeries were also two-stage on 10 wk. old mice, but no renal tissue removed (''Sham'' N = 12 mice/strain). Mice were euthanized at 10 wks. post-surgery. Femoral bone was cleaned, snap-frozen and analyzed by SYBR green real time RT-PCR. Data were analyzed by Mann-Whitney rank sum test; $\alpha = 0.05$. The expression of [A] extracellular signaling genes, LRP5, LRP8, DKK1, sFRP1, and sFRP4; [B] intracellular signaling genes, β-catenin and disheveled-1; and [C] downstream regulation of bone turnover, RUNX2, PIT-1, RAGE, OPG, RANKL, ALP, and LEF1 were measured.

Results: [A] LRP5, sFRP1, sFRP4, and DKK1 increased in the 5/6 Nx C57Bl/6 group (P=0.03, 0.001, 0.05 and 0.07, respectively compared to Sham C57Bl/6). Expression of these genes appeared lower in the 5/6 Nx FVB group compared to Sham FVB but data were not significant. [B] Intracellular signaling genes were not significantly changed with 5/6 Nx in either strain (P>0.05); however, they all appeared to increase in the 5/6 Nx C57Bl/6 but decrease in the 5/6 Nx FVB group. [C] RAGE and ALP increased in the 5/6 Nx C57Bl/6 group (P=0.03 and 0.03 respectively). However, Pit-1 and Lef1 decreased significantly in the 5/6 Nx FVB group (P=0.03 and 0.02 respectively). Conclusion: This study demonstrates that in mice 1) CKD alteration of bone metabolism involves the Wnt signaling pathway. This study further demonstrates that in mice 2) baseline bone density likely modulates this Wnt signaling. The *low density* bone of the C57Bl/6 is resistant to changes in CKD while the *high density* bone of the FVB is more susceptible. To our knowledge, this is the first study connecting Wnt signaling with baseline bone density. This new information is important to the development of bone therapies for patients with kidney disease.



C57Bl/6 with CKD



FVB with CKD

MO0428

Induction of CXC Chemokines in Human Mesenchymal Stem Cells (hMSCs) by Stimulation with Secreted Frizzled-Related Proteins (sFRPs) through Non-Canonical Wnt Signaling. David Bischoff*[1], Jian-hua Zhu[2], Nalini Makhijani[1], Dean Yamaguchi[3]. [1]VA Greater Los Angeles Healthcare System, USA, [2]VA Greater Los Angeles Healthcare System, USA, [3]VA Greater Los Angeles Healthcare System, USA

CXC chemokines, CXCL5 and CXCL8, are elaborated from hMSCs during differentiation with osteogenic differentiation medium (OGM) and dexamethasone (DEX), and may be involved in angiogenic stimulation during bone repair. We showed that components of both canonical and non-canonical Wnt signaling are involved in the stimulation of CXCL5 in OGM. Conditioned medium (CM) from L-cells expressing Wnt5a, a non-canonical Wnt, stimulated an increase in CXCL5 mRNA expression and protein secretion in comparison to control L-cell CM. Dkk-1, an inhibitor of canonical Wnt signaling inhibited basal levels of CXCL5 expression at 7 days but not at 10 days. RoR2, a co-receptor for non-canonical Wnt signaling was also significantly up-regulated by OGM and DEX approximately 12-fold. sFRP1, which should inhibit both canonical and non-canonical Wnt signaling, surprisingly enhanced the expression of CXCL8 and to a lesser degree CXCL5 at 7 and 10 days. In addition, all four sFRPs induced CXCL8 expression in a dose- and time-dependent manner with maximum expression at ~150 nM at 7 days although the largest increases in CXCL8 and CXCL5 expression were seen with sFRP1 or sFRP2. Activation of MAPK signaling can enhance CXC ligand expression. Analysis of MAPK signaling showed sFRP1-induced phosphorylation of ERK in hMSCs maximally at 5 minutes. We used siRNA technology to decrease expression levels of several Frizzled receptors (Fzds) in an attempt to identify those receptors that could potentially be involved in sFRP stimulation of CXCL5 and CXCL8. Fzd2, 4, 5, and 7 were chosen since they are known to bind Wnt5a protein, and Fzd6 since it has been shown to bind sFRPs. hMSCs were transfected with siRNA for the Fzds and then treated with sFRPs. Screening experiments indicated that Fzd2, 4, 5 and 6 but not Fzd7 may be involved in the sFRP stimulation of CXCL8 and CXCL5. Subsequent experiments using siRNA directed against Fzd2 verified that Fzd2 is strongly involved in sFRP stimulation of both CXCL5 and CXCL8 with the effect on CXCL8 being greater than that on CXCL5. Conclusions: 1) the expression of the CXC chemokines, CXCL5 and CXCL8, was enhanced in hMSCs undergoing osteoblastogenesis; 2) the non-canonical Wnt pathway appears to be involved in CXC chemokine expression during osteogenic differentiation; 3) sFRPs which stimulated CXCL5 and CXCL8 mRNA expression may do so through the Fzd2 receptor and possibly other non-canonical Fzd receptors and perhaps through ERK signaling.

MO0429

Pharmacokinetics (PK) and Pharmacodynamics (PD) of a Human Monoclonal Anti-FGF23 Antibody (KRN23) in a Long-Term Extension Study of Adults with X-linked Hypophosphatemia (XLH). Xiaoping Zhang*[1], Erik Imel[2], Mary Ruppe[3], Thomas Weber[4], Mark A. Klausner[5], Kavita Gumbhir-Shah[5], Takahiro Ito[5], Maria Vergeire[6], Jeffrey S. Humphrey[5], Francis Glorieux[7], Anthony Portale[8], Karl Insogna[9], Munro Peacock[10], Thomas Carpenter[9]. [1]Kyowa Hakko Kirin Pharma Inc, USA, [2]Indiana University School of Medicine, USA, [3]The Methodist Hospital, USA, [4]Duke University Medical Center, USA, [5]Kyowa Hakko Kirin Pharma Inc., USA, [6]Kyowa Hakko Kirin Pharma Inc., USA, [7]Shriners Hospital for Children & McGill University, Canada, [8]University of California San Francisco, USA, [9]Yale University School of Medicine, USA, [10]Indiana University Medical Center, USA

Objectives: In XLH, abnormally elevated serum FGF23 results in low renal maximum threshold for phosphate reabsorption (TmP/GFR), low serum phosphorus (inorganic Pi), and inappropriately normal 1,25 dihydroxyvitamin D [1,25$(OH)_2$D] with subsequent development of rachitic deformities. Single intravenous and subcutaneous (SC) and 4 monthly SC doses of KRN23 increased TmP/GFR, serum Pi, and 1,25$(OH)_2$D in adults with XLH. We previously reported PK and PK-PD relationships in the 4-month SC study. We report the PK and PK-PD relationships of KRN23 following up to 12 additional monthly SC administrations in an extension study of the initial 4-month protocol.

Methods: Up to 12 SC doses of KRN23 were given every 28 days to 22 adults with XLH who had completed the initial 4-dose study. KRN23 doses (0.05, 0.1, 0.3, 0.6 and 1 mg/kg) were based on a dosing algorithm. Blood and urine samples for assessing PK and PD variables were collected pre-dose and periodically after each dose. Serum samples for KRN23 were analyzed using a validated assay and PD parameters using commercial methods.

Results: The starting KRN23 dose was 0.3 to 1.0 mg/kg. Doses were generally increased for Doses 2 and 3. Doses within individual subjects were stable from Doses 4 to 12 and $\geq$ 85% received 0.6 or 1.0 mg/kg doses. Serum KRN23 levels peaked 7 days after each dose. The correlation between area under the PD effect curve (AUEC) using change from baseline, and serum KRN23 area under the curve (AUC) was better described by an E_{max} model for serum Pi (E_{max} = 329 mg $\times$ day/dL, EC_{50}=10809 µg $\times$ hr/mL), TmP/GFR (E_{max} 409 mg $\times$ day/dL, EC_{50} 16015 µg $\times$ hr/mL) and 1,25$(OH)_2$D (E_{max} 6395 pg $\times$ day/dL, EC_{50} 9146 µg $\times$ hr/mL) compared with a linear model. The AUEC for the change from baseline increased linearly with KRN23 PK exposure (AUC) for several bone biomarkers: serum bone alkaline phosphatase, osteocalcin, P1NP and CTx. There were no meaningful PK-PD relationships for a variety of additional PD and safety parameters (serum calcium, calcitonin, intact PTH, creatinine, 25-hydroxy vitamin D; and 24-hour urine calcium, calcium/creatinine ratio, phosphate and creatinine)

Conclusion: Stability of KRN23 doses and serum levels was achieved after approximately 3 doses of extended monthly KRN23 SC administration. An E_{max} model described the relationship between KRN23 PK exposure and the key PD parameters of serum phosphorus, TmP/GFR and serum 1,25$(OH)_2$D after long-term monthly administration of KRN23 in adults with XLH.

Osteoblast malfunction in the G610C model of osteogensis imperfecta. Lynn Mirigian[1], Elena Makareeva[1], Edward Mertz[1], Joseph Perosky[2], Kenneth Kozloff[3], Sergey Leikin*[4]. [1]National Institutes of Health, USA, [2]University of Michigan, USA, [3]University of Michigan Department of Orthopaedic Surgery, USA, [4]National Institutes of Health, USA

In this study, we investigated osteoblast dysregulation caused by misfolding of type I procollagen with a Cys substitution for Gly610 (from the N-terminal end of the triple helix) in the α2(I) chain. Mice with G610C substitution in one Col1a2 allele exhibit low bone density, hypermineralization of bone matrix, and reduced bone strength. They represent a model for moderately severe osteogenesis imperfecta (OI) caused by Gly substitutions. Calvarial osteoblasts isolated from newborn G610C mice secreted less procollagen yet had more procollagen inside the cell compared to wild type osteoblasts. Pulse-chase labeling of the cultured cells revealed a delay in folding of molecules with the G610C chain. Lower than expected fraction of these molecules in secreted procollagen suggested that they were selectively retained by the cell. The resulting procollagen accumulation is likely responsible for abnormal osteoblast differentiation and function. In bone marrow stromal cell culture, we observed abnormal activation of NFkB signaling and reduced osteoblast colony formation. In calvarial osteoblast culture, we also observed attenuated Smad2 phosphorylation and insufficient stimulation of collagen production in response to TGFb. In vivo, we observed severe osteoblast ER cisternae dilation, abnormal bone deposition (rate, location, and composition), and abnormal relative quantities of Runx2, Sp7, Bglap, and Ibsp transcripts. Osteoblasts appeared to degrade misfolded G610C molecules in lysosomes via autophagy; we found significant additional accumulation of procollagen upon treatment of cultured G610C cells with inhibitors of this pathway (chloroquine and bafilomycin) but not with inhibitors of ER associated degradation

in proteasomes (bortemozib and eeyarestatin). An important role of autophagy was further supported by improvements in bone material properties and differentiation of cultured osteoblasts from G610C mice placed on a low protein diet (8% vs. 18%), although the diet inhibited bone and overall animal growth. We propose that osteoblast adaptation to accumulation of misfolded mutant procollagen alters crucial cell signaling and functions. Better understanding of pathways involved in this cell response may lead to novel therapeutic treatments for OI and other disorders involving procollagen misfolding.

Two Distinct Mutations in *IFITM5* Causing Different Forms of Osteogenesis Imperfecta Using Reciprocal Mechanisms. ADI Reich*[1], Charles Farber[2], Aileen Barnes[3], Patricia Becerra[4], Frank Rauch[5], Wayne A. Cabral[3], Alison Bae[3], Francis Glorieux[6], Thomas Clemens[7], Joan Marini[8]. [1]NIH, USA, [2]University of Virginia, USA, [3]NIH/NICHD/BEMB, USA, [4]NIH/NEI/Protein Structure & Function Section, USA, [5]Shriners Hospital for Children, Montreal, Canada, [6]Shriners Hospital for Children & McGill University, Canada, [7]Johns Hopkins University, USA, [8]National Institute of Child Health & Human Development, USA

Osteogenesis imperfecta (OI) type V is caused by a recurrent dominant mutation (c.-14C>T) in *IFITM5*, which encodes BRIL, a transmembrane ifitm-like protein most strongly expressed in osteoblasts, whose expression coordinates with mineralization. Patients with type V OI have distinctive clinical manifestations with overactive bone mineralization and include mesh-like lamellation on bone histology. Recessive null mutations in *SERPINF1* cause OI type VI, which impairs mineralization. Type VI OI patients have absence of serum PEDF, elevated alkaline phosphatase (ALPL) as children, and bone histology with broad unmineralized osteoid and fish-scale pattern.

We identified a 25-year-old woman with severe OI, who had no characteristics of OI type V. Her dermal fibroblasts (FB) and cultured osteoblasts (OB) displayed minimal secretion of PEDF, but her serum PEDF was normal. *SERPINF1* sequences were normal despite bone histomorphometry typical of type VI OI, and elevated childhood serum ALPL. Exome sequencing on the proband, parents and an unaffected sibling yielded a *de novo* mutation in *IFITM5* in one allele of the proband, causing a p.S40L substitution in the BRIL intracellular domain.

In OB with the *IFITM5* p.S40L mutation, *IFITM5* expression was normal, as was BRIL protein level on western blot and in permeabilized OB by microscopy. Notably, *SERPINF1* expression was decreased in p.S40L OB, and PEDF was barely detectable in conditioned media of S40L cells. OB with the S40L mutation also had decreased expression of *ALPL* and osteocalcin (*OCN*), as seen in primary PEDF defects. In contrast, OB from type V OI, with 5 residues added to the N-terminus of BRIL, have increased *SERPINF1* expression and PEDF secretion during differentiation, and increased *ALPL* and *OCN* expression. The *IFITM5* mutations also have opposite effects on OB mineralization in culture – OB with the 5'-terminal mutation have increased mineralization during differentiation, while mineralization was decreased in S40L OB. OB from both mutations had a collagen related defect, with decreased expression and secretion of COL1A1. Together, these data show that 2 distinct mutations in *IFITM5*generated different forms of OI with distinctive phenotypes using reciprocal mechanisms; the type V OI and p.S40L BRIL are gain- and loss-of-function mutations, respectively. Furthermore, BRIL and PEDF have a relationship that connects the genes for types V and VI OI and their roles in bone mineralization.

MO0432

Whole exome sequencing is efficient for detecting mutations in patients with osteogenesis imperfecta and children with bone fragility. Ikuma Fujiwara*. Tohoku University School of Medicine, Japan

Purpose: Most of the patients with osteogenesis imperfecta (OI) are caused by mutations in either two of the genes for type 1 collagen, *COL1A1* or *COL1A2*. Genetic analysis is useful to predict the clinical course of patients because genotype usually correlates phenotype of the disease. Since the sizes of both *COL1A1* and *COL1A2* are large, time and effort are required for analyzing the genes. In recent years, more than a dozen of genes have been revealed to cause OI, and it is difficult to tell which gene is related only by clinical manifestation except a couple of genes.

Methods: We have performed whole exome sequencing (WES) in three patients clinically diagnosed as OI and a child with bone fragility and low bone mineral density, in whom mutations in *COL1A1*/*COL1A2* were not detected by Sanger sequence. This study was approved by IRB of the institute, and informed consent was obtained from at least one of the parents of each patient. For WES, targeted enrichment was performed using the SureSelect Human All Exon 50Mb kit for twelve individuals. Exon-enriched DNA libraries were sequenced on the Illumina Hiseq 2000 for 101bp. BWA was used to align the sequence reads to the human genome (hg19); all parameters of BWA were kept at the default settings. Following removal of duplicates from the alignments, realignment around known indels, recalibration and SNP/indel calling were performed with Genome Analysis Toolkit (GATK) (1.5). ANNOVAR was used for the annotation against the RefSeq database and dbSNP. We searched for variants in OI causing genes (*IFITM5*, *SERPINF1*, *CRTAP*, *LEPRE1*, *PPIB*, *SERPINH1*, *FKBP10*, *SP7*, *BMP1*, *WNT1*, *TMEM38B*, *CREB3L1*) in addition to *COL1A1* and *COL1A2*.

Results: A missense mutation (p.G326R) in *COL1A1* was found in an OI patient. Two rare variations in *CREB3L1* (p.G92S, p.A411T) were found in another girl with bone fragility. We have not found specific variants in OI causing genes in other patients.

Conclusion: WES is an efficient method to detect variants for OI, but more strategic and deliberate approach is necessary to find new causative genes.

MO0433

Activities of Dysregulated ALK2 Receptor Kinases Provide Insight Into the Protein Structural-Functional Basis of Fibrodysplasia Ossificans Progressiva. Jay Groppe*[1], Mary Rose Tandang-Silvas[2], Anupama Pathi[2], Jingfeng Wu[2], Viet Le[3], Andria Culbert[4], Kristi Wharton[3], Frederick Kaplan[4], Eileen Shore[4]. [1]Texas A&M University Baylor College of Dentistry, USA, [2]TAMU Baylor College of Dentistry, USA, [3]Brown University, USA, [4]University of Pennsylvania, USA

Although structurally similar to the constitutively active type II counterparts, type I or Activin-like receptor kinases (ALKs) are set apart by the helix-loop-helix (HLH) element preceding the conserved Ser/Thr kinase domain that serves a passive role as an inhibitor-to-substrate binding switch according to the longstanding paradigm. Interestingly, signaling can be robustly activated without ligand-mediated assembly of a hetero-tetrameric complex by a single substitution with aspartate at the terminal residue of the regulatory subdomain. A single recurrent mutation in the codon of the penultimate residue, directly adjacent the position of the constitutively activating substitution, causes milder ligand-independent activation of ALK2 that leads to heterotopic bone deposition and secondary skeleton formation in patients presenting with FOP. Structure-based homology modeling showed that the recurrent mutation of classical FOP (R206H) disrupts a conserved ion pair juxtaposed between the FKBP12 inhibitory protein binding site and a loop (L45; β4>β5) conferring substrate protein specificity for the downstream effectors (R-Smads 1/5/8).

To determine the structural and functional basis of the activating effects of the recurrent FOP mutation, ALK2 receptor kinase forms have been produced at milligram scale by means of a baculovirus-insect cell expression system and purified to near homogeneity. Wildtype, R206H mutant, Q207D (aspartate-substituted) and HLH subdomain-truncated (208ntrunc) forms were compared through an array of *in vitro* kinase activity assays and diverse protein-protein interaction analyses that were complemented by comparison of signaling read-out (p-Smad) in primary mouse embryonic fibroblasts and cultured *Drosophila* S2 cells. We observed that FKBP12 buffered but did not strictly inhibit kinase activities *in vitro* and had no detectable effect on basal signaling in wildtype fibroblasts. On the other hand, the HLH subdomain alone diminished the activity of the wildtype kinase as shown by comparison with mutant and variant forms. In addition, an absolute requirement for the HLH subdomain was observed for Smad phosphorylation despite significantly elevated kinase activity upon truncation. Hence rather than passively serving as obligate sites of binding and phosphorylation, the juxtamembrane regulatory element plays active and direct roles in autoinhibition of the kinase and recruitment of substrate, safeguarding through coupling the processes.

MO0434

Association between Nance-Horan Syndrome and Fragility fractures in a young man. Are Connexins the Connection?. Manju Chandran*[1], Bart Clarke[2], Robert D Tiegs[2], Matthew Tan[1], Peter Byers[3], Ching Lin Ho[4]. [1]Osteoporosis & Bone Metabolism Unit, Singapore General Hospital, Singapore, [2]Division of Endocrinology, Diabetes, Metabolism & Nutrition, Mayo Clinic, USA, [3]Collagen Diagnostic Laboratory, Department of Pathology & Medicine (Medical Genetics), University of Washington, USA, [4]Glaucoma Service, Singapore National Eye Centre, Singapore

Introduction: A pathogenic variant in the single copy of the *NHS* gene causes Nance-Horan (Congenital Cataract-Dental) syndrome, an X-linked disorder with ocular, dental and auricular manifestations [1]. Bone loss and osteoporosis have not been described in association with NHS before. We present the case of a young man with low bone density and multiple low trauma compression fractures of the spine that were likely associated with his cataract–dental syndrome.

Case: A clinical diagnosis of Nance Horan Syndrome was made in a 24 year old Chinese male with congenital cataracts when he presented with the characteristic phenotype of micropthalmos, sclerocornea and peg shaped teeth. His mother also was noted to have some ocular features of the disease. 3 years later, he presented with a history of falling from standing height. X-Rays of his spine revealed compression fractures of T12, L1 and L3 vertebrae and a superior end plate fracture of L2. He recalled a history of a similar fall several years ago in his teens, however he had not had X-rays done then. He was 181 cm tall and weighed 73.6 kg. He had well developed secondary sexual characteristics and there were no other obvious physical deformities or stigmata such as blue sclerae. Plasma testosterone, FSH, LH, intact PTH, calcium, phosphorus, liver function tests, alkaline phosphatase, renal function, thyroid

function, cortisol level, and blood count were normal as were the serum and urine protein electrophoresis. There was no hypercalciuria. 25-OHD level was 26.4 ng/ml. DXA scan showed a femoral neck BMD of 0.631 gm/cm2 (Z-score: -2.2). Bone Scan showed only vertebral fractures. Sequencing of COL1A1 and COL1A2 genes did not show any coding sequence mutations or mutations in the nearby splice site domains. PCR based genotyping performed on blood of the patient and his mother showed a previously unreported pathogenic variant (c.565+1G>T) in the NHS gene in both individuals.

Discussion: The genes implicated in congenital cataract syndromes include members of the connexin family of gap junction proteins [2]. Connexins 43 and 45 have been found to be associated, specifically, with osteogenesis[3]. The intriguing possibility exists that mutations in the NHS gene could be responsible for the very unusual bone fragility in this young man with no other identifiable cause. It raises very interesting questions on the hitherto unexplored connection between connexins, bone development and fragility in humans.

Controlled local delivery of Trametinib combined to rBMP2 promotes osteoblast differentiation and bone healing in $Nf1_{Osx}^{-/-}$ mice. Jean De La Croix Ndong*[1], David Stevens[2], Guillaume Vignaux[2], Sasidhar Uppuganti[2], Daniel Perrien[3], Xiangli Yang[1], Jeffry Nyman[3], Eva Harth[2], Florent Elefteriou[1]. Neurofibromatosis type I (NF1) is an autosomal dominant disease with an incidence of 1/3000, caused by mutations in the *NF1* gene, which encodes the RAS/GTPase-activating protein neurofibromin. Non-bone union following fracture (pseudarthrosis) in children with NF1 remains a challenging orthopedic condition to treat. Recent progress in understanding the biology of neurofibromin suggested that NF1 pseudarthrosis stems primarily from defects in the bone mesenchymal lineage and hypersensitivity of hematopoietic cells to TGFb. However, clinically relevant pharmacological approaches to augment bone union in these patients remain limited. In this study, we report the generation of a novel conditional mutant mouse line used to model NF1 pseudoarthrosis, in which *Nf1* can be ablated in an inducible fashion in osteoprogenitors of post-natal mice, thus circumventing the dwarfism associated with previous mouse models where *Nf1* is ablated in embryonic mesenchymal cell lineages. An *ex vivo*-based cell culture approach based on the use of $Nf1^{flox/flox}$ bone marrow stromal cells showed that loss of *Nf1* impairs osteoprogenitor cell differentiation in a cell-autonomous manner, independent of developmental growth plate-derived or paracrine/hormonal influences. In addition, *in vitro* gene expression and differentiation assays indicated that chronic ERK activation in *Nf1*-deficient osteoprogenitors blunts the pro-osteogenic property of BMP2, based on the observation that only combination treatment with BMP2 and the MEK inhibitor Trematinib promoted the differentiation of *Nf1*-deficient osteoprogenitors. The *in vivo* preclinical relevance of these findings was confirmed by the improved bone healing and callus strength observed in $Nf1_{osx}^{-/-}$ mice receiving Trematinib and BMP2 released locally at the fracture site via a novel nanoparticle and polyglycidol (PEG)-based delivery method. Collectively, these results provide novel evidence for a cell-autonomous role of neurofibromin in osteoprogenitor cells and insights about a novel targeted approach for the treatment of NF1 pseudoarthrosis.

MO0436

Familial hypocalciuric hypercalcemia associated with a novel homozygous loss-of-function mutation, E671D, of the calcium-sensing receptor gene. Filomena Cetani[1], Simona Borsari[2], Elena Pardi[2], Brunella Bagattini[2], Federica Saponaro*[2], Claudio Marcocci[3]. [1]University Hospital of Pisa, Italy, [2]Department of Clinical & Experimental Medicine, University of Pisa, Italy, [3]University of Pisa, Italy

Familial Hypocalciuric Hypercalcemia (FHH) is an autosomal inherited dominant disease characterized by mild to moderate asymptomatic hypercalcemia, relative hypocalciuria, and inappropriately normal PTH levels. Fractional urinary excretion of calcium is important to distinguish patients with FHH from others forms of primary hyperparathyroidism (PHPT). The calcium/creatinine clearance ratio is <0.01 in FHH and higher in PHPT. Heterozygous and homozygous/compound heterozygous mutations of calcium sensing receptor gene (CASR), a G-protein-coupled receptor, are responsible for FHH type 1 and neonatal severe hyperparathyroidism (NSHPT), respectively. NSHPT is a much more serious disorder characterized by marked calcemia, hypotonia, skeletal demineralization, and can occur in the offspring of patients with FHH. In this study we report the case of 61-years-old woman referred to our Department for suspected PHPT. Biochemical analysis revealed high serum calcium (13 mg/dl) and ionized calcium (1,9 mmol/l) levels, PTH moderately elevated (78 pg/ml) and calcium/creatinine clearance ratio <0.01, suggestive of FHH. Serum calcium screening of her relatives showed normal values in the mother, brother and sons, while the father and the half-sister had mild hypercalcemia (10,3 and 10,9 mg/dl, respectively). Of note, her parents were consanguineous. Germline proband and parents' DNA was extracted from peripheral blood cells and the entire coding region and splice junctions of the CASR gene were directly sequenced. The proband was homozygous for the change c.2013G>C, that resulted in a novel missense mutation, E671D. The same mutation, in a heterozygous state, was present in the her parents and absent in 100 chromosomes of healthy control subjects. In conclusion, we identified a novel homozygous mutation, located in the first extracellular loop of CASR, in an adult woman with hypercalcaemia and hypocalciuria. The proband was born in good health and has had a normal neurological growth, so we can assume that the mutation E671D could have a mild effect. So far, at least three similar cases with homozygous presentation and a FHH phenotype have been described in the literature and functional studies of the mutations showed a mild functional inactivation in-vitro, demonstrating that not all CASR mutations found in a homozygous state necessarily cause neurodevelopmental defects due to an elevated hypercalcemia in infancy and childhood, but can resemble a classical FHH phenotype.

MO0437

Lysinuric Protein Intolerance Presenting with Multiple Fractures. Lindsay Burrage*[1], Jennifer Posey[2], Marcus Miller[2], Pengfei Liu[2], Matthew Hardison[2], Sarah Elsea[2], Qin Sun[2], Yaping Yang[2], Alecia Willis[2], Alan Schlesinger[2], Carlos Bacino[2], Brendan Lee[1]. [1]Baylor College of Medicine, USA, [2]Baylor College of Medicine, USA

Lysinuric Protein Intolerance (LPI), an autosomal recessive disorder, is caused by mutations in *SLC7A7*, which encodes a subunit of the dibasic amino acid transporter. LPI is characterized by urinary losses of lysine, ornithine, and arginine that result in a secondary ureagenesis defect, and thus, the typical presenting features include vomiting, irritability, and symptomatic hyperammonemia after consumption of protein-rich meals. Pulmonary alveolar proteinosis, renal dysfunction, macrophage activation syndrome, and osteoporosis are other possible long-term complications of this disorder. Here, we describe a 6-year-old male with history of short stature, speech delay and fragility fractures who has been treated with bisphosphonates. Evaluation for heritable forms of brittle bone diseases including sequencing of *COL1A1*/*COL1A2* was normal. Whole exome sequencing identified a nonsense mutation in one allele of *SLC7A7* and array comparative genomic hybridization detected a deletion involving the second allele. Biochemical testing was consistent with the diagnosis of LPI. Our patient's atypical presentation highlights the importance of including LPI in the differential diagnosis of idiopathic osteoporosis in the pediatric population even in the absence of other typical presenting features of this disorder.

MO0438

Phosphate Metabolism in Craniometaphyseal Dysplasia (CMD): Dietary Phosphate Restriction Reduces Increased Bone Mass in a CMD Mouse Model. Yaling Liu[1], Eliane Dutra[2], Zhifang Hao[1], Ernst Reichenberger[2], I-Ping Chen*[2]. [1]University of Connecticut Health Center, USA, [2]University of Connecticut Health Center, USA

Mutations in the pyrophosphate (PPi) transporter ANKH are responsible for craniometaphyseal dysplasia (CMD), which is characterized by progressive thickening of craniofacial bones and flared metaphyses of long bones. Mutant ANK fails to adequately transport PPi into the extracellular matrix. PPi inhibits and phosphate (Pi) promotes mineralization. Here, we examine whether an imbalance of the Pi/PPi ratio leads to an abnormal skeleton in a CMD knock-in mouse model ($Ank^{KI/KI}$) and in CMD patients.

Homozygous $Ank^{KI/KI}$ mice have lower serum Pi levels, increased *Fgf23* mRNA and hypomineralized bone. FGF23 is secreted by bone to increase Pi wasting and to decrease $1,25\text{-}(OH)_2D_3$ by reducing *1-α hydroxylase*, *Npt2a* and by increasing *Cyp24a1* upon binding to *Fgfr1* and *Klotho* in kidney. Unexpectedly, the FGF23 protein level in $Ank^{KI/KI}$ femurs was immunohistochemically normal. Serum of $Ank^{KI/KI}$ mice had an increased trend of intact FGF23 and significantly higher levels of the C-terminal FGF23 fragment suggesting enhanced proteolytic processing of FGF23. Renal expression of *1-α hydroxylase*, *Npt2a*, *Npt2c, Cyp24a1, Fgfr1, Klotho* were not significantly different but serum levels of 25-hydroxyvitamin D were significantly lower in $Ank^{KI/KI}$ mice.

To examine the effects of dietary Pi on the skeletal phenotype, $Ank^{+/+}$ and $Ank^{KI/KI}$ mice were exposed to high Pi (1.5%) or low Pi (0.3%) diet from birth for 13 weeks. Dietary Pi restriction reduced hyperostotic mandibles and extensive diaphyseal trabeculation in femurs whereas high Pi diet aggravated massive jawbone development and decreased the endosteal and periosteal perimeters of femurs of $Ank^{KI/KI}$ mice. We suggest that dietary phosphate restriction protects against effects of an increased Pi/PPi ratio caused by impaired PPi transport activity of mutant ANK. Interestingly, osteopontin (OPN), an inhibitor of mineralization, was significantly increased in $Ank^{KI/KI}$ mice and in CMD patients suggesting that it may act as a compensatory mechanism for decreased extracellular PPi. Plasma analysis showed that 3 out of 7 CMD patients had vitamin D deficiency or insufficiency while PTH and FGF23 were normal.

In summary, changes of *Fgf23*, Pi and OPN levels are likely compensatory mechanisms rather than etiologic factors for CMD. Therefore, low Pi diet or the use of Pi binders may benefit CMD patients.

MO0439

Phosphaturic Mesenchymal Tumour (PMT) of the Ethmoid Sinus, Confirmed with Chromogenic In-Situ Hybridization for *FGF23*. Aliya Khan*[1], Iman M'Hiri[2], Andrew L. Folpe[3], Waleed Khan[2], Christopher Marriott[4], Chaudhry Aslam[2], Gavino Perez[5], Sebastien Hotte[6], Lach Boleslaw[7]. [1]McMaster University, Canada, [2]Oakville Bone Centre, Canada, [3]Mayo Clinic, Department of Laboratory Medicine & Pathology, USA, [4]McMaster University , Department of Nuclear Medicine, Canada, [5]McMaster University , Department of Internal Medicine, Canada, [6]McMaster University,Division of Oncology, Department of Medicine, Canada, [7]McMaster University, Division of Pathology, Department of Medicine, Canada

Oncogenic Hypophosphatemic Osteomalacia (OHO) is a rare metabolic bone condition caused in almost all instances by a fibroblast growth factor -23 (FGF-23) secreting phosphaturic mesenchymal tumour (PMT).PMTs occur in bone and in soft tissue and are usually benign with very rare malignant examples. PMTs express FGF-23 at the mRNA and protein level. Following excision of the tumour, phosphate homeostasis normalizes. An accurate diagnosis and confirmation of the presence of a PMT is clinically invaluable.

A 58-year-old man with multiple lytic lesions in the pelvis, ribs, and acetabulum was referred for assessment following exclusion of malignancy. Serum phosphate and1,25dihydroxyvitaminD (1,25D) levels were low at 0.54 mmol/L,and 26 pmol/L respectively. Hyperphosphaturia was present(Table 1).Tetracycline double labelled bone biopsy revealed osteomalacia. Bone scan showed intense sacroiliac activity with a healing insufficiency fracture of the sacrum.(fig 1) BMD was relatively well maintained.

FGF-23 assays are currently not available in Canada. CT scans of the head, chest, abdomen and pelvis were reported as normal. A whole body MRI was declined by the patient. Treatment with calcitriol and phosphate resulted in improvements in serum phosphate however urinary phosphate also increased. His bone pain, myalgias and muscle weakness progressed. An octreotide scan with tomographic CT coregistration of the head, neck, and abdomen was performed. A 1 cm lesion was identified in the left ethmoid sinus with excessive uptake of octreotide .Figure 2. In retrospect this lesion was also present on the head CT obtained in 2005 but not reported.

Following surgical resection of the ethmoid sinus tumour serum phosphate, 1,25D and alkaline phosphatase normalized.The symptoms of myalgias, arthralgias and muscle weakness resolved.BMD improved The biopsy specimen was further evaluated at the Mayo Clinic, where the diagnosis of a morphologically benign PMT was confirmed, and the tumour shown to express *FGF-23* mRNA by chromogenic in situ hybridization (CISH) on formalin-fixed, paraffin-embedded tissue sections (RNA-Scope, Advanced Cell Diagnostics, Hayward, CA, USA).

Figure 3 shows the morphological features of the tumour (A) and Figure 4 shows the *FGF23* CISH (B).

Conclusion:

Oncogenic hypophosphatemic osteomalacia is caused by PMTs. CISH for FGF-23 is a valuable diagnostic tool capable of confirming the presence of a PMT in resected tissue.

MO0440

Volumetric characteristics of cortical and trabecular bone in patients with acromegaly meassured by pQCT. Jorge Malouf*[1], Elena Valassi[2], Iris Crespo[2], Jaume Llauger[3], Ana Marin[4], Susan Webb[2]. [1]Hospital de la Santa Creu i Sant Pau, Spain, [2]Endocrinology department, Hospital Sant Pau, Centro de Investigación Biomédica en Red de Enfermedades Raras, Spain, [3]Radiology department. Hospital de la Santa Creu i Sant Pau., Spain, [4]Internal Medicine Department. Hospital de la Santa Creu i Sant Pau, Spain

Growth hormone (GH) excess in acromegaly is deleterious for bone. DXA is not the optimal technique for the evaluation of bone in patients with acromegaly, since it is influenced by bone size and it does not differentiate between trabecular and cortical compartments.

The aim of this cross-sectional study was to evaluate the volumetric bone parameters in patients with acromegaly (AP) and compare them with healthy controls (HC).

Thirty-six patients were included (19 men and 17 women). Mean age was 47 ± 8 years. Sixteen patients had active acromegaly , 20 had controlled acromegaly and 21 subjects were healthy controls paired by sex, age and BMI. A volumetric quantitative CT (vQCT) was performed to each subject according to the Mindways® scan acquisition instructions. The analysis of the volumetric parameters was performed using the BIT (bone investigational tool) from Mindways.

Volumetric bone mineral density (vBMD) of L2-L4 was inferior in AP than in HC (111 ± 39 vs.132 ± 30 mg/cm3 and 105 ± 39 vs. 127 ± 32; $p<0.05$). When isolating trabecular bone from the total hip (THTvBMD), femoral neck (FNFTvBMD) and trochanteric region (TRTvBMD), the volumetric BMD of AP was lower than in HC (122 ± 20 mg/cm3 vs. 140 ± 20; 143 ± 21 vs. 124 ± 27 and 123 ± 18 vs. 138 ± 19; $p<0.01$). Regarding the cortical component, mass and volume were higher in AP than in HC (4 ± 2 vs. 3 ± 1 mg y 6 ± 4 cm3; $p<0.01$). None of the structural parameters of the femoral neck (cross sectional área [CSA], cross sectional moment of inertia [CSMI], average cortical thickness [ACT], section modulus [z] and buckling ratio [BR] showed statistically significant differences between AP and HC.

This study shows significant differences between cortical and trabecular compartments in AP versus HC. Even if the observed increase in the cortical mass and volume would suggest significant structural changes in AP , the geometric parameters in the femoral neck were not different as compared with HC. Further analysis is in progress to explain where the differences in both the trabecular and cortical compartments are most critical in AP.

MO0441

A 4-year retrospective longitudinal study: muscle mass and bone loss. Sun Mi Park*[1], Yong-Ki Min[2]. [1]Samsung Medical Center, Sungkyunkwan University School of Medicine, South Korea, [2]Samsung Medical Center, South Korea

Objective

Many studies have focused on the relationship between muscle mass and bone mass in that sarcopenia associated with low bone mass. Muscle mass could be an indicator of bone mineral density (BMD). There is no longitudinal data examined the rate of muscle declining and bone loss rate. To determine whether age-related muscle mass declining could be a predictor of the bone loss, we investigated the relationship of muscle mass and bone mass changes during a 4-year period.

Methods

We reviewed medical records of 1,053 postmenopausal women retrospectively who had undergone periodic (baseline, 1-year, 2-year, 4-year) comprehensive health examinations at the health promotion center of Samsung Medical Center from 2007 to 2012 and 497 subjects (45-81 years) were finally eligible. Lean mass and fat mass were measured with InBody 720 analyzer and BMD on lumbar spine and femur were evaluated using dual-energy X-ray densitometry. Appendicular lean mass (ALM)/height^2, lean mass percentage and ALM percentage were calculated as proposed in previous studies.

Results

Lean mass, ALM/height^2, lean mass percentage and ALM percentage were significantly positively associated with BMD (lean mass, ALM/height^2 in lumbar spine (LS), femoral neck (FN) and total hip (TH), lean mass percentage in LS and FN; $P < 0.001$, lean mass percentage in TH, ALM percentage in LS and FN; $P < 0.05$). By the fourth year of follow up period, ALM/height^2 changes significantly positively associated with BMD changes on LS, FN and TH (ΔLS; $P = 0.007$, ΔFN; $P = 0.003$, ΔTH; $P < 0.001$) after adjustment for age, smoking, exercising status and fat mass.

Conclusion

Body composition, especially lean mass and ALM/height^2, contribute to current BMD in postmenopausal women. In postmenopausal women, ALM/height^2 changes with aging were most strongly associated with bone mass loss.

MO0442

A Novel 3D QCT Technique to Quantify the Muscle-Lipid-Composition in the Thigh and its Association with Fracture of the Proximal Femur. Alexander Muehlberg*[1], Oleg Museyko[2], Bastian Gerner[2], Dominique Töpfer[2], Valérie Danielle Bousson[3], Jean-Denis Laredo[4], Klaus Engelke[1]. [1]University of Erlangen, Germany, [2]University of Erlangen, Germany, [3]Service de Radiologie OsteoArticulaire, France, [4]Service de Radiologie OstéoArticulaire, France

Introduction: The characterization of muscle morphology and function is important in sarcopenia and other muscle diseases. CT imaging has been used to quantify muscle volume and density. Here we developed a new analysis technique to also quantify the spatial muscle-lipid distribution. CT is widely available, relatively cheap, quick and in the apendicular skeleton radiation exposure is low. It was the specific aim of this study to apply this new technique to discriminate patients with acute femur fractures from unfractured controls.

Material und Methods: The 3D QCT analysis consists of a semiautomatic segmentation of the skin and of the *fascia lata* (FL), which separates subcutaneous adipose tissue (SAT) and intermuscular adipose tissue (IMAT). Inside the FL in each voxel muscle and lipid concentrations were determined based on the CT value relative to that of SAT. In addition to standard parameters (adipose tissue and muscle volume and density), the muscle-lipid-distribution was analyzed using structural descriptors such as texture, topology, or roughness. The new method was applied in QCT-Datasets (120kV, 170mAs, slice thickness 1 or 1.25mm, pitch 1) of 89 patients of the EFFECT-Study (36 patients with fresh proximal femur fractures, age 73.2 ± 9.4y and 53 controls, age 80.5 ± 11.1y) [1]. In the fractured subjects the contralateral leg and in the controls the left leg was analyzed. For fracture discrimination a best subset analysis was performed to construct multivariate models consisting of soft tissue or BMD descriptors that were selected by a univariate analysis adjusted for age and BMI.

Results: The figure shows the muscle-lipid segmentation results. The table shows Area-Under-Curve (AUC) of a BMD model (parameters: troch trab BMD & neck cort thick) and a soft tissue model (parameters: local inhomogeneity of muscle & local anisotropy (directedness) of adipocytes within the muscle). In the EFFECT cohort the soft tissue model was superior to the BMD model; the combination of the soft tissue and bone model achieved the best discrimination. A model of standard parameters like muscle density and volume added only little discriminative power compared to the bone model alone.

Conclusion: The analysis of the structural muscle-lipid distribution using a novel 3D QCT analysis technique may contribute to the understanding of hip fracture etiology. In contrast simple measurements of lean and fat volume did not give comparable results.

Bioelectrical Impedance Spectroscopy: A Reproducible Method of Muscle Mass Assessment. Yosuke Yamada*[1], Bjoern Buehring[2], Diane Krueger[2], Neil Binkley[2], Dale Schoeller[1]. [1]University of Wisconsin, Madison, USA, [2]University of Wisconsin, Madison, USA

Loss of leg muscle mass and function with aging increases falls and fracture risk. Widely accessible methods to detect muscle loss are confounded by the presence of multiple tissues, e.g., bone, fat, skin, etc. DXA is often used to evaluate lean mass but does not directly measure muscle. In fact, DXA essentially measures water and cannot distinguish intracellular (ICW) from extracellular (ECW) water. As Bioelectrical Impedence Spectroscopy (BIS) measures ICW, it may be a more specific marker of muscle mass. We hypothesized that BIS measurements would better correlate with muscle function than DXA lean mass. The aims of this study were to assess: 1) BIS reproducibility and 2) Correlate muscle function with BIS measured ICW and DXA lean mass in adults.

BIS was measured in 15 adults mean age 40.5 ± 16.1 (range 20-72) years by 3 technologists 3 times on the same day. Additionally, in 57 healthy adults (44W/13M age 26-76 years), total body DXA was performed. Resistance of ICW (RICW) and ECW (RECW) was measured by segmental BIS to estimate leg total water (TW), ICW and ECW. Leg muscle power was measured by jumping mechanography and grip strength by dynamometer. Correlation coefficients were statistically compared using Meng's statistical method.

The %CV for duplicate BIS ICW measures taken without repositioning was negligible (0.5%). When the same technician repositioned leg electrodes, the BIS CV was 2.2% and between technician CV was 2.6%. Thus, the total CV would be 3.5%, corresponding to 1.8% of the between subject ICW range in the reproducibility cohort. DXA leg lean mass (LLM) was only weakly correlated with age (r=-0.35) while BIS leg ICW displayed a significantly stronger correlation ($r=-0.51$, $p=0.01$). Moreover, BIS indicated a greater decrease with age than DXA (12.8% vs 6.7% per decade). The ratio of BIS ECW to ICW increased with age ($r=0.72$, $p<0.001$) indicating a relative ECW expansion with age that may blunt the ability of DXA to detect muscle loss. BIS ICW correlated better ($p=0.007$) with muscle power than DXA LLM ($r=0.88$ vs $r=0.79$).

In conclusion, BIS very reproducibly measures ICW. In a cross-sectional study, BIS ICW was more highly correlated with age and muscle power than DXA lean mass. Thus DXA measured LLM underestimates age effects on skeletal muscle mass and function due to ECW masking a lower amount of leg muscle mass. Further research is needed to determine if/how a combination of BIS and DXA may optimize fracture risk assessment.

Fibromodulin reprogrammed progenitor cell-based therapy for skeletal muscle generation. Zhong Zheng*[1], Pu Yang[2], Omar Velasco[3], Elisabeth Lord[3], Kambiz Khalilinejad[3], Olivia Yue[3], Maxwell Murphy[3], Soyon Kim[3], Min Lee[3], Xinli Zhang[4], Kang Ting[4], Chia Soo[3]. [1]UCLA, USA, [2]Sichuan University, China, [3]UCLA, USA, [4]University of California, Los Angeles, USA

Background: Millions of people suffer from deficient muscle mass caused by congenital musculoskeletal deformities, severe trauma or salvage surgeries. Unfortunately, *de novo* formation of skeletal muscle is unsatisfactory in these scenarios due to the lack of enough endogenous myogenic progenitor cells, while current cell-based restorative strategies for skeletal muscle generation are hindered by numerous obstacles, such as inadequate cell availability, limited cell spreading, poor survival ability, and tumorigenesis. Recently, our research group reported a simple method to reprogram somatic cells, such as dermal fibroblasts, to a multipotent state using a single extracellular molecule, fibromodulin (FMOD), instead of using oncogenes or an integrative genomics approach. The FMOD reprogrammed progenitor (FReP) cells do not exhibit tumorigenicity but demonstrate exceeding potential to generate skeletal muscle both *in vitro* and *in vivo*, making them a safer candidate for *in situ* skeletal muscle generation.

Methods: To generate large volume muscle tissues *in vivo*, it is important to maintain an appropriate cellular localization and retention to preserve cell-to-cell interaction. In this study, an injectable, photopolymerizable hydrogel composed of methacrylate glycol chitosan and type I collagen (MeGC/CI) was used to encapsulate $5x10^5$ FReP cells for transplantation in tibialis anterior (TA) muscle pouch SCID mouse model to develop a simple process for *in situ* skeletal muscle generation.

Results: Immunostaining showed more than 90% of MeGC/CI gel-encapsulated FReP cells with intense myogenic signals after a 3-week *in vitro* myogenic differentiation. qRT-PCR revealed marked increased expression of muscle-specific transcription factors and reduced expression of essential pluripotent regulators in FReP cells during the *in vitro* myogenic differentiation. Furthermore, with or without *in vitro* pre-myogenic differentiation, MeGC/CI gel-encapsulated FReP cells not only survived and differentiated into skeletal muscle tissue *in vivo*, but also significantly increased (~25%) the skeletal muscle mass of SCID mouse TA muscle at 1-month post-implantation.

Conclusion: In this study, we demonstrate the feasibility and ease of using MeGC/CI gel-encapsulated FReP cells for *in situ* skeletal muscle generation without tumorigenic risk. The FMOD reprogramming technology has promising future applications in reconstructive surgery that requires muscle augmentation and regeneration.

Macro- and Microstructural Outcomes of Leg Muscle and Bone are Similar in Postmenopausal Women With and Without Osteoporosis. Amanda Lorbergs*[1], Michael Noseworthy[2], Norma MacIntyre[1]. [1]McMaster University, Canada, [2]McMaster University, Canada

Bone fragility is predicted by small muscle size in combination with greater fat infiltration. It is unknown if magnetic resonance imaging (MRI)-based outcomes of muscle composition differ in women with osteoporosis. Thus, we aimed to: 1)

compare MRI-based muscle and fat outcomes in healthy postmenopausal women with and without osteoporosis, and 2) determine the associations between muscle, fat and bone outcomes.

The sample (n=35, mean(SD)age=70(4)y) included 18 postmenopausal women with osteoporosis matched for age and physical activity with 17 postmenopausal women without osteoporosis. All women with osteoporosis were taking bone sparing medications. MRI (3T GE DiscoveryMR750) was used to evaluate muscle outcomes in the tibialis anterior (TA), tibialis posterior, soleus (SOL) and gastrocnemius (GC). TA, SOL and GC muscle and intramuscular fat volumes (cm^3) and total intermuscular fat volume (cm^3) were quantified from segmented proton density weighted images. Muscle microstructure was evaluated with diffusion tensor (DT)-MRI, which assesses mean water diffusivity (MD,mm^2/s) and fractional anisotropy (FA), a structural index of diffusivity. Muscle density (MuD,mg/cm^3), volumetric bone density and geometry (polar stress strain index, SSIp) were determined at the 66% tibia site using peripheral quantitative computed tomography (pQCT, Stratec XCT2000). One-way ANOVAs were performed to compare group means for each muscle, fat and bone outcome. Between-tissue associations were assessed using Pearson correlation coefficients.

Women with and without osteoporosis were similar in height (p=0.7) and weight (p=0.9). No group differences were observed in MD or FA for any leg muscle (all p>0.1). Similarly, muscle, intramuscular fat and intermuscular fat volumes and MuD did not differ (all p>0.3). Both groups had comparable values for tibia bone density and geometry. SSIp was positively correlated with MD in the SOL (r=0.55) and GC (r=0.49), FA in the SOL (r=0.37) and muscle volume in the TA (r=0.38) and GC (r=0.38). Our cross-sectional findings suggest that muscle, fat and bone outcomes are similar our sample of postmenopausal women with and without osteoporosis. Medication use may explain the group similarities, but longitudinal evaluation is warranted to determine if these outcomes change with treatment. Between-tissue correlations indicate that bone geometry is moderately related to site-specific muscle outcomes, but not fat macro- and microstructure in the leg.

MO0446

Muscle mass and adiposity, muscle strength, and physical performance vary by gender as risk factors for hip fracture: the Age Gene/Environment Susceptibility Study-Reykjavik. Thomas Lang*[1], Sigurdur Sigurdsson[2], Gunnar Sigurdsson[3], Kristin Siggeirsdottir[2], Vilmundur Gudnason[4], Tamara Harris[5]. [1]University of California, San Francisco, USA, [2]Icelandic Heart Association, Iceland, [3]Landspitali, Iceland, [4]Icelandic Heart Association Research Institute, Iceland, [5]Intramural Research Program, National Institute on Aging, USA

Muscle loss and increased muscle adiposity are linked to poorer physical function and increased hip fracture risk in the elderly. However, little is known about how gender influences muscle mass and muscle adiposity and function as these predict risk. .

We acquired hip CT scans in 4724 subjects (57% female) aged 66-90 years in Age, Gene/Environment Susceptibility Study (AGES-REYJAVIK), a study of community-dwelling men and women in Reykjavik, Iceland. CT analyses provided lean cross-sectional area (CSA, a muscle mass measure) and attenuation (HU, a measure of fatty infiltration and muscle quality) of the hip extensor muscles. We also measured timed up and go (TUGO) and knee extensor strength. As co-variates affecting physical performance and body composition, we included age, BMI, height, self-reported health status, and self-reported physical activity. Within gender, we used three logistic regression models. First, we computed age-adjusted odds ratios (OR/SD) individually for all of the variables listed above. Second (Model A), we computed OR/SD for CSA, HU, TUGO and strength individually after adjustment for co-variates. A third model (Model B) examined predictor values simultaneously.

Over 7.7 years of follow-up, 68 men and 134 women had hip fractures (See Table). In age-adjusted logistic regressions, lower CSA, strength, and physical activity were significant risk factors for hip fracture in both men and women, but lower HU (poorer muscle quality) and higher TUGO time were significant only in men. Poorer health, and lower BMI were significantly associated with incident hip fracture only in women. In Model A, reduced hip CSA was individually associated with incident hip fracture in both men and women, but lower HU and strength and higher TUGO time continued to be significant in men but not women. When CSA, HU, strength and TUGO were combined in Model B, higher TUGO time and lower extensor HU were independent risk factors in men. In women, no independent risk factors remained. Although men and women shared some muscle and function-related risk factors for hip fracture, several risk factors were significant in only one gender. In women, but not in men, the relationship of muscle size and strength to hip fracture appeared to be explained by a combination of poorer health, lower BMI and lower physical activity. These results support the importance of gender for the design of preventive strategies related to function and body composition.

Table

Age-adjusted logistic regression (OR/SD)		
	Men	Women
Leg Strength	1.37 [1.11, 1.70]	1.46 [1.17, 1.82]

MO0447

Muscular mass (MM) diferentiates women with low bone mass (BM) and osteoporotic fractures from those with low BM and no fractures. Silvina Mastaglia[1], Alicia Bagur[2], Beatriz Oliveri[3], Carlos Mautalen*[4]. [1]Laboratorio De Enfermedades Metabólicas Oseas, CONICET-UBA, Argentina, [2]Mautalen Salud e Investigacion, Argentina, [3]Mautalen, Salud e Investigación, Argentina, [4]Centro de Osteopatías Médicas, Argentina

In a retrospectic study of 41 women over 60 years of age, 38 of them had a BMD below - 1 SD of the total skeleton. Body composition obtained by DXA was reanalyzed. Eleven of these patients had suffered an osteoporotic fracture (6 vertebral, 4 non vertebral and 1 both). Muscular strenght or performances were not assessed.

The results of the whole group were: Age 75 $\pm$ 8 y.o., body mass index (BMI) 25.4 $\pm$ 4.0 kg/m^2, fat mass (kg) 24.1 $\pm$ 6.9, lean mass (kg) 34.1 $\pm$ 3.4 and total skeleton T-score -2.03 $\pm$ 0.82. Apendicular (aMM) (kg/m^2) 5.99 $\pm$ 0.72. Arms MM (arMM) (kg/m^2) 1.44 $\pm$ 0.21 and legs MM (lMM) (kg/m^2) 4.55 $\pm$ 0.6. The T-score of the aMM was -1.16 $\pm$ 1.03.

aMM had a significant correlation with lean mass (r= 0.63; p< 0.001) but a weak correlation with fat mass (r= 0 .42;p<0.01). arMM and lMM had the same correlation with lean mass (r= 0.63; p<0.001) and somewhat reduced correlation among them (r= 0.57; p<0.001)

Nine patients (25%) had an aMM below 2 SD of young reference woman (Presarcopenia) and 12 (31%) patients had a T- score between -1 and -2 SD (low aMM)

The group of patients with osteoporotic fractures (Fx) (n=11) was compared with the group without fractures (NoFx)(n=27) Although the former had greater age, lower BMI, lower fat mass, and lower BMD T-score the differences on this items were not significant. In contrast, statistically significant differences were observed on aMM (5.49 $\pm$ 0.57 vs. 6.16 $\pm$ 0.68 < p 0.005) aMM T-score (0.86 $\pm$ 0.96 vs. 1.87 $\pm$ 0.81 p < 0.005), arms MM (1.24 $\pm$ 0.18 vs. 1.51 $\pm$ 0.15; p< 0.001), legs MM (4.7 $\pm$ 0.6 vs. 4.25 $\pm$ 0.4; p < 0.03) and total lean mass (32.3 $\pm$ 25 vs. 35.2 $\pm$ 37.0; p < 0.02)

Five out of 11 of Fx patients had Presarcopenia and 5/11 had low aMM. One obese patient of this group had a normal aMM. In contrast only 15% of NoFx patients had Presarcopenia, and 27% low aMM.

These results emphasize the need to assess MM on patients with osteopenia with or without osteoporotic fractures to detect a risk factor for bone and general health. The study should also include evaluation of muscular strength and performance.

MO0448

Nutrition and Physical Activity Determinants of Muscle Adiposity and Bone Density Measured by MRI and pQCT. Andy Kin On Wong*[1], Karen Beattie[2], Hardik Valand[3], Laura Pickard[2], Alexandra Papaioannou[4], Jonathan Adachi[5]. [1]McMaster UniversityUniversity Health Network, Canada, [2]McMaster University, Canada, [3]McMaster University, Canada, [4]Hamilton Health Sciences, Canada, [5]St. Joseph's Hospital, Canada

Objectives: 1) To assess how physical activity relates to lower limb bone and muscle properties; and 2) to evaluate the relationship between the same muscle and bone outcomes and each of dietary protein and creatine intake.

Methods: Women $\geq$ 50 years old from the CaMOS Hamilton site completed a 1.0 tesla (T) peripheral (p) MRI (fast-spin echo) and pQCT (20 mm/s, 38 kVp) scan at 66% of the tibial length. Inter+intramuscular fat (IMF) was segmented from muscle on MR images (5x2.0 mm thick, 195 µm resolution) using a region-growing algorithm. Total IMF area (A) and volumes (Vol), as well as total muscle proton density (PD) were determined. Muscles on pQCT images (2.3 $\pm$ 0.5mm thick, 500 µm resolution) were manually segmented from subcutaneous fat and bone using a watershed algorithm to compute muscle and cortical bone areas (MCSA, Ct.A) and density (MD, Ct.vBMD). All participants completed a Food Frequency Questionnaire

(FFQ), a Paffenbarger Physical Activity Questionnaire (PPAQ) and the Physical Activity Scale for the Elderly (PASE) with reference to activities within the last 7 days. Local grocery stores were surveyed to obtain meat wet weight and protein content standardized to serving size for all meat formats. Creatine was estimated based on concentrations published previously. A linear regression analysis quantified the relationship between muscle or bone outcomes and each of PPAQ, PASE, total protein, total creatine, and meat-specific protein and creatine contents, all adjusted for age and body mass index (BMI).

Results: Among 38 women (mean age: 75.3 ± 7.9 years; BMI: 27.03 ± 4.34 kg/m^2), muscle adiposity measures were most variable. None of the women were vegetarian. Women expended a mean 2387 ± 2648 kcal within a week but this did not relate to any muscle or bone outcome. Higher PASE score related to lower IMF.Vol and higher MD (Table I). Larger amounts of fish protein and creatine related to larger muscles and lower overall muscle adiposity while total protein and creatine, or that from other individual sources did not show any relation to muscle properties. Only higher total creatine consumption related to larger Ct.A and Ct.vBMD. These relations remained robust after adjusting for age and BMI.Conclusions: Women who exercise and eat more fish demonstrate larger and leaner muscles. The source of meat for creatine may be important for maintaining muscle quantities. Bone was more influenced by total creatine consumption than overall protein intake.

Table I. Relationship between muscle/bone outcomes and each of physical activity and dietary intake.
Linear regression analyses were performed with each of physical activity scale for the elderly (PASE), fish-derived protein, fish-derived creatine, and total creatine from all food sources as exogenous variables. Muscle (inter+intramuscular fat (IMF) volume, muscle area, proton density and muscle density) and bone (cortical (Ct.) cross-sectional area and volumetric bone density (vBMD)).

MO0449

Nutritional Satus in Sarco-Osteoporotic Older Persons. Ruth Huo*[1], Sandra Bermeo[2], Pushpa Suriyaarachchi[3], Piumali Gunawardene[3], Oddom Demontiero[4], Gustavo Duque[5]. [1]University of New South Wales, Australia, [2]University of Sydney, Australia, [3]Ageing Bone Research Program, The University of Sydney, Australia, [4]The University of Sydney Nepean Clinical School, Australia, [5]Ageing Bone Research Program, University of Sydney, Australia

In older persons, the combination of sarcopenia and osteopenia/osteoporosis has been proposed as a subset of frailer individuals at higher risk of falls and fractures. Nutrition could be a determinant risk factor in the pathogenesis of sarco-osteoporosis (SOP) in older persons. In this study, we aimed to identify the nutritional status that is particular of SOP older persons. 680 subjects (mean age=79, 65% female) were assessed between 2009-2012 at the Falls & Fractures Clinic, Nepean Hospital (Penrith, Australia). Assessment included physical examination, bone densitometry and body composition by DXA, posturography, grip strength, mini-nutritional assessment (MNA), gait assessment (GaitRITE), and blood tests for nutritional status. Patients were divided in 4 groups: 1) osteopenia/osteoporosis (BMD<-1.0 SD); 2) sarcopenia (following the European Consensus criteria); 3) SOP and; 4) normal. Difference between groups was assessed with one-way ANOVA and chi square analysis. Multivariable logistic regression evaluated risk factors for being in the SOP group.

There were 258 SOP (37%), 241 with osteopenia/osteoporosis (35%), 87 just sarcopenic (12%) and 94 normal (15%) individuals. Mean age of SOP individuals was 80.40 years (±7.1 SD). Univariate analyses showed that SOP were more likely than normal to have a BMI lower than 25 (OR 2.42 95%CI 1.45-4.041, p<0.001), a MNA score less than 12 (OR 2.013, 95%CI 1.158-3.497, p<0.05), serum folate less than 20 (OR 4.011 95%CI 1.355-11.876, p<0.01) and hemoglobin less than 130g/L (OR 2.056 95%CI 1.278-3.309, p<0.01). Multivariate analysis showed that a MNA score less than 12 was independently associated with SOP compared to normal when adjusted for age and gender. Hypoalbuminaemia was associated with just osteoporosis (OR: 2.034, 95%CI 1.083-3.819, p<0.01) and just sarcopenia (OR: 1.771, 95%CI 1.025 – 3.062, p<0.01) compared to normal. No differences in vitamin D, eGFR, albumin, corrected calcium, phosphate, or vitamin B12 levels were found between the subgroups.

In summary, we have fully characterized the nutritional status of SOP patients. Our results indicate that close monitoring for low hemoglobin, low serum folate, and low BMI in SOP patients should be combined with appropriate nutritional supplementation as essential components of the clinical and therapeutic approach to SOP older persons.

Osteosarcopenic Obesity Is Associated with Functional Disabilities in Obese Postmenopausal Women. Julia E. Inglis[1], Owen J. Kelly[2], Jasminka Z. Ilich*[1]. [1]Florida State University, USA, [2]Abbott Nutrition, USA

Introduction: Recently, we defined a new condition that encompasses osteopenia/osteoporosis (loss of bone) and sarcopenia (loss of muscle mass and strength) in the presence of obesity and named it osteosarcopenic obesity. This combined condition may be associated with greater functional disabilities and increased risk for falls and fractures than each individual condition alone. The purpose of this study was to identify women with osteosarcopenic obesity, assess some of their functional performance measures and compare them with those in obese-only women.

Methods: The study included 225 obese (%body fat>30) postmenopausal women, age and BMI 61.8±8.5y and 28.9±5.0kg/m2 (mean±SD), respectively. Bone, muscle and fat mass was measured by iDXA (GE Healthcare). Sarcopenia was identified from linear regression residuals utilizing appendicular muscle mass/height2 and osteopenic/osteoporotic status from T-scores of L1-L4 vertebrae and/or femoral neck, resulting in n=37 women with osteosarcopenic obesity who were compared with n=53 obese women (without sarcopenia or osteopenia). Handgrip strength (both arms combined) and 8-meter brisk and normal walking speed/number of steps were assessed.

Results: Results showed significantly lower values for handgrip strength (44.6kg vs. 53.5kg) and slower brisk walking speed (4.4 sec vs. 3.8 sec) in osteosarcopenic obese women compared to obese-only women, p=0.0017 and p=0.0003, respectively by ANOVA adjusted for age and BMI with Scheffe's post hoc tests.

Conclusion: These results indicate a greater decline in function in the obese women diagnosed as osteosarcopenic obese, suggesting a greater need for medical recognition of the fat-bone-muscle triad and specific therapy of this combined condition.

MO0451

The relationship between bone and muscle and its affecting factors. Sangmo Hong*[1], Woong Hwan Choi[2]. [1]Hanyang University, South Korea, [2]Division of Endocrinology, Department of Internal Medicine, College of Medicine, South Korea

Background: Muscle mass was known to related with bone mineral density. However there were few data for affecting factor to this relationship. In this study, we investigated the affecting factor to the relationship between bone and muscle.

Subjects and Methods: The data from a population-based survey, namely, The Korea National Health and Nutrition Examination Survey (KNHANES) IV (08-09) & V(10) (18,007 subjects), were analyzed. We studied the relating factor (anthropometric data and insulin resistance) to bone mineral density(BMD)/[appendicular lean mass(ALM)/(height)^2].

Result: With increasing age, BMD/ALM(ht)^2 was increasing in men (B=0.126, p<0.001) but deceasing in women (B= - 0.408, p<0.001). After adjusting age, fat mass (men: B=-0.186, p<0.001, women: B=-0.162, p<0.001) and waist circumference (men: B=-0.186 , p<0.001, women: B=-0.162, p<0.001), fasting insulin level (men: B=-0.108, p=0.002, women: B=-0.088, p=0.016) was negatively related with BMD/ALM(ht)^2. And insulin resistance (HOMA-IR) was also negatively related with BMD/ALM(ht)^2 (men: B=-0.115 , p<0.001, women: B=-0.121, p<0.001). HDL cholesterol level had positive relation with BMD/ALM(ht)^2 (men: B=0.081, p<0.001, women: B=0.115, p<0.001).

Conclusion: In this study, bone and muscle relation was differing between men and women. And obesity and insulin resistance may be weakening the relationship between bone and muscle.

MO0452

Age-Related Changes in Osteocyte Connectivity and Bone Structure in a Murine Model of Aging. LeAnn Tiede-Lewis*[1], Yixia Xie[2], Vladimir Dusevich[2], Molly Hulbert[2], Mark Dallas[2], Lynda Bonewald[1], Sarah Dallas[1]. [1]University of Missouri - Kansas City, USA, [2]University of Missouri - Kansas City, USA

Age-related bone loss and associated increased fracture risk are major clinical problems. Although previously viewed as quiescent, osteocytes are now known to be important regulators of osteoblast and osteoclast function and play key roles in regulation of bone mass in response to hormonal signals, mechanical loading and aging. Osteocytes are interconnected, not only with each other but also with cells on the bone surface, however it is not clear if this connectivity is maintained with aging. Here we have used multiplexed 3D confocal imaging to compare osteocytes in

young adult (5Mo) and aged (22Mo) C57BL/6 mice and combined this with microCT, histological and electron microscopical analysis.

3D confocal imaging of osteocytes using phalloidin and DAPI staining showed dramatic differences in osteocyte morphology and connectivity with aging in the midshaft of the femur which were more prominent in the distal femur. Aging resulted in a 25% reduction in dendrite number per osteocyte ($p<0.05$) and a 17% reduction in osteocyte number/mm^3 bone ($p<0.05$). Extensive cortical remodeling was seen, resulting in reversal lines that appeared as discontinuities, especially in endocortical regions. Osteocyte dendrites did not connect across these discontinuities, resulting in isolated ''islands'' of osteocytes. Occasionally dendrites were observed without a cell body, suggesting that dying osteocytes may leave dendrite remnants behind. Confocal imaging with the membrane dye DiI confirmed reduced osteocyte dendrite number and connectivity in aged mice. We have previously shown in young mice that osteocytes deposit microvesicles into bone matrix and also found abundant vesicle-like material in bone in aged mice. MicroCT analysis showed decreased trabecular bone volume, expansion of the cortical diameter, irregular cortical thickness and intracortical remodeling in aged mice, with abundant cortical porosities that were more pronounced in females than males. Histological analysis showed that the cortical porosities contained marrow. In aged male mice the growth plate was reduced or absent. Together these data show dramatic differences in osteocyte connectivity and bone geometry and structure with aging. Discontinuities in bone may not only compromise the mechanical properties of the bone but may also impair mechano-responsiveness of osteocytes by decreasing their connectivity. This may partially explain the age-related reduction in skeletal responsiveness to mechanical loading.

MO0453

Autophagy is Activated in Bone and Joint Cells During Lineage Commitment and is Regulated *In Vivo* by Diet and Ageing via SirT1. Emma Morris*[1], Pradeep Sacitharan[1], Victoria Treasure[1], Tonia Vincent[1], James Edwards[2]. [1]University of Oxford, United Kingdom, [2]University of Oxford, United Kingdom

Autophagy is a process of 'good housekeeping'. Cellular debris is degraded and recycled back to preserve energy homeostasis and optimal cell function. Defective autophagy is linked to ageing where impaired clearance reduces cellular activity - a common feature in ageing tissues and age-related disorders including osteoarthritis and osteoporosis. This study uses diet modification and genetically modified mice in combination with molecular and pharmacological approaches to explore the hypothesis that impaired autophagy underlies bone and joint disorders, and may be regulated by known ageing- and energy-related factors, such as the epigenetic modifier SirT1.

Autophagy is activated by nutrient starvation. Serum starvation of chondrocyte (HTB-94) or osteoblast (2T3) cell lines increased SirT1 protein and expression of the essential autophagy-related factor LC3 (western blot and IF staining). In vivo, SirT1 expression is elevated 10-fold in bone and joint tissue of mice on a calorie restricted (CR) diet compared to ad libitum (AL)-fed controls ($p<0.001$). Importantly, CR-fed mice had higher BMD (mgHA/ccm) at 185.7 ± 11.5 Vs 140.3 ± 6.0 in AL-fed controls ($p<0.01$), following long bone μCT analysis. This corresponded with significantly higher trabecular BV/TV in CR-fed mice ($10.8\% \pm 0.4\%$ Vs $6.7\% \pm 0.5\%$, $p<0.0001$), opposite to that observed in SirT1-deficient and ageing mice, suggesting that SirT1 regulation via nutrient sensing pathways may improve autophagy and skeletal integrity. In support of this, LC3 protein expression is decreased in osteoblasts in SirT1-deficient and ageing (24mth) mice compared to WT or young (1mth) respectively, whilst a CR diet significantly elevates LC3 expression (Vs AL).

Pharmacological inhibition of SirT1 (Ex-527; 0.2-10uM) decreased differentiation and functional activity in both cell types, evidenced by reduced gene expression (COL2A1, Aggrecan, $p<0.01$) and mineralisation respectively. Similarly, SirT1 siRNA significantly inhibited growth and activity, whilst pharmacological activation of SirT1 (SRT1720; 0.5-5uM) stimulated the expression of pro-differentiation markers ($p<0.01$). Importantly, pharmacological and molecular regulation of SirT1 concomitantly altered the gene expression of key autophagy markers (Beclin-1, ULK-1, LC3, $p<0.01$) and LC3 conversion.This data suggests that the ageing-related molecule SirT1 may mediate dietary effects, such as following CR, in the bone and joint by controlling autophagy in these cells.

MO0454

Do Senescent Cells Accumulate in the Bone Microenvironment with Aging?. Joshua Farr*[1], Daniel Fraser[2], David Monroe[3], Sundeep Khosla[4]. [1]Mayo Clinic, USA, [2]Mayo Clinic, USA, [3]Mayo Foundation, USA, [4]Mayo Clinic College of Medicine, USA

With aging, there is now overwhelming evidence that cells can undergo cellular senescence, which results in the permanent arrest of proliferation. Moreover, because with advancing age senescent cells accumulate in tissues and secrete factors that cause inflammation, these ''bad'' cells and their senescence-associated secretory phenotype (SASP) have been hypothesized to disrupt tissue morphology and function and to promote degenerative pathologies. To date, however, age-related cellular senescence effects in bone have received insufficient attention.

To assess whether senescent cells accumulate in the bone microenvironment of aged mice *in vivo*, we measured senescence-associated β-galactosidase (SA-β-Gal) abundance – an established biomarker of cellular senescence. As evident in Figure, both the bone cortex (Panel A) and bone marrow (Panel B) of old (24 month) wild-type (WT) C57BL/6 female mice stained strongly for SA-β-Gal. By contrast, SA-β-Gal abundance was nearly undetectable in matched young (6 month) WT female mice (Figure C and D). Next, we harvested bones from young (6 month) and old (24 month) WT C57BL/6 female mice ($n = 6$ per group) and obtained RNA from bone marrow derived hematopoietic lineage negative (lin-) cells, which represent a highly enriched osteoprogenitor cell fraction, and from cortical bone that had been flushed to remove marrow cells. Quantitative reverse transcription-polymerase chain reaction analysis revealed that transcript levels of $p16^{Ink4a}$, a principle mediator of senescence, were significantly elevated in both the bone cortex (by 2.7 fold; $P < 0.001$) and bone marrow (by 4.1 fold; $P < 0.05$) of old relative to young mice. In addition, p19 and p53 expression levels were also higher in the bone marrow of aged mice. Because the SASP has not been previously characterized in bone, we also examined a panel of genes associated with SASP acquisition in various soft tissues. Interestingly, expression levels of Ccl2, Icam1, Mmp12, and Sfrp1 were significantly (all $P < 0.05$) higher in cortical bone cells of old versus young mice.

These findings thus indicate that senescent cells accumulate in the bone microenvironment and acquire multiple SASP components with aging. Therefore, senescent cells are present at the expected time and site of osteoporosis. Our findings point to the need to establish if and how senescent cells are causally implicated in mediating age-related bone loss and whether their removal can delay or prevent this loss.

MO0456

Role of sonic hedgehog in the process of fracture healing with aging. Tsuyoshi Shimo[1], Kenichi Matsumoto*[2], Naito Kurio[3], Tatsuo Okui[2], Yuu Horikiri[2], Akira Sasaki[4]. [1]Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sci, Japan, [2]Okayama University Graduate School of Medicine, Dentistry & Pharmaceutical Sciences, Japan, [3]Japan, Japan, [4]Okayama University, Japan

Introduction: Previously, we have reported that sonic hedgehog (SHH) signaling was activated in osteoblasts at the dynamic remodeling site of a bone fracture. In this study, we compared and examined the distribution patterns of SHH and functional effect of SHH signaling on the osteoclastogenesis between young-aged and elderly mice during fracture healing.

Methods: The right eighth ribs of male ICR mice (8-week-old and 60-week-old) were fractured, resected, decalcified, and immunohistochemical staining and RT-PCR analysis were performed. To evaluate the effects of Hedgehog signaling on osteoclastogenesis associated with aging in vitro, osteoclast formation assay and pit formation assays were performed by using mouse bone marrow cells.

Results: SHH was expressed in bone marrow cells in the young-aged rib of mice fractured site on day 3. However, SHH protein and mRNA was barely detectable in the fractured site in the elderly rib of mice. Tartrate-resistant acid phosphatase (TRAP) positive cell number at the margin of the cortical bone were significantly greater in young-aged mice than elderly mice. On the other hand, osteoclast precursor

cells derived from bone marrow cells were cultured with receptor activator for nuclear factor-κB ligand (RANKL), TRAP positive cells were significantly greater in elderly mice than young-aged mice. Cyclopamine, anatagonist of smoothened, suppressed the RANKL upregulated osteoclast formation and resorption greater in elderly mice than young-aged mice, and SAG, agonist of smoothened, rescued the inhibition.

Conclusion: SHH signaling was suppressed in bone marrow cells and down-regulated osteoclast formation and resorption at the dynamic remodeling site of an elderly bone fracture.

Role of the Oxidized Tryptophan Metabolite L-Kynurenine in Age Induced Bone Loss. Mona El Refaey*[1], Eileen Kennedy[2], Qing Zhong[1], Kehong Ding[1], William Hill[3], Xing-Ming Shi[1], Jianrui Xu[4], Wendy Bollag[4], Monte Hunter[4], Mark Hamrick[5], Carlos Isales[1]. [1]Georgia Regents University, USA, [2]Univesity of Georgia, USA, [3]Georgia Regents University & Charlie Norwood VAMC, USA, [4]Georgia Regents University, USA, [5]Georgia Health Sciences University, USA

Age-dependent bone loss has been well documented in both human and animal models. Although the underlying causal mechanisms are not known changes in hormonal status or circulating levels of inflammatory cytokines have been implicated. We previously reported that aromatic amino acids activated signaling pathways in osteoprogenitor cells involved in protein synthesis in vitro and that in contrast the oxidized metabolites of these aromatic amino acids blocked the activation of these anabolic pathways and activated catabolic pathways instead. Our group had also previously shown that C57BL/6 mice have a characteristic pattern of bone gain with a peak around 12 months, followed by a subsequent marked decline in bone mass by 24 months of age. Since it has been proposed that aging is associated with an increase in the generation of damaging reactive oxygen species, our hypothesis was that the oxidized products of dietary aromatic amino acids could play a role in aged induced bone loss by altering osteoprogenitor cell differentiation or activating osteoclastic activity. In this study, we first examined the bone marrow concentration of the oxidized aromatic amino acids in mature (12 month) vs aged (24 months) C57Bl6 mice and found that kynurenine, the oxidized product of the aromatic amino acid tryptophan, was found in the highest concentration. Thus, we tested the effects of kynurenine, fed as a dietary supplement, on the bone mass of twelve-month-old C57BL/6 mice compared to a normal protein diet to see if it would induce a pattern consistent with age related bone loss. Twelve-month-old, male C57BL/6 mice were fed one of four diets; 18% protein diet (normal protein diet); 8% protein diet + tryptophan; 8% protein diet + kynurenine (50 μM) and 8% protein diet + kynurenine (100 μM) for 8 wks. Bone densitometry and micro-CT analyses demonstrated significant bone loss with the kynurenine diet. Histological and histomorphometric studies showed a decrease bone formation and an increase in osteoclastic activity in the kynurenine groups, these animals also had increased serum pyridinoline, a marker of bone breakdown. Thus, these data demonstrate that feeding an oxidized product of an essential amino acid induces bone loss in a pattern consistent with accelerated aging and we propose that one of the mechanisms involved in age induced bone loss may be from alterations of dietary nutrients by the increased generation of reactive oxygen species associated with aging.

MO0458

Effects of Aging on Bone and Muscle in Male and Female Mice Lacking a Single Allele of β–catenin in Osteocytes. Nuria Lara*[1], Julian Vallejo[2], Mark Begonia[3], Mark Dallas[3], Madoka Spence[3], Leticia Brotto[3], Marco Brotto[1], Mark Johnson[4]. [1]University of Missouri - Kansas City, USA, [2]UMKC, USA, [3]University of Missouri-Kansas City, USA, [4]University of Missouri, Kansas City Dental School, USA

We have shown previously that 6 month old mice lacking one allele of β–catenin in osteocytes (HET cKO) (β–catenin fl/+ X Dmp1-Cre mice) do not respond to anabolic loading. We also observed a greater loss of trabecular bone in females versus males. In this current study we sought to determine the effect of aging on bone loss and muscle function in these mouse models.

Analysis of femurs from 18 month old controls and HET cKO mice using microCT showed differences in the cortical compartment in male controls (n=3) versus male HET cKO (n=6) in BV/TV (%) 91.1 ± 0.78 vs 88.8% ± 1.01, cortical thickness (mm) 0.19 ± 0.01 vs 0.15 ± 0.02 and bone area (mm^2) 0.99 ± 0.08 vs 0.82 ± 0.06 respectively ($p<0.05$). Females showed no changes in cortical bone. Controls and HET cKO of both genders had significantly decreased trabecular bone compared to 6 month old animals. Using reference point indentation (RPI) we observed that the indentation distance increase was greater in male HET cKO mice compared to other groups. Muscle function in these mice was assessed in the Extensor Digitorum Longus (EDL) and Soleus muscles using a well-established ex-vivo contractility assay. In the female EDL specific force (N/cm^2) at submaximal frequency of stimulation (20 Hz) was greatly reduced in the HET cKO (9.7 ± 2.0) vs controls (17.5 ± 12.5) (n=12, $p<.05$), however, in Soleus there was no difference. In female EDL and Soleus the % of maximal tetanic force was significantly higher in HET cKO vs control at both high (120 Hz) and low (20 Hz) levels of stimulation. In female Soleus the % force remaining at submaximal frequency of stimulation was significantly higher in controls vs HET cKO after zero Calcium or after 5 min of fatigue stimulation, while the EDL showed no differences in these functional endpoints.

These studies demonstrate that aging results in loss of trabecular bone in both genders. Deletion of a single allele of β-catenin in osteocytes in male mice also results in changes in their cortical compartment not observed in females with aging. The observed changes in muscle function with aging resulting from the loss of a single allele of β-catenin in osteocytes could reflect decreased loading of bone and/or might reflect the loss of an unknown bone-to-muscle secreted factor important for muscle function. These data support a central role of β-catenin in osteocytes in the maintenance of bone and muscle across aging and/or crosstalk between these two tissues.

MO0459

Skeletal muscle index using height overestimate muscle mass in the elderly women: Japanese Population-based Osteoporosis (JPOS) cohort study. Takahiro Tachiki*[1], Masayuki Iki[1], Jun Kitagawa[2], Naonobu Takahira[3], Junko Tamaki[4], Yuho Sato[5], Etsuko Kajita[6], Sadanobu Kagamimori[7], Yoshiko Kagawa[8], Hideo Yoneshima[9]. [1]Kinki University Faculty of Medicine, Japan, [2]Kitasato University, Japan, [3]Kitasato University, Japan, [4]Osaka Medical College, Japan, [5]Jin-ai University, Japan, [6]Nagoya University, Japan, [7]University of Toyama, Japan, [8]Kagawa Nutrition University, Japan, [9]Shuwa General Hospital, Japan

Aim: Sarcopenia is a syndrome characterized by progressive and generalized loss of skeletal muscle mass and strength leading to an increased risk of adverse outcomes such as physical disability, poor quality of life and mortality. Skeletal muscle index (SMI: appendicular muscle mass (AMM) /$height^2$) is used to assess muscle mass and is included in a diagnostic criterion of sarcopenia. Muscle mass decreases with aging. In the elderly, however, SMI may not decrease with advancing in age due to age-related height reduction. Arm span is closely related to height in young adults and does not decrease in the elderly as much extent as seen in height. Therefore, use of arm span instead of height in calculation of SMI may improve accuracy of SMI in the elderly. This study aimed to evaluate the accuracy of SMI using height and arm span by comparing their relationship with aging.

Methods: The subjects were 450 women aged 50 to 91 years at baseline (mean age, 70.2 ± 7.9 years) who participated the baseline and 15- or 16-year follow-up surveys in the Japanese Population-based Osteoporosis (JPOS) cohort study. All subjects had undergone natural menopause more than 10 years before follow-up, and did not have abnormalities in bone metabolism. Subject's height was measured at baseline and at followed-up, and arm span was determined at baseline. AMM was measured by using dual-energy X-ray absorptiometry (QDR4500A, Hologic, USA) at followed-up. Height-SMI was calculated from AMM divided by height squared at followed-up. Arm span-SMI was calculated with arm span the instead of height. The Pearson correlation coefficient was used to determine the correlations of age with SMI and arm span-SMI. Statistical significance was defined a priori as $p<0.05$.

Results: Height of subjects was 152.7 ± 5.4 cm at baseline, and decreased to 150.6 ± 6.0 cm at follow-up. Mean SMI using baseline height was 6.66 ± 0.66, which increased to 6.85 ± 0.70 when using height at follow-up. Arm span-SMI was 6.77 ± 0.71 kg/m^2. There was no significant correlation between height-SMI at follow-up and age whereas arm span-SMI was significantly negatively correlated with age ($r = –0.23$, $p < 0.01$).Conclusions: The lack of age-related changes in height-SMI was considered to be a consequence of a reduction in height in elderly women. We conclude that height-SMI overestimates muscle mass in older people and recommend the use of arm-span SMI for them.

MO0460

Reducing Fall and Unsteadiness of Gait through Mechanical Loading of Vertebral Facet Joints. Mehrsheed Sinaki*. Mayo Clinic, USA

Objective: This study was conducted to determine the outcome of dynamic counterstrain and reorientation of specific vertebral facet joints to achieve reduction in risk of falls by reducing gait unsteadiness.

Subjects and Methods: Two groups of subjects were identified in our outpatient clinic. Group A consisted of 36 patients who had gait disorder and propensity to falls, referred to our outpatient clinic for fall prevention. To meet the inclusion criteria all had to have comprehensive musculoskeletal and neurological evaluations. Subjects in this group were not able to return for follow up due to the distance from our institution. They all signed the consent form and were videotaped for gait analysis.

Group B consisted of fourteen subjects who were able to return for follow up and all underwent two supervised training sessions in our outpatient clinic. They had formal laboratory gait analysis and computerized dynamic posturography at baseline and follow up. They were instructed for a 4-week spinal proprioceptive extension exercise dynamic (SPEED) program to be performed at home with use of a weighted kypho- orthosis (WKO). The WKO when applied properly accentuates a patient's perception of spinal joint position.

Intervention: All subjects had the trial of spinal proprioceptive extension exercise dynamic (SPEED) program.

Outcome: Subjects had either laboratory gait analysis, computerized dynamic posturography and strength evaluation or were videotaped.

Results: All subjects in group A were videotaped before and after WKO trial and displayed noticeable improvement often to their surprise. They decided to implement the program at home. Subjects in group B returned after a 4-week implementation of prescribed treatment and, showed a significant change in balance (P=.003) and several gait parameters (P<.05). Mean back extensor strength improved significantly from baseline (144.0±46.5 N) to follow-up (198.6±55.2 N; P<.OOl).

Conclusion: Balance, gait, and risk of falls improved significantly through mechanical stimulation of the vertebral facet joints and application of counterstrain to specific areas of spine. This method of intervention might potentially lead to novel investigations for managing patients with unsteadiness of gait and propensity to falls.

Differential Bone Regeneration Starts as early as Seven Days after Marrow Ablation in Two Mouse Strains. Meghan Moran*[1], Amarjit Virdi[2], D. Rick Sumner[2]. [1]Rush Medical College, USA, [2]Rush University Medical Center, USA

It is well-established that mouse strains exhibit varied intact bone phenotypes, including bone mass, bone mineral density and mechanical properties. Various mouse strains and genetic models also exhibit differential responses to injury challenges such as ear punches, articular cartilage notches and fracture healing. However, there is limited data on intramembranous bone regeneration after an injury challenge in different mouse strains. We previously established that bone regeneration varies among different inbred wild type mouse strains using a mechanical marrow ablation model. From that study, we identified good (FVB/N) and poor (Balb/c) bone regeneration strains. There are time-dependent phases involving inflammation, repair and remodeling.

In this study, we aimed to identify during which phase the previously identified differential bony response occurred. To do this, we focused on the good (FVB/N) and the poor (Balb/c) bone regeneration strains. We performed mechanical marrow ablation of the medullary canal in 11 week old FVB/N and Balb/c virgin female mice. Animals were euthanized 7 days and 21 days post-ablation. All bone within the medullary canal in the region between 30% and 60% of the total femur length was measured by microCT (6 μm voxels). This region is normally lacking bone in intact animals. The sample size was 6 animals per strain.

We found that BV/TV differences were present by 7 days and were still present at 21 days (Table 1, ANOVA strain effect p = 0.031, time effect p = 0.005, strain X time p = 0.258). Mean BV/TV varied between 3.48% at 7 days and 9.43% at 21 days post-ablation in FVB/N mice. This is approximately a 3-fold increase in BV/TV during 21 days. Mean BV/TV values were less but also varied from 1.89% at 7 days to 4.62% at 21 days in Balb/c mice. The differences in BV/TV over time and between strains were due mainly to differences in trabecular thickness.

The findings of the present study suggest that differential bone regeneration occurs during the repair phase and persists through the remodeling phase.

Time	Strain	Mean (%)	SD (%)
7 days	FVB/N	3.48	1.27
	Balb/c	1.89	1.17
21 days	FVB/N	9.43	5.78
	Balb/c	4.62	3.05

Table 1. Mean BV/TV Values for FVB/N and Balb/c at 7 and 21 days post-ablation

Osteogenic Capillaries Spatially Orient Pericapillary Osteoblasts to Direct Endochondral Ossification of the Malleus. Ichiro Takada[1], Kouji Shimoda[1], Yoshiaki Kubota[1], Masatsugu Ema[2], Yoshihiro Takeda[3], Nobuhito Nango[4], Wataru Yashiro[5], Atsushi Momose[5], Latifa Bakiri[6], Erwin Wagner[6], Koichi Matsuo*[7]. [1]School of Medicine, Keio University, Japan, [2]Shiga University of Medical Science, Japan, [3]Rigaku Corporation, Japan, [4]Ratoc System Engineering Co., Ltd., Japan, [5]Tohoku University, Japan, [6]Spanish National Cancer Research Centre (CNIO), Spain, [7]School of Medicine, Keio University, Japan

Endochondral ossification is a developmental process by which cartilaginous anlagen are replaced by bone. Once cartilage is vascularized and removed, bone matrix is laid down by osteoblasts. However, the spatio-temporal relationship between capillary endothelial cells and bone-forming osteoblasts remains elusive. Here we report that clusters of osteoblasts surrounding the capillary loop in the murine malleus produce bone matrix such that the diameter of the capillary lumen rapidly decreases over two weeks after weaning. Synchrotron X-ray tomographic microscopy demonstrated a roughly concentric, cylindrical arrangement of osteocyte lacunae along capillaries, indicative of pericapillary bone formation. Remarkably, the reduction in capillary volume was significantly inhibited by both constitutive and inducible overexpression of the transcription factor Fra-1 (*Fosl1*) in transgenic animals. Finally, a concentric relationship between osteoblasts and endothelial cells was also observed at the growth plate and fracture healing sites of long bones in Fra-1 transgenic and wild-type mice. These data support the concept that, during endochondral ossification, osteogenic capillaries accompanied by pericapillary osteoblasts establish the orientation of microscopic bone formation to fill spaces within the original cartilage.

MO0463

***Fgfr*1 and *Fgfr*2 signaling in the osteoprogenitor lineage is essential for skeletal growth and development.** Kannan Karuppaiah*[1], Kai Yu[2], Craig Smith[3], David Ornitz[4]. [1]Washington University School of Medicine in St. Louis, USA, [2]Seattle Children's hospital, USA, [3]Washington University St. Louis, USA, [4]Washington University School of Medicine, USA

Cell-specific roles for Fibroblast Growth Factor (FGF) signaling in skeletal development and the requirement for FGF-signaling for skeletal homeostasis and response to injury are not well understood. To explore the functions of FGF receptors 1 and 2 (FGFR1 and FGFR2) in the osteoprogenitor-lineage, we have conditionally inactivated *Fgfr1* and *Fgfr*2 using the *Osterix-Cre* deleter allele and floxed alleles of *Fgfr1* and *Fgfr*2 (DFF) to generate double conditional knockout (DCKO) mice. Lineage-specific expression of *Osx-Cre* was examined using the *ROSA26 mT/mG* and *ROSA26R-lacZ* reporter alleles. This lineage analysis revealed expression in most of the cells lining trabecular and cortical bone, approximately 20% of cells clonally distributed in the proliferating and hypertrophic chondrocyte regions of the growth plate, and in some cells within the bone marrow stroma. At birth, DCKO mice appeared phenotypically normal, however, showed an ~50% reduction in postnatal growth (total body weight) compared to control (DFF or *Osx-Cre*) mice. DEXA analysis revealed that the DCKO mice had a normal body fat content but significantly reduced bone mineral content. X-ray analysis showed reduced bone density and a proportionally smaller skeleton. Micro-CT analysis of long bones revealed a reduced trabecular BV/TV, bone mineral density (BMD), trabecular number, trabecular thickness, an increased trabecular separation, and a reduced cortical BV/TV in DCKO compared to control mice. Histological analysis of the long bones of P21 DCKO mice confirmed the reduced cortical thickness and showed decreased mineralized bone and reduced unmineralized bone matrix (osteoid) but normal osteoclast number. To explore the mechanisms accounting for decreased longitudinal bone growth we examined growth plate histology and cell proliferation in 3-week-old (P21) DCKO mice. Interestingly, DCKO mice showed a significantly reduced proliferating zone length and an 80% reduction in growth plate chondrocyte proliferation but a normal appearing hypertrophic chondrocyte zone. Molecular analysis revealed reduced expression of Type I Collagen and *Mmp13* and increased expression of *Fgfr3*. These observations suggest a mechanism in which FGFR signaling in osteoprogenitor cells, mature osteoblasts, or bone marrow stroma indirectly regulates chondrocyte proliferation, resulting in reduced longitudinal bone growth, and in which FGFR signaling in osteoblasts impairs osteoblast maturation and anabolic activity.

MO0464

Bivariate genetic association analysis of pediatric total-body DXA parameters identifies two novel genetic variants that jointly influence bone mineral content and bone area. John P. Kemp*[1], Carolina Medina-Gomez[2], Nicole M. Warrington[1], Denise H.M. Heppe[2], Nicholas J. Timpson[3], Ling Oei[2], Beate St Pourcain[3], Claudia J. Kruithof[2], M. Carola Zillikens[2], Albert Hofman[2], André G. Uitterlinden[2], George Davey Smith[3], Vincent WV. Jaddoe[2], Jonathan H. Tobias[4], Fernando Rivadeneira[5], David M. Evans[3]. [1]University of Queensland Diamantina Institute, Translational Research Institute, Australia, [2]Erasmus University Medical Center, Netherlands, [3]MRC Integrative Epidemiology Unit, University of Bristol, United Kingdom, [4]School of Clinical Sciences, University of Bristol, United Kingdom, [5]Erasmus University Medical Center, The Netherlands

Aim: Genome-wide association (GWA) studies of osteoporosis traditionally involve univariate genetic association analysis of bone mineral density (BMD). As BMD is influenced by changes in bone mineral content (BMC) and bone area (BA), examining BMD alone may not detect genetic variants that have similar effects on BMC and BA. Moreover, simulation studies and statistical theory suggest that bivariate association analysis can be more powerful than genetic association analysis of univariate measures. Hence, we investigated whether bivariate genetic association analysis of BMC and BA could identify novel loci.

Methods: GWA meta-analysis was performed on 9393 subjects from the Avon Longitudinal Study of Parents and Children and the Generation R Study, using

HapMap2 imputed genotype data and DXA measures of BMC and BA [measured at the upper limbs (UL), lower limbs (LL), and total-body less head (TB)]. For each cohort, canonical correlation analysis was performed using best guess genotypes, adjusting for sex, age, weight, height and ancestry informative principal components. Meta-analysis using Fisher's product of *P*-values was conducted for ~2.3 million autosomal SNPs and compared to univariate GWA association meta-analyses of BMD, BMC and BA.

Results: Seven known BMD-associated loci reached genome-wide significance (GWS) at one or more skeletal sites: *WNT4*, *GALNT3, CENPW*, *WNT16, CPED1, PTHLH* and *RIN3*. Two novel loci [20p11.22 (*GDF5:* $P_{UL}=4\times10^{-9}$) and 17q24.3 (*KCNJ2:* $P_{TB}=4\times10^{-8}$)] achieved GWS and an additional four loci displayed strong association in the bivariate analyses: 13q33.2 (*DAOA*: $P_{TB}=7x10^{-8}$), 5q35.1 (*SH3PXD2B:* $P_{LL}=8\times10^{-8}$), 10q22.1 (*ADAMTS14*: $P_{LL}=5\times10^{-7}$) and 3q26.1 (*MIR-720,* $P_{UL}=3\times10^{-7}$). No relationship was detected between the *GDF5* locus and BMD ($P\geqslant0.3$), despite varying degrees of association being observed for BMC and BA at the UL ($P_{BMC}=2\times10^{-5}$, $P_{BA}=2\times10^{-8}$), LL ($P_{BMC}=3\times10^{-2}$, $P_{BA}=1\times10^{-7}$) and TB ($P_{BMC}=2\times10^{-2}$, $P_{BA}=2\times10^{-4}$). Nominal associations ($P\leq5\times10^{-2}$) between the *KCNJ2* locus and BMD were observed at the UL and TB, but not the LL (*P=0.9*), while varying magnitudes of association with BMC and BA were detected at the UL ($P_{BMC}=4\times10^{-8}$, $P_{BA}=4\times10^{-8}$), LL($P_{BMC}=2\times10^{-4}$, $P_{BA}=2\times10^{-6}$) and TB ($P_{BMC}=3\times10^{-8}$, $P_{BA}=1\times10^{-9}$).

Conclusion: Bivariate genetic association analysis appears to be a powerful method for identifying novel genetic variants (missed by univariate analyses of BMD), that may influence bone growth and development via changes in bone mineralization and bone size.

Functional Roles of IGF-II on Cartilage during Postnatal Bone Growth under the Normal and Inflammatory Condition. Tomoya Uchimura*, Li Zeng. Tufts University, USA

Postnatal cartilage development is an important aspect of bone development. Despite its importance, precise mechanisms that govern early postnatal growth, which is growth hormone-independent, remain largely elusive. In addition, postnatal bone growth is subject to factors that are absent in utero. Here, we show that IGF-II has a previously unidentified role in postnatal bone growth. Our data indicate that IGF-II is essential for early postnatal cartilage development in terms of growth in length and girth. In addition, IGF-II plays an important role in resisting inflammation-induced abnormal development of growth plate.

Our IHC analysis showed that IGF-II is strongly expressed in articular cartilage and proliferating chondrocytes, but weakly in hypertrophic chondrocytes in the mouse metatarsal bone. Igf-II mutant bones are shorter and thinner, particularly between P0 and P10. Mutant bones showed increased hypertrophic differentiation (Col X), but similar proliferation rates (Ki67) in the growth plate compared to wild type. In contrast, mutant bones showed delayed hypertrophic differentiation in the secondary ossification center with higher levels of Ki67 staining. The perichondrium of Igf-II mutant bones was 1-2 cell layers thinner with reduced Sox9 and Ki67 staining. These data suggest a role of IGF-II in chondrocyte maturation as well as the maintenance and chondrogenic potential of the perichondrium in postnatal bone growth.

Under inflammatory stimulation of IL-1ß in ex vivo cultures, wild type metatarsal bones had severe longitudinal growth defects, reduced Col II and increased Col I, MMP13 and NF-κB/p65 expression in the growth plate and peri-articular surface. Igf-II mutant bones showed further IL-1ß-induced growth defects and cartilage matrix destruction, and exogenous IGF-II inhibited IL-1ß activity in wild type and partially did so in the Igf-II mutant. However, exogenous IGF-I only rescued the defects in the wild type, but not Igf-II mutant. These data suggest an essential role of IGF-II in preventing inflammatory stimuli-induced growth defects and cartilage destruction and indicate a functional difference between IGF-I and IGF-II.

This work has implications in understanding growth hormone-independent bone growth in early stages of postnatal development as well as bone growth arrest in children with chronic inflammation.

MO0466

Nell-1 is a Functional Mediator of Runx2 in Regulating Chondrogenic Differentiation. Chenshuang Li*[1], Jie Jiang[1], Kang Ting[1], Xuepeng Chen[2], Yanheng Zhou[3], Chia Soo[4], Xinli Zhang[1]. [1]University of California, Los Angeles, USA, [2]University of California, Los Angeles, USA, [3]and Hospital of Stomatology, Peking University, China, [4]University of Carlifornia, Los Angeles, USA

Objectives: The lack of Runx2 results in delayed chondrogenesis. Nell-1 functions downstream of Runx2 in osteogenesis, which partially rescues bone defects in $Runx2^{+/-}$ mice. This study aims to examine the functional interaction of Nell-1-Runx2 during chondrogenesis at *in vitro, ex vivo* and *in vivo* levels. Methods: Nell-1 overexpression transgenic(CMV-Nell-1) mice were crossmated with $Runx2^{+/-}$ mice to get $Runx2^{-/-}$/CMV-Nell-1 and $Runx2^{-/-}$ newborns for gross and histological comparasion. The limb explants from E14.5 $Runx2^{-/-}$ were cultured with/without rhNELL-1 for histological and immunohistochemical evaluation. At cellular and molecular levels, primary embryonic mesenchymal progenitor cells from limb bud of E11.5 wild-type(WT) or $Runx2^{-/-}$ underwent chondrogenesis in pellet culture with/without rhNELL-1. The correlation of chondrogenic markers expression and morphological evolution was assessed by qPCR, histological and immunohistochemical staining. The activation of Ihh signaling and possible involvement of Runx3 in Nell-1 induced-chondrogenesis in absence of Runx2 were also analyzed from gene and protein levels. Results: Phenotypically, Nell-1 rescues $Runx2^{-/-}$ chondrocyte maturation partially in neonatal femurs revealed by skeletal staining, histology and Collagen X expression. This rescuing effect was recapitulated in $Runx2^{-/-}$ limb *ex vivo* model with exogenous rhNELL-1 treatment. Notably, the endogenous level of Nell-1 in $Runx2^{-/-}$ primary chondrocytes was only a fraction of that in WT cells, and the upregulation of Nell-1 was achieved in chodnrocytes by AdRunx2 transduction. The delayed chondrogenic differentiation in $Runx2^{-/-}$ pellets at both early and late stages was partially rescued with rhNELL-1 stimulation, which were evidenced by chodrogenic markers expression and morphological changes. Interestingly, rhNELL-1 increased gene expression of Ihh, Patched and Gli in $Runx2^{-/-}$ chondrocytes dose-dependently. The expression pattern of Ihh signaling molecules in $Runx2^{-/-}$/CMV-Nell-1 femur was partially restored. Furthermore, the upregulation of Runx3 and Aggrecan and downregulation of Pthrp and Pthr1 with rhNELL-1 in $Runx2^{-/-}$ cells were also observed. Conclusion: Our data clearly demonstrate that Nell-1 functions as a key functional mediator of Runx2 in chondrogenesis in addition to osteogenesis. The activation of Ihh signaling pathway is likely an underlying mechanism Nell-1 takes among the complex signaling networks of Runx2 in regulating chondrogenesis.

Parathyroid hormone receptor signaling in dental mesenchymal progenitors is essential for tooth root formation. Wanida Ono*[1], Noriaki Ono[2], Henry Kronenberg[1]. [1]Massachusetts General Hospital, USA, [2]University of Michigan School of Dentistry, USA

Dental root formation is a dynamic process involving a series of epithelial-mesenchymal interactions, in which neural crest-derived dental mesenchymal cells are recruited and participate in biomineralization of dentin and cementum. Parathyroid hormone-related protein (PTHrP) and its PTH/PTHrP receptor (PPR) play crucial roles in organogenesis. PPR haploinsufficiency is associated with non-syndromic primary failure of tooth eruption in humans. However, how the PTHrP-PPR system regulates dental root morphogenesis is unknown. Here we show that PPR signaling in dental mesenchymal progenitors is essential for tooth root formation. Lineage-tracing experiments using tamoxifen-inducible *creER* recombinases with a *Rosa26*-tomato reporter revealed that cells expressing osterix (Osx), but not type I collagen (Col1), were root-forming mesenchymal progenitors contributing to all relevant cell types during molar root morphogenesis. Analysis of a *LacZ* knock-in allele showed that cells in the dental follicle and on the root surface predominantly expressed *PTHrP*. Deletion of the *PPR* in root-forming progenitors using *Osx-cre*, but not in mature mineralizing cells using *osteocalcin (Oc)-cre* or *dentin matrix protein 1 (Dmp1)-cre*, led to failure of eruption and significantly truncated roots lacking the periodontal ligament that resulted in ankylosis to the alveolar bone. Overexpression of a constitutively active PPR in Col1-expressing cells (*Col1-caPPR*) was insufficient to rescue these phenotypes. To further understand mechanisms regarding how PPR-deficient cells contribute to root formation, we conducted lineage-tracing experiments using the *Osx-creER*, *Rosa26*-tomato reporter and PPR-floxed alleles. Deletion of the PPR in Osx^{+} progenitors at postnatal day 3 led to accelerated cementoblast differentiation that formed thick cellular cementum. qPCR analysis of FACS-sorted PPR-deficient $Tomato^{+}$ cells showed a upregulation of nuclear factor I/C (*Nfic*), the putative transcription factor critical to root formation, and genes associated with mineralization including *Bsp, Opn* and *Dmp1*. Histone deacetylase-4 (HDAC4) appeared to be a candidate downstream mediator of PPR signaling, as its deletion using *Osx-cre* partially recapitulated the PPR root phenotype. These findings indicate that PPR signaling in dental mesenchymal progenitors is essential for orchestrated differentiation of cementoblasts, underscoring the importance of the PTHrP-PPR system in dental root formation and tooth eruption.

The *Hox* program in adult tissues: Continuing roles for embryonic patterning genes during skeletal regeneration. Danielle Rux*[1], Ilea Swinehart[2], Daniel Lucas-Alcaraz[2], Aleesa Schlientz[2], Steven Goldstein[3], Kenneth Kozloff[4], Deneen Wellik[5]. [1]University of Michigan, USA, [2]University of Michigan, USA, [3]University of Michigan Orthopaedic Research Lab, USA, [4]University of Michigan Department of Orthopaedic Surgery, USA, [5]University of Michigan Medical Center, USA

Hox genes are a unique and highly conserved set of transcription factors whose most prominent role is to pattern the limb and body axis. The four chromosomal clusters of mammalian *Hox* genes (A, B, C, and D) are subdivided into 13 paralogous groups based on sequence similarity and cluster position. Specifically, the *Hox11* paralogous group (*Hoxa11*, *Hoxc11*, and *Hoxd11*) patterns the axial sacral region and the limb zeugopod region (radius/ulna and tibia/fibula). Complete loss of *Hox11* function results in severe patterning defects of these elements during development. Using our *Hoxa11eGFP* knock-in allele, we have shown that *Hox11* is expressed broadly in early limb bud mesenchyme and is then quickly restricted to the zeugopod. It is excluded from the condensing chondrocytes that will become the skeletal elements, but is highly expressed in the perichondrium through newborn stages. Recently, we found that *Hox11* expression is retained in periosteum in adult animals, and also becomes predominant in the endosteum and the bone marrow stroma of the zeugopod. Importantly, GFP-positive cells are absent from other regions of the limb demonstrating that the regional-restriction of *Hox* is retained through adulthood. To examine the potential roles for *Hox* genes in adult tissue, we have performed regional fracture injuries in our mutants. First, we show that *Hox11* expression is expanded at the site of fracture injuries performed in zeugopod regions, specifically. Notably, it is strongly expressed in the periosteal-derived stromal layer of cells surrounding the callus. Second, we show that loss of *Hox11* function results in aberrant callus formation and delayed bridging of the fracture site compared to controls. Cartilage deposition is significantly reduced in *Hox11* mutants at all stages of repair, while new bone formation farthest from the fracture site appears unaltered. Our results are consistent with defects in endochondral ossification while intramembranous ossification appears unaffected. Additionally, remodeling of the bony callus is severely perturbed. Of note, loss of *Hox11* function does not affect repair in other regions of the limb. Continued work is focused on identifying cell type(s) in which *Hox11* is expressed to shed light on its function during bone regeneration. Overall, data presented, demonstrate a continued role for *Hox11* in adult bone tissue and, more broadly, suggests that the regionally-restricted *Hox* program is retained from embryonic development.

Vitamin D dose-response in young children 2 to 8 y of age: a 12 wk randomized clinical trial to establish requirements in the absence of ultra-violet beta solar radiation. Neil Brett*[1], Paula Lavery[2], Sherry Agellon[2], Catherine Vanstone[2], Jonathon Maguire[3], Frank Rauch[4], Hope Weiler[5]. [1]McGill University, Canada, [2]McGill University, Canada, [3]University of Toronto, Canada, [4]Shriners Hospital for Children, Montreal, Canada, [5]McGill University, USA

Canadian children do not meet the recommended dietary intake for vitamin D (VTD). Both VTD and calcium are well established as fundamental nutrients for calcium homeostasis and bone health. Yogurt and cheeses have only 15-30% of the VTD that fluid milk contains. No Canadian studies have investigated longitudinally, the amounts of dietary VTD needed to support current targets of VTD status. The objective was to determine whether a dose-response will be observed in response to a regular diet, one that meets the EAR and one that meets the RDA for vitamin D intakes. Healthy children 2 to 8 y (n=77) from Greater Montreal, randomized into age strata, consumed 1 of 3 dietary VTD targets (200, 400 or 600 IU/ day) for 12 wk starting in the winter. Fasting blood was sampled at baseline and 12 weeks for measurement of total serum 25(OH)D (Liaison, Diasorin) as well as ionized calcium (ABL80 Flex, Radiometer) followed by standardized anthropometry, demographics plus activity and dietary questionnaires. Data analysis used a mixed model ANOVA accounting for fixed effects (sex, age strata, dietary group, time) and random effects (e.g. baseline 25(OH)D and demographics) with *post-hoc* Bonferroni adjustment. Data are mean $\pm$SD unless otherwise indicated. The participants were 54.5 % male (42/77) were 72.7 % (56/77) white and had healthy mean BMI z-scores of 0.50 (+ 0.85). Seventy five (97.4%) children (5.1 $\pm$ 1.9 y) completed the study with compliance of 86% for yogurt and 84% for cheese with no difference among dietary groups or age categories. Baseline VTD intakes were not different whereas intakes significantly differed at 12 wk (Table 1). No differences were observed in baseline 25(OH)D, while at 12 wk both the EAR and RDA groups had significantly higher VTD status compared to control (Figure 1A) and had a positive change in VTD status from baseline (Figure 1B). Average ionized calcium was within normal limits (1.15-1.38 mmol/L) in all groups. However, a group by time interaction (P=0.027) suggested ionized calcium values declined in the control group by 12 wk, but did not reach statistical significance (P=0.0585) with no differences in the EAR or RDA groups. This data in healthy young children suggests that increasing dietary VTD intakes ameliorates the negative effects of the non-VTD synthesizing winter months on VTD status.

Table 1. Vitamin D intake (IU/d) in young children.

Assessment	Control group	EAR target group	RDA target group
FFQ baseline	269 $\pm$ 136^a (n=24)	237 $\pm$ 103^a (n=26)	225 $\pm$ 129^a (n=25)
FFQ follow up	239 $\pm$ 77^a (n=24)	424 $\pm$ 141^b (n=25)	559 $\pm$ 175^c (n=25)
24 h follow up	247 $\pm$ 135^a (n=24)	379 $\pm$ 152^b (n=23)	514 $\pm$ 324^c (n=25)

ADULT BONE AND MINERAL WORKING GROUP

WG1

A Case of a Family with Subclinical Hypoparathyroidism. Cory Wilczynski, MD[1]; Pauline Camacho, MD, FACE[1]. [1]Department of Endocrinology & Metabolism, Loyola University Medical Center, Maywood, Il 60157.

Introduction: Subclinical hypoparathyroidism is rare and even more if not caused surgically. The causes for hypoparathyroidism are similar to other endocrine disorder surgical, autoimmune, genetic and infiltrative. Familial hypoparathyroidism can be seen in cases of polygandular autoimmune syndrome type 1 which consists of hypoparathyroidism, chronic mucocutaneous candidiasis and adrenal insufficiency. In subclinical cases where patients have normal calcium but PTH is decreased there is thought to be increased risk of hypocalcemia after bisphosphonate therapy but not much is known about the disease genetics. Here we present three cases of subclinical hypoparathyroidism that occurred in a mother, daughter, and son. Their history, presentation, and laboratory evaluation that eventually led to their diagnosis will be discussed.

Case Description: Case 1 is a 51 year-old female was initially evaluated in endocrine clinic for history of multiple metatarsal fractures, manubrium fracture, and hypercalcuria. Dual-energy x-ray absorptiometry (DXA) one year prior was had T scores of −1.7 at the lumbar spine, 0.4 at the femoral neck, and −1.4 at the hip. Her past medical history included hypothyroidism and polycystic ovarian syndrome. Family history was significant for a mother with osteoporosis and daughter with

history of multiple fractures (case 2). Laboratory values on initial evaluation showed elevated urinary calcium of 366 mg/24 hr, serum calcium of 9.6 mg/dL, serum phosphorus of 3.8 mg/dL vitamin D 25-OH total of 72 and intact parathyroid hormone (PTH) of 3 pg/mL. After three months of treatment with hydrochlorothiazide, 24 hr urinary calcium was reduced to 275 mg/24 hr and her PTH normalized to 13 pg/ml.

Case 2 involves the 22 year old daughter of the subject in case1. Her history included numerous fractures starting two years prior to presentation. She fractured her wrist falling off a bike, 4 metacarpals after catching a football, and a metatarsal fracture. All fractures were low-trauma. During her work up, patient sustained another fracture to her left foot after a fall. She was started on teriparatide for one month but stopped because did not like injections. Laboratory evaluation revealed a normal urinary calcium of 117 mg/24 hr, serum calcium 9.4 mg/dL, vitamin D 25-OH of 23, serum phosphorus 3.8 mg/dL and intact PTH that was initially normal at 13 pg/mL but had decreased when rechecked 10 months later to 9 pg/mL. Z scores on her DXA were −1.7 at the lumbar spine, and −0.7 at the femoral neck.

Case 3 is a 22 year old male who is the son of the subject in case 1 and fraternal twin of subject in case 2. He did not present with any fracture history but rather was seen for right foot pain. His laboratory values included a serum calcium of 9.6 mg/dL, phosphorus of 3.2 mg/dL, vitamin D 25OH of 42, bone specific alkaline phosphatase of 14.8 ug/L and intact PTH of 9 pg/ml. DXA showed a normal bone mineral density with Z score of 0.5 in lumbar spine and 0.4 at the femoral neck. .

Discussion: This is a case of three family members with hypoparathyroidism. Two of the three subjects had suffered fractures. The treatment for overt hypoparathyroidism with the deficient hormone is still not approved. Treatment is symptomatic control with calcium and calcitriol. Even less is known about the usefulness for treatment of subclinical hypoparathyroidism. In this article, we discussed three family members with evidence of hypoparathyroidism and two with potentially symptomatic side effects of their disease which included fractures. The genetics and heritability of hypoparathyroidism outside of an autoimmune polyglandular syndrome needs to further investigation. Further research into the potential benefits and risks of treatment with hormone replacement is also required as that has potential to reduce hypercalcuria that was seen in case 1.

WG2

Familial Intermittent Hypercalcemia, Hypercalcuria with elevated Calcitriol, low PTH, Chronic Nephrolithiasis and Osteopenia. Derek T O'Keeffe MD PhD[1,2], Peter J Tebben MD[1,2], Rajiv Kumar MD.,[1,3] Ravinder J Singh PhD[4], Robert A. Wermers, M.D.[1,2]. [1]Department of Internal Medicine, [2]Division of Endocrinology, Diabetes, Nutrition, and Metabolism, [3]Division of Nephrology and Hypertension and [4]Department of Laboratory Medicine and Pathology, Mayo College of Medicine, Mayo Clinic, Rochester, Minnesota, USA.

Introduction:
Familial syndromes of non-PTH mediated intermittent hypercalcemia associated with hypercalcuria and elevated 1,25-dihydroxyvitamin D are rarely encountered and likely, the underlying cause often is unrecognized.

Case:
A 60 year old man presented with a history of intermittent hypercalcemia, low PTH, hypercalciuria, elevated 1,25-dihyroxyvitamin D and normal 25-hydroxyvitamin D. He also has had nephrolithiasis (>40yrs) requiring several urological interventions and ultimately causing urethral strictures. He reported two previous fractures: right clavicle, age four, after falling out of a tree and left wrist, age 14, after pole vaulting. A bone mineral density showed osteopenia with a femoral neck T-score = −1.6. His physical exam was unremarkable with a height of 178.8 cm, weight of 87.8 kg, BMI of 27.49 and blood pressure of 90/55 mmHg.

He had a significant family history (six siblings) with the same clinical picture (chronic urinary calculi, hypercalcemia, hypercalciuria, and low PTH). He denied any use of medications associated with hypercalcemia. He denied calcium or Vitamin D supplements. A chest radiograph showed a calcified aorta, but no evidence of any granulomatous disease or tumour burden.

His laboratory evaluation revealed a serum calcium = 10.6 (8.9–10.1 mg/dl), PTH = 14 (15–65 pg/ml), serum phosphorous = 3.5 (2.5–4.5 mg/dl), serum albumin = 4.3 (3.5–5 g/dl), 25-hydroxyvitamin D = 69 (20–80 ng/mL). 1,25-dihydroxyvitamin D = 70 (18–64 pg/mL), serum creatinine = 1.5 (0.8–1.3 mg/dl), eGFR 48 (>60 ml/min/BSA), serum magnesium = 1.9 (1.7–2.3 mg/dl). His CBC, electrolytes, ACE, TSH, UA and SPEP were all normal. A 24 h urine calcium was 207 (25–300 mg/spec) in the context of a diet restricted in dietary calcium intake. A urinary calculi analysis was 50% calcium phosphate (apatite), 30% calcium oxalate monohydrate, 20% calcium oxalate dihydrate.

Given his family history, a 24,25-dihydroxyvitamin D level was performed by the Mayo Medical Laboratory and was 0.15 ng/mL (based the 25-hydroxyvitamin D, expected value 4–10 ng/ml). Repeat testing confirmed this result, consistent with the inability to convert 25-dihydroxyvitamin D to 24,25-dihydroxyvitamin D due to a CYP24A1 mutation.

Conclusion:
Familial P450 (24-hydroxylase) enzyme abnormality (CYP24A1 mutation) is a rare cause of familial 1,25-dihydroxyvitamin D mediated hypercalcemia due to the reduced ability to convert 1,25 dihydroxyvitamin D to 1,24,25-trihydroxyvitamin D. It is important to recognize this entity through the measurement of 24,25-dihyroxyvitamin D, and initiate appropriate treatment measures including dietary calcium and oxalate restriction, high fluid intake, and possibly use of medications such as ketoconazole.

WG3

The Primacy of Parathyroid Hormone over Fibroblast Growth Factor 23 in Renal Phosphorus Handling. MJ McKenna[1,2], M Morrin[1], M Sloman[3], K Guegan[3], M O'Keane[1], M Kilbane[1]. [1]Metabolism Laboratory, and [2]Department of Endocrinology, St. Vincent's University Hospital, Dublin, Ireland; and [3]Molecular Genetics Laboratory, Royal Devon & Exeter NHS Foundation Trust, Exeter, UK.

Context The principal determinant of serum phosphorus is the tubular maximum reabsorption of phosphorus (TmP/GFR). This is mainly regulated by parathyroid hormone (PTH), ionized calcium, renal function, and fibroblast growth factor 23 (FGF23); all four factors are associated with lowering the (TmP/GFR). Animal studies suggest a dominant effect of PTH compared to FGF23 on renal phosphorus handling. Renal phosphorus wasting due to excessive FGF23 is seen in rare conditions such as X-linked hypophosphatemia (XLH) and tumour-induced osteomalacia (TIO). We have recently reported that total parathyroidectomy in a case of XLH ameliorated renal phosphorus wasting despite a very high FGF23 level. There are two reports of similar findings in two adults with TIO. We sought to explore the relative roles of PTH and FGF23 on renal handling of phosphorus in clinical cases.

Participants Three groups attending an endocrine bone clinic were studied: group 1, patients with FGF23-mediated hypophosphatemia (n=16); group 2, patients with bone and mineral disorders (n=37); group 3, patients with XLH and hypoparathyroidism post total parathyroidectomy (n=2) and a patient with hypophosphatemic bone disease due to congenital renal tubular acidosis.

Outcomes We measured FGF23, PTH, renal phosphate threshold (TmP/GFR), ionised calcium, 25-hydroxyvitamin D (25OHD) and a panel of bone turnover markers in all patients, as well as genetic mutation analysis in patients with congenital hypophosphatemia.

Results In group 1, *PHEX* sequencing diagnosed XLH in 12 patients, 1 patient had autosomal dominant hypophosphatemic rickets (ADHR) secondary to a mutation in *FGF23*, 1 patient had no mutation currently known to cause congenital hypophosphatemia, and 2 patients had TIO. In the combined groups 1 and 2, following partial correlation analysis, there was a significant association between TmP/GFR and PTH (r=−0.369, p=0.008) and with FGF23 (r=−0.463, p=0.001). After adjusting for disease category, there was a significant correlation between TmP/GFR and PTH (r=−0.357, p=0.001). In the patients with congenital hypophosphatemia, FGF23 levels were within the reference range (<100 RU/ml) in 5 of 14 patients. In those with elevated levels, they ranged from 115 RU/mL to 525 RU/mL, with the highest result in a 62 year old man who had a mildly elevated creatinine at 108 μmol/ml with an estimated glomerular filtration rate (eGFR) of 63 ml/min. The two cases of TIO had persistently elevated FGF23 levels but were different in terms of severity. The more severe case with persistent Looser zones had a TmP/GFR of 0.27 mmol/L and an FGF23 of 934 RU/mL; the other case had a TmP/GFR of 0.54 mmol/L and an FGF23 of 134 RU/mL. The two patients with XLH, who were rendered hypoparathyroid after surgery, had undetectable PTH levels; TmP/GFR were within the normal reference range at 0.88 mmol/L and at 0.92 mmol/L despite extremely high FGF23 levels at 13,030 RU/mL and 4,310 RU/mL, respectively. Serum creatinine levels were elevated at 157 μmol/L and 191 μmol/L giving eGFR of 37 ml/min and 29 ml/min, respectively. The third member of group 3, who had renal tubular acidosis and nephrocalcinosis, presented with waddling gait and bilateral femur shaft looser zones. His TmP/GFR was low at 0.66 mmol/L, and FGF23 was the lowest recorded at 27 RU/mL.

Conclusions While FGF23 is a determinant of TmP/GFR in congenital and acquired disorders of dysregulated FGF23 production, it would appear that the dominant regulator of renal phosphorus handling is PTH and that the FGF23 effect on TmP/GFR is dependent on PTH secretion. We conclude that the primacy of PTH over FGF23 in renal phosphorus handling is evident in both clinical cases and animal studies.

Drug Induced Fanconi's syndrome and Metabolic Bone Disease (Hypophophatemic Osteomalacia) due to nucleotide reverse transcriptase inhibitors: Need for increased physician awareness, prospective surveillance and prompt therapy. M Honasoge, L Reddy, T Kamala, SS Srikanta. (Henry Ford Hospital Detroit, USA, and Jnana Sanjeevini Medical Centre and Diabetes Hospital, Bangalore, India).

Introduction: Hepatitis B viral infection has been successfully treated and long term viral remissions achieved over the past decade with the use of nucleotide reverse transcriptase inhibitors. Hypophosphatemic osteomalacia and Fanconi's syndrome due to renal tubular damage have been reported with the long term use of these drugs to maintain viral remission. Despite the Black Box warning, there appears to be a lack of awareness and surveillance and thus a delay in diagnosis.

Case Report: A 78 year old Asian male was evaluated in the endocrine clinic for progressive right hip pain, weakness, poor balance and weight loss over 8 months. X-ray and CT scan of pelvis were normal. MRI of the pelvis showed an undisplaced [spontaneous] subcapital fracture of the right femur. Past medical history included: ulcerative colitis (quiescent on mesacol), and hepatitis B on long term antiviral therapy with Adefovir (2005 - current), previous attempt to stop Adefovir was associated with viral relapse. Metabolic investigations: Hypophosphatemia [2.2 mg/dl (2.5–4.8)], hypouricemia [1.4 mg/dl (3.5–7.2)], normokalemia [4.1 meq/l (3.5–5.5)], elevated alkaline phosphatase [191 u/l(53–128)], normocalcemia [9.34 mg/dl (8.8–

10.6)], normal iPTH [22 pg/ml(15–68)], Serum 25(OH) vitamin D [28 ng/ml(30–199)], proteinuria [1.4 G/24 h] with aminoaciduria; HCO3 21.4 mmol/L, S creatinine 1.44 mg/dl (0.6–1.1), eGFR 49 ml/min. Bone markers: C.Telopetide [814 pg/ml(<854)], P1NP [147 ng/ml (14–86)], bone alkaline phosphatase [33 ug/L(6–30)], osteocalcin [3.1 ng/ml (upto 30)] and urine DPD/creatinine ratio [6.28 nmol DPD/nmolCr (2.3–5.4)]. BMD (T-score): Osteopenia left femoral neck (−2.3), left total hip (−1.6) and severe osteoporosis right femoral neck (− 4.1); and right total hip (−3.4), normal lumbar spine (L1 – L4: −0.6) and forearm (Ultra distal: −0.8). Dotonac PET CT (for oncogenous osteomalacia): normal; Isotope bone scan: Increased technetium uptake in right femoral neck, bilateral femoral heads, sacroiliac joints, scapulae and ribs. Management: Adefovir has been withdrawn (HBV DNA undetectable; LFT normal), and oral phosphate, 1-25(OH) vitamin D and calcium supplementation started.

Conclusion: Increased physician awareness, prospective surveillance for renal tubular dysfunction and prompt therapy for drug induced proximal renal tubulopathy and resultant metabolic bone disease are crucial in patients on long term therapy with nucleotide reverse transcriptase inhibitors group of drugs [Reported prevalence of hypophosphatemia and osteomalacia being about 35% and 12%, respectively – Adefovir], with ethnic [Asians] predisposition. Annualized prevalance of renal tubular dysfuction was 15% in a US population over 9 years with age as the main predisposing factor. The reports that newer agents such as entecavir are less prone to cause mitochondrial toxicity including renal tubular dysfucntion needs to be confirmed.

Restoration of Bone Remodeling with Teriparatide in a Patient with Severely Suppressed Bone Turnover. R. Mills[1], J.E. Brunner[2], S. Qiu[1], S. Palnikar[1], S.D. Rao[1]. [1]Division of Endocrinology, Diabetes, Bone & Mineral Disorders; Henry Ford Health System Detroit, MI. [2]Endocrinology and Diabetes Care Center; Toledo, Ohio.

Background: Severely suppressed bone turnover (SSBT) is a state in which bone mechanical property/mineral density relationships are compromised resulting in unusual fractures. Although SSBT was originally described in bisphosphonate treated patients, it shares many features of adynamic bone disease in dialysis patients and age related low-turnover osteoporosis; differing only in the degree of suppression. Bone biopsy is essential to establish SSBT. To our knowledge there are no reports describing restoration of normal bone turnover after teriparatide therapy in patients with SSBT.

Case report: A 60 year old white woman with osteoporosis and multifactorial SSBT developed multiple fractures (bi-malleolar, distal femur, intertrochanteric) over one year. Serum PTH (22 pg/mL; normal 10–75) and 25-hydroxyvitamin D levels (80 ng/mL; normal >20) were normal with mild hypercalcemia (1.37 mmol/L; normal 1–1.35). In vivo double tetracycline labeled bone biopsy established the diagnosis of SSBT. Patient was treated with teriparatide for 2 years and a repeat bone biopsy showed complete resolution of SSBT with restoration of normal bone remodeling. Relevant bone histomorphometric data are in the Table.

Measurement	Pre-Rx	Post-Rx	Ref. Mean
Cortical Bone Volume (% TV)	86.90	92.70	93.80
Cortical Thickness (mm)	0.84	0.45	1.22
Trabecular Bone Volume (% TV)	8.90	12.20	20.40
Trabecular Thickness (μm)	61.70	114.00	135.00
Osteoid Surface (% BS)	0.00	6.35	20.60
Osteoid Width (μm)	0.00	10.89	8.48
Osteoid Volume (% BV)	0.00	0.96	5.95
Osteoblast Surface (% OS)	0.00	10.67	2.63
Eroded Surface (% BS)	0.16	0.41	7.65
Osteoclast Surface (% NOS)	0.00	0.06	1.27
Mineralizing Surface (%BS)	0.00	0.60	7.66
Mineral Appositional Rate (MAR) (μm/day)	0.00	0.34	0.53
Bone Formation Rate (Surface) (μ3/μ2/year)	0.00	0.59	15.30

Conclusion: The results of the bone biopsy demonstrate the benefit of teriparatide for SSBT. To the best of our knowledge this is the first case describing reversal of SSBT confirmed by bone biopsy. We extrapolate that the use of teriparatide would be of benefit in SSBT stemming from anti-resorptive medication use.

WG6

Arterial Dissection and Associated COL1A1 Sequence Variants in Adult Osteogenesis Imperfecta. Jay Shapiro, Kennedy Krieger Institute.

Osteogenesis Imperfecta (OI) is a systemic disorder in which mutations involving type I collagen occur in 90 % of individuals. Abnormalities of the mitral or aortic valves and aortic dilatation occur in adult OI. However, Involvement of central or peripheral vessels is not appreciated. **Purpose**: This report describes: a) internal carotid, vertebrobasilar, iliac and femoral circumflex artery dissections in five adults with OI types I and IV and, b) COL1A1 and COL1A2 sequence variants. **Results**: Case 1: A 37 year old male type I OI experienced spontaneous dissection of the distal right common iliac artery extending into the right external iliac artery with focal dissection of the left common iliac artery. Case 2: A 35 year old male, type I OI, acutely developed facial tingling. CT angiogram revealed a spontaneous right carotid artery dissection and previous bilateral focal dissections within the origins of the common iliac arteries Case 3: A 54 year-old woman, type IV OI, developed numbness of her left arm and two days later, awoke with a sharp frontal/occipital headache. CT angiogram of the head and neck demonstrated dissection of the right internal carotid artery starting at the C-1 level with mural thrombus and significant stenosis of the true lumen. Case 4: A 30 year-old woman, type I OI presented with 4 weeks of sub-acute left-sided headache, left arm weakness, dysphagia, and voice change. MRI showed marked attenuation of the internal carotid artery with bulbus ectatic dilatation distal to the left carotid artery bifurcation. There was long segment dissection involving the left vertebral artery extending from the proximal V-1 segment to V-3 junction. Case 5: A 58 year old female with type IV OI hospitalized and heparinized for DVT, experienced spontaneous dissection of the left medial femoral circumflex artery and a decrease in hemoglobin to 2.8 mg. In these patients different COL1 sequence variants were found. Case # 1: c.544-1G>T: #2: c.1405C>T, p. (Arg469*);#3: c.3505G>A, p.(Gly1169Ser): #4: c.4327_4333delinsCTGGA p.(Ala1443Leufs*107). In 3 previously reported cases of arterial dissection the following COL1 mutations occurred: Mayer, 1996; c.572G>C, p.Gly191Ala: Matouk, 2011c.3532G>A: and Kaliaperumal, 2011; *c. 3532-2A>G.* **Conclusions:** Adult OI may be associated with spontaneous vascular dissection. Arterial dissection may involve both type I collagen and other matrix proteins as yet undefined, 2) Life threatening arterial dissection in adult OI is underreported.

WG7

A Case Report: A Patient With Extensive Osseous Sarcoidosis ("Holes in Her Bones"). E Cong and SJ Silverberg. Division of Endocrinology, Columbia University Medical Center, New York, NY.

Sarcoidosis, a multi-system inflammatory disorder, affects the bones in about 3-13% of patients. Osseous sarcoidosis is usually localized to the hands and feet with preservation of the cortical borders of the bone. While generally asymptomatic and not progressive, rarely osseous sarcoid lesions may be found in other locations including the vertebra and may be progressively destructive, thereby causing fractures. There are currently no evidence based guidelines with regards to treatment for osseous sarcoidosis, and case reports illustrate that it responds poorly to corticosteroids as well as to other drugs used in treating the illness. We report a case of a patient with extensive osseous sarcoidosis.

A 49 year old premenopausal Hispanic female with no past medical history presented to Columbia University Medical Center with dyspnea on exertion, dry cough, progressive dysphagia and bone pain. On CT scan, she was found to have numerous lesions involving the lungs, liver, lymph nodes and bones. An extensive workup was negative for infectious and malignant etiologies. Biopsy of a mediastinal lymph node and left iliac crest lesion revealed non-caseating granulomas consistent with sarcoid. ACE level was 14 U/L [9–67]. Prednisone was begun at 50 mg/day with a prolonged taper, along with calcium and vitamin D supplementation. All symptoms resolved including her bony pain. Imaging at three months showed improvement in the pulmonary nodules, but skeletal lesions were unchanged.

She was referred to the endocrinology clinic for management of her bone disease, which involved the left occiput, right humeral head, left scapula, bilateral clavicles, multiple ribs, spine at L5, T4, T10, T12, right sacral hila, and bilateral ileum, acetabulum and proximal femur. Hand X-rays were negative for lytic lesions. No fractures were seen. Laboratory evaluation included: calcium 8.8 mg/dl [8.7–10.2], ionized calcium 1.23 mmol/L [1.12–1.32], phosphorous 3.6 mg/dl [2.5–4.3], parathyroid hormone 42 pg/ml [8–51], 25-hydroxyvitamin D <13 ng/ml [30–80], 1,25-dihydroxyvitamin D 29 pg/ml [15–75], alkaline phosphatase 30 U/L [33–96], GFR >60 mL/min/1.73 m^2, 24 hour urine calcium 37 mg/24 hrs [150–300]. Bone turnover markers included a serum c-telopeptide level of 345 pg/ml [premenopausal range: 40–465], osteocalcin 19 ng/ml [11–50], procollagen type-I propeptide 35 ug/L [20–200], bone-specific alkaline phosphatase 4.6 ug/L [4.5–16.9]. BMD by DXA at the lumbar spine, femoral neck, total hip, and 1/3 left forearm was normal [T-score: LS 0.9, FN 0.2, TH 0.5, RAD 1.4]. VFA did not show vertebral compression. HRpQCT of the left distal tibia and radius showed very low cortical density at the distal tibia (T-Score -3.7). Total density was preserved due to high trabecular density. Cortical porosity measurement is pending. Skeletal survey confirmed the lesions seen on CT without fracture. Bone scan showed multiple radiotracer avid lesions including those corresponding to her left femur lesions.

In summary, this patient with extensive osseous sarcoidosis had normal DXA BMD but markedly low cortical BMD at a weight bearing site. Steroid treatment did not improve her bony lesions, although it improved her pain. Bone turnover activity was not very elevated despite widespread high avidity lesions on bone scan, including several at sites at high risk for fracture. Previous reports suggest that patients with osseous sarcoidosis have high fracture risk even in the setting of normal BMD. She is also at risk for progressive bone loss due to incipient menopause and ongoing steroid therapy. Once she is vitamin-D replete we will consider osteoporosis therapy, and monitor for any changes in her osseous lesions.

WG8

Osteosarcoma in a patient with pseudohypoparathyroidism type 1b due to paternal uniparental disomy of chromosome 20q. Yumie Rhee*, MD, PhD, Chang Gon Kim, MD, Su Jin Lee, MD, Jo Eun Kim, MD. Department of Internal Medicine, Yonsei University College of Medicine, Seoul, Korea.

Pseudohypoparathyroidism type 1b (PHP1b) is the result of end-organ resistance to parathyroid hormone (PTH) in the absence of any features of Albright' osteodystrophy. The function of the Gs protein is solely controlled by maternally originated Gs specifically in the renal proximal tubules, thus its loss or imprinting error in the maternal GNAS give rise to impaired PTH action, resulting in reduced 1,25-OH vitamin D synthesis, increased phosphate excretion, and hypocalcemia. As PTH responsiveness is intact in the bone and parathyroid glands, theoretically it can lead to overt hyperparathyroid bone disease due to chronically elevated PTH levels, which may be exacerbated by low 1,25-OH vitamin D levels.

A 21-year-old Korean male, presenting with gum swelling at the right mandible, was referred to the Department of Oncology with the impression of sarcoma-like lesion by the tissue biopsy. Curative surgical resection by segmental mandibulectomy was performed followed by reconstruction with fibular flap of left leg. A 2.5X5.0X3.0 cm white infiltrating mass showed anaplastic and pleomorphic spindle-cells with myxoid stroma and osteoid formation fulfilling the histological criteria of conventional osteoblastic osteosarcoma.

To further investigate the reason for the low calcium level (6.1 mg/dL; normal 8.5~10.5 mg/dL) and high phosphorus level (6.3 mg/dL; normal 2.5~4.2 mg/dL), consultation to us was done. Elevated intact PTH level (250 pg/mL; normal, 15~65 pg/mL) with low 1,25-OH vitamin D level (9.7 pg/mL; normal 19.6~54.3 pg/mL) reflected the failure of target tissues to respond appropriately to the biological actions of PTH on the proximal renal tubule. Bone mineral density showed osteopenia at the lumbar spine. Additionally, thyroid function test revealed TSH resistance (Free T4 level 1.24 ng/dL; normal 0.70~1.48 ng/dL, TSH 9.61 μIU/mL; normal 0.35~4.94 μIU/mL). He revealed no specific past history except somewhat short stature (165 cm, 2.0 SD below the mean for age) with normal mentation and without any shortening of fingers. With the impression of PHP1b, conventional sequencing for GNAS was performed but with no genetic mutation identified within exon 1–13 and exon-intron boundaries. Therefore, multiplex ligation-dependent probe amplification (MLPA) for analysis was pursued revealing hypermethylation at NESP 55 and hypomethylation at GNAS A/B and XL suggesting loss of maternal methylation pattern. In a uniparental disomy (UPD) analysis using microsatellite markers on chromosome 20 (D20S117, D20S889, D20S115, D20S112, D20S107, D20S178, D20S196, D20S100, D20S496, D20S459, D20S173), there was no maternal alleles inherited at markers (D20S196 and D20S100 which represent 20q13.13 and 20q13.2) flanking the GNAS locus. Generally, most patients with sporadic PHP-1b are known to have deletions in the multiple differentially methylated regions (DMRs) of the GNAS. Rarely, paternal UPD of chromosome 20 (patUPD 20) causing PHP 1b had been reported in 8 patients up to now including this case.

In this condition, as the skeletal PTH responsiveness is untouched or even elevated, persistent stimulation of PTH on osteoblasts results in elevated bone remodeling. In preclinical rat model treated with high dose of recombinant PTH (1–34) for nearly entire life span, osteosarcoma had occurred. There were three patients having previous hyperparathyroidism out of 1234 patients with osteosarcoma investigated in the M.D. Anderson Cancer Center. Here we report an adolescence patient with osteoblastic osteosarcoma and PHP1b where the PTH resistance on renal proximal tubule with over-responsive PTH to skeleton might have incurred a bone tumor.

WG9

Transient Osteoporosis of the Hip Associated with Alcohol Consumption. K. Asadipooya, L Graves. University of Kansas Medical Center, Kansas City KS.

Background: Transient Osteoporosis of the Hip (TOH) is a condition of acute bone marrow edema of the hip without obvious cause. It is a transient clinical condition of unknown etiology and mechanism that typically affects women, especially in the last trimester of pregnancy, as well as middle-aged men. It has been represented in the literature as Bone Marrow Edema syndrome (BMES), Regional Migratory Osteoporosis (ROM) and Reflex Sympathetic Dystrophy (RSD). We present a case in which the onset and recurrence of symptoms appeared related to increased alcohol consumption.

Case Report: A 59-year-old male presented with acute right hip discomfort and limping. There was no precedent trauma and no history of underlying arthritic condition. The pain was aggravated by standing and walking and relieved by supine position with hip flexion. On physical examination he had mild limitation of motion of the right hip but no tenderness in Log Roll, FABER and FADIR test. His typical alcohol consumption was 6 units per week. Four weeks prior to the onset of pain he had increased this to 24 units per week. Following the onset of pain he reduced his alcohol consumption. Pain subsequently improved but then returned again following 1–2 days of increased alcohol. This pattern repeated itself again 1–2 weeks later. Evaluation revealed a normal general chemistry panel, complete blood count, TSH, and 25-OH vitamin D. MRI revealed extensive bone marrow edema in the right femoral head and neck, with the diagnosis being transient bone marrow edema or early avascular necrosis of the right hip. DXA of the spine and hip were normal. In consultation with his orthopedic surgeon, protected weight bearing activity using crutches for walking was recommended. Following 8 weeks of reduced weight bearing, and reduce alcohol intake, the pain resolved and with no further limp. A repeat MRI revealed no femoral head collapse, persistent but improved edema with no fracture lines present, most consistent with TOH.

Discussion: Patients with TOH or bone marrow edema syndrome involving other sites may present with a wide range of clinical and radiological manifestations, and some likely never seek medical assistance. *Lakhanpal* et al. reported 56 patients (33 men and 23 women) with transient regional osteoporosis who presented with monoarticular or oligoarticular joint pain aggravated by weight bearing. Eighteen (32%) of the patients had pain at rest and six (10%) had nocturnal pain. The joints of lower extremities were more commonly involved and hip was the most commonly affected joint. Smoking appeared to be a potential risk factor. Biopsy of the affected area has revealed edema and reactive bone formation in the marrow, high bone turnover and absence of fat necrosis, suggesting vasomotor response as opposed to osteonecrosis. The prognosis of BMES is usually good and it has a benign and self-limiting course.. The relationship to alcohol suggested by this presentation was similarly suggested in 2 of 22 patients with BMES reported by *Karantanas et al*, 2008. Though alcohol has multiple potential effects on bone formation and resorption a clear mechanism to BMES is unclear.

Conclusion: TOH or other BMES should be considered in the diagnosis of acute bone pain with findings of edema by MRI. The differential diagnosis should include ischemic injury (avascular necrosis of femoral head), infection (septic arthritis and osteomyelitis), neoplastic diseases, trauma (stress fracture), inflammatory diseases, degenerative process, metabolic diseases and neurological disorders.
