ABSTRACT OF DISSERTATION

VAN DER WAALS CLUSTERS OF

AROMATIC MOLECULES STUDIED USING

SUPERSONIC MOLECULAR JET SPECTROSCOPY

van der Waals (vdW) clusters of aromatic solutes with various solvents are studied in the gas phase using supersonic molecular jet spectroscopy. Calculations involving ground state cluster binding energy, geometry, and intermolecular vibrational structure are also presented to complement the experiments. The analyses include: spectroscopic studies and theoretical modeling of the intermolecular vibronic structure of benzene solvated by argon, methane, water, and ammonia; spectroscopic studies and theoretical modeling of the intermolecular vibronic torsional structure in benzene solvated by methane, deuteromethane, and carbon tetrafluoride; solvation of pyrazine and pyrimidine by both small hydrocarbon and hydrogen bonding solvents; the study of pyrazine and pyrimidine dimers; and the solvation of macrocycles such as free base phthalocyanine (H_2Pc) and magnesium phthalocyanine (MgPc) by small hydrocarbon solvents, hydrogen bonding solvents, and carbon dioxide.

The benzene/solvent studies lead to the elucidation of the detailed nature of the intermolecular vibrational structures and the geometries/symmetries present in the clusters. These studies reveal that the majority of the intermolecular vibronic transitions observed involve vdW bending and torsional motion parallel to the solute pi cloud. Furthermore, the clusters behave rigidly with regard to internal rotation of the cluster subunits and the clusters possess unique equilibrium geometries.

The pyrazine and pyrimidine/solvent and dimer studies demonstrate the detailed effects of the solute ring nitrogens on cluster geometry and on the role of hydrogen bonding in the clusters.

The H_2Pc and MgPc/solvent cluster experiments and models suggest that stable solute solvation sites are located over the phthalocyano core and not over peripheral ring centers. Forbidden low frequency cluster chromophore out-of-plane vibronic transitions are also induced by solvation in both the H_2Pc and MgPc clusters.

ABSTRACT OF DISSERTATION

VAN DER WAALS CLUSTERS OF
AROMATIC MOLECULES STUDIED USING
SUPERSONIC MOLECULAR JET SPECTROSCOPY

van der Waals (vdW) clusters of aromatic solutes with various solvents are studied in the gas phase using supersonic molecular jet spectroscopy. Calculations involving ground state cluster binding energy, geometry, and intermolecular vibrational structure are also presented to complement the experiments. The analyses include: spectroscopic studies and theoretical modeling of the intermolecular vibronic structure of benzene solvated by argon, methane, water, and ammonia; spectroscopic studies and theoretical modeling of the intermolecular vibronic torsional structure in benzene solvated by methane, deuteromethane, and carbon tetrafluoride; solvation of pyrazine and pyrimidine by both small hydrocarbon and hydrogen bonding solvents; the study of pyrazine and pyrimidine dimers; and the solvation of macrocycles such as free base phthalocyanine (H_2Pc) and magnesium phthalocyanine (MgPc) by small hydrocarbon solvents, hydrogen bonding solvents, and carbon dioxide.

The benzene/solvent studies lead to the elucidation of the detailed nature of the intermolecular vibrational structures and the geometries/symmetries present in the clusters. These studies reveal that the majority of the intermolecular vibronic transitions observed

involve vdW bending and torsional motion parallel to the solute π cloud. Furthermore, the clusters behave rigidly with regard to internal rotation of the cluster subunits and the clusters possess unique equilibrium geometries.

The pyrazine and pyrimidine/solvent and dimer studies demonstrate the detailed effects of the solute ring nitrogens on cluster geometry and on the role of hydrogen bonding in the clusters.

The H_2Pc and MgPc/solvent cluster experiments and models suggest that stable solute solvation sites are located over the phthalocyano core and not over peripheral ring centers. The H_2Pc/hydrocarbon cluster results parallel those obtained for the benzene and N-heterocycle/hydrocarbon clusters. The H_2Pc and MgPc/alcohol cluster spectra and calculated geometries suggest that the solvent OH groups are intimately involved in the intermolecular interactions. Forbidden low frequency cluster chromophore out-of-plane vibronic transitions are also induced by clustering. This low frequency motion is characterized using an out-of-plane normal coordinate analysis on the H_2Pc moiety.

ACKNOWLEDGMENTS

I would like to extend my thanks to a number of people whose assistance and support have proved invaluable in making graduate school a worthwhile experience for me. Uppermost of those who have spurred by interest in the details of molecular spectroscopy is Elliot R. Bernstein. I am deeply indebted to Elliot for his constant encouragement and generous advice in my research. His clear insight and helpful discussions were often the only reasons why explanations for several of the effects discussed in this manuscript were pursued.

I am grateful to the members of my Graduate Advisory Committee for taking the time to participate in my research endeavors.

I would like to thank Dr. Joseph Wanna and Dr. Mark Schauer for teaching me the "tricks of the trade". Without them this dissertation would not be nearly as impressive.

I am extremely grateful to Lt. Col. Chester Dymek, the staff at Frank J. Seiler Research Laboratory, and the people behind the United States Air Force Academy Faculty Program for making it possible for me to pursue my education in conjunction with my Air Force career.

Most of all, I would like to thank my lovely wife Lisa, my son Joe Jr., and my daughter Deanna. I am deeply indebted to them for the sacrifices they made and for their encouragement and emotional support during this period of endeavor in my life.

To

Ida M. Menapace,

Janet J. Juranek, and

John E. Juranek Sr.,

With Love... Joe

TABLE OF CONTENTS

CHAPTER ONE

INTRODUCTORY COMMENTS AND OVERVIEW

Introduction.

The material contained in this dissertation is largely presented in five publications. In the spirit of completeness and accuracy, these papers are incorporated directly into the dissertation. The first three papers appear as chapters in the body of the manuscript. The remaining two papers appear in reprint form as appendices. The rest of the dissertation entails the introductory comments and overview, unpublished results, future/proposed experiments, conclusions, and the computer programs utilized in this work.

The introductory comments and overview are meant to tie together the body of the dissertation since directly presenting the publications tends to fragment the discussion. They will also provide the reader with the general notions underlying the work presented in detail in each major section or chapter of the dissertation.

The unpublished results contain mostly those data which are not important enough to appear in papers, or data which need additional work to interpret. The data are presented in the dissertation to establish a record of the research conducted in specific areas and to provide future investigators with a basis for further study.

The future/proposed experiments involve both theoretical and experimental studies of solute/solvent cluster systems similar to those

presented in this dissertation. The primary motivation in these proposed experiments is to provide for continued research on cluster systems using the models, procedures, and experimental set-ups currently available in the Bernstein group laboratory.

The presentation of the computer programs used in the cluster studies is largely for the convenience of future investigators. The programs serve as easy references for those conducting research in the same or similar areas as well as provide documentation on the "how to's" of the models used in the studies.

Overview.

The five publications incorporated into this dissertation are divided into five chapters. The work covers: 1) the experimental study and theoretical modeling of the intermolecular vibronic structure of benzene solvated by argon, methane, water, and ammonia; 2) the experimental study and theoretical modeling of the intermolecular vibronic torsional structure in benzene solvated by methane, deuteromethane, and carbon tetrafluoride; 3) the detailed study of the solvation of pyrazine and pyrimidine by both small hydrocarbon and hydrogen bonding solvents; 4) the study of pyrazine and pyrimidine dimers; and 5) the solvation of macrocycles such as free base phthalocyanine and magnesium phthalocyanine by small hydrocarbon solvents, hydrogen bonding solvents, and carbon dioxide. This overview is intended to tie together the major results of these studies and to create a sense of unity and purpose for the studies.

The Vibronic Structure of Solute/Solvent van der Waals Clusters

A large body of data has been accumulated in this laboratory for small aromatic molecules such as benzene, pyrazine, and pyrimidine solvated

with small hydrocarbon solvents such as methane, ethane, and propane, and hydrogen bonding solvents such as water and ammonia. These spectroscopic studies yield observables such as spectral shift which can be related to the difference between the cluster binding energy between the ground and electronic excited states and to cluster geometry. In the majority of the cluster spectra, intermolecular vibronic transitions are observed which can be used to elucidate the cluster symmetry/geometry, electronic state mixing, and the intricacies of the intermolecular potential surface.

Modeling of the intermolecular interaction between the cluster constituents also complements the spectroscopic studies. These calculations allow one to elucidate some physical properties of the clusters such as ground state cluster binding energy and geometry. The calculations always yield results consistent with experimental observations in regard to the number of cluster configurations observed, their respective binding energies, and their qualitative geometries. Modeling of the intermolecular vibronic structure in these molecules adds to the understanding of the cluster systems as it allows one to obtain detailed information on cluster geometry/symmetry and to elucidate the intricacies of the potential established between the cluster constituents.

Presently, little information is available, either experimentally or theoretically, on the details of the intermolecular vibrational structure in the solute/solvent cluster systems. Furthermore, the van der Waals (vdW) modes are interesting as they play a key role in dynamical energy transfer processes in the clusters as well as represent precursors to a variety of motions occurring in liquids and solids.

The modeling of the intermolecular vibrational structure in this study is approached by extending the empirical models previously used to

calculate cluster ground state geometry and binding energy to include modeling of the ground state vdW motion. The vdW vibrational structure is modeled using a normal coordinate analysis in which the clusters are treated as "giant molecules" whose motion is governed by a force field describing both the intra- and intermolecular motion. The intermolecular force field is based upon an atom-atom Lennard-Jones potential function including general non-bonding (6-12), hydrogen bonding (10-12), and monopole charge (1) terms.

Using this model, the eigenvalues and eigenvector normal modes for the vdW motion occurring in benzene$(Ar)_1$, /$(CH_4)_1$, /$(H_2O)_1$, and /$(NH_3)_1$, and s-tetrazine$(Ar)_1$ are calculated. The results of these calculations are then used to assign the vdW motions observed in vibronic spectra of the aforementioned cluster systems which are obtained using 1- and 2-color time-of-flight mass spectroscopy (TOFMS). Agreement between the calculations and experiments is excellent for cluster binding energies, symmetries, and vdW frequencies. Essentially, the $S_1 \leftarrow S_0$ vibronic transition of the clusters are completely assigned based upon these calculations.

A number of approximate "diatomic molecule" models are also considered in this study to analyze the vdW structure in benzene$(Ar)_1$. The cluster vdW modes are modeled using three methods: 1) a Taylor series expansion of the intermolecular potential along the vdW stretching and bending coordinates; 2) a Morse potential fit to the intermolecular potential along the vdW stretching and bending coordinates; and 3) a semi-classical energy level fit to the intermolecular potential using the JWKB method. The models essentially treat the clusters as simple two particle systems whose motions are restricted to

the principle axes of a Cartesian coordinate system and can, thereby, be analyzed using a diatomic molecule type approximation. These models are considered to show the consistency of the calculations between each diatomic molecule model and the intermolecular normal coordinate analysis.

The experimental and theoretical studies on the benzene/solvent systems give rise to several interesting notions which involve the detailed nature of the intermolecular interaction. First, the studies reveal that the weak vdW potential between the cluster solute and solvent is, for the most part, the same for the ground and excited electronic states. Second, the majority of the observed vdW vibronic transitions observed in the cluster spectra are those involving vdW bending and torsional motions parallel to the aromatic π system. Third, these modes are quite active in the Herzberg-Teller vibronic coupling mechanism. And fourth, vdW motions for which the cluster solvent penetrates the aromatic π system of the solute have high frequencies and are typically not observed.

The Intermolecular Vibronic Torsional Structure in Solute/Solvent vdW Clusters: Benzene/Methane, /Deuteromethane, and /Carbon Tetrafluoride - The modeling of the intermolecular motion in the vdW clusters discussed above is basically approached using, more or less, a rigid molecule bound energy well approximation. This approach seems quite reasonable for the vdW stretching and bending degrees of freedom which are essentially translations of the cluster constituents relative to one another. The vdW torsional modes, on the other hand, could in principle not be oscillatory. They could be free or hindered rotation of the cluster solvent relative to the cluster solute. In this regard the

intermolecular normal coordinate analysis may not faithfully reproduce the vdW torsional motion present in the clusters.

To study this possibility, we chose to analyze benzene clustered with methane, deuteromethane, and carbon tetrafluoride. The motivation for studying this "isotopic" cluster solvent series centers upon the elucidation of the vdW torsional structure. Two limiting cases can be proposed in regard to the torsional structure in benzene$(CH_4)_1$, benzene$(CD_4)_1$, and benzene$(CF_4)_1$. In one case, the clusters can possess free internal rotation in which the cluster solvent freely rotates in three dimensions against the benzene frame and the system can be considered internally non-rigid. In the other case, the clusters possess torsional oscillations for which the cluster solvent librates against the benzene frame with a residence time long enough to give rise to "vibration like" motion in an internally rigid molecule regime. Understanding the vdW torsional motion is particularly interesting in these systems as the limiting cases pose questions regarding the physics governing the vdW torsional structure: 1) do the clusters posses free/hindered internal rotation or do they possess torsional oscillations; and 2) in either case, what is the dependence of the intermolecular potential upon the relative orientation of the cluster constituents?

In the studies, the clusters are probed spectroscopically using supersonic molecular jet expansion and 2-color TOFMS techniques. The cluster $S_1 \leftarrow S_0$ intermolecular vibronic structures are then characterized by calculational modeling of the vdW motion. The calculations include: 1) an intermolecular normal coordinate analysis which treats all six vdW modes under a harmonic oscillator assumption; and 2) a three-dimensional hindered rigid rotor analysis which treats only the intermolecular torsional motion.

In the experimental and theoretical studies on the benzene$(CH_4)_1$, benzene$(CD_4)_1$, and benzene$(CF_4)_1$ systems, several interesting results are obtained. First, the cluster vibronic spectra show that the clusters are at least semi-rigid systems with regard to internal rotation of the cluster subunits and that the clusters possess unique equilibrium geometries. Second, the spectra demonstrate that the intermolecular motion present in the systems is oscillatory and, through the "isotopic" shifts observed, that the low-lying eigenstates are nearly harmonic. They are not admixtures of vdW bends, stretches, and free internal rotation as would occur if the clusters were internally non-rigid. Third, both the intermolecular normal coordinate analysis and the three-dimensional hindered rigid rotor analysis indicate that the vdW torsional structure is oscillatory and that the motion is constrained by an orientationally dependent intermolecular potential whose barrier height is on the order of the cluster binding energy.

Hydrogen Bonded and Non-Hydrogen Bonded vdW Clusters: Comparison between Clusters of Pyrazine, Pyrimidine, and Benzene with Various Solvents - The study of the solvation of pyrazine, pyrimidine, and benzene by both small hydrocarbon and hydrogen bonding solvents has led to detailed information about the structure and energetics present in the solute/solvent systems. Our chief motivations for studying these clusters center upon the elucidation of the effects of the ring nitrogen atoms in pyrazine and pyrimidine solutes on cluster geometry and on the role of hydrogen bonding in the pyrazine, pyrimidine, and benzene cluster systems. These studies are of interest as hydrogen bonding interactions are known to play an important role in the intra- and intermolecular interactions responsible for secondary and tertiary

structure, molecular dynamics, and ionic and molecular solvation. Assignment of the spectra obtained in these studies is accomplished through the determination of the cluster spectral shifts, ionization energies, relative intensities, molecular forbidden cluster transitions, and intermolecular potential/cluster geometry calculations. Computer modeling of the cluster systems has proven essential to the understanding of the spectroscopic data. Through the interplay of the computer modeling of these clusters and the spectroscopic data, it is possible to assign probable geometries to many of the spectroscopic features. In many cases this allows one to find the spectral shift corresponding to a specific geometry of a cluster. The assignment of a geometry to the spectral shifts leads to some general conclusions about the types of interactions responsible for the spectral shifts.

In these studies we find that the clusters fall into two general categories: 1) a conventional set containing the aromatic solute/hydrocarbon solvent clusters; and 2) benzene, pyrimidine, pyrazine ammonia and benzene water clusters. The aromatic solute/hydrocarbon cluster spectra are quite similar to one another in that they all possess bathychromic shifts with respect to the isolated chromophore transition. The cluster binding energies and calculated geometries are also similar. The presence of the nitrogen atoms in the aromatic ring of the pyrazine and pyrimidine solutes has a relatively small although discernible effect on the overall intermolecular interaction. In particular, the solvent hydrogen atoms preferentially orient towards the solute nitrogen atoms.

The solute/hydrogen bonding solvent cluster systems, on the other hand, possess vibronic spectra which are all unique and surprisingly

erratic. In these clusters the spectral shifts range from -100 to 500 cm^{-1}, the vdW vibronic motion in the systems range from nonexistent to intense, the vdW modes are in some cases highly perturbing to the solute vibronic structure and energy, and the number of unique cluster geometries range from one to three in an apparently random fashion. In spite of these differences the models used to calculate the cluster geometries and binding energies corroborate the experiments as far as the comparison can be made in regard to cluster symmetry, number of configurations observed, and red and blue shifts in regard to hydrogen bonding. The hypsochromic shifts observed in the pyrazine and pyrimidine ammonia clusters suggest that hydrogen bonding between the ring nitrogen and the solvent hydrogens may be contributing to some extent to the total intermolecular interaction responsible for cluster formation/stabilization. The benzene/ammonia and benzene/water spectra seem to suggest that some type of hydrogen bonding may be occurring in the benzene/water system between the aromatic π cloud and the solvent moiety as the benzene$(H_2O)_1$ spectral shift is hypsochromic whereas the benzene$(NH_3)_1$ spectral shift is bathychromic.

Supersonic Molecular Jet Studies of the Pyrazine and Pyrimidine Dimers - The understanding of the solute/solute interactions in the pyrazine and pyrimidine dimer systems is of interest for a number of reasons. First, the dimers serve as model systems for condensed phase structure, dynamics, and nucleation and growth of molecular aggregates. Second, the dimers provide insight into the understanding of the secondary and tertiary structures present in more complicated molecules. And third, studying these clusters in the gas phase yields information on the major interactions responsible for dimer formation and what types of

dimer geometries are most probable in an isolated environment free from the extraneous perturbations present in liquid and solid phases.

The pyrazine and pyrimidine dimers are analyzed using supersonic molecular jet expansion and 2-color TOFMS techniques for which the mass selected optical spectra of the first excited singlet $n\pi^*$ transitions of the dimers are observed. On the basis of what we have learned from the study of the simple solute/solvent clusters, we are able to analyze the dimer systems using cluster ionization energy, vibronic structure, spectral shift, and modeling of the intermolecular potential between the cluster subunits. The interplay of the spectroscopic data and the calculations allows us to obtain a consistent set of geometries for the dimers present in the supersonic expansion.

In the pyrazine dimer system, the experiments and calculations suggest that the both parallel hydrogen bonded and perpendicular dimers are present in the supersonic expansion. The calculations also predict a parallel stacked/90^0 rotated dimer which is *not* observed. This species most likely forms an excimer in the excited state with a short lifetime and a large red shifted and broad spectrum. The major distinction between the two observed dimer species is determined to be the difference in the involvement of the π clouds in the overall dimer interaction as evidenced by differences in the cluster ionization energy between the two cluster species.

In the pyrimidine dimer, the calculations yield four planar hydrogen bonded species and a parallel stacked/displaced species. The observed dimer vibronic spectra are consistent with these calculated geometries. As in the pyrazine dimer, the ionization energy proves to be an important contribution in determining the number of different

dimer geometries responsible for the observed spectra. Additionally, we find that the dimer spectral shifts depend upon the specific cluster geometry. A bathychromic shift is associated with the parallel stacked/displaced dimer and hypsochromic shifts are associated with the planar hydrogen bonded dimers.

To explore further the agreement between the experiments and calculations on the dimer systems, we also conducted calculations on the tetrazine dimer. Three calculated geometries are obtained for the tetrazine dimer: a parallel stacked/90^{o} rotated species, a planar hydrogen bonded species, and a perpendicular species. In this study we find that the calculated geometries are in agreement with geometries determined from rotational analysis.

Computer modeling is determined to be an essential component to the study of these dimer systems. The spectroscopic data are needed to validate the computer modeling techniques, and the calculations help to assign spectra which are otherwise quite puzzling. In this way the interplay between spectroscopy and computer modeling leads to a better understanding of the structure and energetics of the solute/solute systems.

Supersonic Molecular Jet Studies of Phthalocyanines and Their vdW Clusters with Small Molecules - In these studies, free base phthalocyanine (H_2Pc) and magnesium phthalocyanine (MgPc) clustered with solvents such as small hydrocarbons (C_nH_{2n+2} (n=1, 2, 3)), hydrogen bonding solvents (H_2O, MeOH, EtOH), and CO_2 are analyzed in an isolated ultracold molecular environment. The clusters are generated using a high temperature continuous supersonic molecular jet especially designed for efficient generation and study of the species in the gas phase. The

advantages of the supersonic molecular jet are exploited in these studies as the complicated phthalocyanine spectra are dramatically simplified and the solvent or environmental perturbations present are controlled in a set and reproducible manner.

Our basic motivation for studying these systems centers upon elucidation of the solvation properties of the macrocycles in a controlled and well-defined environment. In this regard, supersonic molecular jet investigations on the H_2Pc and MgPc solute/solvent clusters can contribute to the resolution of a number of important concerns dealing with the behavior of the systems on the microscopic scale. Questions that we considered in these cluster studies are 1) what are the ground and excited state binding energies between the phthalocyanines and various solvents, 2) what are the preferential interaction sites on the phthalocyanine moiety, 3) what are the most favorable cluster geometries, 4) what types of interactions are important in the intermolecular interaction established between the solute and the solvent, and 5) are changes to the chromophore symmetry/geometry induced by clustering.

The H_2Pc and MgPc solute/solvent clusters are characterized by analysis of their gas phase fluorescence excitation spectra and modeling of the intermolecular potential between the cluster solutes and solvents. In these studies, we find that forbidden cluster chromophore out-of-plane motion is induced by clustering and that elucidation of the nature of this out-of-plane motion is essential to the understanding of the cluster spectra and in the identification of the number of different clusters of a specific composition observed. This prompted us to conduct an out-of-plane normal coordinate analysis on H_2Pc to

characterize the motion. The comparison between these calculations and the experiments makes possible the identification of specific species/geometries responsible for the cluster vibronic transitions observed in the spectra.

Several interesting results are obtained from the cluster studies. First, the cluster vibronic spectra and calculations suggest that stable H_2Pc and MgPc solvation sites are located over the phthalocyano core. Local minima over peripheral ring centers are either nonexistent or too shallow to accommodate minimum energy bound state geometries. Second, the H_2Pc/hydrocarbon cluster experimental and theoretical results parallel those obtained for benzene and the N-heterocycle/hydrocarbon clusters. The spectral shifts observed in these solvent series are all bathychromic and the magnitudes of the spectral shifts increase with increasing solvent size and polarizability. Third, the H_2Pc and MgPc/alcohol cluster spectra and calculated geometries suggest that the solvent OH group is intimately involved in the intermolecular interactions and contributes significantly to the observed spectral shifts. Fourth, MgPc clusters display weak vdW interactions between the cluster solute and solvent. Actual complexation in which the solvent donates electron density to the solute does not occur. Fifth, excited electronic state splitting may occur in the MgPc clusters due to the reduction in system symmetry upon cluster formation. The degenerate Q band in the isolated MgPc spectrum appears to split into its two components, Q_x and Q_y, in the cluster spectra. Finally, forbidden low frequency cluster chromophore out-of-plane motion is induced by clustering in both the H_2Pc and MgPc systems. Intensity of this motion arises from the reduction of the chromophore symmetry in the clusters.

CHAPTER TWO

THE VIBRONIC STRUCTURE OF SOLUTE/SOLVENT VAN DER WAALS CLUSTERS

Introduction.

The combination of laser spectroscopy and supersonic molecular jet expansions has made possible the study of a wide array of weakly bound van der Waals (vdW) molecules in the gas phase. These clusters, formed in the jet expansion, are stable in the post-expansion region and can be studied as isolated molecules. They are interesting both theoretically and experimentally because of their unique characteristics such as low binding energies, large intermolecular equilibrium distances, and low frequency intermolecular vibrational modes. Furthermore, the vdW clusters only slightly perturb the individual properties of their molecular constituents.[1] These characteristics set the vdW cluster apart as a distinct phase of matter to be explored and understood.

The electronic-vibrational spectroscopy of aromatic molecules like benzene[2-4] and s-tetrazine[5] clustered with various solvents reveals interesting information regarding unique cluster characteristics. Specifically, the studies show detailed information pertaining to the intermolecular energetics and dynamics of cluster interactions, especially in the area of the clusters' low frequency vdW vibrational modes. These modes are of considerable interest since they represent the precursors of a variety of condensed phase eigenstates such as phonons in

liquids and solids. They are also key factors in cluster dynamics as they play a major role in the energy transfer processes of intramolecular vibrational redistribution (IVR) and vibrational predissociation (VP).

Presently, little information is available concerning the detailed intermolecular vibrational structure in molecule-molecule clusters either experimentally or theoretically. The majority of the theoretical work on cluster energetics and dynamics to date is focused upon the intermolecular modes in simple atom-molecule systems. The energetic studies range from quantitative treatment of the vdW stretch and qualitative discussion of the vdW bends[1,6,7] in the atom-molecule clusters to full quantitative treatment of both the vdW bends and stretch[16] in systems for which the intermolecular potential is easily modeled. In dynamical studies,[6,7] primary emphasis is placed upon the vdW stretching mode since it is presupposed that this motion is the major contributor to IVR and VP processes. The clusters are thereby treated quantitatively using a "dumbbell" approximation in which the intermolecular motion is restricted to a stretching mode form. Within this approximation, neglecting the quantitative contributions of the bending/torsional vdW modes in the dynamical scheme seriously limits the application of theoretical treatments to IVR and VP phenomena occurring in molecule-molecule clusters. The stretching mode "restriction" dictates that only certain energy transfer processes can be modeled, specifically those which involve the vdW stretch. Experimental evidence of the theory's limitation[1] is found in the observation of energy transfer from prepared states tangential to the vdW stretching motion. Part of the difficulty of incorporating the vdW bending and/or torsional modes into the theory is that no model has been demonstrated which

describes adequately either their energetics or mode nature in molecule-molecule clusters.

In previous publications,[8] we have used theoretical calculations to elucidate structure and binding energy in the vdW cluster ground state. Combining these calculations with experimental observables such as binding energies, ionization energies, spectral shifts, relative feature intensities, and the appearance of cluster constituent, symmetry forbidden, transitions has aided considerably in spectral assignment and understanding. The calculations always yield results consistent with experimental observations in regard to the number of cluster configurations observed, their respective binding energies, and their qualitative geometries.

In the majority of the cluster spectra studied, vdW vibronic features are observed and sometimes assigned based upon overtone and combination band analysis. In other cases, however, these vibronic features are numerous and complex, making elucidation of the mode fundamentals difficult and sometimes impossible. The vdW vibronic feature assignments have been made based upon the assumptions that the vdW stretch occurs at higher frequency and with greater intensity than vdW bends and torsions. Assigning spectra using these assumptions is a difficult task without a priori knowledge of vibronic mode nature since one must consider that, in nonlinear polyatomic molecule-molecule clusters, six vdW modes exist of which only one is a stretching mode. (In a non-linear atom-polyatomic molecule cluster, three vdW modes exist).

The studies reported in this publication involve the calculation of a complete set of ground state vdW vibrational modes for

benzene$(Ar)_1$, s-tetrazine$(Ar)_1$, benzene$(CH_4)_1$, benzene$(H_2O)_1$, and benzene$(NH_3)_1$. The calculations are performed using a self-consistent pairwise atom-atom intermolecular potential developed by Scheraga, et al.[9] containing general nonbonding (6-12), general hydrogen bonding (10-12), and monopole charge parameters. The calculated ground state vdW modes are compared with cluster vibronic spectra previously studied in this[2,3] and other laboratories.[5] Consequently, a number of spectral reassignments are suggested. Vibronic selection rules governing the vdW cluster $S_1 \leftarrow S_0$ transitions are also derived based upon calculated ground state cluster mode symmetry, cluster geometry, and experimental observation. Within this framework, ramifications of Herzberg-Teller vibronic coupling are discussed as they pertain to experimental observations of Franck-Condon forbidden transitions.

The calculated vdW vibrations are presented for all systems considered as eigenvector normal modes and eigenvalue energies determined via normal coordinate analysis of the entire vdW cluster.[10] In performing the calculations, the high frequency intramolecular vibrations of the cluster constituents are assumed to be completely uncoupled from the low frequency vdW modes.

Simpler models are also considered in studying the vdW transitions of benzene$(Ar)_1$. The system is studied using four methods: 1) a Taylor series expansion of the intermolecular vdW potential along the three Cartesian axes in which the term coefficients are related to the vibrational frequencies in these directions; 2) a Morse potential fit to the intermolecular vdW potential along each of the three Cartesian axes; 3) a Morse potential fit to the intermolecular vdW potential using $\beta = \frac{6}{R_o}$;[1,6,7] and 4) a semi-classical energy level fit to the

intermolecular vdW potential using the JWKB method. These studies are presented to show the consistency of the calculations and to reveal the advantages and pitfalls of the models. The four models involve treating the vdW clusters as simple two particle systems whose motions are restricted to the principle axes of the Cartesian coordinate system. The intermolecular vdW potential surfaces are thereby reduced to one-dimensional potential functions which can be analyzed in a diatomic molecule approximation.

The above outlined approaches are all based more or less on a rigid molecule, bound potential energy well approximation. This approach would seem quite reasonable for the stretching(s) and bending (b_x and b_y) degrees of freedom which are essentially translations of the components of the vdW molecules with respect to one another. Torsional modes (t_x, t_y, t_z), on the other hand, could in principle be modeled by a free/hindered rotor formalism.[11,12] A one-dimensional "free rotor" description has been applied to the symmetry axis (z) torsional motion of benzene and toluene $(CH_4)_1$, $(CD_4)_1$ and $(CF_4)_1$ and compared to the experimental observations. Preliminary results suggest that this approach does not faithfully reproduce the experimentally observed spectra for this "isotopic" series in terms of line shapes, intensities, major features, and the number of observed transitions. A three-dimensional "free rotor" model has also been applied to this problem in order to treat all torsional modes (t_x, t_y, t_z) simultaneously. Similar difficulties are experienced in fitting the experimentally observed spectra. An account of these studies will be submitted for publication in the near future.

The driving motivation in these studies is to answer the following questions: 1) if parametric calculations involving cluster

geometry and binding energy are consistent with experiment, can the same data set be utilized to calculate intermolecular vibrational modes; and 2) what are the advantages and pitfalls of the various models in regard to the complexity of calculation, the approximations made, and the nature of the results obtained?

Experimental Procedures.

Experimental data pertaining to the benzene$(Ar)_1$ vdW vibronic spectrum are obtained employing the experimental apparatus and procedures similar to those used previously to study vdW clusters.[8] The benzene$(Ar)_1$ $S_1 \leftarrow S_0$ spectrum is recorded using a pulsed supersonic molecular jet expansion in combination with 1-color time-of-flight mass spectroscopy (TOFMS). A single Nd^{+3}/YAG pumped LDS 698 dye laser whose output is frequency doubled and then mixed with the Nd^{+3}/YAG 1.064 μm fundamental is used to probe the 6_0^1 region of the benzene$(Ar)_1$ cluster. A 5% Ar in He mixture is placed inline with liquid benzene in a trap maintained at room temperature. This three component gas mixture is then expanded using a pulsed nozzle maintained at 100 psig backing pressure. Apparatus chamber pressure is maintained at or below 4×10^{-6} torr during the experiment.

Theoretical Considerations.

The normal coordinate analyses of the vdW clusters are conducted employing the GF methods of Wilson.[10] These methods involve solving the characteristic equation of 3N-6 coupled harmonic oscillators for its 3N-6 non-zero eigenvalues and eigenvectors. The approach is to treat the vdW cluster as a "giant molecule" and treat both the intramolecular vibrational modes and the intermolecular vdW modes simultaneously. The

intermolecular vdW potential field used in the analyses is expressed in an intermolecular coordinate system. In this coordinate system, the intermolecular force field is diagonal in the 3N dimensional space.

The cluster constituent intramolecular vibrational frequencies are considerably higher than those of the vdW modes. A reasonable approximation in this context then is to assume that the intramolecular modes are completely uncoupled from the low frequency vdW modes. Thus, the intramolecular modes are taken to be those of the cluster constituents. The constituent force fields are generated using the central force approximation[11] including out-of-plane motion terms. Since the vdW modes arise from the restriction of cluster constituent translations and rotations and the central force approximation adequately reproduces these degrees of freedom, the necessary uncoupling of the intramolecular modes and the intermolecular vdW modes is maintained along with providing adequate vdW mode calculational results. Other, more sophisticated force field approximations are tested in the calculations; the central force approximation is determined to be adequate for calculations of the vdW modes. The only restriction which applies is that the intramolecular field yields mode eigenvalues in the proper frequency regions.

Within the central force approximation, the force field contains only diagonal terms in the internuclear coordinate system. This diagonal force field provides a simple and convenient means of using approximate force constants for intramolecular motion in the calculations. The intramolecular force constants chosen are those pertaining to general functional group stretches and bends.[11]

The most convenient choice for a coordinate system as the working basis for matrix diagonalization is the Cartesian system. This

coordinate system is chosen since it is the system used in the present cluster configuration calculations, and more importantly, it is the coordinate system in which the $\underline{G}^{-1}$ matrix is diagonal and obvious.

In order to combine the intermolecular and intramolecular force fields algebraically, the force fields are transformed into the Cartesian coordinate system. The transformation yields two 3N dimensional $\underline{F}$ matrices. The intramolecular $\underline{F}$ matrix is designated as $\underline{F}_o$ and the intermolecular $\underline{F}$ matrix is designated as $\underline{F}'$. The $\underline{F}_o$ matrix consists of two diagonal blocks containing the coordinates of cluster constituent intramolecular motion. The $\underline{F}'$ matrix contains two off-diagonal blocks and diagonal entries corresponding to the "perturbations" yielding the vdW motion. Adding these two matrices results in the "giant molecule" $\underline{F}$ matrix of order 3N. This matrix is left-multiplied by the $\underline{G}$ matrix and numerically diagonalized with the eigenvalues and eigenvectors being determined in the usual fashion. Upon diagonalization, the eigenvalues and eigenvectors of intramolecular motion are identified along with those corresponding to cluster translation and rotation. These modes are discarded and the remaining modes are the eigenvalues and eigenvectors of the ground state vdW modes.

The intermolecular force constants used in the normal coordinate analysis are generated from the intermolecular vdW potential by making a harmonic oscillator approximation. Within this approximation, the force constant is simply the second derivative of the potential function,[9]

$$U(r_{ij}) = \sum_{i=1}^{n}\sum_{j=1}^{m}\left[\left\{\frac{A^{kl}}{r_{ij}^{12}} - \frac{C^{kl}}{r_{ij}^{6}}\right\}(1 - \delta_{HB}^{ij}) + \frac{332.0q_iq_j}{Dr_{ij}} + \left\{\frac{A'^{kl}}{r_{ij}^{12}} - \frac{C'^{kl}}{r_{ij}^{10}}\right\}\delta_{HB}^{ij}\right] = U(r_{ij})_{NB} + U(r_{ij})_{MC} + U(r_{ij})_{HB} \qquad 2.1$$

The potential function contains a general nonbonding potential (NB), a monopole charge potential (MC), and a general hydrogen bonding potential (HB) ns a general nonbonding potential (NB), a monopole charge potential (MC), and a general hydrogen bonding potential (HB) in a Lennard-Jones (6-12-1-10-12) form. The total intermolecular interaction is taken as a sum of pairwise atom-atom interactions over all the atoms of each cluster constituent. The r_{ij}'s are the atom-atom distances between atom i on constituent k and atom j on constituent l. The r_{ij}'s represent the coordinates in which the intermolecular force field is diagonal. The second derivative of Equation 2.1 with respect to r_{ij} gives the force constant of the atom-atom interaction as,

$$K_{ij}(r_{ij}) = \sum_{i=1}^{n} \sum_{j=1}^{m} \left[\left\{ \frac{12 \cdot 13 \cdot A^{kl}}{r_{ij}^{14}} - \frac{6 \cdot 7 \cdot C^{kl}}{r_{ij}^{8}} \right\} \times \right. \tag{2.2}$$

$$\left. (1 - \delta_{HB}^{ij}) + \frac{2 \cdot 332.0 q_i q_j}{D r_{ij}^{3}} + \left\{ \frac{12 \cdot 13 A'^{kl}}{r_{ij}^{14}} - \frac{10 \cdot 11 \cdot C'^{kl}}{r_{ij}^{12}} \right\} \delta_{HB}^{ij} \right]$$

in which the K_{ij}'s are elements of the $\underline{F}'$ matrix expressed in intermolecular coordinates. These terms are evaluated at the equilibrium configuration of the cluster assuming that the cluster constituents are frozen with regard to intramolecular motion. The potential term coefficients used in the configurational and intermolecular vibrational mode calculations (Equations 2.1 and 2.2) on the systems studies are derived from the theory and data set described by Scheraga et al.[9]

Three additional models are employed to study the benzene$(Ar)_1$ vdW cluster as a test case. In these models, the vdW cluster is assumed to be a "diatomic molecule" in the sense that the system is considered to be composed of two particles, the benzene molecule (solute) and the

argon atom (solvent). The vdW modes are assumed to arise from restric ted one-dimensional motion of the benzene molecule relative to the argon atom. Only the atom-molecule benzene$(Ar)_1$ cluster will be considered using these models since its vdW modes are easily characterized by simple translations along any of the three Cartesian axes. The vdW stretching mode is taken as motion restricted to the one-dimensional translation moving the cluster constituents apart in opposite directions. The vdW bending modes are considered to be motions restricted to one-dimensional translations which move the cluster constituents parallel to one another in opposite directions.

In the first model considered, one-dimensional potential curves are mapped out by translating the solvent atom relative to the solute molecule in one of the three Cartesian directions. The intermolecular vdW potential is assumed to be represented by a Taylor series expansion about the equilibrium intermolecular distance, R_0 in the form,

$$U(R) = U(R_0) + \left(\frac{dU}{dR}\right)_{R=R_0} R + \frac{1}{2}\left(\frac{d^2U}{dR^2}\right)_{R=R_0} R^2 + \frac{1}{6}\left(\frac{d^3U}{dR^3}\right)_{R=R_0} R^3 + \frac{1}{24}\left(\frac{d^4U}{dR^4}\right)_{R=R_0} R^4 + \ldots \qquad 2.3$$

The expansion coefficients are evaluated by a polynomial fit to the potential curves taking the displacement vector R as the independent variable and U(R) as the dependent variable. The second-order polynomial fit coefficient determines the effective harmonic force constant governing the frequency of bound state motion. The energy of this motion is given by[12]

$$\omega_e = \frac{1}{2\pi c}\left(\frac{k_{eff}}{\mu}\right)^{1/2} \qquad 2.4$$

with

$$k_{eff} = \left(\frac{d^2U}{dR^2}\right)_{R=R_0} = 2(\text{second-order coefficient})$$

$$\frac{1}{\mu} = \frac{1}{m_1} + \frac{1}{m_2}$$

m_1 = solute mass $\qquad$ m_2 = solvent mass

The third and fourth order polynomial fit coefficients represent an anharmonic correction term to the energy. From perturbation theory, the correction can be written to first order as[12]

$$\omega_e\chi_e = \frac{3h^2}{32\pi^4\omega_e^2\mu^2c^2}\left(\frac{5g^2h}{8\pi^2\omega_e^2\mu c} - j\right) \qquad 2.5$$

with

$$g = (\text{third-order coefficient}) = \frac{1}{6}\left(\frac{d^3U}{dR^3}\right)_{R=R_0}$$

$$j = (\text{fourth-order coefficient}) = \frac{1}{24}\left(\frac{d^4U}{dR^4}\right)_{R=R_0}$$

Higher order terms are neglected in the anharmonic corrections since $\omega_e >> \omega_e\chi_e >>$ other corrections. A polynomial least-squares fit to tenth order in R is determined to be sufficient to faithfully reproduce the one-dimensional potential curves generated via translation. In passing we note that the Taylor series expansion could also be evaluated directly by taking successive derivatives of Equation 2.1. This may be the method of choice if one is only interested in the lowest order terms in evaluating Equation 2.4 or 2.5 or if one is interested in a more "exact" reproduction of the potential curves in the vicinity of the dissociation limit.

The second model considered involves fitting the one-dimensional potential energy curves, derived in the same manner as previously discussed, to a Morse function of the form,[15]

$$U(R) = D_e(e^{-2\beta(R-R_o)} - 2e^{-\beta(R-R_o)}). \qquad 2.6$$

The energy levels and anharmonic corrections are evaluated using

$$\omega_e = \beta \left(\frac{D_e h}{2\pi^2 c\mu}\right)^{1/2} \qquad 2.7$$

$$\omega_e \chi_e = \frac{\beta^2 h}{8\pi^2 c\mu} \qquad 2.8$$

The last model used involves an energy level fit based upon the semi-classical JWKB method.[13] In this model, the energy levels are determined from the quantization of the action integral according to the Bohr-Sommerfeld restrictions. The governing equation is

$$I = (2\mu)^{-1/2} \oint [E - U_{eff}(R)]^{1/2} dR = h(v + 1/2) \qquad 2.9$$

Energy level determination is accomplished by numerical integration of (2.9) taking $U_{eff}(R)$ as the one-dimensional intermolecular vdW potential in a tenth order polynomial form. The path of integration is taken over one complete motion cycle with the boundary conditions established by the intermolecular potential at a specific energy E.

The three "diatomic molecule" models are similar to the linear oscillator model described by Leutwyler et al.[16] In all of the approximations, the atom-molecule systems are assumed to be composed of three uncoupled linear oscillators. The potential surface in these degrees of freedom can thereby be modeled by one-dimensional potential functions.

The models presented here differ from that present in ref. 16 in the respect that the linear oscillator model[16] treats the system as strongly anharmonic; the Taylor series expansion, and Morse fit models treat anharmonicity from the perturbational standpoint. In this respect, the JWKB method is probably the most similar to the linear oscillator model since both approximations fit the intermolecular mode energies using the physical boundary conditions established by the intermolecular potential.

Results.

A. Benzene$(Ar)_1$.

Figure 2.1 and Table 2.1 present the benzene$(Ar)_1$ vdW cluster $^1B_{2u} \leftarrow {}^1A_{1g}$ spectrum recorded in the region between 38561 cm^{-1} and 38710 cm^{-1} using 1-color TOFMS. The cluster 6_0^1 is "red shifted" by 21 cm^{-1} with respect to the benzene 6_0^1. The bathychromic shift is indicative of the greater binding energy in the cluster S_1 state relative to the cluster S_0 state. Three vibronic features are observed to the blue of the cluster 6_0^1. No features are observed in the symmetry "forbidden" benzene 0_0^0 region; therefore, the cluster must have at least a three-fold axis of symmetry.

Figure 2.2 and Table 2.2 contain the calculational results of the ground state configuration and vdW modes of benzene$(Ar)_1$. Configurational calculations yield a single geometry of minimum energy for the cluster possessing C_{6v} symmetry, Figure 2.2. In this geometry, the argon atom lies 3.44 Å above the benzene molecular plane along the z (six-fold) axis. The ground state cluster binding energy is calculated at 287 cm^{-1} which makes the excited state binding energy 308 cm^{-1}. The calculated intermolecular distance of 3.44 Å compares well with that of

Normal Coordinate Analysis	40.0	11.0

a) Energy presented is for a harmonic oscillator model. Values in parentheses are first order anharmonicity corrections calculated from "diatomic molecule" models. vdW mode representations as per Figure 2.2.

3.45 ± .2 Å obtained from rotational analysis,[15] adding independent proof to the adequacy of the calculations in predicting detailed information on cluster structure.

The eigenvalue energies from the normal coordinate analysis of benzene$(Ar)_1$ are 40 cm^{-1} and 11 cm^{-1} for the vdW stretch and vdW bends, respectively. The eigenvector normal modes, Figure 2.2, reveal that the vdW stretch entails purely perpendicular motion of the argon atom relative to the benzene molecular plane. Furthermore, the calculations reveal that the two-fold degenerate vdW bending mode involves some combination of motion parallel to the benzene molecular plane. Both of these eigenvector results are consistent with group theoretical arguments as expected.

The "diatomic molecule" model calculations yield three sets of vdW mode energies. The average mode frequencies are 40 cm^{-1} for the vdW stretch, $s_z(a_1)$ and 10 cm^{-1} for the vdW bends $b_{xy}(e_1)$. Figures 2.3 and 2.4 show the details of the one-dimensional potential curve mappings and the results of the model calculations. Note that the z-direction potential curve modeling the vdW stretch looks surprisingly similar in form to that of a typical diatomic molecule. All models yield both adequate potential curve fits and consistent vibrational energy level structures.

B. s-Tetrazine$(Ar)_1$.

Figure 2.5 presents the results of the ground state configuration and vdW mode analysis of s-tetrazine$(Ar)_1$. Only the normal coordinate analysis vibrational calculation is presented since this method yields the most informative results for our purposes and the consistency between the eigenvalue/eigenvector results and the "diatomic molecule" results has already been shown for the benzene$(Ar)_1$ case. Configurational calculations yield a single cluster geometry of minimum

Translation is along x(y) axis with z and y(x) coordinates at equilibrium intermolecular distance values. Translation is displayed relative to equilibrium intermolecular distance 3.44 Å. (6-12) potential energy mapping is represented by o; Taylor series expansion and energy levels are represented by ——; Morse fit potential energy curve is represented by ---. Vibrational mode constants as per Table 2.2.

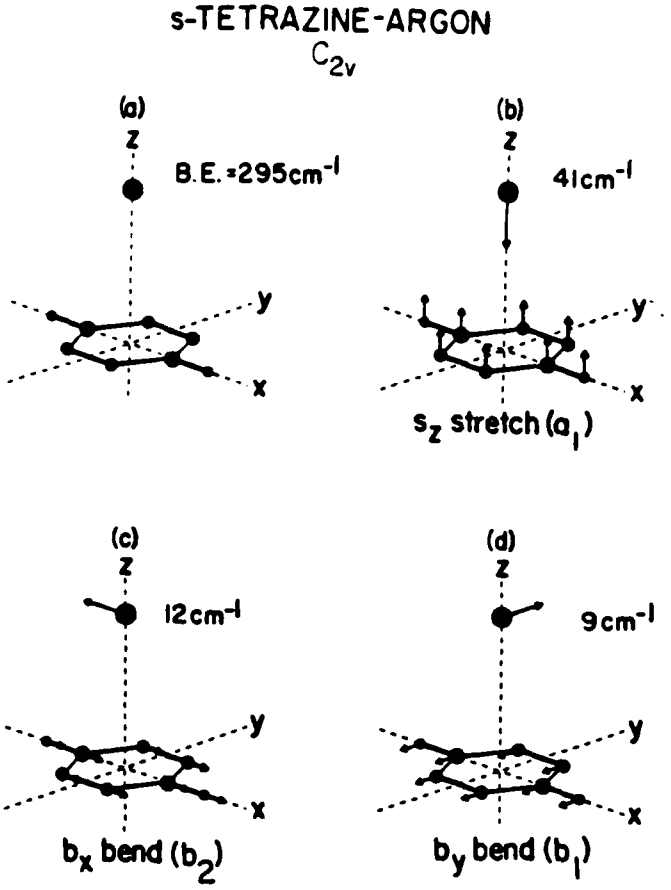

Figure 2.5

Calculated ground state minimum energy configuration (a) and eigenvalue/eigenvector vdW modes (b)-(d) for s-tetrazine$(Ar)_1$. Cluster symmetry is C_{2v} with an equilibrium intermolecular distance of 3.45 Å. Eigenvectors are normalized and displayed at 2x magnification (2 Å total displacement).

energy possessing C_{2v} symmetry, Figure 2.5. In this geometry, the argon atom lies 3.45 Å above the s-tetrazine molecular plane along the z (two-fold) axis. The calculated ground state cluster binding energy is 295 cm^{-1}. The calculated intermolecular distance of 3.45 Å compares extremely well with the intermolecular distance of 3.45 Å obtained from rotational analysis. The calculated binding energy of 295 cm^{-1} also lies within the experimental limits of $254 < D_0'' < 332$ cm^{-1}.[5] Again, the calculations and experiment are in exact agreement.

The normal coordinate analysis eigenvalues are 41.0 cm^{-1} for the vdW stretching mode $s_z(a_1)$, 9 cm^{-1} for the vdW bending mode $b_y(b_1)$, and 12 cm^{-1} for the vdW bending mode $b_x(b_2)$. The eigenvector normal modes, Figure 2.5 show that the vdW stretch is restricted to motion perpendicular to the s-tetrazine molecular plane while the vdW bends are restricted to motion parallel to the molecular plane. As in the benzene$(Ar)_1$ analysis, these results are consistent with group theoretical arguments.

C. Benzene$(CH_4)_1$.

The ground state configuration and vdW eigenvalues/eigenvectors for benzene$(CH_4)_1$ are shown in Figure 2.6. The results presented for the geometry and binding energy of benzene$(CH_4)_1$ are in good agreement with previous reports from this laboratory using an exponential-six and Lennard-Jones potential form.[2] In this geometry, Figure 2.6, the methane center-of-mass lies at 3.47 Å above the benzene molecular plane on the principle z (three-fold) axis. The cluster ground state binding energy is 540 cm^{-1}. The normal coordinate analysis reveals six vdW vibrations, two being two-fold degenerate. The ground state vibrational energies are 82 cm^{-1} for the vdW stretch $s_z(a_1)$,

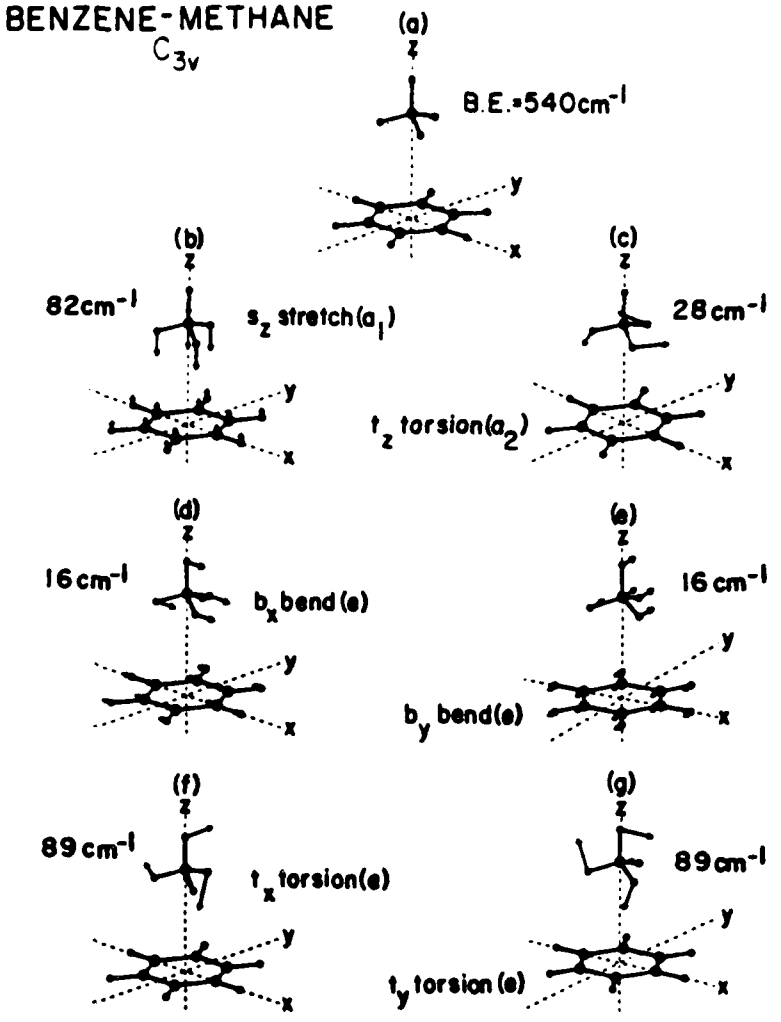

Figure 2.6

Calculated ground state minimum energy configuration (a) and eigenvalue/eigenvector vdW modes (b)-(g) for benzene$(CH_4)_1$. Cluster symmetry is C_{3v} with an equilibrium intermolecular distance of 3.47 Å. Eigenvectors are normalized and displayed at 2x magnification (2 Å total displacement).

16 cm^{-1} for the vdW bends $b_{xy}(e)$, and 28 cm^{-1} and 89 cm^{-1} for the vdW torsions $t_z(a_2)$ and $t_{xy}(e)$, respectively. The eigenvector normal modes, Figure 2.6, transform as the translational and rotational representations of the C_{3v} point group, as indicated. The vdW stretching mode transforms as the translation of the cluster constituents away from one another along the z (three-fold) axis. The vdW bending modes transform as some combination of cluster constituent translations in opposite directions perpendicular to the three-fold axis in the xy plane. One vdW torsion mode transforms as a rotation of the cluster constituents about the z (three-fold) axis in opposite directions. The remaining two vdW torsions transform as rotations about orthogonal axes perpendicular to the three-fold axis.

D. Benzene$(H_2O)_1$.

The calculated benzene$(H_2O)_1$ geometry used in the normal coordinate analysis is similar to that calculated previously.[3] Only one minimum energy configuration, which has a binding energy of 504 cm^{-1}, is found. As shown in Figure 2.7, the cluster geometry possesses C_s symmetry with the H_2O center-of-mass located 3.15 Å above the benzene molecular plane.

Six ground state vdW vibrations are calculated for the C_s cluster geometry. Their corresponding eigenvalues and eigenvectors are shown in Figure 2.7. The six vdW modes consist of a vdW stretch at 159 cm^{-1}, two vdW bends at 14 cm^{-1} and 18 cm^{-1}, and three vdW torsions at 40 cm^{-1}, 50 cm^{-1}, and 156 cm^{-1}. The eigenvector normal modes transform as the translational and rotational representations of the C_s point group: the vdW stretch transforms as a z translation; the vdW bends transform as x and y translations; and the vdW torsions transform as R_x, R_y, and R_z rotations.

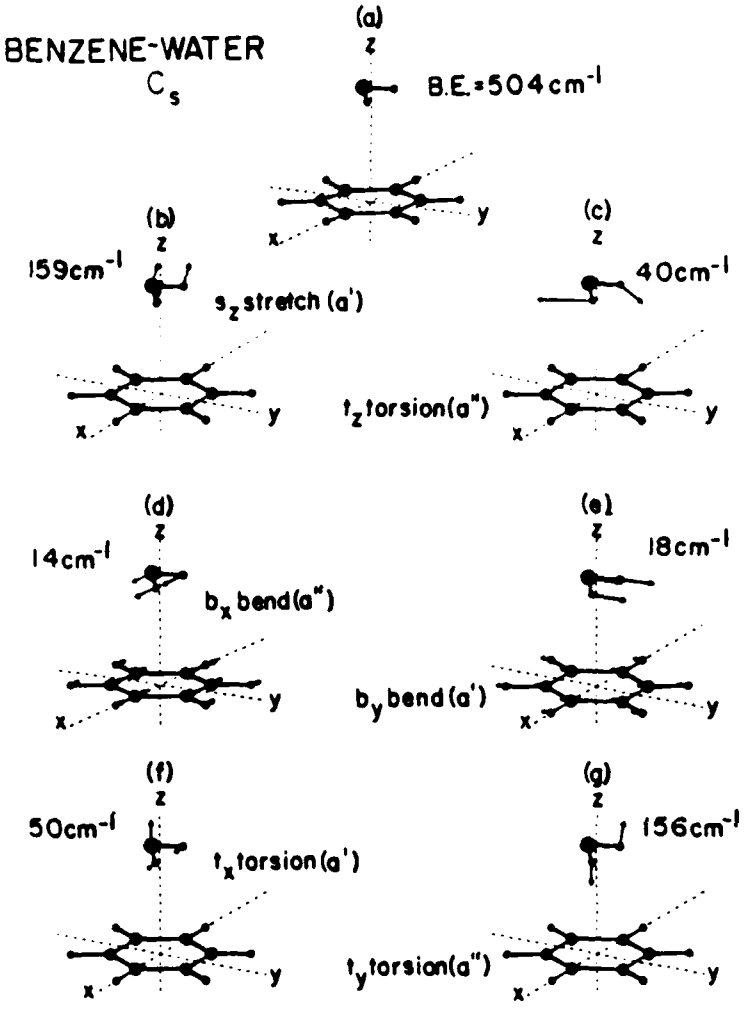

Figure 2.7

Calculated ground state minimum energy configuration (a) and eigenvalue/ eigenvector vdW modes (b)-(g) for benzene$(H_2O)_1$. Cluster symmetry is C_s with an equilibrium intermolecular distance of 3.15 Å. Eigenvectors are normalized and displayed at 2x magnification (2 Å total displacement).

E. Benzene$(NH_3)_1$.

Configurational calculations on the benzene$(NH_3)_1$ cluster reveal two minimum energy geometries similar to those obtained previously.[3] One cluster geometry possesses C_{3v} symmetry with a binding energy of 711 cm^{-1} while the other possesses C_s symmetry and a binding energy of 608 cm^{-1}. In the C_{3v} cluster, Figure 2.8, the NH_3 center-of-mass is located 3.23 Å above the benzene molecular plane along the z (three-fold) axis. In the C_s cluster, Figure 2.9, the NH_3 center-of-mass is located 3.29 Å above the benzene molecular plane.

Using the potential surfaces generated from these two configurations, six ground state vdW vibrations are calculated for each geometry. Their corresponding eigenvalues and eigenvectors are shown in Figures 2.8 and 2.9. The C_{3v} cluster ground state normal modes transform in the same manner as those of benzene$(CH_4)_1$. In the C_s cluster, the ground state normal modes transform similar to those of benzene$(H_2O)_1$.

Discussion.

To compare the calculated and experimentally observed vdW modes, we assume that the intermolecular potential surface of the cluster is identical in both S_0 and S_1 electronic states. This assumption is justifiable if one considers that cluster fluorescence excitation and dispersed emission spectra are similar for the vdW vibronic transitions.[4] Furthermore, the small spectral shifts of the chromophore and the weak intensity of the vdW modes signify only small changes in cluster binding energy. This is probably indicative of only slight variations of the potential surface between S_0 and S_1 electronic states.

Comparisons between calculation and experiment are made using group theoretical arguments based on the selection rules governing the

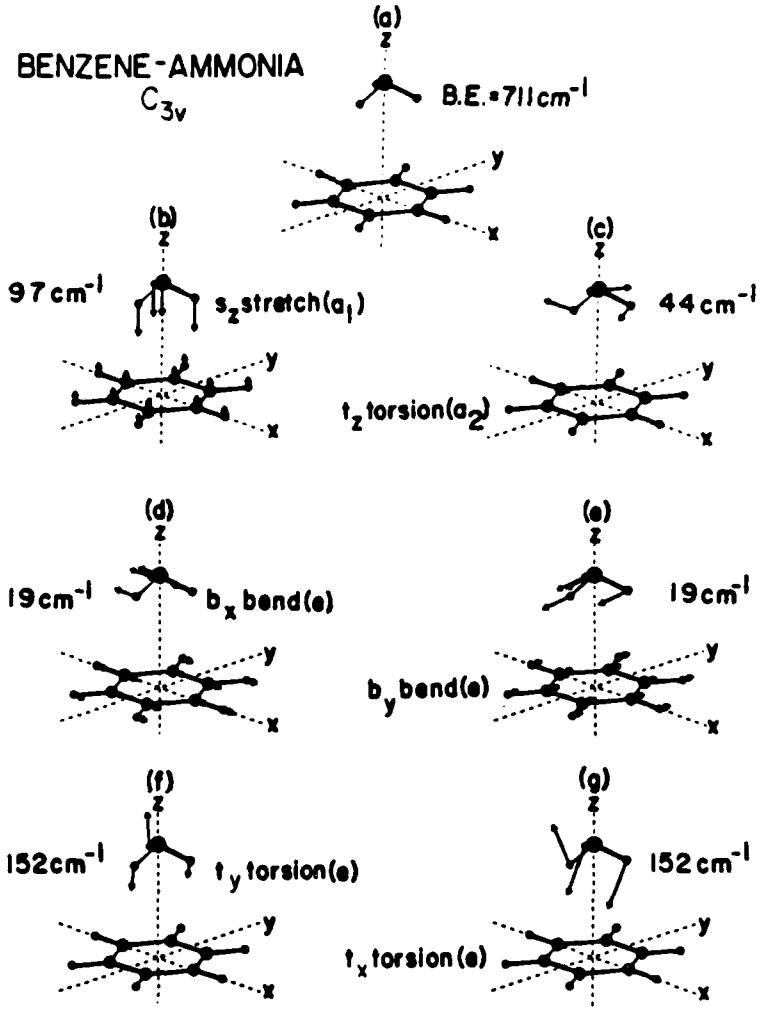

Figure 2.8

Calculated ground state minimum energy configuration (a) and eigenvalue/eigenvector vdW modes (b)-(g) for benzene$(NH_3)_1$. Cluster symmetry is C_{3v} with an equilibrium intermolecular distance of 3.23 Å. Eigenvectors are normalized and displayed at 2x magnification (2 Å total displacement).

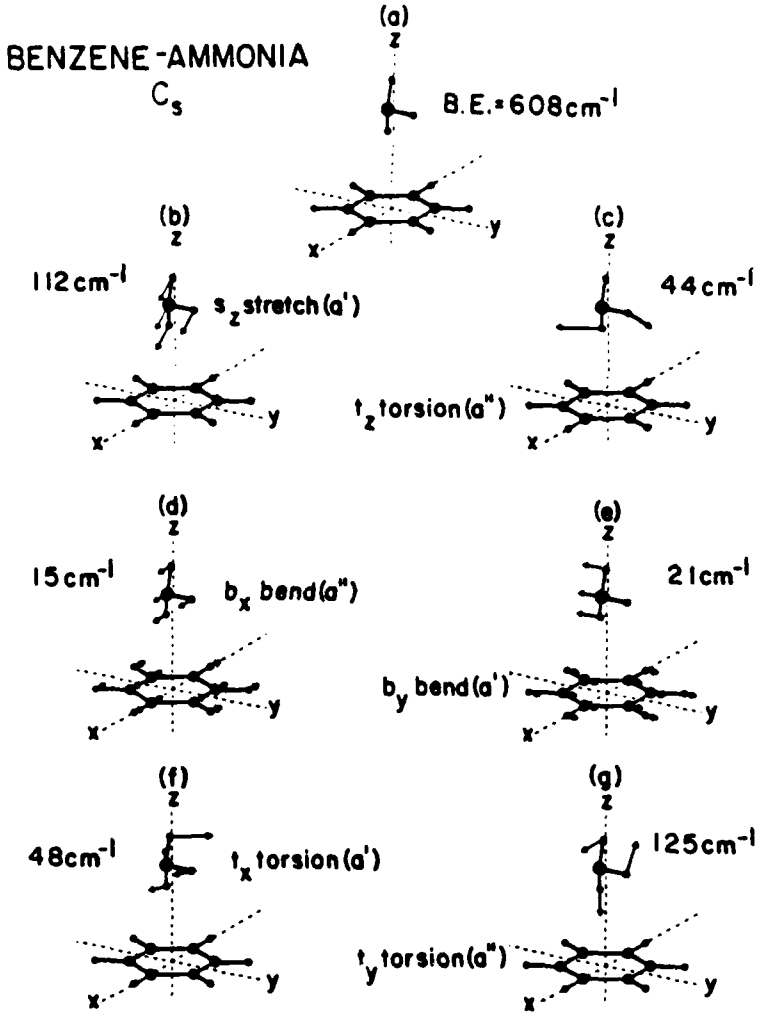

Figure 2.9

Calculated ground state minimum energy configuration (a) and eigenvalue/eigenvector vdW modes (b)-(g) for benzene$(NH_3)_1$. Cluster symmetry is C_s with an equilibrium intermolecular distance of 3.29 Å. Eigenvectors are normalized and displayed at 2x magnification (2 Å total displacement).

vibronic transitions. Specifically, transition moment matrix elements are qualitatively analyzed using the crude adiabatic approximation for which the vibrational mode dependence on the electronic wave function is explicit. In this case, a standard Herzberg-Teller (HT) expansion and adiabatic wave functions are used[14] with the electronic wave function vibrational mode dependence truncated at second order.

Using this expansion, two unique types of spectra can be generated. First, one could consider that the vdW modes do not participate in the vibronic coupling scheme (Case I) and that they merely enter into the expansion as an additional scalar product (overlap integral). This argument dictates that only totally symmetric Franck-Condon progressions and combination bands are spectroscopically observed. Furthermore, the intensities of these features are solely derived from the cluster chromophore vibronic mode with which they are in combination. Alternately, one could consider the vdW modes to be capable of vibronic coupling (Case II). In this case, they enter into the HT transition moment equation in the same manner as other vibronically active modes. The operator responsible for these transitions would be of the form

$$\left(\frac{\partial^2 U}{\partial Q_6 \partial q_{vdW}}\right)_{Q_6=Q^0_6,\, q_{vdW}=q^0_{vdW}} Q_6 q_{vdW} \qquad 2.10$$

in which Q_6 is the cluster ν_6 vibrational mode and q_{vdW} is a specific cluster vdW mode. This argument allows the possibility of observing nontotally symmetric vdW fundamentals with "borrowed" intensity due to interelectronic state mixing.

In the individual cluster discussions, the above two cases are considered in order to assign and understand the observed cluster vibronic spectra.

A. Benzene$(Ar)_1$.

Comparison of the calculated ground state vdW vibrations of benzene$(Ar)_1$ and the experimental $^1B_{2u} \leftarrow {}^1A_{1g}$ vibronic spectrum, Figure 2.1, Table 2.1, and Table 2.2, shows that vibronic assignments can be made based upon calculations for all models analyzed. Considering the transition moment matrix elements for the benzene$(Ar)_1$ $S_1 \leftarrow S_0$ transition under C_{6v} symmetry, one should expect to observe totally symmetric combination bands of the vdW stretch built upon the cluster 6_0^1. The selection rule for these combination bands is $\Delta v = 0, \pm 1, \pm 2, \ldots$ Also, one should expect to observe nontotally symmetric vdW bend combinations with the 6_0^1 with the selection rule being $\Delta v = 0, \pm 2, \pm 4 \ldots$ These selection rules hold for both Case I and Case II type spectra and imply that the vdW modes do not enter into the vibronic intensity borrowing mechanism.

The calculated vdW stretching mode at 40 cm^{-1} compares quite well with the experimental vibronic feature at 39.7 cm^{-1} to the blue of the benzene$(Ar)_1$ 6_0^1. Thus, this feature is assigned to the benzene$(Ar)_1$ vdW stretch/cluster 6_0^1 combination band 6_0^1 $s_z(a_1)_0^1$ based upon the $\Delta v = 0, \pm 1, \pm 2 \ldots$ selection rule.

For vdW bending modes, only odd overtones are expected to be observed as pointed out above. The experimentally observed features at 30.9 cm^{-1} and 61.8 cm^{-1} to the blue of the cluster 6_0^1 correspond to overtone features of the vdW bends; using the $\Delta v = 0, \pm 2, \pm 4 \ldots$ selection rule, the former feature is the first overtone of the vdW bends and the latter is the third. Considering the 30.9 cm^{-1} feature as the first overtone places the symmetry forbidden bend fundamental at about 15.5 cm^{-1}. This energy lies close to the calculated two-fold

degenerate ground state vdW bend at 11 cm^{-1}. Thus, these two spectral features are assigned to the benzene$(Ar)_1$ vdW bends first and third overtone/cluster 6_0^1 combination bands, $6_0^1\ b_{xy}(e_1)_0^2$ and $6_0^1\ b_{xy}(e_1)_0^4$.

Ramifications of Herzberg-Teller vibronic coupling in the benzene$(Ar)_1$ cluster are obvious. From the derived vibronic selection rules and experimental observation, the benzene$(Ar)_1$ cluster spectrum is best assigned based upon benzene Herzberg-Teller coupling (i.e., the 6_0^1 feature is allowed) with vdW totally symmetric modes and combinations forming short, weak Franck-Condon progressions built upon the intense benzene transition. In addition, the calculated and observed[15] C_{6v} cluster symmetry is verified by the vdW vibronic structure.

B. s-Tetrazine$(Ar)_1$.

The selection rules governing the s-tetrazine$(Ar)_1$ vdW vibronic transitions under C_{2v} symmetry arise from Case I Franck-Condon arguments. The totally symmetric vdW stretch should be observed to the blue of the cluster 0_0^0 following a $\Delta v = 0, \pm1, \pm2, \ldots$ selection rule. The vdW bends should only be observed in odd overtones ($\Delta v = 0, \pm2, \pm4 \ldots$) built on the allowed s-tetrazine 0_0^0 transition. As in the benzene$(Ar)_1$ cluster, no Case II distinction can be made for s-tetrazine$(Ar)_1$ and thus no vdW Herzberg-Teller vibronic coupling is expected. Unfortunately, a complete experimental spectrum showing the details of the s-tetrazine$(Ar)_1$ vdW modes is not, as yet, available. The only information in this regard is the identification of the vdW stretching mode at 44 cm^{-1} to the blue of the cluster 0_0^0 by Levy et al.[5] Other vdW features at 66 cm^{-1} and 108 cm^{-1} to the blue of the cluster 0_0^0 are observed, but they are neither assigned nor are their spectra published.

Figure 2.10 and Table 2.3 compare the calculated ground state vdW mode frequencies with those observed in the s-tetrazine$(Ar)_1$ $^1B_{3u} \leftarrow {}^1A_g$

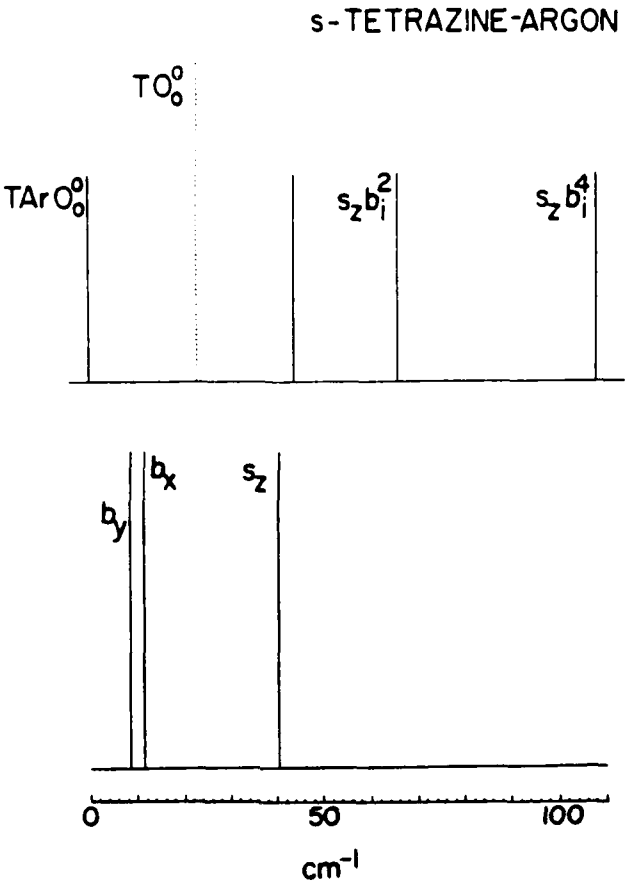

Figure 2.10

Schematic $^1B_{3u} \leftarrow {}^1A_g$ spectrum (from ref. 5) and calculated ground state vdW modes of s-tetrazine$(Ar)_1$. Energy scale is relative to s-tetrazine$(Ar)_1$ 0_0^0 transition (18104.9 cm^{-1}). Relative feature intensities are not shown. Feature positions and assignments as per Table 2.3 and Figure 2.5. vdW bends are represented by b_1 in schematic spectrum (see text for explanation).

vdW vibronic spectrum. The experimentally assigned vdW stretch at 44 cm^{-1} to the blue of the cluster 0_0^0 corresponds to the 41 cm^{-1} calculated ground state stretch. This motion, like that in the benzene$(Ar)_1$ cluster, involves perpendicular motion of the argon atom relative to the s-tetrazine molecular plane. Based upon ground state calculations, the feature 66 cm^{-1} to the blue of the cluster 0_0^0 probably corresponds to a vdW stretch/vdW bend overtone combination band, $s_z(a_1)_0^1\ b_x(b_2)_0^2$ or $s(a_1)_0^1\ b_y(b_1)_0^2$; the feature at 108 cm^{-1} probably corresponds to the next allowed bend overtone/stretch combination band $s(a_1)_0^1\ b_x(b_2)_0^4$ or $s(a_1)_0^1\ b_y(b_1)_0^4$. No speculation with regard to which band is responsible for the features observed will be made since no spectra of sufficient sensitivity are available for analysis.

C. Benzene$(CH_4)_1$.

In a previous analysis of the benzene$(CH_4)_1$ cluster,[2] three major vdW vibronic features were reported in the cluster 6_0^1 region: these features were assigned to a bend fundamental (27.3 cm^{-1}), a stretch fundamental (32.3 cm^{-1}), and a stretch overtone (51.4 cm^{-1}). The assignments were made based upon the assumptions described in the Introduction.

Considering the HT transition moment matrix elements and assuming a Case I type spectrum, the selection rules for the benzene$(CH_4)_1$ vdW vibronic transitions are $\Delta v = 0, \pm1, \pm2, \ldots$ for the vdW stretch and $\Delta v = 0, \pm2, \pm4, \ldots$ for the vdW bends and torsions when in combination with the cluster 6_0^1.

The selection rules involved in Case II can be viewed in two ways. The selection rules can be derived using the calculated cluster symmetry of C_{3v}, or they can be derived by considering the cluster

symmetry as C_{6v}. The latter situation arises since the methane center-of-mass is calculated at 3.47 Å above the benzene molecular plane. At this distance, the methane could be viewed as a sphere above the benzene molecular plane and, hence, the use of the C_{6v} point group to represent the vdW mode symmetries could be warranted.

In C_{3v} symmetry Case II, the selection rules for vdW mode combinations with the cluster 6_0^1 are $\Delta v = 0, \pm 1, \pm 2, \ldots$ for all six vdW modes. If C_{3v} is the correct cluster physical symmetry and HT vdW coupling exists, all modes can be observed in the cluster 6_0^1 region. In C_{6v} symmetry, Case II, the selection rules for the vdW mode combinations with the cluster 6_0^1 are $\Delta v = 0, \pm 1, \pm 2, \ldots$ for the vdW stretch $s_z(a_1)$ and torsion $t_z(a_2)$ and $\Delta v = 0, \pm 2, \pm 4, \ldots$ for the two-fold degenerate vdW bends $b_{xy}(e_1)$ and torsions $t_{xy}(e_1)$. In this approximate high symmetry, only the cluster 6^1 and vdW mode t_z are capable of vibronic coupling for the 6_0^1 transition.

Comparison of the experimental 6_0^1 vibronic spectrum of benzene$(CH_4)_1$ and the calculated ground state vdW vibrations is shown in Figure 2.11 and Table 2.4. The observed feature at 27.3 cm^{-1} to the blue of the cluster 6_0^1 corresponds to the t_z torsion calculated at 28 cm^{-1}. Thus, this feature and its observed overtones at 51.4 cm^{-1} and 73.5 cm^{-1} are reassigned to 6_0^1 vdW torsion combination bands $6_0^1\ t_z(a_2)_0^1$, $6_0^1\ t_z(a_2)_0^2$, and $6_0^1\ t_z(a_2)_0^3$, using the C_{3v} Case II or C_{6v} Case II $\Delta v = 0, \pm 1, \pm 2, \ldots$ selection rule. The $\Delta v = 0, \pm 1, \pm 2, \ldots$ selection rule suggests that for the benzene$(CH_4)_1$ system vdW mode Herzberg-Teller vibronic coupling is an important component of the overall intensity mechanism. In the present case, the occurrence of the nontotally symmetric t_z torsion progression implies that the vdW modes are

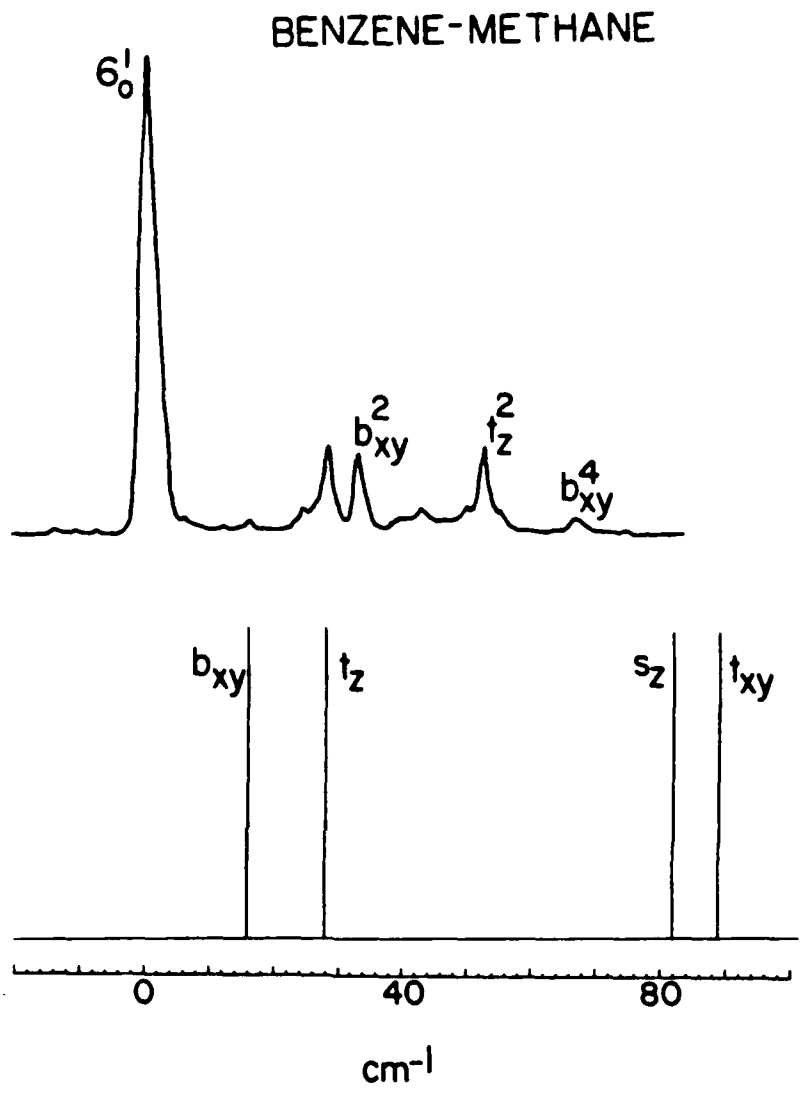

Figure 2.11

Mass selective $S_1 \leftarrow S_0$ spectrum (ref. 2) and calculated ground state vdW modes of benzene$(CH_4)_1$. Energy scale is relative to benzene$(CH_4)_1$ 6_0^1 transition (38567.6 cm^{-1}). Feature positions and assignments as per Table 2.4 and Figure 2.6.

b) vdW mode representations as per Figure 2.6.

vibronically active and that assuming them to be nonparticipants in the coupling mechanism oversimplifies the physics necessary to explain the cluster's spectroscopy.

The intense feature at 32.3 cm^{-1} to the blue of the cluster 6_0^1 corresponds to the first overtone of the two-fold degenerate vdW bending mode, $6_0^1\ b_{xy}(e)_0^2$, calculated at 16 cm^{-1}. This identification is based upon the observation of a feature at 64.6 cm^{-1} which corresponds to the third overtone of the bends. Furthermore, weak intensity features are observed at about 16.1 cm^{-1} and 48.4 cm^{-1} which could correspond to the vdW bend fundamentals and second overtones. The observation of these features adds proof to the arguments suggesting that the vdW modes are, at least, minor participants in the Herzberg-Teller vibronic coupling scheme. The cluster symmetry and, hence, spectroscopy are thereby also best described using the calculated C_{3v} point group in conjunction with Herzberg-Teller coupling rather than the approximate C_{6v} point group. Based upon this, the features at 32.3 cm^{-1} and 64.6 cm^{-1} are reassigned to vdW bend overtone combinations with the cluster 6_0^1; $6_0^1\ b_{xy}(e)_0^2$ and $6_0^1\ b_{xy}(e)_0^4$ using the C_{3v} selection rule $\Delta v = 0, \pm 1, \pm 2, \ldots$ The features are assigned in Table 2.4 and Figure 2.11. The weak features at 16.1 cm^{-1} and 48.4 cm^{-1} are assigned to $6_0^1\ b_{xy}(e)_0^1$ and $6_0^1\ b_{xy}(e)_0^3$. Based upon the relative intensities displayed in the spectrum, vdW vibronic coupling is an important factor in the intensity of this progression involving the e symmetry bending modes.

Neither the vdW stretch $s_z(a_1)$ nor the two-fold degenerate torsions $t_{xy}(e)$ are observed in the 6_0^1 spectrum. This could be due to poor Franck-Condon factors for these vibronic transitions since they are both calculated to be at relatively high energies (ca. 82 cm^{-1} and

89 cm^{-1}, respectively). Moreover, these modes could be participating in VP since the total energy $6_0^1\ s_z(a_1)_0^1$ or $6_0^1\ t_{xy}(e)_0^1$ is close to that of, if not above, the cluster's S_1 binding energy. Both the vdW stretch and t_{xy} torsions involve motion perpendicular to the benzene molecular plane: this motion could couple well to the VP process.

D. Benzene$(H_2O)_1$.

The $S_1 \leftarrow S_0$ vibronic spectrum of benzene$(H_2O)_1$ previously observed in this laboratory[3] possesses two unique spectral regions located around the cluster 0_0^0 and 6_0^1 containing vdW vibronic features. No vdW vibronic assignments were made in either region and no correlation between the regions was suggested.

Examination of the HT transition moment matrix elements using C_s symmetry and Case I considerations leads to the selection rules $\Delta v = 0, \pm1, \pm2, \ldots$ for the vdW s_z stretch, b_y bend, and t_x torsion and $\Delta v = 0, \pm2, \pm4, \ldots$ for the b_x bend, t_y and t_z torsions. Under Case II arguments, the selection rule is $\Delta v = 0, \pm1, \pm2, \ldots$ for all six vdW modes: all modes are capable of vibronic coupling.

Vibronic spectra of benzene$(H_2O)_1$ in both cluster 0_0^0 and 6_0^1 regions are reproduced in Figure 2.12 along with the calculated ground state vdW mode energies. The observed feature at 5.2 cm^{-1} (4.8 cm^{-1}) to the blue of the cluster 0_0^0 (6_0^1) transition corresponds to the vdW b_x bend fundamental calculated at 14 cm^{-1}. The observed feature at 16.2 cm^{-1} (15.8 cm^{-1}) to the blue of the cluster 0_0^0 (6_0^1) transition corresponds to the calculated totally symmetric vdW b_y bend at 18 cm^{-1}. Additionally, the observed features at 34.6 cm^{-1} (34.6 cm^{-1}) and 49 cm^{-1} (48.4 cm^{-1}) to the blue of the cluster 0_0^0 (6_0^1) transition are associated with the $t_z(a'')$ and $t_x(a')$ torsion fundamentals calculated at 40 cm^{-1}

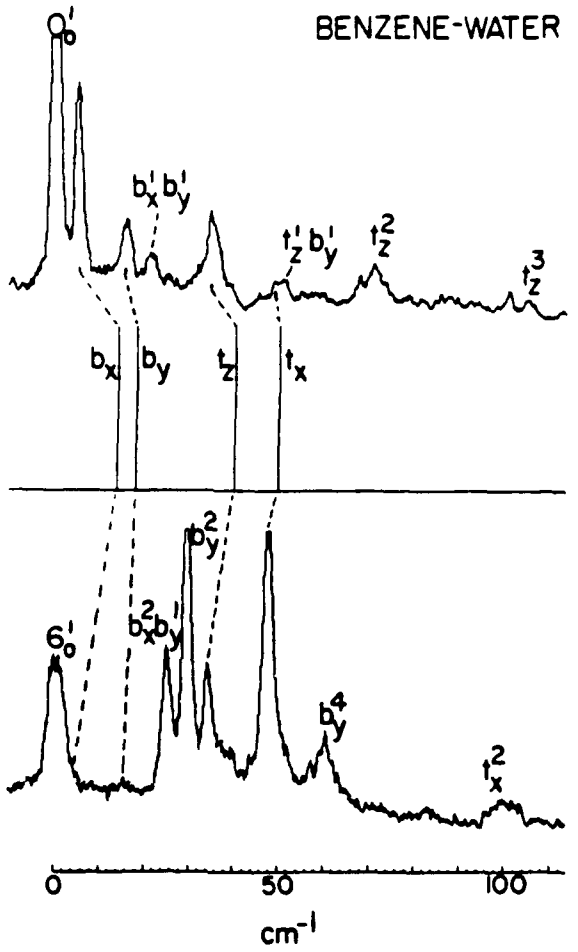

Figure 2.12

Mass selective $S_1 \leftarrow S_0$ spectra (ref. 3) and calculated ground state vdW modes of benzene$(H_2O)_1$. Energy scale is relative to benzene$(H_2O)_1$ 0_0^0 and 6_0^1 transitions (38168.6 cm^{-1} and 38655.4 cm^{-1}, respectively). Feature positions and assignments as per Table 2.5 and Figure 2.7. s_z and t_y vdW modes are not shown.

and 50 cm^{-1}, respectively. The occurrence of the nontotally symmetric fundamentals implies that the $\Delta v = 0, \pm 2, \pm 4, \ldots$ selection rule for Case I in which the vdW modes are not vibronically coupled is violated. The violation suggests that the vdW modes participate in the vibronic coupling scheme and that the $\Delta v = 0, \pm 1, \pm 2, \ldots$ selection rule should apply to all six vdW modes (Case II). Based upon this, the spectra are best assigned, Table 2.5 and Figure 2.12, using both nontotally and totally symmetric vdW progressions.

Assigning the benzene$(H_2O)_1$ spectra using the C_s point group representations corroborates the calculated cluster geometry. Treating the cluster in approximate high symmetries, such as C_{2v}, leads to selection rules which are clearly violated when applied to spectral observation and assignment. Specifically, the bend and torsion fundamentals are forbidden under these higher symmetry approximations. Furthermore, the spectral assignments using C_s symmetry arguments suggest that the water constituent is likely located above the benzene molecular plane.

Neither the vdW s_z stretch nor the t_y torsion are observed in either spectral region. This as in the benzene$(CH_4)_1$ case, probably results from poor Franck-Condon factors for these particular modes; they are both calculated to be at relatively high energies (ca. 159 cm^{-1} and 156 cm^{-1}, respectively). Moreover, in the 6_0^1 region, these modes could be participating in VP since the total energy of the system at these levels (486.8 + 159 cm^{-1} for the stretch; 486.8 + 156 cm^{-1} for t_y) is close to, if not above, the cluster binding energy (ca. = 500 cm^{-1}). The decrease in the hypsochromic shift and the shift of intensity maximum in the vdW manifold in going from the cluster 0_0^0 to the 6_0^1 may also be indicative of the VP process.

E. Benzene$(NH_3)_1$.

Benzene$(NH_3)_1$ clusters recently observed in this laboratory[3] yield spectra in both the cluster 0_0^0 and 6_0^1 regions. Two cluster geometries are calculated for the system, one possessing C_s symmetry and the other possessing C_{3v} symmetry. From symmetry arguments the C_s symmetry cluster is the only contributor to the 0_0^0 spectrum while both cluster geometries contribute to the 6_0^1 spectrum. Neither of these spectra were analyzed nor assigned in the initial observation since they are so complicated. They were merely presented as an indication of the notion that cluster vibronic spectra can sometimes be very extensive and congested.

The benzene$(NH_3)_1$ C_s symmetry cluster follows the same vdW vibronic selection rules as derived for the benzene$(H_2O)_1$ cluster. In this symmetry, the selection rules for Case I are $\Delta v = 0, \pm1, \pm2, \ldots$ for the vdW stretch, b_y bend, and t_x torsion and $\Delta v = 0, \pm2, \pm4, \ldots$ for the b_x bend, t_y and t_z torsions. In Case II the selection rule is $\Delta v = 0, \pm1, \pm2, \ldots$ for all six vdW modes. Furthermore, the calculated cluster geometries are qualitatively similar. Hence, their 0_0^0 spectra should be qualitatively similar: this is borne out in both experimental results and vibrational mode calculations.

The benzene$(NH_3)_1$ C_{3v} symmetry cluster follows the same vibronic selection rules as presented for benzene$(CH_4)_1$. Here the selection rules are either $\Delta v = 0, \pm1, \pm2, \ldots$ for the vdW stretch and $\Delta v = 0 \pm2, \pm4, \ldots$ for the vdW bends and torsions (Case I) or $\Delta v = 0, \pm1, \pm2, \ldots$ for all six vdW modes (Case II).

The calculated ground state vibrational energies and the observed cluster 0_0^0 and 6_0^1 vibronic spectra are compared in Figure 2.13. Due to

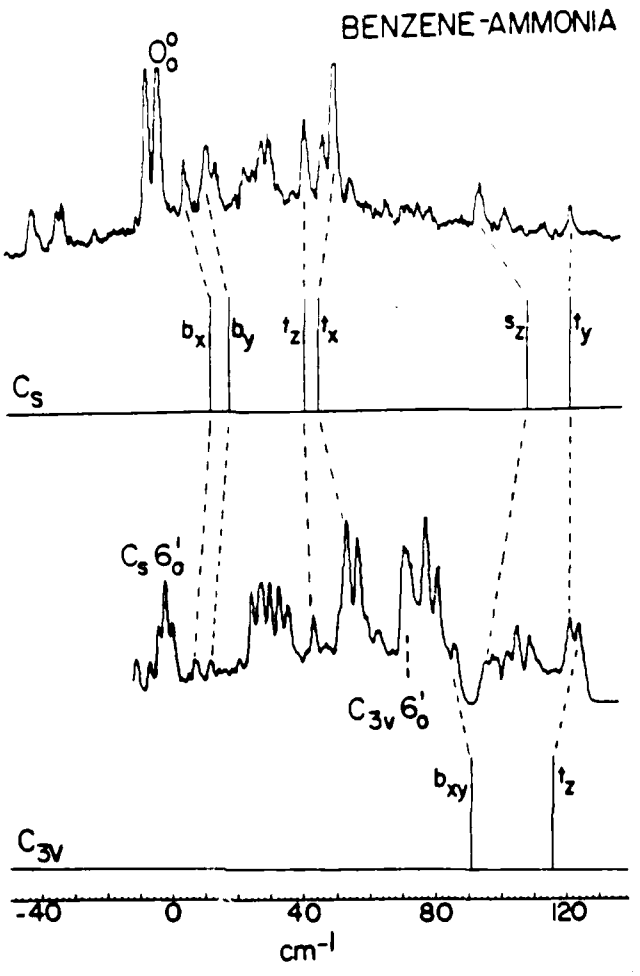

Figure 2.13

Mass selective $S_1 \leftarrow S_0$ spectra (ref. 3) and calculated ground state vdW modes of benzene$(NH_3)_1$. Energy scale is relative to benzene$(NH_3)_1$ 0_0^0 and 6_0^1 transitions for C_s cluster (38021.1 cm^{-1} and 38514.7 cm^{-1}, respectively). Feature positions and assignments as per Table 2.6 and Figure 2.8 and 2.9. C_{3v} cluster s_z and t_{xy} modes are not shown.

the complex nature of the spectra which possibly results from hot bands, only tentative assignments of the vdW mode progressions are made. The tentative assignments are based upon both vibrational mode calculations and upon inference from the benzene$(H_2O)_1$ and benzene$(CH_4)_1$ cluster spectra.

In the 0_0^0 spectrum, the most intense low energy feature is assigned to the origin of the cluster's $S_1 \leftarrow S_0$ transition. The smaller intensity features to the red of this feature are thus hot bands which yield the sequence structure in the 0_0^0 region. The observed feature at 8.8 cm^{-1} to the blue of the cluster 0_0^0 corresponds to the nontotally symmetric vdW b_x bend fundamental calculated at 15 cm^{-1}. Additionally, the observed features at 15.0 cm^{-1}, 45.1 cm^{-1}, 54.2 cm^{-1}, 99.6 cm^{-1}, and 127.7 cm^{-1} correspond to the calculated b_y bend (21 cm^{-1}), t_z torsion (44 cm^{-1}), t_x torsion (48 cm^{-1}), stretch (112 cm^{-1}), and t_y torsion (125 cm^{-1}). The occurrence of the nontotally symmetric fundamentals suggests that the vdW modes participate in vibronic coupling (Case II) and that the $\Delta v = 0, \pm 1, \pm 2, \ldots$ selection rule should apply to all six vdW modes. Using this selection rule, the spectrum is best assigned, Table 2.6, using both nontotally and totally symmetric vdW progressions.

In the 6_0^1 spectrum, the most intense low energy feature is assigned to the cluster 6_0^1 vibronic origin. This assignment bears a resemblance to the benzene$(H_2O)_1$ 6_0^1 spectrum in the respect that the 6_0^1 features for both clusters are red shifted relative to that observed at the $S_1 \leftarrow S_0$ origins (ca. 25 cm^{-1} for benzene$(NH_3)_1$ and 35 cm^{-1} for benzene$(H_2O)_1$.

Table 2.6 presents the C_s symmetry geometry assignments in the 6_0^1 region. The assignments are made using the vdW fundamentals identified

c) C_{3v} cluster 6_o^1 contributions tabulated relative to C_s cluster 6_o^1 origin as in Figure 2.13.

in the 0_0^0 spectrum and $\Delta v = 0, \pm 1, \pm 2, \ldots$ selection rule for all six vdW modes (Case II).

The contribution of the C_{3v} symmetry benzene$(NH_3)_1$ cluster to the 6_0^1 spectrum is observed starting with the feature at 72.9 cm^{-1} to the blue of the C_s cluster 6_0^1. Assignment of this feature to the C_{3v} cluster 6_0^1 is based upon the observation that no intense features are seen in either the benzene$(NH_3)_1$ 0_0^0 or the benzene$(H_2O)_1$ 6_0^1 spectra at this energy. The observed feature at 15 cm^{-1} to the blue of the C_{3v} cluster 6_0^1 corresponds to the two-fold degenerate vdW b_{xy} bends at 19 cm^{-1}. The observed feature at 53 cm^{-1} to the blue of the C_{3v} cluster 6_0^1 is associated with the calculated t_z torsion at 44 cm^{-1}. As in the benzene$(CH_4)_1$ case, the observation of the b_{xy} and t_z fundamentals implies that the vdW modes participate in the vibronic coupling mechanism (Case II) and that the $\Delta v = 0, \pm 1, \pm 2, \ldots$ vibronic selection rule applies for all vdW modes. Based upon this, the best assignments for the C_{3v} cluster vdW vibronics are tabulated in Table 2.6.

F. Morse $\frac{6}{R_0}$ Model.

Calculations of the ground state vdW modes of benzene$(Ar)_1$ are also conducted using a model described by Jortner et al.[1,6,7] This model contains a main feature which, at first glance, appears to make it generally applicable in predicting vdW stretching mode frequencies from calculated cluster binding energies and equilibrium intermolecular distances. However, the model turns out to be incorrect in this application. The model employs a simple relationship between the cluster equilibrium intermolecular distance R_0 and the Morse potential parameter β. The relation is derived by equating the second derivative of Equation 2.6 with the second derivative of a single term (6-12)

potential function. This derivation yields the relation $\beta = \frac{6}{R_o}$ which can be used to predict the vdW stretching mode frequency by diatomic Morse fit methods.

Substituting $\beta = \frac{6}{R_o}$ and the calculated ground state cluster binding energy into Equation 2.7 yields a vdW stretching mode energy of 47 cm^{-1} for benzene$(Ar)_1$ employing Scheraga's potential parameters. Even though the calculated vibrational energy is qualitatively correct, Figures 2.14 and 2.3 show that the $\beta = \frac{6}{R_o}$ relation results in an inadequate reproduction of the potential curve, especially in the critical region near the equilibrium intermolecular distance. At R_o, the $\beta = \frac{6}{R_o}$ fit overestimates the curvature of the potential by about 33% with respect to the curvature calculated from the one-dimensional potential energy mapping (1746 $cm^{-1}/Å^2$ versus 1312 $cm^{-1}/Å^2$) and, therefore, overestimates the stretching mode energy. Additional calculations using the potential data described in ref. 1 and the above approximate model also result in an inadequate potential curve reproduction, Figure 2.15. The potential curvature at R_o using the $\beta = \frac{6}{R_o}$ fit is overestimated by about 37% with respect to the corresponding curvature calculated via potential energy mapping (2322 $cm^{-1}/Å^2$ versus 1695 $cm^{-1}/Å^2$). In this case, the vdW stretching mode is calculated at 55 cm^{-1}.

The failure of the model under both data sets suggests that the model itself is inadequate in this application. The model fails in this application since the $\beta = \frac{6}{R_o}$ relation holds exactly only in systems in which the molecule-atom Lennard Jones parameters have been determined directly. Applying this approximate model to a case in which the potential function is represented by pairwise atom-atom potentials does not take into account the differing contributions of each interaction to the

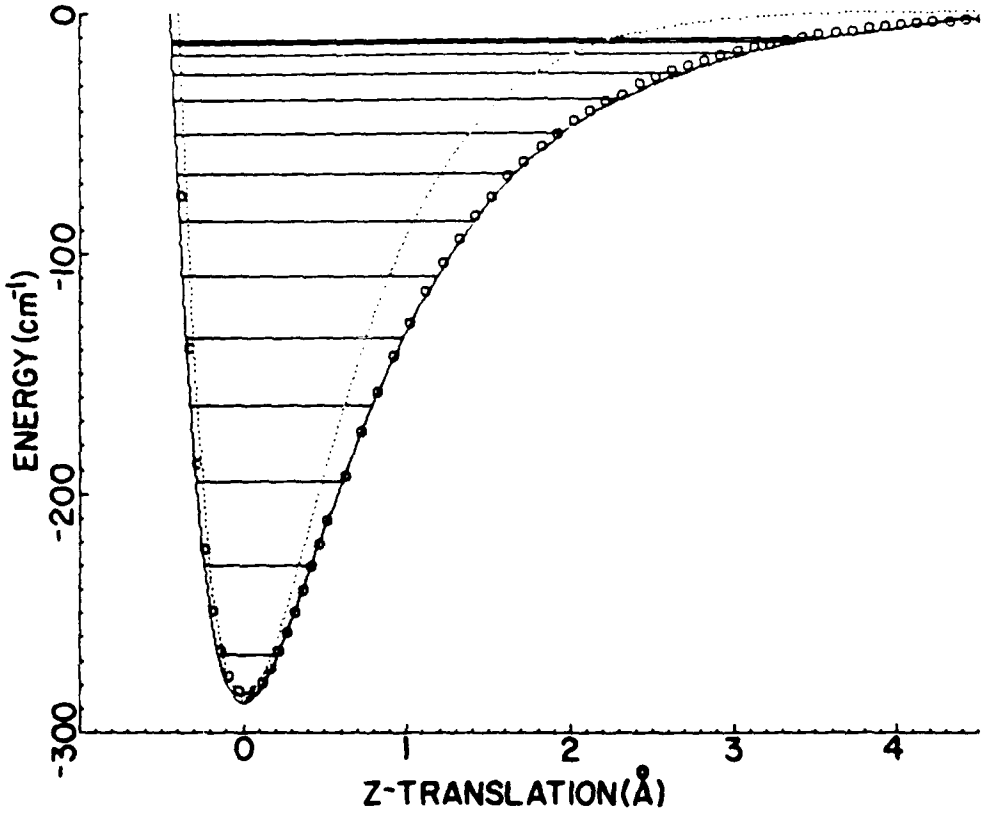

Figure 2.14

z-direction (vdW stretch) potential energy mapping of benzene$(Ar)_1$ and $\beta = \frac{6}{R_0}$ Morse fit. Translation is relative to equilibrium intermolecular distance, 3.44 Å. (6-12) potential energy mapping using data set from ref. 9 is represented by o; Taylor series expansion and energy levels are represented by ——; $\beta = \frac{6}{R_0}$ Morse fit potential energy curve is represent by ---. Taylor series vibrational mode constant as per Table 2.2. $\beta = \frac{6}{R_0}$ Morse fit vibrational constants are $\omega_e = 47.22\ cm^{-1}$, $\omega_e\chi_e = 1.94\ cm^{-1}$.

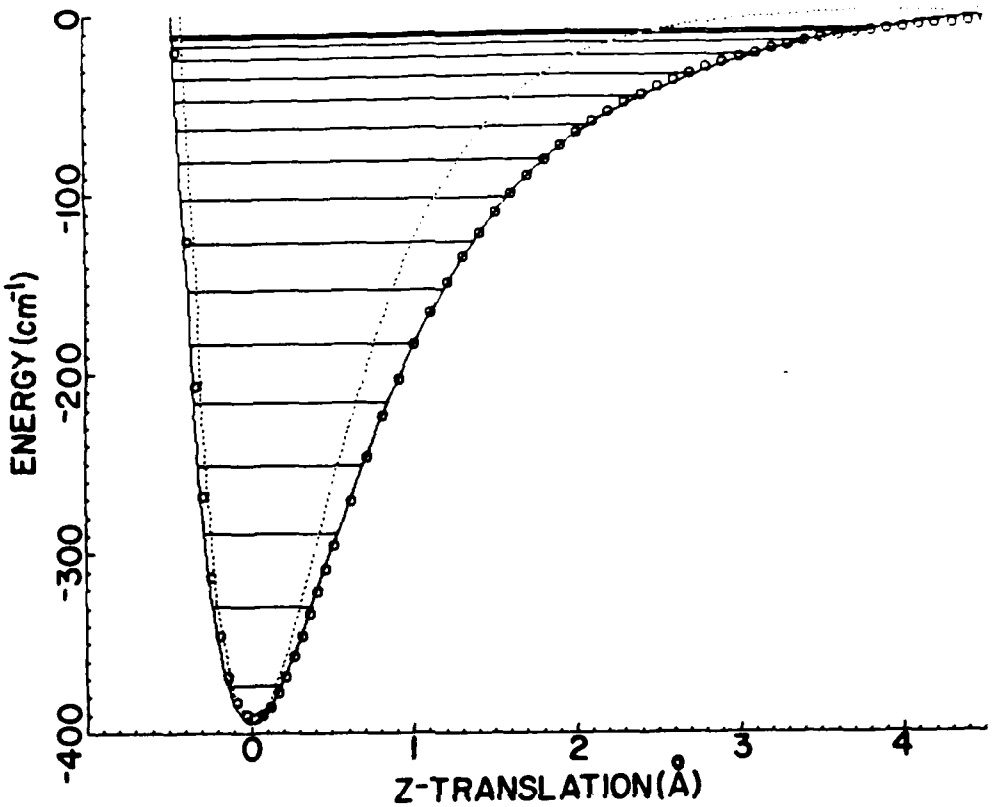

Figure 2.15

z-direction (vdW stretch) potential energy mapping of benzene$(Ar)_1$ and $\beta = \frac{6}{R_o}$ Morse fit. Translation is relative to equilibrium intermolecular distance, 3.5 Å. (6-12) potential energy mapping using data set from ref. 1 is represented by o; Taylor series expansion and energy levels are represented by —— with ω_e = 46.68 cm^{-1} and $\omega_e\chi_e$ = 1.81 cm^{-1}; $\beta = \frac{6}{R_o}$ Morse fit potential energy curve is represented by ---. $\beta = \frac{6}{R_o}$ Morse fit vibrational mode constants are ω_e = 54.84 cm^{-1} and $\omega_e\chi_e$ = 1.90 cm^{-1}

potential energy and the equilibrium intermolecular distance. In this more complicated situation, no analytic relationship between β and R_0 exists.

Comparing the vdW stretching mode energies calculated using Jortner's and Scheraga's data sets suggests that a significant difference exists between the two data sets. Benzene$(Ar)_1$ configurational calculations using Jortner's data set yield a single cluster geometry of C_{6v} symmetry with the argon atom located 3.5 Å above the benzene molecular plane. In this case, the ground state cluster binding energy is 395 cm^{-1}. This binding energy is 108 cm^{-1} greater than that calculated using Scheraga's data set. The binding energy of 287 cm^{-1} calculated using Scheraga's data set is probably more accurate since the benzene$(Ar)_1$ ground state binding energy should be very similar to that calculated for s-tetrazine$(Ar)_1$. In the latter case, the calculated ground state binding energy of 295 cm^{-1} compares well with that observed experimentally, $254 < D_0'' < 332$ cm^{-1}.[5] Furthermore, generating Lennard-Jones parameters using the data set of ref. 1 yields a binding energy of 359 cm^{-1} for s-tetrazine$(Ar)_1$ which is clearly not as accurate as the binding energy reported in this work. The difficulty is due to the consolidation of atom-atom parameters from different data sets. In this respect, great caution must be taken when consolidating parameters since each parameter set is, in general, only self-consistent and may have no meaning when combined with parameters from other sets.

Conclusions

TOFMS studies have been employed to determine the general geometry and symmetry of vdW clusters in the gas phase. Through computer modeling, a correlation between the details of the cluster geometry and

spectral features has been demonstrated. Specifically, the parametric calculations yield useful information regarding cluster geometry, binding energy, and the vdW vibrations. These calculated results are consistent with experiment and serve as predictive and analytic tools which can be used to elucidate and understand the details of vdW cluster energetics.

Of the several models considered in studying the intermolecular vdW modes, simple diatomic approximations yield adequate results when applied to atom-molecule clusters. On the other hand, for molecule-molecule clusters a normal coordinate analysis is essential. The normal coordinate analysis is especially useful for analyzing systems which have little or no symmetry since no a priori knowledge of vdW mode nature is necessary to generate potential energy surface mappings.

Reassignments of and assignments to cluster vdW modes have been made based upon the knowledge gained from calculation. From comparison of calculation and experiment, several conclusions result. First, the actual excited state normal mode vdW frequencies are well fit by the calculated ground state cluster potential. This conclusion, though not surprising, gives independent proof of the invariance of the weak vdW potential between ground and excited electronic states as well as providing a means of using ground state vdW vibrational structure to predict vdW vibronic structure. Second, in the majority of the clusters analyzed, the observed vdW vibrations are those involving bending and torsional motions parallel to the aromatic π system. Furthermore, these modes are, in general, quite active in the Herzberg-Teller vibronic coupling mechanism and significant interelectronic state mixing results. Third, vdW motions which penetrate the aromatic π system have high

frequencies and are only observed in systems in which the Franck-Condon factors and binding energies are favorable. Finally, the observed vibronic structure supports the calculated cluster geometry in all cases.

Acknowledgment

We wish to thank Professor W. Klemperer for a number of helpful, informative, and stimulating discussions concerning van der Waals molecules and the nature of their vibrational spectra.

CHAPTER THREE

THE INTERMOLECULAR VIBRONIC TORSIONAL STRUCTURE IN SOLUTE/SOLVENT VAN DER WAALS CLUSTERS: BENZENE/METHANE, /DEUTEROMETHANE, AND /CARBON TETRAFLUORIDE

Introduction.

van der Waals (vdW) complexes of aromatic molecules with hydrocarbon solvents form a class of supramolecular systems whose intermolecular bonding has several interesting features. First, the intermolecular interaction is small and is dominated by long-range dispersive attractions and short-range exchange repulsions. These two features allow the interaction to be modeled using an intermolecular potential of known functional form. For example, the interaction can be modeled by additive atom-atom potentials set in a Lennard-Jones or an Exponential Six format.[1] Second, the interaction potential surface only changes slightly, if at all, upon electronic excitation of the cluster chromophore. Thus, small spectral shifts of the chromophore electronic transition and weak intensity intermolecular vdW mode vibronic transitions are observed.[2,3] Third, the interaction results in the formation of specific minimum energy cluster configurations. These geometries are interesting since they give insight into the nucleation processes and solvation geometry occurring in both gas and condensed phase systems.[1] Fourth, the small binding energy of the complex and the low frequency vdW vibrational modes are important since they play an essential role in

intramolecular vibrational redistribution (IVR) and vibrational predissociation (VP) cluster dynamic energy transfer processes.[4] And fifth, cluster structure, binding energy, vdW modes and dynamics (IVR and VP) are essentially dependent on the actual cluster structure and the intricacies of the intermolecular interaction.[3,5]

In this paper, we report the spectroscopic results of the benzene/deuterated methane (ben$(CD_4)_1$) and benzene/carbon tetrafluoride (ben$(CF_4)_1$) clusters together with calculated modeling of selected cluster characteristics. The spectroscopic results include the $\pi^* \leftarrow \pi$ vibronic spectra of the clusters in their respective benzene constituent 6^1_0 regions.

The calculated results include the geometry, the binding energy, and the full eigenvalue/eigenvector intermolecular vibrational structure for the electronic ground state of each cluster. The intermolecular ground state vibrational structure is modeled by two methods: (1) an intermolecular normal coordinate analysis (NCA) which determines all six intermolecular vdW mode fundamentals under a harmonic oscillator assumption,[3] and (2) a three dimensional hindered rigid rotor analysis (HRRA) for which an anisotropic perturbation [illegible] appropriate to the cluster solvents considered [illegible] potential well. The intermolecular [illegible] obtained under a hindered [illegible]

The [illegible]

cluster [illegible]

structure [illegible]

cluster [illegible]

govern the [illegible]

ramifications of Herzberg-Teller (H-T) coupling for the observation of "forbidden" vibronic transitions.

The motivation for studying these systems concerns the elucidation of the vdW torsional structure. Two limiting cases can be proposed in regard to the torsional structure of ben$(CH_4)_1$, ben$(CD_4)_1$, and ben$(CF_4)_1$. In one case, the clusters possess free internal rotation between the cluster solute and solvent. The cluster solvent (CH_4, CD_4, or CF_4) rotates freely in three dimensions against the benzene framework and the system is considered nonrigid. In the other case, the clusters possess torsional oscillations for which the cluster solvent librates against the benzene frame with a residence time long enough to give rise to "vibration like" motion in a rigid molecule regime.

Elucidation of the vdW torsions is of particular interest in these systems since the aforementioned limiting cases pose questions regarding the actual physics governing the torsional structure. (1) do the clusters possess free internal rotation between the cluster solute and solvent or (2) they possess torsional oscillations for which the [illegible] behave more or less harmonically, and (3) in either [illegible]

mixed with the Nd^{+3}/YAG 1.064 μm fundamental is used to probe the clusters' $S_1 \leftarrow S_0$ transition in the isolated benzene 6_0^1 region ($^1B_{2u} \leftarrow {}^1A_{1g}$; $\pi^* \leftarrow \pi$). Subsequent ionization of the clusters is accomplished using a R590 dye laser whose output is frequency doubled and mixed with the Nd^{+3}/YAG 1.064 μm fundamental. The ionization laser output is set at 45112 cm^{-1}. A 5% mixture of deuterated methane or carbon tetrafluoride in helium is placed inline with liquid benzene in a trap at room temperature. The three component mixture is expanded using a pulsed molecular jet nozzle having a 500 micron orifice while maintaining 100 psig backing pressure. Apparatus chamber pressure is maintained at or below 5 x 10^{-6} torr during the experiments.

Theoretical Considerations.

The NCAs are conducted using the same methods as described in our previous publication on vdW *cluster vibronic structure*[3] For $ben(CD_4)_1$ the calculated cluster ground state geometry, force field and binding energy are taken as those of $ben(CH_4)_1$. Only the masses are changed for the deuterium hydrogen substitutions in the NCA. For $ben(CF_4)_1$ the cluster ground state geometry and binding energy are calculated via intermolecular energy minimization employing the methods previously

cluster solvent rotates freely in three dimensions against a fixed cluster solute framework. Application of a specified perturbation field results in the eventual restriction of this free rotation to torsional oscillation as the perturbation field magnitude is increased; that is, rotation ceases and vibrational oscillatory motion begins as the residence times of the solvent in the torsional potential well becomes longer.

In the 3D-HRRA, both cluster constituents are assumed internally rigid, their respective internal geometries remaining constant and at "equilibrium". The cluster solvents are taken as the rotating portions of the clusters since their zero field rotational constants are orders of magnitude greater than those of the cluster solute. The hindered solvent rotations are presupposed to contribute to the spectral features observed along with the intermolecular bending and stretching modes.

The 3D-HRRA involves setting up a molecule fixed coordinate system (x,y,z) and a space fixed coordinate system (ξ, η, ζ) on the cluster solvent as shown in Figure 3.1. Both systems have their origins at the nuclear center of mass of the cluster solvent. The molecule fixed coordinate system is chosen such that its principle axes lie along the C_2 rotational axes of the solvent tetrahedron (T_d point group symmetry). The space fixed coordinate system [illegible]

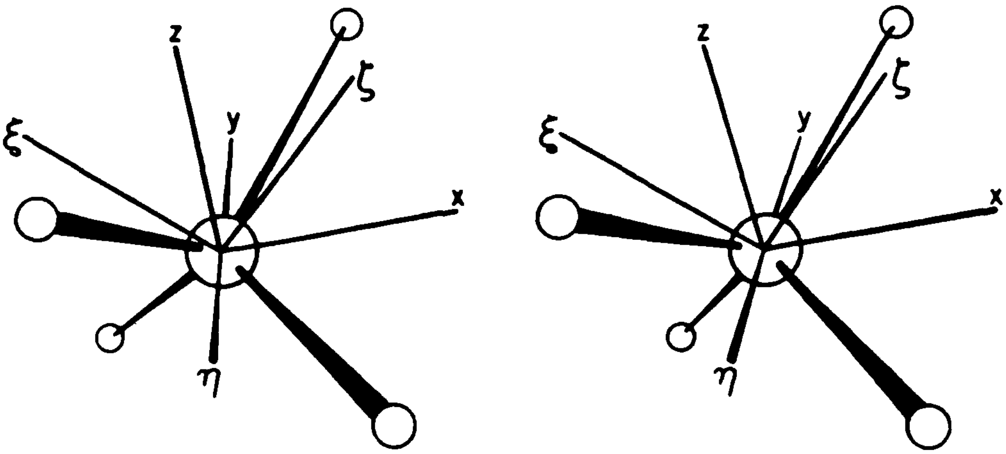

Figure 3.1

Stereoscopic projection of solvent tetrahedron showing relative orienta- tion of the molecule fixed (x,y,z) and space fixed (ξ,η,ζ) coordinate systems used [illegible] the [illegible] HMPA. The (x,y,z) coordinate system is located [illegible] coordinate system

of the rotational coordinates. Since a solvent rotation is periodic over 360 degrees, the potential can be expressed by an even function Fourier series written as[7]

$$V(q) = V_0/2 + \sum_{p=1}^{\infty} A_p \cos(pq) \qquad 3.1$$

with q a function of the rotational coordinates and V_0 taken as the barrier height to internal rotation. The function q is determined by the potential dimensionality and the number of minima in the potential along each of the rotational coordinates. The first cosine term in the series describes the major form of the potential, and the rest of the terms in the series "fine tune" the potential shape. Since the coefficients A_p in these terms are assumed to be small, the series can be truncated at its first cosine term without sacrificing the general potential shape. *Doing this yields the mathematically convenient potential form:*

$$V(q) \quad \frac{V}{2}(1 \quad \cos(q)) \qquad (2)$$

The symmetry of the cluster solvents can be employed to determine the dimensionality of and the number of minima in the potential [illegible]

potential magnitude depends upon the relative displacements of all three rotational coordinates as,

$$q = 2\theta + 2\chi + \phi \qquad 3.3$$

Inserting Equation 3.3 into Equation 3.2 yields the three dimensional potential function used in the calculations:

$$V(\theta, \phi, \chi) = \frac{V_o}{2} [1 - \cos(2\theta + 2\chi + \phi)] \qquad 3.4$$

in which V_0 is the barrier height to internal rotation. The rotational wavefunctions chosen as the basis set for the calculation are the rigid rotor symmetric top wavefunctions which depend on the curvilinear coordinates and on the quantum numbers J, k and m. Under zero field conditions, these wavefunctions are solutions to the spherical top Schrodinger equation,[8]

$$\frac{B}{\hbar^2} J^2 |Jkm\rangle \quad E^J_{rot} |Jkm\rangle \qquad 3.5$$

with eigenvalues corresponding to those of the spherical top cluster [illegible] upon application of the perturbation field. The eigenvalues are [illegible] diagonalization of the energy matrix [illegible]

$$|J' - J''| \leq 2 \qquad 3.7$$
$$|k' - k''| = 2 \qquad 3.8$$
$$|m' - m''| = 1. \qquad 3.9$$

Diagonal matrix elements contain only the zero field spherical top energies and a $V_0/2$ potential term.

The resulting matrix is diagonalized for a selected value of V_0 yielding eigenvalues corresponding to the solvent torsional eigenstates at the specified perturbation. The perturbation is varied until a reasonable fit with the experimental spectrum is obtained. The calculations are performed on a Cyber 205 computer using a basis set consisting of 680 wavefunctions to ensure convergence of the lowest eigenstates at their proper eigenvalues. Only the torsional structures of ben$(CH_4)_1$ and ben$(CD_4)_1$ are calculated since their respective rotational constants are large enough that the coupling of the rotational levels does not require an extremely large basis set to insure convergence. Matrix elements are determined via numerical integration using a nonadaptive integration routine. The matrix is prediagonalized into a tridiagonal form using orthogonal similarity transformations[9] and diagonalized using an implicit QL method[10] The rotational constants used for methane and deuterated methane are 5.2 cm^{-1} and 2.6 cm^{-1} respectively

difference between S_1 and S_0 for ben$(CD_4)_1$ is nearly identical to that of ben$(CH_4)_1$. Ten pronounced intermolecular vibronic features are observed to the "blue" of the cluster 6^1_0. As in the case of the ben$(CH_4)_1$ cluster, no features are observed in the symmetry forbidden benzene 0^0_0 region. Thus, the cluster geometry must possess at least a three-fold axis of symmetry.

The calculated ben$(CD_4)_1$ geometry (Figure 3.3) is assumed to be the same as that calculated for ben$(CH_4)_1$. The geometry possesses C_{3v} point group symmetry. In this geometry, the CD_4 center-of-mass lies 3.47 Å above the benzene molecular plane along the three-fold rotational axis. The ground state binding energy in this configuration is calculated at 540 cm^{-1}. Using the cluster "red shift" of 41.2 cm^{-1}, the excited state binding energy is calculated to be 581 cm^{-1}.

The NCA reveals six vdW vibrations (Figure 3.3 and Table 3.1), two being two-fold degenerate. The ground state vibrational energies are 75 cm^{-1} for the vdW stretch $s_z(a_1)$, 15 cm^{-1} for the bends $b_{xy}(e)$, and 20 cm^{-1} ($t_z(a_2)$) and 64 cm^{-1} ($t_{xy}(e)$) for the vdW torsions. The eigenvector normal modes (Figure 3.3) transform in an identical fashion to those calculated for ben$(CH_4)_1$. The vdW stretching mode transforms as the translation of the cluster constituents away from one another along the z (three fold) axis. The vdW bends transform as some combination of cluster constituent translations [illegible] perpendicular to the three [illegible]

[illegible]

The 3D HRRA results are also included in Table 3.1 for the lowest eigenstates in the torsional manifold. The torsional mode structure is calculated for V_0 = 300 cm^{-1} and B = 2.6 cm^{-1}. This perturbation results in a reasonable fit for the torsional features observed experimentally. The torsional "zero point energy" is 75 cm^{-1}. Two distinct torsional manifolds result from the calculations: one manifold has eigenvalues grouped quartically (nearly four-fold degenerate located at approximately 21 cm^{-1}, 46 cm^{-1}, and 75 cm^{-1} above the zero point energy) and the other manifold has eigenvalues grouped octally (nearly eight-fold degenerate located at approximately 68 cm^{-1} above the torsional zero point energy).

For comparison, the observed vibronic features for ben$(CH_4)_1$ are reproduced in Table 3.1 along with the results of the NCA and the 3D-HRRA. The NCA results for ben$(CH_4)_1$ are those reported previously.[3] The 3D-HRRA torsional structure is calculated for V_0 = 300 cm^{-1} and B = 5.2 cm^{-1}. This perturbation is chosen since it is assumed that the barrier to internal rotation is nearly identical in the two systems as they only differ by isotopic substitution and have the same electronic structure. Additionally, using the same potential barrier of electronic origin for both CH_4 and CD_4 clusters provides a check on the validity of the model in predicting the torsional mode structure of the clusters. For ben$(CH_4)_1$ the torsional zero point energy is 96 cm^{-1} [illegible] two distinct torsional [illegible] eigenvalues grouped quartically at [illegible]

B Ben$(CF_4)_1$

Figure 3.4 and Table 3.2 present the ben$(CF_4)_1$ cluster spectrum recorded using 2-color TOFMS in the region between 38578.6 cm^{-1} and 38702.6 cm^{-1}. Unlike the ben$(CD_4)_1$ and ben$(CH_4)_1$ cluster 6_0^1 transitions, the ben$(CF_4)_1$ cluster 6_0^1 is blue shifted by 6.1 cm^{-1} with respect to the benzene 6_0^1. The small hypsochromic shift indicates that the binding energies in the S_0 and S_1 states are nearly identical with the ground state binding energy being slightly greater. The relative displacement between the two potential surfaces is also small since only 5 vdW transitions are observed and their intensities decrease abruptly at about 50 cm^{-1} above the cluster 6_0^1 origin. No cluster spectrum is observed in the forbidden benzene 0_0^0 region indicating that the cluster possesses at least a three-fold rotation axis. This result is not unexpected since the same observation is made for the ben$(CH_4)_1$ and ben$(CD_4)_1$ systems. The ground state configuration and vdW eigenvalues/eigenvectors are shown in Figure 3.5 and Table 3.2. Only one minimum energy geometry is calculated for the cluster. The geometry has C_{3v} point group symmetry with the CF_4 center-of-mass at 3.43 Å above the benzene molecular plane along the three-fold axis. The cluster ground state binding energy is 1064 cm^{-1}.

The NCA reveals six vdW vibrations. Their ground state vibrational energies are 69 cm^{-1} for the vdW stretch $s_z(a_1)$, 11 cm^{-1} for the vdW bends $b_{xy}(e)$, and 13 cm^{-1} ($t_z(a_2)$) and 36 cm^{-1} ($t_{xy}(e)$) for the vdW torsions. The eigenvector normal modes transform as the translational and rotational representations of the C_{3v} point group as indicated and in the same manner as those for ben$(CH_4)_1$ and ben$(CD_4)_1$.

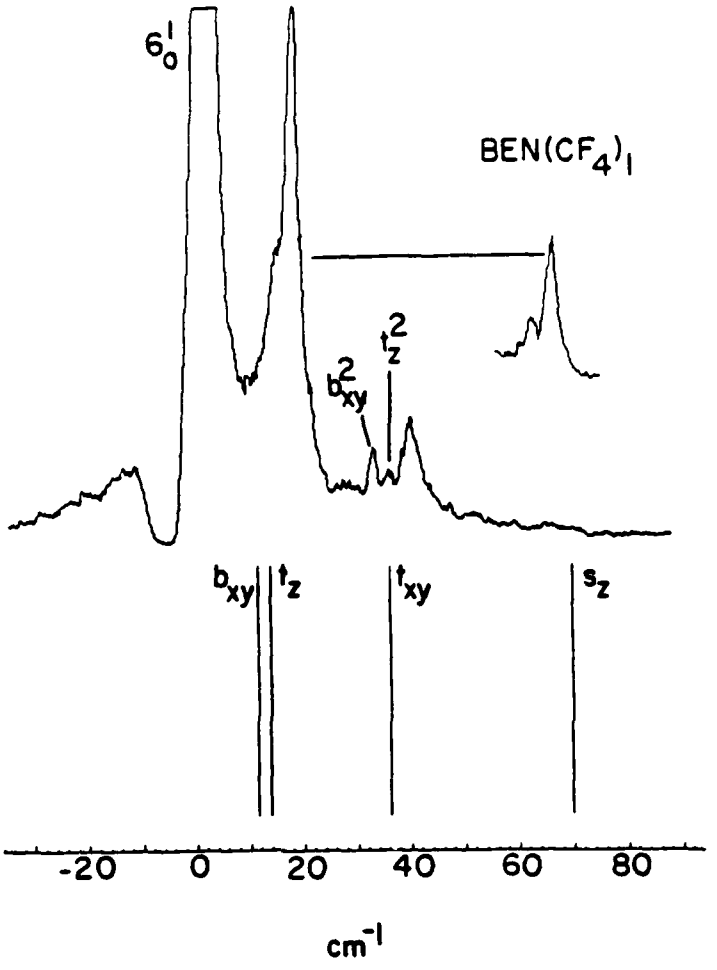

Figure 3.4

Two-color TOFMS $S_1 \leftarrow S_0$ spectrum and calculated ground state vdW modes (NCA) of ben$(CF_4)_1$. Energy scale is relative to ben$(CF_4)_1$ 6_0^1 transition (38614.7 cm^{-1}). Feature positions and assignments as per Table 3.2 and Figure 3.5.

b) vdW mode representations as per Figure 3.4.

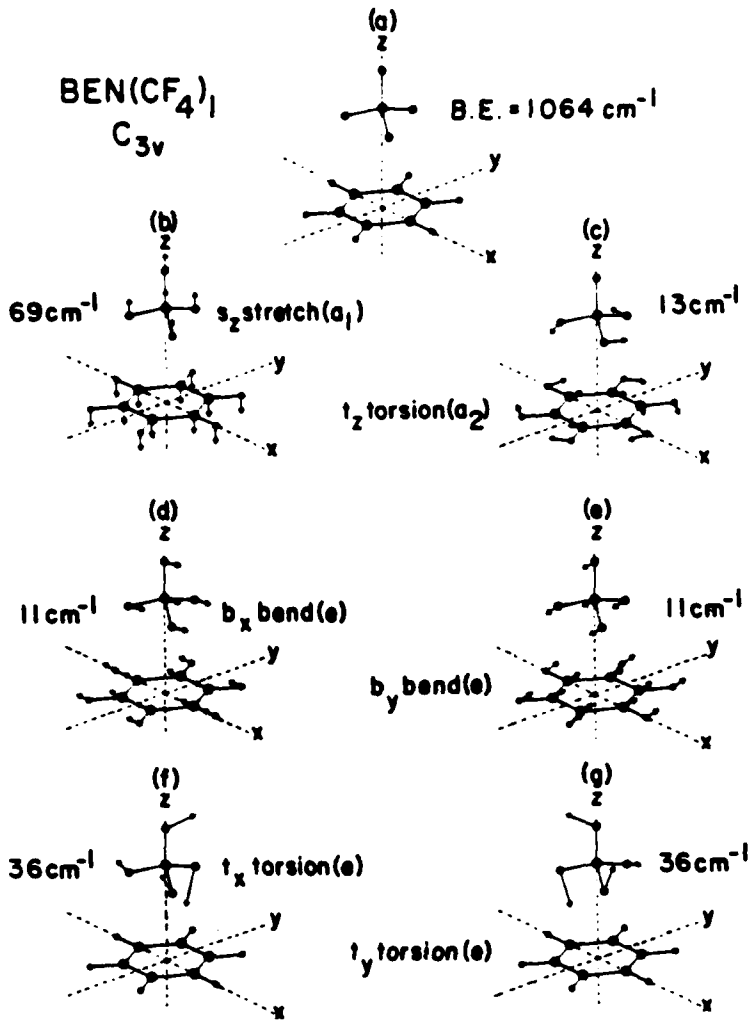

Figure 3.5

Calculated ground state minimum energy configuration (a) and NCA eigenvalue/eigenvector normal modes (b) - (g) for ben$(CF_4)_1$. Cluster symmetry is C_{3v} with an equilibrium intermolecular distance of 3.43 Å. Eigenvectors are normalized and displayed at 2x magnification (2 Å total displacement).

Discussion

In comparing the calculated ground state vdW vibrational structure and experimental vdW vibronic structure, we assume that the intermolecular potential surfaces of the clusters studied are identical in both the S_1 and S_0 electronic states. Additionally, we utilize the group theoretical arguments developed in our previous publication[3] on *vdW cluster vibronic structure to assign and understand* the observed cluster spectra.

A. $Ben(CD_4)_1$.

The calculated ground state vdW vibrations (NCA) of $ben(CD_4)_1$ and the experimental vibronic spectrum is shown in *Figure 3.2 and Table* 3.1. As previously,the assignments are made by direct comparison between the calculations and the experimental vibronic spectra. The intense feature at 22.5 cm^{-1} to the blue of the cluster 6_0^1 corresponds to the t_z torsion calculated at 20 cm^{-1}. Thus this feature and its observed overtones at 48.4 cm^{-1}, 70.5 cm^{-1}, and 100 cm^{-1} are assigned to 6_0^1 vdW combination bands $6_0^1t_z(a_2)_0^1$, $6_0^1t_z(a_2)_0^2$, $6_0^1t_z(a_2)_0^3$, and $6_0^1t_z(a_2)_0^4$. The features at 32 cm^{-1} and 62.7 cm^{-1} to the blue of the cluster 6_0^1 correspond to the first and third overtones of the two-fold degenerate vdW bending modes whose fundamental is calculated at 15 cm^{-1}. They are assigned to the 6_0^1 combination bands $6_0^1b_{xy}(e)_0^2$, and $6_0^1b_{xy}(e)_0^4$, respectively. The feature at 58.1 cm^{-1} to the blue of the cluster 6_0^1 is assigned to a two-fold degenerate t_{xy} vdW torsions/cluster 6_0^1 combination band, $6_0^1t_{xy}(e)_0^1$. The t_{xy} torsion fundamental is calculated at 64 cm^{-1}. With this assignment and that of the t_z torsion, the feature at 84 cm^{-1} is assigned to the $6_0^1t_{xy}(e)_0^1t_z(a_2)_0^1$ combination band. The vdW stretch is calculated at 75 cm^{-1}. This mode is identified in the

cluster vibronic spectrum at 72.9 cm^{-1} to the blue of the cluster 6_0^1 origin and is thus assigned as $6_0^1 s_z(a_1)_0^1$. Under this scheme, we assign the features at 93.3 cm^{-1} and 97.5 cm^{-1} as $6_0^1 s_z(a_1)_0^1 b_{xy}(e)_0^1$ and $6_0^1 s_z(a_1)_0^1 t_z(a_2)_0^1$ combination bands.

The torsional structure resulting from the 3D-HRRA for ben$(CD_4)_1$, (Table 3.1), confirms the torsional assignments made using the NCA. The quartically grouped torsional levels at 21 cm^{-1}, 46 cm^{-1} and 75 cm^{-1} correspond to those associated with the t_z torsion and its overtones in the cluster spectrum at 22.5 cm^{-1}, 48.4 cm^{-1} and 70.5 cm^{-1}. The octally grouped torsional levels at 68 cm^{-1} correspond to the t_{xy} torsion assigned at 58.1 cm^{-1}.

The correspondence between these levels and those calculated using the NCA can be understood as follows. In the 3D-HRRA, four symmetrically equivalent minima exist in the torsional potential surface. These minima correspond to the four ways of placing the solvent tetrahedron upon the solute with a tetrahedral face toward the solute molecular plane. If the barrier between these minima is infinitely high, penetration of the local wavefunctions through the barrier separating the potential minima does not take place. In this case, each "well" contains eigenstates corresponding to intermolecular torsions which occur with small amplitude about each potential well minimum. Since the four "potential wells" are identical in shape and depth, a four-fold "structural" degeneracy exists in which all four potential wells contain identical torsional structure. Thus, for example, a non degenerate torsional eigenstate actually has a four fold structural degeneracy, etc.

Considering the actual situation in which the potential barrier is finite, tunneling occurs and the "structural" degeneracy is lifted via interaction of the local wavefunctions through the potential barrier. The eigenstate splitting due to this tunneling may, or may not, be observed depending on the experimental resolution and the relative difference between the eigenstate energy and the barrier height. Splitting of the "structural" degeneracy in the lower portion of the potential well is minimal unless the barrier is low. Based on the calculations, energy level splittings of the first few sets of eigenstates should not be observed unless the barrier is below 150 cm^{-1}.

At moderate barriers (about 300 cm^{-1}), the eigenstates in the lower portion of the well are nearly degenerate and behave more or less harmonically. For all practical purposes, we can assume these levels to be degenerate. The torsional level structure can then be determined from the eigenstates in one of the minima. Thus, the 3D-HRRA torsional structure calculation simplifies into the NCA. Physically, the cluster can be considered at least "semi-rigid" in the respect that it has a definable equilibrium configuration. The potential energy barrier separating one minimum from the others in the potential surface is large and may be of the order of the cluster binding energy.

The vibronic structure in both the ben$(CH_4)_1$ and ben$(CD_4)_1$ spectra suggests that the systems are more or less rigid. None of the observed vibronic state energies follow a free rotor formalism for which the energy level structure is described by Equation 3.2. If the systems behaved nonrigidly, the free rotor eigenstates would lie at approximately $2.6J(J+1)$ cm^{-1} and $5.2J(J+1)$ cm^{-1} for ben$(CD_4)_1$ and ben$(CH_4)_1$, respectively, and a $\Delta J = \pm 1$ selection rule would govern the transitions

In the ben$(CH_4)_1$ and ben$(CD_4)_1$ systems, the t_z torsional mode shifts by 17.6 % upon deuterium substitution of the cluster solvent. Both the NCA and 3D-HRRA models predict a 28.6% frequency shift for t_z, while the free rotor model would predict a 50% frequency shift for t_z upon deuteration. Considering that only one mode is taken into account and the mode couplings may be different in the protonated and deuterated clusters, we conclude that torsional tunneling does not take place in the lower levels of the ben$(CH_4)_1$ and ben$(CD_4)_1$ cluster potential wells and that the clusters can be considered to be rigid.

The negligible isotopic red shift in the b_{xy} bends also suggests that the cluster is rigid and that the entire observed spectrum is not solely due to internal rotation. The same rationale holds for the vdW stretch: its observation also dispels the notion that only rotor modes occur in the spectrum. No experimental isotopic shift can be determined for the stretching mode, however, since it is not observed in the ben$(CH_4)_1$ system. Theoretically, the mode should red shift by 8.5% upon deuteration of the cluster solvent. The ben$(CH_4)_1$ stretch should then be at about 80 cm^{-1} in the vibronic spectrum based upon the observed stretch in the ben$(CD_4)_1$ system. (The ben$(CH_4)_1$ stretch is calculated by the NCA to be at 82 cm^{-1}).

The ben$(CD_4)_1$ cluster spectrum is also substantially richer than the ben$(CH_4)_1$ spectrum in the respect that both the vdW stretch and t_{xy} torsions are observed along with well developed t_z torsion and bend progressions. This is probably due to more favorable Franck-Condon factors in the ben$(CD_4)_1$ case resulting from the isotopic substitution.

As is the case for ben$(CH_4)_1$, H-T coupling influences the vibronic intensities (selection rules) in the ben$(CD_4)_1$ spectrum. The

nontotally symmetric modes t_z, t_{xy} and b_{xy} all appear in the spectrum with $\Delta v = 0, \pm 1, \pm 2, \pm 3, \ldots$ selection rules as can be seen in Figure 3.2 and Table 3.1.

B. $Ben(CF_4)_1$.

Comparison of the calculated ground state vdW vibrations (NCA) of $ben(CF_4)_1$ and the experimental cluster spectrum is presented in Figure 3.4 and Table 3.2. The intense feature at 17.4 cm^{-1} to the blue of the $ben(CF_4)_1$ 6_0^1 corresponds to the t_z torsion calculated at 13 cm^{-1}. Thus, this feature and its first overtone at 35.4 cm^{-1} are assigned to the 6_0^1 vdW combination bands $6_0^1\ t_z(a_2)_0^1$ and $6_0^1 t_z(a_2)_0^2$. The shoulder feature at 15.7 cm^{-1} to the blue of the cluster 6_0^1 corresponds to the vdW two-fold degenerate b_{xy} bend fundamental calculated at 11 cm^{-1}. Taking this feature as the combination band $6_0^1 b_{xy}(e)_0^1$ leads to the assignment of the b_{xy} bend first overtone $6_0^1 b_{xy}(e)_0^2$ at 32.3 cm^{-1}. Finally, the spectral feature at 39.5 cm^{-1} in the $ben(CF_4)_1$ spectrum corresponds to the t_{xy} torsion calculated at 36 cm^{-1}. Thus, the feature is assigned to the combination band $6_0^1 t_{xy}(e)_0^1$.

The $ben(CF_4)_1$ spectrum, like the $ben(CD_4)_1$ and $ben(CH_4)_1$ spectra, suggests that the system is rigid. Since the rotational constant for CF_4 is small (ca. 0.18 cm^{-1}), the free rotor energy level structure should appear at about .37 cm^{-1} intervals. This structure is not observed. Instead, the spectrum possesses oscillatory torsional structure commensurate with the NCA theoretical predictions. These theoretical and experimental results demonstrate the rigidity of the systems.

The $S_1 \leftarrow S_0$ excitation of the $ben(CF_4)_1$ cluster involves very little change in cluster geometry. In this spectrum, the progression

intensities decrease dramatically at energies greater than the 6_0^1 cluster origin. In the lowest two vdW mode progressions, the intensities decrease approximately 13% between the mode fundamentals and the first overtones. Furthermore, the high energy vdW stretch calculated at 69 cm^{-1} is not observed. At these high energies, the Franck-Condon factors must be very small.

The observation of the nontotally symmetric vdW b_{xy} bends and the t_z torsion progressions with a $\Delta v = 0, \pm 1, \pm 2 \ldots$ selection rule suggests that interelectronic state mixing (H-T coupling) is an important contributor to the mode intensity mechanism. As in the ben$(CH_4)_1$ and ben$(CD_4)_1$ cases, H-T coupling becomes apparent in the low lying vdW modes of the ben$(CF_4)_1$ system. In fact, the interelectronic state mixing is substantial in the ben$(CF_4)_1$ system and can be demonstrated by the observation of the well defined bend fundamental at 15.7 cm^{-1} and by the observation of the t_{xy} torsion fundamental (39.5 cm^{-1}). Both of these latter features should not be observed if H-T coupling is not present.

Summary and Conclusions.

Two-color TOFMS and supersonic molecular jet techniques have been employed to study the $S_1 \leftarrow S_0$ vibronic spectra of ben$(CD_4)_1$ and ben$(CF_4)_1$ vdW clusters. These studies reveal detailed information regarding the geometries, the intermolecular energetics, and the physical nature of the vdW interactions present in the systems. The experimental observations demonstrate that the clusters are at least semi-rigid systems possessing unique equilibrium geometries and that the intermolecular motion present in the systems is oscillatory. Through comparison of these spectra with those of ben$(CH_4)_1$ previously studied in this

laboratory, the isotopic shifts observed in the [illegible] vibronic structures demonstrate that all the low lying intermolecular eigenstates are nearly harmonic. They are not admixtures of [illegible] intermolecular bends and stretches and free intermolecular rotation as would occur if the clusters behaved nonrigidly.

The rigidity of the clusters is further demonstrated by theoretical treatment of the intermolecular motion. Both the NCA and 3D HRRA models indicate that the intermolecular torsional motion is oscillatory and that the motion is constrained by an orientationally dependent intermolecular potential. Detailed analysis of the intermolecular interaction reveals that the torsional motion is governed by a three dimensional potential possessing torsional barriers on the order of the cluster binding energy. At this barrier magnitude, torsional tunneling in the lower portions of the potential is minimal and the residence time of the cluster constituents in a particular well minimum is substantially longer than the timescale of experimental observation.

The assignment of geometry and identification of the intermolecular modes using the theoretical models has also proven useful in understanding the physics governing the spectroscopic properties of the clusters. The observation of nontotally symmetric intermolecular mode fundamentals and combination bands in the vibronic spectra suggest that interelectronic state mixing (H-T coupling) is an important factor in the overall intensity mechanism governing the transitions. Additionally, the interelectronic state mixing is most important for the low-lying intermolecular bending and torsional modes.

Both the NCA and the 3D-HRRA adequately model the intermolecular modes in the systems studied; however, the NCA is the more useful here

and z displacements may or may not be present depending on the values of the K and m quantum numbers. Given the geometry of the system then low barrier one dimensional rotation (solvent rotating around the cluster three fold (X bond axis) is not possible. Basically the two dimensional hindering in bent$(X_4)_3$ clusters is insufficient to produce the one dimensional rotation occuring in "attached tops" such as toluene [11]

Acknowledgment

We wish to thank Professor W. Klemperer for many helpful discussions and suggestions concerning the rigidity of vdW molecules.

SUPERSONIC MOLECULAR JET STUDIES OF PHTHALOCYANINES AND THEIR VAN DER WAALS CLUSTERS WITH SMALL MOLECULES

Introduction.

Supersonic molecular jet spectroscopy can be utilized to study weakly bound solute/solvent van der Waals (vdW) clusters in the gas phase.[1] These investigations have increased our understanding of the intra- and intermolecular energetics and dynamics present in the solute/solvent systems as well as the nucleation and growth of small clusters.[2-11] The vdW clusters studied in our laboratory thus far center around aromatic hydrocarbon and N-heterocycle solutes clustered with small hydrocarbon and hydrogen bonding solvents. We are currently expanding our studies of solute/solvent systems to include clusters of small molecules with macrocycles, such as free-base phthalocyanine (H_2Pc) and magnesium phthalocyanine (MgPc).

Considerable interest exists in phthalocyanine (Pc) compounds as coloring agents, photosensensitizers, organic semiconductors, and as model systems for biologically important species, such as porphyrins. Pc's have exceptional color, chemical, temperature, and solubility characteristics which make them attractive for use as coloring agents in commercial dyeing and painting processes.[12] The unique electrical properties of Pc's serve as building blocks in a number of important technical applications involving electronic devices. For example, thin film

sandwich photovoltaic cells containing Pc's have been fabricated which possess photocurrent quantum efficiencies of as much as 10%.[13] Pc films have also been shown to possess both n- and p- type semiconductor properties.[14]

Of particular interest are the interactions between Pc's and other molecular species. Pc films have been observed to respond electrically to the presence of vapors such as BF_3, NO_2, and NH_3.[15] Interaction between the film surface and the vapors produces reversible and reproducible film conductivity changes which make the measuring of molecular concentrations of these species at the ppm to ppb levels possible. Pc's and porphyrins have also been studied as photocatalysts for the reduction of water to hydrogen.[16] Photochemical generation of hydrogen from water is a very attractive goal for photochemical storage of solar energy. Since water does not absorb at solar wavelengths present at the earth's surface, the photoreductive reactions must be sensitized by dyes. Pc's are good candidates as dyes in this respect since they absorb in the visible spectrum where peak solar radiation occurs.[17] The elucidation of the trapping and transduction mechanisms of solar energy into useful chemical energy is of particular importance in these systems as it may yield insight into the understanding of the basic process of photosynthesis in biologically active systems such as green plants and bacteria.[18] Studying the interactions between Pc's and small "solvents" may also prove useful in understanding the transport and storage of small molecules and the transfer of electrons in a variety of biologically active species such as hemoglobin, myoglobin, and cytochromes.[19]

Supersonic molecular jet investigations can contribute to the resolution of a number of important concerns dealing with the behavior of Pc/solvent systems on the microscopic scale. Questions that can be considered are (1) what are the ground and excited state interaction energies between Pc and various solvents, (2) what are the preferential intermolecular interaction sites on the Pc moiety, (3) what are the most favorable cluster geometries, (4) what types of interactions are important in the intermolecular potential established between the solute and solvent, and (5) are changes in the chromophore symmetry/geometry induced by clustering. The answers to these questions will certainly be helpful to those employing Pc's or related systems in reactions and other chemical processes.

In this paper, we report the spectroscopic results of H_2Pc and MgPc clustered with hydrocarbon solvents (CH_4, C_2H_6, and C_3H_8), hydrogen bonding solvents (H_2O, MeOH, EtOH), and CO_2 along with the calculated modeling of selected cluster characteristics. The spectroscopic results include the $\pi^* \leftarrow \pi$ fluorescence excitation (FE) spectra of the clusters near the Pc 0_0^0 transition. The calculated results include the ground state geometry and the binding energy for each of the cluster systems studied. The H_2Pc cluster spectra and calculated geometries and binding energies are compared with those obtained for the MgPc clusters. Differences and similarities between the H_2Pc(MgPc) clusters and the aromatic hydrocarbon and N-heterocycle clusters are discussed. Specifically, trends in spectral shifts, relative solute/solvent orientations, and binding energies are noted. Finally, the results of an out-of-plane normal coordinate analysis for Pc are discussed and compared to both Pc and cluster spectra within the first few hundred wavenumbers of the origin transition.

Experimental Procedures.

The majority of the apparatus used in these experiments has been previously described;[2-7] therefore, only a description of the equipment and procedures unique to the present studies will be discussed. A high temperature continuous supersonic nozzle fabricated to generate and analyze the H_2Pc and MgPc clusters in shown in figure 6.1. The expansion region is constructed by welding a stainless steel pinhole (Micro Engineering) A onto a 1/4 inch tube connector gland (Cajon VCR) B. The pinhole/gland is attached to the nozzle backing region C using a 1/4 inch tube connector (Cajon VCR) D. Stainless steel gaskets are used to insure proper connector sealing throughout the nozzle operating temperature range. This setup allows different size pinhole assemblies (nozzle throats) to be attached to the nozzle to obtain various peak experimental backing pressure and gas throughput conditions. A 100 micron pinhole is used to perform the expansion in the H_2Pc and MgPc cluster experiments. The nozzle backing region is constructed from 1/2 inch stainless steel tubing. The tubing extends through the vacuum chamber wall E passing through a vacuum quick disconnect (MDC Vacuum) F. Connection of the nozzle to the expansion gas line is accomplished using a stainless steel tube connector (Swagelok) G. Solid samples are placed in the nozzle backing region using a quartz "boat" H which can be inserted into the nozzle through the expansion gas line connection. The "boat" facilitates access to the nozzle backing region while the nozzle is in the vacuum chamber and is heated. It allows for easy inspection of the sample during and after an experiment without nozzle removal or nozzle cooling. The nozzle is heated using two heating coils (ARI Industries) I located around the expansion and backing regions. The

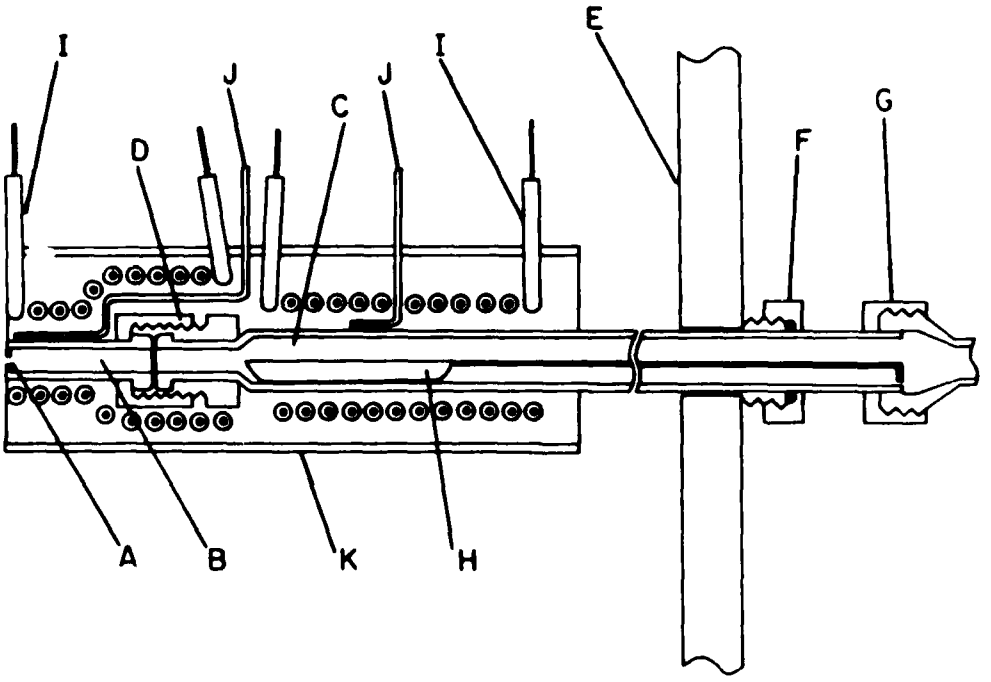

Figure 6.1

High temperature continuous supersonic molecular jet nozzle (see text).

heaters are capable of maintaining the nozzle at temperature up to 650°C. The heaters are independently controlled using two transformer assemblies. Nozzle temperature is monitored using two iron-constantan thermocouples (Omega) J placed around the expansion and backing regions. The nozzle/heater assembly is enclosed in a stainless steel shield K to minimize heat loss and to maintain uniform nozzle heating.

FE spectra of the H_2Pc, MgPc, and their respective solvent clusters are obtained using a Nd^{+3}/YAG pumped DCM (Exciton) dye laser. Dye laser output is 46-60 mJ/pulse in the vicinity of the H_2Pc and MgPc 0_0^0 transitions. Total excited state fluorescence is collected using a f/1.2 5 cm lens focused at 5-8 mm in front of the nozzle throat and detected by a water cooled RCA C31034 photomultiplier tube. The photomultiplier tube output is amplified 10x using an Ortec 9301 amplifier. The signal is then sent to a boxcar/computer for averaging and digital storage. Fluorescence wavelength calibration is provided by an optogalvanic cell with iron and neon lines as standards.

H_2Pc (Aldrich) and MgPc (Eastman Kodak) are purified by vacuum sublimation before use. The solid samples are pelletized prior to insertion into the nozzle to minimize consumption. Granular samples placed in the nozzle are consumed at a rate of ca. 45 mg/hr. Pelletization reduces sample consumption by about a factor of thirty without significant loss in fluorescence intensity.

The H_2Pc and MgPc solid samples are heated to 380-640° C to provide sufficient vapor density to perform the spectroscopy. Methane, ethane, propane or carbon dioxide is doped into helium carrier gas at concentrations of up to 1% (partial pressure). The gas is then mixed with the H_2Pc or MgPc in the nozzle backing region and expanded using

pressures ranging from 100-200 psig. Water, methanol, or ethanol is seeded into the helium carrier gas by passing the carrier gas through an inline trap containing the liquid solvent.

Calculations of the ground state cluster binding energies and geometries are conducted using an empirical intermolecular potential generated from additive atom-atom potentials set into a Lennard-Jones format. The potential includes general non-bonding (6-12), monopole charge (1), and hydrogen bonding (10-12) terms.[20] The H_2Pc and MgPc structures used in the calculations are obtained from crystal structure data.[21] The atom-atom potential for magnesium is approximated using experimentally determined polarizabilities[22], interatomic distance[23], and the Slater-Kirkwood approximation[24]. Atomic partial charges employed to model the monopole charge interaction are taken from extended Huckel[25] calculations. The hydrocarbon and water structures are those previously used in studying benzene and N-heterocycle clusters.[2,8-10] The CO_2, MeOH, and EtOH structures are taken from ref. 26, 27, and 28, respectively.

The out-of-plane normal coordinate analysis for H_2Pc is conducted using the FG matrix method of Wilson et. al.[29] The details of the analysis will be reported elsewhere.[30] Briefly, the nuclear motion is modeled using a set of 82 internal coordinates; 48 C-C(N) bond torsions, 18 C(N)-H bond wags, and 16 C-C(N) bond wags. The valence force field for the $\underline{F}$ matrix consists of the diagonal force constants describing the out-of-plane ground state motions in benzene.[31] In this gross approximation, all H_2Pc bond torsions force constants are assumed to be the same as the C-C torsions in benzene. All bond wag force constants are assumed to be the same as the benzene C-H wags. The secular equation

describing the nuclear motion is symmetry factored into four species sets (B_{1u}, A_u, B_{2g}, and B_{3g}) under the D_{2h} point group. The factored equations are individually diagonalized to yield 15 B_{1u}, 13 A_u, 13 B_{2g}, and 14 B_{3g} out-of-plane frequency eigenvalues and eigenvector normal modes. (See Table 6.1).

Results.

A. Isolated Ultracold Molecular FE Spectra of H_2Pc and MgPc.

Figure 6.2 presents the FE spectrum of the H_2Pc $S_1 \leftarrow S_0$ transition (Q_x band) in the vicinity of the 0_0^0. The spectrum is taken at 200 psig helium backing pressure (P_o), a nozzle expansion region temperature (T_e) of 570°C, and a nozzle backing region temperature (T_b) of 460°C. The general nature of the spectrum has been previously described.[32] The purpose of its reproduction in this paper is 1) to present a detailed account of the low frequency vibronic transitions observed in the vicinity of the 0_0^0 which have not been previously reported in the literature Table 6.2, and 2) to provide an isolated chromophore spectrum which can be compared to the cluster spectra, all of which are taken under nearly identical experimental conditions.

The FE spectrum of the MgPc $S_1 \leftarrow S_0$ transition (Q band) in the vicinity of the 0_0^0 is shown in Figure 6.3. The spectrum is taken using P_o = 120 psig helium, T_e = 630°C, and T_b = 397°C. Table 6.3 lists the energies of the vibronic transitions observed in this portion of the spectrum.

B. Hydrocarbon Clusters: CH_4, C_2H_6, and C_3H_8.

The H_2Pc/hydrocarbon cluster FE spectra observed in the vicinity of the H_2Pc 0_0^0 are presented in Figure 6.4. The energies of

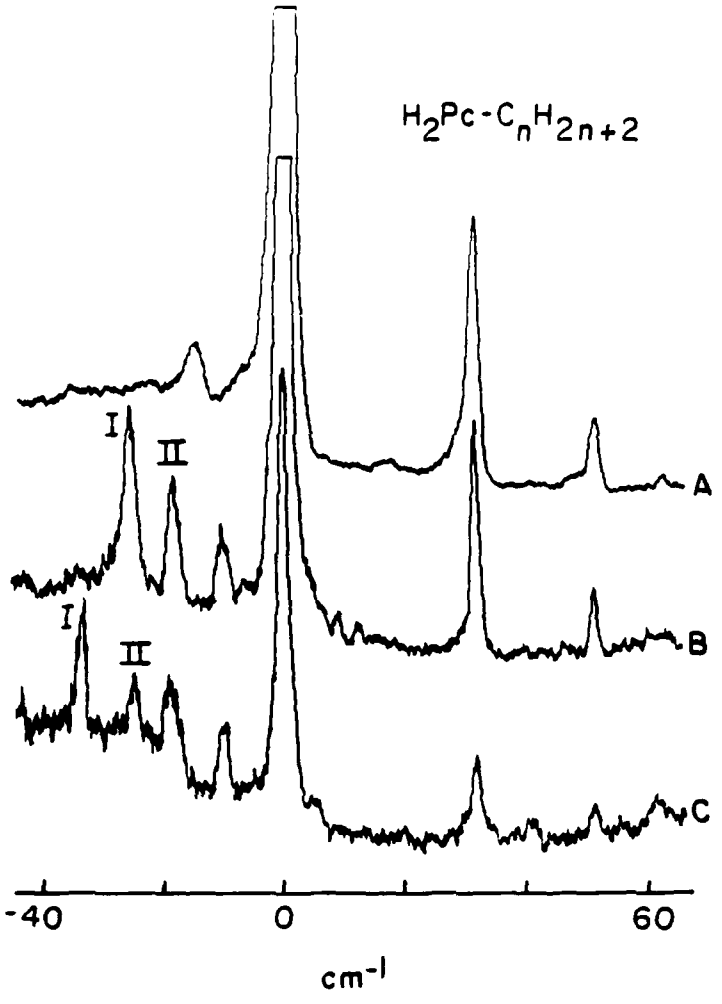

Figure 6.4

PE spectra of H_2Pc/C_nH_{2n+2} clusters in the vicinity of the H_2Pc 0_0^0. The $H_2Pc(CH_4)_1$ spectrum (A) is taken at T_e = 540°C, T_b = 430°C, P_o = 200 psig He, and .1% CH_4. The $H_2Pc(C_2H_6)_1$ spectrum (B) is taken at T_e = 540°C, T_b = 430°C, P_o = 160 psig He, and .1% C_2H_6. The $H_2Pc(C_3H_8)_1$ spectrum (C) is taken at T_e = 580°C, T_b = 435°C, P_o = 160 psig He, and .1% C_3H_8. Peak assignments are given in Table 6.4.

the observed cluster transitions are listed in Table 6.4. In these experiments, solvent concentration is varied between .07 and 1% and the backing pressure is varied between 0 and 300 psig. Below .07% solvent concentration, no cluster transitions are observed; above about .3%, the cluster spectra appear broad and featureless to the red of the H_2Pc 0_0^0. Below 50 psig backing pressure, the spectra become broad; at 100 psig to 300 psig, no new cluster transitions emerge in the region probed.

Sharp spectra of MgPc/hydrocarbon clusters could not be generated. Through the range of .06 to 3% solvent concentration, the spectra vary from no observable cluster transitions to broad cluster bands which extend some 60 cm^{-1} to the red of the MgPc origin.

The ground state geometries calculated for the H_2Pc/hydrocarbon clusters are shown in Figure 6.5. The cluster binding energies and solute/solvent center-of-mass coordinates are listed in Table 6.5. For $H_2Pc(C_2H_6)_1$, a geometry nearly isoenergetic with geometry II is calculated but not shown. The geometry is largely the same as II but has the C_2H_6 long axis rotated by 90° about the H_2Pc symmetry z axis with respect to geometry II. The geometry has a binding energy of 1564 cm^{-1}. For $H_2Pc(C_3H_8)_1$, two additional cluster geometries are calculated and not shown. Geometry III is similar to geometry II in that the solvent C_2 axis lies perpendicular to the H_2Pc molecular plane; however, the C_3H_8 is inverted in this geometry with respect to geometry I. The cluster binding energy is 1975 cm^{-1}. Geometry IV is nearly isoenergetic with geometry I. The geometry is largely the same as II but has the C_3H_8 rotated by 90° about the H_2Pc symmetry z axis. This geometry has a binding energy of 2202 cm^{-1}.

a) The solute center of mass is located at x = y = z = 0 for all clusters.

C. H_2O, MeOH, and EtOH Clusters with H_2Pc and MgPc.

Figures 6.6 and 6.7 and Table 6.6 present the H_2O, MeOH, and EtOH, solute/solvent cluster spectra observed in the vicinity of their respective H_2Pc and MgPc 0_0^0 transitions. The H_2Pc cluster spectra are observed using P_o = 150 psig helium, T_e = 570°C, and T_b = 135°C. The MgPc cluster spectra are observed using P_o = 135 psig helium, T_e = 630°C, and T_b = 480°C.

The ground state geometries calculated for the above mentioned cluster series are shown in Figures 6.8 and 6.9. The cluster binding energies and geometry specifics are listed in Table 6.5. For $H_2Pc(EtOH)_1$, a geometry similar to geometry I is calculated but not shown. The cluster binding energy is 2053 cm^{-1}. This geometry has the EtOH rotated by 90° about the H_2Pc symmetry z axis with respect to I.

D. CO_2 Clusters of H_2Pc and MgPc.

The H_2Pc/CO_2 and $MgPc/CO_2$ FE spectra observed in the vicinity of the cluster chromophore 0_0^0 transitions are shown in Figure 6.10. The cluster transition energies are listed in Table 6.7. In these experiments, both backing pressure and CO_2 concentration are varied. As in the H_2Pc/hydrocarbon cluster experiments, no new or additional sharp cluster transitions are observed under these conditions. The ground state cluster geometries for $H_2Pc(CO_2)_1$ and $MgPc(CO_2)_1$ are shown in Figure 6.11. The cluster binding energies are listed in Table 6.5.

Discussion.

Before analyzing the individual cluster systems in detail, we will discuss the low frequency out-of-plane vibrational motion of isolated H_2Pc and MgPc. Elucidation of the out-of-plane motion in these molecules is essential to the understanding of the cluster spectra and

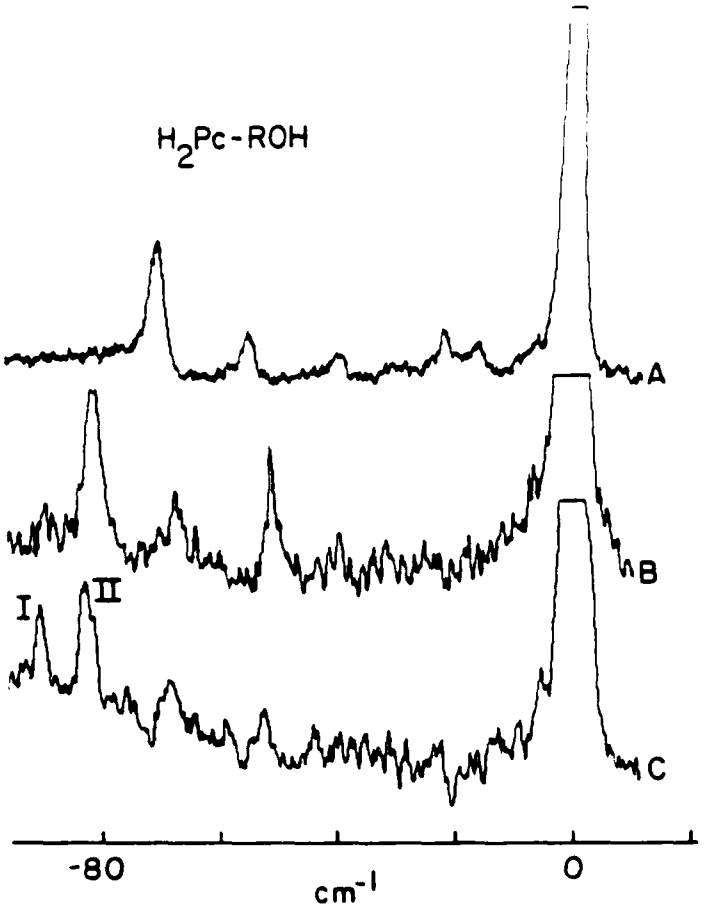

Figure 6.6

PE spectra of H_2Pc/ROH clusters in the vicinity of the H_2Pc 0_0^0. The spectra are obtained using T_e = 570°C, T_b = 435°C, and P_o = 150 psig He. Traces (A), (B), and (C) correspond to $H_2Pc(H_2O)_1$, $H_2Pc(MeOH)_1$, and $H_2Pc(EtOH)_1$, respectively. Peak assignments are given in Table 6.6.

in the identification of the number of different clusters of a specific composition observed. The nature of molecular motion associated with each spectral feature is determined by using the results of an out-of-plane normal coordinate analysis for isolated H_2Pc. Table 6.1 lists the nine lowest energy out-of-plane modes calculated. Given the qualitative nature of the force field used in the analysis, the calculated vibrational energies compare quite well with the fundamental energies inferred from the observed overtone transitions presented in Figure 6.2 and Table 6.2.

Three B_{1u} fundamentals are calculated at 14.8, 24.5 and 84.0 cm^{-1}. In the isolated H_2Pc spectrum, these vibrations are observed as symmetric overtones at 31.2 (A_0^2), 51.8 (B_0^2), 62.0 (A_0^4), and 163.7 (C_0^2) cm^{-1}. The symmetry forbidden fundamentals are thus located at 15.6, 25.9 and 81.9 cm^{-1} using a harmonic oscillator assumption. Two A_u modes calculated at 33.1 and 71.7 cm^{-1} correspond to the forbidden out-of-plane fundamentals at 35.7 and 70.9 cm^{-1} which are observed as overtones at 71.4 (D_0^2), and 141.7 (E_0^2) cm^{-1}. The two B_{2g} (B_{3g}) modes calculated at 38.6 (38.2) and 72.1 (71.4) cm^{-1} correspond to the fundamentals of the observed overtone transitions at 85.4 and 100.6 (F_0^2 or H_0^2) cm^{-1} and at 176 and 203.1 (G_0^2 or J_0^2) cm^{-1}. The low energy out-of-plane vibronic transitions in the vicinity of the MgPc origin are similarly assigned (Figure 6.3 and Table 6.3).

Five out of the nine lowest energy out-of-plane vibrations are responsible for the vibronic transitions observed in the first 100 cm^{-1} of the H_2Pc S_1 manifold. These five modes involve large amplitude displacements of the four isoindole groups comprising H_2Pc. The qualitative forms of the motion can be described by the two sets of

operations indicated in Figure 6.12: (a) the tilt of the isoindole groups around the line A through the pyrrole α carbons; and (b) the rotation of the isoindole groups around the line B between the inner ring nitrogens and the midpoint between outer benzene carbons. The B_{1u} vibration calculated at 14.8 cm^{-1} corresponds to (a) type motion in which a set of opposite isoindole groups tilts out of the molecular plane in one direction and other set of opposite isoindole groups tilts out of the plane in the opposite direction. The B_{1u} vibration calculated at 24.5 cm^{-1} is similar to the 14.8 cm^{-1} mode; however, all the isoindole groups tilt out of the plane about the A axis (Figure 6.12) in the same direction. The mode form looks similar to the forming of a "bowl" out of the phthalocyano skeleton. The A_u mode (33.1 cm^{-1}) involves type (b) motion of adjacent isoindole groups in one direction and the other two adjacent isoindole groups in the opposite direction. The motion looks like "ruffling" of the molecular skeleton. The B_{2g} mode (38.6 cm^{-1}) corresponds to (a) and (b) type motions of opposite isoindole groups. The vibration form is such that one set of the opposite groups tilts out of the molecular plane about A in different directions. The other set of opposite groups rotates about B in the same direction. Overall, the motion looks similar to the forming of a "chair" out of the phthalocyano moiety. The B_{3g} mode (38.2 cm^{-1}) form is similar to that associated with the B_{2g} mode. The motion is the same in both cases; however, the (a) and (b) motion is exchanged between the two opposite groups in the B_{3g} mode with respect to the motion in the B_{2g} mode.

Chromophore out-of-plane fundamental and/or overtone transitions are observed in the vicinity of the cluster origins (vide infra) for all of the H_2Pc and MgPc systems discussed below. The observation of the

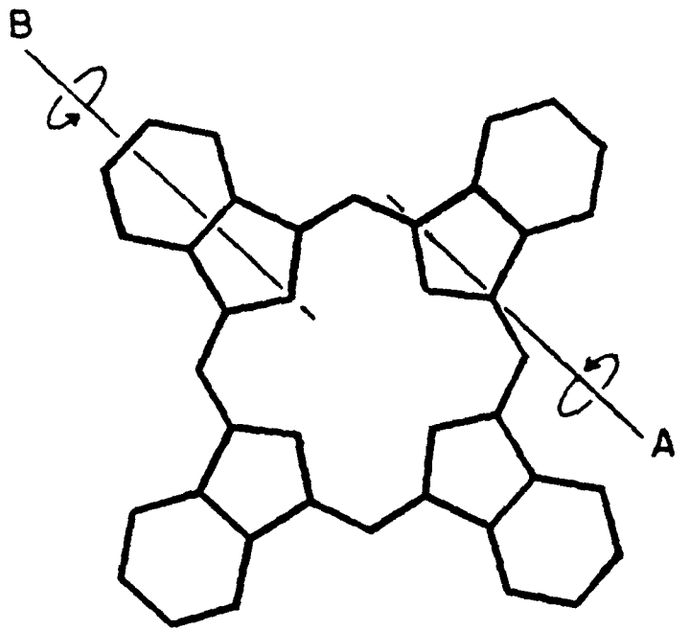

Figure 6.12

Operations showing qualitative out-of-plane vibrational motion in $H_2Pc/MgPc$.

cluster chromophore out-of plane fundamentals in the cluster spectra can be rationalized using the results of the above normal coordinate analysis and group theoretical arguments: clusters have reduced symmetry with respect to the isolated chromophore H_2Pc or MgPc but nearly identical chromophore molecular vibrations. For example, in the $H_2Pc(H_2O)_1$, the symmetry is reduced from D_{2h} to, at most, C_{2v} (see Figure 6.8). Under this reduced symmetry, the forbidden B_{1u} fundamental vibrations in isolated H_2Pc correlate to A_1 vibrations in C_{2v}. The modes are therefore fully allowed by symmetry and should, in principle, be observed if Frank-Condon factors are favorable.

vdW vibrational mode eigenvectors and eigenvalues have been calculated for a number of different solute/solvent systems, including benzene, pyrazine, etc. with many of the same solvents employed in this work.[10,11] Based on these previous studies, we can estimate that the lowest energy vdW modes for the H_2Pc and MgPc/solvent systems are ca. 50 cm^{-1}. Thus, features between cluster origins and ca. +50 cm^{-1} are most likely not vdW vibronic modes of the clusters. Moreover, these same studies demonstrate that high energy vdW modes (> 50 cm^{-1}) do not have large intensity due to poor Franck-Condon factors. A fuller discussion of these issues is presented below.

On the basis of the above notions, the cluster spectra are analyzed using four premises. First, the cluster transitions are identified as those features not associated with the isolated H_2Pc or MgPc moiety. Second, the cluster origins are assigned to be the lowest energy cluster transitions observed. Third, the cluster vibronic manifolds associated with each of the origins should, and do, exhibit chromophore out of plane fundamental and overtone transitions

commensurate with those observed and/or calculated for isolated H_2Pc or MgPc. And fourth, due to the similarity between the vdW potential surfaces for the chromophore S_0 and S_1 states and the relatively large energies (see below) of the vdW modes in these systems, little if any vdW vibronic mode intensity should be observed.

A. Hydrocarbon Clusters of H_2Pc and MgPc.

The H_2Pc/methane spectrum, Figure 6.4a and Table 6.4, exhibits a cluster transition at 14.6 cm^{-1} to the red of the H_2Pc 0_0^0. This transition is assigned to the 0_0^0 of a single H_2Pc/methane species. As discussed above, features 31.3 and 51.3 cm^{-1} to the blue of the cluster 0_0^0 correspond to cluster chromophore out-of-plane symmetric overtones, A_0^2 and B_0^2. Both transitions are shifted by -14.6 cm^{-1} with respect to their corresponding transitions in the isolated H_2Pc spectrum. The A_0^1 transition is not observed as it may be weak and/or within the linewidth of the H_2Pc isolated molecule 0_0^0.

The cluster transitions are most likely due to $H_2Pc(CH_4)_1$ since no new additional sharp transitions are observed when either the CH_4 concentration or the backing pressure is increased. Increasing the CH_4 concentration and/or backing pressure should yield higher order clusters. From prior experience with other solute/solvent cluster systems,[2-9] higher order clusters typically yield more than one set of cluster transitions. Additive shifts are also observed in most cases resulting from inhomogeneous nucleation processes in which solvent molecules bind symmetrically to opposite sides of the chromophore molecular plane.

The predominance of 1:1 solute/solvent clusters in the expansion may be rationalized on the basis of large solute/solvent binding energy

versus small solvent dimer binding energy. In the systems presently studied, the solute/solvent binding energies are sufficiently large that when a solvent dimer collides with a solute molecule, the dimer dissipates some of the cluster binding energy via vibrational predissociation. This interactive collision leaves one solvent molecule bound to the solute while the other solvent carries off enough of the cluster energy to stabilize the vdW bond until further collisional cooling can take place. These notions would lead one to conclude that 1:1 solute/solvent clustering predominates in the other clusters systems analyzed as well.

The existence of a single $H_2Pc(CH_4)_1$ geometry responsible for the cluster origin in the spectrum is further corroborated by the ground state configuration calculation depicted in Figure 6.5a. In this geometry, the CH_4 cluster subunit is situated above the H_2Pc plane and is coordinated to the π-cloud of the aromatic ring. The cluster geometry is interesting in the respect that the cluster solvent uniquely lies nearly over the H_2Pc core: none of the several potential cluster sites located over each of the H_2Pc closed ring subunits is apparently a true local minimum. One can envision three distinct cluster sites on the H_2Pc moiety: 1) above the H_2Pc core (most stable); 2) above one of its four five-membered rings; or 3) above one of its four six-membered rings (least stable). If all three of these sites were physically accessible, three different cluster spectral shifts should be observed corresponding to the three distinct sites. Since the single cluster origin in the spectrum suggests that only one geometry is stable, two out of the three speculated minima are either nonexistent or not sufficiently deep to accommodate bound state geometries. The observed

cluster origin at -14.6 cm^{-1} from the H_2Pc 0_0^0 probably corresponds to a geometry very similar to the calculated one (Figure 6.5a).

H_2Pc clustered with ethane, Figure 6.4b and Table 6.4, reveals two cluster origins at 25.9 and 18.8 cm^{-1} to the red of the H_2Pc 0_0^0. Two weak transitions to the blue of the H_2Pc 0_0^0 correspond to cluster chromophore out-of-plane vibrations A_0^2 built upon the two cluster origins. The transition at -10.3 corresponds to the fundamental of the out-of-plane cluster chromophore vibration A_0^1 (15.6 cm^{-1}) built upon the origin at -25.9 cm^{-1}. The cluster chromophore fundamental built upon the cluster origin at -18.8 cm^{-1} is not observed as it may be weak and/or within the linewidth of the H_2Pc 0_0^0.

These cluster manifolds most likely correspond to $H_2Pc(C_2H_6)_1$ clusters since, as in the $H_2Pc(CH_4)_1$ case, as both concentration and backing pressure are varied, the spectrum does not yield any additional sharp transitions. Furthermore, no additive spectral shifts are observed indicative of higher order clusters with ethane subunits situated above and below the H_2Pc plane. The same arguments used to rationalize the predominance of 1:1 clusters in the $H_2Pc(CH_4)_1$ case are applicable to this system as well.

The two $H_2Pc(C_2H_6)_1$ cluster geometries shown in Figure 6.5b support the assignment of two cluster geometries. Both geometries have the C_2H_6 situated over the center of the H_2Pc core as found for $H_2Pc(CH_4)_1$. Geometry I should yield a larger spectral shift than geometry II based upon polarizability arguments previously discussed for single ring cluster systems.[2,8] Briefly, the species with the larger spectral shift is associated with the solute/solvent relative orientation for which the direction of the large solvent polarizability is

perpendicular to the solute molecular plane. Using this argument, a geometry similar to I would be associated with the cluster origin 25.9 cm^{-1} to the red of the H_2Pc 0_0^0. As mentioned in the Results Section, two specific solvent orientations are consistent with the qualitative solute/solvent geometry of calculated $H_2Pc(C_2H_6)_1$ configuration II (see fig 6.5b). One would not expect a spectroscopic difference between the two geometries as they differ by a 90^0 rotation about the symmetry z axis of H_2Pc. These two directions as far as the H_2Pc moiety is concerned should be roughly equivalent in terms of polarizabilities and π-cloud overlap.

The H_2Pc/propane clusters, Figure 6.4c and Table 6.4, are assigned on the basis of similar arguments presented for the other two hydrocarbon clusters studied. In the spectrum, two $H_2Pc(C_3H_8)_1$ cluster origins appear at 33.4 and 25.1 cm^{-1} to the red of the H_2Pc 0_0^0. Two cluster vibronic manifolds to the blue of each origin are assigned to cluster chromophore vibronic fundamentals and first overtones. For the cluster manifold beginning at -33.4 cm^{-1}, the A_0^1 occurs at 14.8 cm^{-1} to the blue of the cluster 0_0^0. For the cluster manifold beginning at -25.1 cm^{-1}, the A_0^1 and A_0^2 occur at 15.7 and 31.4 cm^{-1} to the blue of the cluster 0_0^0.

Geometries similar to those shown in Figure 6.5c could be associated with the two observed cluster manifolds. Different spectral shifts for the two geometries most likely result from difference in π-cloud solvation. The propane solvent interacts less with the H_2Pc π-cloud in geometry II than in geometry I since the C_2 axis of the cluster solvent (direction of small polarizability) is perpendicular to the H_2Pc molecular plane in geometry II but parallel to the plane in

geometry I. A geometry similar to I could thus be responsible for the cluster manifold beginning at -33.4 cm^{-1} and a geometry similar to II could be associated with the manifold beginning at -25.1 cm^{-1}.

The $H_2Pc(C_2H_6)_1$ and the $H_2Pc(C_3H_8)_1$ spectra exhibit A_0^1 transitions which are forbidden in isolated H_2Pc. A similar change in selection rules upon clustering has been reported for the benzene/solvent systems.[2,9-11] In the latter systems, the observations suggest that the presence of the cluster solvent over the solute molecular plane is sufficient to induce the forbidden benzene 0_0^0 transition if the threefold rotation axis of the solute is destroyed. Furthermore, the selection rules governing the intermolecular vdW motion follow the reduced symmetry of the cluster systems. This minimum perturbation may also be the driving force which induces the vibronic transitions in the H_2Pc/hydrocarbon clusters. The perturbation in the present instance may even be large enough to cause the cluster chromophore to adjust its geometry in an attempt to wrap itself around the cluster solvents to establish optimal π-cloud overlap. The observation of the B_{1u} fundamental at 15 cm^{-1} serves as evidence supporting this notion as molecular displacement along this coordinate appears to yield favorable Franck-Condon factors. The A_0^1 transition is also observed in all the other H_2Pc and MgPc clusters studied as well. These observations would lead one to conclude that the clusters are not planar in the excited electronic state.

In general the H_2Pc/hydrocarbon cluster series is similar to the benzene and N-heterocycle/hydrocarbon cluster series previously studied.[2,8,10,11] The H_2Pc/hydrocarbon clusters $S_1 \leftarrow S_0$ transitions all exhibit bathychromic shifts with respect to the cluster chromophore

transition. The direction of the shifts is the same as that observed in the single ring cluster systems. These shifts indicate that the binding energies of the clusters become larger in the electronic excited state than in the ground state. Upon excitation, the cluster chromophore π-cloud expands and becomes more diffuse. The π-cloud can thus participate more effectively in intermolecular bonding. The net result is stabilization of the vdW bond and a larger binding energy in the cluster S_1 state relative to the S_0 state.

As in the single ring cluster systems, the H_2Pc/hydrocarbon cluster spectral shifts and calculated binding energies increase with increasing solvent size and π-cloud overlap. The shifts also depend upon the relative orientation of the cluster solute and solvent. The spectral shifts for the H_2Pc/hydrocarbon series are about a factor of two smaller than those observed in the single ring aromatic/hydrocarbon systems. The difference in the spectral shift magnitudes can be attributed to smaller changes in the intermolecular interaction resulting from smaller overall π-cloud overlap between the solute and the solvents at the H_2Pc core site. The conjugated π-electron path in H_2Pc circles around the core yielding a π-cloud "void" at the central core of the molecule. Thus, cluster solvents situated over the core do not overlap with the solute π-cloud as much as they do in single ring systems. The large size and extensive delocalization of the solute π-cloud may also be contributing factors since they minimize electron density changes at the binding site when an electron is promoted from a π- and a π^*-orbital.

The cluster geometries calculated for the H_2Pc/hydrocarbon series compare well with the geometries calculated, and in some cases

experimentally verified, for the single ring cluster series as far as the cluster solvent orientations are concerned. The geometries, however, are unique in the respect that both the spectra and the calculations suggest that the favorable binding site is the H_2Pc core and is not at peripheral ring centers.

The one major difference between the H_2Pc/hydrocarbon cluster spectra and the benzene/hydrocarbon cluster spectra is the absence of observable intermolecular vdW mode intensity in the H_2Pc cluster spectra. The lowest energy vdW motion (bending) is expected to be observed at about 50 cm^{-1} to the blue of the cluster origins based upon calculational modeling of intermolecular mode energetics.[10,11] The vdW stretch is expected to occur at about 100 cm^{-1} above the cluster origin. The absence of $\Delta v = \pm 1$ vdW mode transitions in the H_2Pc clusters may be due to poor Franck-Condon factors. The large size and extensive delocalization of the H_2Pc π-cloud yields little change in the electron density at the cluster site when a single electron is promoted from a π- to a π^*-orbital. Thus, one might expect that the intermolecular potential surfaces of the two states are nearly superimposable even though the binding energy of the excited state is slightly different (ca. 1%) than that of the ground state. The net result is the observation of vdW sequence structure ($\Delta v = 0$) giving rise to cluster origins and cluster chromophore vibrations only. These arguments probably hold for all the cluster systems investigated in this study as well.

B. H_2O, MeOH, and EtOH Clusters of H_2Pc and MgPc.

H_2Pc clustered with H_2O. Figure 6.6a and Table 6.6, yields a spectrum exhibiting a single cluster vibronic manifold with an origin 71.2 cm^{-1} to the red of the H_2Pc 0_0^0. The single cluster (chromophore)

vibronic manifold suggests that one H_2Pc/H_2O species is responsible for the observed spectrum. The spectrum is assigned to $H_2Pc(H_2O)_1$ based upon the same arguments developed for the H_2Pc/hydrocarbon clusters. The assignment is supported by the ground state configuration calculations for which a single geometry is obtained, Figure 8a. In this geometry, the H_2O is situated over the H_2Pc core. The transitions at 15.7, 31.2, and 47.6 cm^{-1} to the blue of the cluster 0_0^0 correspond H_2Pc out-of-plane vibrations A_0^1, A_0^2 and A_0^3. The feature at 55.1 cm^{-1} to the blue of the cluster 0_0^0 corresponds to the B_0^2 cluster chromophore transition.

Clustering H_2Pc with MeOH yields a cluster spectrum, Figure 6.6b and Table 6.6, associated with $H_2Pc(MeOH)_1$ which has an origin 82.0 cm^{-1} to the red of the H_2Pc 0_0^0. The cluster chromophore out-of-plane vibrations A_0^1 and A_0^2 are observed at 16.3 and 31.4 cm^{-1} to the blue of the cluster 0_0^0. The assignment of a single cluster manifold is supported by the single calculated ground state geometry obtained (Figure 6.8b).

H_2Pc cluster with EtOH, Figure 6.6c and Table 6.6, yields a spectrum exhibiting two cluster (chromophore) vibronic manifolds which can be assigned as due to two $H_2Pc(EtOH)_1$ species. The first cluster origin is at 90.9 cm^{-1} to the red of the H_2Pc 0_0^0 and the second cluster manifold begins at 83.3 cm^{-1} to the red of the H_2Pc 0_0^0. The cluster chromophore vibrations A_0^1 and A_0^2 can be identified in these manifolds at 16.1 and 31.7 cm^{-1}.

The two $H_2Pc(EtOH)_1$ cluster species responsible for the observed spectrum can be associated with geometries similar to those shown in Figure 6.8c. In geometry I the EtOH solvent interacts more with the H_2Pc π-cloud than in geometry II and, therefore, geometry I should

exhibit a larger spectral shift. Thus a geometry similar to I could be associated with the cluster whose origin is at 90.9 cm^{-1} and a geometry similar to II could be associated with the cluster whose origin is at -83.3 cm^{-1} with respect to the H_2Pc 0_0^0.

The H_2Pc/H_2O, /MeOH, and /EtOH cluster spectra suggest that the solvent OH group is intimately involved in the intermolecular interaction. The red shifts for all three clusters are similar and larger than those observed in the H_2Pc/hydrocarbon systems. The MeOH and EtOH cluster shifts are larger than that observed in the H_2O cluster suggesting that the shifts are dependent upon the combined effects of the OH group and the hydrophobic portions of the cluster solvents. If, on the other hand, the alkyl groups were pointing toward the solute, one would expect the spectral shifts for MeOH/EtOH clusters to be similar to those observed in the hydrocarbon clusters. In these geometries, the alkyl groups would be the major contributors in the intermolecular interaction.

The large spectral shifts, the interaction of the OH group with H_2Pc, and the ground state configuration calculations lead one to postulate that hydrogen bonding may be occurring in these cluster systems. Hydrogen bonding can occur to some extent between the solute inner ring nitrogens and/or pyrrole hydrogens and the solvent OH group: the H_2Pc inner ring nitrogens have large electron density[19,33] which can enhance the hydrogen bonding of solvent OH groups. Since the observed chromophore transition is $\pi^* \leftarrow \pi$, a large red shift can be expected.

The $MgPc(H_2O)_1$, $(MeOH)_1$, $(EtOH)_1$ cluster spectra, Figure 6.7 and Table 6.6, are very similar to one another. The $MgPc(H_2O)_1$ spectrum can be assigned as arising from two different cluster manifolds with origin

at 16.6 and 18.3 cm^{-1} to the blue of the MgPc 0_0^0. Cluster chromophore out of plane vibrations are observed for both manifolds. The A_0^1 and the A_0^2 are observed at 13.9 (11.2) cm^{-1} and 29.1 (29.8) cm^{-1} to the blue of the origins B_0^2 transitions are observed at 57.1 (56.9) cm^{-1}. The $MgPc(MeOH)_1$ and $MgPc(EtOH)_1$ spectra are similarly assigned.

The $MgPc(ROH)_1$ series differs from the $H_2Pc(ROH)_1$ series in three aspects. First, the $MgPc(ROH)_1$ spectra exhibit hypsochromic shifts with respect to the isolated MgPc spectrum. The direction of the spectral shifts indicate that the solute and solvents interact more strongly in S_0 than in S_1. The major difference between the two solute systems studied is the phthalocyano core environment; the pyrrole hydrogens in H_2Pc are replaced by a magnesium in MgPc. The hypsochromic shift suggests that the core is responsible for the larger ground state interaction. The greater stabilization in the ground state can, in principle, be due to interactions ranging from weak nonbonded vdW interactions to actual complexation in which the solvent donates an electron pair to the solute via the central metal atom.[19] On the basis of the size of the spectral shifts observed, the interaction is most likely due to weak vdW interactions. If the solvent were to donate significant electron density to the central Mg atom in MgPc (a coordination bond formation) or if the Mg were to move significantly out of the Pc molecular plane,[34] cluster formation would drastically perturb the chromophore electronic environment and yield relatively large spectral shifts. Observation of weak vdW interactions between MgPc and H_2O, EtOH, and phenol in the IR region leads to similar conclusions.[35]

Second, the spectral shifts in the $MgPc(ROH)_1$ series are virtually identical. This observation suggests that the OH group is

intimately involved in the interaction and, furthermore, is largely responsible for the observed spectral shifts. The ground state configuration calculations, Figure 6.9, support the notion that the OH group is the major contributor to the interaction. All three calculated geometries depicted in Figure 6.9 have the solvents situated so that the OH groups point towards the MgPc core. Moreover, one would not expect to observe sharp cluster transitions if the hydrophobic portions of the solvents were the major contributors to the interaction.

Third, the $MgPc(ROH)_1$ spectra show two nearly isoenergetic cluster origins and vibronic manifolds. These cluster features could be due to either two cluster species which are nearly spectroscopically identical or they could be due to the splitting of the two-fold degenerate chromophore S_1 state via vdW cluster formation. The former situation probably does not occur since these doublets are present in all the MgPc clusters observed. One would not typically expect to see this type of coincidence in the different cluster systems especially when two solvent series are considered. In MgPc clusters, clustering reduces the system symmetry (see Figure 6.9 for example) and the four-fold symmetry axis of the MgPc chromophore is destroyed. The degenerate Q band (E_u in D_{4h}) may thus split into Q_x and Q_y bands (B_{2u} and B_{3u} in D_{2h}); the splitting is small, however, due to the small perturbation caused by vdW clustering. Similar removal of degeneracies occurs for benzene clusters,[2,9,10] and for ground state vibrations of $MgPc/H_2O$, /EtOH, and /phenol systems.[35]

C. CO_2 Clusters of H_2Pc and MgPc.

H_2Pc clustered with CO_2, Figure 6.10a and Table 6.7, yields a spectrum with a single cluster origin blue shifted by 14 cm^{-1} with

respect to the isolated H_2Pc 0_0^0. The cluster manifold is assigned to a $H_2Pc(CO_2)_1$ species. Cluster chromophore out-of-plane vibrations A_0^1 (15.4 cm^{-1}) and A_0^2 (30.7 cm^{-1}) built upon the cluster origin are also observed. The calculated ground state geometry, Figure 6.11a, further supports the existence of a single cluster species responsible for the spectrum. In this geometry, the CO_2 moiety is situated over the H_2Pc core.

The $H_2Pc(CO_2)_1$ spectrum is different than the other H_2Pc clusters studied in that it is the only system exhibiting a hypsochromic shift. The exact nature of the interaction responsible for the spectral shift in this system is not known and more work on CO_2 solute/solvent systems is necessary to establish a firm argument. On the basis of the interactions responsible for the spectral shifts in the hydrocarbon and hydrogen bonded solute/solvent systems, the major interaction responsible for the shift appears to involve solvent/solute π-cloud overlap. In the ground state, the solute and solvent most likely interact through π-π interactions. Upon excitation the diffuse nature of the solute π^* state reduces the interaction between the π systems and results in a loss in S_1 binding energy relative to S_0.

MgPc clustered with CO_2, Figure 6.10b and Table 6.7, reveals a cluster spectrum with two parallel vibronic progressions. The appearance of the two cluster manifolds is probably due to the same type of electronic state splitting that occurs in the $MgPc(ROH)_1$ systems. The cluster origins are blue shifted by 17.9 and 22.6 cm^{-1} with respect to the MgPc 0_0^0. As in $H_2Pc(CO_2)_1$, well defined cluster chromophore vibronic transitions are observed. The A_0^1 and A_0^2 transitions built upon the origin at 17.9 cm^{-1} occur at 19.9 and 31.1 cm^{-1} to the blue of this

origin. The A_0^1 and A_0^2 transitions built upon the 22.6 cm^{-1} origin occur at 21.1 and 32.3 cm^{-1} to the blue of the origin. The existence of a single $MgPc(CO_2)_1$ species responsible for the cluster transitions is supported by the ground state configuration calculation shown in Figure 6.11b.

The $MgPc(CO_2)_1$ cluster spectrum differs from that of the other MgPc clusters studied in that the magnitude of the hypsochromic shift is smaller for $MgPc(CO_2)_1$. This difference can possibly be attributed to the difference in the major mode of interaction between the solute and solvent. In $MgPc(CO_2)_1$, the major interaction may be due to the same type of π-cloud interaction as suggested for the $H_2Pc(CO_2)_1$ interaction as the spectral shifts are comparable for the two systems. If the solvent oxygen/solute magnesium interaction were the major contributor, one could expect a larger hypsochromic shift comparable to those found for the $MgPc(ROH)_1$ systems.

Summary and Conclusions.

FE spectroscopy is used to probe the optical spectra of vdW clusters of H_2Pc and MgPc in the vicinity of the cluster 0_0^0 transitions. A continuous supersonic molecular jet capable of operating at tempera tures up to 650° C is employed to generate the ultracold molecular beam. Spectroscopic observables, such as spectral shift and forbidden chromo phore vibronic transitions, combined with computer modeling of ground state cluster intermolecular interactions, allow for the elucidation of the nature of the intermolecular potential and qualitative geometry of the H_2Pc and MgPc clusters studied. The conclusions drawn from this work are as follows:

1) The cluster vibronic spectra and theoretical calculations suggest that stable H_2Pc and MgPc clusters have solvents situated over the center of the phthalocyano core. Local minima over peripheral solute rings are either nonexistent or too shallow to accommodate minimum energy bound state geometries;

2) H_2Pc/hydrocarbon clusters are similar to the benzene and N-heterocycle/hydrocarbon clusters previously studied. The spectral shifts in these solute/solvent series are all bathychromic. The magnitudes of the spectral shifts increase with increasing solvent size and polarizability. The qualitative cluster geometries responsible for the observed spectra are similar with respect to solute/solvent orientation is concerned;

3) In both H_2Pc and MgPc clusters, the H_2O, MeOH, and EtOH moieties are situated over the Pc core in such a manner that the OH groups are intimately involved in the intermolecular interactions and contribute significantly to the spectral shifts;

4) Hydrogen bonding may be occurring to some extent between H_2Pc and solvent ROH moieties;

5) MgPc clusters display weak vdW interactions between the cluster solute and solvent. Actual complexation in which the solvent donates an electron pair to the solute does not occur;

6) Forbidden low frequency cluster chromophore out-of plane vibronic transitions are induced by clustering in both H_2Pc and MgPc systems. Intensity due to this motion arises from the reduction of the chromophore symmetry in the clusters. The perturbation may be large enough to cause the cluster chromophore geometry to change in an attempt to maximize π-cloud overlap with the solvent; and

7) Excited electronic state splitting occurs in the MgPc clusters due to the reduction in system symmetry upon cluster formation. The degenerate Q band appears to split into its two components, Q_x and Q_y.

CHAPTER SEVEN

UNPUBLISHED RESULTS

This chapter discusses the results of an out-of-plane normal coordinate analysis on H_2Pc and the results of the 2-color TOFMS experiments on H_2Pc and MgPc. These results are presented to establish an up-to-date record of our work in these areas and to outline the basic approaches used in the analyses.

Out-of-Plane Normal Coordinate Analysis on Isolated H_2Pc.

Out-of-plane fundamental and/or overtone vibronic transitions are observed in the vicinity of the 0_0^0 transitions in the H_2Pc and MgPc spectra as well as in all the H_2Pc and MgPc solute/solvent van der Waals clusters presented in Chapter 6. Elucidation of the out-of-plane motion in these molecules has proven useful in the understanding of the cluster spectra and in the identification of the number of different clusters of a specific composition observed. In this section, we report the details of the out-of-plane normal coordinate analysis on isolated H_2Pc. This normal coordinate analysis is used to determine the nature of the molecular motion occurring in both the H_2Pc(MgPc) molecule and H_2Pc(MgPc) cluster spectra.

The out-of-plane normal coordinate analysis on H_2Pc is conducted using the FG matrix methods described by Wilson et al.[1] These methods essentially involve expressing the secular equation of N-3 coupled harmonic oscillators describing the out-of-plane motion in matrix form

and solving for its N-3 non-zero eigenvalues and eigenvectors. To simplify the calculations, the molecular symmetry of H_2Pc is utilized to symmetry (block) factor the potential energy ($\underline{F}$) and kinetic energy ($\underline{G}$) matrices to yield "submatrices" each of which describes a particular species of vibrational motion dictated by the vibrational symmetry. The analysis is set up by 1) determining the symmetry of the vibrational motion, 2) selecting a complete set of internal coordinates to describe the motion, 3) obtaining the elements of the $\underline{F}$ and $\underline{G}$ matrices in this coordinate scheme, 4) constructing normalized symmetry coordinates using the complete internal coordinate set as a basis, and 5) symmetry factoring the $\underline{F}$ and $\underline{G}$ matrices using the symmetry coordinates.

The H_2Pc molecule is depicted in Figure 7.1a. This planar molecule contains 18 hydrogen atoms, 32 carbon atoms, and 8 nitrogen atoms, and has 55 out-of-plane normal vibrations that are distributed among the following irreducible representations under the D_{2h} point group:

$$\Gamma_{vib} = 15\ B_{1u} + 13\ A_u + 13\ B_{2g} + 14\ B_{3g}$$

Two types of internal coordinates are used to describe the H_2Pc out-of-plane vibrational motion, bond torsion and out-of-plane bond wagging. The bond torsion coordinate, Figure 7.1b, is defined in the situation when the atoms (2 and 3) at each end of a bond are also bonded to additional atoms (1 and 4) by bonds not colinear with the bond connecting atoms 2 and 3. The terminal bonds taken together with the connecting bond define two planes. Nuclear deformation may thus be expressed by the angle τ defined as the dihedral angle between the two

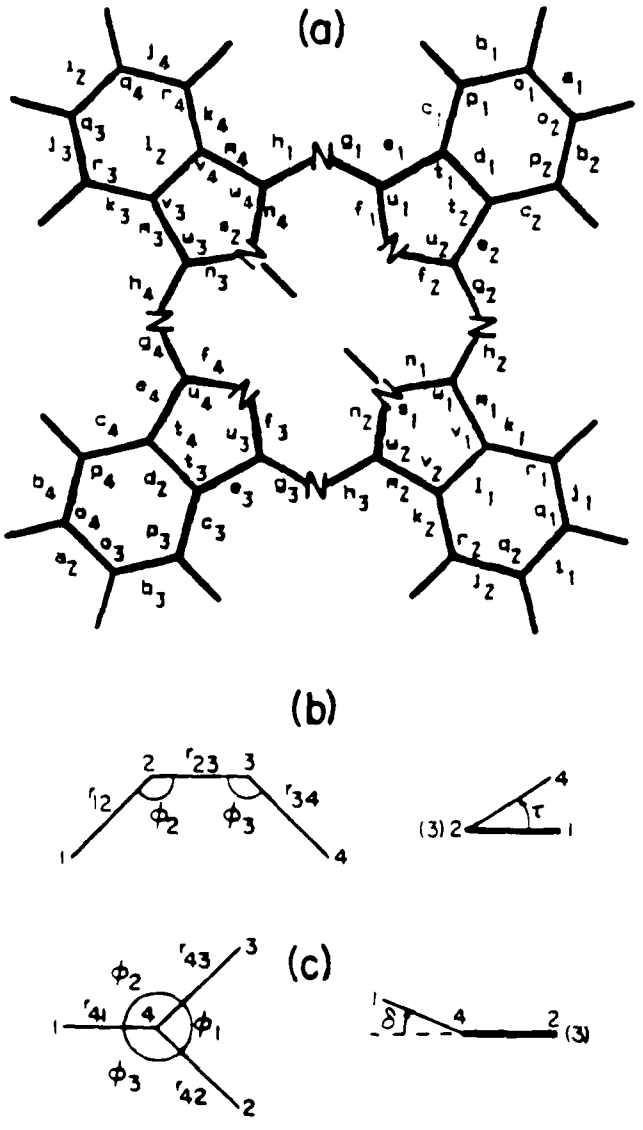

Figure 7.1

a) Out-of-plane internal coordinates used in H_2Pc NCA. Coordinates a-n are bond torsions and coordinates o-w are bond wags. b) Definition of bond torsion τ in terms of bond lengths and bond angles. c) Definition of bond wag γ in terms of bond lengths and bond angles.

planes. The displacement of the atoms in this internal coordinate for atoms 1-4 bonded in sequence is expressed by the following $\bar{s}$ vectors.[1]

$$7.1a \qquad \bar{s}_{\tau_1} = \frac{-\hat{e}_{12} \times \hat{e}_{23}}{r_{12} \sin^2 \phi_2}$$

$$7.1b \qquad \bar{s}_{\tau_2} = \frac{r_{23} - r_{12} \cos \phi_2}{r_{23}\, r_{12} \sin \phi_2} \frac{\hat{e}_{12} \times \hat{e}_{23}}{\sin \phi_2} - \frac{\cos \phi_3}{r_{23} \sin \phi_3} \frac{\hat{e}_{13} \times \hat{e}_{32}}{\sin \phi_3}$$

$$7.1c \qquad \bar{s}_{\tau_3} = [(14)(23)]\, \bar{s}_{\tau_2}$$

$$7.1d \qquad \bar{s}_{\tau_4} = [(14)(23)]\, \bar{s}_{\tau_1}$$

for which the terms in square brackets are permutation operators. Equations 7.1c and 7.1d thereby state that the s_{τ_3} and $\bar{s}_{\tau_4}$ vectors can be obtained by permutation of atoms 1 and 4, and 2 and 3 in the expressions for $\bar{s}_{\tau_1}$ and $\bar{s}_{\tau_2}$.

The out-of-plane wagging coordinate, Figure 7.1c, is defined at an atom for which three coplanar bonds are coincident. The deformation angle γ is formed by atoms 2, 3, and 4. The s vectors describing the atomic displacements in this internal coordinate are [1]

$$7.2a \qquad \bar{s}_{\gamma_2} = \frac{1}{r_{41}}$$

$$7.2b \qquad \bar{s}_{\gamma_2} = \frac{\sin \phi_2}{r_{42} \sin \phi_1}$$

7.2c $$s_{\gamma_3} \quad \frac{\sin\phi_2}{r_{13}\sin\phi_1}$$

7.2d $$s_{\gamma_4} \quad \frac{1}{r_{11}} \quad \frac{\sin\phi_2}{r_{12}\sin\phi_1} \quad \frac{\sin\phi_3}{r_{14}\sin\phi_1}$$

In order to obtain a kinematically complete set of internal vibrational coordinates, bond torsions are chosen at each non-terminal bond, and out of plane wagging coordinates are chosen at each atom for which three coplanar bonds meet.[2] This prescription yields 18 bond torsion coordinates and 34 out of plane wagging coordinates which completely describe the out of plane motion in the H_2Pc moiety. Twenty seven redundancies are distributed among the vibrational symmetries B_{1u}(4), A_u(9), B_{2g}(7), and B_{3g}(7) in this internal coordinate scheme. These redundancies are carried through the calculations so that symmetry coordinates can be used to block factor the secular equation into the four symmetry species sets.

The 18 bond torsion coordinates are located in [illegible] symmetry equivalent sets designated as a-h in Figure 7.1a. The atoms in each coordinate are number using a [illegible] convention [illegible] to define vectors with atom 1 moving in the [illegible] direction and atom 4 moving in the +z direction (Figure 7.1b). Positive [illegible] measured in a counterclockwise direction when looking down the bond between atoms 2 and 3 with atom 2 nearer to the observer. When two or more [illegible] in the molecule contain the bond torsion coordinate, the coordinate is oriented so that its terminal atoms point towards the H [illegible] center and its terminal bonds are situated in a _syn_ conformation.

The 24 out of plane wagging coordinates are located in 9 symmetry equivalent sets designated as o w in Figure 7.1a. The atoms in each coordinate are numbered using a counterclockwise convention (Figure 7.1c). Positive displacement in γ is measured by out of plane motion of atom 1 in the +z direction. Coordinates containing hydrogen (o s) are numbered so that the hydrogen atom is designated as atom 1. Coordinates t and v are oriented such that atom 1 corresponds to the benzene C-H carbon atom. Coordinates u and w are numbered so that the bridge nitrogen atom is designated as atom 1.

The elements of the $\underline{G}$ matrix are obtained using the internal coordinate s vectors (Equations 7.1 and 7.2) and

$$G_{tt'} = \sum_{\alpha=1}^{N} \frac{1}{m_\alpha} s_{t,\alpha} \cdot s_{t',\alpha}$$

(7.4)

for which $\frac{1}{m_\alpha}$ is the reciprocal of the mass of atom α. The non-zero terms in the summation are those corresponding to atoms common to the two internal coordinates t and t' in question. The geometric parameters used to determine the internal coordinate s vectors are based upon the results of a neutron diffraction analysis of H_2Pc.[7] These parameters are not modified, however, to reduce the total number of different G matrix elements that need to be calculated. In this approximation all the isoindole subunits comprising H_2Pc are assumed to contain identical interatomic distances and bond angles. The interatomic distances and bond angles are thus taken as average values of the parameters determined from the crystallographic data. The geometric parameters used in the calculations are presented in Figure 7.2. The G matrix elements calculated from Equations 7.1-3 are given in Table 7.1

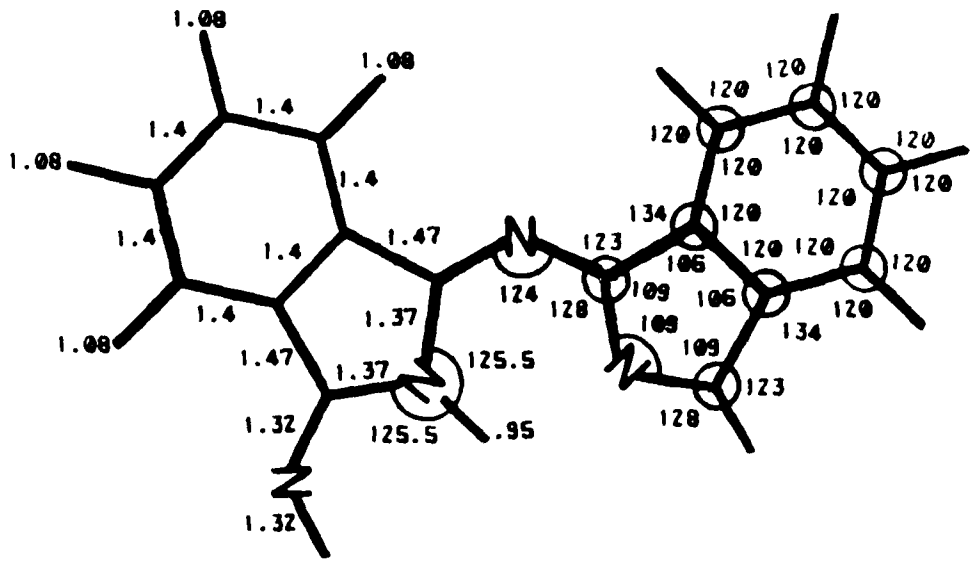

Figure 7.2

Geometric parameters used in H_2Pc NCA. Bond lengths are expressed in angstroms and bond angles are in degrees. The parameters are averaged to D_{4h} symmetry to simplify the calculations.

a) Only those elements necessary to generate the G matrix in terms of symmetry coordinates are shown

The elements of the F matrix in terms of the bond torsion and out-of-plane wagging coordinates, Table 7.2, are simply expressed as valence force constants $F_{tt'}$ for which t and t' correspond to the two internal coordinates in question. For the purpose of this calculation, the F matrix elements are taken as the diagonal force constants describing the out of plane motion of benzene [4]. In this approximation, all H_2Pc bond torsion force constants are assumed to be the same as those corresponding to the C-C torsions in benzene. The out of plane wagging force constants are assumed to be the same as those corresponding to benzene out of plane C-H wags. All off diagonal force constants are taken as zero. This force field scheme, even though not quantitatively accurate, will allow for the elucidation of the general nature of the out of plane motion in H_2Pc, as it will yield characteristic frequencies for the particular molecular segments participating in the various vibrational motions. No attempt is made to refine the force field [illegible] in the calculations since the experimental information on the out of plane vibrations in H_2Pc is limited to those possessing [illegible] infrared active [illegible] [illegible] Chapter 8. Thus the number of force constants that could be determined exceeds the number of experimental frequencies available.

a) From Chapter 6 and References 5-7.

frequencies obtained from the vibronic spectrum discussed in Chapter 6 and from infrared spectra.[5-7] The comparison between the experimental vibronic transitions and the calculated mode frequencies is made on the premise that the ground and excited state potential surfaces are nearly superimposable. This notion is demonstrated experimentally by FE and DE spectra of H_2Pc for which the vibrational energies in the S_1 and S_0 states differ by at most 5-10%.[8] Overall, the calculated frequencies compare quite well with those observed given the qualitative nature of the force field used in the analysis. Based upon this calculation, we propose tentative out-of-plane mode assignments for the experimentally observed out-of-plane modes.

The eigenvectors corresponding to the calculated vibrations are listed in Table 7.5. From the eigenvector normal mode forms, the out-of-plane motion can be qualitatively categorized into 1) macrocycle ring deformation, 2) isoindole ring deformation, and 3) C(N)-H out-of-plane wagging motion types.

The 0-100 cm^{-1} region is dominated by macrocycle ring deformation for which large amplitude out-of-plane motion of the four isoindole subunits occurs. This motion is located principally at the pyrrole α carbon/bridge nitrogen bonds (internal coordinates g and h). Modes 1, 2, 29, and 42 possess potential energy distributions (PED's) ranging from 40-70% in these coordinates.[9] From the H_2Pc vibronic spectrum presented in Chapter 6, these modes are observed as symmetric overtones at 31.2(1_0^1), 51.8(2_0^2), 85.4(100.6) (29_0^2 or 42_0^2), and 100.6 cm^{-1}(85.4 cm^{-1}) (42_0^2 or 29_0^2) which places their forbidden fundamental transitions at 15.6, 25.9, 42.7(50.3), and 50.3 cm^{-1}(42.7 cm^{-1}) respectively. Mode 3 is also observed in the far infrared at about

a) Symmetry coordinates contributing less than 1% to the potential energy distribution are not included.

[illegible] cm^{-1}). The eigenvector forms for modes 3, 16, 17, [illegible] and 13 are less characteristic in the g and h internal coordinates as they are dominated by pyrrole α-carbon/bridge nitrogen bond torsions (g and h) coupled with pyrrole skeleton torsion coordinates (e, f, and m). These modes occur in the [illegible] spectrum at [illegible] 71.4(16$_0^2$), 111.7(17[illegible] 176(20[illegible]) [illegible] and 264.1 cm^{-1}(176 cm^{-1}) [illegible] which places their forbidden fundamental transitions at 81.9, 35.7, 70.9, 88(101.6), and 101 cm^{-1} (88 cm^{-1}), respectively.

Isoindole ring deformation occurs mainly in the region between 100 and 700 cm^{-1}. The dominant out-of-plane motions in this region arise from the coupled deformation of the benzene and pyrrole moieties as can be seen by the large PED contributions from the a-f and i-n coordinates in Table 7.5. T. Kobayshi[5] has assigned far infrared bands at 127, 140, 282, and 342 cm^{-1} to isoindole ring deformations on the basis of comparative analyses of free base and metallophthalocyanines. These bands correspond to the calculated modes 4(145.3 cm^{-1}), 5(158.9 cm^{-1}), 6(230.5 cm^{-1}), 7(333.7 cm^{-1}), and 8(362.3 cm^{-1}), respectively. The far infrared studies also show that the band observed at 282 cm^{-1} contains contributions from both the isoindole ring and bridge nitrogen motions. The eigenvector form for mode 6 corroborates this assignment as it possesses a PED of about 25% in the pyrrole α carbon/bridge nitrogen torsion coordinates (g and h).

In the region between 700-1100 cm^{-1}, C(N)-H out-of-plane wagging dominates. From the eigenvector normal mode forms, the C-H vibrations are, for the most part, uncoupled from the H_2Pc ring modes as the out-of-plane wagging coordinates o-r account for between 71 and 97% of the PED's responsible for the motions. The infrared spectrum of H_2Pc

possesses bands at 725, 775, and 945 cm^{-1} which can be attributed to B_{1u} type out-of-plane C-H wagging.[7] The normal coordinate analysis reveals C-H wagging mode frequencies in this vicinity at 735.3 (mode 10), 739.6 (mode 11), 777.5 (mode 12), 962 (mode 13), and 967.8 cm^{-1} (mode 14). The only large discrepancy between the calculated frequencies and the experimental data involves out-of-plane (B_{1u}) wagging motion of the imino hydrogens. This mode is calculated to occur at 1014.4 cm^{-1} (mode 15) with a PED of 49% in the s internal coordinate, but it has been assigned to a band observed in the vicinity of 700 cm^{-1}[6,7] based upon isotopic substitution. Intramolecular hydrogen bonding between the imino hydrogens and adjacent core nitrogen atoms may account for the large difference between the calculated and observed/assigned modes. However, mode 9 calculated at 608.3 cm^{-1} is near the assigned N-H out-of plane wagging frequency and exhibits and 11% PED contribution from the N-H wagging coordinate, s, and 20% from the pyrrole torsion coordinate, m. Performing the normal coordinate analysis using deuterons at the pyrrole nitrogens results in mode 9 red shifting to 536.3 cm^{-1} ($\nu H/\nu D = 1.13$) and mode 15 red shifting to 916 cm^{-1} ($\nu H/\nu D = 1.11$). These results suggest that the mode responsible for the band observed at 711 cm^{-1} could be due to highly coupled motion between the N-H group and the pyrrole ring and not to characteristic N-H motion which should occur in the 900-1000 cm^{-1} region.

SUMMARY AND CONCLUSIONS:

An out-of-plane normal coordinate analysis is conducted on H_2Pc to characterize the large amplitude low frequency motion present in both the isolated H_2Pc and MgPc moieties as well as their respective vdW clusters with small solvents (see Chapter 6). The out-of-plane normal

coordinate analysis is conducted using the FG matrix method. The nuclear motion is modeled by a set of 82 internal coordinates; 48 C-C(N) bond torsions, 18 C(N)-H bond wags, and 16 C-C(N) bond wags. The force field used in the model consists of the diagonal force constants describing the out-of-plane motion in benzene. The resulting eigenvalues and eigenvector normal modes are compared with experiment and tentative assignments are proposed based upon the calculations. In the comparison, observed vibronic symmetric overtone transitions and infrared active B_{1u} vibrational transitions are utilized. Overall, agreement between the observed and calculated frequencies is excellent given the qualitative nature of the force field used in the analysis and the fact that the force field is not refined/fit to the experiments.

H_2Pc AND MgPc 2-Color TOFMS Experiments:

Ultracold 2-color TOFMS spectra of H_2Pc and MgPc could not be observed with the current experimental apparatus configuration available in the laboratory. In initial attempts to obtain 2-color TOFMS spectra of the macrocycles, spectra were observed which were not tunable when the pump laser frequency was varied. Both helium and argon carrier gases were employed to expand the molecules into the vacuum apparatus; however, the spectra were significantly broadened. These results are somewhat surprising since ultracold 2-color TOFMS spectra of small aromatic molecules such as benzene, pyrazine, and aniline have been observed in the existing apparatus.[10-12] One possible explanation for the nontunability is that the molecules are vibrationally/rotationally hot when they reach the section of the apparatus where the spectra are taken. In this case, molecular heating may occur in the section of the apparatus between the supersonic nozzle and the TOFMS flight tube.

In the existing apparatus,[12] Figure 7.3, the supersonic expansion is sampled using a compound angle conical skimmer.[13] The sampled portion of the supersonic expansion then travels about 50 cm to the TOFMS ionization area where it is optically probed. Based upon the aforementioned experimental observations, the expansion could be disturbed to some extent by the presence of the skimmer in the supersonic flow path. In order to understand the interferences in the supersonic flow which result in molecular heating, it is instructive to look at the physical properties of the supersonic expansion before, at, and after the skimmer.

Assuming that the expansion proceeds in an adiabatic and isentropic manner and that the expanding gases can be considered ideal, the centerline translational temperature T_1, the centerline static pressure P_1, and the centerline static density ρ_1 of the expansion before the skimmer can be described by[14]

$$T_1 = \left(1 + \frac{\gamma-1}{2} M_1^2\right)^{-1} T_o \qquad 7.4a$$

$$P_1 = \left(1 + \frac{\gamma-1}{2} M_1^2\right)^{\frac{-\gamma}{\gamma-1}} P_o \qquad 7.4b$$

$$\rho_1 = \left(1 + \frac{\gamma-1}{2} M_1^2\right)^{\frac{-1}{\gamma-1}} \rho_o \qquad 7.4c$$

as a function of centerline Mach number M_1, nozzle backing region stagnation temperature T_o, stagnation pressure P_o, stagnation density ρ_o, and $\gamma = C_p/C_v = 5/3$ for monatomic carrier gases. The centerline Mach

number is a function of downstream distance from the nozzle throat and can be expressed as[15]

$$7.5 \qquad M_1 = 3.26\left(\frac{x - .075D}{D}\right)^{\gamma-1} \Big/ \frac{1}{2}\left(\frac{\gamma+1}{\gamma-1}\right)^{3.26} \left(\frac{x - .075D}{D}\right)^{\gamma-1}$$

for which x is the centerline downstream distance and D is the supersonic nozzle throat diameter. Since the vacuum chamber pressure is finite, acceleration of the expansion will cease at a terminal Mach number which can be determined using Equation 7.4a and[14]

$$7.6 \qquad \frac{T_1}{T_o} = \left(\frac{P_i}{P_o}\right)^{\frac{\gamma-1}{\gamma}}$$

for which P_i is the vacuum chamber static pressure. For the continuous supersonic nozzle used in the experiments, typical nozzle backing pressures are around 150 psig. The static pressure in the vacuum chamber at this backing pressure is about 2×10^{-3} torr. The nozzle throat diameter is typically 100 microns. Using Equations 7.4a, 7.5 and 7.6, the centerline terminal Mach number for the expansion is calculated to be at $M_t = 36$ and is reached at about 4 mm downstream of the nozzle throat.

The supersonic flow properties are described by Equations 7.4-6 until the flow encounters the skimmer or until the flow passes through the Mach disk which is located at a downstream position determined by[15]

$$7.7 \qquad X_{MD} = .67\ D\left(\frac{P_o}{P_i}\right)^{1/2}$$

At the two-point [illegible] processes [illegible] must occur abruptly heat the flow and can return it to subsonic speed. In the experiment conducted, the supersonic flow is sampled at nozzle skimmer distances between 20 and 10 mm which is considerably less than the position of the Mach disk calculated to lie at 132 mm downstream using Equation 7.7.

Figure 7.4 presents the centerline temperature profiles for supersonic expansions beginning at T_o = 773 K and T_o = 298 K as a function of downstream distance x calculated using Equations 7.4 and 7.5 with the centerline terminal Mach number taken at 36. On the basis of the calculations, the temperature profiles for supersonic expansions beginning at elevated temperatures (T_o = 773 K) are largely the same as those beginning at room temperature (T_o = 298 K). Thus, H_2Pc and MgPc should, therefore, be nearly as internally cold before the skimmer as other species observed in the supersonic molecular jet generated by using room temperature expansions assuming that rotational and vibrational temperatures equilibrate near the translational temperature.[15,16] These notions are corroborated experimentally in FE for which ultracold spectra of H_2Pc, MgPc, and their respective solute/solvent clusters are observed. (The FE spectra are taken between 4 and 8 mm from the nozzle throat, well upstream of the Mach disk.)

Large deviation from isentropic flow may occur at the skimmer which can result in molecular heating. The interferences from the skimmer can be attributed to shock waves forming in the expansion as the flow passes through the skimmer. The physical properties of the supersonic flow after passing through the shock waves can be expressed as a function of upstream conditions and the angle of the shock waves with

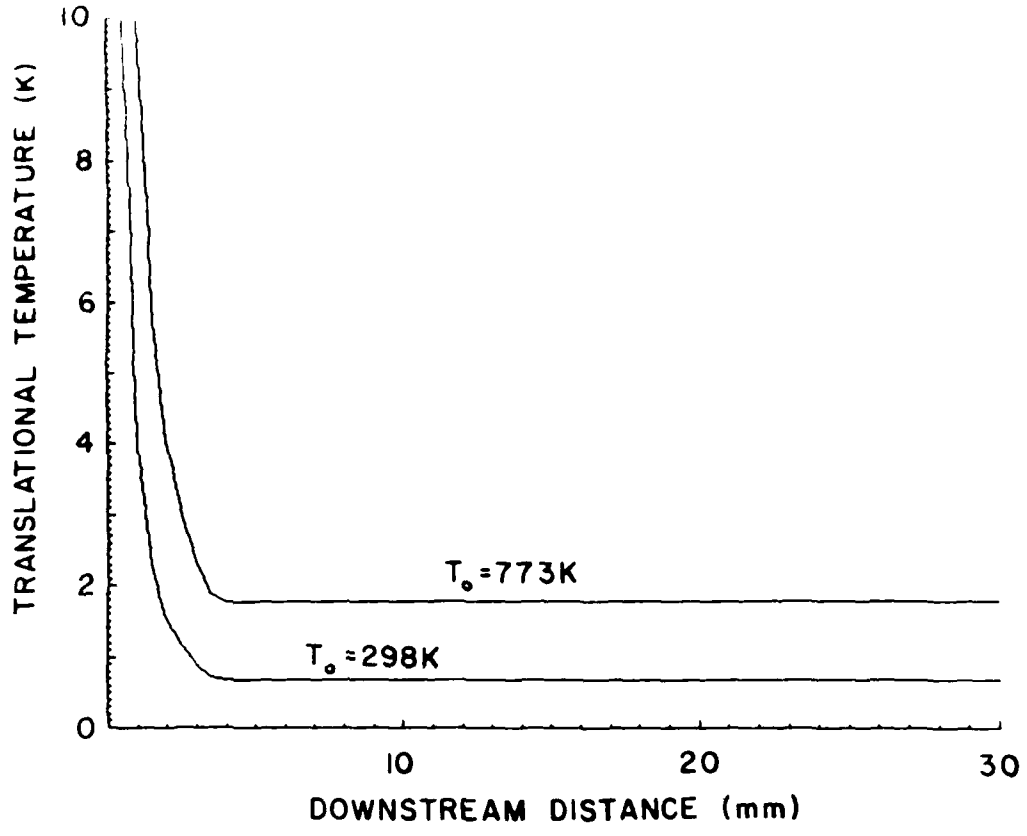

Figure 7.4

Downstream distance versus centerline translational temperature for supersonic expansions beginning at 773 K and 298 K.

respect to the flow direction. The centerline downstream translational temperature T_2, static pressure P_2, and static density ρ_2 are[11]

$$7.8a \qquad T_2 = \left(\frac{2\gamma}{\gamma+1} M_1^2 \sin^2 \varepsilon \frac{\gamma-1}{\gamma+1}\right)\left(\frac{\gamma-1}{\gamma+1} + \frac{2}{(\gamma+1)M_1^2 \sin^2 \varepsilon}\right) T_1$$

$$7.8b \qquad P_2 = \left(\frac{2\gamma}{\gamma+1} M_1^2 \sin^2 \varepsilon - \frac{\gamma-1}{\gamma+1}\right) P_1$$

$$7.8c \qquad \rho_2 = \left(\frac{(\gamma+1)\, M_1^2 \sin^2 \varepsilon}{2 + (\gamma-1)\, M_1^2 \sin^2 \varepsilon}\right) \rho_1$$

for which M_1 is the Mach number just upstream of the shock wave and ε is the flow deflection angle between the shock wave and the flow direction. Downstream/upstream translational temperature ratio versus flow deflection angle for an upstream Mach number of 36 is plotted in Figure 7.5. The plot demonstrates the severe heating effects that can occur in the flow as it passes through the shock wave. The most severe case is at $\varepsilon = 90^0$ which corresponds to a normal shock wave. Here, the downstream temperature is about 405 times the upstream temperature. Even at smaller flow deflection angles (oblique shock waves), the heating is significant. For example at $\varepsilon = 10^0$, the downstream temperature is a factor of 13 greater than the upstream temperature.

Bier and Hagena have shown, by Schlieren photographs, the types of possible skimmer interferences present in the expansion.[17] At large nozzle/skimmer distances, the shock wave system in the expanding jet gas is similar to that depicted in Figure 7.6a, for which the supersonic flow is contained in oblique and normal shock (Mach disk) waves. In

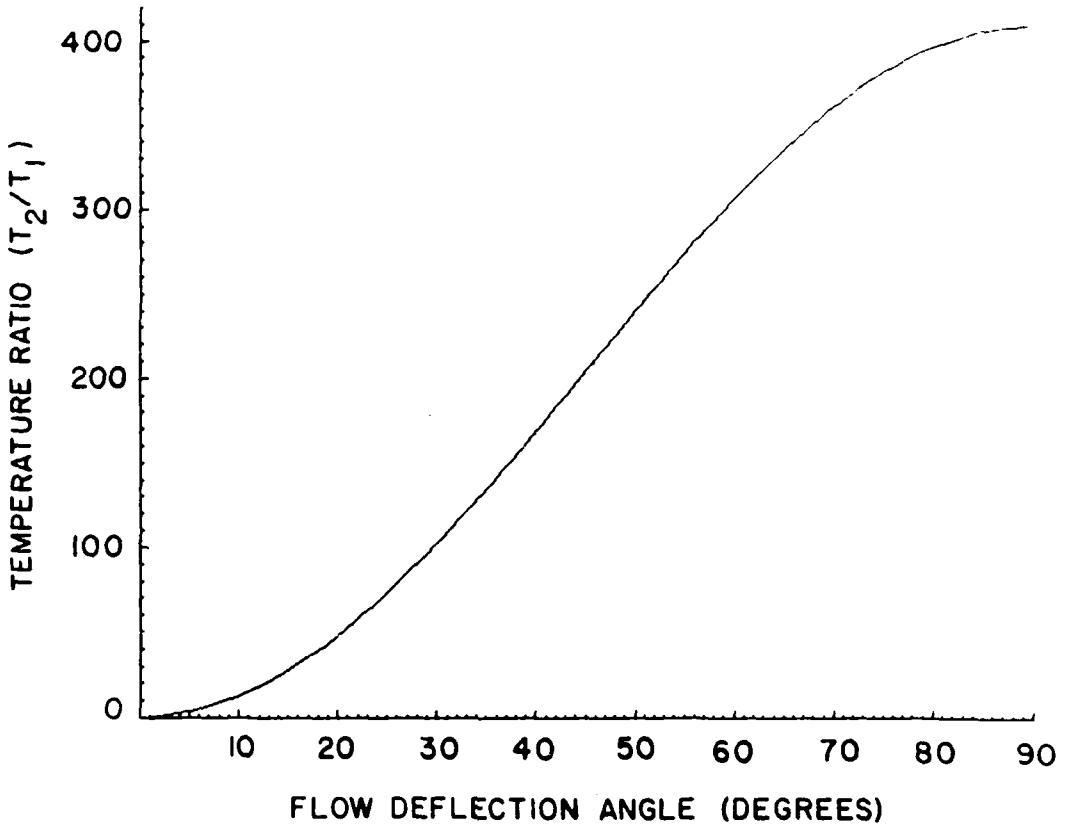

Figure 7.5

Flow deflection angle versus downstream/upstream centerline translational temperature ratio for flow across a shock wave at an upstream Mach number of 36.

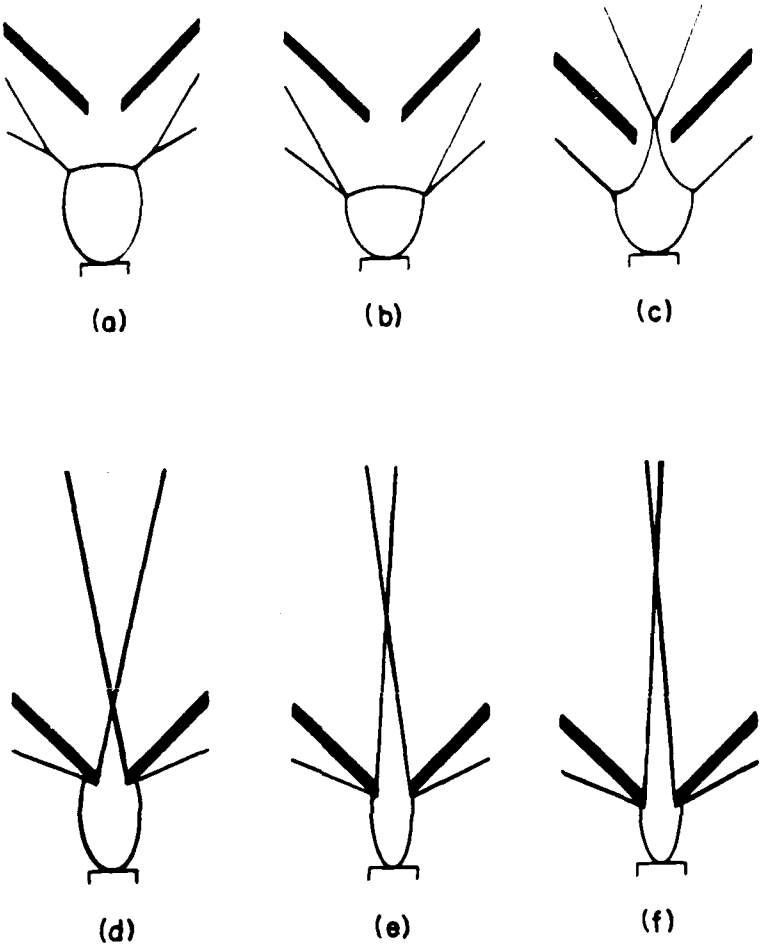

Figure 7.6

Shock wave system in a supersonic molecular jet expansion in the presence of a skimmer downstream of the nozzle throat.

this case, the skimmer orifice lies in the subs[illegible] flow downstream of the normal shock wave. The normal shock wave heats [illegible] molecules penetrate the shock wave boundaries. This interference is the most severe source of nozzle beam heating since all molecules entering the skimmer are in subsonic flow and internally hot. As the nozzle is moved towards the skimmer, the shock system in the jet stream is deformed, and the shock waves move towards the nozzle, Figures 7.6b-7.6c. Here, the normal shock wave is still detached from the skimmer orifice and results in "shock beam" formation. On further approach of the nozzle to the skimmer, the normal shock wave attaches to the skimmer orifice, Figures 7.6d-7.6f. The normal shock wave becomes oblique shock waves on both the upstream and downstream sides of the skimmer. The oblique shock wave upstream of the skimmer should not affect the supersonic flow at this nozzle/skimmer distance unless the skimmer mount or chamber walls are in close proximity of the skimmer orifice. Molecules entering the skimmer are in supersonic flow and may be subsequently heated upon traversing the oblique shock waves downstream of the skimmer. The amount of heating which occurs in the downstream oblique shock system depends upon the static pressure behind the skimmer and upon the flow deflection angle.

Molecular heating which occurs in the shock waves can be thought of as a sequence of collisional energy transfer processes up the molecular vibrational and rotational manifolds. Each elementary step involves the deposition of a small amount of vibrational and rotational energy at the expense of translational energy. Since single ring systems yield ultracold 2-color TOFMS spectra and the macrocycles do not, differences must exist between the collisional energy transfer

processes present in the shock waves at or near the skimmer for the molecular systems considered. Two major distinctions can be cited between the single ring systems and H_2Pc/MgPc which may play a significant role in accounting for the difference in molecular heating by the shock system. First, the macrocycles are about 3 times larger in diameter than the single ring systems. Approximating the molecules as hard spheres, one finds that H_2Pc/MgPc will undergo between 6 and 9 times more collisions in the shock system than the single ring molecules depending upon whether they collide with carrier gas molecules or with other macrocycles. Second, H_2Pc and MgPc possess a large number of vibrational modes compared to the single ring systems (168 for H_2Pc versus 30 for benzene); in particular, many of these modes are of low frequency. H_2Pc has nine ground state vibrational modes with energies below 100 cm^{-1}. These low-lying vibrational levels may facilitate heating of the macrocycles. As the large molecules pass through the shock system, the interconversion of small amounts of translational energy into vibrational energy should be more efficient than in the single ring systems for which the lowest ground state vibrational levels lie at about 400 cm^{-1}. Either or both of these two factors may contribute to the molecular heating of the macrocycles.

Since the skimmer used in the initial experiments did not perform satisfactorily in maintaining internally cold H_2Pc/MgPc beams, a new skimmer was designed to minimize the shock wave effects on the supersonic flow. Particular attention was focused upon the length of the skimmer, the diameter of the skimmer orifice and the interior and exterior skimming angles.

The length of the skimmer is important since the skimmer must be sufficiently long so that the oblique shock wave system does not cause flow perturbations about the skimmer orifice due to skimmer mount or vacuum chamber wall interactions. These interactions tend to degrade supersonic beam skimming by creating a boundary layer at the skimmer mount or chamber walls which rotates the attached shock wave towards a critical angle (more normal to the supersonic flow) which could yield shock wave detachment and the formation of a bow shock wave similar to that shown in Figure 7.6b-7.6c.[17,18]

The diameter of the skimmer orifice dictates the gas throughput of the skimmer.[19] Too large a skimmer diameter will cause TOFMS chamber pumping problems as well as an increase in the intensity of the oblique shock wave system downstream of the skimmer orifice.

The internal skimming angle must be as large as possible to insure that molecules entering the skimmer orifice and striking the skimmer walls can be pumped away fast enough to minimize scattering/heating of the beam molecules.[19,20] Too small an internal skimming angle will cause skimmer choking and boundary layer formation which results in an increase in the oblique shock wave intensity downstream of the skimmer orifice, similar to that occurring if the skimmer orifice diameter is too large.

The exterior skimming angle determines the upstream flow deflection caused by the skimmer. The angle must be kept small enough so that the oblique shock wave will not detach from the skimmer orifice and destroy the supersonic flow before the molecules pass through the skimmer. The maximum flow deflection angle ϵ_{max} which can be negotiated by a supersonic flow without shock wave detachment is given by[14]

$$7.9 \qquad \sin^2\varepsilon_{max} = \frac{1}{\gamma M_1^2}\left(\frac{\gamma+1}{4} M_1^2 - 1 + \left[(\gamma+1)\left(1+\frac{\gamma-1}{2} M_1^2 + \frac{\gamma+1}{16} M_1^4\right)\right]^{1/2}\right)$$

as a function of Mach number M_1 at the skimmer orifice. The maximum flow deflection angle is related to the maximum exterior skimming angle δ_{max} and skimmer Mach number by[14]

$$7.10 \qquad \frac{1}{\tan \delta_{max}} = \left(\frac{9(\gamma+1)}{20} \frac{M_1^2}{M_1^2 \sin^2 \varepsilon_{max} - 1} - 1\right) \tan \varepsilon_{max}$$

The maximum flow deflection angle and the maximum exterior skimming angle are plotted versus Mach number in Figure 7.7.

From Figure 7.7, the maximum flow deflection angle and the maximum exterior skimming angle approach limiting values at Mach numbers above 6. The high Mach number of the supersonic flow used in the experiments thus makes it possible to use a skimmer with exterior skimming angles of up to 46^o. 41^o was selected for the exterior skimming angle used in the new skimmer to provide a safety factor to avoid the occurrence of a normal detached shock upstream of the skimmer orifice. A 35^o interior skimming angle was selected for the new skimmer as it was the largest feasible angle with respect to the exterior skimming angle that the skimmer could be ground without causing structural problems. The skimmer shape was chosen as conical. The length of the skimmer was selected at 47 mm using the exterior skimming angle and a skimmer base diameter of 35 mm. This length is about a factor of 2 larger than that of the skimmer utilized in the initial TOFMS experiments. This larger skimmer should minimize possible upstream boundary layer and chamber wall effects.[14,19,20] The maximum diameter of the skimmer orifice was selected at 2 mm to avoid TOFMS chamber pumping

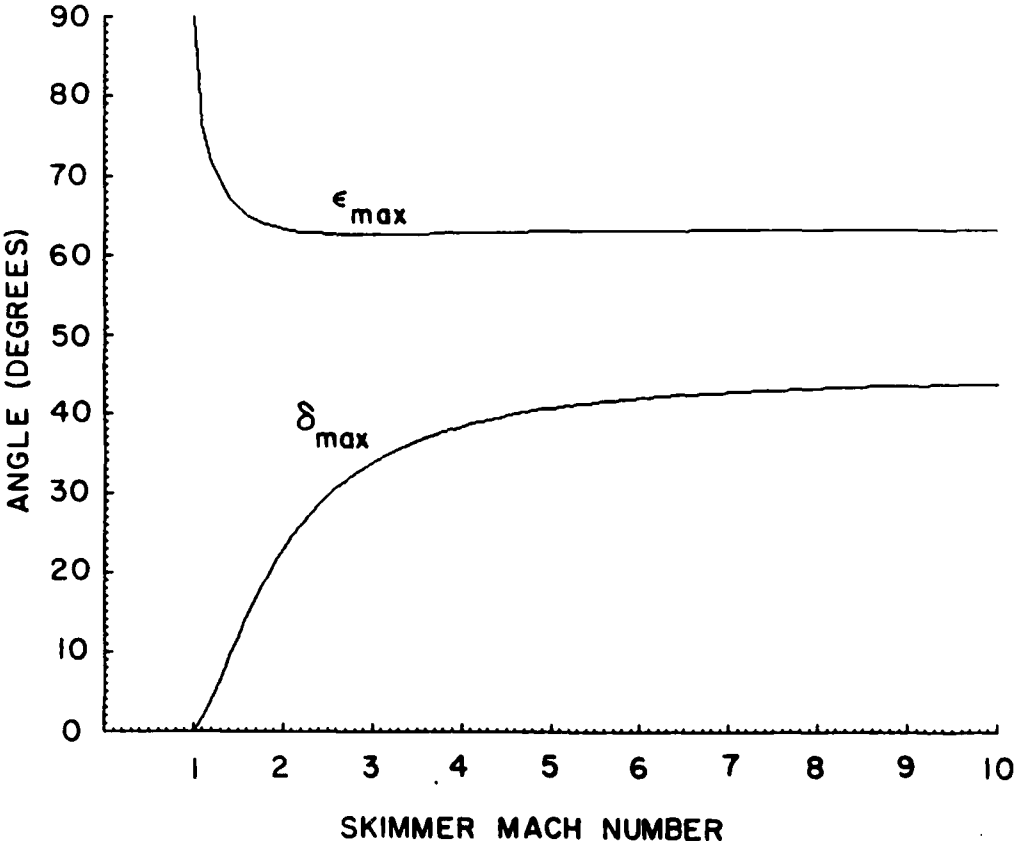

Figure 7.7

problems. Three skimmers were fabricated possessing the above length, skimming angles, and orifice diameters of .5, 1, and 2 mm in order to determine the optimal skimmer configuration since no theoretical relationship exists between skimmer orifice diameter and supersonic flow characteristics. These skimmers should give an indication of the interference caused by the oblique shock system downstream of the skimmer. The intensities of the shock waves should decrease with decreasing skimmer orifice diameter on the basis of skimmer throughput, boundary layer, and skimmer choking arguments.

2-color TOFMS spectra of H_2Pc taken using the three skimmers are shown in Figure 7.8. The spectra are taken using 428^oC nozzle backing region temperature, 560^oC nozzle tip temperature, 25 mm nozzle/skimmer distance, and 2.5 psig argon nozzle backing pressure. On decreasing the skimmer orifice from 2 to .5 mm, the spectra evolve from being broad and featureless (trace A) to being "quasi" cold (trace C). In both traces B and C, the H_2Pc 0_0^0 and A_0^2 are observed; however, the spectra are smeared out by rotational broadening and vibrational sequence congestion. The sequence structure in trace C is about 40 cm^{-1} wide and peaks at about 16 cm^{-1} to the red of the H_2Pc 0_0^0. Similar sequence structure is also observed to the red of the A_0^2. Assuming a 10% decrease in vibrational frequency between the ground and excited states for H_2Pc, a vibrational temperature of about 150 K can be estimated from the observed sequence structure.

These experiments identify the skimmer as being the major source of interference in the supersonic expansion. In particular, the observations suggest that the downstream oblique shock system is responsible for the molecular heating since the interference decreases with

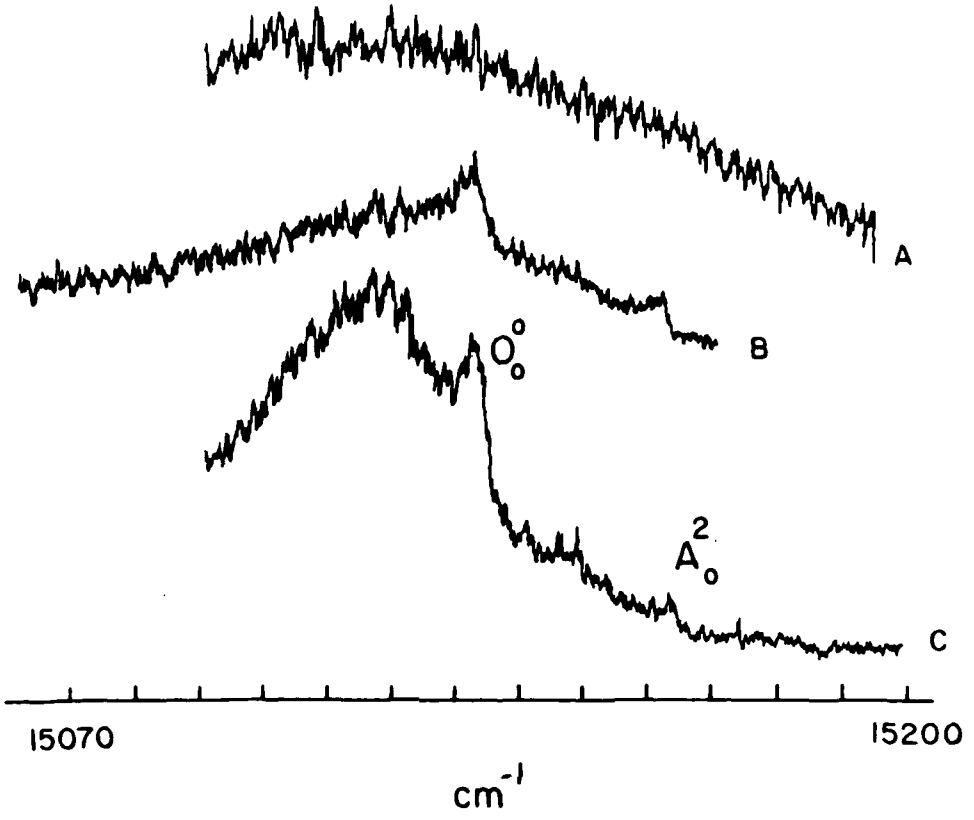

Figure 7.8

2-color TOFMS of H_2Pc in the vicinity of the Q_x band 0_0^0. Trace A taken using a 2 mm skimmer orifice. Trace B taken using a 1 mm skimmer orifice. Trace C taken using a .5 mm skimmer orifice.

decreasing skimmer orifice diameter. The maintenance of at least some degree of cold internal temperatures in the spectrum taken using the .5 mm orifice skimmer (trace C) demonstrates that the downstream shock wave intensity is still large enough to cause observable skimmer interference in the supersonic flow. This notion is corroborated by experiments using higher backing pressures of argon carrier gas (up to 50 psig) which yield broad spectra that can be attributed to an increase in the downstream skimmer interferences similar to those observed using the 2 mm orifice skimmer.

As mentioned above, the intensity of the downstream oblique shock wave depends upon the static pressure in the vacuum chamber directly downstream of the skimmer. In order to minimize the interference caused by the downstream shock system, the static pressure in this area should be kept lower than the upstream static pressure so that skimmer choking and boundary layer formation does not occur.[14,19,20] In the existing apparatus (Figure 7.3), the region between the skimmer and the TOFMS chamber is constructed using two lengths of 2 inch diameter (4 1/3 inches long) and 3 1/2 inch diameter (4 1/3 inches long) tubing and a 3 inch gate value assembly (4 1/3 inches long). The region directly downstream of the skimmer is displaced by about 70 cm from the TOFMS chamber diffusion pump. The tubing between the two vacuum chambers essentially forms a "dead end" region with a leak provided by the skimmer which may not be adequately evacuated by the TOFMS chamber pumping system. A pressure gradient may thus be present in this region which may give rise to the shock system interference observed.

Other vacuum systems[21] which utilize skimmers to sample the supersonic expansion differ in design from our existing apparatus.

These systems possess two key design features that minimize the effects of the downstream shock waves. First, the vacuum systems are designed for the efficient removal of gas molecules from the post-skimmer region by pumping directly downstream of the skimmer with pumps capable of sustaining static pressures of about 10^{-6} torr. Second, the systems allow for minimization of chamber wall/boundary layer effects in the post-skimmer region by making the chambers large and divergent with respect to the skimmer base. Neither of these features is incorporated in the existing apparatus design.

A proposed modification to the existing apparatus which incorporates the aforementioned design features is shown in Figure 7.9. The modification involves replacing the 3 inch gate valve, the interchamber tubing, and the 6 inch chamber connecting ports with 12 inch connecting ports and a 16 inch port flange with a divergent hole bored in its center. The 12 inch connecting ports will provide for more than adequate divergence downstream of the skimmer as well as provide for more efficient pumping of the region by the existing TOFMS pumping system. The 16 inch flange serves as both a chamber divider and as a skimmer mounting surface. The skimmer can be mounted in the chamber by clamping its base over the hole in the 16 inch flange with a small flange assembly. For FE experiments, the skimmer can be removed a a sealing plate can be placed over the flange hole to isolate the FE chamber from the TOFMS chamber. The connecting ports can be constructed with different lengths so that the 16 inch flange/skimmer assembly can be located closer to the TOFMS flight tube. This will allow for an overall shorter nozzle/TOFMS ionization area distance which should increase the molecular density at the ionization area by a factor of $2500/X_2$ for which X is the nozzle/TOFMS ionization area distance in cm.

SUMMARY AND CONCLUSIONS:

Initial attempts to obtain ultracold 2-color TOFMS spectra of H_2Pc and MgPc yielded negative results. Both helium and argon carrier gases were employed to expand the macrocycles into the vacuum apparatus; however the spectra were significantly broadened. The nontunability of the spectra with varying pump laser frequency was attributed to molecular heating of the H_2Pc and MgPc moieties by shock waves in the vicinity of the skimmer used to sample the supersonic expansion. New skimmers were designed to minimize the shock wave effects on the supersonic flow. "Quasi" cold 2-color TOFMS spectra of H_2Pc were obtained using these skimmers. Experiments identified the skimmer as being the major source of interference in the molecular expansion. In particular, the observations suggest that a downstream (Chamber II) oblique shock system is responsible for the molecular heating. Through identification of key apparatus design factors which should minimize the downstream shock wave effects, proposed modifications to the existing laboratory apparatus are suggested. The proposed modifications involve enlarging the region downstream of the skimmer to allow for more effective pumping and to minimize skimmer choking and boundary layer effects in the post-skimmer region.

CHAPTER EIGHT

FUTURE EXPERIMENTS AND CONCLUSIONS

This chapter presents the basic ideas and motivations for future experiments which can be conducted using the techniques and experimental set-ups currently available in the Bernstein group laboratory. The proposed studies entail those experiments that will extend or complement the work presented in this dissertation. This chapter also summarizes the conclusions drawn from the work accomplished on the molecules and clusters presented in Chapters 2-7. The conclusions include the most important results obtained from the work. For specific conclusions pertaining to each of the systems studies, the appropriate chapters in the dissertation should be consulted.

Future Experiments.

Effects of Macrocycle Ring Substitution on Solvation - The high temperature supersonic molecular jet techniques utilized to study H_2Pc, MgPc, and their respective vdW clusters with small solvents (Chapter 6) also gives us the opportunity to study the effects of ring substitution in the macrocycles on their solvation properties in an ultracold isolated environment. For example in the H_2Pc and MgPc cluster studies, major differences exist between the two cluster solutes in that the H_2Pc clusters exhibit enhanced stabilization in the S_1 state relative to the S_0 state whereas the MgPc clusters exhibit enhanced stabilization in the

S_0 state relative to the S_1 state. This difference appears to be due to the magnesium substitution in the phthalocyano core. Furthermore, the spectra suggest that the intermolecular interactions between MgPc and solvents having lone electron pairs possess major contributions from the central magnesium atom and the solvent electron pairs.

These observations pose several questions pertaining to the physics and chemistry responsible for the solvation properties of the phthalocyanines (Pc's). Questions that can be considered include: 1) are the solvation properties of Pc's dependent upon the specific metal atom present in the phthalocyano core; 2) does the relative stabilization of one electronic state over another depend upon the specific central metal atom; 3) do cluster geometries and solute solvation sites change significantly with different central metal atoms; and 4) are the central metal atoms in the Pc moieties responsible for a major portion of the intermolecular interaction.

To explore the effects of central metal atom substitution in Pc's, initial experiments can be conducted on zinc phthalocyanine (ZnPc). The fluorescence quantum yield for ZnPc is about .3 which is comparable to those for H_2Pc (.7) and MgPc (.6).[1] This quantum yield is large enough to allow for observation of ZnPc and its respective vdW clusters in fluorescence excitation experiments. The experiments could initially entail clustering ZnPc with solvents such as those used in the H_2Pc and MgPc studies. By comparing the ZnPc cluster spectra and calculated cluster geometries with those for the MgPc cluster systems, the effects of the central metal atom on cluster properties can be explored. Subsequent experiments in this area could include spectroscopic and modeling studies on Pc's containing cadmium, sodium, and lithium.

Another set of experiments which can be conducted to study the effects of ring substitution on the Pc solvation properties involves the analysis of a tetrabenzoporphyrin (TBP) solute series clustered with various solvents. Macrocycles which can be initially studied in this class include free base tetrabenzoporphyrin (H_2TBP), magnesium tetrabenzoporphyrin (MgTBP), and zinc tetrabenzoporphyrin[2] (ZnTBP). This class of compounds offers the opportunity to study the effects of the solute bridge nitrogens on the solvation properties of the Pc class as H_2TBP, MgTBP, and ZnTBP differ from their respective Pc analogues only by replacement of the bridge nitrogens in Pc by methine bridges in TBP. The TBP compounds proposed for study also possess fluorescence quantum yields (.46 for H_2TBP, .55 for MgTBP, and .35 for ZnTBP)[1] which are favorable for observation in a supersonic molecular jet fluorescence excitation experiment. Through the analysis of the cluster spectral shifts, chromophore vibronic structures, and calculational modeling of the cluster geometries and binding energies, the effects of the bridge nitrogens on the macrocycle solvation properties may be established. Cluster studies using the TBP solutes are interesting and important as they will provide the link between the Pc's and their biologically active analogues, the porphyrins, in regard to cluster geometry, binding energy, preferred solute solvation sites, and major interaction types responsible for solvation.

Aromatic Solute/Aromatic Solvent Clusters - All the aforementioned Pc and TBP solutes can be clustered with a number of small aromatic solvents such as benzene, pyrazine, pyrimidine, and pyridine. Studying these clusters gives us the opportunity to explore cluster

energetics and dynamics from the point of view of both the cluster solute and solvent. Supersonic molecular jet studies can be conducted by probing both the Pc/TBP solute and the benzene/N-heterocycle solvent optical transitions. The studies will yield insight into the importance of the solvent aromatic π cloud and/or nonbonded electron pairs on solvation. For example, clustering MgPc with pyrazine should provide detailed information on the participation of the solvent nonbonded electron pairs with the magnesium central metal atom. If the solvent nonbonded electron pairs are major contributors in cluster formation/stabilization, the $n\pi^*$ transition in pyrazine should not exist or be highly perturbed (blue shifted). The cluster systems are also interesting in the respect that they may allow one to determine if changes in the cluster binding energy upon electronic excitation depend on the specific electronic excitation analyzed. In particular, one could ask the question: will the change in cluster binding energy be different in magnitude if the cluster solvent optical transition is probed rather than the cluster solute optical transition? Furthermore, these studies may yield information on differences in the relative stabilization of the solute and solvent electronic states. Do the spectral shifts observed when probing the solvent optical spectrum differ in sign than those observed when probing the cluster solute spectrum; that is, are the spectral shifts both bathychromic or hypsochromic or is the solvent spectral shift bathychromic and the solute shift hypsochromic (or vice versa)?

Phthalocyanine and Porphyrin Vibronic Structure - Up to this point, we have only considered analyzing the Pc and TBP macrocycles in cluster systems. The vibrational spectroscopy of these molecules is

also important in the understanding of the vibrational structure present *in biologically significant* systems. In particular, elucidation of the vibrational structure in the Pc and TBP systems may yield valuable information regarding which portions of the macrocycles participate in the various vibrational motions. Supersonic molecular jet studies on isolated Pc and TBP can contribute to the resolution of the excited state energetics present in the systems since the techniques greatly simplify the vibronic spectra and thus facilitate their interpretation. As discussed in Chapter 6, the low frequency motion present in the H_2Pc and MgPc vibronic spectra is characterized using the results of an out-of-plane normal coordinate analysis; and in Chapter 7, the calculations on H_2Pc are compared to infrared data. These studies make it possible for us to determine the detailed nature of the out-of-plane motion occurring in specific regions within the H_2Pc vibrational manifold. In order to obtain a complete understanding of the macrocycles vibrational structure, the in-plane motion should be characterized. The vibronic spectra of the Pc and TBP molecules presented above can be analyzed using the results of both in-plane and out-of-plane normal coordinate analyses. In these studies, the in-plane motion can be modeled using a refined force field determined from normal coordinate analyses on the in-plane motion occurring in porphyrins.[3-7] The combination of calculational modeling and spectroscopic studies on these systems should increase our understanding of the structural changes (nuclear motion) occurring in the various electronic states as well as the extent of interelectronic state mixing (vibronic coupling) between the different electronic states in the macrocycles. These studies will also be useful in the basic understanding of the spectroscopy in more complex systems such as substituted Pc's and porphyrins.

$\pi - \pi$ Solute/Solvent Interaction in Clusters - The $MgPc(CO_2)_1$ and $H_2Pc(CO_2)_1$ clusters presented in Chapter 6 exhibit vibronic spectra with distinctive spectral shifts. The $H_2Pc(CO_2)_1$ cluster is the only cluster observed with H_2Pc which possesses a hypsochromic shift upon excitation to the S_1 state. The $MgPc(CO_2)_1$ cluster also exhibits a hypsochromic shift comparable to that observed in $H_2Pc(CO_2)_1$. The exact nature of the intermolecular interaction responsible for the spectral shifts is not known; however, based upon cluster experiments with alcohol and hydrocarbon solvents, it is possible to speculate that π-π solute/solvent interactions may be responsible for the observed spectral shifts. To study this behavior, a series of experiments on single ring solutes such as benzene, pyrazine, and pyrimidine solvated by carbon dioxide, carbon monoxide, and oxygen can be conducted using 2-color TOFMS techniques. The benzene/solvent vibronic spectra will reveal whether the solvents orient perpendicular or parallel to the solute molecular plane through the observation of forbidden cluster chromophore transitions. In these studies, the spectral shifts may be related to particular cluster geometries which may yield information on the major interactions contributing to the intermolecular potentials between the solutes and solvents. The pyrazine and pyrimidine/solvent clusters may tell us about the effects of the ring nitrogens on the cluster geometry, binding energy, and solute solvation. Computer modeling of cluster geometry, binding energy, and intermolecular vibrational structure may also aid in the understanding of the intricacies of the intermolecular interactions present in these systems.

vdW Vibrational Structure in N-Heterocycle Dimers and Solute Solvent Clusters - Calculation of the intermolecular vibrational structure for the N-heterocycle dimers and solute/solvent clusters discussed

in Chapters 4 and 5 can also be conducted. The modeling studies of the N-heterocycle solute/solvent clusters are interesting since they may show the effects of the solute nitrogen atoms on the intermolecular vibrational structure when compared to the analogous benzene solute/solvent clusters. Furthermore, the studies are important as little to no intermolecular vibronic structure is observed in the cluster spectra. In this regard the studies will yield predictions of the frequencies of those vdW modes not observed in the spectra as well as aid in assigning the weak features present in some of the spectra. Intermolecular vibrational structure modeling of the N-heterocycle dimer systems could serve as a major contribution to the understanding of their spectroscopy. The studies may be useful in the determination/ confirmation of the dimer geometries responsible for the observed spectra as well as help to elucidate the nature of the intermolecular energetics and dynamics present in the systems. Of particular interest is the elucidation of the vdW torsional structure present in the planar dimers, especially for the vdW torsional coordinate in which the cluster subunits rotate/librate about an axis joining their centers-of-mass. This motion is similar to torsional motion occurring in polyring systems such as biphenyl and biphridyl. Studying the torsional motion in the clusters may yield information concerning the long-range (π-electron effects) and short-range (hydrogen-hydrogen repulsions) interactions present between the cluster subunits which may be considered precursors to the interactions responsible for the potential well shape in the polyring systems. The studies will also contribute to the understanding of hydrogen bonding interactions in the cluster systems and how it affects cluster geometry and intermolecular energetics.

Conclusions.

Supersonic molecular jet expansion, TOFMS, and FE spectroscopic techniques have been employed to study the gas phase optical spectra of a wide array of weakly bound vdW clusters in an ultracold isolated molecular environment. The techniques have proved useful in studying the vdW clusters of aromatic molecules ranging from benzene and its N-heterocyclic analogues to macrocycles such as H_2Pc and MgPc solvated by small hydrocarbons/fluorocarbons, small alcohols, water, ammonia, argon, and carbon dioxide. The studies reveal detailed information regarding the geometries/symmetries, the intermolecular energetics, and the physical nature of the vdW interactions present in the cluster systems. Spectroscopic observables, such as cluster spectral shifts, forbidden cluster chromophore vibronic transitions, vdW motions, and cluster ionization energies, combined with computer modeling of cluster ground state binding energies, geometries, and intermolecular energetics proves essential in the analysis and understanding of the physics involved in cluster formation, stabilization, and behavior.

The experimental and theoretical studies of the benzene/solvent clusters reveal detailed information regarding cluster geometries, symmetries, and the nature of the intermolecular vibronic motion present in the systems. In these studies, we found that the preferred benzene solvation site is located over the aromatic π cloud where solute/solvent vdW interaction is maximal. Through computer modeling, we have demonstrated the correlation between cluster geometry and spectral features. Specifically, we showed that the calculations yield useful information regarding cluster geometry, binding energy, and intermolecular vibrational structure. These calculated results are consistent with

experiment and can be used to elucidate the details of vdW cluster energetics. By comparing the calculations and the experiments, we are able to assign cluster vibronic transitions to specific cluster geometries and to specific vdW vibrations.

Detailed experimental and theoretical studies of the intermolecular torsional structure in the benzene/solvent clusters show that the clusters are rigid systems with regard to internal rotation of the cluster subunits. In this regard, the clusters possess unique equilibrium geometries for which the intermolecular motion is oscillatory. The motion is not an admixture of vdW bends, stretches, and free internal rotations as would occur if the clusters were internally nonrigid.

The N-heterocycle/solvent cluster studies demonstrate that the solute ring nitrogen atoms influence, to some extent, both the cluster geometry and spectroscopy. In the N-heterocycle/hydrocarbon clusters, we find that the presence of the nitrogen atoms in the aromatic rings has a small but discernible effect on the intermolecular interaction. In particular, the solvent hydrogen atoms preferentially orient towards the solvent nitrogen atoms. The overall behavior of these clusters with regard to geometry, binding energy, and spectroscopy, however, is very similar to that found in the benzene/hydrocarbon clusters.

The N-heterocycle/water and ammonia clusters, on the other hand, clearly demonstrate major interactions between the ring nitrogens and the solvent hydrogens. These studies suggest that hydrogen bonding is present between the ring nitrogens and the solvent hydrogens as evidenced by the hypsochromic spectral shifts present in the cluster spectra.

The single ring/solvent clusters also exhibit spectra and calculated geometries consistent with the notion that the intermolecular potential is primarily composed of solute/solvent π cloud interactions. In this regard, the preferred solvation sites on the cluster solutes are located over the aromatic π clouds. Thus, the cluster geometries are such that the solvents lie over the center of the solutes unless other large intermolecular interactions are present which may alter this behavior. In particular, hydrogen bonding interactions present in the N-heterocycle and benzene/solvent systems appear to cause geometrical changes in the clusters. The changes range from simple reorientation of the solvents to minimize solute ring nitrogen/solvent hydrogen distance or solvent hydrogen/solute π cloud distance to large reorganization of the cluster geometry from a "sitting atop" configuration to planar hydrogen bonded geometries as suggested by pyrimidine/ammonia and N-heterocycle dimer studies.

The spectroscopic studies of phthalocyanines and their respective vdW clusters with small molecules take advantage of the characteristics of the supersonic molecular jet. This technique makes it possible to simplify the complicated phthalocyanine spectra and to control the solvent and environmental effects on the chromophores in a set and controlled manner. The interplay of spectroscopy and an out-of-plane normal coordinate analysis enables us to characterize the low-lying out-of-plane motion present in H_2Pc and MgPc. The correlation between the spectra and the calculations is excellent which allows for the elucidation of the motion types observed in the first few hundred wavenumbers of the H_2Pc/MgPc S_1 manifolds. The correlation also makes possible the identification of specific species/geometries responsible for the

cluster vibronic spectra observed in the vicinities of the chromophore Q band origins.

In the cluster studies, we find that the H_2Pc/hydrocarbon cluster experimental and theoretical results parallel those observed for the benzene and N-heterocycle/hydrocarbon clusters. The cluster geometries favor forms for which solvent/solute π cloud overlap is maximal. The spectral shifts are all bathychromic and the magnitudes of the shifts increase with increasing solvent size and polarizability. The H_2Pc and MgPc/water and /alcohol clusters exhibit spectra and calculated geometries which demonstrate that the solvent OH groups are large contributors to the spectral shifts and intermolecular interactions. In all the cluster systems studies, the preferred H_2Pc and MgPc solvation sites are located over the phthalocyano core. As in the benzene/water and benzene/ammonia clusters, the H_2Pc and MgPc clusters exhibit reduced symmetry with respect to the isolated chromophores. This reduction in symmetry is demonstrated by the observation of forbidden chromophore transitions and S_1 state splitting in the clusters.

Overall, computer modeling proved to be an essential component of the studies on both the isolated molecules and the cluster systems. The spectroscopic data obtained are necessary to validate and refine the models used, and the calculations help to assign and understand spectra which are otherwise difficult, if not impossible, to uniquely interpret. In this way, the combination of spectroscopy and computer modeling leads to an increased understanding of the behavior of the molecules and clusters over what could be obtained by either study alone.

(Received 13 December 1985; accepted 1 May 1986)

Solute–solvent clusters of pyrazine, pyrimidine, and benzene (solutes) and C_nH_{2n+2} ($n = 1,2$), NH_3, and H_2O (solvents) are studied by the techniques of supersonic molecular jet spectroscopy and two-color time-of-flight mass spectroscopy (two-color TOFMS). Spectral shifts, van der Waals (vdW) modes, dissociation energies, and vdW mode–solute mode vibronic couplings are characterized for most of the observed clusters. Based on these data and previous results for hydrocarbon systems, cluster geometries can be suggested. Lennard-Jones potential (6-12-1) calculations are also performed for these clusters and in all instances for which comparisons can be readily made, calculated and experimentally estimated geometries and binding energies agree completely. Clusters of *N*-heterocyclic solutes and H_2O are not observed experimentally. Systematics and trends among the clusters reported herein and those previously reported are discussed and analyzed.

I. INTRODUCTION

Supersonic molecular jet spectroscopy has made possible the study of a wide variety of weakly bound, solute–solvent van der Waals (vdW) clusters in the gas phase. Cluster investigations have enhanced our understanding of intra- and intermolecular interactions and potentials, vibrational energy dynamics and chemical reactions, structural properties of small aggregates of solute and solvent molecules, and nucleation and growth of small clusters. Clusters can also be considered as model systems for condensed phase behavior. Moreover, these vdW systems can be thought of as an important new state of matter in which the static and dynamic properties of small aggregates of weakly coupled molecules can be studied.

vdW clusters, after being produced in a supersonic jet expansion, can be probed by three distinct techniques: fluorescence excitation (FE), dispersed emission (DE), and two-color time-of-flight mass spectroscopy (two-color TOFMS). The latter technique is employed most often in our studies of clusters because it gives unique cluster identification, brackets the cluster binding energies, and elucidates cluster vibrational energy dynamics and vibrational predissociation.

In the past few years, we have reported several studies of vdW clusters using the three spectroscopic techniques mentioned above.[1–7] Cluster geometry, binding energy, nucleation and growth dynamics, and limits on the vibrational energy dynamics and vibrational predissociation times have been determined. The vdW solute–solvent clusters investigated initially are for the most part restricted to aromatic hydrocarbon solutes (e.g., benzene and toluene) and small alkane solvents (CH_4,C_2H_6, and C_3H_8) in which only one type of interaction, that is one potential form, is found to be important for the solute–solvent coordination. Expanding on these previous studies we are now exploring solute–solvent clusters with *N*-heterocyclic solutes (e.g., pyrazine and pyrimidine) and alkane solvents and *N*-heterocyclic solutes with hydrogen bonding solvents (e.g., water and ammonia). The initial report of this effort for pyrazine and methane, ethane and propane clusters has already appeared.[7]

In this paper we discuss the two-color TOFMS study of pyrimidine clustered with CH_4 and C_2H_6, pyrazine and pyrimidine clustered with NH_3, and benzene clusters with H_2O and NH_3. The pyrimidine–alkane clusters are presented for comparison with the previously published[7] pyrazine–alkane data: The effect of the ring nitrogen atoms on the cluster geometry can thereby be evaluated. The pyrazine and pyrimidine ammonia clusters reveal the role of hydrogen bonding interactions in simple clusters. Benzene–water and –ammonia clusters serve as an example of clusters with these more complicated solvent systems (i.e., two possible interaction potentials) interacting with aromatic hydrocarbons. Theoretical and experimental studies of such a series of systems should eventually lead to a fuller understanding of solute–solvent coordination structure, dynamics, and the hydrogen bonding interaction.

Although extensive efforts were made and a wide variety of experimental conditions explored, pyrazine and pyrimidine clusters with water were not observed. Both FE and two-color TOFMS detection techniques were employed. A broad feature (roughly 50 cm^{-1} FWHM) was observed in FE at 580 cm^{-1} to the blue of pyrazine 0_0^0 transition for pyrazine and water expanded with helium. No signal, however, was observed at the pyrazine water mass channel for two-color TOFMS. We must thus conclude that the pyrazine and the pyrimidine water clusters have not been observed. Either the excited $n\pi^*$ state of the cluster is dissociative or internal conversion or intersystem crossing is so rapid for these clusters that the lifetime of the $n\pi^*$ state is greatly reduced ($\sim$0.1 ps). Pyrimidine–fluorinated alcohol clusters

also exhibit broad features and reduced lifetimes.[8]

Hydrogen bonding interactions are known to play an important role in intra- and intermolecular interactions important for secondary and tertiary molecular structure, molecular dynamics, and ionic and molecular solvation. Hydrogen bonding interactions have received attention in previous supersonic molecular jet spectroscopic studies: These systems include phenol clustered with various proton accepting molecules,[9] indole and 2-aminopyridine clustered with various solvents,[10] benzoic acid dimers,[11] *s*-tetrazine dimers,[12] 1,4-dihydroxyanthraquinone,[13] and methylsalicylate.[14] In most instances blue-shifted cluster spectra are found due to the cluster stabilization of the ground state and destabilization of the excited state.[15]

In this and our other cluster studies, the experimental data are supplemented by potential energy Lennard-Jones (LJ) atom–atom (6-12-1) calculations of cluster structure, binding energy, and internal motion. The calculations and the potential are discussed thoroughly in our previous studies.[7] The LJ calculations produce identical geometries but slightly lower binding energies than the exp-6 potential form used in earlier calculations.[1-6] The LJ hydrogen bonding (LJ-HB) potential form proves to be more versatile than the exp-6 form since many more constants for different types of atom–atom interactions have been independently reported for the LJ potential.[16] None of the potential parameters employed in this work is fit to the cluster data.

As is well known and widely accepted, geometries of isolated molecules and clusters are best obtained through spectroscopic observation of rotational structure. In fact, rotational structure of a number of simple clusters has been observed under molecular jet conditions: *s*-tetrazine and iodine with He and Ar[17] and aniline with Ne and Ar.[18] The resolution available to us at present is 0.08 cm^{-1}; at this resolution only rotational envelopes are observable which do not lend themselves readily to a unique interpretation of cluster structure. We calculate that 0.005 cm^{-1} resolution would be required to resolve rotational structure for $C_4H_4N_2(NH_3)_1$ etc., under the restriction of a rigid geometry. We are thus for the present forced to employ less direct methods to obtain cluster geometry. Assignment of the spectra is accomplished through the determination of ionization energies, spectral shifts, relative intensities, (molecular) symmetry forbidden cluster transitions, and potential calculations. The understanding of these more complex systems rests heavily on the previous data obtained for other clusters.[1-7] For all systems discussed in this paper, complete agreement between spectroscopic data, calculations, and results for previously analyzed solute–solvent clusters is found.

II. EXPERIMENTAL PROCEDURES

The experimental apparatus and procedures are similar to those used previously for the study of vdW clusters. The vacuum system consists of two chambers with a pulsed nozzle and mass detection system in the second chamber. A skimmer separates the pulsed nozzle and the time-of-flight mass spectrometer. The first chamber contains either a pulsed or cw nozzle, the molecular beam from which can be taken into the second chamber through a skimmer. FE and DE experiments are carried out in the first chamber.

The two independent lasers used in the two-color TOFMS experiments are Nd^{+3}/YAG pulsed lasers the doubled output of which pumps two dye lasers. The dye laser output can be mixed with the 1.064 μm Nd^{+3}/YAG fundamental, frequency mixed and doubled, or just doubled using various nonlinear KDP crystals. The laser output can be extended from greater than 4.5 to ~0.215 μm. One laser is employed to excite the cluster to its first excited $n\pi^*$ or $\pi\pi^*$ electronic state and the second laser then ionizes this cluster starting from the S_1 vibronic manifold. The maximum ionization energy achievable with this second laser is roughly 46 500 cm^{-1}.

The solute or cluster chromophore is typically placed in an in-line trap or filter cup directly behind the pulsed valve. Water is placed in a trap before the valve and solute; the helium carrier gas passes over both materials and into the valve. Gaseous solvents are premixed with the helium carrier gas in a holding tank (~2000 psi) at concentrations varying from 2.0 to 0.1 mol/mol%.

The LJ potential function (6-12-1) with the additional HB form is described in detail in a previous publication.[7] Table I contains a list of the previously unreported constants employed with this potential form. Pyrazine and pyrimidine structures used in the calculations are obtained from Ref. 19.

III. RESULTS

This section contains the experimental and calculational results for the various clusters investigated. We first present pyrimidine with methane and ethane for comparison with the previously reported pyrazine clusters.[7] Pyrimidine and pyrazine ammonia clusters are then discussed and benzene water and ammonia clusters are presented for a comparison with the N-heterocyclic systems. Based on previous experience with a number of different clusters,[1-7] we have not made an extensive experimental study of the binding energies of these clusters. We rely on the calculations which have always fallen within the range bracketed by the experimental two-color TOFMS data. Preliminary checks made on both pyrazine and pyrimidine clusters are in agreement with the calculations. Vibrational vdW modes observed in the spectra will not be assigned in this publication. Future publications will assign them as bends, stretches, torsions, and combinations utilizing a normal coordinate calculational analysis.[20]

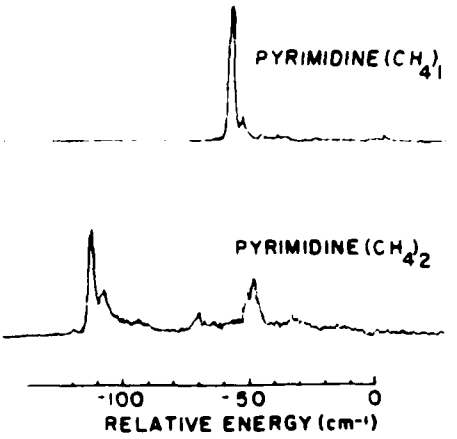

FIG. 1. Two-color time-of-flight mass spectra (two-color TOFMS) of pyrimidine $(CH_4)_1$ and pyrimidine $(CH_4)_2$ in the region of the pyrimidine origin (31 073.0 cm^{-1}).

A. Pyrimidine–methane

Figure 1 and Table II present the data for the pyrimidine $(CH_4)_1$ and $(CH_4)_2$ complexes taken near the pyrimidine 0_0^0 transition (31 073.0 cm^{-1}). The cluster of pyrimidine $(CH_4)_1$ has a spectral shift of $-56.6\ cm^{-1}$ and a low frequency mode at 4.5 cm^{-1} from this origin. These spectra are obtained by two-color TOFMS. Hints of other vdW modes can also be seen in the trace in Fig. 1 but we are hesitant to report such weak transitions. Pyrimidine $(CH_4)_2$ spectra clearly show two clusters, similar to previously reported clusters for other aromatic systems.[1-7] The feature at $-112.1\ cm^{-1}$ in Fig. 1 is assigned as the 0_0^0 transition of the isotropic (symmetric), additive shift cluster and the feature at $-47.2\ cm^{-1}$ is attributed to the 0_0^0 transition of the anisotropic (asymmetric) cluster with both methanes on the same side of the aromatic ring. Note that without both mass and energy resolution, the spectra of pyrimidine $(CH_4)_1$ and $(CH_4)_2$ would not be resolved and the clusters could not be separated and uniquely identified. A vdW mode at 5.1 cm^{-1} from the isotropic cluster origin is observed.

Potential energy calculations using LJ potentials for these clusters generate geometries and binding energies comparable to those previously reported for other aromatic–alkane systems and in complete accord with the above experimental findings (see Fig. 2). Calculations for pyrimidine $(CH_4)_1$ clusters yield only one geometry for which the methane is coordinated with the aromatic π system of the pyrimidine ring. The calculated binding energy for this cluster is 514 cm^{-1}. The methane–carbon atom is above the ring at 3.5 Å and is shifted ~0.1 Å from the ring center toward the nitrogen atoms. The three hydrogen atoms of methane that point down toward the ring are equidistant from the ring at 3.1 Å; two of these hydrogens point directly at the ring nitrogen atoms. Again in agreement with the main experimental observations for these clusters, the calculations for pyrimidine $(CH_4)_2$ clusters yield two distinct geometrical arrangements. The isotropic cluster has a calculated binding energy of 1029 cm^{-1} and the anistropic cluster has a calculated binding energy of 879 cm^{-1}.

B. Pyrimidine–ethane

The pyrimidine $(C_2H_6)_1$ spectrum is quite complicated, consisting of a number of low intensity features and an intense feature at $-60.7\ cm^{-1}$ with respect to the pyrimidine

TABLE II. Observed peaks in the spectra of pyrimidine–methane clusters.

Species	Energy (vac cm^{-1})	Energy relative to pyrimidine 0_0^0 (cm^{-1})	Energy relative to cluster 0_0^0 (cm^{-1})	Assignment[a]
$C_4H_4N_2(CH_4)_1$	31 016.4	−56.6	0	0_0^0
	31 020.9	−52.1	4.5	
$C_4H_4N_2(CH_4)_2$	30 960.9	−112.1	0	iso 0_0^0
	30 966.0	−107.0	5.1	
	31 025.8	−47.2	0	aniso 0_0^0

[a] The $-112.1\ cm^{-1}$ shift is associated with two methanes added symmetrically above and below the pyrimidine ring (isotropic), as shown in Fig. 2. The $-47.2\ cm^{-1}$ shift is associated with the anisotropic configuration, as shown in Fig. 2.

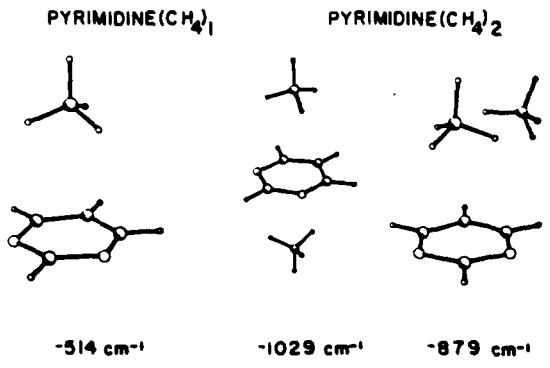

FIG. 2. Minimum energy configurations and binding energies for pyrimidine $(CH_4)_1$ and pyrimidine $(CH_4)_2$ as obtained using the LJ potential calculation described in the text.

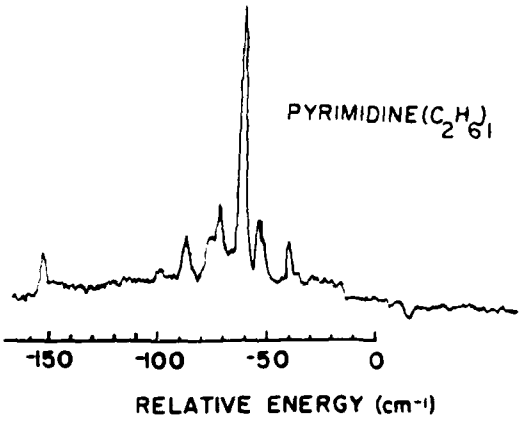

FIG. 3. Two-color TOFMS of pyrimidine $(C_2H_6)_1$ in the region of the pyrimidine origin.

origin (see Fig. 3). We might expect that little vdW vibronic intensity would be observed, based on pyrazine and other pyrimidine clusters. In order to begin to interpret these features we must consult the vapor phase room temperature pyrimidine monomer spectrum.[21] In these reports, features at -156 and $+22\ cm^{-1}$ are assigned as the $16a^1_1$ and $16b^1_1$ sequence bands, respectively. The feature that appears in Fig. 3 at $-39.1\ cm^{-1}$ may be assigned as the $16b^1_1$ sequence band of the pyrimidine $(C_2H_6)_1$ cluster built on the intense $-60.7\ cm^{-1}$ cluster origin. If this identification is correct, then *the clusters of pyrimidine* $(C_2H_6)_1$ *are hot* ($T_{vib} \approx 260$ *K*) and the features in Fig. 3 and Table II at -153.5, -99.3, -86.9, and $-75.4\ cm^{-1}$ may well be hot bands associated with the cluster origins at -71.4, -60.7, and $-52.7\ cm^{-1}$. Apparently the cluster formation process for pyrimidine ethane tends to warm the cluster. Table III summarizes these results.

Supersonic expansion of pyrimidine apparently does not produce the expected cooling for vibrational modes $16b_1$ and $16a_1$. Vibrational temperatures for the $16b_1$ mode have been reported to be in excess of 200 K. Ito and co-workers[21d] have also observed the $16b^1_1$ transition for pyrimidine clustered with argon and nitrogen. In the present work, changes in backing pressure from 10 to 120 psi do not change the relative band intensities: apparently these modes present a bottleneck for vibrational cooling.

As can be seen in Fig. 4, three different configurations are calculated to be stable for the pyrimidine $(C_2H_6)_1$ cluster. Configuration I has the long axis of ethane perpendicular to the plane of the pyrimidine ring. Configurations II and III have the ethane molecule long axis more or less parallel to the plane of the ring; for configuration II, the axis of ethane lies between a nitrogen and a carbon and for configuration III this axis lies between two carbon atoms. In each instance a CH_3 group lies more or less over the ring center.

C. Pyrimidine–ammonia

The pyrimidine $(NH_3)_1$ two-color TOFMS spectrum in the range 300 to 500 cm^{-1} to the blue of the pyrimidine origin is presented in Fig. 5. The three features are associated with the 0^0_0 transitions of the pyrimidine $(NH_3)_1$ clusters. The lack of significant vdW vibrational mode intensity indicates that the ground and excited state vdW potentials are nearly identical. The large cluster blue shift implies a strong hydrogen bonding interaction between the pyrimidine and the ammonia. The spectrum of Fig. 5 is taken with an ioniza-

tion energy of 45 110 cm^{-1}; lowering the ionization energy to $\sim$42 000 cm^{-1} the two nearly degenerate features at $+367$ cm^{-1} decrease in intensity much more rapidly than the feature at $+496$ cm^{-1}. Table IV gives the energies and assignments for the pyrimidine $(NH_3)_1$ clusters. Based on the idea that the three features in this spectrum are associated with three different pyrimidine $(NH_3)_1$ cluster geometries, the two nearly isoenergetic configurations must be quite similar. The feature at $+496$ cm^{-1} must correspond to a different (more hydrogen bonded) geometry.

Three different configurations are calculated for the pyrimidine $(NH_3)_1$ cluster using the LJ–HB potential form (see Table I and Ref. 7). Two of these configurations have the ammonia above the pyrimidine plane and the third configuration has the NH_3 molecule not above the ring. These clusters are presented in Fig. 6 along with the calculated cluster binding energies. Configuration I has the ammonia N-atom 3.2 Å above the pyrimidine ring with the three ammonia hydrogen atoms pointing down toward the π cloud. The two closest hydrogen atoms of the ammonia in this configuration are 2.7 Å from the pyrimidine plane. In configuration II, the ammonia nitrogen atom is 3.2 Å above the ring plane and points in the general direction of the ring N atoms. The closest two ammonia hydrogen atoms to the ring are at 2.7 Å. This cluster has a somewhat lower binding energy than cluster I (667 vs 689 cm^{-1}). In the third pyrimidine $(NH_3)_1$ configuration, the ammonia molecule does not reside over the pyrimidine ring: the NH_3 has a N–H bond in

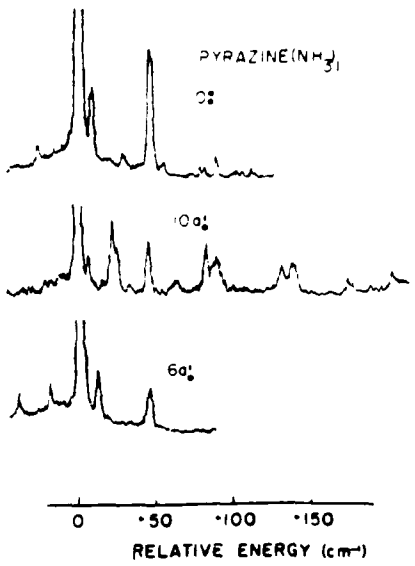

FIG. 7. Two-color TOFMS of pyrazine $(NH_3)_1$ at the origin, $10a_0^1$ and $6a_0^1$ regions are shown. The cluster origin (0 cm^{-1}) is + 117 cm^{-1} to the blue of the pyrazine origin.

the plane of the pyrimidine ring with the H atom pointing to one of the pyrimidine nitrogens, 2.23 Å from it. The ammonia nitrogen is displaced in the *xy* plane by 3.3 and 2.8 Å along the *x* axis and *y* axis, respectively, as shown in Fig. 6, configuration III. This configuration has a calculated binding energy of 537 cm^{-1}.

D. Pyrazine–ammonia

The pyrazine $(NH_3)_1$ spectra in the 0_0^0, $10a_0^1$, and $6a_0^1$ regions are presented in Fig. 7. One first notices the significant difference between these data and those of pyrimidine $(NH_3)_1$. The spectra all strongly suggest that only one configuration is present for the pyrazine $(NH_3)_1$ system. The intense feature in the 0_0^0 spectrum is the cluster origin at + 117 cm^{-1} from the pyrazine 0_0^0 transition. The remaining features of this spectrum are vdW vibrational modes of the cluster. They will be analyzed in a future publication.[20] Table V gives the energies and the features observed in the spectrum. In this case, the ground and excited state potential surfaces must be significantly different.

The cluster $10a_0^1$ transition is quite different from the cluster 0_0^0 or $6a_0^1$ transitions. From this one concludes that strong vdW-internal mode coupling exists for the $10a^1$ out of plane ring mode.[22] The vdW overtones and combination bands extend to more than 180 cm^{-1} from the $10a_0^1$ cluster origin feature. This is particularly striking in comparison with the $6a_0^1$ vibronic band.

Only one configuration is calculated for the pyrazine $(NH_3)_1$ cluster using the LJ plus HB potential function, in agreement with expectations from the spectra. The ammonia molecule hydrogen bonds to the ring nitrogens, through two ammonia hydrogens. The nitrogen atom of the ammonia molecule is 3.2 Å above the ring plane with all three hydrogens pointing toward the ring. This geometry is depicted in Fig. 8. The calculated binding energy of the cluster is 677 cm^{-1}.

E. Benzene–ammonia

The origin and 6_0^1 transitions of the $C_6H_6(NH_3)_1$ cluster are observed in two-color TOFMS. One can immediately conclude that at least one configuration of this cluster does not retain the benzene threefold axis. The spectra are traced in Fig. 9. The spectra for both transitions are far more complicated than any other cluster previously reported from our laboratory. Regions with similar structure can be found in the 0_0^0 and 6_0^1 spectra; in particular, the regions around + 20, − 20 and − 60 cm^{-1} in each spectra bear some resemblance to one another. Nonetheless, features appearing in one spectrum do not appear in the other, and therefore at least two clusters of different geometry are probably responsible for the 6_0^1 transition. The 0_0^0 transition could arise from one reduced symmetry cluster. Since very little *a priori* spectroscopic analysis seems possible in this situation at the present time, great stock must be placed in the calculations.

Two different configurations are calculated for the $C_6H_6(NH_3)_1$ cluster and both of them have the NH_3 molecule placed over the ring. Configuration I in Fig. 10 preserves the benzene C_3 axis and configuration II does not. The high symmetry cluster has the N atom 3.3 Å from the ring plane and the three H atoms of NH_3 are 2.9 Å above the ring plane. Configuration II has the N atom 3.3 Å above the plane and slightly shifted from the ring center. Two H atoms of the

NH_3 point towards C–C bonds and one points away from the ring plane. The NH_3 H-atoms in this configuration are at 2.9 (two of them) and 4.3 Å from the ring. The calculated binding energies of these two configurations are given in Fig. 10. Configuration II alone must generate the 0_0^0 spectrum in Fig. 9.

F. Benzene–water

The $C_6H_6(H_2O)_1$ cluster 0_0^0 and 6_0^1 are presented in Fig. 11. They are strikingly different from those of $C_6H_6(NH_3)_1$ (Fig. 9) but bear a strong resemblance to the pyrazine $(NH_3)_1$ spectra displayed in Fig. 7, as well as spectra of other systems studied in our laboratory.[1–7] In particular, a very clear vibronic progression is present for the 0_0^0 spectrum and will be analyzed in a future publication.[20] Table VI gives

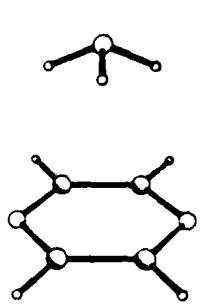

FIG. 8. Minimum energy configuration and binding energy for pyrazine $(NH_3)_1$ as obtained using a LJ HB form potential calculation.

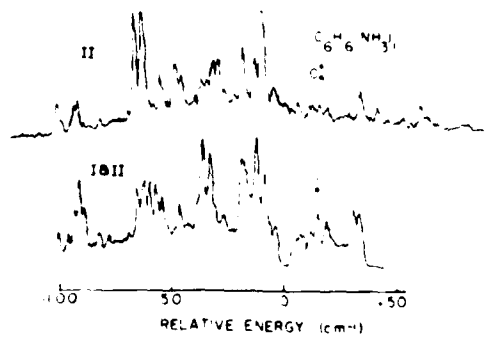

FIG. 9. Two-color TOFMS of benzene $(NH_3)_1$ in the region of the benzene 0_0^0 and 6_0^1 transitions.

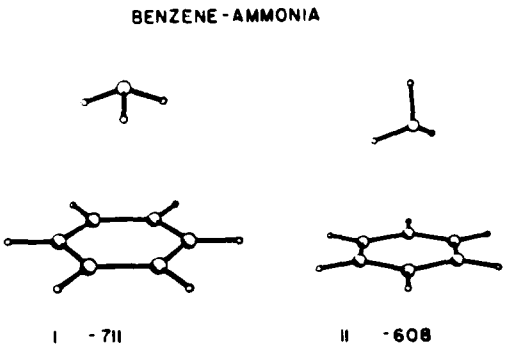

FIG. 10. Minimum energy configurations and binding energies for benzene $(NH_3)_1$ as obtained using a LJ potential calculation.

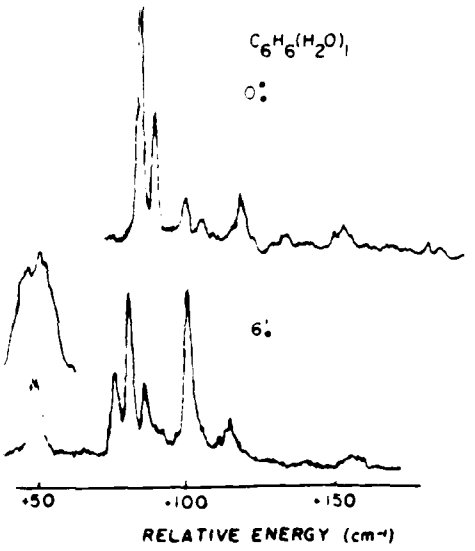

FIG. 11. Two-color TOFMS of benzene $(H_2O)_1$ in the region of benzene origin 0_0^0 and 6_0^1. An expanded scale insert is shown of the 6_0^1 origin of the cluster.

these features and their energies. The 6_0^1 spectrum of $C_6H_6(H_2O)_1$ has a different shift (+ 50 vs + 85 cm^{-1}) and a different general pattern than the 0_0^0. In addition, the 6_0^1 origin is split by roughly 1 cm^{-1}. Considerable vibronic coupling must occur between the in plane carbon–carbon stretch 6^1 and the vdW modes. The $C_6H_6(H_2O)_1$ cluster two-color TOFMS spectra are observed only at a higher ionization energy than required to observe the 6_0^1 spectrum of bare C_6H_6. The $C_6H_6(H_2O)_1$ spectra depicted in Fig. 11 are taken with an ionization laser energy of 44 480 cm^{-1} compared to 36 100 cm^{-1} for the benzene monomer. The ionization energy for the benzene water cluster is 3300 cm^{-1} higher than that of the benzene monomer.

Only one geometry is calculated for the $C_6H_6(H_2O)_1$ cluster employing the LJ potential. The configuration and binding energy are given in Fig. 12. The oxygen atom of water is roughly centered over the ring at 3.2 Å above it and the water hydrogen atoms are at 3.0 Å above the ring. The calculated water benzene binding energy is 505 cm^{-1}.

IV. DISCUSSION

Cluster geometry is determined through analysis of two-color TOFMS data for individual clusters and through calculations of cluster geometry and binding energies using an augmented LJ potential. Calculated binding energies have

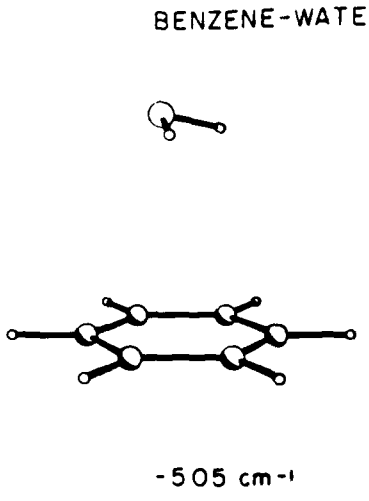

FIG. 12. Minimum energy configuration and binding energy for benzene $(H_2O)_1$ as obtained using a LJ potential calculation.

always been roughly bracketed by the experimentally observable range defined by two solute molecule vibrations (e.g., 520 to 850 cm^{-1} for the 1:1 complex).[1-7]

Before discussing the details of the clusters observed, some general remarks are in order. First, one should take note of the great apparent differences between the spectra of the various clusters studied: pyrazine and pyrimidine hydrocarbon spectra show little vdW vibronic structure but intense origins; the pyrazine $(NH_3)_1$ spectrum displays elaborate and well developed vibronic progressions with a $+117$ cm^{-1} cluster shift for a single cluster; the pyrimidine $(NH_3)_1$ spectra consist only of intense origins for three large shift ($+366$, $+368$, $+496$ cm^{-1}) configurations with no vdW vibronic development; the benzene $(NH_3)_1$ spectra are red shifted, and too complex to interpret without further calculations; and the benzene $(H_2O)_1$ spectra are blue shifted with extensive vdW structure. Second, and perhaps even more astonishing, the LJ–HB (where appropriate) potential calculations parallel and reinforce these differences in all cases. That is, for example, the calculations suggest one hydrogen-bonded configuration for pyrazine $(NH_3)_1$ but three hydrogen-bonded configurations for pyrimidine $(NH_3)_1$, in agreement with the straightforward interpretation of the spectra. Third, the binding energies of the clusters seem relatively insensitive to the detailed configuration of the cluster. Fourth, spectral shifts are found to be a sensitive function of the detailed geometry of the cluster. Proximity to the π system is important for cluster red shifts, while hydrogen bonding yields in general cluster blue shifts with respect to the solute monomer origin.

A. Pyrimidine–methane

In the pyrimidine $(CH_4)_1$ cluster the CH_4 molecule is situated above the pyrimidine ring coordinated to the π cloud of the aromatic ring. The cluster has a simple spectrum with little vdW vibronic intensity following the pyrimidine vibronic origins. The cluster spectrum is red shifted, indicating that the excited state cluster is more tightly bound than the ground state cluster by roughly 60 cm^{-1}. The overall appearance of the spectrum is similar to that of pyrazine methane.[7]

The additive shift features in the spectrum of pyrimidine $(CH_4)_2$ are attributed to the isotropic (symmetrical) geometry with a methane molecule on either side of the pyrimidine ring. The feature at -47.2 cm^{-1} in the pyrimidine $(CH_4)_2$ spectrum is attributed to the anisotropic configuration with both CH_4 molecules on the same side of the ring. In this asymmetric geometry, one methane is more or less above the ring, and responsible for most of the CH_4–π–cloud interactions, and the other methane molecule is off the ring interacting primarily with the first methane, contributing little to the cluster spectral shift.

The overall behavior of this cluster system with regard to geometry, binding energy, and cluster population in the beam is very similar to that found for benzene, toluene, and pyrazine methane species.[1-7]

B. Pyrimidine–ethane

The pyrimidine $(C_2H_6)_1$ cluster is similar to the pyrazine $(C_2H_6)_1$ cluster:[7] both clusters have three geometrical configurations and each configuration of the two clusters has a similar binding energy. These configurations are also similar to those of the benzene $(C_2H_6)_1$ cluster with the exception that, in the *N*-heterocyclic systems, two parallel orientations of the C_2H_6 long axis with respect to the ring plane are now possible.

The identification of calculated geometries with the three distinct spectroscopic features is of course tentative but can be pursued in the spirit of the arguments and correlations employed with the benzene and pyrazine systems.[1-7] Referring to Figs. 3 and 4, the feature at -71.4 cm^{-1} can be associated with configuration I, the intense feature at -60.7 cm^{-1} can be associated with configuration II, and the -52.7 cm^{-1} feature is associated with configuration III. The lack of vdW vibronic structure for these transitions must be due to the similarity between the ground and excited state potentials for the clusters.

C. Pyrimidine–ammonia

The pyrimidine $(NH_3)_1$ clusters have a unique spectrum which can only be interpreted as due to three distinct configurations with no vdW mode progression intensity following the well defined origins. Calculations, as pointed out previously, give exactly these conclusions and identification of origins in the spectrum with configurations seems straightforward. Configurations I and II of Fig. 6 are associated with the features at 366 and 368 cm^{-1} in Fig. 5. These two configurations are quite similar and have less hydrogen bonding interaction than the more blue-shifted single feature at 496 cm^{-1}. The large spectral blue shifts of ~ 365 and ~ 500 cm^{-1} must arise from the strong hydrogen bonding interactions. While none of these observations seem particularly striking in and of itself, in comparison with the pyrazine $(NH_3)_1$ and benzene $(NH_3)_1$ results, they are surprising; these will be discussed below.

D. Pyrazine–ammonia

The pyrazine $(NH_3)_1$ cluster spectrum is completely different from that of pyrimidine $(NH_3)_1$. The cluster 0_0^0 is shifted $+117\ cm^{-1}$ from the pyrazine 0_0^0, only one cluster geometry is present, and a rather extensive vdW vibronic structure is built upon the origin. The $6a_0^1$ spectrum is quite similar. Two intense vdW vibronic transitions are associated with these cluster transitions. The $10a_0^1$ vibration region of the pyrazine $(NH_3)_1$ cluster, on the other hand, looks quite different from these other features and vibronic interactions between the out of plane $10a^1$ carbon–carbon mode and the vdW modes are quite evident in the overall vibronic intensity pattern in the $10a_0^1$ region.

Calculations predict only one configuration for this cluster system. The fact that the potential energy calculations can accurately parallel the spectral data for pyrimidine and pyrazine ammonia clusters which are clearly so different, gives us a high degree of confidence in the calculational process, the binding energies, and the potential form accuracy.

E. Benzene–ammonia

Assignment of the benzene $(NH_3)_1$ spectra has not been attempted as yet because the spectra are too complicated. We present them only as part of the general picture indicating what spectra of relatively simple clusters of such systems can be like. The benzene $(NH_3)_1$ clusters yield much more complicated spectra than either pyrazine or pyrimidine $(NH_3)_1$ clusters do. In the benzene $(NH_3)_1$ cluster, strong vdW vibronic interactions must be important for the cluster transition intensity.

Both calculated configurations (Fig. 10) contribute to the 6_0^1 transition but only configuration II generates the 0_0^0 spectrum. Note too, that both configurations most likely generate a red shift.

F. Benzene–water

Any $C_6H_6(H_2O)_1$ cluster will in principle generate a 0_0^0 transition. The 0_0^0 spectrum of $C_6H_6(H_2O)_1$ (Fig. 11) thus strongly suggests that only one cluster geometry is realized for this system. The $C_6H_6(H_2O)_1$ 0_0^0 transition is much like the pyrazine $(NH_3)_1$ spectrum. Well developed vdW vibronic features are observed. The 6_0^1 spectrum implies strong vibronic mixing between the in plane carbon–carbon deformation 6^1 and the vdW bends and torsions: the cluster shift is different for 6_0^1, as is the intensity pattern. The cluster shift at the 0_0^0 transition is $+85\ cm^{-1}$ which indicates that the cluster excited state is destablized with respect to the ground state. The blue shift may be related to the unique hydrogen bonding capabilities of the H_2O molecule with the π system of benzene. The calculated binding energy is probably $\sim 50\ cm^{-1}$ low for this cluster because the 6_0^1 transition at 0_0^0 plus $520\ cm^{-1}$ is observed. We have previously noted that the LJ potential binding energy is roughly $50\ cm^{-1}$ low compared to exp-6 and experimental values.[7]

An infrared study of the 1:1 benzene–water complex in an argon matrix has been reported.[23] The work suggests that the water molecule hydrogen bonds to the benzene π system in a manner nearly identical to that found in the calculations presented in Fig. 12.

V. CONCLUSIONS

The clusters studied in this work fall into two broad categories: a conventional set containing pyrimidine hydrocarbon clusters, the spectra of which are quite similar to those of other aromatic and pyrazine hydrocarbon systems, and benzene, pyrimidine, and pyrazine ammonia and benzene water clusters, the spectra of which are all unique and surprisingly erratic. In the latter grouping, spectral cluster shifts range from -100 to $+500\ cm^{-1}$, vdW vibronic spectra range from nonexistent to intense, vdW modes can be highly perturbing to the solute vibronic structure and energy, and the number of cluster configurations varies from one to three in an apparently arbitrary fashion. These differences notwithstanding, the Lennard-Jones (6-12-1) potential, augmented appropriately with hydrogen bonding interactions (10–12) as required, always gives geometry and binding energy results that are in complete agreement with the spectra as far as the comparison can be made (i.e., symmetry, numbers of configurations, red and blue shifts with regard to hydrogen bonding, etc). The atom–atom LJ potential form has been chosen for these calculations because a large number of parameters for different types of atoms are available in the literature.

The benzene $(NH_3)_1$ and $(H_2O)_1$ spectra are quite different from one another. The shifts for these two clusters and their geometries seem to emphasize the importance of hydrogen bonding in the benzene $(H_2O)_1$ cluster.

Pyrazine and pyrimidine water clusters are not found in these studies although they have been extensively investigated. These clusters are not observed perhaps because their excited states are dissociative, but more likely because of rapid excited state intersystem crossing and/or internal conversion.

APPENDIX TWO

SUPERSONIC MOLECULAR JET STUDIES OF THE PYRAZINE AND PYRIMIDINE DIMERS

Supersonic molecular jet studies of the pyrazine and pyrimidine dimers[a)]

J. Wanna, J. A. Menapace, and E. R. Bernstein
Department of Chemistry, Condensed Matter Sciences Laboratory, Colorado State University, Fort Collins, Colorado 80523

(Received 13 December 1985; accepted 8 April 1986)

Mass selected optical spectra for the first excited singlet $n\pi^*$ states of the pyrazine and pyrimidine dimers are presented. The species are created in a pulsed supersonic jet expansion. The spectra are analyzed based on ionization energy, vibronic structure, and relative energy with respect to the isolated monomer (cluster spectroscopic shift). Calculations of binding energy and geometry for these dimers are carried out employing a Lennard-Jones (6-12-1) and hydrogen bonding (10-12-1) potential. In the case of pyrazine, calculations and experiments agree that both parallel planar hydrogen bonded and perpendicular dimers are present in the expansion. The calculations also predict a parallel stacked and 90° rotated pyrazine dimer which is not observed. This latter species most likely forms an excimer in the excited state with a short lifetime and a highly red shifted broad spectrum. In the case of pyrimidine, calculations yield four planar hydrogen bonded species and a parallel stacked and displaced species. The spectra for the pyrimidine dimer are consistent with these configurations, in agreement with the calculations. No perpendicular configuration is calculated for the pyrimidine dimer and no spectroscopic features require postulating the existence of such a configuration. To explore further the agreement between calculated and experimental results for aromatic dimers, calculations are also presented for the tetrazine dimer. Three calculated geometries are obtained for the tetrazine dimer: a parallel stacked and 90° rotated species, a planar hydrogen bonded species, and a perpendicular species. Experimental spectra and calculations are in basic agreement for all dimers studied and, in general, support one another.

I. INTRODUCTION

Molecular dimers are of interest for a number of reasons. They can serve as model systems for condensed phase structure, dynamics, and nucleation and growth. Vibrational dynamics and reactions can be studied in clusters through the observation of vibrational dephasing or intramolecular vibrational redistribution (IVR) and vibrational predissociation (VP). Dimers also provide a model for higher order (i.e., secondary, tertiary, etc.) structure of more complex, flexible molecules. Finally, these small clusters can be treated as a new, weakly coupled state of matter appropriate in its own right for investigation and focused attention.

Small clusters or dimers are best studied by molecular jet techniques,[1-6] as the species are thereby isolated and free of extraneous perturbations. Of the molecular supersonic jet spectroscopy techniques available, the most useful is two-color time of flight mass spectroscopy[1] (2-color TOFMS) because many different clusters [e.g., dimers, trimers, dimers $(He)_n$, etc.] are simultaneously produced in the expansion process. Two-color TOFMS selects a cluster of particular mass, does not allow fragmentation of clusters to take place, thus maintaining mass integrity of the clusters, and yields a plot of cluster ion intensity in the chosen mass channel as a function of the cluster absorption spectrum.

Dimers of benzene, toluene, and benzene–toluene have been studied in our laboratory using the 2-color TOFMS technique.[1] Coupled with the experimental findings, a potential energy calculation of the structure and binding energy of these dimers based on an exponential-six (exp-6) function has also been reported.[2] Spectroscopic data and potential energy calculations have been analyzed to arrive at a set of consistent geometries for these dimers. The benzene dimer is suggested to have a parallel displaced structure and the toluene and toluene–benzene dimers are suggested to have both parallel displaced and perpendicular geometries. The benzene dimer characterization rests on isotopic substitution, absence of resolved splittings at the cluster 0_0^0, observation of only one feature, respectively, for $(C_6H_6)_2$, $(C_6D_6)_2$, and $C_6H_6C_6D_6$ at the cluster 0_0^0, and calculations employing the observed molecular quadrupole moment of C_6H_6 to set partial and atomic charges and multipolar terms. In all instances, the experiments and calculations appear to arrive at self-consistent and independent conclusions which are in agreement with one another.

Molecular jet studies of other isolated dimers have also been reported. Rotationally resolved fluorescence excitation and dispersed emission spectra of tetrazine,[3] phenyltetrazine,[4] and dimethyltetrazine[5] dimers have been reported. Hydrogen bonded benzoic acid[6] and benzoic acid–*p*-toluic acid[7] dimers have also been studied.

In this paper we report rotationally resolved 2-color TOFMS of pyrazine and pyrimidine isolated molecules at a resolution of 0.08 cm^{-1}. Unfortunately, this is insufficient resolution to obtain rotationally resolved 2-color TOFMS of the pyrazine and pyrimidine dimers. Computer simulations, based on a reasonable symmetric top algorithm, predict a resolution of at least 0.005 cm^{-1} (150 MHz) is needed to observe rotational structure for the dimers, assuming they are rigid.

[a)] Supported in part by grants from ONR and the Philip Morris Corporation.

 0021-9606/86/140777-08$02.10

In addition to the experimental spectroscopic methods used to study these dimers, potential energy calculations utilizing a Lennard-Jones (LJ; 6-12-1) potential are performed to yield minimum energy geometries and binding energies. This potential form is replaced with a LJ-hydrogen bonding (HB; 10-12-1) form for the appropriate set of atoms. The calculation and parameters employed are discussed and presented in an earlier publication.[5] These potentials, with literature parameter values, give the same results as the exp-6 with dipole–dipole, dipole–quadrupole, and quadrupole–quadrupole terms for the benzene, toluene, and benzene-toluene (and pyrazine and pyrimidine) dimers. The major advantage of the LJ form presently used in our studies is that more atomic parameters are available in the literature[9] and experimental multipole moments are not required for each system.

Dimer geometry is determined through analysis of experimental (e.g., shifts, ionization energies, origin identification, vibronic analyses, etc.) and calculational results.

II. EXPERIMENTAL PROCEDURES

A pulsed valve supersonic molecular jet system is used to generate the dimers. The pulsed valve is mounted in the mass spectroscopy chamber of a two chambered vaccum system. Since the duty cycle of the valve is roughly 10^{-3}, the 10 in. diffusion pump on the chamber and the 6 in. diffusion pump on the TOFMS flight tube adequately handle the gas load and maintain the chamber pressure below 2×10^{-6} Torr. The system is described in previous publications.[1,8] The beam passes through a skimmer and then into the ionization region of a TOFMS. Two separately tunable lasers provide the photons for the $S_0\rightarrow S_1$ transition and the $S_1\rightarrow$cluster ion transition.

Rotationally resolved 2-color TOFMS are obtained through pressure tuning of the grating box of the pump ($S_0\rightarrow S_1$) dye laser oscillator cavity. The output of this laser is narrowed by an etalon placed between the dye cell and the grating in the oscillator cavity. The doubled output from this dye laser is 0.08 cm^{-1} in width. The laser can be scanned over roughly 20 cm^{-1} for a N_2 pressure variation of 10 to 1500 Torr.

Pyrazine and pyrimidine are obtained from Aldrich Chemical Company and used without purification. The sample is placed in a trap behind the pulsed valve through which He flows at 120 psig.

The LJ potential energy function and calculational procedure have previously been described.[8] The additional constants needed for this work are the (aromatic) N···H hydrogen bonding values: $B = 8.244\times10^{3}$ kcal $Å^{10}$/mol and $A' = 3.2897\times10^{4}$ kcal $Å^{12}$/mol. In order to check the LJ potential form, in particular for the pyrimidine dimer, LJ plus multipolar (i.e., dipole–dipole, dipole–quadrupole, and quadrupole–quadrupole) potential calculations are also performed.[2] The pyrimidine dipole and quadrupole moments[10] are taken to be -2.97×10^{-18} esu cm and -1.91×10^{-26} esu cm^2, respectively.

Calculations are also reported which simulate the rotational structure of pyrazine and pyrimidine monomers and dimers. A symmetric top model is employed for this fit because it is simple, reasonably accurate, and in general is well suited to the purpose of roughly predicting the unresolved dimer structure. Both molecules are nearly symmetric tops ($\kappa\approx0.9$). The form of the equations and methods employed are given by Herzberg.[11] The rotational temperature achieved in our system is ~2 K. The rotational constants used in the dimer rotational spectra calculations are found from the calculated LJ geometries. The molecular geometries can be found in Ref. 12 for pyrazine and Ref. 13 for pyrimidine.

III. RESULTS

A. Pyrazine dimer

The spectrum of the pyrazine dimer at the 0_0^0 transition is presented in Fig. 1 at two ionization energies, both of which are lower than the minimum ionization (second photon) energy of 44 000 cm^{-1} required to observe the 2-color TOFMS of the pyrazine monomer. Lowering the ionization energy from 43 182 to 42 185 cm^{-1} causes three of the dimer related peaks to disappear: these features are found at −11.0, 12.0, and 26.2 cm^{-1} on the scale of Fig. 1. From the nature and appearance of these features, the +12 and +26 cm^{-1} peaks are quite likely vibrations built on the −11 cm^{-1} origin of a given configuration cluster. The intense features that remain at the lower ionization energy are found at −26.3, −5.8, +34.1, and 50.7 cm^{-1}. From this variation of ionization energy one can determine that at least two configurations of the pyrazine dimer are present in the su-

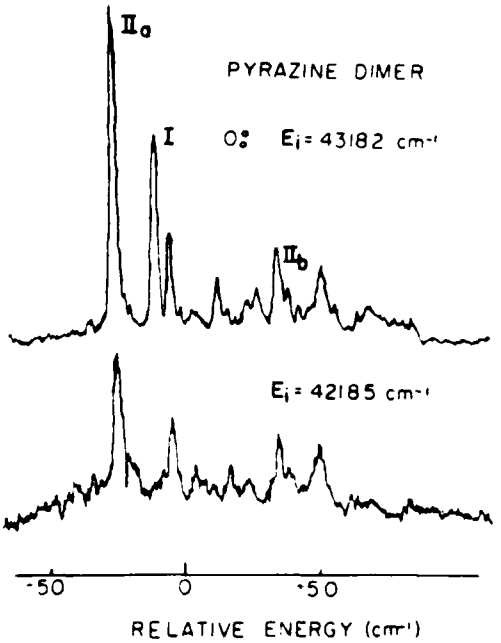

FIG. 1. Two-color TOFMS of the pyrazine dimer in the region of the pyrazine origin at two different ionization energies, top trace at an ionization energy of 43 182 cm^{-1} and the lower trace at an ionization energy of 42 185 cm^{-1}. The pyrazine origin at 30 876 cm^{-1} lies at 0 cm^{-1} on the scale of the figure.

personic jet expansion. The pyrazine-d_4 dimer 0_0^0 spectrum at two different ionization energies is presented in Fig. 2; the similarity between the pyrazine-h_4 and -d_4 dimer spectra is quite striking and reinforces our identification of origins and vdW vibronic features. The features that vanish at lower ionization energy are found at -11.5, 11.5, 25.5, and 64.1 cm^{-1} with respect to the pyrazine-d_4 0_0^0 transition (31 030.4 cm^{-1}). These should be compared with the numbers in Table I. The features that remain with lower ionization energy are located at -26.9, -6.5, 31.0, and 45.9 cm^{-1}.

The spectra of the pyrazine dimer at other pyrazine vibronic origins are presented, along with the 0_0^0 spectrum for comparison, in Fig. 3. The feature at roughly $+61$ cm^{-1} in this figure ($+34.1$ cm^{-1} in Fig. 1) is clearly an additional origin. The energy values and shifts for these features are presented in Table I. Since the pyrazie dimer is still observed at $10a_0^2$, its binding energy is greater than 800 cm^{-1}. No other features, appearing in the dimer mass channel, are found within -400 cm^{-1} of the pyrazine 0_0^0 transition. The spectra of the pyrazine-d_4 dimer at these other vibronic monomer origins are again very similar to those of the pyrazine-h_4 dimer. We concluded from these spectra (not presented) that the third origin for the deuterated dimer lies at 31.0 cm^{-1} from the 0_0^0 of the deuterated monomer.

Utilizing a Lennard-Jones potential function with a hydrogen bonding form, three configurations for the pyrazine dimer are calculated. Two of these configurations, a planar hydrogen bonded form and a perpendicular form, are displayed in Fig. 4. A parallel, stacked and 90° rotated structure

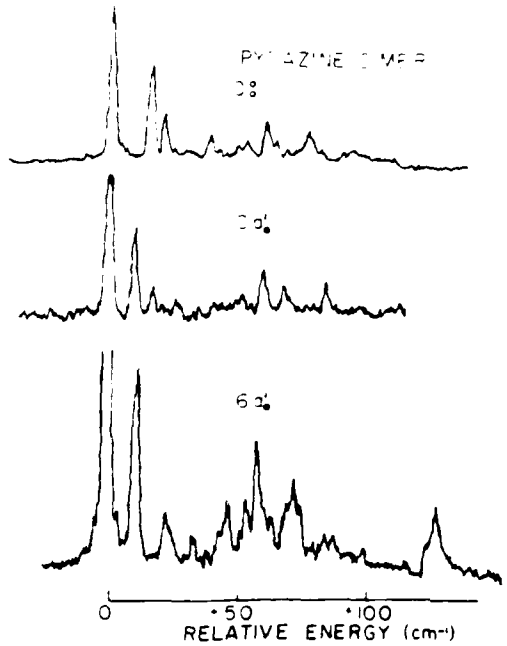

FIG. 3. Two-color TOFMS of the pyrazine dimer in the 0_0^0, $10a_0^2$, and $6a_0^1$ regions. These spectra are taken at high ($\sim 43\,200$ cm^{-1}) ionization energy.

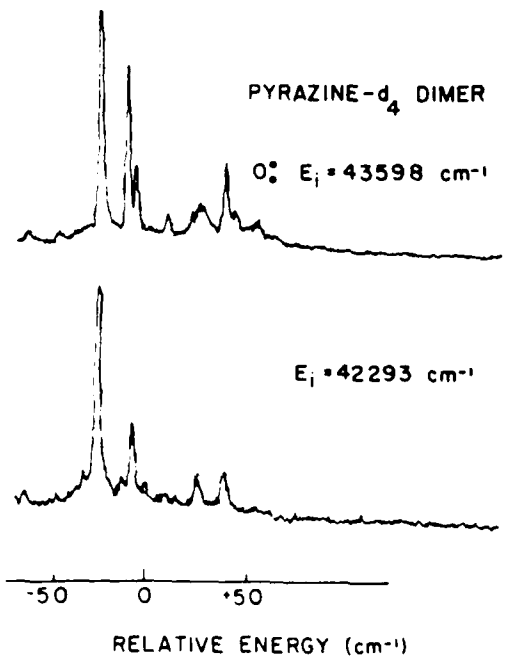

FIG. 2. Two-color TOFMS of the pyrazine-d_4 dimer in the region of the pyrazine-d_4 origin. Two different ionization energies are presented. The pyrazine-d_4 monomer origin lies at 0 cm^{-1} on the scale of the figure. Compare to Fig. 1 for the pyrazine-h_4 dimer.

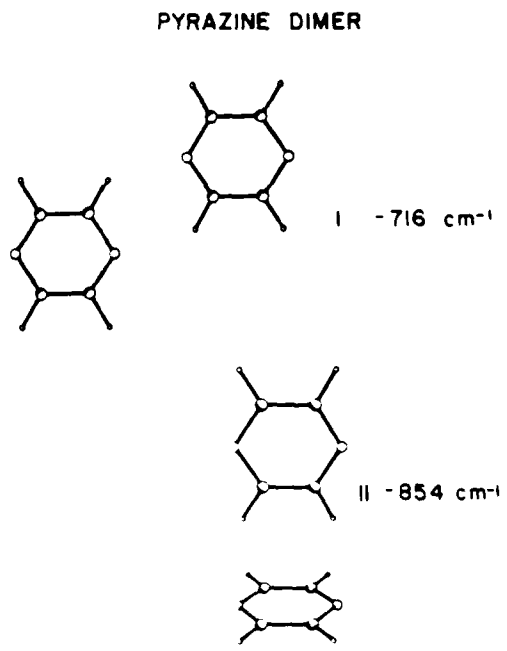

FIG. 4. Minimum energy configurations and binding energies of pyrazine dimer as obtained with a LJ plus HB potential calculation.

is also found. The binding energies for the former two configurations are presented in the figure. In the planar geometry the ring centers are at 5.6 Å from each other and the suggested C–H···N hydrogen bonds are 2.3 Å long. The pyrazine at the stem of the perpendicular configuration is situated in a symmetric position above the base pyrazine, with two of its hydrogens pointing to the base pyrazine nitrogens and equidistant from them. This perpendicular configuration has a 4.6 Å pyrazine center to center separation and apparent 2.6 Å H···N bond lengths.

B. Pyrimidine dimer

Three segments of the pyrimidine dimer 2-color TOFMS spectrum in the 0_0^0 region are displayed in Fig. 5 for two different ionization energies. Based only on the position and appearance of these segments we suggest that the features at -168 and $+296$ cm^{-1} are each associated with different geometries. The grouping of features in the $+170$ cm^{-1} region must be associated with more than one dimer configuration, as these eight sharp, relatively intense features are clearly not vdW vibronic progressions built on a single 0_0^0 origin. The minimum ionization energy for the pyrimidine monomer is near 44 090 cm^{-1} above the $^1B_1(n\pi^*)$ excited state at 31 073 cm^{-1}. As can be seen from Fig. 5, features in two of the three regions displayed disappear as the ionization energy is lowered from 44 363 to 42 320 cm^{-1}.

Calculations using a LJ–HB potential function yield four planar configurations, a parallel stacked head-to-tail displaced configuration, and a parallel stacked undisplaced configuration with the two pyrimidine molecules rotated 90° with respect to each other. The latter configuration most likely does not contribute to the observed dimer spectrum since it will probably form an excimer. No perpendicular geometry is calculated even with the LJ–HB potential augmented with multipolar terms. Figures 6 and 7 give those calculated geometries for the pyrimidine dimer which can produce the observed spectral features. The parallel displaced geometry shown in Fig. 6 is head-to-tail displaced by 0.6 Å along the CH–CH line from the molecular center; the interplane separation is 3.3 Å. The calculated binding energy for this dimer is 1478 cm^{-1}.

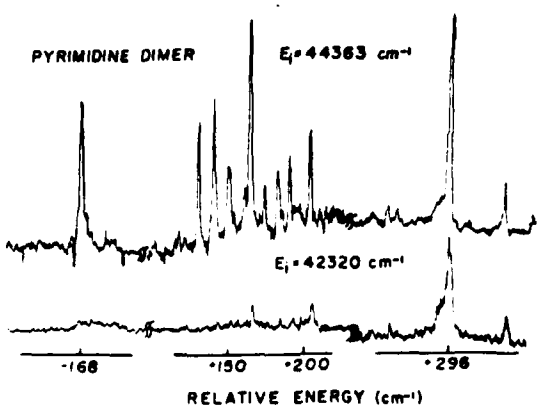

FIG. 5. Three segments of the 2-color TOFMS spectra of the pyrimidine dimer at two ionization energies, top trace at an ionization energy of 44 363 cm^{-1} and the lower trace at an ionization energy of 42 320 cm^{-1}. The energy scale is relative to the pyrimidine monomer 0_0^0.

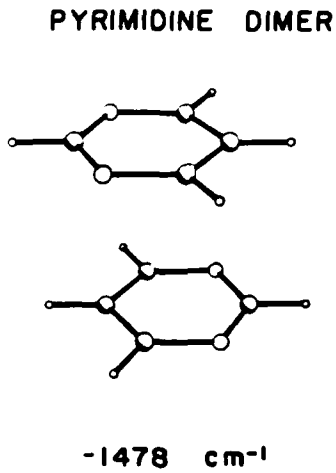

FIG. 6. Minimum energy configuration and binding energy for the stacked pyrimidine dimer as obtained with a LJ plus HB potential calculation.

The planar configurations are displayed in Fig. 7. Configuration I has a center to center distance of 5.5 Å, two N—H hydrogen bonds (2.3 Å separation), and a calculated binding energy of 709 cm^{-1}. Configurations II, III, and IV also display some hydrogen bonding but to a lesser extent than that displayed in configuration I. In these latter three cases, the less "acidic" hydrogens, not between the two N atoms, are involved in the "hydrogen bonds": the pyrimidine molecule center to center distance is ~6.0 Å and the calculated binding energies range from 400 to 430 cm^{-1}, substantially less than the binding energy for configuration I. Configuration II has two N–H hydrogen bonds each of 2.9 Å. Configurations III and IV have a nitrogen atom of one pyrimidine equidistant from two hydrogens of the other pyrimidine with an apparent hydrogen bond distance of 2.9 Å. Planar configurations in which two nitrogens are facing each other are not stable.

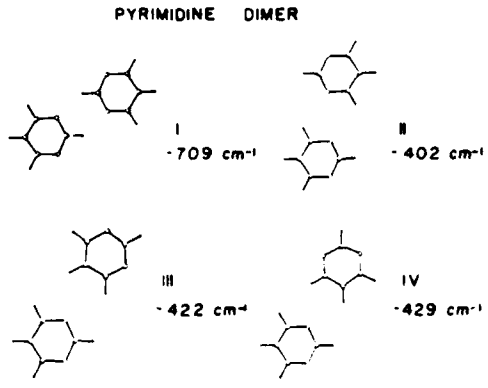

FIG. 7. Minimum energy configurations and binding energies for the planar pyrimidine dimers as obtained with a LJ plus HB potential calculation.

C. Rotational structure

Rotationally resolved 2-color TOFMS data can be obtained for the pyrazine and pyrimidine monomers using the resolution presently available in our laboratory ($\Delta\nu \sim 0.08$ cm^{-1}). The spectra are presented in Fig. 8. These well resolved spectra evidence a central Q branch with well developed R and P branches to the high and low energy sides, respectively. The calculated rotational structures for these transitions are presented in Fig. 9. In order to make the fit look reasonable, a 0.1 cm^{-1} Gaussian linewidth was incorporated in the calculated spectrum.

Considering that a symmetric top equation is used for the fit, the agreement between the calculated and experimental results is excellent. The purpose of this exercise is to observe and calculate the rotational spectrum of a dimer. One can see from Fig. 10 (top) that the rotational structure of the pyrazine dimer is not evident at this laser linewidth. Similar conclusions arise from the spectra of the benzene dimer (see Fig. 11). Computer simulations of the pyrazine dimer spectrum (based on the symmetric top calculations), show that a ~ 0.005 cm^{-1} laser linewidth is required to resolve rotational transitions for the aromatic dimers (Fig. 10 bottom). An attempt to fit the rotational contours to parallel or perpendicular transitions of parallel or perpendicular dimers demonstrates that no convincing conclusions concerning dimer geometry can be reached in this manner. In fact, the spectra of the parallel and perpendicular pyrazine dimer origins do not appear different at this resolution. The calculated contours are found using rotational constants of $A'' = 0.0611$, $B'' = 0.0157$, and $C'' = 0.0141$ cm^{-1} for the perpendicular dimer and $A'' = 0.0381$, $B'' = 0.0153$, and $C'' = 0.0112$ cm^{-1} for the parallel planar dimer.

IV. DISCUSSION

A. Pyrazine dimer

In the following paragraphs, only the pyrazine-h_4 dimer results will be discussed in detail. The similarity between the pyrazine-h_4 and -d_4 dimer results obviates the need for discussion of these data separately.

One of the most important experimental observations concerning the pyrazine dimer is the change in the spectrum as a function of ionization laser or second photon energy. Lowering the ionization laser energy by 1000 cm^{-1} to 42 185 cm^{-1} causes three features to disappear: two of these are assigned as vibrations built on a single origin (see Table I and Fig. 1). Further reduction of the ionization energy to 41 721 cm^{-1} results in no observed TOFMS spectrum for the pyrazine dimer. At least two different geometries of the pyrazine dimer are therefore present in the beam. The dimer with the higher ionization energy is probably a symmetrical dimer with two symmetry equivalent molecules because only one origin is associated with the high ionization energy spectrum.

Different geometries will possess different ionization energies depending on the involvement of the π clouds in the overall dimer interaction. For example, a planar hydrogen bonded dimer would probably have a poor ion "solvation" or stabilization and might therefore have a higher ionization energy. This geometry would in addition have only one spec-

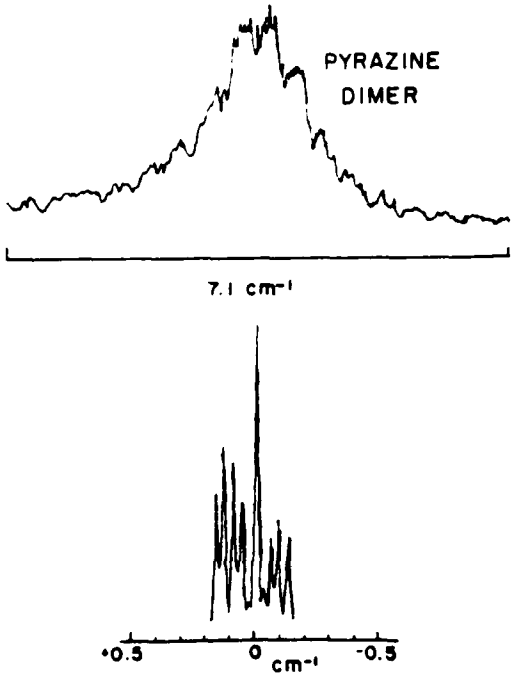

FIG. 10. Two-color TOFMS rotational spectrum of the pyrazine dimer origin (top) and computer simulated rotational spectra of the pyrazine dimer origin (bottom). The origin is at 30 849.5 cm^{-1} (-26.5 cm^{-1} origin in Fig. 1). The FWHM is roughly 2 cm^{-1}. The 30 865.0 cm^{-1} origin looks nearly identical to this one at the experimental resolution.

troscopic origin. A perpendicular geometry dimer would, on the other hand, probably evidence two features and a lower ionization energy due to the π-cloud involvement of the "horizontal" pyrazine in the stabilization of the ion.

The calculations give three general geometries for the pyrazine dimer: a parallel planar, a perpendicular, and a parallel stacked on 90° rotated geometry. The latter geometry is not discussed in this work because it likely is not important for any of the spectroscopic observations presented earlier. The remaining two configurations give rise to three separate spectra: one for the parallel planar geometry (I) and two for the perpendicular geometry (base IIa and stem IIb).

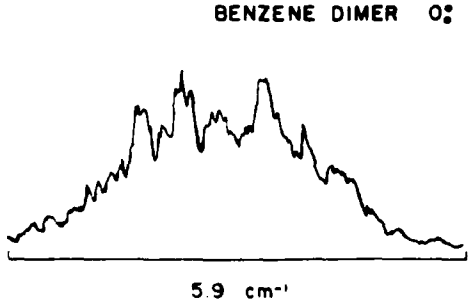

FIG. 11. Two-color TOFMS of the benzene dimer 0_0^0 transition at 0.08 cm^{-1} resolution. Most of the "features" in this trace are noise and are not reproducible.

TABLE I. Pyrazine dimer.

[a] See Fig. 4.

Table I gives the assignment of the dimer spectra. The planar geometry (I) is assigned to the origin at -11 cm^{-1} (Fig. 1) since this single origin feature is associated with the higher ionization energy. The other two origins at -26.5 and $+34.1$ cm^{-1} (Fig. 1) with respect to the pyrazine monomer origin are assigned to the perpendicular dimer because they both show the same low ionization energy. The base (IIa) is associated with the red shifted origin and the stem (IIb) is associated with the blue shifted origin. This latter correlation between spectra and calculated structures is based on the argument presented in previous publications[1,2] relating solvent cluster shifts and π-cloud involvement in the solute–solvent interaction: the larger the red shift, the more direct is the interaction between the system and the solvent. Thus the base molecule should be expected to have a larger red shift than the stem molecule.

The pyrazine $6a^1$ (in-plane C–C stretch) and $10a^1$ (out-of-plane C–C bend) vibrational modes show strong interaction with the van der Waals modes (Fig. 3).

B. Pyrimidine dimer

The ionization energy for the pyrimidine dimer system is again an important piece of information used to help determine the number of different configurations responsible for

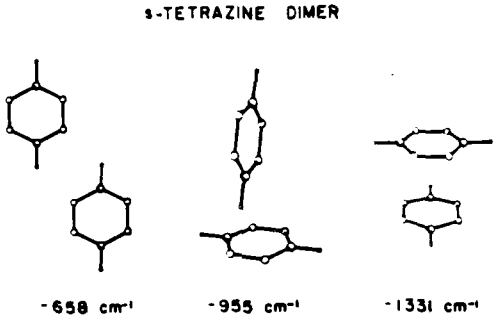

FIG. 12. Minimum energy configurations and binding energies for the tetrazine dimer as obtained with a LJ plus HB potential calculation.

the observed spectra and, perhaps, their geometry. Lowering the ionization by 2 043 cm^{-1} to 42 320 cm^{-1} causes the feature at -168 cm^{-1} to disappear, the features at $\sim +175$ cm^{-1} nearly to disappear, and the feature at $+296$ cm^{-1} to reduce in intensity. In addition, dimer spectral shifts can also be employed to associate calculated geometries with spectroscopic features: red shifted origins can be assigned to parallel stacked geometries, and blue shifted origins to planar hydrogen bonded forms. Perpendicular geometries can be responsible for both red and blue shifts depending on which molecule of the dimer is involved.[1]

LJ–HB potential calculations suggest one parallel stacked head-to-tail displaced, one parallel stacked rotated, and four parallel planar configurations for the pyrimidine dimer. No perpendicular geometry can be calculated using LJ–HB or a multipolar form.[1,2] All calculations give nearly identical geometries and binding energies for the parallel planar and stacked configurations.

The features at -168 cm^{-1} is suggested to be due to the parallel stacked and displaced head-to-tail geometry. One would expect this structure to have only one spectroscopically observed 0_0^0 transition and a substantial red shift. The remaining features in the spectra, due to their significant blue shifts, must be attributed to planar hydrogen bonded dimers. The feature at $+296$ cm^{-1} is suggested to be due to configuration I shown in Fig. 7. This configuration of the pyrimidine dimer forms two hydrogen bonds both of which involve the hydrogen atoms between the two ring nitrogen atoms on each pyrimidine: these hydrogens are the most electropositive (acidic) hydrogens on the ring. This configuration also has the monomers closest to each other (5.5 Å compared to 6.0 Å in the others). These factors suggest that configuration I gives rise to the most blue shifted feature in the spectra. The remaining three configurations II, III, and IV must generate the features in the $+175$ cm^{-1} region. Configuration II is a symmetrical dimer and will account for one feature while configurations III and IV each will account for two features since the pyrimidines in these last two configurations are not symmetry equivalent. Assigning these features to configurations II, III, and IV is a difficult task without further information: five of the eight major features in this region can, however, be associated with origins of configurations II, III, and IV.

The parallel planar hydrogen bonded configuration I is assigned to the large blue shift, low ionization energy feature, and the parallel stacked displaced geometry is assigned to the large red shifted, high ionization energy feature. On the other hand, the parallel planar pyrazine dimer is assigned to the feature with the higher ionization energy (and also a small red shift). Clearly the two dimers have a very different electronic structure and the component monomers must interact in a different manner. A possible explanation for these apparent differences is that the N–C–N moiety of the pyrimidine system becomes the positive end of the molecular ion which is in turn well solvated in the parallel planar dimer thus lowering the ionization energy, and that the loss of electron density in the N–C–N region in the $n\pi^*$ excited state reduces the hydrogen bond energy thus increasing the energy of the excited S_1 state and causing a dimer blue shift. Similar arguments can be rendered to rationalize a negligible shift for the pyrazine system. We caution, however, that all such qualitative reasoning is subject to verification by more rigorous quantum mechanical calculations.

To ensure that our LJ–HB potential can produce other perpendicular dimer configurations, we have calculated the geometries expected for the tetrazine system. The tetrazine dimer has been studied by Levy and co-workers,[3] who have reported two geometries: a parallel planar configuration and a perpendicular configuration. These experiments involve rotationally resolved fluorescence excitation spectra. Our calculations generate three geometries for this dimer: a parallel planar configuration, a parallel, stacked and 90° rotated configuration, and a perpendicular configuration, as shown in Fig. 12. The calculated perpendicular configuration has one hydrogen of the stem tetrazine pointing towards an N–N

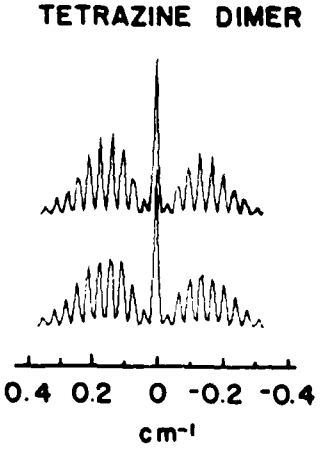

FIG. 13. Calculated rotational contours of the parallel polarized transition of the perpendicular tetrazine dimer centered at 18 272.0 cm^{-1} (0 cm^{-1} in the figure). The upper trace is calculated using the rotational constants obtained from the perpendicular configuration reported in Ref. 3(a). The lower trace is calculated using the rotational constants obtained from the perpendicular configuration reported in this work. A symmetric top model is assumed for both calculations and the intensities used are those of Ref. 3(a). The rotational constants employed are given in the text, in the symmetric top approximation $\bar{B}'' = (B'' + C'')/2$.

bond of the base tetrazine. In this configuration the plane of the stem tetrazine bisects the two N–N bonds of the base tetrazine. Levy's published perpendicular configuration[3(a)] has one hydrogen of the two C–H bonds of the stem tetrazine pointing toward one C–H bond of the base tetrazine and the plane of the stem tetrazine passing through the two C–H bonds of the base tetrazine. Rotational constants reported by Levy and obtained from a rotational analysis of the perpendicular configuration for parallel polarization are $A'' = 0.072\,87$ cm^{-1}, $B'' = 0.017\,22$ cm^{-1}, and $C'' = 0.016\,49$ cm^{-1}. Rotational constants obtained from our calculated perpendicular configuration are $A'' = 0.064\,58$ cm^{-1}, $B'' = 0.016\,44$ cm^{-1}, and $C'' = 0.018\,466$. These two sets of rotational constants render reasonably similar spectra, as can be seen in Fig. 13.

V. CONCLUSION

The analysis of the structure and properties of the pyrazine and pyrimidine dimers is based on an interpretation of ionization energy dependence, van der Waals vibronic structure, dimer spectral shifts, and potential energy calculations with LJ–HB and multipolar forms.

Variation of the ionizing laser energy allows different configuration dimers of a particular species to be identified. The pyrazine (h_4 and d_4) dimer has two identified geometries based on ionization energy dependence and vibronic analysis. Given the dimer spectral shifts and calculations, these have been associated with a planar parallel hydrogen bonded configuration and a perpendicular configuration. A third geometry, planar stacked and rotated 90°, is calculated but not observed probably due to excimer formation.

The pyrimidine dimers absorb in three spectral regions. The lowest energy feature is thought to be the calculated head-to-tail parallel stacked displaced geometry, the highest energy feature is assigned as a parallel planar strongly hydrogen bonded form in which the most electropositive H atoms are involved in the hydrogen bonding. The features at $+175$ cm^{-1} are attributed to different planar configurations which are only weakly hydrogen bonded through the less acidic hydrogens on the rings.

Dimer spectral shifts are expected to follow the rules determined previously for solute–solvent clusters: the major red shift mechanism is π-system coordination or overlap between the two molecules and the major blue shift mechanism is hydrogen bonding. Ionization energies can be rationalized in accordance with the general notions of ion solvation by either the π system in the case of pyrazine or the N–C–N hydrogen bonding region in the case of pyrimidine.

Calculations are also presented for the tetrazine dimers to compare parallel planar and perpendicular spectroscopically assigned geometries and our calculations. Calculations predict, and experiments suggest, perpendicular geometries for toluene, benzene–toluene, pyrazine, and tetrazine but not for benzene. Moreover, calculations predict, and experiments are consistent with, the absence of perpendicular geometries for the pyrimidine dimer. Perhaps one of the most remarkable results of this study is the rather large number of different, roughly equal binding energy configurations found for the N-heterocyclic aromatic dimers in general.

APPENDIX THREE

"ECCEMP2"

```
10 !!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!
20 ! Program name: ECCEMP2
30 !
40 ! This program calculates cluster binding energy and geometry using an empiri
50 ! cal atom-atom Lennard-Jones potential. The potential includes 6-12 general
60 ! non-bonding, 10-12 general hydrogen bonding , and 1 monopole charge terms.
70 ! The program will perform calculations on clusters composed of up to three
80 ! molecules (subunits).
90 !
100! Geometry and binding energy optimization is accomplished by analyzing the
110 ! forces and torques on the cluster subunits which result from the intermole
120 ! cular potential between the cluster subunits. The molecules are translated
130 ! in three dimensions and rotated about the their centers-of-mass in three
140 ! dimensions in response to the forces and torques. Binding energy and
150 ! geometry optimization is achieved by simultaneously manipulating the six
160 ! degrees of freedom until the forces and torques are zero; that is, until
170 ! minimum energy and optimal geometry are obtained.
180 !
190 ! This program also calculates the intermolecular force field for van der
200 ! Waals vibrational mode modeling which can be conducted using the VDWNCA
210 ! program. The ECCEMP2 program will determine the intermolecular force
220 ! field for clusters containing up to 25 atoms total (solute+solvent).

APPENDIX FOUR

"VDWNCA"

```
10 !!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!
20 ! Program name: VDWNCA
30 !
40 ! This program calculates van der Waals cluster intermolecular vibrational
50 ! modes using a normal coordinate analysis (NCA). The NCA is conducted using
60 ! the FG matrix method. The clusters are treated as "giant molecules" in the
70 ! NCA for which the intra- and intermolecular motions are treated
80 ! simultaneously. The intermolecular force field used in the calculations is
90 ! generated using ECCEMP2 and is stored on disc as H2OEIG. The intramolecular
100! force fields are taken as those of each cluster sunubit. Both the intra-
110! and intermolecular force fields are treated using the central force and
120! harmonic oscillator approximations.
130 !
140 !
150 !
160 ! NOTICE: This program will not run with documentation contained in program
170 ! if not more than 256 Kbyte RAM is available.

5745 ' Intramolecular force fields for cluster subunits.
5750 '
5755 ' The force fields are generated using the central force approximation and
5760 ' expressed as force constants in a cartesian coordinate system. The
5765 ' following data statements are for the intramolecular force fields in
5770 ' Benzene-(Methane)1. They are included to give an example on how the
5775 ' force fields are generated. Since the benzene subunit is planar, the
5780 ' central force field constants must be modified to incorporate
5785 ' out-of-plane motion. This is accomplished by setting the atoms composing
5790 ' benzene slightly out-of-plane. One angstrom  provides sufficient
5795 ' out-of-plane displacement to account for the out-of-plane force field.
5800 '
5805 ' The force fields are entered as force constants between adjacent atoms
5810 ' and between atoms displaced by one intervening atom. The atoms in
5815 ' each cluster subunit are numbered in the same order as used in the
5820 ' ECCEMP2 calculation. The force constants used are those corresponding to
5825 ' general functional group stretches and bends.
5830 '
5835 '
5840 ' Order of data entries:

APPENDIX FIVE

"H_2PCNCA"

```
10!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!!
20 ! Program name: H2PCNCA
30 !
40 ! This program performs an out-of-plane normal coordinate analysis (NCA) on
50 ! free base phthalocyanine. The NCA is conducted using the FG matrix method.
60 ! The out-of-plane motion is modeled using the internal coordinates described
70 ! in chapter 7 of this dissertation. This particular program calculates the
80 ! Au vibrations. The B1u, B2g, and B3g vibrations can be calculated by
90 ! replacing the data statements with those appropriate for the specific
100 ! vibration symmetry. The data statements for the B1u, B2g, and B3g
110 ! vibrations are included at the end of this program.

"3DHRRA"

```
C-----------------------------------------------------------------------
C Program: 3DHRRA
C
C This program calculates vdW torsional modes for benzene(methane)1 type
C clusters. The torsional modes are calculated for a specified
C torsional barrier height and torsional potential form. The
C torsional modes are treated using rigid rotor
C symmetric top wavefunctions as a basis set. Under free rotation, these
C wavefunctions are solutions to the spherical top Schrodinger equation.
C Upon application of the torsional potential, the torsional mode
C eigenvalues are obtained by diagonalizing the energy matrix
C which describes the hindered rotational/librational motion.
C-----------------------------------------------------------------------
C
      PROGRAM 3DHRRA
C
C-----------------------------------------------------------------------
C A(*)=Energy matrix to be diagonalized.
C D(*)=Diagonal elements of tridiagonal matrix, or eigenvalues of
C diagonalized matrix.
C E(*)=Subdiagonal elements of tridiagonal matrix.
C ZAP(*)=Orthogonal transformation matrix to tridiagonalize A(*).
