13. ABSTRACT (Maximum 200 words)

A particle entrainment simulator was used to simulate conditions during resuspension events in order to investigate how resuspension affects the chemical behavior of hydrophobic organic contaminants such as PCBs and PAHs in the coastal marine environment. Organic contaminants were evaluated in bulk sediments, sized fractionated sediments and resuspended particulate material. The sediments evaluated represented distinctions in contaminant loadings and sediment textural characteristics. It was concluded that contaminants are injected into the overlying water column in direct response to the severity of the resuspension events. In general, on a volume normalized basis (i.e., mass L^{-1} of water) the contaminants showed elevated levels as the applied shear increased from 2 to 5 dynes cm^{-2}; however, on a mass normalized and organic carbon normalized basis, the chemical loadings decreased with increasing applied shear. Differences in the general behavior were traced to the textural and chemical differences of the bulk sediments used for resuspension experiments. It was concluded that the exact behavior of the contaminants was likely related to the amount of and contaminant load on material entrained during resuspension events and represents the interplay of: (1) dilution from depleted coarse grained material, (2) fortification from more highly loaded coarse grained materials as in the case of PAHs with log K_{ow} >6 and (3) the effects from fine grained highly enriched material.

INTRODUCTION

The degree of ecological stress that hydrophobic organic contaminants (HOCs) exert on the marine environment is directly related to their concentration in the various compartments of the system, the time in each of the compartments, and the rate of exchange between compartments. The processes that control the removal of HOCs from the water column compartment include, lateral or advective outflow, volatilization, bioaccumulation, degradation and burial in the sediments. Since the sediments are repositories for many particle active contaminants, it is important to understand the mechanisms that control chemical flux so that the potential effects from contaminated resuspended sediments can be assessed. Within the active sediment layer a natural periodic resuspension–deposition succession takes place corresponding to wind or tidally induced energy frequencies. In addition, by feeding, locomotion, and habitat formation, benthic animals resuspend sediments or otherwise modify physical resuspension (Davis, 1993). A sufficient treatment of the factors affecting transport and resuspension can be found in a recent summary article (Bedford, 1994). In dynamic systems such as coastal areas, pelagic organisms will be exposed to significant temporal concentration shifts as exchange between compartments takes place. For example, Boehm has shown that PCB, PAH, and coprostanol levels can change by as much as a factor of ten over one tidal cycle (Boehm, 1983). These changes appear to be controlled by a complex function of the movement of contaminated suspended and resuspended sediments in the water body.

The purpose of this study was to investigate how the concentration of hydrophobic organic toxics on resuspended particles varied with:

- applied bottom shear
- resuspended sediment concentration
- bulk sediment contamination
- bulk sediment mineralogy

The study is based on experiments using the Particle Entrainment Simulator (PES, **Figure** 1) (Tsai and Lick, 1986). The sediments used for the experiments were obtained from Black Rock Harbor, CT and Narragansett Bay, RI.

MATERIALS AND METHODS

Sampling

Sediment samples were taken from 2 sites in Narragansett Bay, RI and one site in Black Rock Harbor near Bridgeport, CT (**Table** 1). Sediment from Black Rock Harbor had been previously collected using a 0.1 m^2 gravity box corer (Rogerson *et al.*, 1985). The sediment was subsequently homogenized and sieved to remove shells and sediments of greater than 1 mm, placed in nitrogen purged sealed drums and stored at 4 °C.

Sediments from Narragansett Bay were collected using a Smith–MacIntyre grab sampler. Subsamples (plugs) were obtained by carefully inserting a 12.7 cm diameter stainless steel tube into the sediment making sure that the surface of the sediment remains undisturbed. Locations of the subsamples were selected to capture the undisturbed surface layer. The subsamples were immediately transferred to a precleaned specially designed glass plug cylinder and were covered with seawater and kept at 4 °C in the dark until laboratory tests were initiated, usually within 24 to 48 hours of collection.

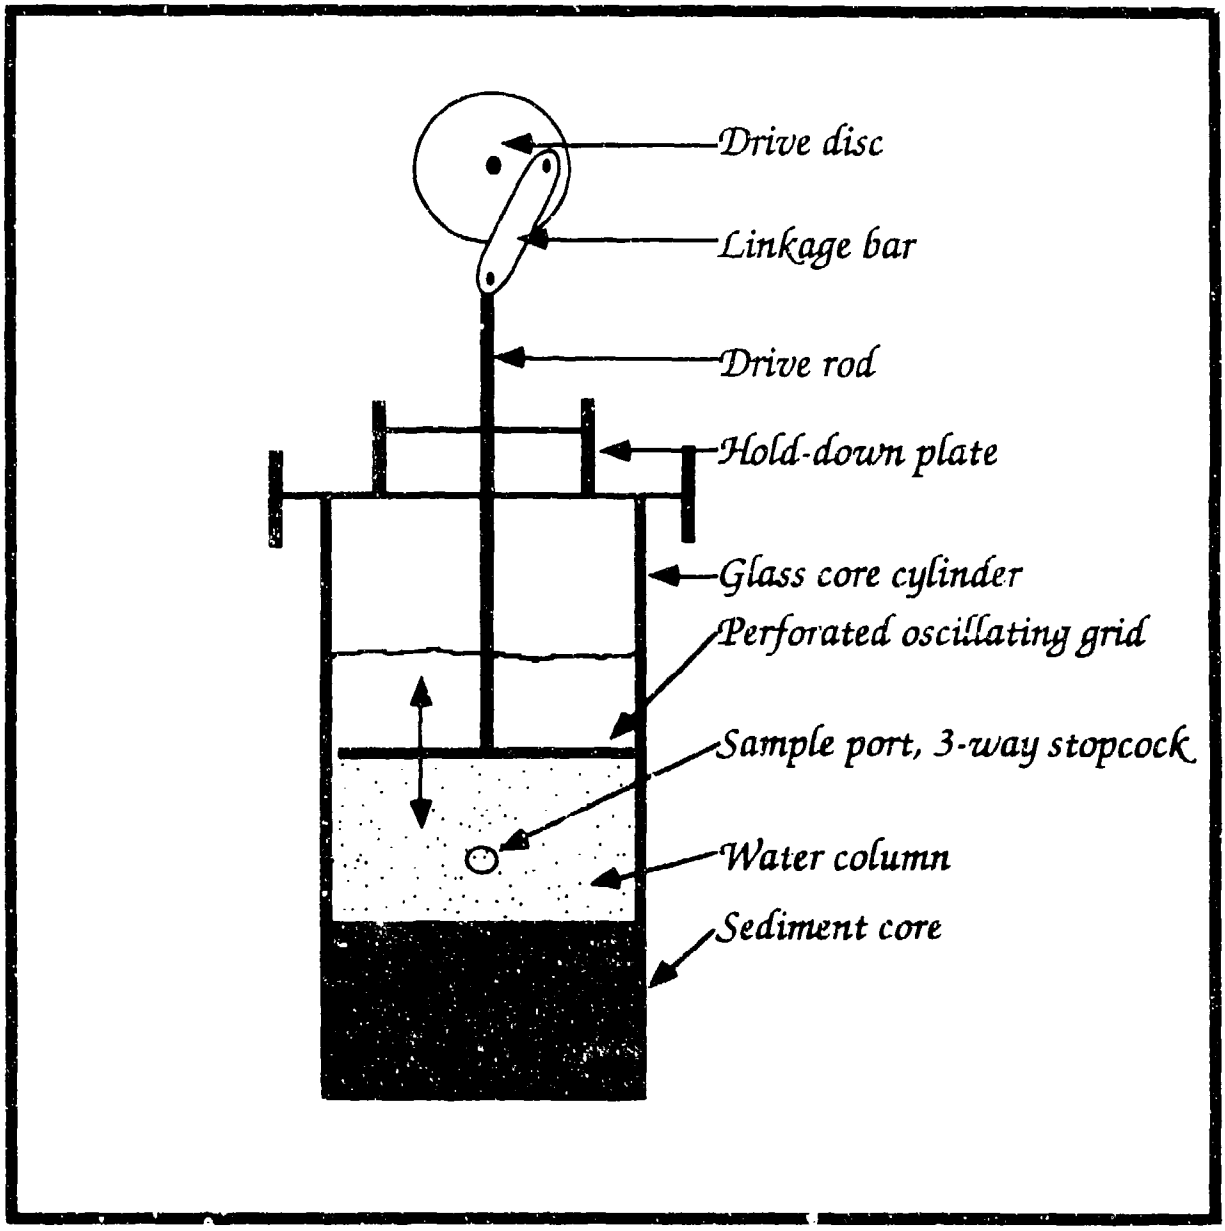

Figure 1. A schematic view of the Particle Entrainment Simulator (PES) used during the resuspension experiments.

Table 1.
Sampling data for the study

Site	Location PES-Sediment	Collection Type	Depth m
BRH – Black Rock Harbor, CT	41°09'N 73°13'W	Box Corer	Unk.
Narragansett Bay, RI			
PR – Providence River (Gaspee Pt.)	41°45.37'N 71°22.20'W	S-M	5.5
RP – Rocky Point	41°41.59'N 71°20.94'W	S-M	6.1

S-M = Smith-MacIntyre grab (0.1 m^2).

Experimental

Each sediment sample was securely positioned in the PES and underwent resuspension experiments according to previously outlined procedures (Keith *et al.*, 1991; Lavelle and Davis, 1987). Briefly, sediment plug cores were positioned such that the sediment was 2-3 cm below the furthest extent of the oscillating disk. The sediments were subjected to artificial resuspension experiments using the PES under two to four resuspension energy levels ranging from 2 to 5 dynes cm^{-2}. The applied shear stresses were considered typical of tidally induced near bottom shear stresses (Bokuniewicz *et al.*, 1991; Keith *et al.*, 1991) but lower than others (Partheniades, 1965). During each experiment, after the core was mounted to the PES apparatus, the simulator was adjusted to a known oscillation magnitude (seconds $cycle^{-1}$) corresponding to a pre-calibrated shear stress. The shear stress levels that the PES has been calibrated at are 2, 3, 4, and 5 dynes cm^{-2}, corresponding to 0.16, 0.12, 0.10, and 0.08 s c^{-1} of the perforated disk (Lavelle and Davis, 1987).

The determination of the steady state condition was accomplished by evaluating the turbidity of the overlying water using a single beam spectrophotometer (i.e., Bausch & Lomb, Spectronic 20). If the variability in measured percentage transmission was less than a two per cent, the system was considered to be at steady state for the given shear level; thereupon samples were taken. It was not always necessary to track the response of the system up to the steady state condition; previous experience allowed samples to be evaluated after approximately 15 minutes to assess the variation in turbidity. **Figure** 2 depicts typical light attenuation data (100-% T) for the cores examined. Samples for total resuspended solids concentration, hydrophobic organic, particle size, and organic carbon were collected under steady state conditions.

All collected sediment samples were evaluated for organic contaminant loadings (PCBs and PAHs), organic carbon content and particle size - textural properties. Filtrate samples were evaluated for dissolved phase organic contaminants. Bulk sediments were also studied for organic contaminants, organic carbon and particle size - textural properties.

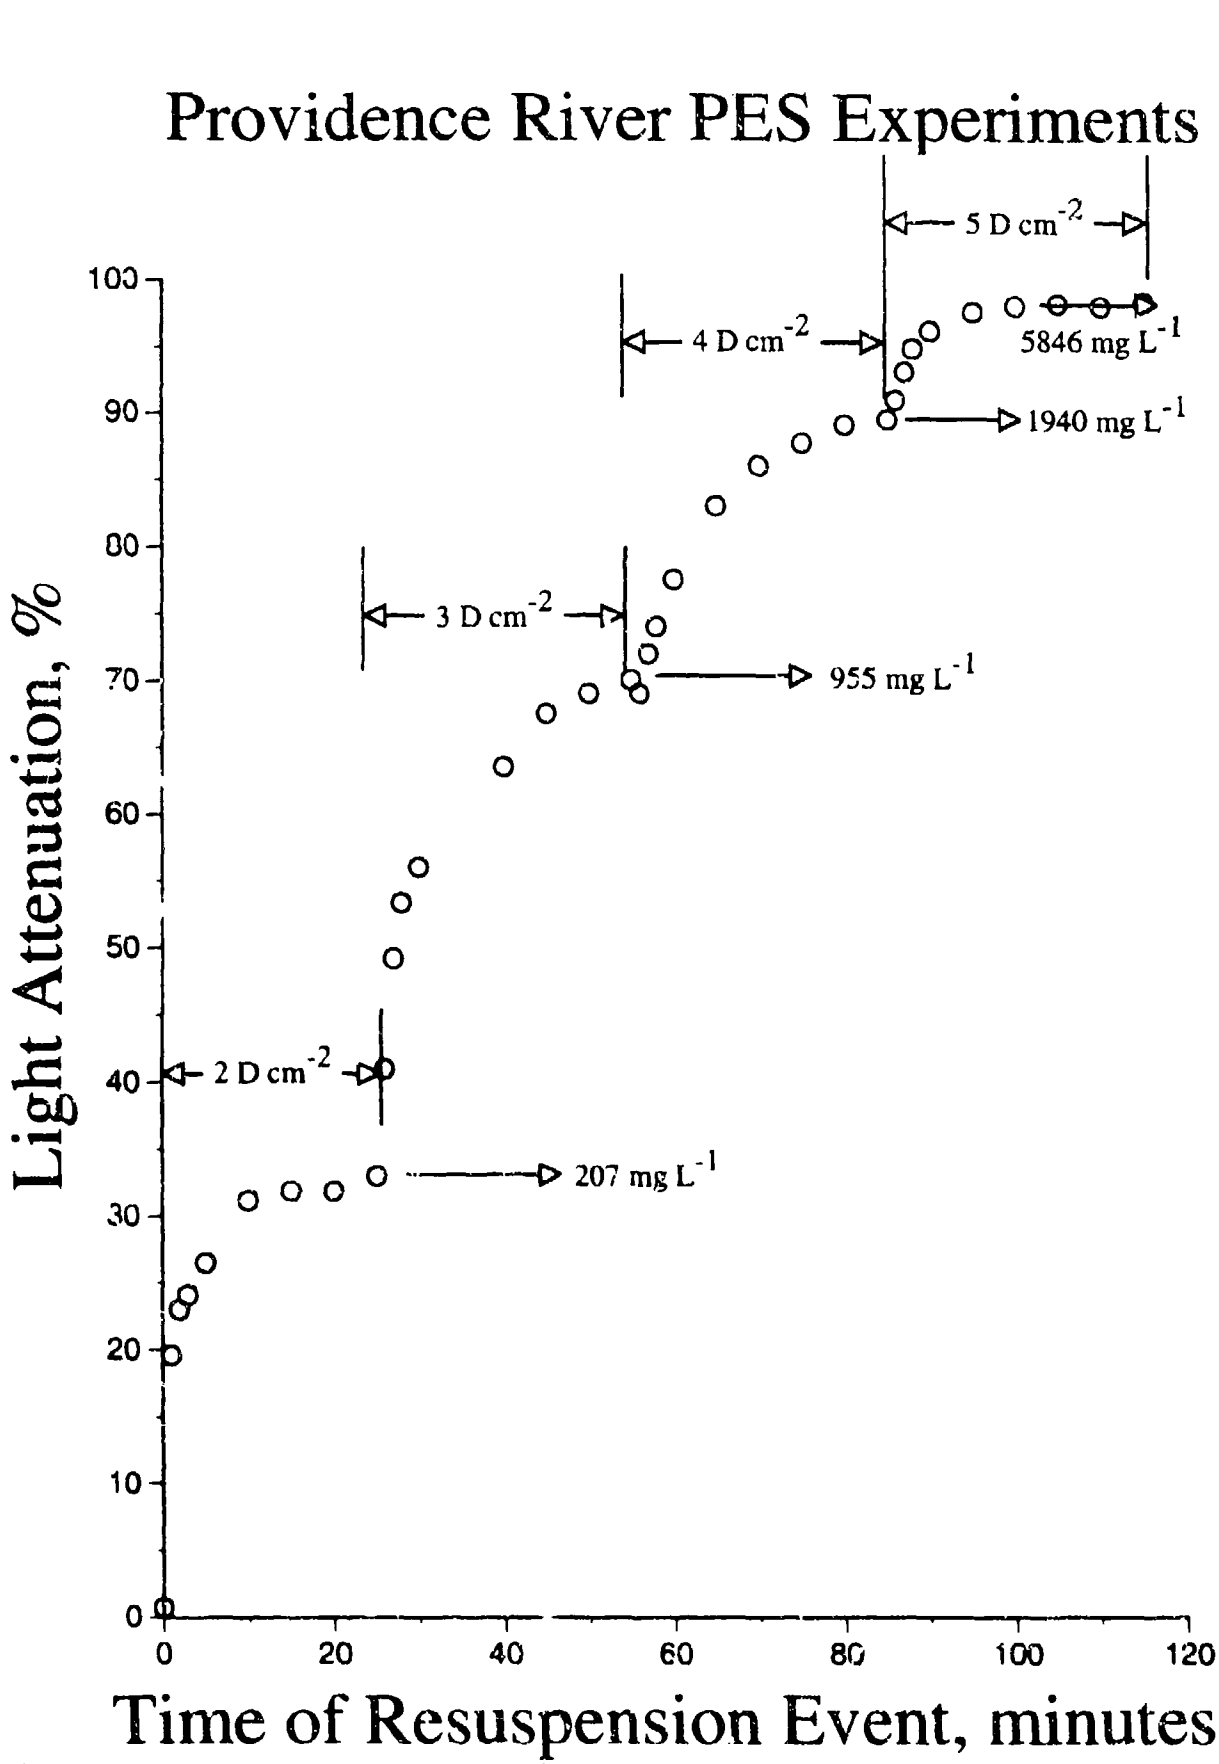

Figure 2. A typical light attenuation curve for the resuspension studies.

Analytical

Hydrophobic Organic Contaminants

The samples were extracted with methanol or acetonitrile to isolate the organic contaminants from the particulates. After polarity enhancement with high-purity water and solvent exchange into hexane, the extracts were separated into multiple fractions using micro-silica gel column chromatography. The organic contaminants in the different fractions were measured by high resolution capillary gas chromatography (GC) relative to internal standards, using gas chromatography-mass selective detection (HP 5971 GC-MSD) and gas-chromatography-electron capture detection (HP 5890 I GC-ECD). The analytical methods have been described in detail (LeBlanc *et al.*, 1992; Latimer *et al.*, 1991; Latimer *et al.*, 1990; Pruell and Quinn, 1985).

Quality assurance was accomplished through various means to certify that all analytical operations were under quality control. The precision of the procedures was measured as the relative standard deviation (RSD) of replicate analyses, which were conducted on selected samples over the course of the project. In most cases, the RSDs were 10% or better. The accuracy of the procedures was measured as percentage recovery of a standard mixture (containing analytes) spiked into blank samples at concentrations similar to the lower values that were determined in the field samples. These fortified blanks were analyzed over the course of the projects. In most cases, the recoveries were within 80-120 percent of the concentration in the spiked mixture, and in many cases the values were within ±10%. In addition, accuracy was measured as percentage recovery of specific organics in Standard Reference Materials (SRM), including NIST SRM 1649 (Urban Dust-PAHs), NIST 1941 (PAHs, PCBs in Marine sediment) and Canadian NRC SRM HS-2 (PCBs in marine sediment) carried through the entire analytical procedure. This was done several times over the course of the projects, and at least 70% of the analytes were within 70-130 percent of the stated values, and many were within ±10%.

The average detection limits for a 0.01 g (dry weight) sample are approximately as follows: individual PAHs 20 ng/g, individual chlorobiphenyl congeners 2 ng/g. However, actual detection limits can be as low as 0.2 and 0.01 ng/g, respectively, depending upon the mass of particulate material in the sample. For dissolved organic constituents the detection limits are 1 ng/L for PAHs and 0.05 ng/L for chlorobiphenyls and pesticides.

Particle Size and Organic Carbon

The percentages by volume of sand, silt, and clay in suspended sediments and bulk sediments were obtained using two methods: (1) a Brinkmann Particle Analyzer CIS1000; (2) wet sieving and using a settling column with gravimetric measurement. The procedures for analysis using the CIS1000 are outlined in the standard operating manual at the ERL-N. Briefly, chilled samples are diluted into a flask containing deionized water and a chemical surfactant. Samples are then mixed and allowed to stand for 12 to 24 hours; afterward, the sample is sonicated and further mixed. The sample solution is then introduced into the scanning chamber to undergo analysis. Deionized water is used to check the instrument background.

The second method involved the wet sieving of sediment to remove the > 0.063 mm particles (i.e., sand) followed by the application of Stokes settling law in a large graduated cylinder to determine the amount of silt and clay. This method is widely used and is highly reproducible (Mueller *et al.*, 1992; Keith *et al.*, 1991).

RESULTS AND DISCUSSION

Particle Dynamics During Resuspension

The major factors that determine the magnitude and duration of entrainment and deposition of sediments are: the nature of the fluid mechanics, the composition and the spatial distribution of the

bottom material. The nature of the fluid mechanics includes the momentum fields at the various boundary layers in the near bottom environment including: (1) motions of long and short-period surface gravity and/or internal waves; (2) mean flow; (3) Coriolis effects; (4) turbulence from shear, bottom roughness, wave breaking, etc.; and (5) stratification effects (Bedford, 1994). Tidal currents and wind induced resuspension is particularly important in estuaries (Sanford, 1994). Entrainment and deposition are also a function of the nature of the bottom material. Specifically, geotechnical characteristics (e.g., particle texture/mineralogy), water content, and extent of biological activity all modify the magnitude of resuspension. Fine-grained particles are easily resuspended leaving behind the larger grained materials that act to armor the sediments against further entrainment (Lavelle and Davis, 1987). As the sediments age they compact, forming a more cohesive substrate that causes the rate of entrainment to decrease with depth, all other variables being equal (Lick and Kang, 1987). These processes limit resuspension to a finite amount at any given stress. Infaunal and epifaunal organisms can have a positive or negative effect on the entrainment rates. Organisms such as *Yoldia limatula*, *Macoma tenta*, and *Pectinaria gouldi* cause resuspension by their biofunctions (feeding, locomotion, and habitat development) (Davis, 1993; Davis and Means, 1986; Bender and Davis, 1984). Motile organisms such as *Nucula annulata* can act to destabilize cohesive sediments which makes them more susceptible to resuspension (Davis and Means, 1986).

Entrainment, expressed as a rate (E), given as,

$$E = h\frac{dC}{dt} \qquad (\text{as } C \rightarrow 0)\,, \qquad (1)$$

is the flux of sediment across the sediment water interface under conditions when the concentration (C) of sediments in the overlying water (h = depth of overlying water) is near zero (Fukuda and Lick, 1980). E will decrease as the resuspension event continues until ($dC/dt = 0$) the rate of entrainment is equal to the rate of deposition (D). The light attenuated by the resuspended material will vary with turbidity and TSS concentration. It must be noted that the detection of LA is affected by the saturation of the detection system. Others have noted that 100% attenuation can be approached at 3000 mg L^{-1}. For the bedded sediments from Narragansett Bay this approach to saturation did not occur until the shear was at 4-5 dynes cm^{-2}. The Black Rock Harbor PES cores were highly unstable owing to the small particle sizes of the sediments; this instability lead to very fast entrainment and quick saturation of the spectrophotometric detector used to measure turbidity. The attenuation measurements near the saturation point are unreliable and require dilution and re-measurement to obtain reasonable LA estimates. Previous authors have derived equations to predict the concentration of suspended solids from LA (Davis, 1993; Keith *et al.*, 1991; Lavelle and Davis, 1987). Using the light attenuation-time relationships (see **Figure** 2 for an typical curve), and the equation,

$$C_{ss\ (g\,L^{-1})} = \left[\left(\frac{-1}{k1}\left(\ln\left(k2 - \frac{LA}{k3}\right)\right)\right]^{\frac{1}{k2}} \qquad (2)$$

previously published (Davis, 1993; Keith *et al.*, 1991) TSS concentrations were calculated for all the PES samples. The k values published are constants empirically derived from a variety of sediment types. In addition to the semi-empirical equation previously published, the measured TSS concentrations were used to establish a relationship to LA under the actual experimental conditions. The best fit of these data was obtained using an exponential function (**Figure** 3):

$$C_{ss\ (mg\,L^{-1})} = 47.8\, e^{(3.89E\text{-}2\ LA)} \qquad (3)$$

The equation was reasonably accurate for LA ranging from 30-90% and as such it was applicable to TSS concentrations up to approximately 2000 mg L^{-1}. **Figure** 4 presents the predicted results for the bedded sediments for the two equations. Equation 3 yielded reliable TSS levels for the 2, 3, and 4 dynes cm^{-2} shear levels but underestimated them for the 5 dynes cm^{-2} experiments. The calculated solids concentrations, using the semi-empirically derived equation (equation 2), showed

a slight overestimation at the lower applied shears but was more predictive at the higher energy levels. Again one must keep in mind that inaccuracies in TSS estimates are greatest when the spectroscopic detector becomes saturated.

Once the TSS concentrations were estimated entrainment rates could be calculated using the previously published equation (Lavelle and Davis, 1987):

$$E = \frac{\alpha_1 h}{(1 - \frac{C_o}{\alpha_2})} \qquad (4)$$

Where α_1 is the rate of change in concentration during conditions where deposition was likely minimal (less than 5 minutes); α_2 is the equilibrium concentration; and C_o is the initial concentration. This equation is based on assumptions derived from the conditions encountered using the PES: a) no radial dependence to erosion or concentration; b) minimal vertical dependence to the concentration; c) the resuspended particles have a single deposition velocity. As expected, the entrainment rates generally increased with increasing applied shear, confirming what others have noted: that shear is one of the controlling factors in resuspension behavior (Partheniades, 1965).

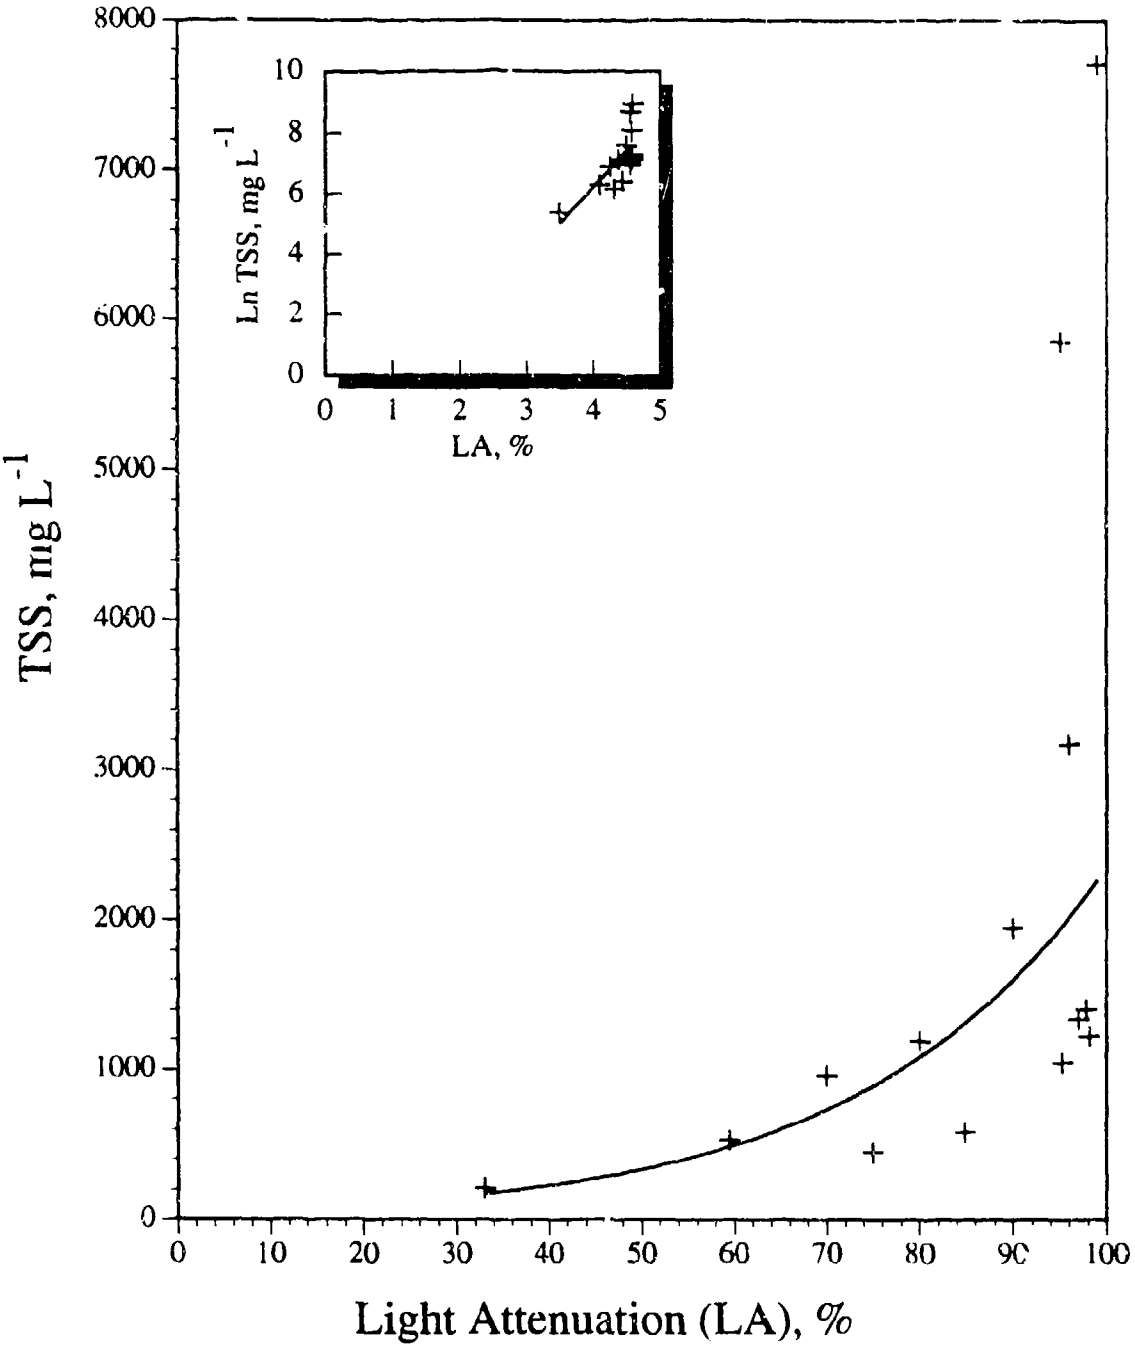

Figure 3. The relationship between light attenuation and total suspended solids during the resuspension experiments.

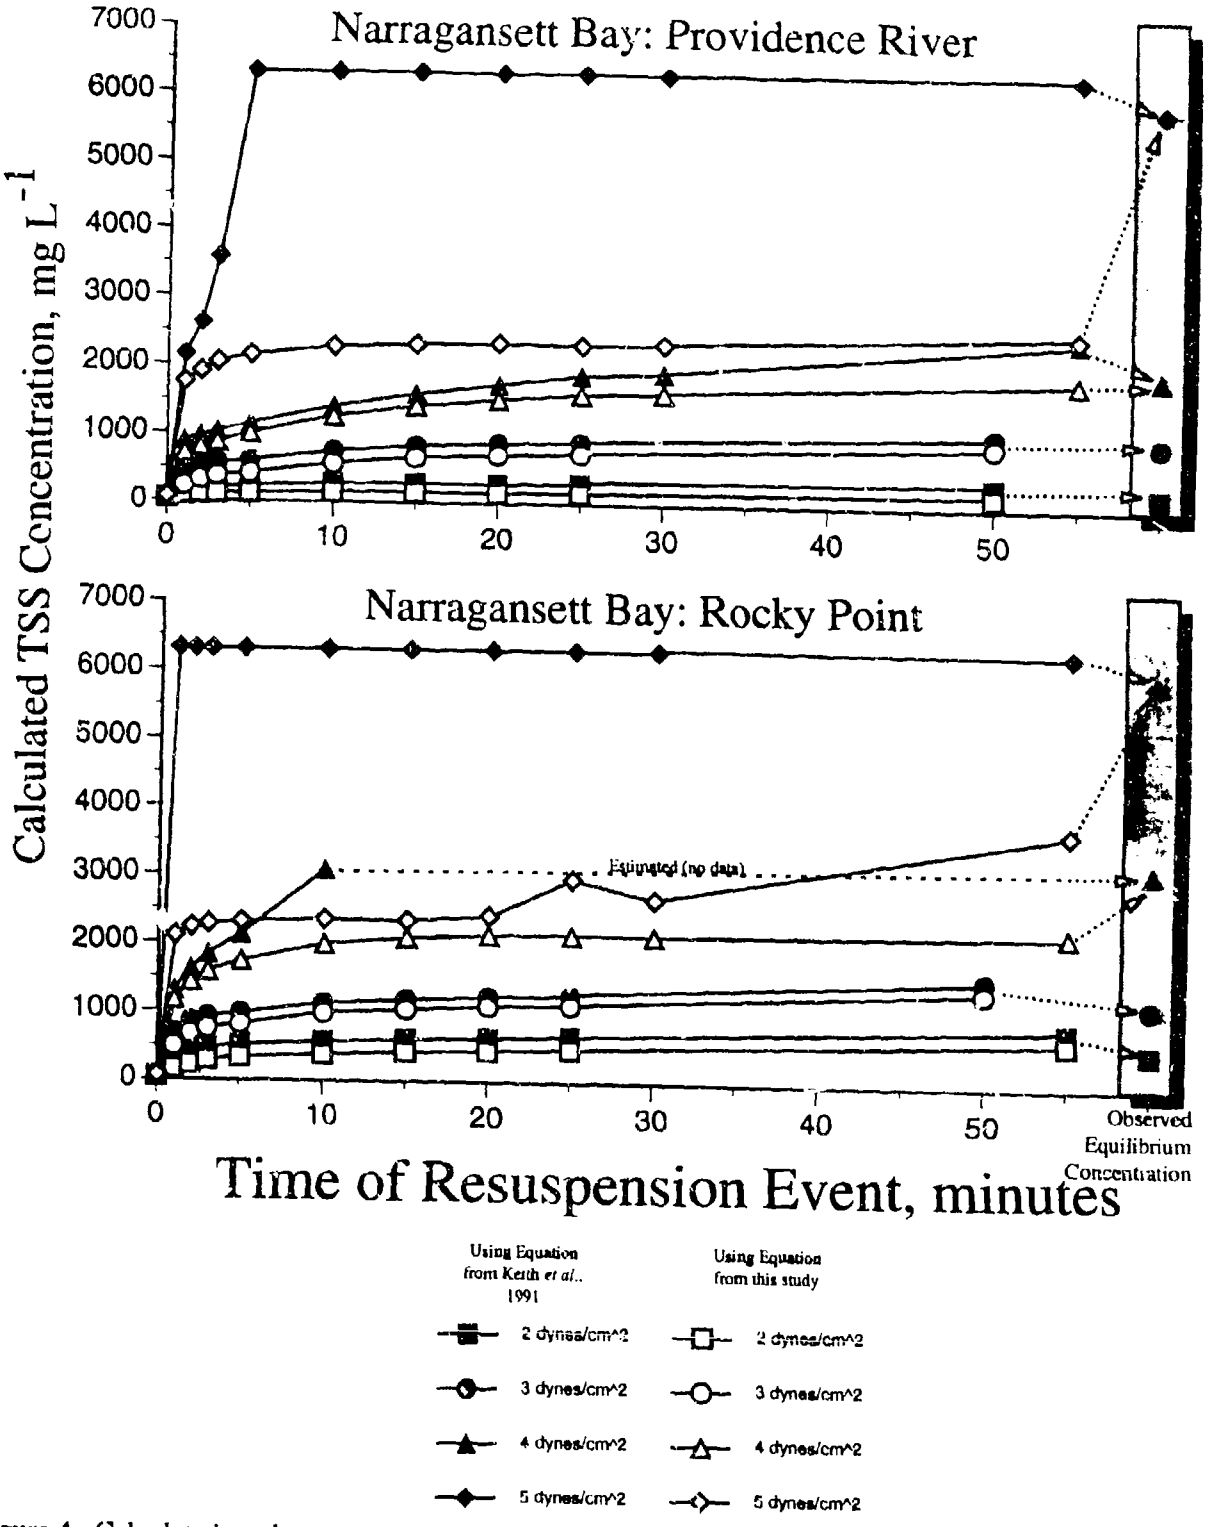

Figure 4. Calculated total suspended solids concentrations using equations from this as well as other studies.

The mass entrainment rates calculated for the PES experiments were greater than those measured using sediments from Puget Sound or other parts of Narragansett Bay (**Table 2** and **Figure** 5). The reasons are likely due to the differences in sediment particle size distribution, mineralogy or water content as well as biological influences. Sediment texture properties and water content have been found to be correlated with entrainment rate (Keith *et al.*, 1991). Although the data from the literature is incomplete it appears that textural/grain size factors are not sufficient to explain the differences. For example, of the sediments compared, NB station 12 (**Table** 3) had a mean grain size of 13.5 µm that was considerably lower than the sediment with the smallest grain sizes in this study (i.e., BRH = 29.5 µm VWM). Moreover, the other two sediment cores tested in this study had mean grain sizes (PR = 84.6 and RP = 81.5 µm) well above the next closest sediment (NB station 6, which had a value of 51 µm). The explanation for the higher entrainment rates must lie in the differences either in water content of the sediments or biological influences. Linear increases in sediment water content have been shown to cause logarithmic increases in E (Fukuda and Lick, 1980). The sediments evaluated during the present study do show a range in water content but the data do not correlate with the observed differences in entrainment rates. Thus, biological influences are the most likely cause of the higher entrainment rates observed in this study. In the case of BRH sediments there were no living benthic or epibenthic faunal observed throughout the experiments; in marked contrast, however, there were large numbers of amphipods, decapods and small worms in both of the sediments from Narragansett Bay. The paradox lies in the fact that an "abiotic" sediment (BRH) and highly biotic sediments (PR and RP) all give greater entrainment rates than other sediments. Considering that the total resuspension rate is the result of two independent and one interacting processes as expressed in the following equation:

$$R_t = R_p + R_{pb} + R_b \qquad (5)$$

the term, R_b denotes resuspension caused by biota, the term, R_p, indicates physical resuspension and the term, R_{pb} denotes enhancement or retardation of physical resuspension due to biological interaction. It is here assumed that the brief duration of the PES experiments as well as the stress caused by the experiments themselves limit R_b to a minimum value. Due to the character of the BRH sediments the only active process is resuspension would be strictly due to the applied shear (R_p is large) and that R_{pb} would be small so that there was no reduction in R_t due to biological stabilization. In the case of the two bedded sediments tested, the presence of large numbers of benthic faunal, that can serve to destabilize the sediment surface (large positive R_{pb}), is presumed the cause of the higher entrainment rates. It has been shown that the presence of certain species can increase the entrainment rate by as much as 8 -fold over entrainment rates from sediments that are abiotic (Davis, 1993).

The mass of solids entrained into the overlying water column ranged from 4 to 1700 g m^{-2} for the Black Rock Harbor dredge material, and 3 to 700 g m^{-2} for the bedded sediments. Previous studies of resuspension using Narragansett Bay sediments yielded lower maximum solids fluxes (0.04 to 402 g m^{-2}) (Keith *et al.*, 1991). The flux of resuspended particulates followed an exponential fit for the cores where applied shear was above 3 dynes cm^{-2} (**Figure** 6). The slopes were relatively constant ranging from 1.0 to 1.2; however, the intercepts ranged from 3.4 to 9.6 g m^{-2}, displaying different behavior between the sediments. The dredge spoil cores (BRH) had similar intercepts (i.e., 8.5 and 9.6, respectively for BRH experiment 2 and 3, mean = 9.1 g m^{-2}) which were approximately twice as great as the intercepts for the bedded natural sediments (i.e., PR and RP). The results are consistent with the fact that bedded sediments are more cohesive and had been armored against resuspension due to the abundance of larger grained sediments or through the action of infaunal organisms. The natural bedded sediments were observed to have a wide variety of infaunal organisms that could be responsible for the decreased entrainment compared to the abiotic BRH sediments; some have shown that certain biological adhesion can stabilize sediments from resuspension (Grant *et al.*, 1982) ; however, as noted above, the stabilization was not great compared to sediments elsewhere.

The change in the particle characteristics over the duration of the resuspension events gives insight into how sediments react under different turbulence conditions in the marine environment. In the

case of the bedded sediments from the Providence River, the amount of sand, although variable, showed a slight decrease, while the amount of clay increased markedly (from 2 to 7%) as the applied shear increased from 2 to 5 dynes cm^{-2} (**Figure** 7A, PR PES). The amount of silt remained relatively constant over the course of the experiment for this sediment. These changes were manifested by a decrease in average grain size of resuspended particles with increasing turbulence. It has been demonstrated that for fine grained sediments, as applied shear increases and suspended sediment concentration increases the steady state particle diameter decreases (Lick, 1994). The behavior of the Providence River sediment was in contrast to that of the other bedded sediments (Rocky Point Core, RP PES) as well as the dredge spoil sediment (i.e., BRH PES 1, 2, & 3 **Figure** 8).

The Rocky Point resuspension experiments reveal a sediment the upper few millimeters of which, on average, are a mix of silt and very fine sand (vfsand). Under steady state conditions of low turbulence (2 dynes cm^{-2}) the particles resuspended are composed of 73% silt and 24% very fine sand, with 3% coarse clay (cclay). As turbulence increased, the proportion of silt decreased (to 58%) with a concurrent increase in vfsand (to 39%). Even though the fraction of clay increased (**Figure** 7B), because of its small total proportion, the increase was less important than the increased sand levels. As a consequence, the mean particle diameters get larger as the applied shear increased (**Figure** 8). The BRH sediments exhibited similar behavior, although the amount of sand was less (**Figure** 7C-E).

The mean particle sizes of the resuspended sediments from the bedded sediments were less than the mean particle size of the bulk sediments, whereas the particle sizes of the resuspended sediments and the bulk sediments from the dredge spoil samples were similar. The bedded and dredge sediments had very different bulk geotechnical characteristics (mean grain size: PR = 85 μm; RP = 82 μm; BRH = 30 μm): the Narragansett Bay sediments consisted of nearly 50-50 silt-fine sand; whereas the Black Rock Harbor sediments were mainly comprised of silt (85%). The bulk sediment characteristics are taken from approximately the top 5-10 mm of sediment. Conceptually, during a resuspension episode, small slices of the bedded sediments are entrained into the overlying water column (Calvo *et al.*, 1991a). The material resuspended will be reflective of the sediments from subsequent depths, the characteristics of which will depend upon the profile of the particles with depth in the sediment. Using measured and estimated porosity (69.7-92.3%) and density data (1.5 g cm^{-3}, (Calvo *et al.*, 1991a)) for the bulk sediments, the depths involved during the resuspension events are composed of only the upper 1 mm of sediments, even at the highest experimental applied shears. Thus within these limits, as shear is increased, greater and greater depth populations of particles are entrained. The Black Rock Harbor sediments display a relatively homogeneous sediment whose characteristics do not change markedly with increasing applied shear. This is consistent with the published information on the collection and handling of this material (Rogerson *et al.*, 1985). The data indicate that the Providence River sediments are thus composed of smaller and smaller particles with depth; however, at some depth there needs to be a cache of larger sized particles since the bulk sediment is mainly comprised of fine sand. In contrast, the Rocky Point sediments are graded to larger sized particles with depth. It must be noted that the resuspension at 2 dynes cm^{-2} contains, in all likelihood, both the surface flocuulant layer and the more cohesive - larger sized particle layers just below. No data are available for shear levels less than 2 dynes cm^{-2}; however, others have indicated marked differences in entrainment at the 1 dynes cm^{-2} levels where presumably populations of small particles are entrained at different rates than the larger particles (Lavelle and Davis, 1987).

In summary therefore, the behavior of the resuspended particulates, during periods of shear from 2 - 5 dynes cm^{-2}, revealed differences between bedded relatively cohesionless sediments from Narragansett Bay and more silty, and homogeneous sediments associated with a dredge spoil. The dredge material resuspended readily and showed little change in particle characteristics under widely different applied shears. In contrast the magnitude and type of particles resuspended from bedded sediments appear to be a strong function of the characteristics of the sediment horizons in the upper mm of sediment as well as the applied shear.

Chemical Changes During Resuspension

Interfacial processes play a major role in the fate of contaminants in the marine environment. The sediment-water interface is an active area in which autochthonous and allochthonous particles and associated contaminants settle from the overlying water column. The in-place sediments are well-known repositories for many particle active contaminants including trace metals (Schults *et al.*, 1987), radionuclides (McLean *et al.*, 1991), nutrients (Nixon *et al.*, 1986), and organic contaminants (Latimer and Quinn, In prep.; Latimer *et al.*, 1991). Early in the diagenetic timeline contaminants associated with sediments are subject to remobilization. For example, resuspension of anoxic sediments into oxic bottom waters has been shown to release previously coprecipitated metals (Morse, 1994). Although aerial transport of PCBs and PAHs is an important input mechanism to the ocean, once deposited, their dispersion is mainly controlled by particle dynamics. Resuspension of contaminated marine sediments has been identified as a transport mechanism for organic contaminants (PAH, PCB and coprostanol) between the Hudson River estuary and the continental shelf and between the benthos and water column (Boehm, 1983). In Lake Superior, resuspension events were estimated to cause a 50% increase in PCB levels in the overlying water (Baker *et al.*, 1985). Fluxes of carbon, nitrogen, and bacteria from the sediments during resuspension add significantly to the autochthonous pools in the overlying water column (Wainright, 1990). Moran and Moore have demonstrated that resuspended sediments release dissolved Al into the water column and speculated that elevated levels of Al in certain sections of the North Atlantic Deep Water are due to this phenomenon (Moran and Moore, 1991). Moreover, suspended particulate matter has been shown to have higher levels of nutrients and petroleum hydrocarbons than the nearby surficial sediments (Quinn *et al.*, 1992; Oviatt and Nixon, 1975).

The injection of contaminants into the water column under conditions of resuspension can have a direct effect on the biota. Nutrients from resuspended sediments stimulate the growth of water column bacteria and protozoa (Wainright, 1987) and Pruell has demonstrated that filter feeding organisms (i.e., Blue mussels, *Mytilus edulis*) accumulate hydrophobic organic contaminants from resuspended sediments (Pruell *et al.*, 1987), which may cause toxic effects (Hennsen *et al.*, 1994). In the present study, contaminant behavior during the steady state portion of the resuspension episode was investigated. This is the period when E = D and would represent the period of maximum solids injection into the overlying water column.

Solid Phase Interactions

The formation - destruction of resuspended sediment aggregates plays an important role in the adsorption and desorption of particle active contaminants such as PCBs and PAHs. Resuspension events are dynamic, in which particle concentration and collision frequency increases. These events cause a large amount of material to be entrained into the water column and may accelerate various diagenetic processes such as bacterial attack and oxidation. The net result of these processes will be reflected in the particle data measured during the resuspension experiments. The distribution and concentration data were evaluated a number of ways and statistical as well as qualitative measures of interaction were employed to evaluate the processes operating during the resuspension events simulated. On a volume normalized basis (**Figure** 9) the concentration of PCBs and PAHs generally increased either linearly or exponentially with increasing applied shear. This is a consequence of the increased suspended solids entrainment with applied shear noted above. Concentrations of particle associated PCBs increased as much 69 times (PR) as the applied shear increased from 2 to 5 dynes cm^{-2}; for the PAHs an increase of up to 21 times (PR) was measured. These findings reveal that tidal and non tidal turbulence can entrain contaminants into the water column. This behavior has significant implications for dredge spoil disposal sites as well as for urban estuaries and harbors that have large expanses of historically contaminated silty-clayey sediments. Others have noted increases in PCB concentrations in areas of resuspension (Baker *et al.*, 1985). However, due to scale effects and the absence of the u and v contributions to the velocity field, quantitative ecological exposure assessment of the measured concentrations using the PES cannot be readily obtained. Using the PES, others have detected the opposite behavior and attributed it to the entrainment of coarser particles under higher stress conditions (Raccanelli *et al.*, 1989), yet under the present experimental conditions, the coarser particles entrained (**Figure** 7) were insufficient to depress the contaminant concentrations except in the case of the least contaminated Rocky Point sediments. Thus, the view, based solely on textural considerations, that the higher the applied shear the lower the exposure level to the overlying water column and indigenous organisms, is not always the case. Moreover, knowledge of the textural characteristics of the bulk sediment is not predictive of the exposure fields. Indeed, both the PR and RP sediments had similar bulk sediment characteristics (**Figure** 7A and B) yet their behavior was significantly different. Although, one must bear in mind that the bulk sediment data represent the top 5-10 mm of sediment, whereas the PES entrains only the top 1mm.

On both mass and on an organic carbon normalized basis, decreased particle loadings of contaminants with increased applied shear were observed (**Figure** 10). It should be noted that the organic carbon content (range: 3.6-7.3% for resuspended particulates; 2.6-8.3% for bulk sediment) of the resuspended sediments showed similar decreases as applied shear increased, and that the resuspended sediments were generally enriched with respect to the bulk sediments. The trend detected for the total organic contaminants was also observed for many of the individual chlorinated species (**Figure** 11) as well as for the individual aromatic hydrocarbons, up to benzo(e)pyrene (**Figure** 12). Others have noted similar decreases for PCBs (Raccanelli *et al.*, 1989) and attributed the behavior to the preferential entrainment of coarser particles with lower contaminant loadings. Scrutiny of the data, however, reveals subtle exceptions to the general observation noted above. Specifically, the high molecular weight PAHs, those with log $K_{ow} > 6$, exhibited greater loadings at the higher shears. Compare the behavior of fluoranthene (log K_{ow} = 5.22 (Mackay *et al.*, 1992)) with Indeno[1,2,3-cd]pyrene (INP, log K_{ow} = 6.25 (Mackay *et al.*, 1992)) (**Figure** 13). During periods of highest resuspension, when greater amounts of larger

sized particles are present, INP loadings are enhanced. Thus INP and other similar PAHs may be associated with a larger size fraction of particles. This is not an entirely new assertion; it has been shown that in addition to nuclei (< 0.08 μm) and accumulation mode aerosols (< 0.08 - 2 μm) (Bidleman, 1988) PAHs have been observed in coarse mode particulates (> 2 μm) (Broman *et al.*, 1990). These observations suggest that the association of high molecular weight PAHs with larger sized particles may be more widespread than previously suggested.

Since the data suggest that the observed phenomena represent the additive effects of multiple particle pools, it would be expected that using the data on the amount of each of the size fractions resuspended during the experiments and the contaminant loadings associated with them, it would be possible to predict the loadings on the resuspended sediments. Using a simple model, based on the assumption of the conservation of particle mass, predicted versus observed loadings were graphed (**Figure** 14). The predictions for the overall PCB loadings on particles for the bedded sediments were very good, under predicting by only, on average, 25 and 23%, respectively, for the PR and RP sediments. For the dredge material the predicted values were, on average, only 25% of the observed loadings. The predicted PAH loadings were also very good, under predicted by 28% for RP and over predicted by 12% for the PR sediments. Underpredictions of 61% were calculated for PAHs associated with resuspended BRH sediments. We consider that the predicted and observed loadings for the PR and RP particles to be due primarily to the analytical variance in measurements. The cause of the low predictions for the resuspended BRH sediments is not known but would be explained by another pool of sorption substrate acting to make up the difference. This pool may be smaller sized particles, including colloids not collected in the process of sequestering the other size fractions. Depending on the relative size of this pool, these particles may have significant contaminant loadings.

Thus far it can be summarized that during resuspension three phenomena occur: (1) for all of the CBs and PAHs with log $K_{ow} < 6$, particle loadings decrease with increasing shear and increasing TSS levels; (2) loadings of PAH with log $K_{ow} > 6$ increase under the same conditions; and (3) it is clear that in the case of the BRH and RP sediments the entrainment of larger sized particles is directly proportional to shear; this is not the case for the PR sediments, which, although variable, showed relatively stable particle sizes throughout - perhaps tending toward smaller sizes with increased shear. In the cases of the CBs and PAHs with log $K_{ow} < 6$, the fact that the loadings decrease with increasing shear show that two possible processes may be taking place: (1) dilution with larger sized particles containing diminished loadings and (2) desorption of these constituents at higher TSS levels. In the case of the PAHs with log $K_{ow} > 6$, the larger sized particles entrained at greater shears are not as depleted as they were for PCBs and PAHs with log $K_{ow} < 6$.

Solid-Liquid Phase Interactions

The distribution of HOCs between solid and liquid phases is commonly portrayed using a distribution coefficient (K_d) as

$$K_d = \frac{C_p\,(\text{mass gTSS}^{-1})}{C_d\,(\text{mass L}^{-1})} \qquad (6)$$

where C_p is the concentration or loadings of the contaminant in the particle phase and C_d is the concentration in dissolved phase. The K_d is in widespread use in assessing phase associations for particle active constituents such as PCBs and PAHs in aqueous systems. In the present study, distribution coefficients were calculated for PAHs, since these constituents were in high enough concentrations in the dissolved phase for evaluation. The average log K_d value for the individual PAHs was 3.99 ±0.99 (see **Table** 5 for summary). It is well accepted that the active agent for the partitioning of HOCs onto particles is organic carbon; although, the mineral nature of the sorbent is also important (Bush *et al.*, 1990). Thus, if this is the case during resuspension the K_ds for PAHs calculated from published octanol-water partition coefficients together with the fraction organic carbon measured in the samples should compare favorably with the observed coefficients. **Table** 6 gives the compilation of the predicted log K_d values for all of the PAHs measured. The average values (3.57 ±1.0) compare favorably with the measured coefficients. However, a close evaluation of the data divulges that measured partitioning was skewed toward higher K_ds than would be predicted from organic carbon alone (**Figure** 15). An explanation of this would lie in the presence of other active surfaces in addition to the organic carbon; it is possible that sorption onto mineral surfaces may be an additional means to elevate the K_d values. Another possibility is that there are differences in the nature of the organic carbon that would influence its binding capacity for HOCs. Some have invoked diagenetically "new" organic matter as an active substrate for binding PCBs in the sediments during resuspension (Calvo *et al.*, 1991b); however, in the present study, changes in the C/N ratio, an indication of the freshness of the organic material, were minimal, ranging from 7.4 to 9.1 during the PES resuspension events.

The distribution coefficients evaluated on a total TSS, or on a textural proportion and organic carbon weight basis (e.g., $K_{cclay} = C_{cclay}\,(\text{mass } g_{cclay}^{-1}) / C_d$) show characteristic decreased values in relation to increased suspended solids levels, particularly for the Providence River sediments (**Figure** 16); however, the decreases were less than what has been observed for other HOCs in the Great Lakes (Baker *et al.*, 1986). Under conditions with a surplus of active sorption sites, the thermodynamic partition coefficient should be independent of any bulk property of the system and would reflect the equilibrium relationship between the sorbed and non-sorbed chemical. However, an inverse relationship between the distribution coefficients and the solids concentration, known as the "solids effect," first discussed by Donald O'Connor and John Connolly in 1980 (O'Connor and Connolly, 1980), has been widely observed in the environment. Three mechanisms have been proposed to explain the observed phenomenon (**Figure** 17). Mechanism 1 originally postulated by Voice (Voice *et al.*, 1983) and later elaborated on by others (Gschwend and Wu, 1985) posits the presence of an additional phase corresponding to those particles that are non-settling, including colloidal materials. Thus HOCs are partitioned between the dissolved, settling particle, and non-settling particle phases (i.e., NSP). In most sorption determinations, it has been argued, that this third phase is not adequately taken into account and the HOCs that properly should be considered in the particle phase are ascribed to the dissolved phase. It is further hypothesized that the concentration of colloids is proportional to the concentration of the larger particulates; thus. the result is that at higher concentrations of TSS the partition coefficient decreases because the numerator becomes increasingly large. The other two mechanisms, invoked to explain the K_d behavior, are based upon particle interactions either through agglomeration or through desorption (Di Toro and Horzempa, 1985); each yielding a lowering of available substrate (or active sites) for sorption as TSS levels increase. The fact that the K_ds calculated in the present study do not change greatly with increased TSS levels may be due to a continuous addition of new substrate suitable to bind any dissolved contaminants available. In many cases this substrate is the larger sized particles entrained. Although these larger particles may not have the binding capacity of smaller particles,

due to their abundance, they are adequate to provide additional binding sites. Moreover, the assumption that the concentration of NSPs is proportional to the measured TSSs appears not to be the case during the resuspension events studied, since if NSPs were equally more abundant at higher shears the K_d values would decrease more than what was observed.

CONCLUSIONS

The interaction of in-place contaminated sediments with the overlying water column and indigenous biota is a relatively new area of study. The paradigm, that previously classified sediments as sinks for contaminants, is now known to be an oversimplification. Studies aimed at evaluating the chemistry and dynamics of hydrophobic organic contaminants during resuspension are important to understand the role that in-place sediments have in the transport and fate of contaminants at the sediment-water interface. The present study was designed to investigate the resuspension phenomenon in the laboratory using a particle entrainment simulator. In these experiments, sediments, having a variety of contaminant, and textural characteristics, were artificially resuspended by applying turbulence equivalent to surface shears from 2 to 5 dynes cm^{-2}. The objectives were to evaluate contaminant chemistry and dynamics as a function of resuspension magnitude. Important insight was gained from these laboratory studies that would not have been possible from field studies since all of the important variables would have been difficult to control or measure. Several conclusions on the chemistry and dynamics of HOCs during resuspension were obtained:

(1) The degree of entrainment of particles was related to the experimental shear applied and the characteristics of the bulk sediments. It was found that the bedded sediments had lower entrainment rates than the dredge materials due to the presence of greater amounts of larger grained sized particles.

(2) The sizes of the particles entrained from the bedded sediments changed with increasing resuspension magnitude and were likely due to non-uniform characteristics of sediment with depth in the zone of resuspension (up to 1 mm). In the case of the more highly contaminated Providence River sediments the mean particle size increased with applied shear; whereas for the less contaminated Rocky Point sediment the particle sizes decreased over the same applied shear range. Moreover both of these sediment types exhibited particle size distributions during resuspension that were skewed toward smaller particles than those of the bulk sediments.

(3) The particle size distribution for the dredged material was relatively constant under widely different resuspension conditions and was similar to the bulk sediment characteristics.

(4) On a mass loading and an organic carbon loading weight basis, the entrained particulate material was modestly depleted in PCBs and PAHs with Log $K_{ow} < 6$ as the applied shear and the amount of overall material were resuspended into the overlying water column. Alternately, higher molecular weight PAHs (log $K_{ow} > 6$) showed enriched loadings under the same conditions. On a volume weighted basis the amount of organic contaminants increased in the water column as resuspension energy increased.

(5) The distribution of PAHs between the dissolved and particulate phases (K_ds) showed relatively minor decreases with increased applied shear and TSS levels during the resuspension events.

Two processes are the likely causes of the contaminant behavior during resuspension:

(a) Dilution due to the entrainment of larger sized particulates depleted in PCBs and lower molecular weight PAHs (log $K_{ow} < 6$). This particle pool, however, was relatively enriched in high molecular weight PAHs (log $K_{ow} > 6$). In addition, this mechanism would explain the behavior of K_ds during resuspension.

(b) Agglomeration or particle collisions causing loss of binding sites or desorption of PCBs and low molecular weight PAHs from resuspended particulates as applied shear and TSS levels increased. High molecular PAHs were not as affected by this phenomenon possibly due to

stronger binding on particles. Mechanism b however, would cause relatively large decreases in K_ds during resuspension; this was not observed.

Acknowledgments–

We wish to thank the many scientists and technicians, ship captains and advisors that helped make this study a success. In particular, we are very thankful for the help that Dr. Wayne Davis and Mr Darryl Keith of EPA's Environmental Research Laboratory - Narragansett (ERLN) gave us in all the biological, chemical, and geological aspects of the study. Ms. Karen Salomon helped in the early stages of the study on QA/QC; she conducted the many resuspension experiments in concert with Paul Ferri at the ERLN. Ms. Meredith Slater was an invaluable help in all analytical aspects of the study. We acknowledge Captain Mark Gustafson and Mr. Jim Allan of URI's R/V *Laurie Lee* , for their help in obtaining sediment cores and clam samples. We thank Mr. David Butler and his staff at URI's equipment development lab for overseeing the fabrication of the all glass PES sediment plug holders.
